# A Method for the Preparation of Methylmetal Compounds[*]

BY DR. W. SUNDERMEYER AND DIPL.-CHEM. W. VERBEEK [1]
ANORGANISCH-CHEMISCHES INSTITUT DER UNIVERSITÄT GÖTTINGEN (GERMANY)

*Dedicated to Professor W. Klemm on the occasion of his 70th birthday*

*A new method has been developed for the preparation of methylmetal compounds from methyl chloride and the chlorides of boron, aluminum, silicon, tin, phosphorus, antimony, or mercury. Fused salts are used as solvents, and metals are suspended in these to act as halogen acceptors. The metals are recovered, together with chlorine, by electrolysis. This process, which can be carried out continuously and quantitatively, can be used for the preparation of technically important methylmetal compounds that cannot be obtained directly by the "Mülheim aluminum alkyl method".*

## I. Methylation with Methylmetal Compounds

The discovery of the alkylzinc compounds made possible for the first time the preparation of other organometallic compounds (methylsilicon, alkyltin, and methylboron compounds). However, since dimethylzinc can only be obtained from methyl iodide and zinc, and since it is very volatile and self-inflammable, its use as a methylating agent is confined to special cases.

Dimethylmercury was formerly also obtainable only from methyl iodide, but it has been found that methyl bromide can be used together with sodium amalgam. Despite its toxicity, $Hg(CH_3)_2$ is a very valuable methylating agent, since it is neither self-inflammable nor excessively volatile, and since it is soluble in the common solvents. It has recently become possible to prepare dimethylmercury from methyl chloride, which is both cheap and readily available.

The best-known of the older reactions used for the methylation of metal halides is probably the Grignard synthesis. However, this reaction is difficult to control, proceeds discontinuously, and requires the use of large quantities of ether; moreover, the magnesium chloride formed is usually rejected, in spite of the fact that it contains all the chlorine involved in the reaction, and in spite of the cost of magnesium. It has recently been discovered that the reaction can be controlled if the metal is used in large pieces [2]. The largest Grignard plant, which is used for the large-scale production of organosilicon compounds [3], is in the U.S.A. In spite of its general applicability, the use of the Grignard reaction in industry is restricted to the production of special products, since too many by-products and auxiliary products are involved [4].

An industrial process was developed some years ago for the production of organoaluminum compounds by the reaction of aluminum and hydrogen with olefins [5]; since then, the use of these compounds as alkylating agents has increased [6]. However, it is not possible to make use of all three alkyl groups, except in the alkylation of metal fluorides, or unless alkali metal chlorides are added to bind the aluminum chloride formed [6, 7].

The partially methylated compounds $CH_3AlCl_2$ and $(CH_3)_2AlCl$ [8] can be used as methylating agents, but

they do not react with some metal halides [6], while in other cases they give very low conversions. The main reason for this is the fact that no reaction medium has yet been found that affords good contact between the reactants at the required temperature and also dissolves the resulting aluminum chloride away from the surface. Furthermore, the alkylaluminum halides are difficult to handle in the free form. Whereas the methylation of trimethylchlorosilane and dimethyldichlorosilane takes place even at low temperatures, the methylation of methyltrichlorosilane and of silicon tetrachloride proceeds only at about 250 °C and about 30 atm. Moreover, the conversion into the technically important dimethyldichlorosilane takes a very long time [9–11], and it is almost impossible to obtain yields greater than 50 %, since the solid methylaluminum chloride does not react completely and appears to be regenerated from aluminum chloride and methylchlorosilanes [12].

Silicates such as bentonite or talc react with methylaluminum chloride to form methylchlorosilanes, but the principal product, with a yield of 74 %, is tetramethylsilane [13]. It is doubtful whether this process, which is carried out discontinuously in the solid phase and in a pressure vessel (300 °C, 250 atm, 6 h), will ever attain industrial importance. However, it shows the extreme conditions required for the preparation of tetramethylsilane, which is essential for the comproportionation reaction. A similar process permits the synthesis of trimethylboron from boron trioxide [14].

## II. Methylation in the Presence of Metals that Bind Halogens

The Wurtz synthesis is particularly useful for the preparation of organometallic compounds from starting materials that are not reduced by the alkali metal before they have entered into the desired combination with the alkyl halide. Thus silicon tetrachloride reacts with methyl chloride in the presence of lithium to form methylchlorosilanes [15], and tin tetrachloride reacts with methyl chloride in the presence of a sodium suspension to form tetramethyltin [16]. However, the use of the Wurtz synthesis is often impossible owing to reduction of the metal halide by the alkali metal, reaction of two alkyl halides with each other, and above all the relatively high cost of the halogen-binding metals (acceptor metals). The reaction of the acceptor metals is generally incomplete, since the halides formed are insoluble in the solvent used, and consequently block the surface of the metal. All the acceptor metal and the halogen with which it has combined are useless at the end of the reaction.

Other acceptor metals have also been used. Thus methyltrichlorosilane has been further methylated to a small extent with methyl chloride at 450 °C in the presence of aluminum or zinc turnings; this reaction was accompanied by thermal decomposition to form more highly methylated chlorosilanes [17] and by dismutation ("automethylation") to form dimethyldichlorosilane and $SiCl_4$. Silicon tetrachloride does not react under these extreme conditions.

Somewhat better results are obtained in reactions in which the metal itself is made to react with methyl chloride in the presence of an acceptor metal. The best-known and economically the most important synthesis of this type is the preparation of tetraalkyl-lead compounds (anti-knock agents) from alkyl chloride and a lead-sodium amalgam [18]. Tin-sodium [19] and tin-magnesium [20] alloys have been converted in a similar manner into tetraalkyltin. The methylated metal can also act as the acceptor metal, and in this case the desired methylmetal halides are obtained directly; unfortunately, however, this possibility is restricted to a few examples [21], the best-known of which is the Rochow synthesis for methylchlorosilanes and phenylchlorosilanes. Even here, however, the dimethylchlorosilane is always accompanied by undesirably large quantities of the other methylchlorosilanes. Methyltrichlorosilane in particular is often a very undesirable by-product. It is difficult to alter the course of the reaction in such a way as to favor the formation of one methylchlorosilane without simultaneously changing the proportions of the other products, particularly the more highly chlorinated $CH_3SiCl_3$ and $SiCl_4$. The commercial grades of silicon react with methyl chloride only at high temperatures, and the reaction proceeds very slowly. Thus, the silicon must have a very high purity, as must the copper or silver catalyst. All these factors [21] combine to make the synthesis expensive and present an obstacle to the wider use of silicones.

The above discussion explains the efforts that have been made to improve the Rochow synthesis, or to find a new route to the methylchlorosilanes [21]. These efforts are being directed particularly towards the preparation of more highly methylated products, since these can be used for the production of dimethyldichlorosilane by reaction with silicon tetrachloride (which can be obtained from inexpensive ferrosilicon or silicon scrap), or for the preparation of organosilicon compounds with organofunctional groups.

## III. Principle of a New Process

The reaction of methyl chloride with halides of boron, aluminum, silicon, tin, phosphorus, antimony, or mercury is particularly satisfactory if the acceptor metal is finely suspended in a melt of a non-oxidizing salt. We shall illustrate this process for the preparation of tetramethylsilane.

If silicon tetrachloride and methyl chloride are led into a suspension of aluminum in a sodium chloride/aluminum chloride melt, tetramethylsilane and aluminum chloride are formed in quantitative yield.

$$3\ SiCl_4 + 12\ CH_3Cl + 8\ Al \xrightarrow[180\ °C]{} 3\ (CH_3)_4Si + 8\ AlCl_3 \quad (1)$$

The difference between this reaction and the usual Wurtz synthesis is that the acceptor metal is not an alkali metal, and that the metal halide formed is soluble in the solvent, *i.e.* in the molten salt. Thus a free metal surface is always available until the metal has been completely consumed. Moreover, if the system is chosen correctly, more solvent (in this case $AlCl_3$) is formed in the course of the reaction; ordinary solvents, on the other hand, often become a paste-like mass towards the end of the reaction, owing to the insolubility of the metal halide.

Another important advantage is that the acceptor metal halide can be reconverted into the acceptor metal (Al) and the halogen ($Cl_2$) by electrolysis of the melt.

$$8\ AlCl_3 \rightarrow 8\ Al + 12\ Cl_2 \quad (2)$$

The overall equation is therefore:

$$3\ SiCl_4 + 12\ CH_3Cl \xrightarrow[180-220\ °C]{NaCl/AlCl_3/Al} 3\ (CH_3)_4Si + 12\ Cl_2 \quad (3)$$

The recovered chlorine can be used either for the preparation of fresh silicon tetrachloride or for the oxychlorination of methane.

$$Si + 2\ Cl_2 \rightarrow SiCl_4 \quad (5)$$

$$4\ CH_4 + O_2 + 2\ Cl_2 \rightarrow 4\ CH_3Cl + 2\ H_2O \quad (6)$$

The process is not confined to the preparation of tetramethylsilane but can also be used for the synthesis of other (mostly permethylated) methylmetal compounds. The yields are usually quantitative.

$$CH_3SiCl_3 + 3\ CH_3Cl \rightarrow (CH_3)_4Si + 3\ Cl_2 \quad (7)$$

$$SnCl_4 + 4\ CH_3Cl \rightarrow (CH_3)_4Sn + 4\ Cl_2 \quad (8)$$

$$BCl_3 + 3\ CH_3Cl \rightarrow (CH_3)_3B + 3\ Cl_2 \quad (9)$$

$$SbCl_3 + 3\ CH_3Cl \rightarrow (CH_3)_3Sb + 3\ Cl_2 \quad (10)$$

$$HgCl_2 + 2\ CH_3Cl \rightarrow (CH_3)_2Hg + 2\ Cl_2 \quad (11)$$

$$AlCl_3 + 2\ Al + 3\ CH_3Cl \rightarrow 3\ CH_3AlCl_2 \quad (12)$$

$$3\ PCl_3 + 6\ CH_3Cl + 4\ Al \rightarrow 3\ (CH_3)_2PCl \cdot AlCl_3 + AlCl_3 \quad (13)$$

## IV. Choice of the System Melt/Acceptor Metal

Although there are a large number of possible combinations, most of those given in Table 1 contain salts with low melting points; moreover, the acceptor metal in each case can be recovered from its halide, so that continuous operation is possible.

Melts containing two or three components are used at the eutectic composition, in order that advantage may be taken of the low melting point, since many methylmetal compounds are unstable at high temperatures. The melting points of simple or mixed fluorides are generally too high [22], and for this reason chloride melts are generally used. Since the halogen is completely recovered, it is even feasible in some cases to use the more expensive bromides or iodides. The halogen in the reactants should be the same as that in the melt, and the melt should consist partly of the halide formed from the acceptor metal. Under these conditions, the composition, and hence the melting point, of the melt remains practically constant throughout the reaction.

Table 1. Melt/Acceptor metal systems.

| Melt | Acceptor metal | State of the acceptor metal in the melt | Temp. [°C] |
|---|---|---|---|
| $NaCl/AlCl_3$ (or LiCl) | Al | solid | >90 |
| | Al/Hg | liquid | 120 |
| | Zn | solid | 150 |
| | Mg | solid | 150 |
| | Mg | solid | 150 |
| $NaBr/AlBr_3$ | Al | solid | 200 |
| $HgCl_2/KCl$ | Hg | liquid | 182 |
| $ZnCl_2/KCl$ (or NaCl) | Zn | solid | 230 |
| | Zn/Hg | liquid | 230 |
| | Zn/Mg | solid | 230 |
| $SnCl_2/KCl$ | Sn | liquid | 231 |
| | Sn/Hg | liquid | 231 |
| | Sn/Zn | liquid | 231 |
| LiCl/KCl | Li | liquid | 352 |
| | Li/Sn | liquid | 352 |
| | Li/Pb | liquid | 352 |
| $MgCl_2/KCl/CaCl_2$ | Mg | solid | 425 |
| $CaCl_2/NaCl$ | Na | liquid | 508 |

Alkali metals form true solutions in their molten halides, but only at very high temperatures [23]. This is also true of alkaline earth metals. Most other metals remain suspended in the melt, particularly since the solubility of metals in melts decreases when several salt components are used. The dehalogenation can also be brought about by any "subhalides" that may be formed, but the metals that are most suitable for use as halogen acceptors are capable of forming stable methylmetal halide intermediates, which are soluble in the melt, and which act as transfer agents for the methyl group, *e.g.* aluminum or magnesium.

Even when alkali metal chlorides are added, the reaction cannot be carried out above the melting point of most acceptor metals, owing to the high vapor pressure of the melt, and the instability of the products. The metals, with the exceptions of mercury, tin, lead, bismuth, and certain alloys, can therefore be separated electrolytically only in the form of powders or flakes. Aluminum and zinc separate from the water-clear melts as fine silvery crystals; since these crystals are not covered with an oxide layer, they react with the methyl chloride about three times as rapidly as commercially available aluminum powder. If the aluminum is deposited electrolytically from an equimolar melt of sodium and aluminum chlorides, it contains enough sodium chloride for the complexing of the methylaluminum dichloride during the subsequent reaction with methyl chloride (cf. Section VIII).

## V. Starting Materials and the Course of the Reaction

Under the conditions used, higher alkyl halides generally form hydrogen halide and olefins. Chlorobenzene and bromobenzene, on the other hand, react to form the phenylmetal compounds [24].

Table 2. Metal halides that can be methylated in salt melts.

| | |
|---|---|
| $BX_3$, $KBF_4$ | (X = F, Cl, Br, I) |
| $AlX_3$ | |
| $SiX_4$, $Na_2SiF_6$ | |
| $SnX_2$, $SnX_4$, $K_2SnX_6$ | |
| $PX_3$, $SbX_3$ | |
| $HgX_2$ | (Y = B, Al) |
| $(R)_nY\,X_{3-n}$ | (Z = Si, Sn) |
| $(R)_nZ\,X_{4-n}$ | (R = Alkyl, Aryl) |

The metal halides used in this reaction are listed in Table 2. It is also possible to use halides of these metals containing organic groups, particularly methyltrichlorosilane, which is obtained by the Rochow synthesis. Owing to the asymmetry of the molecule, this substance is much more easily methylated (95 % conversion, quantitative yield) than silicon tetrachloride (80 % conversion) [11].

Many of the metal halides listed in Table 2, *e.g.* tin tetrachloride and mercury(II) chloride, are directly reduced by the acceptor metal to the metals or to alloys. It is necessary in such cases to use acceptor metals that form a stable methylmetal halide with the methyl chloride introduced initially, *e.g.* aluminum in an $NaCl/AlCl_3$ melt. In the presence of excess sodium chloride, the methylaluminum dichloride formed dissolves as the complex $Na[CH_3AlCl_3]$ and cannot be distilled out of the melt. It is only then that the metal halide is added. This reaction can also be carried out continuously (Section VI). Much higher conversions are obtained with an excess of intermediate in the melt.

Other metal halides (*e.g.* silicon halides) can be introduced together with the methyl chloride into the suspension of the acceptor metal, and electrolysis can be carried out simultaneously with the reaction, so that the reaction proceeds at once in accordance with Equation(3).

Phosphorus trichloride reacts with many metals to form phosphides. In this case, however, even if $Na[CH_3AlCl_3]$ is formed first, the reaction does not yield trimethylphosphine, since the initially formed dimethylchlorophosphine reacts with aluminum chloride to form the complex $(CH_3)_2PCl\cdot AlCl_3$, which is not methylated further. Since this complex is more stable than the $NaAlCl_4$ in the melt, it cannot be destroyed by the addition of sodium chloride. In the system $KCl/AlCl_3$, in fact, it was not possible to isolate even doubly methylated phosphines [25].

## VI. Apparatus

A semicontinuous form of the process (Fig. 1) has been found to be particularly effective on the laboratory scale. The reaction vessel is $^2/_3$ to $^3/_4$ filled with *e.g.* an $NaCl/AlCl_3$ melt. At a potential of about 10 volts (current about 50 amp), aluminum flakes separate out either loosely or in the form of a sponge, while chlorine is liberated. The cathode (a) consists *e.g.* of a disk of sheet steel, and the anode (b) [several rods arranged in a circle, or a cylindrical sheet] is made of tungsten. Since the level of the liquid falls during the electrolysis, the anode must be adjustable in the vertical direction, in order that the current density may be kept constant. The acceptor metal separates out at a current density of more than 3 amp/dm², generally in the form of fine crystals (cf. also [26]). The tendency of the crystallites to grow towards the anode is overcome by slow rotation (about 10 r.p.m.) of the gas-inlet stirrer (c). When enough acceptor metal has been precipitated, the gas volume is flushed with an inert gas to remove the chlorine. Methyl chloride and vaporized metal halide are then introduced, either simultaneously or one after the other, through the tube (d) until all the acceptor metal has been consumed. Before the exhaust gases leave the reaction vessel, they are returned to the melt several times through the gas-inlet stirrer (c), to ensure that conversion is complete. This stirrer sucks in the vapors or gases above the liquid surface through holes in the hollow shaft; the gases are then returned to the melt through the side-arms of the stirrer by centrifugal force (about 2800 r.p.m.). The volume of the melt is the same at the end of the reaction as at the beginning. The electrolysis is then repeated (current yield more than 90 %) in preparation for the next reaction.

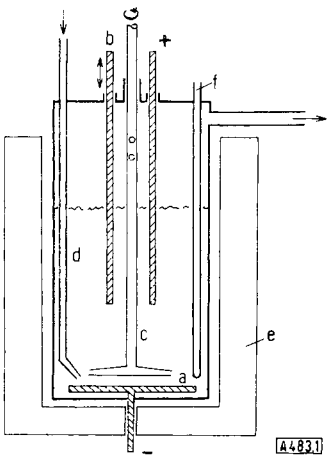

Fig. 1. Semicontinuous process (with formation of an intermediate).
a: Cathode
b: Anode
c: Gas-inlet stirrer
d: Inlet tube
e: Oven
f: Thermocouple

In the continuous process, the electrolysis is carried out during the reaction of the methyl chloride with the metal halide. In this case, the cathode and anode zones, which were arranged one above the other in the semicontinuous method, must be separated to prevent contact of the halogen liberated at the anode with the reactants. If neither the methyl chloride nor the metal halide alone reacts with the acceptor metal, the electrolytic cell may be fitted with a diaphragm, a metal gas-inlet stirrer being used as the cathode.

[24] A report on these experiments, which have not yet been completed, will appear later.

[25] We are grateful to Dr. *R. Schliebs* for providing literature references.

[26] *R. Dötzer*, Chemie-Ing.-Techn. *36*, 616 (1964).

In another form of the continuous (and of the discontinuous) process, the melt in the cathode compartment is layered upon a liquid metal, *e.g.* mercury, tin, or lead; this metal acts as the cathode, and the precipitated acceptor metal dissolves in it to form an alloy. The arms of the gas-inlet stirrer are placed in the liquid metal, and act as an electric lead. It has been found, however, that with liquid metals, most of which are very dense, it is difficult to introduce the gases or to suspend the metal in the melt.

The system $NaCl/AlCl_3/Al$ has been found to be particularly suitable (low reaction temperature, ready reaction of methyl chloride with Al, intermediate formation of $Na[CH_3AlCl_3]$, which can be used in excess). It was therefore desirable to develop a continuous process using this system. Fig. 2. shows a reaction vessel in

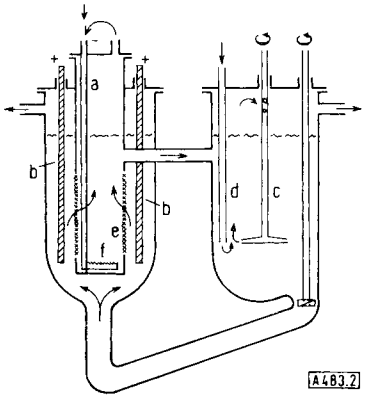

Fig. 2. Continuous process (with formation of an intermediate)

a: Cathode
b: Anode
c: Gas-inlet stirrer
d: Inlet tube
e: Diaphragm
f: Sintered metal

which contact between the $Na[CH_3AlCl_3]$ and the anode is prevented by the use of a diaphragm (e), and in which this intermediate is produced and consumed in two different compartments.

During the electrolysis of the $NaCl/AlCl_3$ melt, methyl chloride is introduced through a sintered metal diaphragm (f), which also acts as the cathode, and which is connected *via* an insulated inlet tube to the source of direct current. The unreacted methyl chloride is recycled, so that the final product no longer contains methyl chloride, and the separation process is therefore eliminated or simplified. The $Na[CH_3AlCl_3]$ formed in the cathode compartment is led into the reaction vessel on the right, where it reacts with the metal halide, which is blown in as a vapor or added as a powder.

The materials balance of the reaction steps is given by the following equations:

$$2\ NaAlCl_4 \rightarrow 2\ NaCl + 2\ Al + 3\ Cl_2$$

$$3\ CH_3Cl + 2\ Al + 2\ NaCl + NaAlCl_4 \rightarrow 3\ Na(CH_3)AlCl_3$$

$$3\ Na(CH_3)AlCl_3 + BCl_3 \rightarrow 3\ NaAlCl_4 + (CH_3)_3B$$

The melt is pumped back into the anode compartment, whence it passes through the diaphragm (e) and back into the cathode compartment. This circulation of the melt ensures that no $Na[CH_3AlCl_3]$ passes through the diaphragm from the cathode to the anode compartment, where it could undergo electrochemical decomposition.

## VII. Results

a) 3000 g of $NaAlCl_4$ electrolysed at 220 °C and 368.2 ampere-hours; 123.5 g of Al and 447 g of chlorine liberated (current yield: 92 %, based on chlorine); 350 g of $CH_3Cl$ introduced over 4 hours.

b) 240 g of $SiCl_4$ introduced over 8 hours, 58 g of $SiCl_4$ recovered (75.6 % conversion); 94.5 g of $(CH_3)_4Si$ obtained (quantitative yield).

c) Preparation as in (a); 170 g of $CH_3SiCl_3$ introduced over 7 hours, 16 g of $CH_3SiCl_3$ recovered (90.5 % conversion); 91 g of $(CH_3)_4Si$ obtained (quantitative yield).

d) Preparation as in (a); 220 g of $SnCl_4$ introduced at 200 °C over 5 hours; complete conversion; 142.6 g of $(CH_3)_4Sn$ obtained (95 % yield).

e) Preparation as in (a); 138 g of $BCl_3$ introduced at 150 °C; quantitative conversion; 65 g of $(CH_3)_3B$ obtained (99 % yield).

f) Preparation as in (a); 210 g of $HgCl_2$ added over 3 hours; 170.5 g of $(CH_3)_2Hg$ obtained (95.5 % yield).

g) Preparation as in (a); 205 g of $SbCl_3$ added over 15 min at 200 °C; 57 g of $(CH_3)_3Sb$ obtained [yield: 48 %, thermal decomposition of the $(CH_3)_3Sb$].

h) Preparation as in (a); $KBF_4$ introduced; immediate reaction to form $BCl_3$, followed by further reaction in accordance with (e); yield: 74.3 %. Some of the $KBF_4$ did not reach the melt (adhesion to the walls) and could not be recovered, hence the poor yield.

i) Preparation as in (a); 130 g of $PCl_3$ introduced over 2 hours at 150 °C; formation of $(CH_3)_2PCl$, which remained in solution as the $AlCl_3$ complex.

k) 300 g of Al electrolytically deposited from 1500 g of $NaAlCl_4$ in 2600 g of mercury; 139 g of $CH_3Cl$ and 137 g of $CH_3SiCl_3$ introduced at 220 °C; conversion: 35 %, yield of $(CH_3)_4Si$: 75 %; formation of ethane.

l) 1500 g of tin under a melt of 924 g of KCl and 4550 g of $SnCl_2$; 210 g of $CH_3Cl$ introduced over 4 hours at 300 °C, 62 g of $CH_3Cl$ unreacted (conversion: 70 %); 106 g of $(CH_3)_3SnCl$ obtained (yield: 54.5 %; the rest remained in solution).

m) 3800 g of tin under 822 g of LiCl and 938 g of KCl; electrolysed at 400 °C until 90 g of lithium were dissolved in the tin (current yield: 91.2 %); 100 g of $CH_3Cl$ and 100 g of $CH_3SiCl_3$ introduced over 5 hours; 18 g of $CH_3Cl$, 6 g of $(CH_3)_4Si$, and 22 g of $(CH_3)_3SiCl$ obtained. Introduction of chlorobenzene and trimethylchlorosilane (1:1) led to a 25 % yield of phenyltrimethylsilane.

n) As in (m), but with a liquid lead cathode; $C_6H_5Cl$ and $(CH_3)_3SiCl$ introduced; yield of $C_6H_5Si(CH_3)_3$: 28 %.

## VIII. Summary

It is possible with the aid of molten salts to prepare methylmetal compounds easily, cheaply, and safely. The need to handle free alkylaluminum and other readily oxidizable organic compounds is eliminated, since these occur (if at all) only in solution. The reactants are generally introduced in the gaseous form, and the products are also removed as gases, so that no changes in the reaction vessel are required during the operation, and the reactions can be carried out continuously. The final products do not contain solvents. The metal halides, which are obtained from crude precursors, are made to react at relatively low temperatures; the use of a salt melt as the solvent permits the quantitative reaction of the acceptor metal and the recovery of all the halogen.

The reaction generally leads to the permethylated metal compound, which can be converted into industrially important methylmetal chlorides. The latter, *e.g.* methyl chlorosilanes, can probably also be obtained directly, if the reaction is allowed to proceed for a long time under pressure and in the presence of an excess of the metal halide, but this process is only semi-continuous [27].

The process is restricted to the preparation of the methyl compounds, since higher alkyl halides are dehalogenated to form olefins, or else react with alkylaluminum dichloride to form higher hydrocarbons [28]. In the reaction of methyl chloride, on the other hand, small quantities of ethane have been found in only a few cases. Another restriction is due to the fact that although metal fluorides are methylated by the $[CH_3AlCl_3]^{\ominus}$ ion, the melt cannot be regenerated by electrolysis in this case.

Many metal chlorides can be methylated with trimethylaluminum, but in many cases only one methyl group of the alkylaluminum is used, owing to the establishment of an equilibrium between the two methyl compounds. Thus zinc and cadmium chlorides react to give the corresponding dimethyl compounds, together with dimethylaluminum chloride [29]. The alkylating power becomes weaker as the number of methyl groups on the aluminum decreases, and none of the Group IIB chlorides can be methylated with methylaluminum dichloride [6]. It is equally surprising to find that while zinc and cadmium chlorides cannot be converted into the methyl compounds by this reagent, mercury(II) chloride reacts with the $[CH_3AlCl_3]^{\ominus}$ ion to form dimethylmercury. This provides a simple method for the preparation of large quantities of this methylating agent. The other permethylated compounds described here have also recently been used for transmethylations. For example, dimethylmercury can be prepared from trimethylboron [30]. Tetramethylsilane can be used for the methylation of gallium chloride [31], and tetramethylstannane is suitable both for the preparation of methylgallium dichloride [31] and for the methylation of germanium halides [32].

# Applications and Limitations of Magnetic Methods in Free-Radical Chemistry

BY PROF. DR. E. MÜLLER, DR. A. RIEKER, DR. K. SCHEFFLER, AND DIPL.-CHEM. A. MOOSMAYER [1]

CHEMISCHES INSTITUT DER UNIVERSITÄT TÜBINGEN (GERMANY)

*Dedicated to Wilhelm Klemm in memory of the work done together*

*The paper describes the application and limitations of magnetic methods to the problems of free-radical chemistry (detection and quantitative investigation of the free-radical state, relationships between structure and free-radical formation, "distribution" of the unpaired electron, detection of mesomeric C, O, N, P, As, and Sn radicals, g-factors, triplet states, and hyperfine structure). The problem of the diradical is described, and the paper closes with a discussion of the "Selwood effect".*

## A. Introduction

In 1934, *E. Müller, W. Klemm,* and *W. Schüth* [2] published the first paper describing attempts to settle the long disputed problem of the existence of diradicals on the basis of an investigation into the magnetic properties of diphenyldiazomethane. The negative result was contrary to the opinion prevalent at that time, and further studies were therefore necessary.

Since only one attempt [3] to determine the paramagnetism of a free radical had been published prior to this paper, it was necessary first to lay the foundations of the magnetochemistry of free radicals. This work was carried out between 1933 and 1936 in Danzig in collaboration with *I. Müller-Rodloff, W. Bunge, W. Wiesemann,* and *F. Teschner.* The Gouy balance was used for the determination of the paramagnetism.

## B. Applications and Limitations of the Gouy Method

### 1. Principles

The Gouy method [4] is based on the fact that a paramagnetic substance is drawn into a non-homogeneous magnetic field, whereas a diamagnetic substance is repelled. Thus if the samples in question are suspended from a sensitive balance in a non-homogeneous magnetic field, this effect produces an apparent increase in the weight of a paramagnetic substance or an apparent decrease in the weight of a diamagnetic substance. The molar susceptibility found from the apparent change in weight consists of three components: the diamagnetic susceptibility $\chi_{dia}$, which is independent of temperature, the paramagnetic susceptibility $\chi_{para}$, which is temperature-dependent, and an additional term $\chi_\rho$, which is usually small, and which is independent of temperature:

$$\chi_{mol} = \chi_{dia} + \chi_{para} + \chi_\rho.$$

For the determination of small paramagnetic susceptibilities, the diamagnetic susceptibility, which is then appreciably greater, must be known very accurately if the error of the method is to remain small. For this reason, measurements on free radicals are always accompanied by the determination of the diamagnetic susceptibility of the non-radical containing one hydrogen atom more; the diamagnetic susceptibility of the free radical is then found by subtraction of the Pascal increment for one H atom. We shall return to this during the discussion of the "Selwood effect".

The term $\chi_\rho$, which is usually small, is generally neglected. It has been attributed to internal magnetic polarization. *H. J. Dauben, Jr.* [5] recently expressed the view that $\chi_\rho$ is due to the magnetic anisotropy of the compound, and could be used for the determination of the aromaticity of aromatic and quasi-aromatic compounds. Future work must show whether this view is correct and can be applied reliably.

A self-recording version of the Gouy balance has been developed by *W. Rüdorff* and *D. Greifeneder* [6].

### 2. Detection of Free Radicals with the Gouy Balance

#### a) Monoradicals

The first step in our magnetochemical studies was to decide whether the paramagnetism of free radicals is due to spin and orbital moments or simply to the spin moment of the unpaired electron. The latter is the case if the Curie law or the Curie-Weiss law

$$\chi_P\,(T-\Theta) = C$$

is valid for $\Theta \ll T$ and a monomeric free radical gives $\mu_{eff} = \sqrt{3} = 1.73$ Bohr magnetons. Radicals of this type are in the $^2\Sigma_{1/2}$ state.

It is important that the substance under examination be very pure. For this reason we first studied the nitrogen radicals *(1)–(3)* (Table 1) which can be relatively easily obtained in the pure form [7]. The $\mu_{eff}$ values obtained agree with those expected from theory. Difficulties were encountered in the preparation of Goldschmidt's hydrazyl *(3)*; similar difficulties have been reported by other workers [8].

The carbon radicals studied were Ziegler's pentaphenylcyclopentadienyl *(4)* and Schlenk's tribiphenylmethyl

Table 1. Magnetic behavior of some nitrogen, carbon, and oxygen radicals.

| Radical | Θ | $\mu_{eff}$ | Temp. [°K] |
|---|---|---|---|
| *(1)* | − 3° | 1.71 | 291 |
| *(2)* | − 6° | 1.76 | 293 |
| *(3)* | −10° | 1.74 | 293 |
| *(4)* | −12° | 1.7 | 293 |
| *(5)* | −18° | 1.7 | 293 |
| + 1 $C_6H_6$ (solid) | −18° | 1.6 | 90 |
| in 2.82 % benzene soln. | −18° | 1.78 | 294 |

[8] a) *H. J. Friedrich*, Z. Naturforsch. *19b*, 663 (1964); b) *J. J. Lothe* and *G. Eia*, Acta chem. scand. *12*, 1535 (1958); c) *T. Laederich* and *P. Traynard*, C. R. hebd. Séances Acad. Sci. *254*, 1826 (1962).

*(5)* [9]. On theoretical grounds [10], *(4)* is expected to possess both spin and orbital moments. The measurements showed, however, that even in this case there is no appreciable orbital moment, but only a spin moment ($^2\Sigma_{1/2}$ state) (Table 1).

It is particularly difficult to obtain tribiphenylmethyl *(5)* in the pure state [11]. It is generally prepared as the benzene adduct, a value for which is given in Table 1. According to this value, *(5)* must be almost completely monomeric in the solid state and, according to other values, in dilute solution. Slight association appears to take place only at low temperatures.

The Gouy method has also proved suitable for the study of the aroxyls. Thus at the time of the discovery of the first stable aroxyl, 2,4,6-tri-t-butylphenoxyl *(6)*, this was the only method by which it could be identified as a completely monomeric free radical [12].

The existence of a $^2\Sigma_{1/2}$ state in organic free radicals gives rise to further applications of the Gouy method. Thus it has been found from magnetic measurements that the heat of dissociation of hexaphenylethane in benzene is $-11.6 \pm 1.7$ kcal/mole [13]. This is in excellent agreement with the value of $-11.3$ kcal/mole found by *K. Ziegler* [14] by another method. *W. Theilacker* and his co-workers used the Gouy method to study the steric effect of *ortho*-groups in triarylmethyls, and showed that hexa-(*o*-methylphenyl)ethane in a 0.1 M solution in benzene at 19 °C is 87 % free radical, while *o*-t-butylphenyldiphenylmethyl is practically 100 % free radical [15].

Dimethylpyronepotassium, 2-methylchromonepotassium, and 2,3:6,7-dibenzoxanthonepotassium, which are regarded as metal ketyls because of their bright, intense colors in the solid state, are diamagnetic in the solid state, *i.e.* they are not free radicals. In xanthonepotassium, there is one free spin for every four xanthone molecules. The structures of these and similar compounds (*e.g.* benzilpotassium) are not yet known. Other metal ketyls, particularly those that are soluble, such as benzophenonepotassium or tetraphenylcyclopentadienonepotassium, exist more or less as free radicals in a pinacol anion/ketyl equilibrium. The potassium derivative of Michler's ketone is the first known compound that exists completely in the form of the ketyl radical [16, 17].

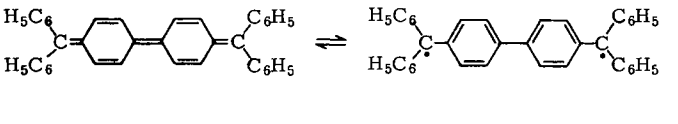
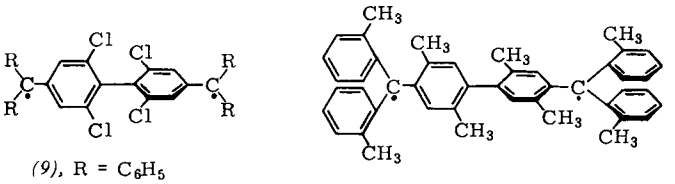
### b) Detection of Diradicals by the Gouy Method

Measurements carried out with the Gouy balance have shown that the Chichibabin hydrocarbon *(7)* (which was formerly regarded as a typical carbon diradical) and many similar compounds are diamagnetic and should therefore be formulated as quinonoid structures (limits of error: 1–3 % of diradical, cf. also [11]).



*(7)* *(8)*



*(9)*, R = $C_6H_5$

*(10)*, R = $C_6H_4$-$C_6H_5$ *(11)*

In order to obtain carbon diradicals, it is necessary to prevent the formation of a quinonoid arrangement. Thus, since *meta*-quinones cannot exist, the Schlenk hydrocarbon *(8)* should behave as a "double" triphenylmethyl [18]. This substance is in fact paramagnetic [19]. Unfortunately, however, its association behavior has not yet been elucidated.

Formation of a quinonoid form is also impossible in the case of biphenyls of the type *(9)* and *(10)* [20, 21]. The free radical *(11)* is also unable to undergo association [22]; in accordance with the theory, therefore, $\mu_{eff} = 2.43\ \mu_B$ (theoretical value: $\sqrt{6} = 2.45\ \mu_B$) [11].

Finally, diradicals can also be obtained if the free-radical centers are separated by saturated and suitably substituted carbon atoms [23]. Even triradicals and tetraradicals with structures of this type are known [24], and it is quite conceivable that polyradicals exist in polymeric compounds.

### 3. Limitations of the Gouy Method

The disadvantages of the Gouy method are as follows:

1. The diamagnetic "ballast" is always included in the measurements.
2. Relatively large quantities of the substance are required (0.1–1 g).
3. The measurements generally take several hours.
4. Because of 3, only long-lived radicals (half-lives $\gg$ 1 h) can be studied.

One distinct advantage of the Gouy method, however, is that it can be used for the quantitative determination of the free radical content of a sample.

## C. Applications and Limitations of the ESR Method

### 1. Principles

Paramagnetic substances can now be studied in much greater detail by electron spin resonance (ESR) [25] than by means of the Gouy balance.

#### a) Electron Spin Resonance

The electron spin of a free radical may align either parallel to or anti-parallel to an external magnetic field. These two states differ in their energies, the difference being proportional to the field strength $H_o$:

$$\Delta E = g \cdot \mu_B \cdot H_o$$

($\mu_B$ = Bohr magneton; g = a constant, which is specific for the free radical in question, and which is approximately 2 for $^2\Sigma_{1/2}$ states, see below). Exposure of the free-radical sample to electromagnetic waves of the frequency $\nu$ for which the resonance condition

$$h\nu = g \cdot \mu_B \cdot H_o$$

is satisfied leads to transitions between the two energy levels, resulting in measurable absorptions of the radiation energy [26]. Nearly all ESR studies are carried out with 3 cm waves, which correspond to a field strength of $H_o \approx 3300$ gauss.

The relaxation times ($10^{-5}$ to $10^{-6}$ sec) typical of organic free radicals in solution are such that it is possible, in routine work, to detect a free-radical concentration of $10^{-6}$ mole/l in a volume of about 0.5 ml.

#### b) The g-Factor

The position of the spectrum in the magnetic field is determined by the magnitude of the factor g. Deviations of this factor for organic radicals from the value for a completely free electron (2.0023) are due to spin-orbital coupling of the unpaired electron. This coupling is so slight in the case of the light elements that the g-factors of the common organic radicals are within 0.2% of that of the free electron. Larger deviations indicate some localization of the unpaired electron on a heavy atom. Thus an accurate knowledge of the spin-orbital coupling would enable us to draw conclusions regarding the spin-density distribution.

In triplet ground states (two unpaired electron spins $\uparrow\uparrow$), transitions between the terms with $m_s = +1$ and $m_s = -1$ are no longer forbidden, owing to the interaction of the two unpaired electrons. Since the difference in the energies of these terms is given, to a first approximation, by

$$\Delta E = 2 \cdot g \cdot \mu_B \cdot H_o$$

this transition gives rise to an ESR signal at the field strength 0.5 $H_o$, with a formal g-factor of

$$g' = 2\,g \approx 4.$$

The intensities of these half-field transitions are closely related to the difference between the energies of the triplet and singlet states. Where there is complete degeneracy of the two states, these transitions are strictly forbidden. This provides a method of differentiating between the triplet state of a radical (with a higher singlet state) and a diradical (triplet-singlet degeneracy, cf. p. 14).

#### c) Hyperfine Structure

By far the most important phenomenon of an electron-resonance signal is its splitting into several components, *i.e.* the hyperfine structure (HFS) [26]. This is due to the magnetic interaction of the free electron with atomic nuclei ($^1H$, $^{14}N$, $^{13}C$, $^{17}O$, *etc.*) in the molecule. The magnitude of this interaction is proportional to the probability that the unpaired electron will be found on the nucleus in question, and is reflected in the distances between the components of the signal, *i.e.* in the coupling parameters a of the various nuclei. Thus, in many cases measurement of the coupling parameters can provide information about the probability that the unpaired electron will be found on the various nuclei and their neighbors (or more precisely, about the spin density of the unpaired electron on the nuclei). For example, in a free radical of the type $\dot{>}C-H$, the spin density $\rho_C$ of the p-electron on the carbon satisfies the equation

$$a_H = Q\rho_C$$

($a_H$ = coupling parameter of the proton; $Q \approx -23$ gauss). Spin densities on other nuclei can be calculated from the HFS with the aid of fundamentally similar equations.

### 2. Applications of the ESR Method

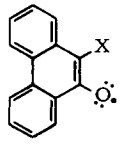
#### a) Detection of Free Radicals

ESR measurements have shown that several compounds, which had previously been regarded as free radicals, exhibit little or no paramagnetism. Thus the "stable

[25] *E. Zavoiskii*, J. Physics (Moscow) *9*, 245 (1945); Chem. Zbl. *40*, 1073 (1946).

[26] Detailed descriptions of the ESR method: a) *K. Scheffler*, Z. Elektrochem., Ber. Bunsenges. physik. Chem. *65*, 439 (1961); b) *A. Horsfield*, Chimia *17*, 42 (1963); c) *K. H. Hausser*, Chimia *14*, 153 (1960); d) *J. R. Morton*, Chem. Reviews *64*, 453 (1964); e) *M. C. R. Symons*, Adv. phys. org. Chemistry *1*, 284 (1963); f) *D. J. E. Ingram*: Free Radicals as Studied by Electron Spin Resonance, Butterworths, London 1958.

oxygen radicals" *(12)–(16)* [27] have been found by ESR measurements to be diamagnetic [the free-radical content of *(16)* is approximately 0.1% [28]; no paramagnetism in *(15)*]. When solutions of the dimer of *(16)*



*(12)*, X = $OCH_3$
*(13)*, X = $OC_6H_5$
*(14)*, X = Br
*(15)*, X = Cl
*(16)*, X = $OC_2H_5$

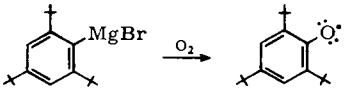
in benzene or toluene were kept in the dark, no dissociation could be detected with the magnetic balance at temperatures of up to 50 °C [29].

On the other hand, the free-radical nature of other compounds was first demonstrated by the ESR method. In addition to the sulfur radicals (which will be discussed later), these substances include the unstable carbon radicals such as methyl [30], 2-cyano-2-propyl [31], and other alkyl radicals [30], as well as cyclopentyl [30], cyclopentadienyl [32], cyclohexyl [30], cyclohexenyl [32], cyclohexadienyl [30], cycloheptyl [30], and tropyl [33].

A useful method for the ESR investigation of less stable radicals is the irradiation of suitable compounds in solution, in the solid state, at low temperatures, or in an olefin or alcohol matrix [30,32,34]. For ESR studies on free radicals in biological systems, the reader is referred to the literature [35].

The ESR method has recently been used for the detection of free-radical intermediates in chemical reactions. Thus studies have been carried out on the decomposition of aliphatic peroxides to form peroxy radicals [36] and the formation of aroxyls from quinonoid peroxides [37]. 4-Dimethylaminophenoxyl [38] was shown to occur during the photolysis of aryldiazonium salts, and free radicals have even been detected in Friedel-Crafts reactions [39] and in the addition of HBr to olefins catalysed by ultraviolet light [40].

Finally, ESR signals of free radicals have been observed when Grignard compounds were treated with oxygen or quinones [41]; for example, in the presence of air, 2,4,6-tri-t-butylphenylmagnesium bromide forms the aroxyl *(6)*.

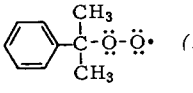


*(6)*

### b) Investigations Based on the g-Factor

#### α) *Monoradicals (g ≈ 2)*

Apart from the detection of free radicals by the observation of an ESR signal, the accurate determination of the g-factor is also important, particularly for solid samples, which do not exhibit hyperfine structure.



*(17)*

Thus the g-factor of *(17)* is 2.0187 [36,42]. The unpaired electron in *(17)* must therefore be largely localized on a heavier element (participation of orbital magnetism), *i.e.* on oxygen.

A similar situation is found in free radicals containing sulfur, selenium, or phosphorus [43,44]. Thus when diphenyl disulfide vapor or tetraphenyldiphosphine vapor is exposed to light, a paramagnetic solid is deposited on a cold finger cooled with liquid air; the only method by which these solids could be shown to exhibit the character of sulfur radicals or phosphorus radicals was by determination of their g-factors [44].

#### β) *Triplet States (g ≈ 4)*

Triplet states occur in bisaroxyls, such as bisgalvinoxyl *(18)* [45] and fluorenylidenebisphenoxyl *(19)* [46].

In the case of the radical *(20)*, on the other hand, the halffield resonance could not be observed [47]. The

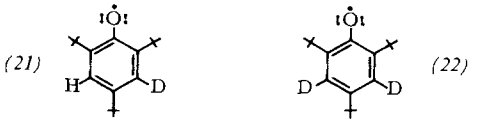
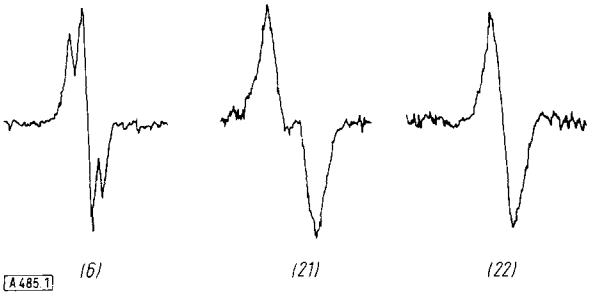
## c) Examples of Hyperfine Structure Studies

The following shows a number of applications of HFS studies for the case of the aroxyls [54].

The ESR spectrum of 2,4,6-tri-t-butylphenoxyl *(6)* and the spectra of radicals with similar structures consist of three lines having the relative intensities 1:2:1 (Fig. 1). Thus the unpaired electron is not localized on the oxygen atom; instead, the spectrum shows the existence of an interaction between the odd electron and the nuclear spin of the equivalent *meta*-protons of the aromatic ring.



(21) (22)



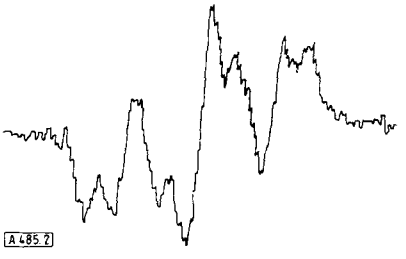
A 485.1 (6) (21) (22)

Fig. 1. ESR spectra of the free radicals *(6)*, *(21)*, and *(22)*.

In order to check this conclusion, the *meta*-protons were successively replaced by deuterium [*(21)*, *(22)*]. As expected [55], the triplet becomes a doublet (1:1) when the first proton is replaced, and a singlet when both protons are replaced (Fig. 1) [56,57]. To check for a free electron density on C-1 of the ring, [1-$^{13}$C]-2,4,6-tri-t-butylphenoxyl *(23)* [58] was synthesized with a $^{13}$C content of 53.1 %. The ESR spectrum of this aroxyl (Fig. 2) contains seven components. These are to be

(23) (24)

expected from the superposition of the triplet due to the unlabelled aroxyl (46.9 %) on the doublet of triplets due to the [1-$^{13}$C]-aroxyl (53.1 %) if there is any coupling of the unpaired electron with C-1 ($^{13}$C: I = $^1/_2$, $\mu_I$ = 0.70216 $\mu_K$).



A 485.2

Fig. 2. ESR spectrum of *(23)*.

The coupling parameter $a_{^{13}C}$ = 9.6 gauss gives approximately 1.75 % for the 2s component of the unpaired electron on C-1 of the ring.

The ESR spectrum of [$^{17}$O]-2,4,6-tri-t-butylphenoxyl *(24)* containing 6 % of $^{17}$O (Fig. 3) [superposition of the triplet due to the unlabelled *(6)* on the sextet of triplets due to *(24)*] shows that the spin density for the oxygen atom in *(6)* and *(24)* is also finite ($a_{^{17}O}$ = 10.23 gauss, corresponding to a 2s component of 1.25 %) [59].

With better resolution, *(6)* exhibits an additional HFS due to the t-butyl groups (Fig. 4) [26a,60]. It is found that

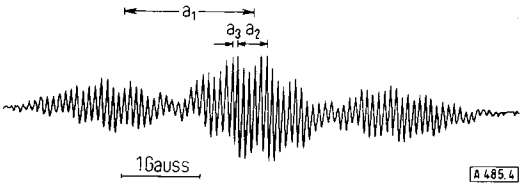

Fig. 4. ESR spectrum of *(6)* at higher resolution than in Fig. 1.

$a_2$ = 0.37 gauss for the *para*-t-butyl group, and $a_3$ = 0.074 for the *ortho*-t-butyl groups ($a_1 = a_{Hmeta}$). The unpaired electron must therefore have a finite spin density on all the ring carbon atoms and on the oxygen atom of *(6)* ("shared" electron) [61].

Similar observations have been made for many other aroxyls [57,62] (including the unsubstituted phenoxyl [63]) and for semiquinones [64].

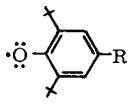
Studies by *G. A. Russel et al.* [65] on alicyclic semiquinones have shown that conclusions regarding the conformations of these compounds can be drawn from the ESR hyperfine structure. This method should be useful im the study of steroid ketones.

The interactions between the substituents and the aromatic ring in the aroxyls were studied in detail. Substituents modify the spin density distribution in the ring, and the unpaired electron can have a finite spin density on certain atoms of a substituent, characterized by the coupling parameters a of the HFS splitting. A few examples are given in Table 2.

$a_{Hmeta}$ increases by a factor of from 3 to 5 as we pass from substituents with a (+E) effect to electron-attracting substituents; however, there is no linear relationship with Hammett's σ-values. It can also be seen from Table 2 that there is a finite spin density even on atoms situated some distance away from the aroxyl ring and linked to the ring by multiple bonds, hetero-atoms, or even single bonds. Owing to the resulting HFS splitting, the ESR method provided the first means of detecting mesomeric selenium, phosphorus, arsenic, and tin radicals.

The spin density distribution can be determined in a similar manner for other radicals, such as nitrogen radicals [56] or hydrocarbon anion-radicals [73].

Table 2. Coupling parameters in aroxyls



(in benzene at 20 °C).

| R | Coupling parameters [gauss] $a_{Hmeta}$ | Coupling parameters [gauss] Other a-values | Lit. |
|---|---|---|---|
| $N(CH_3)_2$ | <0.15 | $a_N$ = 5.04; $a_{CH_3}$ = 4.54 | [66] |
| NC | 0.88 | $a_N$ = 5.06 | [66] |

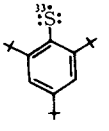
[a] The hydrogen of the methine group is taken as Hα.

The first evidence for the existence of sulfur radicals in solution was recently provided by the observation of a $^{33}S$-hyperfine structure in the ESR spectrum of the radical *(25)* in solution [74].



*(25)*

The hyperfine structure can also be used for the study of solvent effects on free radicals [75]. Owing to complexing of the free radical with the solvent, the overall electron distribution, and hence also the spin density distribution (the a values) will depend on the solvent.

The electron distribution, and hence the hyperfine structure of the ESR spectrum, can also vary with temperature, possibly as a result of a change in the ease of rotation of certain substituents (*e.g.* the $NH_2$ group [76] or the O=CH group [77].

### 3. Advantages and Disadvantages of the ESR Method

Since the ESR method can be used for low free-radical concentrations and small measuring volumes, the sensitivity of detection is very much greater than with static methods.

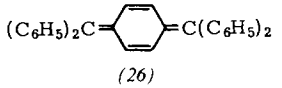
Another advantage of ESR spectroscopy as compared with the Gouy method is the fact that the former is not affected by the diamagnetism of the sample.

In the quantitative evaluation of the ESR signals by comparison with the spectra of standard substances, interference may arise as a result of differences in the relaxation time. Furthermore, the accuracy of such an evaluation depends on the state of the standard. This can be an important disadvantage in the determination of free-radical contents.

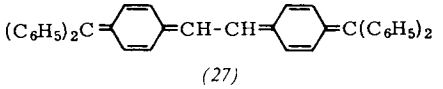
### D. The Ortho-Para Hydrogen Conversion

When high-temperature equilibrium hydrogen is adsorbed on charcoal at the temperature of liquid air, it is converted into a mixture containing from 40 to 50 % of para-hydrogen (nuclear spins: ortho ↑↑, para ↑↓). The o:p ratio is displaced back towards the equilibrium value (3 o-$H_2$: 1 p-$H_2$ at room temperature) by collision of the ortho/para $H_2$ molecules with free radicals. The content of para-hydrogen is determined by measurement of the thermal conductivity between 100 and 200 °K, since the specific heats of ortho- and para-hydrogens differ most at 170 °K. *G.-M. Schwab* [78] has shown that this method can be used for the determination of carbon monoradicals and diradicals.

However, the free radical contents found by this method for the Thiele hydrocarbon *(26)*, the Chichibabin hydrocarbon *(7)*, and the compound *(27)* (which was synthesized by *Wittig*) are higher than those found by the Gouy [79] or ESR methods (cf. p. 14).



*(26)*



*(27)*

Recent calculations by *H. Hartmann* [80] have shown that even in the singlet ground state, the compounds *(26)*, *(7)*, and *(27)* bring about a para-ortho hydrogen conversion. The calculated rates of the conversion agree in their sequence and in their order of magnitude with the values found experimentally by *Schwab*. Thus the ortho-para hydrogen conversion is not a suitable method for the study of substances of this type (diradicaloids [79]).

The method has the advantage, however, that it depends only on the presence of the nuclear spin moments (of $H_2$) and the electron spin in the free radical, and is therefore unaffected by the diamagnetic ballast. Moreover, it is not a difference method, and it is as sensitive as the Gouy method.

### E. Susceptibility Determinations by Measurement of the Nuclear Magnetic Resonance

The position of a nuclear resonance signal depends on the strength H of the magnetic field that acts on the nucleus. H is made up of the external magnetic field $H_o$, the magnetic field $H_{dia}$ induced by the external field, and the field $H_{para}$ of the paramagnetic particles present in the sample. Thus under the influence of $H_{dia}$ and $H_{para}$, the $H_o$ signal undergoes a characteristic shift

$$\Delta H/H = (2\pi/3)\cdot\Delta\chi_V$$

provided that cylindrical cells are used [81,82]. ($\Delta\chi_V$ is the change in the volume susceptibility of the sample; the total susceptibility $\chi = \chi_{dia} + \chi_{para}$).

Thus the shift $\Delta H/H$ can be used to find the magnetic susceptibility of a free radical by examination of the solution of a standard substance alone in one part of a (cylindrical) concentric double tube, and with the addition of the free radical in the other part. If the observed shift is $\Delta f$ [c/s], the gram susceptibility $\chi$ of the solution can be calculated [83] from:

$$\chi = 3\,\Delta f/2\pi f m + \chi_s + \chi_s\,(d_s - d_l)/m$$

(f = measuring frequency in c/s, m = quantity of substance in 1 ml of solution, $\chi_s$ = gram susceptibility of the solvent, $d^s$ = density of the solvent, $d_l$ = density of the solution). It is assumed that there is no interaction between the standard and the paramagnetic sample.

*H. J. Friedrich* [8a,83] confirmed the above two equations by careful measurements. For very pure [7,81] α,α-diphenyl-β-picrylhydrazyl *(3)* in nitromethane with 10 % by volume of acetonitrile, he found $\chi_{para} = +1273 \times 10^{-6}$ (20 °C), and hence $\mu_{eff} = 1.73\ \mu_B$; this is in excellent agreement with the values found earlier [7] by the Gouy method (cf. Table 1).

*Friedrich* showed [84] that a number of free-radical ammonium salts of the type $(R \cdots X \cdots X \cdots R)^{\oplus}\ Y^{\ominus}$ [85], in which *e.g.* R=*N*-ethylquinol-2-yl, X=N, and $Y=ClO_4$ [85], exist as monomers.

According to *K. H. Hausser* [60], the NMR method can also be used to investigate the structures of free radicals [as, for

example, *(6)*], as long as the ESR coupling parameters a and the viscosity of the solvent are small, whereas the radical concentration and the temperature must be high. From such NMR spectra coupling parameters a can be found which are below the limits of detectability of the ESR method.

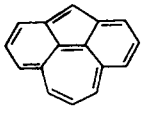
## F. Unsolved Problems

### 1. The Diradical Problem

In an atropic diradical such as *(7)*, the spins of the two unpaired electrons are practically independent of each other. The singlet ($^1\Sigma$) and triplet ($^3\Sigma$) states are degenerate, and the spin moments are present in the ratio of their statistical weights ($\uparrow\downarrow : \uparrow\uparrow = 1:3$). This gives a magnetic moment of $\sqrt{6}\ \mu_B$, which agrees with the value found by the Gouy method (see p. 8). According to p. 9, there should be no (g = 4)-resonance in the ESR spectra of these compounds. Carbon radicals of this type are known as diradicals [79].

These diradicals should be distinguished from compounds with a true triplet state ($\uparrow\uparrow$, $\mu_{eff} = \sqrt{8}\ \mu_B$ [79]) which is at a lower energy level than the singlet state. The latter can, in principle, be detected by susceptibility measurements and by the presence of the half-field resonance ($g \approx 4$). This situation is found in the oxygen molecule ($O_2$), as well as in *e.g.* the oxygen diradicals *(18)* and *(19)*.

An example of a hydrocarbon that should have a triplet ground state [86], or at least a triplet state that can be easily excited by heat, is cyclohepta[*def*]fluorene *(28)*; however, this compound has not yet been prepared [87].



*(28)*

Singlet-triplet transitions in nitrogen radicals have already been described [88]. (For nitrogen triradicals, see [24].)

Let us now consider the Chichibabin hydrocarbon *(7)* and its analogs. According to the Gouy method these substances are diamagnetic, and should be assigned quinonoid structures. However, the much more sensitive ESR method indicates the presence of free radicals in concentrations of up to 4% [90]. The triplet state ($g' \approx 4$) cannot be detected. The $^{13}C$ hyperfine structure indicates the presence of two independent half-molecules (radicals) [91]. Thus the paramagnetic components of these substances, which can be assigned a quinonoid structure, appear to be present as diradicals [92], and are therefore similar to *e.g.* the Schlenk hydrocarbon *(8)* [93].

Former differences between theoretical calculations and experimental results (which were referred to as paradoxes in the physical sense [94]) appear to have been eliminated by recent calculations [95].

However, compounds of the type *(7)* differ from atropic diradicals in their high reactivities, their intense colors, and the fact that (where the biphenyl system is planar) they can be formulated as quinones. If there were no physical difference between these substances and the atropic diradicals, how would we explain the difference in their chemical properties? Is this, therefore, another paradox?

### 2. The "Selwood Effect"

In the course of attempts to measure the heats of dissociation of hexa-*p*-biphenylethane and hexa-*p*-t-butylphenylethane, *Selwood* and *Dobres* [96] found only 70% dissociation into monoradicals, instead of the expected 100%. Moreover, the apparent degree of dissociation was independent of the temperature. Since the Gouy method and the hydrogen ortho-para conversion led to different conclusions for compounds like the Chichibabin hydrocarbon *(7)* (cf. however [80]), the authors tried to find an explanation for this difference. They assumed that it was due to a fundamental error in the determination of the diamagnetic correction. As has already been mentioned, this correction can be found, for example, by measurement of the diamagnetic susceptibility of the non-radical compound with one hydrogen atom more, and subtraction of the Pascal increment for the hydrogen atom from the result. If this correction where found to be wrong for one radical, doubt would be cast on the Gouy method as a whole. *Selwood* proposed the following explanation for this effect. According to quantum theory, the additional resonance that is possible in free radicals such as the triarylmethyls (distribution of the unpaired electron over all the carbon atoms of all the aromatic nuclei)

---

[86] *P. Baumgartner, E. Weltin, G. Wagnière,* and *E. Heilbronner,* Helv. chim. Acta *48*, 751 (1965).

[87] For the excitation of the triplet state in rubrene, cf. *M. Wilk,* Z. Elektrochem. *64*, 936 (1960). This author gives the dark value $\chi_{mol} = -620$ ($\times 10^{-6}$) for rubrene. The correct value, however, is −340. Thus the difference from the value on irradiation (−280) is only +60, *i.e.* equivalent to a diradical content of 1 to 2%; this value is within the limits of error, cf. [19].

[88] *R. Kuhn, H. Katz,* and *W. Francke,* Naturwissenschaften *22*, 808 (1934), were the first to report the temperature-dependence of the magnetism of porphyrindin. Our measurements [89] showed the presence of a diamagnetic low-temperature form ($\uparrow\downarrow$) and a paramagnetic high-temperature form ($\uparrow\uparrow$) ($\Delta W \approx 0.5$ kcal/mole).

contributes to the stability of the radical. Owing to the increase in the ring current, this additional resonance gives rise to an additional diamagnetism perpendicular to the plane of the aromatic ring. In other words, the additional resonance stabilization of free triarylmethyl radicals is accompanied by a marked increase in the molecular anisotropy. The susceptibility values obtained by *Selwood* lead to reasonable results (100 % dissociation) if the diamagnetic correction is increased by 80 %. This means an increase of 240 % in the total molecular susceptibility perpendicular to the plane of the ring. No theoretical explanation has yet been found for this anisotropy effect. Attempts to prove the "Selwood effect" have so far shown the opposite [97].

We have already referred [79] to the experimental difficulties encountered in the preparation of radicals such as those studied by *Selwood* (cf. [111]). Moreover, the usual diamagnetic corrections were found to give radical contents of 100 % for other radicals (cf. p. 7/8). We are therefore of the opinion that, in spite of *Selwood*'s objections, the magnetochemical method as described by Gouy is still suitable for use in susceptibility measurements on free radicals [98].

*The Gouy method may be regarded as the precursor of many physical methods (such as infrared, ESR, and NMR spectroscopy) that have now become indispensable aids to the organic chemist. Eugen Müller is very grateful to Wilhelm Klemm for the opportunity to take part in the early development of this method.*

# The Separation of Zirconium and Hafnium by Liquid-Liquid Partition of their Thiocyanates [1]

BY PROF. DR. WERNER FISCHER, DR. B. DEIERLING, DR. H. HEITSCH, DR. G. OTTO, DR. H.-P. POHLMANN, AND DR. K. REINHARDT

INSTITUT FÜR ANORGANISCHE CHEMIE DER TECHNISCHEN HOCHSCHULE HANNOVER (GERMANY)

*Dedicated to Professor W. Klemm on the occasion of his 70th birthday*

*The partition equilibria of zirconium and hafnium thiocyanates between water and methyl isobutyl ketone have been studied under various conditions. Since the system shows extremely marked deviations from Nernst's distribution law, the two elements cannot be prepared in a very pure state by a simple multi-stage partition. By the use of suitable additives and a new scheme of material flow, however, a continuous process using 23 mixer settlers has been developed, by means of which $ZrO_2$ containing less than 10 p.p.m. of $HfO_2$ and $HfO_2$ containing only 0.3 % of $ZrO_2$ can be obtained from a zirconium-hafnium mixture (hafnium content: 1 to 2 %).*

Methods based on distribution between two liquid phases are particularly valuable for the separation of substances with very similar properties. The advantages of these methods are the ease of multi-stage repetition of the individual steps, the possibility of continuous and automatic operation, the fact that the process can be carried out at room temperature, and the consequent savings in time and power. Since there is no interference due to adsorption, formation of mixed crystals, *etc.*, the efficiency of separation remains essentially constant up to very high purities. The separation of zirconium and hafnium by distribution of their thiocyanates between two solvents has the additional advantages that the separation factors are relatively high, and that high concentrations can be used in both phases, so that the volumes of liquid required and the dimensions of the equipment need not be large.

Nevertheless, there are also a number of difficulties. The problems of the ease of oxidation of thiocyanic acid and the susceptibility of zirconium and hafnium salts to hydrolysis can be overcome by careful operation. However, fundamental problems arise as a result of the marked variation of the distribution coefficient with experimental conditions (temperature, concentrations of the necessary five or six reactants). Because of this variation, it is almost impossible to obtain a complete picture of the position of all the equilibria, and the extremely wide variations of the partition coefficients lead to special difficulties in the multi-stage solvent extraction.

[1] 16th Communication on the separation of inorganic substances by partition between two liquid phases. 15th Communicaton: *W. Fischer, K.-J. Bramekamp, M. Klinge,* and *H.-P. Pohlmann,* Z. anorg. Chem. *329,* 44 (1964).

Some 15 years ago the separation of zirconium and hafnium became important in nuclear technology, owing to the large difference between the neutron capture cross sections of the two elements and because of the desirable properties of metallic zirconium. Since the purity requirements were high (*e.g.* $<100$ p.p.m. of Hf in Zr), liquid-liquid extraction seemed to offer a particularly suitable method of separation. For this reason, American workers (1949) and the present authors (1950) tried to make use of an earlier observation [2] that high separation efficiencies could be achieved by the distribution of the thiocyanates of the two elements between water and diethyl ether. However, in view of the volatility of ether and the associated fire hazard, as well as its tendency to promote the oxidation of thiocyanic acid, it was desirable to use some other solvent. When the results of the American workers (which had originally been kept secret) [3] became available, it was found that they, like we ourselves [4], had also found aliphatic ketones to be suitable. The most readily available of these ketones is methyl isobutyl ketone [5], which will be referred to as hexanone in the remainder of this paper. Industrial processes have been developed [6] both in the U.S.A. and in Germany on the above basis.

The present paper, which is confined to partition between water and hexanone, will deal with the rather complex chemistry of the process, insofar as it has been elucidated; we shall also describe a plant for separation on the kilogram scale [7], which differs in a number of important points from previous designs.

## I. Chemical Principles

The partition coefficient K is defined as the ratio of the total concentrations of all the species of an element or substance in the two phases existing in equilibrium, *i.e.*, $K = c_H/c_W$ (H = hexanone, W = water). The separation factor $\beta$ is the ratio of the partition coefficients, *i.e.* $\beta = K_{Hf}/K_{Zr}$. For other definitions, see [8]. The zirconium and hafnium contents of a sample are always expressed as the percentages by weight of $ZrO_2$ and $HfO_2$ in the oxide prepared from the sample.

The partition coefficient of thiocyanic acid between water and hexanone at 20 °C and at concentrations of 1–2.3 M in the aqueous solution is about 1.8 [9,11]. It is 3 % smaller at 35 °C than at 15 °C. It is slightly depressed by the addition of $(NH_4)_2SO_4$, and considerably increased by $NH_4SCN$ or $H_2SO_4$. This common ion effect indicates that thiocyanic acid is not completely dissociated [9]. Hexanone extracts only 5 % of the ammonium thiocyanate from an equal volume of an almost saturated aqueous solution of this salt. No sulfate can be detected in hexanone that has been equilibrated with 2 M aqueous sulfuric acid, and chloride enters the hexanone phase only to a very small extent [9].

The procedure used in the work described in this section was very similar to that reported earlier [9]. The two phases were always used in equal volumes. The Zr and Hf contents were determined either by X-ray analysis (for apparatus see [10]) or by neutron activation analysis [12].

The partition of Zr and Hf thiocyanates exhibits considerable temperature-dependence. In the extraction of zirconium from a 1.3 M aqueous solution of HSCN containing from 1.5 to 22 g/l of $ZrO_2$, the partition coefficient of zirconium decreases by about 2 % per degree as the temperature is raised from 15 to 35 °C. The experiments described below were carried out at 20 ± 0.5 °C. When the desired temperature was reached, the distribution equilibria were already established.

### a) Effect of Concentration

The partition of zirconium and of hafnium between solutions of thiocyanic acid in water and in hexanone was first studied in the absence of other substances. The two elements were added to the solutions as the solid oxide chlorides. Figs. 1 and 2 show how the partition coefficient of zirconium is affected by its concentration in the aqueous phase at various constant thiocyanic acid concentrations in the hexanone phase, and *vice versa*. The curves for hafnium follow a similar trend, but the values of K are always higher (*i.e.*, hafnium has a greater tendency to enter the organic phase), generally by a factor of about 5 [9,11].

The thiocyanic acid concentrations were always measured before the zirconium or hafnium salts were added because small quantities of added salts have practically no effect on the distribution of the acid, while large quantities interfere with its determination.

The partition coefficients vary by two powers of ten in the concentration range studied. If these values were also valid for mixtures of the two elements, separation factors, $\beta$, of higher than 50 should be obtained at high zirconium concentrations and low hafnium concentrations, while when the relative concentrations are reversed, $\beta$ should be less than 1, *i.e.*, the zirconium should pass preferentially into the hexanone. In practice, however, the partition of each element is influenced by the addition of the other in the same manner as by an increase in its own concentration. For this reason, all separation factors obtained in the partition of mixtures ($ZrO_2$:$HfO_2$ = 99:1 to 5:95) are between 3 and 6 [9,11].

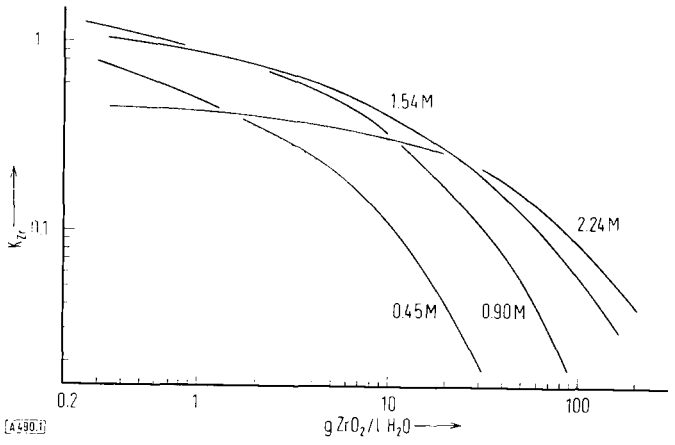

Fig. 1. Partition coefficient of zirconium, $K_{Zr}$, as a function of the equilibrium concentration of zirconium in the aqueous phase, for various concentrations of HSCN in hexanone (in equilibrium with the aqueous phase before the zirconium salt is added).

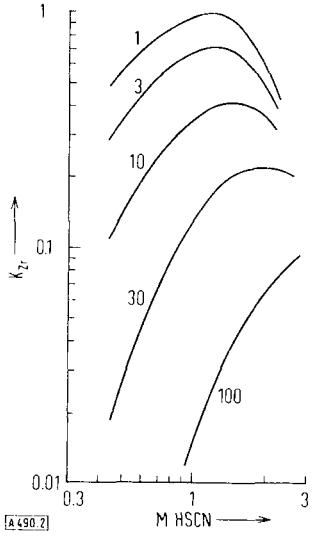

Fig. 2. Partition coefficients of zirconium, $K_{Zr}$, as a function of the concentrations of HSCN in hexanone (in equilibrium with the aqueous phase before the Zr salt is added). The numbers beside the curves denote the concentrations (in g/l) of $ZrO_2$ in the aqueous phase (after partition).

They increase with increasing HSCN concentrations, and high metal concentrations [100 to 150 g/l of (Zr, Hf)$O_2$ in the aqueous phase] also seem to favor β values near the upper limit. Experiments with radioactive tracers or using neutron activation analysis [12] showed [11] that the separation factors are also of this order in the range of $ZrO_2$:$HfO_2$ ratios from $10^2$ to $10^5$ that are of interest for the preparation of zirconium compounds with very low hafnium contents. No confirmation was found for an earlier observation [9] that β increases with decreasing hafnium content.

A quantitative treatment of the experimental results with a view to finding what chemical species are involved is impossible at the high concentrations used, since the activities of the species are unknown. The results reported here, as well as those of unpublished work [13], indicate the following two points to be important for a qualitative interpretation:

1. The aqueous phase must be assumed to contain numerous complexes of zirconium with $SCN^-$, $OH^-$, and $H_2O$, of which only non-electrolytes with a high SCN content, such as $Zr(SCN)_4$, can be extracted. For a given quantity of thiocyanic acid, an increase in the zirconium content will lead to an increase in the proportion of non-extractable complexes with low SCN contents, and hence to a decrease in the partition coefficient (see Fig. 1). This explains the unusual observation that as the concentration of zirconium in the aqueous phase *increases*, the concentration in the organic phase passes through a maximum and then *decreases* (see Fig. 3). The zirconium concentration at which the maximum occurs increases with the quantity of thiocyanic acid available. The slopes of the curves in Fig. 1 become smaller at lower zirconium concentrations, *i.e.* the partition coefficient tends towards a constant value. This probably means that the zirconium in each phase is largely present as a single species; the number of Zr atoms per complex molecule must be the same in each phase, and the species themselves may even be identical. In agreement with this, the zirconium contents at which the curves in Fig. 1 approach the horizontal increase with the concentration of thiocyanic acid. – Similar relationships are found in the case of hafnium. Thus the effects of zirconium and hafnium on each other are due to competition for thiocyanate ions. The reason for the preferential extraction of hafnium, therefore, is either that the extractable species of this metal are more stable than those of zirconium or that they have higher (individual) partition constants.

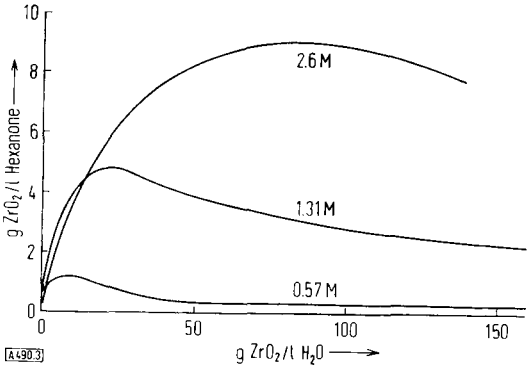

Fig. 3. Concentration of zirconium in the hexanone phase as a function of its concentration in the aqueous phase. The concentration of HSCN in hexanone (in equilibrium with the aqueous phase before the Zr salt is added) is shown on the curves.

2. The relationships described would require a monotonic increase in the partition coefficient with HSCN concentration at a given Zr concentration. The observed maximum (Fig. 2) is probably due to the facts that one liter of pure hexanone corresponds to only 8 moles, and that solvation of the thiocyanic acid at higher concentrations leads to a considerable decrease in the quantity of "free" hexanone available for the extraction of the zirconium thiocyanate. At high Zr concentrations (Fig. 2), a large proportion of thiocyanate is bound by the zirconium, so that both phases contain less free thiocyanic acid; consequently, the maximum then occurs at higher concentrations. The increase in $K_{Zr}$ with increasing HSCN concentration before the maximum is reached is not due to the suppression of hydro-

[13] *G. Dittrich*, Diploma Thesis, Technische Hochschule, Hannover 1964, and unpublished results.

lysis by the increasing $H^+$ concentration. In fact, the effect of the hydrogen ions acts in the opposite direction; thus the partition coefficients are unchanged by addition of $NH_4Cl$, whereas they are reduced by addition of hydrochlorid acid [9]. This hydrogen-ion effect is probably due to suppression of the dissociation of thiocyanic acid, resulting in the displacement of the distribution in favor of hexanone (see above). The consequent decrease in the thiocyanate content of the aqueous phase must have a depressing effect on the extraction of the zirconium, and this effect is aggravated, in our view, by the accompanying decrease in the quantity of "free" hexanone present.

b) Addition of Sulfates

Already in our first experiments with ether [2], we found that sulfate ions have a favorable effect on the separation efficiency. It was assumed that while the more stable of the (non-extractable) sulfate complexes is that of zirconium, the more stable (extractable) thiocyanate complex is that of hafnium.

Fundamentally similar results were obtained in systematic experiments [7] in which hexanone was used instead of ether. Figs. 4 and 5, in which (in contrast to Figs. 1 and 2, where a logarithmic presentation is used) the values are plotted on linear scales, show the effect of added ammonium sulfate on the partition of zirconium and of hafnium (separately) between aqueous and ketonic solutions of HSCN.

The equilibrium concentrations of thiocyanic acid are changed slightly by the addition of ammonium sulfate; thus $c_{Hexanone}$ is decreased from 2.2 to 2.0 and $c_{water}$ increased from 1.2 to 1.4 M HSCN by an $(NH_4)_2SO_4$ concentration of 1.11 M. The uppermost curve in Fig. 4 [no $(NH_4)_2SO_4$] corresponds to the curve for 2.24 M HSCN in hexanone in Fig. 1.

The addition of ammonium sulfate leads to a decrease in the partition coefficient, this decrease being greater for zirconium than for hafnium. In comparing Figs. 4 and

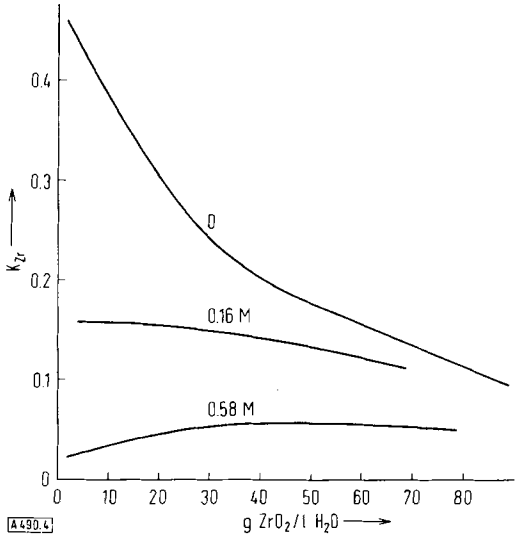

Fig. 4. Influence of ammonium sulfate on the partition coefficient $K_{Zr}$ of zirconium. HSCN concentration before the addition of the other substances 1.2 M in water and 2.2 M in hexanone. The values beside the curves denote the molarity of $(NH_4)_2SO_4$/l in water.

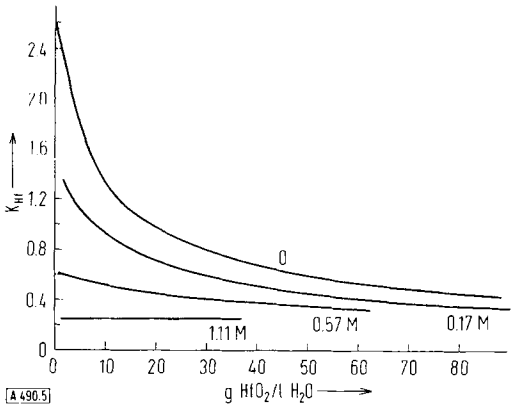

Fig. 5. Influence of ammonium sulfate on the partition coefficient of hafnium, $K_{Hf}$. See legend to Fig. 4.

5, it should be noted that the results shown for hafnium extend to higher sulfate concentrations. The sulfate effect is relatively stronger at low metal concentrations than at high concentrations, and in the case of zirconium this leads to the appearance of a maximum at higher sulfate concentrations. At low Zr concentrations, *i.e.* when there is a large excess of sulfate and thiocyanate, the non-extractable sulfate complex is evidently formed in preference to the thiocyanate complex. At intermediate Zr concentrations, the sulfate is no longer present in sufficient excess to bind such a large proportion of the zirconium, so that more of the latter is available for the formation of thiocyanate complexes. When the Zr concentration is further increased, the proportion of extractable zirconium is again decreased as a result of the effect demonstrated in Fig. 1 and described in Section I a.

If the ammonium sulfate is replaced by sulfuric acid, the partition coefficient of hafnium is further reduced by the hydrogen-ion effect described above. This effect has little influence on zirconium.

The addition of sulfate favors the separation of Zr and Hf by intensifying the differences in the behavior of the two metals; at the same time, however, the partition of both elements is considerably displaced in favor of the aqueous phase, with the result that separations on the preparative scale require large volumes of hexanone. It is known [2,4] that the addition of ammonium thiocyanate leads to a displacement in favor of the organic solvent, and that this effect is stronger for hafnium, so that the separation is further improved. Fig. 6 shows this effect for zirconium; for further data, see [7]. The maximum produced by the addition of sulfate is accentuated when ammonium thiocyanate is also present.

The addition of thiocyanate has a very different effect on the partition of hafnium in the presence of sulfate. The effect is strong even at low Hf concentrations, so that the difference between the behavior of Hf and Zr is very pronounced in this concentration range (see Fig. 7). Moreover, the dependence of the effect on the metal concentration is not the same for the two elements. The situation is further complicated by the fact that a change in the initial concentration of thiocyanic acid (which was kept constant in the experiments to which Figs. 6 and 7 refer) has a very marked effect on the partition coefficient [7].

Similar experiments on Zr-Hf mixtures gave even better results than were expected from Fig. 7. Fourteen experiments were carried out with from 2 to 23 g of metal oxide per liter of aqueous phase and from 30 to 95 % of $HfO_2$ in the (Zr-Hf) starting material, and with HSCN

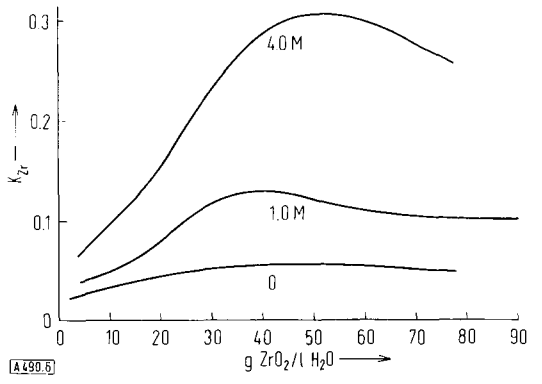

Fig. 6. Influence of $NH_4SCN$ (concentrations in water noted on the curves) on the partition coefficient of zirconium, $K_{Zr}$. The aqueous phase is also 0.57 to 0.58 M in ammonium sulfate. HSCN concentration before the addition of any other substances: 1.2 M in water and 2.2 M in hexanone.

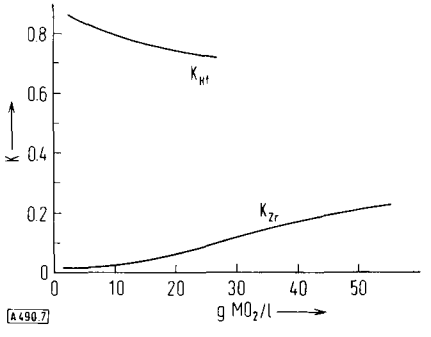

Fig. 7. Partition coefficients $K_{Hf}$ and $K_{Zr}$ as functions of the metal concentration, g $MO_2$/l, in the aqueous phase after the addition of 1.1 mole of $(NH_4)_2SO_4$ and 4.0 moles of $NH_4SCN$ per liter of aqueous phase. HSCN concentration before the addition of other substances: 1.2 M in water and 2.2 M in hexanone.

concentrations ranging from 0.4 to 2.6 M in hexanone; 1.1 mole of $(HN_4)_2SO_4$ and 4 moles of $NH_4SCN$ were added per liter of aqueous phase. With one exception, these experiments gave separation factors $\beta$ from 40 to 110. This method can be used with success for the separation of smaller quantities of material, and particularly for the preparation of very pure samples.

These conditions are less suitable for the processing of large quantities of material by multi-stage distribution, since it then becomes desirable to recover the large quantities of thiocyanate that must be used, and since the separation factors are probably lower at higher metal concentrations.

In the presence of 0.57 to 1.1 M $(NH_4)_2SO_4$, addition of 4 moles of $NH_4SCN$ per liter of aqueous phase causes the concentration of HSCN in the hexanone to increase from 2.2 to 2.6 or 2.7, while the concentration in the aqueous phase decreases from 1.2 to 0.7 or 0.8.

Frequent checks on (Zr, Hf) solutions with and without sulfate, and containing at least 1 M HSCN, revealed no changes in the partition coefficients when the solutions were stored for 24 hours at 20 °C, although such changes (probably due to slow hydrolysis) had been troublesome in earlier work with a different procedure [2].

### c) Oxidation of Thiocyanic Acid

In the course of several weeks' operation of the mixer settlers described below, air oxidation of the thiocyanic acid (which can be recognized by the precipitation of yellow products with very low solubilities in water and in hexanone) led to only a light deposit on the walls of the vessels, and did not cause any troublesome decrease in the HSCN concentration, provided that this was not appreciably greater than 2.6 M in the hexanone or than 1.4 M in the aqueous phase, and provided that the (Zr, Hf) sample to be processed had been largely freed from iron (*e.g.* by recrystallization as the oxide chloride from concentrated hydrochloric acid), since iron catalyses the oxidation of thiocyanic acid.

## II. Technical Principles

The multiplicative separation experiments were carried out in a multi-stage plant, which was capable of operating up to 36 of the previously developed [14] mixer settlers. The material flow scheme, with periodic addition of the mixture to be separated, differed from conventional practice in that the aqueous phase was introduced and discharged in batches, while the hexanone moved continuously in counter-current to the aqueous phase in such a way that at any moment, each mixer settler contained a finite volume of aqueous solution, together with only a minimum of the ketonic solution. The process was described in detail in an earlier publication [8] and its operation has been studied mathematically by *Horn* [15]. It differs from the usual processes (*e.g.* with two continuously moved solvent streams) in that only half as many mixer settlers are required in order to obtain a given separation efficiency, and the quantity of solvent required is also somewhat smaller.

The process is periodic in operation. Under quasi-stationary conditions, each successive period or cycle is identical with every other. For example, one cycle of an 11-stage partition (the results of which will be discussed below) is as follows (see Fig. 8): The plant comprises 14 mixer settlers (also referred to below as partition units or simply units) arranged in two lines or in a circle. Three of these (light circles in Fig. 8) are held in reserve. Numbers 1 to 10 are taken over, with their contents, from the previous cycle. A volume of the heavier solvent (water) is introduced into no. 11, where it remains as long as this mixer settler is in use. At the beginning of the cycle, no. 6 is supplied with a quantity of the mixture to be separated. Light solvent is then fed at a constant rate into no. 1. As the lighter solvent is introduced, brought into contact with the heavier phase, and then separated from the latter again, it is passed directly into no. 2 (so that no. 1 always contains the absolute minimum working volume of the light phase). In no. 2 it is treated in exactly the same manner, and so on. When a certain volume of the

[14] *W. Fischer et al.*, Angew. Chem. *66*, 317 (1954).
[15] *F. Horn*, Chemie-Ing.-Techn. *36*. 99 (1964).

light phase has passed in this way through stages 1 to 11 and has left no. 11 as the head fraction, the heavy phase from no. 1 is taken off as the tail fraction. This mixer settler is then taken into reserve, and the reserve unit next to no. 11 is charged with aqueous solution. Thus there are still 11 units in operation, but these are displaced by one unit in a clockwise direction from those used in the previous cycle. The new set of operating units are then re-numbered from 1 to 11 [8]. This completes one cycle.

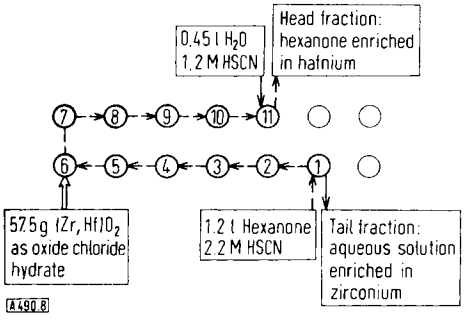

Fig. 8. Scheme of a partition cycle.
→ aqueous phase; — — → hexanone phase.

In conventional processes in which two solutes are to be separated by means of two liquid phases flowing in opposite directions, $v_l/v_h$ must be such that the extraction factor of one of the substances $G_1 = K_1 v_l/v_h > 1$, while that of the other $G_2 = K_2 v_l/v_h < 1$ ($v_l$ and $v_h$ are the volumes of the light and heavy phases, respectively, passing through the system per unit time or per cycle). Owing to the unsymmetrical flow of the two phases in our process, the reference value 1 is replaced by a somewhat different value [8]; however, we can disregard this in the following discussion.

If the partition factors in a plant fluctuate, the separation efficiency must suffer. If both G values in some part of the plant are greater than 1, for instance, both substances will move with the light phase, while in other parts they are moving in opposite directions.

Often the mixture to be separated is introduced as a solution in one of the solvents. If the mixture is dissolved in the heavy solvent, the ratio $v_l/v_h$ is lowered between the feed stage and heavy-phase discharge, so that the G values of all the species present will also be lower in this part of the plant. If, on the other hand, the mixture is dissolved in the light solvent, $v_l/v_h$ is increased in the other part of the plant. Both effects lower the overall separating effect of the plant. For this reason it is generally preferable to introduce the mixture in the solid form, particularly if the partition coefficients, K, of the components of the mixture are not very different [16].

In our case the G values are very inconstant, owing to the large variation of the partition coefficients. The concentration of the mixture to be separated is necessarily greatest in the feed stage. In the case of a mixture with an initial $HfO_2$ content of 1 to 2 %, there is only a slight decrease in concentration on the zirconium side of the plant, whereas the decrease on the hafnium side is very rapid. This leads to a wide variation of the partition coefficients. For large-scale separations it is desirable that the volumes of liquids used be as small as possible, *i.e.* that the concentrations be as high as possible. Under these conditions, however, the partition coefficient is most strongly affected by changes in concentration (see Fig. 1). Furthermore, the influence of the thiocyanic acid concentration and of any added sulfate or thiocyanate must also be taken into account. Even in the absence of the latter effects the K values, and hence the G values, of zirconium and hafnium can be expected to vary at least by a factor of ten in a multi-stage distribution plant, whereas the two values normally differ by a factor of only 5. It is therefore doubtful whether any extensive separation of Zr and Hf could be achieved in a single operation by multiplicative distribution; in any case, the difficulties would probably be very considerable. Owing to the complexity of the chemistry involved, the most favorable operating conditions could not be calculated in advance. The only profitable approach was that of systematic experiments, the results of which are discussed below.

## III. Development of a Multi-Stage Liquid-Liquid Extraction Process

Since the partition equilibria are strongly dependent on the temperature, the experiments were carried out in a room maintained at 20 ± 1 °C. The materials used were samples of zirconium oxide chloride hydrate containing 1.4 or 2 % of $HfO_2$ (based on the oxide). It is extremely important to ensure that the samples are free from products of further hydrolysis and from powdered zirconium ore. Since these substances are insoluble in water, they do not take part in the partition equilibria; when they are peptized or suspended and are not retained by the filters, they remain in the aqueous phase with the zirconium, with the result that the hafnium content of the latter cannot be reduced beyond a certain limit. As a precaution, we used oxide chloride samples prepared below 70 °C by the introduction of zirconium tetrachloride into hydrochloric acid and recrystallization from 6 M hydrochloric acid.

In choosing the conditions for the technical separation of large quantities by continuous multi-stage liquid-liquid extraction, it is not essential that the separation factor should be as high as possible. A lower separation efficiency of one partition operation can generally be compensated by the use of a larger number of stages; while this raises the initial cost of the plant, it does not complicate the operation appreciably. It is more important that other conditions, including economic restrictions, should be satisfied, *e.g.* insensitivity to small variations in procedure, easy processability of the final fractions, good phase separation, avoidance of corrosion, recovery of additives, low solvent consumption, *etc.* On the basis of these considerations, the Zr-Hf starting material was introduced as the solid oxide chloride hydrate and distributed between hexanone and water containing HSCN at concentrations of 2.2 M and 1.2 M respectively (for the preparation of the solutions see [9]), although the separation factors obtained by this method were only 4 to 5.

[16] German Patent 1134662 (Sept. 16th, 1960), Degussa; inventors: *W. Fischer* and *H. Renner*.

A point that has no bearing on the separation, but which is advantageous in practice, is that the hexanone solution leaving the plant as the head fraction should be passed through 2 or 3 other mixer settlers, each of which contains 500 ml of 3 M $H_2SO_4$; this set of units is changed after each cycle in the same way as the set used for the separation. The "washing stage" taken out of the process at each cycle then contains the Hf(+Zr) of the head fraction; the "washed" hexanone, on the other hand, contains only HSCN, and is re-used after correction of the HSCN concentration.

The procedure described below was used to determine the operating data for the plant described in Section II and to improve on the results obtained. The following factors were initially kept constant (cf. Fig. 8):

1. number of stages,
2. composition of starting mixture,
3. stage into which the mixture is fed,
4. quantity of mixture added per cycle,
5. HSCN contents of the solvents introduced at the ends of the plant,
6. volume of aqueous HSCN solution added per cycle.

Thus the only variable is the volume of hexanone introduced per cycle. If this is too large, the quantity of hafnium removed in the head fraction is larger, and the quantity of zirconium in the tail fraction smaller, than the quantities of the two elements added per cycle with the starting mixture. Consequently, the Hf/Zr ratio gradually decreases in all the stages, including that into which fresh mixture is fed at the beginning of each cycle. If the volume of hexanone used per cycle is too low, the situation is reversed. With the optimum hexanone feed, the Hf/Zr ratio in this stage is roughly equal to that in the starting mixture, and the quantities of the two metals removed are equal to the quantities added.

The Hf and Zr contents of the head and tail fractions, respectively, and the Hf/Zr ratio in the feed stage were systematically determined, and the quantity of hexanone introduced per cycle was varied until the above requirements were satisfied for at least some 10 cycles. The above "fixed" factors were then altered with the object of improving the purity of the fractions. The results are shown in Table 1.

Table 1. Operating data for the distribution plant under various operating conditions. Solvent added per cycle: 450 ml of 1.2 M aqueous HSCN ($v_h$) and various volumes (column 3, $v_l$) of 2.2 M HSCN in hexanone.

| Up to cycle no. | Number of stages | $v_l$ (ml) | Mixture [b] added in stage no. | Tail fraction, % of $HfO_2$ in the oxide | Head fraction, % of $ZrO_2$ in the oxide |
|---|---|---|---|---|---|
| 20 | 11 | 1200 | 6 [c] | 0.14 | 46 |
| 36 | 11 | 1100 | 6 [d] | 0.05 | 42 |
| 53 | 11 | 750 | 6 [e] | 0.04 | 25 |
| 70 | 13 | 780 | 6 [e] | — | 13 |
| 108 | 17 | 780 | 8 [e] | 0.04 | 12 |
| 131 | 17 | 880 [a] | 7 [e] | 0.02 | 0.3 |
| 168 | 23 | 900 [a] | 13 [e] | $<$0.001 | $0.2_5$ |

[a] Plus 0.05 M $H_2SO_4$ in the aqueous phase.

[b] 57.5 g of (Zr, Hf)$O_2$ containing 1.4 or 2 wt-% of $HfO_2$ were added per cycle, in the form of the oxide chloride hydrate.

[c] No addition of ammonium thiocyanate.

[d] Plus 20 g of ammonium thiocyanate.

[e] Plus 40 g of ammonium thiocyanate.

The result of the first 20 cycles corroborated the result of a 33-cycle fractionation carried out under similar conditions[9b, 17]; in this case a total of 5 kg of (Zr, Hf)$O_2$ was processeed in an apparatus with a larger capacity, and the products obtained were a $ZrO_2$ sample containing 0.13 % of $HfO_2$ and an $HfO_2$ sample containing 50 % of $ZrO_2$.

After the twentieth cycle, the state of the plant was checked by analysis (see Table 2 a). The concentration of metal in the aqueous phase showed a very large change, amounting to roughly a factor of 40 between the middle and the hafnium side. Consequently, the partition coefficients K changed by a factor of 6 between stage 1 and stage 11. The partition factors $G = Kv_l/v_h$ should always be $> 1$ for hafnium and $< 1$ for zirconium. Since $v_l/v_h$, according to Table 1, is equal to $1.2/0.45 = 2.7$, $G_{Hf}$ in stage 1 is only 1.1, while $G_{Zr}$ in stages 9 and 11 is greater than 1. The separation must therefore be poor. This is clear from the separating effect S, which is equal to the Hf/Zr ratios in the aqueous phases of two adjacent stages:

$$S = (Hf/Zr)_n/(Hf/Zr)_{n-1}$$

For the flow scheme used, the average separating effect S should be roughly equal to the separation factor $\beta$ [8, 15]. However, a comparison of the last two columns in Table 2 shows that while the $\beta$ values for the multistage plant (as in the individual experiments) are between 4 and 5, the separating effects S are much smaller, and (as expected) their values between stages 9 and 11 are close to 1 (S = 1 means that there is no separation).

The $HfO_2$ content of the oxide removed from stage 11 in the hexanone phase after cycle 20 (Table 2: 39.7 %) is not the same as the $HfO_2$ content of the oxide in the head fraction of cycle 20 (Table 1: 54 %). This is because the head fraction is the total hexanone removed during the cycle, whereas the instantaneous concentrations vary with the periodicity of the cycle[8, 15].

To obtain a better separation, it is necessary to reduce the variation of the partition coefficients. Since these vary with the concentration of the metal, we could introduce a partial phase reversal (reflux) at the hafnium end of the plant, where the resulting hold-up would lead to the desired increase in the concentration of the metal. However, this would be very laborious in the present case. We therefore chose a chemical method. If ammonium thiocyanate is introduced into stage 6 with the (Zr, Hf) mixture, most of the thiocyanate remains in the aqueous phase. In the course of the successive cycles, therefore, this substance moves with the zirconium, and so increases the partition coefficients in stages 1 to 6, *i.e.* just where an increase is required. Part of the ammonium thiocyanate could also form thiocyanic acid with any $H^+$ ions that might result from further hydrolysis of the (Zr, Hf) oxide chloride. The distribution of this thiocyanic acid would favor the hexanone phase, *i.e.* the acid would migrate with the hafnium through stages 7 to 11, where it would lower the partition coefficients in accordance with Fig. 2. However, SCN determinations in the various stages of the plant showed that this effect is of practically no importance in comparison with the increase in the partition coefficients in stages 1 to 6[7].

Table 2. The state of the partition plant
(a) after cycle 20 (11 stages, mixture added in stage 6, no $NH_4SCN$ added),
(b) after cycle 53 (11 stages, mixture added in stage 6, 40 g of $NH_4SCN$ added per cycle)

| Stage no. | Aqueous phase | | Hexanone phase | | $K_{Hf}$ | $K_{Zr}$ | Separation factor $\beta = K_{Hf}/K_{Zr}$ | Average separating effect, S |
|---|---|---|---|---|---|---|---|---|
| | g of $(Zr,Hf)O_2$/l | % of $HfO_2$ in oxide | g of $(Zr,Hf)O_2$/l | % of $HfO_2$ in oxide | | | | |
| | | | | a) after cycle 20 | | | | |
| 1 | 109.4 | 0.14 | 9.8 | 0.66 | 0.42 | 0.089 | 4.7 | 1.8 |
| 3 | 139.5 | 0.48 | 15.0 | 2.5 | 0.56 | 0.106 | 5.3 | 1.7 |
| 5 | 142.2 | 1.3 | 15.3 | 6.0 | 0.49 | 0.102 | 4.8 | 1.55 |
| 7 | 34.6 | 3.1 | 9.75 | 13.1 | 1.18 | 0.25 | 4.7 | 1.55 |
| 9 | 8.6 | 7.2 | 4.6 | 24.3 | 1.80 | 0.44 | 4.1 | 1.27 |
| 11 | 3.5 | 11.0 | 2.6 | 39.7 | 2.66 | 0.50 | 5.3 | |
| | | | | b) after cycle 53 | | | | |
| 1 | 105.7 | 0.04 | 21.4 | 0.26 | 1.0 | 0.202 | 5 | 2.7 |
| 3 | 144.8 | 0.3 | 37.3 | 1.2 | 1.0 | 0.255 | 3.9 | 2.2 |
| 5 | 152.2 | 1.4 | 43.4 | 2.6 | 0.53 | 0.281 | 1.9 | 1.3 |
| 7 | 84.3 | 2.5 | 30.7 | 7.2 | 1.05 | 0.35 | 3.0 | 1.8 |
| 9 | 11.2 | 7.8 | 6.0 | 31.5 | 2.16 | 0.40 | 5.4 | 2.1 |
| 11 | 2.3 | 26.5 | 2.8 | 69.3 | 3.16 | 0.51 | 6.2 | |

It can be seen from Table 1 that the purity of the final fractions is appreciably increased by the addition of 20 or 40 g of ammonium thiocyanate (corresponding to concentrations of 0.6 and 1.2 moles/liter of aqueous phase, respectively). The larger concentration leads to a change by a factor of 3 in the $HfO_2/ZrO_2$ ratios of the two fractions. This is due to the increase in the partition coefficients on the zirconium side of the plant (Table 2), which leads to a considerable improvement in the separating effect S (last column in Table 2). Owing to the higher partition coefficients, moreover, the volume of hexanone used per cycle can be reduced from 1200 to 750 ml. Further, the values of $K_{Hf}$ and $K_{Zr}$ have been smoothed out in spite of the fact that the variation of the metal concentrations is even greater than after cycle 20.

After cycle 53, the number of stages was increased in an attempt to obtain a further increase in the purity of the final fractions. As can be seen from Table 1, two extra stages give a slight improvement in the purity of the hafnium fraction, but no further improvement is obtained by the use of four more stages. All the S values (Table 3a) are, accordingly, very low after cycle 108. Experience with other systems shows that this result is generally valid: where there is a wide variation of the partition coefficients, an increase in the number of stages brings little or no improvement. In the present case this is because $K_{Zr}$ again varies widely (by a factor of 4), and because in spite of the low volume ratio $v_l/v_h = 0.78:0.45 = 1.7$ (see Table 1), the calculated values of $G_{Zr}$ for stages 13 to 17 are greater than 1. Table 3a also shows that the separation factors $\beta$ in stages 3 to 9, *i.e.* in the zirconium part of the plant (with the exception of stage 1) are relatively low (close to 3). This phenomenon had already become noticeable after cycle 53, and is in agreement with Fig. 7 for the high metal concentrations present on the Zr side of the plant. It is probably also a result of the addition of $NH_4SCN$, and for this reason the quantity of the latter added should not be further increased.

An improvement can be expected only if the variation in the partition coefficients can again be reduced, and particularly if that of Zr in stages 13 to 17 can be lowered sufficiently to give an extraction factor G of less than 1.

Table 3. The state of the partition plant
(a) after cycle 108 (17 stages, mixture added in stage 8, 40 g of $NH_4CNS$ added per cycle),
(b) after cycle 131 (17 stages, mixture added in stage 7, 40 g of $NH_4SCN$ added per cycle, aqueous phase also contains $H_2SO_4$ at a concentration of 0.05 M).

| Stage number | % of $HfO_2$ in the oxide | | $K_{Hf}$ | $K_{Zr}$ | $\beta$ | S |
|---|---|---|---|---|---|---|
| | Aqueous phase | Hexanone phase | | | | |
| | | a) after cycle 108 | | | | |
| 1 | 0.04 | 0.17 | 0.8 | 0.20 | 4 | 2.1 |
| 3 | 0.18 | 0.60 | 0.77 | 0.23 | 3.3 | 1.5 |
| 5 | 0.42 | 1.40 | 0.87 | 0.26 | 3.4 | 1.4 |
| 7 | 0.80 | 2.9 | 1.05 | 0.28 | 3.7 | 1.7 |
| 9 | 2.3 | 6.1 | 0.95 | 0.35 | 2.8 | 1.7 |
| 11 | 6.1 | 25.4 | 2.12 | 0.41 | 5.2 | 1.6 |
| 13 | 14.5 | 43.5 | 2.67 | 0.59 | 4.5 | 1.3 |
| 15 | 22.0 | 60.6 | 3.53 | 0.65 | 5.5 | 2.0 |
| 17 | 54.1 | 80.6 | 2.83 | 0.80 | 3.5 | |
| | | b) after cycle 131 | | | | |
| 1 | 0.02 | 0.13 | 1 | 0.18 | 6 | 2.7 |
| 3 | 0.15 | 0.55 | 0.8 | 0.22 | 3.7 | 1.6 |
| 6 | 0.6 | 2.3 | 1.0 | 0.25 | 3.9 | 1.9 |
| 8 | 2.2 | 8.9 | 0.93 | 0.21 | 4.4 | 2.4 |
| 10 | 11.9 | 46.0 | 2.01 | 0.32 | 6.3 | 2.4 |
| 12 | 44.5 | 87.3 | 2.26 | 0.26 | 8.6 | 2.6 |
| 14 | 84.0 | 97.6 | 2.23 | 0.29 | 7.7 | 2.7 |
| 16 | 97.4 | 99.5 | 2.16 | 0.4 | 5 | |

This can be achieved by the addition of a small quantity of sulfate to the aqueous phase, as was shown in Section I. The concentrations of Hf and Zr in the hafnium side of the plant are low. According to Figs. 4 and 5, therefore, even a small quantity of sulfate should lead to a marked decrease in $K_{Zr}$ and to a smaller decrease in $K_{Hf}$, with the additional result that the separation factor should be increased. On the zirconium side of the plant, on the other hand, the metal concentrations are very high, so that a small quantity of added sulfate should have very little effect. This is confirmed by the results of cycle 131 (Tables 1 and 3) for 0.05 mole of $H_2SO_4$ per liter of water, where the same number of stages is used as before. The hafnium content of the zirconium fraction is reduced by half, while the zirconium content of the hafnium fraction is reduced to $^1/_{40}$th of its original value. The partition coefficients of the two elements differ by a factor of only 2. Owing to the reduction of the partition coefficients on the hafnium side, the quantity of hexanone introduced per cycle

must be increased slightly, *i.e.* from 780 to 880 ml. However, the improvement in the separation, which is also reflected in the S values, is not due entirely to the decrease in the variation of the partition coefficients; the sulfate has also increased the separation factors $\beta$, even on the Zr side of the plant. When this procedure was used, the metal concentration in stage 7 after the addition of the mixture increased to 235 g of (Zr, Hf)$O_2$ per liter of water.

Under these circumstances, an increase in the number of stages could now be expected to have a favorable effect. The addition of six stages to the Zr side, so that the mixture was introduced in stage 13 instead of stage 7, produced no appreciable change in the Hf fraction (Table 1), but reduced the $HfO_2$ content of the zirconium fraction to less than $^1/_{20}$th of its original value. This was confirmed by neutron activation analysis [12] on most of the tail fractions between cycle 144 and cycle 168. Even in stage 5, the $HfO_2$ content is less than 60 ppm. Thus the overall separating effect [8], *i.e.* the change in the $HfO_2/ZrO_2$ ratio between the head fraction and the tail fraction, is $4 \times 10^7$.

The American process mentioned in the introduction gives a zirconium product containing less than 100 ppm of hafnium and a hafnium product containing about 2 % of Zr from a starting material comparable to that used in the present work, *i.e.* the overall separating effect is $5 \times 10^5$ [3b]. This process is also based on partition between water and hexanone in the presence of HSCN and $NH_4SCN$. The essential differences between this and the process described in the present paper are: (a) the mixture is introduced in the form of an aqueous solution; (b) 3.5 M hydrochloric acid is used as the aqueous phase, probably to achieve a partial reflux; (c) the apparatus consists of spray columns. In order to achieve the purities mentioned above, it is necessary to use many columns in series to give a total length of 305 ft (93 m) (excluding washing and recovery plant).

The fact that the overall separating effect obtained by us with only 23 mixer settlers was almost two powers of ten higher is probably mainly due to the following factors:

1. Better attainment of equilibrium in mixer settlers than in columns.
2. Special mode of operation of the new materials flow scheme.
3. Constant attempts to restrict the variation of the partition coefficients within the plant.
4. The effect of added sulfate, which has a favorable effect on both the partition coefficients and the separation factors, the partition coefficients being affected only in the part of the plant in which this is desirable.

# The Chemistry of Protactinium

BY PRIV.-DOZ. DR. C. KELLER

LEHRSTUHL FÜR RADIOCHEMIE, TECHNISCHE HOCHSCHULE KARLSRUHE, AND INSTITUT FÜR RADIOCHEMIE, GESELLSCHAFT FÜR KERNFORSCHUNG MBH., KERNFORSCHUNGSZENTRUM KARLSRUHE (GERMANY)

*Dedicated to Professor W. Klemm in honor of his 70th birthday*

*Protactinium exhibits an ambivalent chemical behavior. In non-aqueous solutions and in the solid state, both quadrivalent and quinquevalent protactinium has properties which characterize it as a typical actinide element. On the other hand, investigations in aqueous solution show quinquevalent protactinium to be a homologue of niobium and tantalum. It exhibits – except in hydrofluoric acid solutions – a marked tendency to undergo irreversible hydrolysis and condensation reactions, which leads to the situation that tracer amounts (ca. $10^{-12}$ mole/l) and macroscopic amounts ($10^{-3}$–$10^{-6}$ mole/l) of protactinium often behave differently. Reduction with strong reducing agents gives aqueous solutions of Pa(IV), the properties of which again correspond in general to those of Th(IV) and show no relation to Nb(IV). Our knowledge of the chemical behavior of this rare radioelement has been advanced, in particular, by the production in 1958–1960 of 100 g of pure protactinium – the largest amount so far – from residues of the British production of uranium.*

## 1. Introduction

Element 91, protactinium, comes between thorium and uranium in the periodic table. On the basis of the radioactive displacement laws, *Fajans*, *Russell*, and *Soddy* predicted in 1913 that the decay of UI ($^{238}U$) to UII ($^{234}U$) must take place through an isotope of thorium and the then unknown element 91. *Fajans* and *Göhring* [1] later found this intermediate ($UX_2$ = $^{234m}Pa$)

[1] *K. Fajans* and *O. Göhring*, Naturwissenschaften *1*, 339 (1913).

and, because of its short half-life of 1.2 min, gave it the name "Brevium". In 1918, *Hahn* and *Meitner*[2] isolated a long-lived isotope of $UX_2$ from pitchblende residues and, because it is the parent of actinium, called it "protoactinium". This name was later changed to protactinium, and has been accepted internationally. With the discovery of UZ, the ground state of $^{234}Pa$, *Hahn* discovered the first example of nuclear isomerism[3].

The first chemical investigations with macroscopic amounts of protactinium were carried out by *von Grosse* at the end of the 'twenties in *Hahn*'s Institute. A more detailed study was begun only during the second world war within the framework of the Manhattan Project. Numerous papers on protactinium also appeared from the 'thirties onwards from the Curie Laboratory of the Institut du Radium in Paris; thus, for example, *Haissinsky* and *Bouissières* demonstrated a lower valence state of protactinium, Pa(IV)[4]. However, it was only the isolation of 100 g of $^{231}Pa$ at Springfield and Harwell (England) in about 1960 that permitted the chemistry of this rare radioelement to be investigated on a broader basis. The growing interest devoted to this element both scientifically and technically is demonstrated by two symposia (Gatlinburg, 1963, and Orsay, 1965) dealing solely with its chemistry.

## 2. Isotopes and the Nuclear Chemistry of Protactinium

Fourteen isotopes of protactinium, with mass numbers ranging from 224 to 237, are known (Table 1). Only three are relatively important:

Table 1. Isotopes of protactinium [5].

| Mass number | Formation reactions | Formation cross-section $\sigma_{max}$ [mb] (at E [MeV]) | Half-life | Mode of decay [a] | Decay energy [MeV] | Capture ($\sigma_c$) and fission ($\sigma_f$) cross-section for thermal neutrons [b] |

[5] A review of protactinium isotopes is given by *E. K. Hyde*, *I. Perlman*, and *G. T. Seaborg*: The Nuclear Properties of the Heavy Elements. Prentice Hall, Englewood Cliffs 1964, Vol. II, p. 693.

$^{231}$Pa is the only isotope of Pa having a sufficiently long half-life to allow work with weighable amounts. To obtain this isotope, we must still, in essence, resort to the working up of residues from the production of uranium. Later, it may also be profitable to isolate the $^{231}$Pa formed by the reaction

$$^{232}\text{Th(n,2n)}^{231}\text{Th} \xrightarrow{\beta^-} {}^{231}\text{Pa}$$

from the residues of the reprocessing of $^{232}$Th-$^{233}$U (Table 2).

Table 2. Calculated composition of a sample of Th (100 g) after irradiation in $\Phi$ (thermal) = 5 $10^{14}$ n/cm$^2$sec, $\Phi$ (epithermal) = $^1/_{12}$ $\Phi$ (thermal) for 28 days (total flux = 1.2 $10^{21}$ n/cm$^2$) [10, 11].

| | |
|---|---|
| $^{232}$Th: | 98.6 g |
| $^{231}$Pa: | 1 mg |
| $^{233}$Pa: | 950 mg |
| $^{233}$U: | 320 mg |
| $^{234}$U: | 65 mg |
| $^{235}$U: | 5 mg |
| fission products: | 60 mg |

The threshold energy of the $^{232}$Th(n,2n) reaction is 6.35 MeV [6], and the effective $^{232}$Th(n,2n)$^{231}$Th cross-section for neutrons with the energy distribution of the fission spectrum is 12.4 ± 0.6 mbarn [7]. The fission threshold for $^{231}$Pa is 0.4 MeV. The effective fission

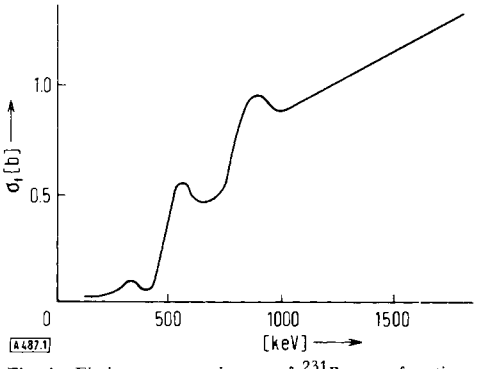

Fig. 1. Fission cross-section $\sigma_f$ of $^{231}_{91}$Pa as a function of the neutron energy.

cross-section increases markedly with increasing neutron energy (Fig. 1) [8]. The half-life of spontaneous fission of $^{231}$Pa is $1.1\times10^{16}$ years [9], which corresponds to 0.3 disintegrations by spontaneous fission per gram per minute.

$^{233}$Pa is an intermediate in the breeding of $^{233}$U from $^{232}$Th according to

$$^{232}\text{Th(n,}\gamma)^{233}\text{Th} \xrightarrow[22.4\ \text{min}]{\beta^-} {}^{233}\text{Pa} \xrightarrow[27.0\ \text{d}]{\beta^-} {}^{233}\text{U}.$$

It is frequently used as a tracer nuclide in chemical investigations.

Because of its short half-life, $^{234m}$Pa is used for demonstrating rapid radiochemical separations [12].

## 3. X-Ray Spectrum and Electronic Configuration of Protactinium

In the X-ray spectrum of $^{231}$Pa, *von Grosse et al.* found 21 lines of the L-series ($\lambda = 586.6\times10^{-11}$ to $1088.5\times10^{-11}$ cm) and 14 lines of the M-series ($\lambda = 252.2\times10^{-11}$ to $518.2\times10^{-11}$ cm) [13–15]. The emission lines at 3957.8 and 4090.1 Å are the most suitable for the spectrographic determination of $^{231}$Pa [14].

According to the "actinide hypothesis", protactinium should possess two 5f electrons. However, the change in atomic radii with atomic number [16] and the Pa–O distance in PaO [17] suggest indirectly a filling of the 6d shell. This finding agrees with calculations of *Cap* [18] on the energies of the 5f and 6d configurations. *Roof* [19] also found no indications of 5f electrons from an analysis of the X-ray absorption coefficients, whereas *Couchois* [20] concluded from irregularities in the X-ray absorption coefficients – in agreement with theoretical considerations due to *Friedel* [21] – that both 5f and 6d electrons are present in Th, Pa, and U. On the other hand, *Jørgensen* [22] showed that the absorption spectrum of Pa(IV) indicates the presence of one 5f electron. A 5f arrangement can also be deduced from the energy of the electron level in a $^{233}$Pa beam [23] and from optical and magnetic investigations on Pa(IV)-doped $Cs_2ZrCl_6$ [24, 25]. The occupancy of the 5f and 6d orbitals of Pa is thus still uncertain. Because of the small differences in energy of the two electron configurations, an easy 5f–6d-transition seems possible.

## 4. Preparation of Pure $^{231}$Pa and $^{233}$Pa

### 4.1. Enrichment and Purification of $^{231}$Pa from Waste Products of the Production of Uranium

As a secondary decay product of $^{235}$U, $^{231}$Pa occurs in uranium minerals in about the same amount as radium (equilibrium concentration 0.3 ppm). The first pure

specimen of Pa was prepared by *von Grosse* in 1927 [26]. From a Pa concentrate (6 mg of $^{231}Pa$ in 525 g) prepared by *Hahn* and *Meitner* [27], *von Grosse* isolated 2 mg of $^{231}Pa_2O_5$. Using a process based only on precipitation methods, in the following years *von Grosse* and *Agruss* [28] obtained 100 mg of pure $^{231}Pa_2O_5$ from 1000 kg of residues (60 % $SiO_2$) of the processing of Joachimsthal uranium ore. The main step in the separation process was the elimination of the $SiO_2$ by an alkali hydroxide fusion and leaching out of the resulting silicate with water. The $^{231}Pa$ was enriched by several $ZrP_2O_7$ precipitations; Zr and Pa were separated by repeated fractional crystallization of $ZrOCl_2$ from 25 % hydrochloric acid.

After 1945, several processes were developed for obtaining weighable amounts of $^{231}Pa$ [29–35]. Coprecipitation processes were always used for the initial enrichment of Pa present in the ppm range, while preliminary and final purifications were carried out mainly with extraction or ion-exchange processes. According to a Russian process [29], more than 95 % of the Pa is coprecipitated with $MnO_2$ from > 1 M $HNO_3$. In a French process [30], Pa(V) is reduced to Pa(IV) with Zn amalgam and is then precipitated as $PaF_4$. In a process of the Mound Laboratories [31], the enrichment of Pa is carried out *via* the precipitation of titanium phosphate.

Between 1950 and 1960, more than 100 g of $^{231}Pa$ was obtained from wastes of the production of uranium at Springfield in England [32–33]. The starting material was about 40 tons of residues from the isolation of uranium (ethereal sludge) containing about 3 ppm of Pa. The residues were leached with cold 4 N nitric acid (2 liters/kg). The uranium was extracted from the resulting solution with tributyl phosphate, and the addition of ammonia then gave a hydroxide precipitate which was dissolved to give a solution 1 N in hydrochloric acid. On addition of aluminum chloride a precipitate was formed containing 75 % of the original Pa. The precipitated product was digested with warm 30 % sodium hydroxide (removal of Al, Si, P) and was then dissolved in concentrated hydrochloric acid. Extraction with diisobutyl ketone separated 95 % of the Pa from the solution, and back-extraction of the organic phase with 8 N HCl + 0.5 N HF led to 52.4 liters of solution with a total of 108.2 g of $^{231}Pa$. Final purification was carried out by anion-exchange.

### 4.2. Separation of $^{233}Pa$ from Irradiated Thorium

Neutron-irradiated metallic thorium is dissolved in a mixture of concentrated HCl + 0.2 N HF. After the addition of borax or $AlCl_3$ (to mask the fluoride ions) the solution is transferred to a small column (height 55 mm, diameter 3 mm) containing an anion-exchange resin (Dowex-1) [36]. Pa, Zr, and Nb remain on the column; Th is not adsorbed. Zr is eluted with 6 N HCl and then Pa with 9 N HCl + 0.1 N HF. The Pa eluate is shaken with an equal volume of diisopropyl ketone, which extracts traces of Fe(III), Sn(IV), and Nb(V). After the addition of borax to the aqueous solution, Pa(V) is extracted with fresh diisopropyl ketone and is thus separated from U, Th, Ti, Zr, *etc.* After back-extraction into 2 N HCl, the Pa(V) is again adsorbed from 10 N HCl on a 3 mm×12 mm column of anion-exchange resin and is eluted with 2.7 N HCl. The first 3–6 drops contain more than 90 % of the original $^{233}Pa$.

Other methods for the purification of $^{233}Pa$ use either a coprecipitation of $^{233}Pa$ with $MnO_2$ [37, 38], $PbO_2$ or $SnO_2$ [39], $Nb_2O_5$ [40], $BaZrF_6$ [41], zirconium phosphate [42], zirconium mandelate [43], or zirconium iodate [42,44], or extraction methods – *e.g.*, extraction with tertiary amines [45], with thionyltrifluoroacetone (TTA) [46,47], with tributyl phosphate (TBP) [48] or tributylphosphine oxide [49], or with branched ketones and alcohols [50].

The separation of Pa from Th by coprecipitation with $MnO_2$ has been used by *Codding et al.* [10,11] to obtain 1 g of $^{233}Pa$ (*ca.* $2\times10^4$ curie) from 200 g of irradiated metallic Th. Here the last purification step was the precipitation of Pa periodate. The heat developed by the pure preparation was sufficient to dry it and to partially decompose the periodate.

## 5. Chemistry of Protactinium in Aqueous Solutions

### 5.1. Ionic Species in Aqueous Solution

Similarly to the chemistry of niobium and tantalum, that of aqueous quinquevalent protactinium is very complicated, apart from solutions in hydrofluoric and sulfuric acids. It is impossible in practice to obtain solutions of Pa(V) which remain stable for a long period and do not gradually undergo unpredictable changes, even in concentrated hydrochloric, nitric, or perchloric acid. This instability can be observed both in solutions of tracer amounts of $^{233}Pa$ and in solutions containing millimole amounts of $^{231}Pa$. In general, the instability increases with increasing concentration of Pa. Consequently, it is now believed that the irreversible changes are due not to hydrolysis, but to condensation reactions [51]:

$$\gtrless Pa\text{-}OH + X^- \underset{\text{reversible}}{\rightleftharpoons} \gtrless Pa\text{-}X + OH^-$$

$$\downarrow\uparrow$$

$$\left[\gtrless Pa\text{-}O\text{-}Pa\lesssim\right]_n : \text{reversible for } n < 4$$

$$\downarrow$$

$$\left[\gtrless Pa\text{-}O\text{-}Pa\lesssim\right]_n : \text{irreversible for } n > 4$$

The re-conversion of the condensed species into the hydroxyl-containing species, which alone are capable of forming complexes by exchange reactions, takes place only slowly, and this explains, for example, why the partition equilibrium in the extraction of Pa(V) with 0.03 M trilaurylamine in diethylbenzene [52] or with 0.1 M 8-hydroxyquinoline in chloroform [53] is still far from being established after several days.

From extraction investigations in the two-phase system Pa(V), $(Li,H)ClO_4/TTA,C_6H_6$, *Guillaumont* [54–57] concluded that in the case of tracer concentrations of $^{233}Pa$ in 1–3 N $H^+$ solutions of Pa(V), the ion $Pa(OH)_3^{2+}$ or $PaO(OH)^{2+}$ is present, and this is hydrolysed to $Pa(OH)_4^+$ or $PaO(OH)_2^+$ at higher pH. From the extraction data, the hydrolysis constant $K_1$ of $Pa(OH)_3^{2+}$ (Fig. 2) was found to be:

$$K_1 = [Pa(OH)_4^+]\,[H^+]\,[Pa(OH_3)_3^{2+}]^{-1} = 9\times10^{-2} \text{ mole/l (at 25 °C).}$$

In contrast, the situation in hydrofluoric acid solutions of Pa(V) is very simple. Raman spectra show that the complex ions $PaF_6^-$ and $PaF_7^{2-}$ present in crystalline double fluorides are also present in hydrofluoric acid solutions [58]. The conductometric titration of $Pa_2O_5 \cdot aq$ with hydrofluoric acid demonstrates the presence of all the intermediate members of the series $PaF^{4+}$ to $PaF_8^{3-}$.

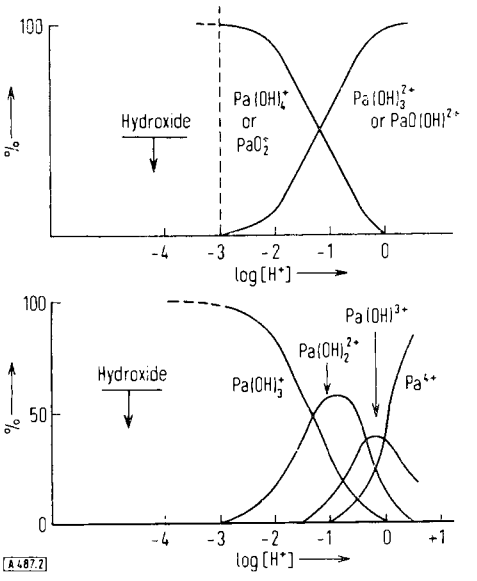

Fig. 2. Hydrolysis of $Pa(OH)_3^{2+}$ (top) and $Pa^{4+}$ (bottom) as a function of the acid concentration at 3 M $(Li,H)ClO_4$.

On the other hand, in mineral acid solutions Pa(IV) behaves as a true actinide(IV) ion. The hydrolysis of $Pa^{4+}$ takes place stepwise (Fig. 2) through $Pa(OH)^{3+}$ (hydrolysis constant $K_{1,1} = 0.725$) and $Pa(OH)_2^{2+}$ ($K_{1,2} = 0.302$) to $Pa(OH)_3^+$ ($K_{1,3} = 0.017$), before $Pa(OH)_4$ precipitates.

Stability constants for $Pa(OH)_3^{2+}$ and $Pa^{4+}$ can be determined from the change in the partition coefficients on the addition of complexing agents (Table 3).

Table 3. Stability constants K of Pa(V) and Pa(IV), determined from the change in the partition coefficients in the extraction of Pa with thionyltrifluoroacetone (TTA) in the presence of complexing agents [55]. Ionic strength 3 M.

| Pa(V) | | Pa(IV) | |
|---|---|---|---|
| Complex [a] | K | Complex | K [b] |
| $Pa(OH)_3Cl^+$ | 1.2 | $PaCl^{3+}$ | 1 |
| $Pa(OH)_2SO_4^+$ [c] | 20 | $PaCl_2^{2+}$ | 1 |
| $Pa(OH)_2(SO_4)_2^-$ | 320 | $PaSO_4^{2+}$ | 42 |
| $Pa(OH)_2(C_2O_4)^+$ | 150 | $Pa(SO_4)_2$ | $1.53\times10^2$ |
| $Pa(OH)_2(C_2O_4)_2^-$ | $5\times10^4$ | $PaF^{3+}$ | $5.35\times10^4$ |
| $Pa(OH)_2F^{2+}$ | $3.6\times10^3$ | $PaF_2^{2+}$ | $1.8\times10^8$ |
| $Pa(OH)_2F_2^+$ | $4.5\times10^7$ | | |
| $Pa(OH)_2F_3$ | $8\times10^{10}$ | | |

[a] Formulation as an oxygen complex, *e.g.* $PaOSO_4^+$, cannot be excluded.

[b] For the reaction $Pa^{4+} + nXm^- \rightleftharpoons PaXn^{(4-nm)+}$.

[c] For the reaction $Pa(OH)_3^+ + HSO_4^- \rightleftharpoons Pa(OH)_2SO_4^+ + H_2O$.

In this way it has been shown that the tendency of $Pa^{4+}$ towards complex formation is greater than that of $Pa(OH)_3^{2+}$ but smaller than that of $Zr^{4+}$. The values for $Pa^{4+}$ fit well into the sequence for the corresponding actinide(IV) complexes.

### 5.2. The Extraction Behavior of Protactinium

Numerous papers have been published on the extraction of quinquevalent protactinium, but little information is available on Pa(IV). From the available investigations on the chemistry of Pa(IV) in solution, it must be

concluded that there are at most only minor differences between Pa(IV) and Th(IV) or U(IV).

In addition to phosphoric acid esters and to amines, which are universal extractants, long-chain branched ketones and alcohols are the best and most specific extracting agents for Pa(V). On the other hand, ethers and carboxylic esters extract Pa(V) extremely poorly. The highest partition coefficients and the best reproducibilities are obtained in extraction from hydrochloric acid solutions. Small amounts of sulfuric acid markedly depress the partition coefficients, except in the case of amines. In nitric or perchloric acid solutions, Pa(V) is hydrolysed readily to polymeric species, which explains the discordant results of different authors. The presence of complexing agents and of $H_2O_2$ substantially prevents the extraction of Pa(V), and extraction is not possible in the presence of fluoride ions.

### 5.2.1. Extraction with Esters of Phosphoric Acid

When undiluted tri-n-butyl phosphate (TBP) is used, the partition coefficient $K_D$ increases with increasing concentration of hydrochloric acid in the aqueous phase [48,59]; in 5 N HCl $K_D \approx 40$, in 8 N HCl $K_D \approx 4.5\times10^3$, and in 12 N HCl $K_D \approx 10^5$. The partition coefficients decrease with increasing dilution of the TBP (*e.g.* with benzene) [60,61]. They are constant over a wide range of Pa(V) concentrations. From the constancy of $K_D$ with time, it must be concluded that $10^{-4}$–$10^{-6}$ M solutions of Pa(V) in *ca.* 3 N $HNO_3$ are stable at 21 °C for at least 100 hours. In 1 N $HNO_3$, on the other hand, $K_D$ decreases rapidly with time, and about 95 % of the Pa(V) is hydrolysed after 3 days [62]. In the extraction of various metal ions with 20 % TBP/kerosine from 2 N $HNO_3$, the partition coefficients decrease in the sequence U(VI) > Np(VI) > Pu(IV) > Pu(VI) > Th(IV) > Np(IV) > Pa(V) > Zr(IV) > Md(III).

Contamination of the TBP with dibutyl phosphate – formed, for example, by hydrolysis or radiolysis of the P–O–C bond – raises $K_D$ markedly; thus, for purified TBP (30 % in kerosine) from 6 N $HNO_3$ $K_D \approx 2.6$, while for TBP containing $10^{-2}$ M of dibutyl phosphate, $K_D \approx 50$ [60].

High partition coefficients for Pa(V) are also exhibited by the mono- and, in particular, the dialkyl esters of phosphoric acid (frequently called liquid cation-exchangers) and by phosphonic esters [60,63–66]. In the extraction of Pa(V) with di-n-octyl phosphate (HX) [*] from hydrochloric acid solution, extraction of $ClO(HX_2)PaX_2Pa(HX_2)OCl$ has been inferred from the distribution curve [67].

### 5.2.2. Extraction with Amines

Amines, frequently called liquid anion exchangers, possess the advantage that extraction is possible even from sulfuric acid solution. With approximately equal numbers of carbon atoms in the amine, $K_D$ decreases in the sequence primary amine > secondary amine > tertiary amine. The partition coefficients depend markedly on the structure of the amine. For example, aromatic groups or double bonds in the carbon chain considerably increase $K_D$ [68]. The type of organic diluent for the amines is not without influence in this connection, *e.g.* $K_D$ for 5 % tributylamine increases with the logarithm of the dielectric constant of the diluent [69]. No radiation effects on the extraction of Pa(V) have been observed for a secondary amine up to a dose of $5\times10^7$ r of $^{60}Co$ γ-radiation [70].

The partition coefficients decrease with increasing concentration of sulfuric acid in the aqueous phase [68,69,71]. Two different slopes of the extraction curves with a break at 7–9 M $H_2SO_4$ have been obtained. In extraction with tribenzylamine in the range 0.4–0.9 M $H_2SO_4$, the extracted Pa(V) sulfato complex contains 2 molecules of amine per Pa atom [72].

Nitrobenzene and benzonitrile have no advantages over ketones as extractants; more than 95 % extraction of Pa(V) takes place only from 7.5 or 8.5 N HCl [69].

While Pa(V) is quantitatively extracted with 5 % tri-n-octylamine from about 6 N HCl, Pa(IV) passes into the organic phase to the extent of more than 95 % only from 10 N HCl [73].

### 5.2.3. Extraction with Alcohols and Ketones

The partition coefficient of Pa(V) increases with increasing acid concentration of the aqueous phase, and, at constant concentration of the acid, they are larger from hydrochloric acid than from nitric acid. At a constant HCl concentration, $K_D$ increases with the concentration of chloride ions. Extraction from HBr solution takes place only at higher acid concentrations than from HCl solution. The extracted Pa(V) species has a solvation number of three in diisobutyl ketone and diisopropyl ketone [74], and only two in amyl acetate and TBP [60]. Under otherwise identical conditions, $K_D$

decreases in the sequence mesityl oxide > diethyl ketone > acetophenone > methyl n-hexyl ketone > diisobutyl ketone > diisopropyl ketone (Fig. 3)[69,74]. From the change in $K_D$ on the addition of fluoride or oxalate, the following sequence of complex-forming tendencies has been established[69,75]:

with respect to fluoride: Pa, Zr > Nb > Ta

with respect to oxalate: Nb > Ta > Pa, Zr

Long-chain alcohols such as diisopropylmethanol[76,77] and diisobutylmethanol[59,76] also have good extraction properties for Pa(V). For the latter, no dependence of partition coefficient on the concentration of Pa(V) was found in the range $10^{-4}$–$10^{-14}$ M of Pa(V)[78].

### 5.2.4. Extraction as a Chelate

The chelate of Pa(V) with hydroxylamine derivatives [such as cupferron (ammonium salt of *N*-nitrosophenylhydroxylamine) and *N*-benzoyl-*N*-phenylhydroxylamine] can be extracted with various organic solvents over a wide range of experimental conditions[38,79–82]. Tartrate and citrate do not interfere with the extraction, and oxalate does so only slightly, while fluoride ions prevent extraction. Extraction with high yield also takes place with salicylic acid at pH 4 from a solution saturated with $CaCl_2$, or with phenylarsonic acid from 0.1–9 M $H^+$ solution[83,84]. In the presence of 8-hydroxyquinoline, Pa(V) can be extracted at pH 3–9 by chloroform to the extent of more than 99.9 % (Fig.4)[53].

The rate of decrease in $K_D$ at pH > 9 shows that the extracted chelate is a dibasic acid.

The extraction of Pa(V) with thionyltrifluoroacetone (TTA or HX) has been investigated thoroughly. A 0.5 M solution of TTA in benzene extracts 80–90 % of Pa(V) from 1–10 N HCl [85]. From the decrease in $K_D$ in the sequence $ClO_4^- > NO_3^- > Cl^- > SO_4^{2-} > F^-$ it may be concluded that the complex-forming tendency

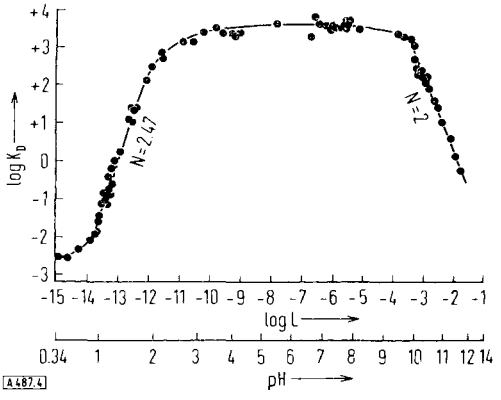

Fig. 4. Extraction of trace amounts of Pa(V) with 0.1 M 8-hydroxyquinoline in chloroform. (Ionic strength 0.1 M (Na,H) $ClO_4$; the partition coefficients were determined by back-extraction). L = concentration of the ionic form of the ligand. The N values on the curves denote the number of 8-hydroxyquinoline ligands per Pa atom.

of Pa(V) increases in this order. Four molecules of TTA are bound per Pa(V) atom in the range 0.5–3 N HCl, and three molecules in the range 0.5–0.015 N HCl. It is therefore concluded that the species $Pa(OH)_3X_2 \cdot 2\,HX$ and $Pa(OH)_4X \cdot 2\,HX$, respectively, are extracted[55,86,87]. In the extraction of Pa(V) from 3 N $HClO_4$ by a 1:1 solution of TBP and TTA in benzene, a synergistic effect has been observed. In this case the extracted species is $Pa(OH)_3X_2 \cdot 2$ TBP[103]. At TTA:TBP ≈ 10:1, however, $Pa(OH)_3X_2 \cdot HX \cdot$TBP is extracted. With > 0.3 M TTA/benzene, about 90 % of the Pa(IV) is extracted as $PaX_4$[88].

## 5.3. The Ion-Exchange Behavior of Protactinium

### 5.3.1. Anion Exchange

Above 3 M $H^+$, the extent of adsorption of Pa(V) from nitric acid and hydrochloric acid solutions on anion exchange resins increases with increasing concentration of the acid[89–93]. In the range 1–4 N $HNO_3$, *Nowikow*

[93] *J. Nowikow* and *G. Pfrepper*, Z. Naturforsch. *18b*, 993 (1963).

and *Pfrepper*[93] found Pa(V)–$NO_3^-$ complexes of composition 1:1 (formulated as $[PaO_x(OH)_yNO_3]$), 1:2($[PaO_x(OH)_y(NO_3)_2]$), and 1:4($[PaO_x(OH)_y(NO_3)_4]$) with stability constants $\beta_1 = 0.68$, $\beta_2 = 3.0$, and $\beta_4 = 11.93$ in 1 N $H^+$. In contrast to statements by *Hardy et al.*[60], most of these complexes appear to be anionic. Above 2 N $H^+$, Pa(V) is also adsorbed from HBr and HI solutions[92,94]; however, the distribution coefficients are two orders of magnitude smaller than in adsorption from hydrochloric acid, which permits the conclusion that the complex-forming tendency of Pa(V) with $Br^-$ and $I^-$ is smaller.

Small amounts of fluoride ions markedly depress the adsorption of Pa(V) from hydrochloric acid solution on anion exchange resins[95–98], a fact which is frequently used for the separation of Pa (*e.g.* in the separation of

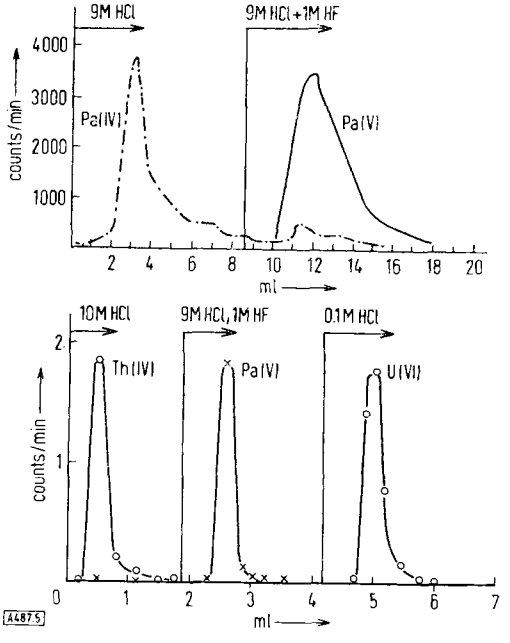

Fig. 5. Ion-exchange separations with Pa.

Top: separation of Pa(IV) and Pa(V) on Dowex 1 anion exchanger. Bottom: separation of Th(IV), Pa(V), and U(VI) on Dowex 1 anion exchanger.

Ordinate: relative activity.
Abscissa: eluate volumes [ml].

Nb, Ta, and Pa or of Pa(IV) and Pa(V), Fig. 5). The distribution coefficients in dilute pure hydrofluoric acid are very high (*ca.* $2\times10^4$ for 0.2 N HF) but decrease markedly with increasing HF concentration (*ca.* $10^2$ in 7 N HF)[92,99].

A similar decrease of $K_D$ with acid concentration is observed in sulfuric acid[71,90–92]. From the shape of the curve it follows that two Pa(V)–$SO_4^{2-}$ complexes exist, namely $[PaO(SO_4)_2]^-$ and $[PaO(SO_4)_3]^{3-}$. The preparation of $H_3PaO(SO_4)_3$ (stable up to about 350 °C, hexagonal with a = 9.743 Å, c = 5.506 Å, Z = 2) by evaporation of a Pa(V) solution containing HF and $H_2SO_4$, and of amorphous $HPaO(SO_4)_2$ and $HPaO_2SO_4$ by thermal decomposition of $H_3PaO(SO_4)_3$, confirms the assumptions on the species in the system Pa(V)-$SO_4^{2-}$[100]. The potassium salt of oxotrisulfatoprotactinic(V) acid, $K_3PaO(SO_4)_3$, had been prepared previously[101]. The corresponding selenato acid $H_3PaO(SeO_4)_3$ (hexagonal with a = 9.743 Å and c = 5.679 Å) has also been isolated[118]. No analogous double sulfates of Nb(V) and Ta(V) are known.

According to *Nowikow* and *Pfrepper*[93], in 1–2 M $H_2SO_4$ a small amount of a 1:1 complex ($[PaO_x(OH)_ySO_4]^-$ with $2x + y = 4$; $\beta_1 = 0.94$ at 1.0 N $H^+$) exists in addition to the Pa(V):$SO_4^-$ 1:2 complex ($\beta_2 = 7.39$ at 1.0 N $H^+$).

Pa(IV) is not adsorbed on anion exchangers from hydrochloric acid solutions[102]. In sulfuric and hydrofluoric acid solutions, too, Pa(IV) has only small $K_D$ values[92], consequently it resembles Th(IV) rather than U(IV).

### 5.3.2. Cation Exchange

The separation of the short-lived $^{234m}Pa$ from its parent $^{234}Th$ – adsorbed on a cation-exchange resin – is possible with the aid of a 5 % citrate solution at pH 2.5[12]. *Moskvin et al.*[103] have determined the stability constants of numerous chelates of Pa(V) with organic acids by ion-exchange processes. On comparing the stability constants of complexes of Pa(V) with inorganic and organic ligands (Tables 3 and 4), it can be seen that most organic complexing agents stabilize Pa(V) to

Table 4. Stability constants of complexes of Pa(V) with some organic acids at 0.25 M ionic strength, calculated from ion-exchange data. An accurate formulation of the individual complexes is not possible and only the Pa(V): complexing agent A ratio can be given [103].

| Acid | Composition Pa(V):A | K |
|---|---|---|
| Lactic | 1:1 | $1.7\times10^2$ |
| α-Hydroxyisobutyric | 1:2 | $3\times10^3$ |
| | 1:3 | $1.0\times10^7$ |

about the same extent as sulfuric acid, while ethylenediaminetetraacetic acid binds Pa(V) ions in complexes about as strongly as hydrofluoric acid. On the other hand, chloride and nitrate ions are only very weak complexing agents for Pa(V). The stability constants increase with increasing ratio of complexing agent to Pa(V) in the complex, *i.e.* the concentration of free Pa(V) ions in the solution decreases.

### 5.4. Paper Chromatography and Ionophoresis

Paper-chromatographic separation of Pa(V) from other elements is possible practically only with solvents containing HF. Thus *Vernois* [104] obtained a satisfactory separation of Nb, Ta, and Pa with a mixture of HCl, HF, and butanol. In solvents free from hydrofluoric acid, no satisfactory separations are obtained because of hydrolysis of Pa(V) [105, 106]. From the migration of Pa(V) in alkaline solvents, *Jakovac* and *Lederer* [107] have inferred the existence of a protactinate anion. Satisfactory separations can also be obtained on Dowex-50 ion-exchange paper [108].

It follows from ionophoretic investigations [109] that Pa(V) is present completely as an anion in 0.6 N HCl + 2 N HF. On the other hand, in hydrochloric acid both cationic species have been detected [61], the proportion of anions increasing with increasing HCl concentration.

### 5.5. Spectrophotometry of Protactinium

"True" solutions of pentavalent protactinium in hydrochloric acid possess an absorption band at about 210 mμ with $\varepsilon \approx 10^4$ [35, 110–113]. In the course of the ageing process (hydrolysis), this band disappears and simultaneously a new band appears at 260 mμ which is ascribed to hydrolysed species. In sulfuric acid solutions of Pa(V), the absorption band migrates from 206 mμ to 222 mμ with increasing sulfuric acid concentration [71]. From the shift and the change in the intensity of the absorption bands of Pa(V) in dilute hydrofluoric acid, *Mirandi* and *Muxart* [114] deduced the existence of at least four Pa–F species.

The first reliable data on the absorption spectra of Pa(IV) were due to *Fried* and *Hindman* [115]. These authors dissolved pure $PaCl_4$ in oxygen-free 1 N HCl and obtained an absorption spectrum with bands at 276 mμ, 255 mμ, and 223.8 mμ which very closely resembles that of Ce(III). The absorption bands of Pa(IV) in other mineral acids differ from those in hydrochloric acid only by their somewhat different positions and intensities [116–118]. As can be shown spectrophotometrically, aqueous solutions of Pa(IV) are stable only in the presence of an excess of reducing agents. The rate of oxidation of Pa(IV) in hydrofluoric acid solution is first order with respect to Pa(IV). Daylight and particularly ultraviolet light markedly accelerate the oxidation [117].

### 5.6. Electrochemistry of Protactinium

#### 5.6.1. Standard Electrode Potential, Redox Potential

The standard potential of the Pa/Pa(V) electrode has not yet been determined. From measurements of the rate of displacement of metallic protactinium from solutions of various concentrations ($10^{-4}$–$10^{-11}$ M) by various metals – a method first used by *Hevesy* and *Paneth* – it has been concluded [119] that the standard potential of the Pa/Pa(V) couple in hydrofluoric acid solution is about −1.0 v. According to *Haissinsky* and *Pluchet*, the redox potential Pa(IV) → Pa(V) + $e^-$ is 0.25 ± 0.03 v [120].

#### 5.6.2. Electrochemical Deposition on Metals

In trace amounts, Pa deposits spontaneously on numerous metal surfaces and on $PbO_2$, particularly from hydrofluoric and sulfuric acid solutions [121, 122]. On lead its deposition follows a Langmuir isotherm; it is assumed that in deposition from hydrofluoric acid solutions, a layer of $PaF_4$ or $PbPaF_7$ is formed on the lead surface. The diffusion constant of the Pa particles in the deposition process is 0.12 $cm^2$/day [123], whereas a value of 0.62 $cm^2$/day has been found [124] from polarographic investigations.

Quantitative cathodic deposition of trace amounts of Pa on stainless steel plates is possible from solutions in 0.2 M $NH_4F$, 0.015 M $NH_4F$ + 0.25 M $NH_4Cl$, or

0.02 M $H_2C_2O_4$ + 0.06 M $HNO_3$, at a current density of about 160 mA/cm². A firmly adherent layer is formed even with the (recommended) codeposition of 50 μg of $U_{nat}$ [125]. However, other authors [126–128] have obtained deposition yields of only 80–95 % except at the expense of extremely long times of deposition.

#### 5.6.3. Polarography of Protactinium

In 3.8 M fluoride solution (pH 7.2; $10^{-3}$–$10^{-4}$ M Pa) two irreversible polarographic waves at −1.29 v and at −1.56 v (referred to a saturated calomel electrode) have been found [124]. The first can be ascribed to the reduction of the Pa(V)-fluoro complex to the corresponding Pa(IV) complex, and the second to the reduction Pa(IV) → Pa(III). The height of the first wave is proportional to the concentration of Pa. In $F^-$-free Pa(V) solutions, only one irreversible wave is found, which is due to the reduction Pa(V) → Pa(IV).

## 6. Behavior of Protactinium in Molten Salts

In concentrations of 1–2 p.p.b. or 50–75 p.p.m. Pa(V) is precipitated from a LiF–$BeF_2$–$ThF_4$ melt (67:18:15 mole-%) by the addition of 1–2 % of solid BeO or $ThO_2$, respectively. The Pa(V) is adsorbed on the surface of the BeO or $ThO_2$. This method can be used for the separation of $^{233}$Pa and $^{233}$U from the fuel of a two-zone molten salt breeding reactor if it is desired to avoid parasitic neutron absorption by the two nuclides and thus to increase the breeding yield [129]. In the distribution of Pa between fused halides and fused metals [$CaF_2$/Th or Th,U], Pa concentrates in the metallic phase [130]; on the other hand, in systems with uranium as the molten metal and LiCl, LiCl/KCl, $AlCl_3$, or $AlCl_3$/KCl as the halide it concentrates in the chloride melt [131, 132].

## 7. Solid-State Chemistry of Protactinium

### 7.1. Metallic Protactinium

Metallic protactinium was first obtained by *von Grosse* [133] by the bombardment of Pa oxide with 35 kev electrons in high vacuum or by thermal decomposition of $PaCl_5$ on a hot wire. However, he gave no information on the properties of the metal. The pure metal is obtained by the reduction of $PaF_4$ with calcium or barium [134–136] at 1300–1400 °C. It has a tetragonal body-centered lattice with a = 3.929 Å and c = 3.241 Å [135, 137]. Two other modifications probably exist: a body-centered cubic modification above 1170 °C and one of lower symmetry, obtained by rapid quenching from 1580 °C to room temperature. The melting point of 1560 °C lies between the values for the neighboring elements thorium (1750 °C) and uranium (1132 °C). Metallic Pa forms no amalgam [138]. The magnetic susceptibility ($\chi = 270\times10^{-6}$ EMU/g) is – like that of tantalum – practically independent of the temperature. Metallic Pa reacts with 6 N HCl very violently at first, but dissolution ceases after a short time. This behavior is ascribed to the formation of a surface oxide layer [135]. With hydrogen at 250–300 °C, metallic Pa forms a hydride $PaH_3$ (cubic, a = 6.648 Å) which is isostructural with $UH_3$ [134].

### 7.2. Halogen Compounds of Protoactinium

#### 7.2.1. Binary Compounds

The evaporation of a solution of Pa(V) in aqueous hydrofluoric acid of Pa(V) gives $PaF_5 \cdot 2\,H_2O$ [139], which decomposes above 160 °C to give the oxide fluoride $Pa_2OF_8$ (body-centered cubic, a = 8.4065 Å, isotypic with $U_2F_9$) which probably contains $F_4Pa$–O–$PaF_4$ bridges. $Pa_2OF_8$ is also formed by direct fluorination of $Pa_2O_5$ at 550 °C and by hydrolysis of $PaF_5$. Pure $PaF_4$ is obtained only by the fluorination of $PaF_4$ with highest-purity fluorine. $PaF_5$ crystallizes in the tetragonal system with the β-$UF_5$ type of structure (a = 11.53 Å, c = 5.19 Å). It is less volatile than $VF_5$, $NbF_5$, and $TaF_5$, but can be sublimed above 500 °C at $10^{-5}$ to $10^{-6}$ mm. $Pa_4F_{17}$ (body-centered cubic, a = 8.507 Å) and $PaF_4$ (monoclinic, isotypic with $ThF_4$ and $UF_4$) can be prepared by the reaction of $Pa_2O_5$ with $H_2$/HF above 500 °C [139, 140]. In contrast to $PaF_5$, $PaF_4$ is insoluble in dilute hydrofluoric acid but dissolves in 15 M $NH_4F$ [117].

The addition of fluoride ions to a sulfuric acid solution of $Pa^{4+}$ gives $PaF_2SO_4 \cdot 2H_2O$ [140]. The preparation of the corresponding uranium compounds suggests an analogy between the ions $UF_2^{2+}$ and $PaF_2^{2+}$ and the stable $UO_2^{2+}$ ion.

$PaCl_5$ is most simply obtained by the reaction of $Pa_2O_5$ with a stream of chlorine saturated with $CCl_4$ vapor at 300–400 °C [141]. Its melting point is 300 °C, but in

vacuum it sublimes above 160 °C. The volatility of $PaCl_5$ can be utilized for various separations, *e.g.* for the recovery of $^{233}Pa$ from neutron-irradiated $ThCl_4$ [142]. $PaCl_5$ crystallizes with a monoclinic lattice (a = 10.25 Å, b = 12.31 Å, c = 8.82 Å, β = 111.8 °C) [143] and, like all protactinium pentahalides, exhibits a structure different from that of the corresponding Nb and Ta pentahalides. Orange $PaBr_5$ (m.p. 317 °C) and black $PaI_5$ are obtained by the reaction of $Pa_2O_5$ with $AlBr_3$ and $AlI_3$, respectively. Purification is possible by vacuum sublimation; however, $PaI_5$ decomposes above 300 °C with liberation of iodine. Both salts are orthorhombic ($PaBr_5$: a = 7.25 Å, b = 12.12 Å, c = 9.13 Å; $PaI_5$: a = 7.22 Å, b = 21.2 Å, c = 6.85 Å).

The reaction of $PaO_2$ with $CCl_4$ or the reduction of $PaCl_5$ with hydrogen at 400–500 °C in a closed system gives $PaCl_4$ (tetragonal; a = 8.377 Å, c = 7.482 Å), isotopic with $UCl_4$ [134].

### 7.2.2. Polynary Compounds

The reaction of $PaF_4$ with an excess of $NH_4F$ gives $(NH_4)_4PaF_8$ [147], which is isotypic with the corresponding U, Np, Pu, and Am compounds [144–146]. By solid-state reaction of RbF with $PaF_4$ the compound 7 RbF·6$PaF_4$ (orthorhombic; a = 9.587 Å, α = 107 °9′) is formed [147], which is isotypic with the analogous Th [148], U [149], and Np and Pu [150] compounds.

Double fluorides of quinquevalent protactinium can be prepared both from aqueous solution and by the fluorination of an alkali metal fluoride / $PaF_4$ mixture. The sparingly soluble $K_2PaF_7$ (which incidentally was the first pure compound of protactinium to be prepared) was first obtained by *von Grosse* [151]. Above 130 °C, it decomposes into $KPaF_6$ and KF [152]. $K_2PaF_7$ is monoclinic [152a] with a = 13.94 Å, b = 6.76 Å, c = 8.24 Å, β = 125,5 °, and Z = 4 (space group $C2/c\text{-}C_{2h}^6$). Each Pa is surrounded by 9 fluorines in an arrangement which may be idealized as a trigonal prism with 3 equatorial fluorines added. These $PaF_9$ groups are linked in infinite chains parallel to [001] by 2 fluorine bridges. The interatomic Pa-F-distances are between 2.13 Å and 2.46 Å.

Depending on the $M^I$:Pa ratio, complex fluorides of the compositions $M^IPaF_6$, $M^I_2PaF_7$, and $M^I_3PaF_8$ can be prepared from hydrofluoric acid solutions of Pa(V) [153–158]. The majority of these double fluorides are isotypic with the corresponding uranium compounds, but not with the compounds of niobium and tantalum, which do not form the $M_3XF_8$ type of compound at all. However, for the $M_3PaF_8$ and $MPaF_6$ double fluorides, approximate structural data are known only for $Li_3PaF_8$ (tetragonal, space group $D_{4h}^6$, a = 10.386 Å, c = 10.89 Å, Z = 8), $Na_3PaF_8$ (tetragonal, space group $D_{4h}^{17}$, a = 5.487 Å, c = 10.89 Å, Z = 2) and $MPaF_6$ (orthorhombic for M = K, Rb, Cs; $KPaF_6$: a = 5.64 Å, b = 5.77 Å, and c = 3.99 Å) [155].

Freshly prepared $Pa_2O_5$·aq dissolves in $SOCl_2$ at room temperature. After the excess of $SOCl_2$ has been distilled off, $SO(PaCl_6)_2$ remains, in contrast to Nb and Ta where the anhydrous chlorides are obtained [153, 159]. $SO(PaCl_6)_2$ decomposes in vacuum above 150 °C. By adding MCl ($M^+ = Cs^+$, $[(CH_3)_4N]^+$, or $[(C_6H_5)_4As]^+$) to the solution of $SO(PaCl_6)_2$ in $SOCl_2$, hexachloro complexes $MPaCl_6$ and octachloro complexes $M_3PaCl_8$ are obtained – the last complex not with $[(C_6H_5)_4As]Cl$, however. Analogous double chlorides can be prepared from U(V), but only hexachloro compounds of Nb and Ta exist. When dissolved in acetonitrile + dichloromethane, $PaCl_5$ forms adducts $PaCl_5$·$R_3PO$ with phosphine oxides $R_3PO$ which are considerably more stable than the pentachloride.

If a tetraalkylammonium bromide is added to a solution of $PaBr_5$, $TaBr_5$, or $NbBr_5$ in acetonitrile, evaporation of the solvent gives a double bromide of the type $M^IM^VBr_6$ [153].

## 7.3. Oxygen Compounds of Protactinium

### 7.3.1. The System Pa–O

In addition to the stoichiometric oxides of quadrivalent and quinquevalent protactinium, there are four oxide phases with a variable oxygen content (Table 5) that can be prepared both by the partial oxidation of $PaO_2$ with oxygen and by the partial reduction of $Pa_2O_5$ with hydrogen. The structures of these compounds can be derived substantially from the fluorite structure, which shows the relationship of $PaO_{2+x}$ to the lower oxides of uranium. Because of the relatively large – in comparison to $UO_2$ – unit cell of $PaO_2$, an increased incorporation of oxygen in interstitial sites of the fluorite lattice is possible without change in structure: in the $PaO_2/O_2$ system up to $PaO_{2.50}$, but in the $UO_2/O_2$ system only up to $UO_{2.35}$.

| $Pa_2O_5 \cdot H_2O$ | | | | | | 200—280 | [163] |

After the addition of $H_2O_2$ to a solution of Pa(V) in dilute sulfuric acid, a precipitate of amorphous, unstable Pa peroxide $Pa_2O_9 \cdot 3H_2O$ is obtained [136, 164]; below 200 °C it is transformed into protactinium pentoxide monohydrate, which is stable up to 280 °C.

### 7.3.2. Polynary Oxides of Protactinium

$Pa_2O_5$ is amphoteric; like a basic oxide, it dissolves in molten hydrogen sulfates, but it reacts as an acidic oxide with alkali metal and alkaline earth oxides. From the solid-state reactions of $PaO_2$ and $Pa_2O_5$ with oxides of other elements, it may be concluded that protactinium behaves as a "true" actinide element (Table 6). Thus with $GeO_2$ or $SiO_2$, $PaO_2$ forms ternary oxides of the type $Pa^{IV}X^{IV}O_4$, which are also known for other quadrivalent actinide elements but not for Nb(IV) and Ta(IV). Further, $Pa^{V}Nb_3O_{10.67}$ corresponds completely to the compounds $UNb_3O_{10.67}$ and $NpNb_3O_{9.5}$, in spite of the different oxygen numbers. With the sesquioxides of the lanthanides and actinides, $Pa_2O_5$ reacts to give double oxides of the type $(M^{III}_{0.5}, Pa^{V}_{0.5})O_2$ with the fluorite structure and a statistical distribution of the heavy metal ions on the $Ca^{2+}$ sites of the $CaF_2$ lattice. Like all binary actinide oxides with fluorite structure, the M(III)/Pa(V) double oxides take up additional $MO_{1.5}$ or $PaO_{2.5}$ in solid solution, the solubility of $MO_{1.5}$ in the $(M_{0.5},Pa_{0.5})O_2$ lattice being a function of

the ionic radius of M (Fig. 6). The lattice parameters of the solid solutions change linearly with the amount of $MO_{1.5}$ dissolved in the $(M_{0.5},Pa_{0.5})O_2$. The solubility increases with increasing temperature. As in the $Li_2O/Pa_2O_5$ system [173], a fluorite phase also exists in the $Li_2O/U_2O_5$ system [174, 175]. Only in compounds of

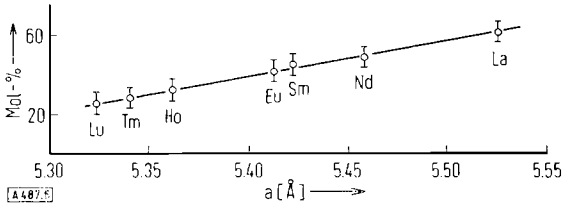

Fig. 6. Solubility of $MO_{1.5}$ in $(M^{III}_{0.5}Pa^{V}_{0.5})O_2$ *versus* lattice parameter.

the type $Ba(M^{II}_{0.5},Pa_{0.5})O_{2.75}$ and $Ba(M^{III}_{0.5},Pa_{0.5})O_3$ with an ordered fluorite structure can a relationship of protactinium to niobium and tantalum be seen; moreover, the uranium compounds of at least the last-mentioned type can also be prepared [176].

### 7.4. Nitrides, Carbides, and Sulfides

Little information is available on the Pa/N, Pa/C, and Pa/S systems [153]. Thermal treatment of $PaCl_5$ with $H_2S/CS_2$ at 900 °C leads to the formation of PaOS, and treatment of $PaCl_5$ or $PaCl_4$ with gaseous $NH_3$ at 800 °C to $PaN_2$. The identification of PaOS and $PaN_2$ was made solely on the basis of their isotypicity with the analogous uranium compounds. PaC can be prepared by the reaction of $PaF_4$ with Ba + C at 1400 °C.

### 7.5. Nitrato Complexes of Pa(V)

The reaction of $N_2O_5$ with $Pa_2O_5$·aq or $PaCl_5$ yields the hexanitrato acid $HPa(NO_3)_6$ [177], whose salts – *e. g.* $CsPa(NO_3)_6$ or $[N(CH_3)_4]Pa(NO_3)_6$ – can also be prepared by the reaction of the hexahaloprotactinates(V) with $N_2O_5$. On the other hand, in the analogous reaction the hexahaloniobates and hexahalotantalates form only oxotetranitro complexes, *e.g.* $CsNbO(NO_3)_4$. All these compounds are very sensitive to hydrolysis, and they were identified mainly on the basis of their infrared spectra.

## 8. Outlook

Within the past few years our knowledge of the chemistry of protactinium has increased to such an extent that many aspects are better known than for the neighboring elements niobium and tantalum. In other fields, however, such as metallurgy, phase diagrams of multi-component systems, and other thermodynamic data, no thorough investigations have yet been carried out. However, this statement applies also to many of the "well-known" elements. If the present interest in protactinium continues and can be increased by the production of a larger amount of $^{231}Pa$, these gaps may rapidly be closed, despite the element's radiotoxicity. Weighable amounts of $^{231}Pa$ can be handled only in airtight glove boxes (the maximum permissible concentration of $^{231}Pa$ in air is $10^{-8}$ mg/m³; that of hydrogen cyanide is 10 mg/m³).

# Novel Approaches to the Synthesis of Some Heterocycles Containing Nitrogen

BY DR. G. DE STEVENS, DR. H. M. BLATTER, AND DR. R. W. J. CARNEY
CHEMICAL RESEARCH DIVISION, CIBA PHARMACEUTICAL COMPANY
SUMMIT, NEW JERSEY (U.S.A.)

*Some syntheses of heretofore unknown pyrimidines, tetrahydroquinazolines, and quinazolines are described. These methods are uniquely simple one- or two-step reactions, general and versatile in scope, and give high yields. Some interesting chemistry associated with these heterocyclic systems is discussed.*

For a number of years we have been involved in the synthesis of new heterocyclic systems for biological evaluation. This work has led to the preparation of a variety of new heterocycles, amongst which are 5,6,7,8-tetrahydrobenzothiazolin-2-ones [1], 5,6,7,8-tetrahydrobenzoxazoles [2, 3], 1,2,4,5-tetrahydro-1,3-benzodiazepines [4], and pyrazolo[1,5-*c*]quinazolines [5]. Recently we have developed some new synthetic routes to 1,2-disubstituted pyrimidines [6], tetrahydroquinazolines [7,8], and quinazolines [9,10], and it is the purpose of this review to present this work in its entirety.

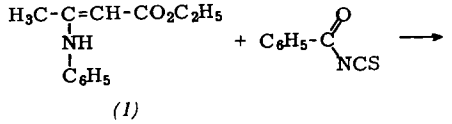
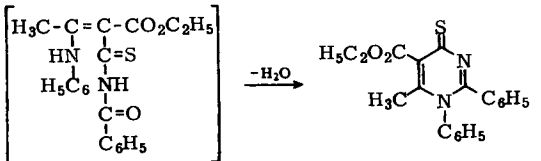
## 1,2-Disubstituted Pyrimidines

In a recent monograph on pyrimidines *Brown*[11] noted that, although many mercaptopyrimidines have been prepared, only the 2-mercaptopyrimidines have been synthesized from a 3-carbon intermediate and an appropriate condensing agent (*e.g.* ethyl cyanoacetate and thiourea). The usual procedure employed to arrive at the 4-mercaptopyrimidines involves the synthesis of the 4-hydroxy- or 4-chloropyrimidines, which are then allowed to react with phosphorus pentasulfide or sodium hydrogen sulfide, respectively. This method has in the past been confined to pyrimidines unsubstituted in the 1-position. 1-Alkyl-4-oxopyrimidines have been prepared in certain cases through alkylation of a 4-aminopyrimidine derivative. The resultant 1-alkyl-4-iminopyrimidine was hydrolysed to the 4-oxo derivative[12]. Thus, a minimum of four steps is required in the preparation of a 1-alkyl-1,4-dihydro-4-thiopyrimidine from the condensation of an appropriate 3-carbon intermediate (*e.g.* malononitrile) with an amidine. The problem becomes even more acute if one considers the synthesis of the previously unknown 1,2-disubstituted 1,4-dihydro-4-thioxopyrimidines and especially the 1,2-diaryl compounds which are not available by conventional routes.

The investigations of *Behrend et al.* during the early part of this century served as a convenient starting point in the preparation of such compounds. *Behrend*[13,14] found that the condensation of ethyl β-aminocrotonate with phenyl isothiocyanate affords not only the anticipated product, 6-methyl-3-phenyl-2-thiouracil, but also ethyl β-amino-α-phenylthiocarbamoylcrotonate. The tendency of ethyl β-aminocrotonate to behave as an enamine towards the isothiocyanate function under certain conditions was thus established. It was with this



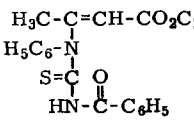
*(1)*



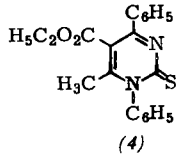
*(2)* *(3)*

observation in mind that we considered the condensation of ethyl β-anilinocrotonate *(1)* with benzoyl isothiocyanate. It was anticipated that the primary product of this condensation reaction would be ethyl β-anilino-α-benzoylthiocarbamoylcrotonate *(2)*. However, when these intermediates were allowed to react in ethyl ether or tetrahydrofuran under mild reflux a bright yellow precipitate was obtained in 60 % yield. The elemental analysis of this compound indicated that the elements of water had been eliminated from the intermediate *(2)*.

The ultraviolet, infrared, and nuclear magnetic resonance spectra along with the elemental analysis strongly supported the assignment of structure *(3)* to this compound. The alternative structure *(4)* was not considered feasible since it required an amide-carbonyl interaction with the carbon bearing the vinyl proton [cf. *(2a)*], a reaction which is not favorable for the elimination of water under the mild reaction conditions described.

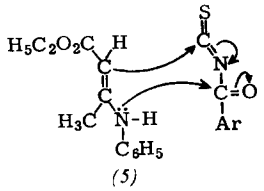


*(2a)*

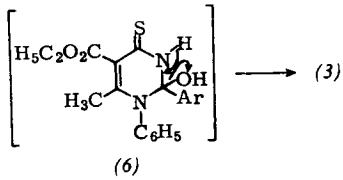


*(4)*

This reaction has been applied to a variety of α,β-unsaturated amino-esters and acyl and aroyl isothiocyanates[6]. Several factors are worthy of note. The reaction conditions are very mild, condensation and ring closure occurring in the absence of an acid or base catalyst and at relatively low temperature (25–50 °C). The reaction seems to be quite general although higher yields of 4-thioxopyrimidines are obtained if the aroyl isothiocyanate is substituted with an electron withdrawing group (*e.g. p*-nitrobenzoyl isothiocyanate). On the other hand, the condensation of ethyl β-anilinocrotonate with *o*-methoxybenzoyl isothiocyanate gives a poor yield and a number of different by-products are formed. These facts suggest the mechanism represented by formulae *(5)–(6)* which requires an electron-deficient carbonyl group to facilitate ring closure and subsequent dehydration.



*(5)*



*(6)*

The isothiocyanate derivatives of aliphatic acids also give good yields. Variations in the structure of the crotonic ester do not significantly affect the course of the reaction. However, condensation of the ethyl β-

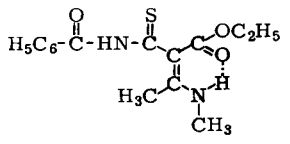
methylaminocrotonate with benzoyl isothiocyanate in *diethyl ether* results in immediate reaction with precipitation of the uncyclized intermediate ethyl α-*N*-benzoylthiocarbamoyl-β-methylaminocrotonate *(7)*, which dissolves in refluxing ethanol or tetrahydrofuran



*(7)*

to undergo ring closure with water elimination. A similar phenomenon was observed with ethyl β-aminocrotonate. However, this ester reacts with acylisothiocyanates in tetrahydrofuran, to give the corresponding 4-thioxopyrimidines directly. Infrared and NMR spectrocsopy were very useful in determining the stereochemistry of *(7)* and related compounds.

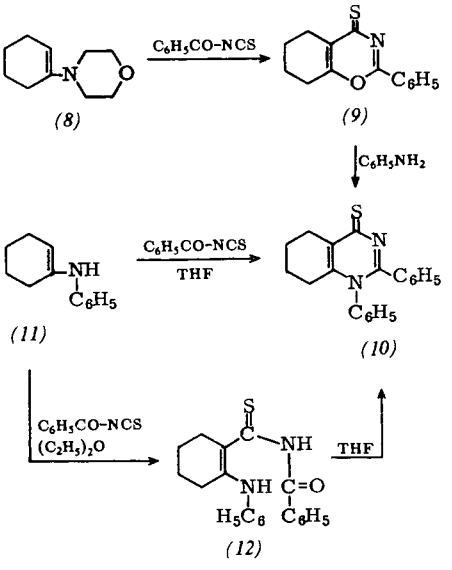
The 1665 $cm^{-1}$ band of ethyl β-aminocrotonate was assigned to the ester carbonyl, and the carbonyl group of the β-anilino derivative absorbs at 1655 $cm^{-1}$. A *cis* relationship between the amino and the ester groups has previously been shown[15]. This assignment is supported by the chemical shifts observed in the NMR spectrum[15]. In addition, ethyl β-diethylaminocrotonate[15] gives two carbonyl bands, 1677 $cm^{-1}$ (strong) and 1655 $cm^{-1}$ (very weak). This fully alkylated amine therefore is a mixture of *cis* and *trans* isomers, with *trans* predominating.

The *cis* stereochemical relationship (*i.e.* the *cis*-orientation of the amino and ester groups) thus apparently holds for the aroylcarbamoyl and thiocarbamoyl derivatives since the ester group absorption is found at 1665–1672 $cm^{-1}$ when the amino group is unsubstituted and at 1657 $cm^{-1}$ when it carries a phenyl substituent. However, this stereochemical assignment has little if any influence on the ring closure reaction since a *cis-trans* equilibrium is feasible in solution. Ring closure could then proceed rapidly through the small amount of *trans* isomer that is always present.

## 1,2-Disubstituted 5,6,7,8-Tetrahydroquinazolines

*Hünig* and *Hübner*[16] reported the formation of 5,6,7,8-tetrahydro-2-phenylbenzoxazine-4-thione *(9)* in 50 % yield from *N*-(1-cyclohexenyl)morpholine *(8)* with benzoyl isothiocyanate. Since 1,3-oxazin-4-ones bear a formal resemblance to 1,4-pyrones with regard to the disposition of the double bonds, and since 1,4-pyrones upon heating with primary amines can readily be transformed into 4-pyridones[17], we explored the reactivity of *(9)* towards such amines.

When *(9)* was refluxed in ethanol with excess aniline, a yellow crystalline material *(10)* was obtained in 59 % yield. Elemental analysis indicated the product to consist of the combined reactants minus water. The ultraviolet absorption spectrum of *(10)* in ethanol shows a shoulder at 254 mμ and a maximum at 342–345 mμ, in marked contrast to that of compound *(9)*, which has



*(8)* *(9)* *(11)* *(10)* *(12)*

maxima at 228–230 mμ, 287 mμ, and 333–335 mμ in dioxane. Evidently the chromophore of the heterocycle *(9)* is substantially altered in this reaction. The absence of NH, OH, or CO bands in the infrared spectrum further suggested that we were dealing with a heterocyclic compound rather than with a ring-opened cyclohexenyl derivative.

To substantiate the structure *(10)*, anilinocyclohexene *(11)* was treated with benzoyl isothiocyanate in tetrahydrofuran. The product was identical with compound *(10)*. However, in diethyl ether the benzoylthiocarbamoyl derivative *(12)* was obtained which, in turn, was converted to *(10)* in refluxing tetrahydrofuran. The isolation of *(12)* and its subsequent conversion to *(10)* relates the mechanism of the formation of *(10)* from *(11)* to the one illustrated for the pyrimidine synthesis.

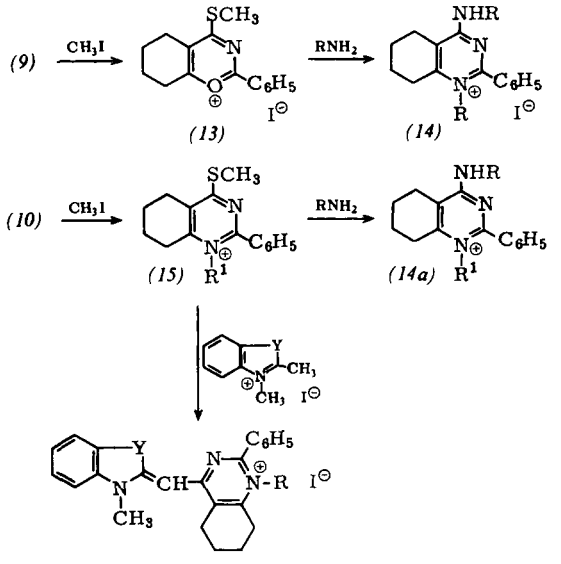
Compound *(9)* reacts with a number of primary amines to afford the previously unknown 1-substituted 5,6,7,8-tetrahydro-2-phenylquinazoline-4-thiones. Treatment of *(9)* with ammonia gives 5,6,7,8-tetrahydro-2-phenylquinazoline-4-thione. These substances are readily converted to the corresponding tetrahydroquinazolin-4-ones with mercuric acetate.

The versatility of *Hünig*'s intermediate benzoxazine *(9)* is illustrated further by its application to the synthesis of tetrahydroquinazolinium salts *(14)* and *(16)*. The reaction of *(9)* with methyl iodide yields the oxonium salt *(13)* which readily condenses with primary amines to form the 1,2-disubstituted tetrahydroquinazolinium iodide in good yields.

The R groups at positions 1 and 4 in these compounds are identical. However, to prepare compounds in which the R groups at positions 1 and 4 are different, it is necessary to treat *N*(1)-substituted 5,6,7,8-tetrahydroquinazolines with methyl iodide. The resulting salts *(15)* are then condensed with a primary amine whose R

[15] *C. F. Huebner, L. Dorfman, M. M. Robison, E. Donoghue, W. G. Pierson,* and *P. Strachan,* J. org. Chemistry *28*, 3134 (1963).
[16] *S. Hünig* and *K. Hübner,* Chem. Ber. *95*, 937 (1962).
[17] *L. F. Cavalieri,* Chem. Rev. *41*, 525 (1947).

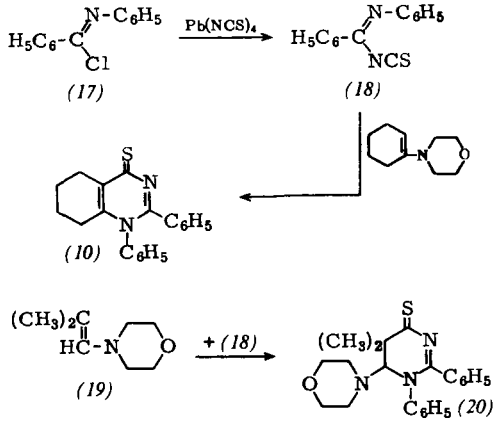
function is different from that already incorporated at the 1-position of the heterocycle. The 4-methylmercapto-5,6,7,8-tetrahydroquinazolinium salts *(15)* also react quite readily with the alkyl iodide salts of 2-methyl-substituted heterocycles, *e.g.* 2-methylbenzothiazole, to afford compounds of the cyanine dye type.



*(16)*, Y = O, S, CH=CH

In the synthesis of compounds related to *(9)* with substituents in the 2-phenyl group, the use of appropriately substituted aroyl isothiocyanates, usually gave intractable tars from which no distinct product could be isolated. This unexpected result limited the utility of the above route to 1-substituted 2-phenyl-5,6,7,8-tetrahydroquinazoline-4-thiones. For this reason it was necessary to devise an alternate route of synthesis of such compounds.

*N*-Arylimidoyl isothiocyanates had already been prepared in our laboratory in connection with another project[9,18]. For example, *N*-phenylbenzimidoylchloride *(17)*, readily obtainable from benzanilide by the



action of thionyl chloride, reacts with lead thiocyanate (in refluxing benzene for 2 h) to afford *N*-phenylbenzimidoyl isothiocyanate *(18)* in good yield.

[18] *H. M. Blatter*, 145th Meeting Amer. Chem. Soc., New York, September 1963; Abstracts of Papers 89 Q.

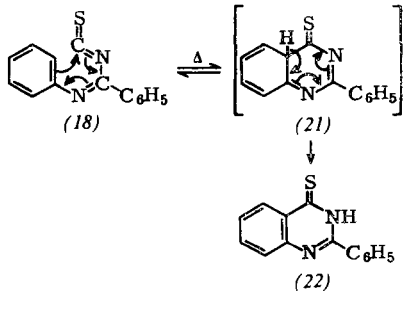
This readily condenses with *N*-(1-cyclohexenyl)morpholine to give *(10)* in fair yield[8]. In fact, this was then found to be a general reaction regardless of the nature of the substituent on the benzene ring. In this way a number of 1,2-disubstituted 1,4,5,6,7,8-hexahydroquinazoline-4-thiones were prepared, which were unobtainable by other routes. These substituted imidoyl isothiocyanates also react with other enamines, *e.g.* *N*-(2-methylprop-1-enyl)morpholine *(19)*, to form dihydropyrimidine-4-thiones *(20)*[8].

## 2-Substituted Quinazolines

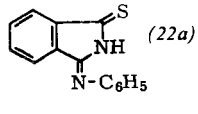
*N*-Phenylbenzimidoyl isothiocyanate *(18)* readily cyclizes to 2-phenyl-3,4-dihydroquinazoline-4-thione *(22)* at temperatures as low as 80 °C (refluxing benzene[9]). This ring closure was carried out with a variety of imidoyl isothiocyanates and represents a general synthesis of 3,4-dihydroquinazoline-4-thiones that enables one to circumvent the use of the often difficultly accessible anthranilic acid derivatives. The reaction occurs regardless of the presence of electron-withdrawing (*e.g.* $NO_2$) or electron-releasing substituents (*e.g.* $OCH_3$) in either benzene ring and particularly in the ring directly involved[19].

It seems likely, therefore, that *cis*-imidoyl isothiocyanates such as *(18)* undergo ring closure by a cyclic, concerted, thermally induced reorganization of the σ- and π-electrons. This would reversibly yield the less stable valence isomer (in brackets) which could stabilize itself through irreversible prototropic shift to form the aromatic 3,4-dihydroquinazoline-4-thione.

Reactions of this type, which includes both the Claisen and Cope rearrangements, have been designated as "no mechanism reactions"[21]; referring to the difficulty, if not impossibility, of describing precisely the transition state or states of such reactions. Such multicenter processes[22] are neither ionic nor free-radical. They are thermally induced,



[19] The alternative possibility that monothioimides such as *(22a)* are formed was ruled out by independent synthesis and



by the fact that such compounds are obtainable only in the presence of Friedel-Crafts catalysts [20].

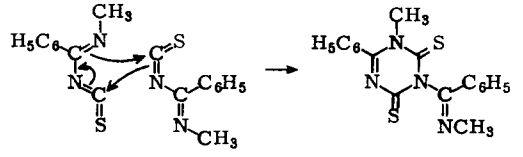
[20] *P. A. S. Smith*, J. Amer. chem. Soc. *82*, 4753 (1960).

[21] *W. v. E. Doering* and *W. R. Roth*, Tetrahedron *18*, 67 (1962).

[22] Review: *S. J. Rhoads* in *P. de Mayo*: Molecular Rearrangements. Interscience, New York, London 1963, Vol. I, p. 655.

are independent of the extramolecular environment, and are often insensitive to internal structural variation. These criteria are fulfilled in the present case.

Usually a red, crystalline imidoyl isothiocyanate dimer can also be isolated, albeit in poor yield. Structure determination by means of analytical and spectral data

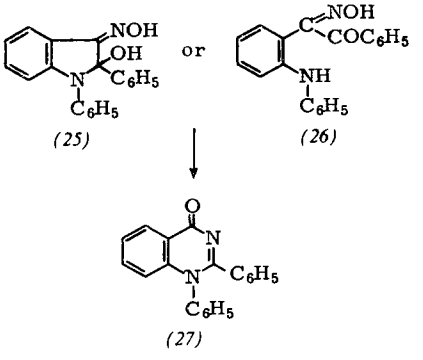


(23) (24)

as well as independent synthesis has established the dimer formed from *N*-methylbenzimidoyl isothiocyanate *(23)* to be the triazine *(24)* [23]. Thus, all the red, crystalline dimers have been assigned the corresponding triazine structures.

## 1,2-Disubstituted 1,4-Dihydroquinazolin-4-ones and their 4-Thioxo Derivatives

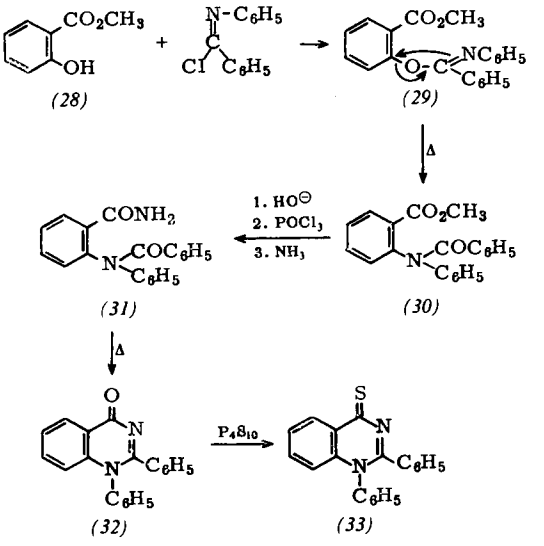
Finally our attention was directed to the synthesis of 1,2-disubstituted 1,4-dihydroquinazoline-4-thiones and their 4-oxo derivatives. A survey of the literature surprisingly revealed that compounds of this type have received little attention. *Huang-Hsinman* and *Mann* [24] reported that 2-hydroxy-3-oximino-1,2-diphenylindoline *(25)*, obtained from 3-amino-1,2-diphenylindole through atmospheric oxidation, is converted by means of ethanolic hydrogen chloride, aqueous sodium hydroxide, or heat alone to a colorless, crystalline substance, m.p. 280–281 °C, whose molecular formula, $C_{20}H_{14}N_2O$, corresponds to that of the quinazolinone *(27)*. These authors acknowledged the tenuity of their structural assignments, and suggested the oxime *(26)* as an alternative to *(25)*.



(25) or (26)

(27)

After a variety of methods to prepare *(27)* and related substances was explored with little success, *e.g.* condensation of *N*-phenylanthranilic acid with benzonitrile [25] or ethyl iminobenzoate [25,26], dehydrogenation of 1,2-diphenyl-1,4,5,6,7,8-hexahydroquinazolin-4-one and -thione with palladium on carbon in cymene, it was decided that the least complicated and most unambigous route to these compounds would be *via* the imido ester *(29)* prepared by condensing methyl salicylate with *N*-phenylbenzimidoyl chloride. Chapman rearrangement [27] of compound *(29)* according to



(28) (29) (30) (31) (32) (33)

the prodecure of *Jamison* and *Turner* [28] yields methyl 2-(*N*-benzoyl-*N*-phenylamino)benzoate *(30)*. Saponification of the ester, followed by conversion to the acid chloride and subsequent amination, gives *(31)* [29]. Heating of this compound for a few minutes at 300 °C gives almost quantitatively the desired 1,2-diphenyl-1,4-dihydroquinazolin-4-one *(32)* [10]; its conversion into the thione *(33)* can be carried out by the conventional method.

Each of these steps gives high yields and is free from complicating side reactions. The method is general and versatile since the nature of the substituents on the benzene rings of the quinazoline ring system and of the 1,2-diphenyl groups is governed by the starting materials, which are readily available commercially or through synthesis.

# The Modifications of Niobium Pentoxide [1]

BY PROF. DR. HARALD SCHÄFER, DR. R. GRUEHN, AND DR. F. SCHULTE

ANORGANISCH-CHEMISCHES INSTITUT DER UNIVERSITÄT MÜNSTER (GERMANY)

*Dedicated with sincere good wishes to Professor Wilhelm Klemm on his 70th birthday*

*Niobium pentoxide crystallizes in numerous modifications. The present paper describes their mode of formation, structures, and thermal properties.*

## 1. Introduction

In his fundamental work on the oxides of niobium [2], *Brauer* distinguished three modifications of niobium pentoxide which, according to their appearance at low, medium, and high temperatures, are denoted by the letters T, M, and H. In the last few years other modifications have been found, and numerous observations have been made on the modes of formation, the structural principles, and the stabilities of these materials. The abundance of observations makes it desirable to subject the available material to a critical review and classification, and thus simultaneously to create a basis for further investigations.

## 2. What is a "Modification"?

The classical concept of polymorphism and its definition of modifications appears unambiguous when we think of, for example, sulfur or phosphorus, but its clarity diminishes when closely related structures are present between which transitions are possible. In such cases a discussion of whether particular modifications exist is not of fundamental importance, since it would be sufficient to characterize the materials by an accurate description of their structure. However, such characterization is still not possible for many substances, and the convenient concept of polymorphism will be abandoned only with reluctance. We must therefore attempt to obtain a more precise definition.

As an example, consider a material MX which – like ZnS – can be prepared in a cubic sequence ABC ABC ABC ... and also in a hexagonal sequence AB, AB, AB .... It is then correct to speak of cubic and hexagonal modifications. Assume now that it is possible to link these two modifications in some way through a region of homogeneity with a statistical distribution of ABC and AB sequences. Even then it appears meaningful to speak of the limiting forms with purely cubic or purely hexagonal structure as modifications, although thermodynamically they belong to the same phase. Obviously, however, it is no longer meaningful to regard any particular compositions $(ABC)_x(AB)_y$ within the range of homogeneity as modifications. However, a *regular* sequence such as ABC AB ABC AB ... must be described as another modification.

In this sense, a modification merely requires an ordered structure: *a corresponding ideal structure can be given for a modification.* It is immaterial for this definition that the actual crystal possesses structure defects. It is equally immaterial whether homogeneity regions or considerable concentrations of vacancies occur (in unordered distribution).

It should be particularly noted that the frequently coincident terms "modification" and "thermodynamic phase" are independent of one another. The definition does not exclude the possibility that – as discussed – several modifications may occur in one phase, or several phases may belong to the same modification. Obviously, however, this will not usually occur.

The above indicates how the concept of modification is to be understood in what follows. Frequently, the structurally less definite symbolism $Nb_2O_5$ in the X-form, *e.g.* in the M-form (or M–$Nb_2O_5$) is to be preferred because of insufficient knowledge of the structure.

## 3. Designation and Characterization of the Modifications (Forms) of Niobium Pentoxide

If all the phases (or modifications) occurring in a chemical system are known, it is convenient to denote these by a sequence of letters $\alpha, \beta, \gamma, \ldots$ which simultaneously gives a sequence in stability or in composition. Such knowledge is still lacking in the case of niobium pentoxide, and for this reason nomenclature proposals of this type are premature and confusing (Table 1). We prefer the neutral symbols given in the first column of Table 1. In almost all cases, these were used also by the authors who first observed the corresponding modification.

The form $Nb_2O_5$-II observed by *Shafer* and *Roy* [3] and identified with *Brauer*'s M–$Nb_2O_5$ [2] is mentioned with the M-form. However, $Nb_2O_5$-II is, according to the interplanar

spacings reported[3], different from all known forms of niobium pentoxide[4] and has therefore also been cited as a new phase.

In the X-ray characterization of $Nb_2O_5$ samples, the large number of lines in the powder diagram and the often slight difference between the X-ray patterns of related modifications must be borne in mind. Guinier photographs with Cu-$K\alpha_1$ radiation are particularly suitable because of the high resolution possible (Fig. 1). The X-ray patterns of the T-, B-, M-, N-, and P-forms are derived from samples prepared by chemical transport (cf. Section 4) in crystals of millimeter size. Interplanar spacings (d values) for most of the observed forms of $Nb_2O_5$ are given in the literature (Table 2). The table also indicates those literature data which agree particularly well with our own observations. Numerical values will therefore be given below only for the M-form.

[18] *R. Gruehn* and *D. Bergner*, unpublished work.

The selection of an X-ray pattern of the M-form suitable as a "standard" for this form presents difficulties: some preparations [25–27] have given Guinier photographs differing clearly from *Brauer*'s M–$Nb_2O_5$ diagram [2]. Other data [9, 11, 22] differ from those of *Brauer* [2] and also to some extent from our own values. In order to be able to describe the X-ray pattern of the M-form, taking into account its variability [11, 13] (which we have also observed), it is convenient to distinguish between two groups of reflections (Table 3):

1. Diffuse reflections with d values (*e.g.* 4.88, 3.57, 2.05 Å) for which no lines of the H-form exist. These diffuse reflections disappear in the M → H conversion by a decrease in their intensity without any observed splitting.

2. Some sharp and some diffuse reflections, whose lines can be assigned to H–$Nb_2O_5$ with the same or almost the same value of d.

*Brauer*'s M–$Nb_2O_5$ diagram [2] contains all the lines of group 1 and also all the diffuse and some sharp reflections of group 2; Guinier photographs of our preparations, however, show other sharp reflections of group 2, which we have denoted in Table 3 by 2+. If the different resolving power of the Guinier compared with the Debye method is taken into account, it would be conceivable that the additional reflections (2+) were unobservable on Debye photographs [2]. However, we cannot exclude the possibility that these reflections arise from a partial M → H–$Nb_2O_5$ conversion and therefore cannot be ascribed to pure M–$Nb_2O_5$. Since, however, our preparations, which were obtained in various ways (cf. Section 4) as powders or needle-like crystals, all give the (2+) reflections, we consider it likely that sufficiently ordered M–$Nb_2O_5$ preparations give all the reflections mentioned (Table 3) [28]. The ratio of the intensities of the diffuse and the sharp reflections depends on the degree of order of the preparations; variations in the literature data are thus understandable.

Table 2. List of references on interplanar spacings (d or Θ values) and on intensities of X-ray reflections. The references in braces give results which are in best agreement with our own observations. The references in parentheses do not give d values but, for example, line diagrams.

## 4. Modes of Formation

Niobium pentoxide can be obtained in many different ways. If the solid oxide is heated for some time at temperatures above 1000 to 1200 °C, the H-form, which is stable under these conditions, is always produced.

The forms of $Nb_2O_5$ prepared at lower temperatures are mostly metastable (cf. Section 7). The method of preparation then also plays a decisive part. If the $Nb_2O_5$ is obtained, for example by oxidation, the resulting form may depend on the nature of the starting material. Moreover, small amounts of impurities may have a stabilizing or directing effect. If the starting material used is "niobic acid" separated from aqueous solution, then in addition to the presence of water, the presence of foreign ions is also of importance. In this connection, we call the niobic acid precipitated from a pyrosulfate digestion "sulfate niobic acid". These preparations of "sulfate niobic acid" (or "chloride niobic acid", *etc.*) are carefully washed and have only a small (but detectable) content of sulfate (or chloride, *etc.*), which cannot be reduced by further washing.

The chemical transport [36] of niobium pentoxide is of particular importance; the reversible formation of gaseous oxide halides $NbOX_3$ (with X = Cl, Br, I) is utilized [37]. For the chloride system, used most frequently, we have

$$Nb_2O_5 + 3\ NbCl_5\ (g) = 5\ NbOCl_3\ (g) \quad (1)$$

This transporting reaction is endothermic, so that $Nb_2O_5$ is consumed in the hot zone ($T_2$) of the reaction tube and deposited in the less hot zone ($T_1$) [37a]. The

[37] *H. Schäfer* and *M. Hüesker*, Z. anorg. allg. Chem. *317*, 321 (1962).

[37a] Under somewhat modified conditions, the transport can also take place exothermally, *i.e.* into the hotter zone, in accordance with the scheme $Nb_2O_5 + 3\ NbX_4\ (g) + 3\ X_g = 5\ NbOX_3\ (g)$. This is important particularly in the preparation of NbOx phases (x < 2.5) [25].

transport is carried out in the presence of free chlorine [$p(Cl_2)$ = 1 atm, 20 °C], so that the appearance of reduced $NbO_x$ phases ($x < 2.50$) is suppressed. The procedure followed in the transport experiments will be described below using H–$Nb_2O_5$ as an example. Fig. 3 shows a transport tube before charging.

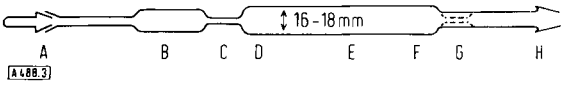

Fig. 3. Charging of a transport tube (fused silica). Length DEF: 12 to 13 cm.

A known amount of $Nb_2O_5$ (250–700 mg) is introduced into the reaction tube at D from H, and subsequently a capillary is drawn at G. After part B of the tube has been charged with the calculated amount of Nb, and A has been closed, the tube is evacuated from H and the section of the tube C–G is heated with a bunsen flame. After cooling, a stream of purified $Cl_2$ is passed through the tube from A. When the air has been displaced, the Nb at B is ignited and $NbCl_5$ is condensed at DEF. The cooled tube, filled with $Cl_2$ at 1 atm (room temperature) is sealed off at C and G. The transport tube C–G has then been charged.

It is then introduced into the predetermined temperature gradient in a horizontal or, if desired, in a sloping position (convection) where it remains for from 3 to 8 days. Under these conditions, the transport of $Nb_2O_5$ from $T_2$ to $T_1$ takes place with the aid of the reversible establishment of the equilibrium (1). If heating is to be discontinued, first only Section D of the tube is removed from the oven, so that the contents of the gas phase deposit there and do not contaminate the transported crystals that have already deposited at EF.

Fig. 4 shows a transport tube with H–$Nb_2O_5$ crystals. The white substance on the left-hand side of the tube consists of the condensed contents of the gas phase (essentially $NbOCl_3$).

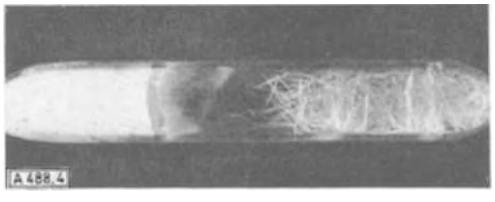

Fig. 4. Transport tube with crystals of H–$Nb_2O_5$. Left: $NbOCl_3$ condensate.

The occurrence of oxygen-poorer $NbO_x$ phases, which is observed, for example, during chemical transport in the absence of $Cl_2$, has also been studied [26, 37–39]. It is important in connection with the forms of $Nb_2O_5$ oxI to oxVI, and it may be mentioned that the O:Nb ratio can be obtained very accurately *via* determination of the $Nb^{4+}$ content.

For a direct determination of small contents of $Nb^{4+}$ [40], samples of 3–15 mg are introduced under vacuum into a degassed KOH–KBr melt, whereupon all the substance dissolves in the form of niobate(V) and an amount of hydrogen equivalent to the content of $Nb^{4+}$ is liberated. The gas evolved is pumped off, compressed with a Töpler pump, and its volume measured in a mercury gas buret; it can also be identified by combustion over CuO. The limits of error may be characterized by the analytical compositions $NbO_{2.420 \pm 0.004}$ and $NbO_{2.480 \pm 0.001}$.

Preparations of all modifications investigated so far with the composition $NbO_{2.49}$ already have a definite blue color. An oxygen deficiency cannot, therefore, be made responsible for the occurrence of numerous colorless forms of $Nb_2O_5$. Contrary assumptions [11, 13] are incorrect.

### TT—$Nb_2O_5$

This form, first described by *Frevel* and *Rinn* [5], was produced as the first state crystalline to X-rays [6] from "sulfate niobic acid" and "chloride niobic acid" on heating at 500 to 600 °C [3, 6, 14]; with longer times of heating, amorphous niobic acid is converted into TT-$Nb_2O_5$ at even lower temperature (*e.g.* 440 °C [6]) [41]. Different samples of niobic acid prepared in the same way may exhibit different rates of conversion, so that an X-ray check is always necessary.

The TT-oxide is also formed when $NbO_2$ is oxidized in air at 320 to 350 °C [41a], amorphous $Nb_2O_5$ being observed as an intermediate [41]. If the oxidation is carried out at higher temperatures (350 to 500 °C), TT–$Nb_2O_5$ is obtained only with very short reaction times [41]. In the reaction of $NbO_2$ with $Cl_2$, in accordance with the equation

$$3\ NbO_2 + {}^3/_2\ Cl_2 = Nb_2O_5 + NbOCl_3\ (g) \quad (2)$$

at 270 to 320 °C, we again obtained the TT-form [41]. The TT-form can also be obtained by oxidation of niobium alloys in air at, for instance, 800 °C [13], as well as by the slow oxidation of Nb or lower oxides arising from it under special conditions [10]. Moreover, TT-$Nb_2O_5$ (together with $Nb_3O_7Cl$) has been observed in the chemical transport of $Nb_2O_5$ in accordance with Eq. (1) for $T_1$ = 350 °C and $T_2$ = 450 °C [15, 26].

The 24-hour oxidation of $Nb_2O_5$ with air at 320 °C is to be recommended as a method of preparing pure TT-$Nb_2O_5$.

### T—$Nb_2O_5$

This form, described by *Brauer* [2], appears when "sulfate niobic acid" or "chloride niobic acid" is heated at 600 to 800 °C [3, 6, 41]. Prolonged heating at, for example, 400 °C (3 days) also leads to the T form [41]. In addition, it can be obtained from TT-$Nb_2O_5$, which changes almost continuously into T-$Nb_2O_5$ on being heated at 600 to 800 °C [41]. The T-form arises in a short time already at temperatures over 400 °C from TT-$Nb_2O_5$ obtained by the oxidation of $NbO_2$ in air at 320 to 350 °C [41]. If $NbO_2$ is oxidized in air at 600 to 800 °C, T-$Nb_2O_5$ is produced after a short time [41]. It is also produced in the oxidation of Nb or Nb alloys below 1000 °C [13]. Under hydrothermal conditions (P = 170 atm, T = 330–380 °C), amorphous "niobic acid"

[38] *R. Gruehn* and *H. Schäfer*, Naturwissenschaften *50*, 642 (1963).

[39] *R. Gruehn*, *D. Bergner*, and *H. Schäfer*, Lecture, Clausthal 1965. Summary: Angew. Chem. *77*, 1082 (1965); Angew. Chem. internat. Edit. *4*, 1087 (1965).

[40] *R. Gruehn*, unpublished work.

[41] *C. Brendel*, Münster, unpublished work.

[41a] TT-$Nb_2O_5$ produced in this way may still contain some amorphous $Nb_2O_5$.

also changes into T-$Nb_2O_5$ [3]. We have now obtained the T-form in single crystals by quenching supercooled $Nb_2O_5$ melts [42] and also by the chemical transport of $Nb_2O_5$ in accordance with Eq. (1) [26, 43].

For crystal formation by means of chemical transport a device has proved satisfactory which permits nucleation and crystal growth to be observed visually at the experimental temperature. A "fused silica oven" constructed for this purpose simultaneously permits a favorable rate of nucleation to be established by varying $T_2$-$T_1$ at constant $T_1$.

In principle, the following arrangement has been used [43]: a fused silica transport tube is fixed centrally in a horizontal silica tube of correspondingly larger cross-section, which carries the two heating coils for establishing the temperatures $T_1$ and $T_2$. The outer cladding of this oven has openings which permit nucleation and the growth of crystals to be observed between the windings of the heating coil. For example, for the preparation of T–$Nb_2O_5$, the temperature is first controlled such that $T_2$ = 890 °C and $T_1$ = 835 °C. Under these conditions, nuclei of T–$Nb_2O_5$ (and of B- and N–$Nb_2O_5$) can be formed. If it can be seen from the shape of the crystals (and from the color, which is yellowish at high temperatures for all $Nb_2O_5$ modifications except B–$Nb_2O_5$) that only T–$Nb_2O_5$ has been produced at $T_1$, $T_2$–$T_1$ is reduced by lowering $T_2$ to 875 °C. This prevents the formation of new nuclei, while the crystals which are already present grow further. The subsequent time of transport is, for example, 5 days. If unwanted crystals of other forms are formed, all nuclei can be removed again by interchanging $T_1$ and $T_2$.

The following procedures are recommended for the preparation of T-$Nb_2O_5$ *powder*:

1. Dehydration of substantially chloride-free washed "chloride niobic acid" at 400 °C (2 hours) with subsequent heating to 600 to 800 °C (10 hours).

2. Oxidation of $NbO_2$ in air at 400 °C for 4 to 5 hours, Samples of T-$Nb_2O_5$ prepared by methods 1 and 2. which cannot be distinguished by their Guinier diagrams, nevertheless show different transformation behavior on further heating [41] (cf. Section 5).

### B–$Nb_2O_5$

This form was first observed in the chemical transport of $Nb_2O_5$ in accordance with Eq. (1) when the deposition temperature $T_1$ was 750 to 850 °C and $T_2$–$T_1$ 100 °C [14, 15] (cf. also [7]). Under these conditions, N-$Nb_2O_5$ and P-$Nb_2O_5$ are formed in addition to B-$Nb_2O_5$, but the characteristic plate-like crystals of the B-form can easily be sorted out. Fig. 5 shows crystals of B- and N-$Nb_2O_5$ that have deposited together in the transport tube. Growth of large untwinned single crystals (cf. Fig. 2) can be achieved in the fused silica oven in the manner described for T-$Nb_2O_5$. Here again, by selection of nuclei, it is possible to obtain B-$Nb_2O_5$ alone, without contamination by other forms of $Nb_2O_5$ [43].

If $Nb_2O_5$ is transported in accordance with Eq. (1) (or by means of the analogous bromide or iodide systems), all the forms of $Nb_2O_5$ obtainable in this way (T, M, H, N, P, B) can be obtained with a blue color, *i.e.* with a low content of $Nb^{4+}$ [25, 26]. However, colorless crystals of stoichiometric composition are obtained when the transport according to Eq. (1) is carried out in an oxidizing atmosphere produced by the introduction of chlorine into the transport tube [$P(Cl_2)$ = 1 atm, 20 °C]. Even under these conditions, however, the B-form – and only this – is usually produced with light blue color [15] (composition, for example, $Nb_2O_{4.994}$). This color further facilitates hand-sorting of crystals of the B-form from mixtures; at higher temperatures it changes to pale green.

Fig. 5. Transport tube with crystals of B- and N–$Nb_2O_5$ deposited together.

The $Nb^{4+}$ content of the blue B-crystals was hardly lowered on ignition (800 °C) in air for several hours [44]. After 80 hours, however, appreciable decoloration had occurred, and after 800 hours the crystals became practically colorless [40].

Crystals of B-$Nb_2O_5$ obtained by the transport method contained less than 0.01 % of Cl [14]. However, this Cl content is not characteristic of the B-modification, since the latter can also be obtained free from chlorine by the oxidation of $NbO_2$.

During transport in the temperature gradient, the nature of the $Nb_2O_5$ added at $T_2$ does not affect the form of $Nb_2O_5$ depositing at $T_1$. Usually H-$Nb_2O_5$ was used as the starting material.

On prolonged isothermal heating at 750 °C in the presence of $NbOCl_3$ as transporting agent, we obtained [26] the pure B-form from T-$Nb_2O_5$ and P-$Nb_2O_5$ [45]. If H-nuclei are also present under these conditions, B-$Nb_2O_5$ is converted into the H-form already at 750 °C [26]; cf. Section 7.

TT-$Nb_2O_5$ and T-$Nb_2O_5$ prepared by the oxidation of $NbO_2$ in air are converted into the B-form [11, 41] by further heating in air (*e.g.* for a few hours at 800 °C; 180 hours at 500 °C) [41]. It is also possible, although less convenient, to start from metallic Nb.

The oxidation of $NbO_2$ in air (24 hours at 320 °C and 24 hours at 850 °C for the subsequent TT → T → B conversion) may be recommended for the preparation of pure B-$Nb_2O_5$ powder.

[42] *W. Mertin*, Münster, unpublished work.

[43] *W. Jagusch*, Münster, unpublished work.

[44] *R. Gruehn, F. Schulte*, and *H. Schäfer*, Angew. Chem. *76*, 685 (1964); Angew. Chem. internat. Edit. *3*, 634 (1964).

[45] All T-$Nb_2O_5$ preparations undergo this T → B conversion, regardless of their history.

M—$Nb_2O_5$

This form, first observed by *Brauer* [2], arises when "sulfate niobic acid" or "chloride niobic acid", or the T-form obtained from "sulfate" or "chloride" niobic acid is heated for some hours at 900 to 950 °C [14,27] (or possibly a shorter time at a higher temperature [2,6]). The M-form has also been observed in the oxidation of Nb and Nb alloys at 1000 °C in air [13] and in the chemical transport of $Nb_2O_5$ *via* $NbOCl_3$ or $NbOBr_3$, with $T_1$ = 850 to 900 °C and $T_2-T_1$ = 100 °C [14,25,26].

It is difficult to prepare pure M-$Nb_2O_5$, since considerable amounts of H-$Nb_2O_5$ are frequently produced together with the M-form (cf. Section 3). In transport experiments, moreover, M-$Nb_2O_5$ and N-$Nb_2O_5$ may be deposited together. There is as yet no reliable method of preparation of the pure M-form.

H—$Nb_2O_5$

This modification of niobium pentoxide is particularly easy to obtain. As far as is known, H-$Nb_2O_5$ arises from any other form on heating in air to about 1100 °C. The same result is obtained when precipitates of niobic acid, *e.g.* from solutions containing sulfate, chloride, bromide, iodide, or fluoride, are heated at 1100 °C or when metallic niobium or lower oxides (NbO, $NbO_2$, $NbO_x$) are oxidized in air at this temperature to $Nb_2O_5$. If single crystals of the M-form are heated at 1100 °C, the single-crystal nature is retained in the transformation to the H-form, while crystals of all other forms of $Nb_2O_5$ are converted into polycrystalline H-$Nb_2O_5$ [44].

The H-form is also produced under hydrothermal conditions (P = 170 atm, T = 1075 °C) [3] and from a melt when, to avoid separation of T-$Nb_2O_5$, it is seeded with H-$Nb_2O_5$ or is cooled very slowly [42] (cf. also [4]). By chemical transport in accordance with Eq. (1), the pure H-form deposits [14] when the lower temperature $T_1$ of the transport tube is at least 950 °C [26]; cf. Fig. 4. In the presence of H-nuclei (cf. B-$Nb_2O_5$) or in the presence of HCl as transporting agent [P(HCl) = 1atm, 20 °C] we obtained H-$Nb_2O_5$ even at 750 °C [26].

N—$Nb_2O_5$

This form arose first in the chemical transport of $Nb_2O_5$ [14,15] in accordance with Eq. (1), the temperature of separation $T_1$ being 830 to 840 °C and $T_2-T_1$ 90 to 100 °C [26]. Under these conditions, often mixtures of N- with M- or H-$Nb_2O_5$ and also some B-$Nb_2O_5$ were obtained. The bundles of needles of N-$Nb_2O_5$ (Figs. 2 and 5) can, however, easily be distinguished.

The formation of the N-form is promoted by the presence of small amounts of fluoride [17,26]. Thus by chemical transport we obtained only the N-form when the quartz tube had been cleaned with dilute hydrofluoric acid (subsequently rinsed with water and heated in vacuum) or when the transport tube contained a little fluoride, *e.g.* 5 mg of $NbO_2F$ per 500 mg $Nb_2O_5$, in addition to the other materials. The N-$Nb_2O_5$ obtained in this way contained $<0.1$ % of F [26,46]. However, even when F was rigorously excluded, crystals of the N-form could be produced by chemical transport, particularly by the selection of nuclei in the fused silica oven ($T_1$ = 840 °C; $T_2$ = 900 °C; cf. T-$Nb_2O_5$) [43]. The N-form has also been obtained under hydrothermal conditions (2000 atm, 900 °C) [17], where OH probably plays the role of F.

*Andersson* and *Åström* [47] obtained N-$Nb_2O_5$ by thermal decomposition of $NbO_2F$; N-$Nb_2O_5$ obtained in this way contains about 0.2 % of F [48]. This method of preparation has been confirmed in our laboratory [49].

The order of magnitude of the F content of preparations of $Nb_2O_5$ has been determined by mass spectrometry. The samples were heated in a graphite crucible to incipient decomposition, and the ion currents corresponding to the gaseous fluorides produced were measured and integrated over time [48]. The limit of detection was 0.05 to 0.1 % of F. The compound $Nb_{31}O_{77}F$ [17,50] was used as an F standard. The mass-spectrometric determination therefore is based on the F-content proposed by structural analysis.

Thermal decomposition of $NbO_2F$ can be recommended for the preparation of pulverulent N-$Nb_2O_5$ (containing about 0.2 % of F): $NbO_2F$ is heated for some hours at 1000 °C in a high vacuum (with the pump running) [49]. Different preparations of $NbO_2F$ can behave somewhat differently with respect to the decomposition temperature (see under P-$Nb_2O_5$). The course of the decomposition should be checked by X-ray analysis, since $Nb_3O_7F$ [47,70] may arise when the time of heating is too short and H-$Nb_2O_5$ when it is too long.

P—$Nb_2O_5$

This form first arose in the chemical transport of $Nb_2O_5$ in the chloride system [Eq. (1)], with $T_1$ = 750 °C and $T_2-T_1$ = 100 °C [14,15]. Meanwhile it has also been prepared by the transport method by *Laves et al.* [8]. Analogous transport in the bromide and iodide systems also gives the P-form in admixture with T- and B-$Nb_2O_5$ at $T_1$ = 650 to 750 °C [25]. The experimental conditions and the specific formation of nuclei play a decisive part. This goes so far that in an earlier stage of the investigations [14] we thought that the P-form was thermodynamically stable over a certain range of temperatures and was obtainable from all other modifications. However, this view was not confirmed, and it is actually very difficult in some cases to obtain P-$Nb_2O_5$ by transport in the presence of $NbOCl_3$ and $Cl_2$.

New experiments have shown that the formation of P-$Nb_2O_5$ is promoted when the transport tube is filled, not with $NbOCl_3$ + $Cl_2$, but with $Cl_2$ (1 atm/20 °C) and small amounts of water, *e.g.* 0.04 to 0.12 mg of $H_2O$/ml of tube volume ($T_1$ = 600, $T_2$ = 800 °C). At present this appears to be the most satisfactory method for the preparation of P-$Nb_2O_5$ [26]. Possibly the formation of P-$Nb_2O_5$ observed previously in transport with $NbOCl_3$ + $Cl_2$ without the addition of water [14] should be ascribed to the water content of the silica.

[46] In the presence of fluorides, $SiO_2$ can be transported from the quartz wall onto the deposited N-$Nb_2O_5$ crystals; the amorphous $SiO_2$ adhering to the surface simulates a high $SiO_2$-content [15] of the $Nb_2O_5$ [27].

[47] *S. Andersson* and *A. Åström*, Acta chem. scand., in press.

[48] *K. Rinke*, Münster; unpublished mass-spectrometric investigation.

[49] *D. Giegling*, Münster, unpublished work.

[50] We are obliged to Dr. *S. Andersson* for the sample.

We obtained the P-form in admixture with T-$Nb_2O_5$ by heating "chloride niobic acid" with a high content of HCl (*e.g.* 8%) to 650–800 °C (in air [15] or in a stream of moist HCl) [26]. The decomposition of $Nb_3O_7Cl$ (in air or in vacuum) at 700 to 800 °C yielded corresponding polycrystalline mixtures of P-$Nb_2O_5$ and T-$Nb_2O_5$ [42].

The use of HCl-containing starting materials obviously has a promoting effect on the formation of P-$Nb_2O_5$. Nevertheless, analyses of P-$Nb_2O_5$ crystals obtained by chemical transport and of precipitates heated to 750 °C gave a Cl content of less than 0.01 % [14].

The P-form also arises during the very slow thermal decomposition (heating from room temperature to 740 °C over 5 days) [41] of $NbO_2F$, which can easily be obtained from $Nb_2O_5$ and hydrofluoric acid.

### ε—$Nb_2O_5$

*Reisman* and *Holtzberg* [4] found a freezing point (1435 °C) corresponding to a metastable phase when an $Nb_2O_5$ melt was supercooled. The ε-$Nb_2O_5$ crystallizing under these conditions remained stable for a few hours above 1400 °C, but was converted exothermally into H-$Nb_2O_5$ on further cooling or on seeding with the latter material. Since it has so far been impossible to investigate this substance by X-rays, the possibility cannot be excluded that one of the known forms of $Nb_2O_5$ crystallized in a metastable state from the melt and caused the observed phenomenon.

### $Nb_2O_5$-I-high

This modification was described by *Shafer* and *Roy* [3] as a stable high-temperature form. According to differential thermal analysis and high-temperature X-ray photographs taken by these authors, at 1285 °C H-$Nb_2O_5$ is converted endothermally and reversibly into $Nb_2O_5$-I-high. The occurrence of this new stable form above 1250 °C has been queried by *Reisman* and *Holtzberg* [4], particularly since the d-values given for $Nb_2O_5$-I-high differ only slightly from those of H-$Nb_2O_5$. The substance observed [3] may have been an $NbO_x$ phase with $x < 2.5$. More accurate investigations on this point should be carried out.

### $Nb_2O_5$-II

This form was reported by *Shafer* and *Roy* [3], who obtained poorly crystalline $Nb_2O_5$-II by heating amorphous "niobic acid" to 880 to 950 °C in air; particularly well crystallized samples were obtained under hydrothermal conditions (P = 170 atm, T = 390 to 1060 °C).

*Shafer* and *Roy* considered their $Nb_2O_5$-II to be identical with *Brauer*'s M-$Nb_2O_5$ [2], but the d values they give for $Nb_2O_5$-II can be assigned neither to the M-form nor to any other form of niobium pentoxide [4]. The behavior of $Nb_2O_5$ under hydrothermal conditions should be investigated further (cf. also the hydrothermal production of N-$Nb_2O_5$).

### The oxI to oxVI Forms of $Nb_2O_5$ [18]

Closely similar $NbO_x$ phases separated by heterogeneous regions [38, 39] can be prepared by chemical transport under reducing conditions [26] and by the reduction of $Nb_2O_5$ (or the oxidation of $NbO_2$) in an $H_2/H_2O$ atmosphere, *e.g.* at 1300 °C [51]. Some of them have also been obtained by tempering oxide mixtures [52–54]. All these deep blue materials correspond to definite structures (Table 5) [35, 53–56]; there are two modifications of the compound $NbO_{2.417}$, corresponding to $Nb_{12}O_{29}$.

The oxidation of this material at 1100 °C in air leads to H-$Nb_2O_5$. A 4-hour oxidation at 650 °C, however, yields other colorless $Nb_2O_5$ preparations that we denote by oxI to oxVI. Their Guinier diagrams are related to those of the initial $NbO_x$ phases, but differ from one another and from that of H-$Nb_2O_5$ (Fig. 1). On subsequent ignition (1100 °C), all these preparations change into the H-form.

Table 5. The $Nb_2O_5$ forms oxI to oxVI [18] and their origin.

| Composition $NbO_x$ by chemical analysis | $NbO_{2.417}$ (I) [55a] | $NbO_{2.417}$ (II) [55a] | $NbO_{2.453}$ [55a] | $NbO_{2.46}$ [39] | $NbO_{2.467}$ to $_{2.480}$ [38, 39] | $NbO_{2.483}$ [39] |
|---|---|---|---|---|---|---|
| Formula corr. to structural analysis | $Nb_{12}O_{29}$ (I) [53, 55] | $Nb_{12}O_{29}$ (II) [53] | $Nb_{22}O_{54}$ [52, 55] | | $Nb_{25}O_{62}$ (upper limit of the phase) [54] | |
| Designation of the 650 °C oxidation product | oxI | oxII | oxIII | oxIV | oxV | oxVI |

The $Nb_2O_5$-forms oxI to oxVI are preparatively and X-radiographically defined. They are undoubtedly closely related. All (or some of them) might belong to the same mixed-crystal phase. Information on whether these materials are to be regarded as modifications in the sense of Section 2 can be given only by structural investigations.

### Other Forms of $Nb_2O_5$

The multiplicity of the forms of $Nb_2O_5$ is not exhausted by those described above. At any rate, we possess some preparations of $Nb_2O_5$ with a different X-ray pattern, which have not yet been investigated further [26, 57].

## 5. "Memory" of Solids

Niobium pentoxide provides a fine example of this term, introduced by *Hüttig*[58]: T-$Nb_2O_5$ can be prepared in three ways; the resulting samples are not distinguishable by X-rays:

a) By oxidation of $NbO_2$ (4-5 h in air) at 500 to 600 °C.
b) By reaction of $NbO_2$ with $Cl_2$; 9–10 h, 270 to 300 °C; [cf. the formation of TT-$Nb_2O_5$ according to Eq. (2)]. Further heating (15 min at 500 °C in air).

c) By heating "sulfate" or "chloride" niobic acid (2 h, 600 °C in air).

However, the preparations "remember" their different origins, and behave differently on further heating[41]: $Nb_2O_5$ (a) is converted into B-$Nb_2O_5$ sharply at 817 °C (differential thermals analysis)

$Nb_2O_5$ (b) changes into B-$Nb_2O_5$ so slowly that the conversion is not complete even after 165 hours at 850 °C.

$Nb_2O_5$ (c) is converted into the forms M-$Nb_2O_5$ + H-$Nb_2O_5$ after heating for 16 hours at 800 °C. Here, therefore, the B-form has been passed over.

The basis of the "memory" of the three $NbO_2$ preparations has not yet been investigated. The first interpretation that comes to mind is incorporation of impurities or the presence of specific structural defects.

## 6. Structures

The crystal structures of the various forms of $Nb_2O_5$ are complicated. Accurate investigations of even the long-known forms have been undertaken only recently.

Octahedral elements are the decisive factor for the structure of the pentoxides. The stoichiometric O/Nb ratio of 2.5 can be achieved by the combination of various octahedral linkages, and this is the reason for the multiplicity of the $Nb_2O_5$ structures.

The situation is even more complicated, as in addition to crystal structures with all metal ions coordinated in a similar manner (a), there are also those containing cations of different coordination (type b; *e.g.* octahedral and tetrahedral coordination occur together). Type (a) includes a structure in which all the cations are surrounded octahedrally by $O^{2-}$ particles. Under these conditions, in addition to a structure of similarly linked octahedra (*e.g.* the $ReO_3$ lattice), modifications are conceivable in which several types of $O^{2-}$ octahedra can be distinguished by the distinct natures of their linkage in the lattice. The various ways of linking the $O^{2-}$ octahedra are expressed formally by the extent to which the $O^{2-}$ ions belonging to an octahedron must be ascribed to the corresponding cation[59]. In this way, for example, the $O^{2-}$ octahedra from which a hypothetical $M_3O_8$ structure[60] could be constructed are divided into two types: (1) octahedra which are joined by corners to all surrounding octahedra, so that each $O^{2-}$ is to be reckoned as belonging to two octahedra. This type of linkage, which is present in $ReO_3$, is designated $[MO_{6/2}]$ or $MO_{3.0}$. In addition, (2) octahedra joined by three corners (3 $O^{2-}$) and two edges (3 $O^{2-}$; here with two other octahedra in each case), are necessary. They are symbolized by $[MO_{3/2}\,O_{3/3}]$ or $MO_{2.50}$ (cf. Fig. 6). $MO_{3.0} + 2\,MO_{2.50}$ give $M_3O_8$.

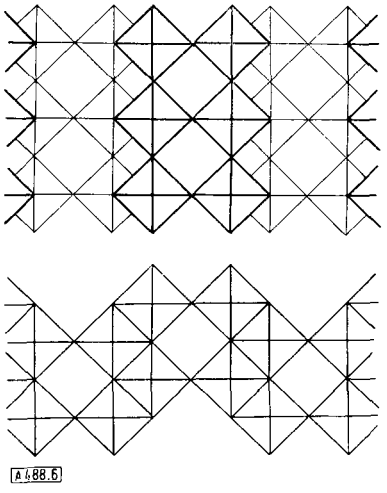

Fig. 6. A particularly simple $M_2O_5$ structure: $V_2O_5$ (highly idealized, after [56]).

Such a notation proves to be expedient for understanding structures in which the unit cell contains a multiplicity of $O^{2-}$ octahedra[40]. It can also be used correspondingly for a structure composed of different $O^{2-}$ coordination polyhedra (type b), particularly octahedra and tetrahedra. If a geometrically simple principle of construction from $O^{2-}$ coordination polyhedra, all possessing the same type of linkage, is required for $Nb_2O_5$, $5/2$ $O^{2-}$ must be assigned to each metal ion; this condition can be realized, for example, by a structure composed of $[MO_{3/2}\,O_{3/3}]$ octahedra. Such $MO_{2.5}$ octahedra exist with various types of linkage; one of these possibilities is observed in the case of B-$Nb_2O_5$. Here $O^{2-}$ octahedra form pairs through a common edge; the linkage *via* $O_{3/3}$ corresponds to that in the rutile lattice[8]; cf. Fig. 7b.

Another geometrically simple arrangement (two $Nb_2O_5$ per cell) is that in which $[MO_{3/2}\,O_{3/3}]$ octahedra are joined by two perpendicular edges with the neighboring octahedra in such a way that a zigzag chain of octahedra is produced. These chains arranged in paralle would be linked to one another by sharing corners. The resulting constructional principle corresponds to that of the highly idealized[56] structure of $V_2O_5$[62] (Fig. 6). A variation of this principle is found in the structure of P-$Nb_2O_5$[62a]. It is worth noting that the chains of octahedra mentioned, with O/Nb = 2.5, occur widely as an *additional* constructional element in several forms of $Nb_2O_5$ and related compounds ($Nb_{12}O_{29}$[53],

[58] *G. F. Hüttig, E. Zeidler,* and *E. Franz,* Z. anorg. allg. Chem. *231*, 104 (1937).

[59] This notation is not completely unambiguous but is adequate to characterize the types of linkage that occur frequently.

[60] This corresponds to the $Nb_3O_7F$ structure [61].

[61] *S. Andersson,* Acta chem. scand. *18*, 2339 (1964).

[62] *H. G. Bachmann, F. R. Ahmed,* and *W. H. Barnes,* Z. Kristallogr., Kristallgeometr., Kristallphysik, Kristallchem. *115*, 110 (1961).

[62a] *F. Laves* and *W. Petter,* 8th Discussion Meeting of the Sektion für Kristallkunde, Marburg 1965.

$Nb_{25}O_{62}$ [54,63]; $Nb_{31}O_{77}F$ [17], $Nb_{17}O_{42}F$ [17], $Nb_3O_7F$ [61], and $Nb_3O_7Cl$ [64]). In the majority of such cases (although the X/Nb ratio is close to 2.5) a structure in which "$MO_{2.5}$" octahedra predominate is avoided, and an arrangement is preferred in which these $MO_{2.5}$ octahedra are "diluted" to a considerable extent by $MO_3$ and $MO_{<2.5}$ octahedra. From another point of view, this means that "block structures" [35] occur. Within the blocks, $MO_3$ octahedra are joined in the manner of $ReO_3$ by corners, while the blocks are bound to one another by edge sharing of octahedra ($MO_{2.5}$ and $MO_{2.5}$) (cf. also Table 6).

The occurrence of different linkage regions can be regarded to a certain extent as "internal disproportionation" of the structural elements (octahedra), while an actual disproportionation into separated phases is excluded, since the Nb already possesses its maximum charge. If we pass to ternary systems with an X/M ratio of 2.5, there is an additional possibility of an actual disproportionation into phases with simpler structures.

The principle of the structure composed of octahedra with various O/Nb ratios (above, below, and equal to $MO_{2.5}$) makes it clear that the stoichiometric ratio O/M = 2.5 has no particular structural significance. Consequently, slightly different O/M values near 2.5 can be realized whenever the charge of the lattice units permits such deviations. Related to this is the fact that numerous phases differing from the stoichiometry O/Nb = 2.5 occur in the reduction of $Nb_2O_5$ [38,39,51–54] and that forms of $Nb_2O_5$ (H [35], N [65]) belong to "structure-related series" [35,56] whose members have different O/M values. Finally, the O/M ratio can also be varied by passing to ternary compounds rich in $Nb_2O_5$ [38,39,63,66]. In this way, a direct structural relationship is obtained between the forms of $Nb_2O_5$ and the related ternary oxides [35,56,63,67].

A discussion of the $Nb_2O_5$ structures from these idealized geometrical points of view provides information on the possible structure variants and on relationships between them, but permits not statements to be made about the thermodynamic stability of the existing arrangements. However, it should be mentioned that the absolute value of the enthalpy of formation of the $Nb_2O_5$ modifications decreases in the sequence B > T > H, while the molar volume increases in that sequence (cf. Section 7). Such a relationship has been observed frequently with other classes of compounds [68].

### B-$Nb_2O_5$

The crystal structure of this modification has been investigated by *Laves et al.* [8]. It belongs to space group B 2/b, and possesses the smallest molar volume (50.2 cm³) of all known forms of $Nb_2O_5$. The anionic lattice consists of a slightly deformed hexagonal close packing of $O^{2-}$; the hexagonal layers run parallel to $(2\bar{1}0)$, with an a-axis in (001). The octahedral cavities of this packing are two-fifths occupied by Nb. The monoclinic cell contains eight $[MO_{3/2}O_{3/3}]$ octahedra occupied by Nb, every two octahedra being linked through an edge to form a pair. Each of the two $O^{2-}$ belonging to a common edge are simultaneously corners of two more octahedra (Fig. 7b); the same type of linkage occurs in the rutile structure (Fig. 7a).

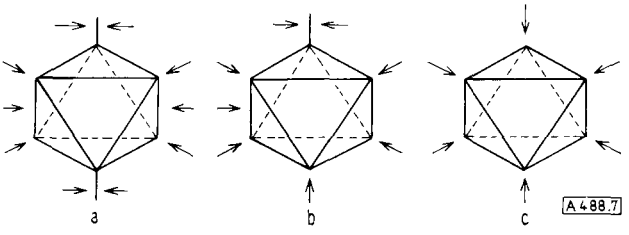

Fig. 7. Types of linkage of $O^{2-}$ octahedra, according to *F. Laves* [8]. a: Rutile $[MO_{6/3}]$. b: B—$Nb_2O_5$ $[MO_{3/3}O_{3/2}]$. c: $ReO_3$ $[MO_{6/2}]$.

Of the other four $O^{2-}$ of the octahedra under consideration, three are joined by corners (cf. $ReO_3$, Fig. 7c) to neighboring octahedra, while one belongs simultaneously to the common edge of another pair of octahedra. The pairs mentioned are arranged parallel to $(2\bar{1}0)$; they are mutually displaced by the width of an octahedron and engage with one another, forming in this way a common "sheet" parallel to (100) with a depth of about a/2 (Fig. 8). These sheets are bound to one another only by sharing corners ($O_{1/2}$). Edge linkages in which $O_{1/3}$ participate occur only within the sheets.

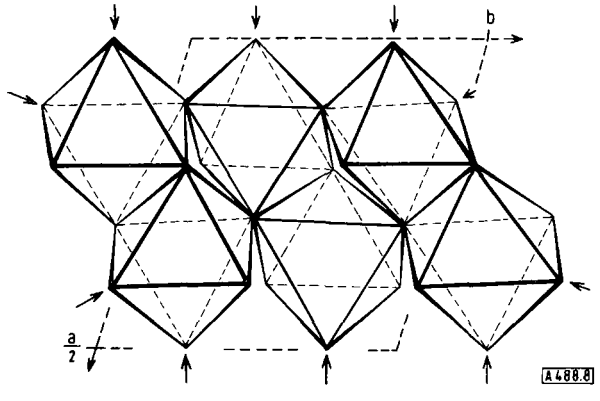

Fig. 8. Structure of B—$Nb_2O_5$. Schematic section of the skeleton of $O^{2-}$ octahedra. ↑ : corner linkage corresponding to $ReO_3$.

The numerous unoccupied octahedral sites present in the B-$Nb_2O_5$ structure obviously offer good possibilities for the incorporation of further metal cations, and this is probably responsible for the fact that B-$Nb_2O_5$ also incorporates additional Nb under extreme conditions, as follows from the blue color of the preparations (cf. Section 4).

### T-$Nb_2O_5$

The crystal structure of this modification, which has the smallest molar volume (about 53 cm³) apart from B-$Nb_2O_5$, is still unknown. Powder photographs by

the Guinier method show a great similarity to T-$Ta_2O_5$, which, however, in contrast to T-$Nb_2O_5$, occurs in several variants [40,69], and also a particular similarity to $Nb_5O_{12}F$ [70]. Other relationships exist with $U_3O_8$ and $\alpha$-$UO_3$. It is possible that the compounds mentioned have an almost hexagonal cationic lattice [71]. Single crystals of T-$Nb_2O_5$ have been prepared only recently, and are now being investigated [42].

The crystal structure of the "pseudohexagonal" [5] TT-$Nb_2O_5$ is perhaps closely related to the structure of T-$Nb_2O_5$. Since a continuous conversion into the T-form seems to occur when TT-$Nb_2O_5$ is heated, with some strong reflections being split and many very weak ones being added, the TT-form should probably be regarded as a less ordered precursor of the T-form [3,6].

### H–$Nb_2O_5$

The crystal structure of this relatively open monoclinic modification (molar volume 58.4 $cm^3$) has recently been determined by *Gatehouse* and *Wadsley* [35]. According to these authors, the structure of the H-form (space group P 2), which contains 28 Nb in the unit cell, is characterized by the occurrence of structural groups related to $ReO_3$. The idealized H-$Nb_2O_5$ structure contains two different structural elements which can be regarded as $ReO_3$-lattice sections of different sizes (and are therefore called "$ReO_3$ blocks"). Within each of these blocks, the corner linkage of the oxygen octahedra continues uninterrupted ($\infty$) in the direction of growth of the needle (b-axis [35]); in both directions perpendicular to b, the extension of the blocks is limited to a typical number of octahedra. The two types of blocks occurring can be formulated as $[3\times4\times\infty]$ and $[3\times5\times\infty]$ [35], the number of octahedra in each edge of a block being given. A section in the b-direction of the length of one octahedron diagonal is sufficient to describe the H-$Nb_2O_5$ structure (and all crystal structures built up correspondingly, cf. N-$Nb_2O_5$) while the characteristics of the structure are represented by a picture of the extension of the blocks in the (010) plane (Fig. 9). It can be seen that the $[3\times5\times\infty]$ blocks are displaced with respect to one another and are bound through the narrow sides into "obliquely running chains" of blocks. The spaces between each two of these parallel series of blocks are filled with $[3\times4\times\infty]$ blocks, the position of which is shifted by b/2 as compared with the $[3\times5\times\infty]$ blocks. This block skeleton, with 27 octahedrally surrounded niobium cations per cell, contains an additional 4/4 Nb in tetrahedral cavities, half of these cavities being occupied by Nb. Here Nb occurs both in octahedral and in tetrahedral coordination.

The shear planes [72] envisaged between the $ReO_3$ blocks are therefore characterized by the fact that here

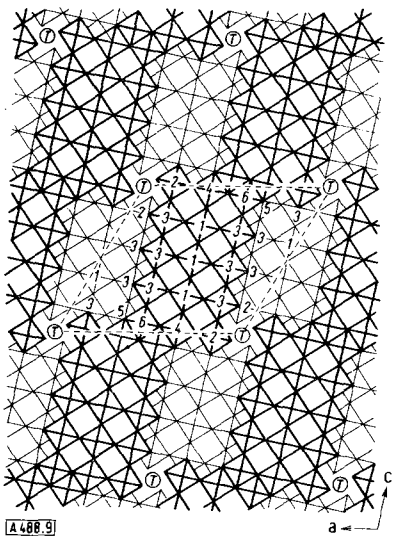

Fig. 9. Structure of H–$Nb_2O_5$, idealized [35]. For the numering of the octahedra, see Table 6. The unit cell is indicated by the broken lines.

the oxygen octahedra of adjacent blocks are bound to one another by sharing edges. At these positions, some of the octahedra possess a formal O/M ratio of less than 2.5, so that the stoichiometry $M_2O_5$ arises from the combination of a total of six types of octahedra differing in their O/M ratio (Table 6).

Table 6. Structure of H–$Nb_2O_5$.

| Linkage symbol | O/Nb | Octahedra per cell | Contribution to the cell content | No. in Fig. 9 |
|---|---|---|---|---|
| $[NbO_{6/2}]$ | 3.00 | 5 | $Nb_5O_{15}$ | 1 |

### M–$Nb_2O_5$

The crystal structure of this form is still unknown. The close relationship of the powder diagrams of the M- and H-forms, which agree in a large number of reflections, permits the assumption of a considerable similarity between the two crystal structures. Since, on heating, the M-form apparently changes continuously into the H-form, the diffuse reflections characteristic for M-$Nb_2O_5$ gradually disappearing, the M-form should perhaps be regarded as a less ordered precursor of the H-form. This is supported by the observation that single

[71] *A. F. Wells*: Structural Inorganic Chemistry. Oxford University Press, Oxford 1962.

[72] *A. D. Wadsley,* Proc. Roy. Soc. New South Wales *92*, 25 (1958), cf. [66b].

[73] Since in the calculation (Table 6), all $O^{2-}$ were formally reckoned in the octahedron skeleton (a), one type of $O^{2-}$ was considered as belonging only to the octahedron ($O_{1/1}$) although this $O^{2-}$ simultaneously forms a corner of the neighboring Nb-occupied tetrahedron and therefore would also be counted partially with this Nb. The simplified distribution used here makes it possible to introduce the Nb contained in tetrahedral cavities in the calculation without reference to its environment (b).

crystals of M-$Nb_2O_5$ change into single crystals of H-$Nb_2O_5$ on heating [44]. X-Ray investigations with single crystals are in progress [28].

A structure in which the arrangement of H-$Nb_2O_5$ already exists in two dimensions while there is defective order in the third has been considered by *Holtzberg et al.* [6].

### N—$Nb_2O_5$

The crystal structure of this form has been investigated by *S. Andersson* [74]. According to this work, the structure of the monoclinic N-form can be related to the $ReO_3$ lattice in a similar manner to that of the H-form. The N-structure contains only *one* type of $ReO_3$ block: $[4\times4\times\infty]$; these (like the $[3\times5\times\infty]$ blocks of the H-form) are displaced with respect to one another and are linked to form obliquely running chains of blocks (Fig. 10). The positions of neighboring chains of blocks

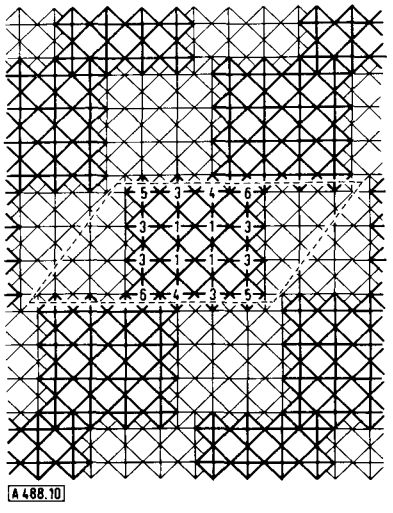

Fig. 10. Structure of N—$Nb_2O_5$. Shown in an idealized manner according to *S. Andersson* [74].

differ in the direction perpendicular to the plane of the figure by half an octahedron diagonal, so that edge sharing can occur at each surface of contact between two blocks. Here the stoichiometry is derived by combination of five types of octahedra differing in their formal O/M ratio (numbers 1, 3, 4, 5, and 6 in Fig. 10; cf. Table 6).

[74] These data were kindly made available by Dr. *S. Andersson* [65].

The lattice of N-$Nb_2O_5$ is closely related to the crystal structures of the compounds $TiNb_2O_7$ [66a], $Ti_2Nb_{10}O_{29}$ (I) (monoclinic) [66b], and $Nb_{12}O_{29}$ (I) (monoclinic) [53,55] and, like these, contains no tetrahedrally coordinated Nb cations.

### P—$Nb_2O_5$

The structure of this form has been investigated by *Laves et al.* [8,62a]. The P-structure contains zigzag chains of $MO_{2.5}$ octahedra like the idealized $V_2O_5$-structure, the zigzag chains being parallel and forming sheets. The chains of neighboring sheets, however, in contrast to idealized $V_2O_5$, are perpendicular to one another. The lattice constants for the tetragonal P-form (from Guinier photographs) [42] are: a = 3.90 Å; c = 25.5 Å; $D_{x\text{-ray}} = 4.54$ g/cm³ (cell content z = 4 $Nb_2O_5$); molar volume: 58.5 cm³.

## 7. Thermal and Thermochemical Behavior

Fig. 11 shows the thermal transformations observed so far [76]. The influence of the history of the preparations can be clearly observed. All the conversions mentioned in the figure take place monotropically, and the transition temperatures are therefore due to kinetics.

Consequently, the time of heating is of great importance as follows, for example, from Fig. 12. On the basis of differential thermal analyses, the signs of the heats of transformation are as follows:

amorphous → T, exothermic [6, 75, 77, 78]
T → B, exothermic [75]
T → H, endothermic [75]
B → H, endothermic [75]
P → H, endothermic [75]

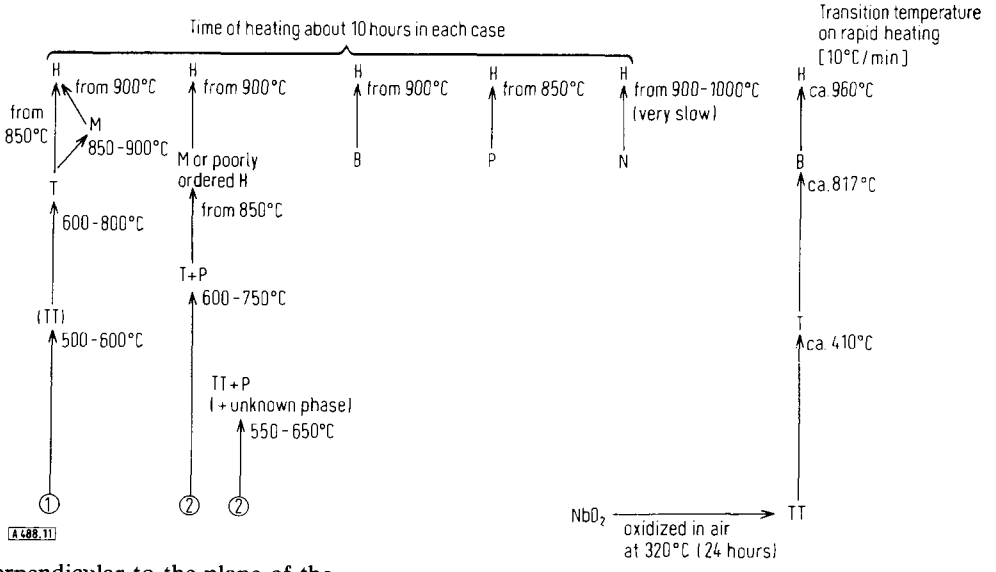

Fig. 11. Conversions of the forms of $Nb_2O_5$ on heating in air [75]. ① = amorphous "chloride niobic acid" or "sulfate niobic acid", thoroughly washed. ② = amorphous "chloride niobic acid" with a high content of HCl.

[75] Unpublished observations in these laboratories.

[76] The H → I-high transformation described by *Shafer* and *Roy* [3], upon which doubt has been cast by *Reisman* and *Holtzberg* [4], is not included.

[77] *J. Böhm*, Z. anorg. allg. Chem. *149*, 217 (1925).

Fig. 13 shows an example of a typical thermogram. The enthalpies of transformation are of the order of one to a few kcal/mole [78].

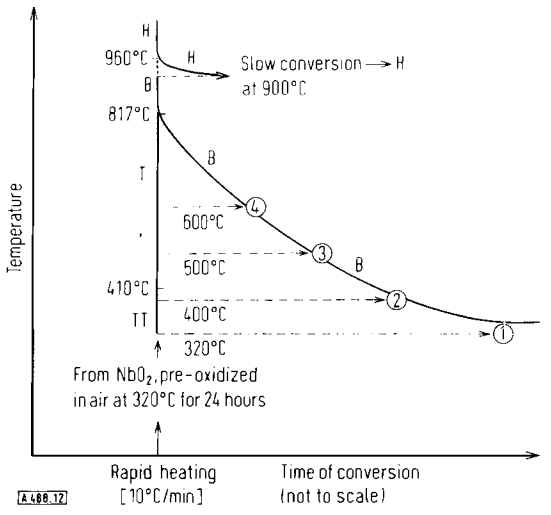

Fig. 12. Influence of time on the conversion of the $Nb_2O_5$ forms TT → T → B [75]. Initial preparation: $NbO_2$ oxidized in air at 320 °C; ① = no conversion into B—$Nb_2O_5$ in 46 days; ② = predominantly B—$Nb_2O_5$ after 14 days; ③ = predominantly B—$Nb_2O_5$ after 90 hours, pure B—$Nb_2O_5$ after 180 hours; ④ = predominantly B—$Nb_2O_5$ after 2 hours.

No indications have so far been found of thermal effects in the TT → T and M → H transformations.

It is significant for thermodynamic stability that on isothermal heating [750 °C, $P(NbOCl_3)$ = 5 atm and $P(Cl_2)$ = 3.5 atm] tablets of mixtures of the P- and B-forms, or of the T- and B-forms, are converted into the pure B-form [26,45]. In contrast to transport in a temperature gradient, no new formation of nuclei was necessary in this case. It is also important that mixtures of the B- and H-forms are converted into the B-form on isothermal heating [650 °C, $P(NbOCl_3)$ = 5 atm and $P(Cl_2)$ = 3.1 atm] [26]. The reversibility of the B → H transformation was first observed in this way.

The thermodynamic data given in the literature ($\Delta H°$ [79]; $S°$ [80]; $C_p°$ [81]) refer to the H-form.

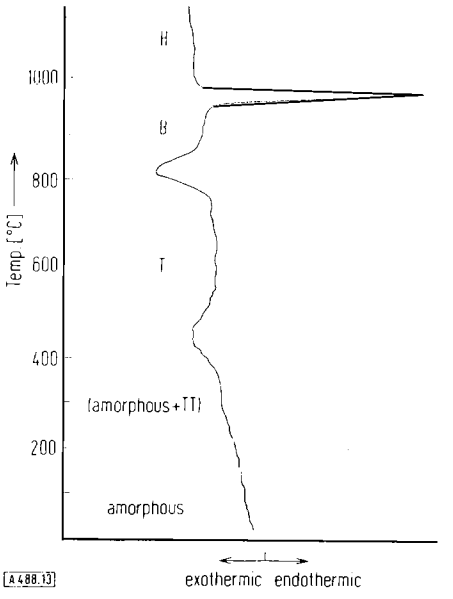

Fig. 13. Differential thermal analysis of the conversions of the $Nb_2O_5$ forms amorphous → T → B → H. Rate of heating: 10 °C/min. Starting material: $Nb_2O_5$ from $NbO_2$ oxidized in air at 320 °C for a short time.

The observations so far available support the assumption that of all the forms, B-$Nb_2O_5$ has the highest absolute value of the enthalpy of formation. Consequently, B-$Nb_2O_5$ is thermodynamically stable at low temperatures. As described, the conversion B → H could be observed at 750 °C, while the reverse conversion is realized at 650 °C. If the mean (700 °C) is taken to be the equilibrium temperature, and if in addition an enthalpy of transformation of 2 kcal/mole is assumed [41], we obtain for the B → H transformation an entropy increase of 2 cal. The increase in entropy can be understood on the basis of the structure.

*This paper contains many previously unpublished observations from our group, for which we thank particularly D. Bergner, C. Brendel, M. Cibis, M. Frorath, D. Giegling, M. Görbing, W. Jagusch, W. Mertin, K. Rinke, and M. Rönspiess. We thank Doz. H. G. von Schnering for many discussions. Finally, we are obliged to the Deutsche Forschungsgemeinschaft and the Verband der Chemischen Industrie – Fonds der chemischen Industrie – for their continuous support.*

# Compounds of Phosphorus with Silicon and Aluminum

BY PROF. DR. G. FRITZ

INSTITUT FÜR ANORGANISCHE CHEMIE
DER TECHNISCHEN HOCHSCHULE KARLSRUHE (GERMANY)

BASED ON INVESTIGATIONS CARRIED OUT WITH DIPL.-CHEM. G. BECKER, DR. G. POPPENBURG, DR. M. ROCHOLL, AND DR. G. TRENCZECK

*Dedicated to Prof. W. Klemm on the occasion of his 70th birthday*

*The formation and properties of silicon-phosphorus and aluminum-phosphorus compounds are described. Silylphosphines are decomposed solvolytically by $H_2O$, $C_2H_5OH$, $NH_3$, hydrogen halides, $C_2H_5I$, and boron halides at the Si–P bond; decomposition may be preceded by formation of an addition compound. Extensive side reactions during the reaction of halogenosilanes with $LiPEt_2$ [1] (formation of $Et_2P–PEt_2$, $HPEt_2$, Si-rich residues) are due to an excess of $LiPEt_2$ in the reaction mixture. The reaction of $LiPEt_2$ with $AlCl_3$, $AlHCl_2$, and $AlH_2Cl$ leads to definite aluminum-phosphorus compounds if only one $PEt_2$ group is present per Al atom, e.g. in $(Cl_2Al–PEt_2)_3$ and $(H_2Al–PEt_2)_3$, or if salts such as $Li[Al(PEt_2)_4]$ and $Li[AlH_2(PEt_2)_2]$ can be formed with an excess of $LiPEt_2$.*

## A. Silylphosphines

The first hydrides containing an Si–P bond were prepared in 1953 by two groups of workers. While *Aylett, Emeléus*, and *Maddock* [2] found the compounds $SiH_3PI_2$, $(SiH_3)_2PI$, and $(SiH_3)_3P$ by the action of $SiH_3I$ on white phosphorus, *G. Fritz* [3] obtained $SiH_3PH_2$ by the reaction of $SiH_4$ with $PH_3$.

$SiH_4$ decomposes at about 400 °C *via* intermediate products into hydrogen and silicon, whereas appreciable thermal decomposition of $PH_3$ takes place only above 550 °C. Equation (1) shows the first step in the decomposition of $SiH_4$ [4].

$$SiH_4 \rightarrow \dot{S}iH_3 + \dot{H} \qquad (1)$$

The following free-radical reactions must be assumed in connection with Equation (1) for the pyrochemical formation of $SiH_3PH_2$ (450 °C, gas phase, reduced pressure)

$$\dot{H} + PH_3 \rightarrow \dot{P}H_2 + H_2 \qquad (2)$$

$$\dot{S}iH_3 + \dot{P}H_2 \rightarrow SiH_3PH_2 \qquad (3)$$

$SiH_3PH_2$ (b.p. 12.7 °C) can be distilled off from less volatile silicon-phosphorus compounds such as $SiH_2(PH_2)_2$ [5]. A blue-black substance of composition $Si_2P$ and amorphous to X-rays, which decomposes at about 600 °C into Si and SiP [6], remains behind. $Si_3PH_2$ is also formed by an electric discharge in mixtures of gaseous $SiH_4$ and $PH_3$, as shown by mass-spectrometric investigation of the products [7]. An electric discharge in mixtures of $SiH_3PH_2$ and $SiH_4$ or of $Si_2H_6$ and $PH_3$ gives $(SiH_3)_2PH$ [8], $Si_2H_5PH_2$, and other products.

### 1. Reactions of Silylphosphine, $SiH_3PH_2$

$SiH_3PH_2$ ignites spontaneously in air [9]. In alkaline solution, the compound is hydrolysed quantitatively in accordance with Equation (4).

$$SiH_3PH_2 + 4\,H_2O \xrightarrow{HO^-} \{Si(OH)_4\} + 3\,H_2 + PH_3 \qquad (4)$$

In an acidic medium the hydrolysis is substantially more complicated. With dilute hydrochloric acid, evolution of $H_2$, $PH_3$, and $SiH_4$ (traces) sets in even below 0 °C, solid silicon oxyhydrides [*] being formed. All of the phosphorus of the $SiH_3PH_2$ is evolved as $PH_3$. Treatment of these decomposition products with alkali liberates the same amount of hydrogen as the alkaline hydrolysis of the $SiH_3PH_2$, namely three moles per mole of $Si_3PH_2$. Consequently, in acid hydrolysis cleavage of the $Si_3PH_2$ molecule begins at the Si–P bond:

$$SiH_3PH_2 + H_2O \xrightarrow{H^+} H_3SiOH + PH_3 \qquad (5)$$

[1] The following abbreviations are used in this paper: Et = $C_2H_5$; Me = $CH_3$; M = alkali metal.

[*] Silicon oxyhydrides are high-molecular weight silicon compounds of uncertain composition, containing SiH, SiO, and SiOH groups.

followed with rising temperature by the decomposition of the silanol according to:

$$n\ H_3SiOH \rightarrow H_2 + \text{silicon oxyhydrides} + \text{traces of } SiH_4 \quad (6)$$

On solvolysis with $C_2H_5OH$, it is possible by working at two temperatures to cause the evolution of $PH_3$ and the formation of $H_2$ from the SiH groups to take place successively [9]. Cleavage of the Si–P bond with $C_2H_5OH$ (anhydrous, saturated with gaseous HCl), in which 1 mole of $PH_3$ is formed according to Equation (7), begins at temperatures as low as about −80 °C.

$$SiH_3PH_2 + EtOH \rightarrow H_3SiOEt + PH_3 \quad (7)$$

If the alcoholic solution is now allowed to warm up slowly to room temperature, evolution of $H_2$ sets in, at first slowly and then more vigorously, according to Equation (8).

$$n\ H_3SiOEt \rightarrow H_2 + \text{traces of } SiH_4 + \text{SiH-containing esters of polysilicic acid} \quad (8)$$

When the reactions (5) and (7) are carried out in the presence of dissolved HCl, $H_3SiCl$ could be formed first, which would then react with $H_2O$ or $C_2H_5OH$ to give $H_3SiOH$ or $H_3SiOC_2H_5$, respectively.

In liquid ammonia the Si–P bond of the $SiH_3PH_2$ is split primarily in accordance with Equation (9).

$$SiH_3PH_2 + NH_3 \rightarrow SiH_3NH_2 + PH_3 \quad (9)$$

The $SiH_3NH_2$ produced gives rise to subsequent reactions leading to high-molecular SiH-containing silicon-nitrogen compounds and $H_2$. $SiH_3PH_2$ reacts with HBr at temperatures as low as about −80 °C:

$$SiH_3PH_2 + HBr \rightarrow H_3SiBr + PH_3 \quad (10)$$

## 2. Syntheses of Organo-Substituted Silylphosphines

The pyrochemical reaction of $SiH_4$ with $PH_3$ yields $SiH_3PH_2$ and some other compounds of this type which have not been investigated; however, the preparation of relatively large amounts in this way is very laborious. We therefore attempted to make polar Si and P compounds react with one another [Eq. (11)] in order to facilitate formation of the Si–P bond by the formation of the salt MX.

$$\equiv SiX + MP= \rightarrow \equiv Si-P= + MX \quad (11)$$

(X = Cl, Br, I; M = alkali metal)

The reaction of $LiPH_2$ with $H_3SiBr$, $H_3SiI$, or $SiH_2I_2$ (in diethyl ether) has so far not led to the desired silylphosphines. Instead, sublimable products of as yet unknown composition are formed. Similar results were obtained [10] in the reaction of $H_3SiI$ with the ether-soluble $LiPEt_2$. *Amberger* and *Boeters* [11] obtained $(SiH_3)_3P$ from $KPH_2$ and $H_3SiBr$ at a low temperature, but the formation of this compound indicates a series of parallel and/or subsequent reactions. In order to reduce the likelihood of side reactions, compounds were used which have no or only a few SiH groups, and in which the other valences of the silicon and phosphorus atoms are substantially blocked by unreactive groups (alkyl groups). The simplest reaction is that of $Me_3SiCl$ with $LiPEt_2$, which gives $Me_3Si–PEt_2$ [12] and $Et_2P–PEt_2$ simultaneously.

Some silylphosphines have been prepared by the reaction of $LiPEt_2$ with methylchlorosilanes and $SiCl_4$. These preparations are always accompanied by side reactions. Thus large amounts of diethylphosphine were produced in reactions which were intended to give SiH-containing substituted silylphosphines, and in reactions with SiH-free chlorosilanes – $SiCl_4$ and $Me_3SiCl$ – tetraethyldiphosphine and silicon-rich residues were formed. The yields of the desired products were correspondingly low [10, 13]. The initial assumption that silylphosphines are transformed into these by-products at higher temperatures can be dismissed, since $MeHSi–PEt_2$ undergoes no change on heating to 80 °C (with the exclusion of air and moisture) [14].

In the reaction of chlorosilanes with $LiPEt_2$, it was observed that the side reactions leading to $HPEt_2$ and $Et_2P–PEt_2$ occur to a smaller extent or not at all when an excess of the halogenosilane is maintained in the mixture during the whole reaction. Side reactions are always favored when the chlorosilane is added in drops to the $LiPEt_2$ solution. In this case, moreover, a red color of the solution is generally observed, which is absent in the presence of an excess of the chlorosilane (addition of $LiPEt_2$ solution in drops to the chlorosilane) [14]. Under these conditions, it was possible to obtain $Me_2HSi–PEt_2$ (b.p. 58.5 °C/25 mm Hg) in accordance with Equation (12).

$$Me_2HSiCl + LiPEt_2 \rightarrow Me_2HSi–PEt_2 + LiCl \quad (12)$$

This compound reacts further with an ethereal solution of $LiPEt_2$ [Equation (13)], as NMR investigations and the isolation of the product have shown.

$$Me_2HSi–PEt_2 + LiPEt_2 \rightarrow Me_2Si(PEt_2)_2 + LiH \quad (13)$$

$Me_2Si(PEt_2)_2$ (b.p. 83 °C/3 mm Hg) is also formed from $Me_2SiCl_2$ and $LiPEt_2$.

With an excess of $H_3SiBr$, $LiPEt_2$ reacts primarily as follows:

$$H_3SiBr + LiPEt_2 \rightarrow H_3Si–PEt_2 + LiBr \quad (14)$$

In spite of the excess of $H_3SiBr$ the compounds $H_2Si(PEt_2)_2$ and $HSi(PEt_2)_3$ arise as by-products [Equations (15) and (16)] as shown by proton resonance investigations [15].

$$H_3Si–PEt_2 + LiPEt_2 \rightarrow H_2Si(PEt_2)_2 + LiH \quad (15)$$

$$H_2Si(PEt_2)_2 + LiPEt_2 \rightarrow HSi(PEt_2)_3 + LiH \quad (16)$$

Subsequently the LiH gives LiBr and $SiH_4$ with the excess of $H_3SiBr$.

$HSiCl_3$ reacts with $LiPEt_2$ with the formation of SiH-containing silylphosphines only if the trichlorosilane is

[15] *G. Fritz, G. Becker*, and *D. Kummer*, unpublished work.

permanently in excess[14]. However, even from such mixtures it is impossible to isolate pure $HSi(PEt_2)_3$, since chlorine-containing silylphosphines are formed simultaneously. Thus $ClHSi(PEt_2)_2$ is formed in addition to $HSi(PEt_2)_3$, but rearranges in accordance with Equation (17), as seen from NMR investigations[15].

$$2\ ClHSi(PEt_2)_2 \rightarrow Cl_2Si(PEt_2)_2 + H_2Si(PEt_2)_2 \quad (17)$$

The reaction of $HSiCl_3$ with $LiPEt_2$ (molar ratio 1:3) at room temperature, or more rapidly on slow heating to 100 °C, leads to a red-brown solution from which diethylphosphine and a red-brown solid of unknown constitution can be isolated.

The compounds obtained are summarized in Table 1. The investigations described give the following picture:

Table 1. Silylphosphines formed by the reaction of $LiPEt_2$ or $LiPMe_2$ with silicon halides. Me = $CH_3$, Et = $C_2H_5$.

| Silicon halide | Silylphosphine | B.p. (°C/mm Hg) | Ref. |
|---|---|---|---|
| $Me_3SiCl$ | $Me_3Si-PEt_2$ | 71–72/20 | [12] |
| $Me_2SiCl_2$ | $Me_2ClSi-PEt_2$ | 53–54/5 | [12] |
| $Me_2HSiCl$ | $Me_2HSi-PEt_2$ | 58,5/25 | [14] |
| $Me_2SiCl_2$ | $Me_2Si(PEt_2)_2$ | 83/3 | [12] |
| $Me_2HSiCl$ | $Me_2Si(PEt_2)_2$ | 83/3 | [14] |
| $SiCl_4$ | $Cl_3Si-PMe_2$ | 50/25 | [12] |
| $SiCl_4$ | $Cl_2Si(PMe_2)_2$ | 47/5 | [12] |
| $SiHCl_3$ | $Cl_2Si(PEt_2)_2$ | | [14] |
| $SiCl_4$ | $ClSi(PMe_2)_3$ | 120/>1 | [12] |
| $SiCl_4$ | $ClSi(PEt_2)_3$ | 138/142/>1 | [10] |
| $SiCl_4$ | $Si(PEt_2)_4$ | 160/1 | [13] |
| $C_6H_5SiH_2Cl$ | $C_6H_5SiH_2-PEt_2$ | 60–61/>1 | [10] |
| $H_3SiBr$ | $H_3Si-PEt_2$ | 53.5/79 | [14] |
| $H_3SiBr$ | $H_2Si(PEt_2)_2$ | *ca.* 110/13 | [14] |
| $SiHCl_3$ | $H_2Si(PEt_2)_2$ | *ca.* 110/13 | [14] |
| $H_3SiBr$ | $HSi(PEt_2)_3$ | | [14] |
| $SiHCl_3$ | $HSi(PEt_2)_3$ | | [14] |
| $SiHCl_3$ | $ClHSi(PEt_2)_2$ | | [14] |

Alkyl-substituted and SiH-containing silylphosphines such as $Me_2HSi-PEt_2$ and $H_3Si-PEt_2$ are stable when atmospheric moisture is excluded, and do not decompose on heating into $HPEt_2$ and compounds of higher molecular weight with Si–Si bonds.

Tetraethyldiphosphine and diethylphosphine are formed in relatively large amounts in the reaction of halogenosilanes with $LiPEt_2$ only if an excess of $LiPEt_2$ is present in the reaction mixture. If, on the other hand, an excess of halogenosilane is maintained, this side reaction is suppressed.

SiH-containing silylphosphines, such as $Me_2HSi-PEt_2$, react further with $LiPEt_2$, the SiH group being converted into an $Si-PEt_2$ group. Even fully alkylated silylphosphines react slowly with $LiPEt_2$.

The side reactions probably can be explained by a first reaction step involving a metal-halogen or metal-hydrogen exchange between silylphosphines containing SiCl or SiH groups [Equations (18) and (19)]; the starting materials and products then react further according to Equations (20) and (21) (in the reaction of $(R_2P)_3SiCl$).

$$(R_2P)_3SiCl + LiPR_2 \rightarrow (R_2P)_3SiLi + ClPR_2 \quad (18)$$

$$(R_2P)_3SiH + LiPR_2 \rightarrow (R_2P)_3SiLi + HPR_2 \quad (19)$$

$$LiPR_2 + ClPR_2 \rightarrow LiCl + R_2P-PR_2 \quad (20)$$

$$(R_2P)_3SiCl + LiSi(PR_2)_3 \rightarrow LiCl + (R_2P)_3Si-Si(PR_2)_3 \quad (21)$$

In addition, a secondary reaction of $LiPR_2$ with the Si–P bond must be considered. Final proof of the reactions represented by Equations (18)–(21) has not yet been obtained.

The reaction of alkali-metal phosphides with silicon halides gives compounds which contain several $SiR_3$ groups on the same phosphorus atom. Thus the reaction of $Me_3SiF$ and $KPH_2$ at low temperatures leads to $(Me_3Si)_2PH$ and $(Me_3Si)_3P$[16]. The same products are formed, together with $Me_3SiPH_2$, in the reaction of a mixture of $LiPH_2$, $Li_2PH$, and $Li_3P$ with $Me_3SiCl$[17,18]. A mixture of $Li_2PH$ and $Li_3P$ reacts with $Et_2SiCl_2$ with the formation of cyclic compounds for which *Parshall* and *Lindsey*[17] propose formulae *(1)* and *(2)*.

*(1)*  *(2)* 
$Me_3Si-P(C_6H_5)_2$ has been obtained by cleavage of tetraphenyldiphosphine with sodium and the subsequent reaction of the $(C_6H_5)_2PNa$ formed with $Me_3SiCl$[19].

Compounds of the type of $Et_3Si-PO(OEt)_2$ and $(EtO)_3Si-PO(OEt)_2$ have been obtained, with other products, from the reaction of $Et_3SiBr$ and $(EtO)_3SiCl$, respectively, with $P(OEt)_3$ or $[(EtO)_2PO]Na$[20–22].

### 3. Reactions of Organo-Substituted Silylphosphines

In distinction to $SiH_3PH_2$, organo-substituted silylphosphines have only one reactive position in the molecule: the Si–P bond. Thus $Me_3Si-PEt_2$ is hydrolysed quantitatively[23] in accordance with Equation (22).

$$Me_3Si-PEt_2 + H_2O \rightarrow Me_3SiOH + HPEt_2 \quad (22)$$

With an excess of EtI or EtBr (or with HI), $Me_3Si-PEt_2$ is split according to Equation (23).

$$Me_3Si-PEt_2 + 2\ EtX \rightarrow Me_3SiX + [Et_4P]X \quad (23)$$
$$X = I, Br$$

In the reaction of equivalent amounts at −78 °C, the stable addition product $Me_3Si-PEt_2 \cdot EtI$ (m.p. 122 °C) is formed, and with the equivalent amount of HI the colorless, crystalline $Me_3Si-PEt_2 \cdot HI$, which is stable

only at −78 °C [24]. The adduct with ethyl iodide reacts further with an excess of ethyl iodide, giving the products of Equation (23).

Investigations of *Nöth* and *Schrägle* [25] have also shown the existence of addition compounds of $Me_3Si-PEt_2$ with $(BH_3)_2$, $BF_3$, $BCl_3$, and $BBr_3$. These addition compounds – $Me_3Si-PEt_2{\cdot}BH_3$ (m.p. 12 °C), $Me_3Si-PEt_2{\cdot}BF_3$ (decomposition at room temperature), $Me_3Si-PEt_2{\cdot}BCl_3$ (stable for short periods at room temperature), and $Me_3Si-PEt_2{\cdot}BBr_3$ (m.p. ≈ 5 °C) – decompose as follows:

$$3\ Me_3Si-PEt_2{\cdot}BH_3 \rightarrow 3\ Me_3SiH + (Et_2P-BH_2)_3 \quad (24)$$

$$Me_3Si-PEt_2{\cdot}BF_3 \rightarrow Me_3SiF + Et_2P-BF_2 \quad (25)$$

$$2\ Me_3Si-PEt_2{\cdot}BX_3 \rightarrow Me_3SiX + (Et_2P-BX_2)_2 \quad (26)$$

(X = Cl, Br).

Cleavage in accordance with Equation (24) sets in only above 80 °C, while with the chlorine and bromine compounds it begins already at room temperature. Silylphosphines containing SiCl and SiH groups, such as $Cl_3Si-PEt_2$ or $H_3Si-PEt_2$, are more sensitive to oxidation and hydrolysis than the completely alkylated compounds. The influence of the substituents on the Si–P bond cannot yet be reviewed.

## B. Aluminum-Phosphorus Compounds

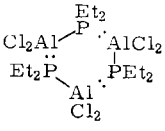
Whereas substitution predominates in reactions between compounds of elements of groups IV and V of the periodic systems, with compounds of elements of groups III and V the formation of adducts is preferred because of their electronic structure. Interesting compounds can sometimes be formed from the adducts by elimination of atoms or groups. The best known example is borazole, which is formed from the adduct $H_3B{\cdot}NH_3$ by the elimination of $H_2$.

The thermal treatment of addition compounds derived from aluminum and phosphorus compounds, however, leads only in a few cases to definite compounds, and is much less productive preparatively than the corresponding treatment of adducts of the compounds of boron and nitrogen. *Davidson* and *Brown* [26] obtained $(Me_2Al-PMe_2)_3$ from $Me_3Al$: $PHMe_2$ [*] by elimination of $CH_4$ at 215 °C. *Burg* and *Mödritzer* [27] obtained aluminum-phosphorus compounds by heating mixtures of aluminum-hydrogen compounds and $HPMe_2$. In the reaction of $ClPMe_2$ with $LiAlH_4$ in liquid $HPMe_2$, they obtained a solid of composition $Me_2PAlH_2$: $PHMe_2$, which could not be separated from the lithium chloride formed at the same time. In the treatment of $HPMe_2$ with $LiAlH_4$ (three weeks, 50 °C), these authors observed the formation of $LiAlH_{0.95}(PMe_2)_{2.93}$ with evolution of $H_2$. Similarly, with $HPMe_2$ they obtained substances of the composition $(Me_2P)_2AlCl$ and $Me_2PAlCl_2$ from $H_2AlCl$ and $HAlCl_2$, respectively (two weeks, 60 °C). A substance $LiAl(PH_2)_4$, formed from $LiAlH_4$ and $PH_3$ on prolonged heating, has also been reported [28].

These investigations show that the formation of definite aluminum-phosphorus compounds by thermal decomposition of the adducts is very complicated, and unsatisfactory from the preparative point of view. Consequently, attempts have been made to convert polar compounds of the two elements (aluminum halides and alkali-metal phosphides) into substances containing the Al–P bond, since the formation of LiCl favors this route. $LiPEt_2$ and $AlCl_3$ (molar ratio 1:1) react quantitatively in ether according to

$$LiPEt_2 + AlCl_3 \rightarrow LiCl + Cl_2Al-PEt_2 \quad (27)$$

After the bulk of the LiCl has precipitated, a clear ethereal solution is obtained, which separates into two layers when most of the ether is distilled off. White crystals of composition $Cl_2Al-PEt_2$ separate from the lower layer on cooling, and these do not redissolve in an excess of hot ether [29]. As is evident from the change in solubility, the substance is no longer monomeric. According to cryoscopic molecular weight determinations in $POCl_3$, $(Cl_2Al-PEt_2)_3$ *(3)* is present.



*(3)*

The trimerization is understandable because it leads to a six-membered ring in which the electron pair of the phosphorus atoms occupy the octet vacancies of the aluminum atoms. The solution of *(3)* in $POCl_3$ is stable for only a short time, as can be seen both from the yellow coloration and from the change in the freezing point depression with time. The decomposition takes the course (28).

$$(Cl_2Al-PEt_2)_3 + 3\ POCl_3 \rightarrow 3\ Et_2P-AlCl_2{:}OPCl_3 \quad (28)$$
*(3)*

The breakdown of the cyclic compound *(3)* is to be expected when a reactant with a lone electron pair displaces the phosphorus from its coordination position with respect to the aluminum. $POCl_3$ evidently is such a reagent. The reaction of 1 mole of $AlCl_3$ with 3 moles of $LiPEt_2$ in ether is also quantitative. Highly viscous products are formed, which contain aluminum and phosphorus in the expected ratio of 1:3 but which can hardly be regarded as compounds of definite molecular weight [30,31]. These products contain $[Al(PEt_2)_3]_n$ units with $n > 3$, and probably also the ether adduct $(Et_2P)_3Al{:}OEt_2$.

$[Al(PEt_2)_3]_n$ is also obtained by the reaction of crystalline $(Cl_2Al-PEt_2)_3$ *(3)* with 6 moles of $LiPEt_2$, a reaction in which one had hoped to obtain $[Al(PEt_2)_3]_3$. It must be assumed that the appearance of oligomers

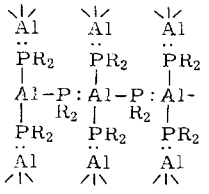
with $n > 3$ is based on the same principle as the formation of $[Cl_2Al{-}PEt_2]_3$ *(3)*. However, when several $PR_2$ groups are attached to the aluminum, these can form cross-links, as shown in Scheme 1.



Scheme 1.

The reaction of $HAlCl_2$ with 2 moles of $LiPEt_2$ also gives a highly viscous product of indefinite molecular size.

Aluminum-phosphorus compounds of definite molecular weight are formed when cross-linking is suppressed by limiting the number of coordinating groups on the Al atom to one [31]. Thus the reaction

$$3\ H_2AlCl + 3\ LiPEt_2 \rightarrow (H_2Al{-}PEt_2)_3 + 3\ LiCl \qquad (29)$$

leads to the compound $(H_2Al{-}PEt_2)_3$, which melts at 1–2 °C and spontaneously ignites in air but which can be distilled without decomposition [32].

Aluminum-phosphorus compounds prepared in this way have a pronounced tendency to form salt-like compounds with an excess of $LiPEt_2$ [33]. Thus the viscous $[Al(PEt_2)_3]_n$ obtained from 1 mole of $AlCl_3$ and 3 moles of $LiPEt_2$ reacts with further $LiPEt_2$:

$$[Al(PEt_2)_3]_n + n\ LiPEt_2 \rightarrow n\ Li[Al(PEt_2)_4] \qquad (30)$$

to give a compound of m.p. 224–226 °C. This compound is also formed directly from $AlCl_3$ and the stoichiometric amount of $LiPEt_2$ [Equation (31)].

$$AlCl_3 + 4\ LiPEt_2 \rightarrow Li[Al(PEt_2)_4] + 3\ LiCl \qquad (31)$$

The colorless, crystalline $Li[AlH_2(PEt_2)_2]$, which ignites spontaneously in air, is formed by the following reactions:

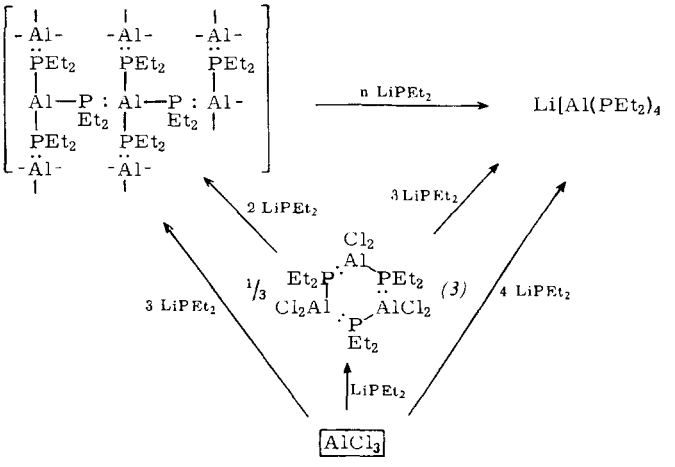
$$H_2AlCl + 2\ LiPEt_2 \rightarrow Li[AlH_2(PEt_2)_2] + LiCl \qquad (32)$$

$$(H_2Al{-}PEt_2)_3 + 3\ LiPEt_2 \rightarrow 3\ Li[AlH_2(PEt_2)_2] \qquad (33)$$

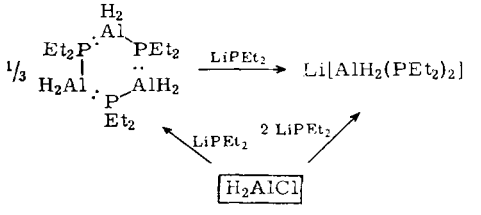
Evidently the formation of salt-like compounds is favored over that of the trimeric and higher-molecular-weight compounds [31]. $Li[AlH_3PEt_2]$ can be obtained directly from freshly-prepared $AlH_3$ [Equation (34)].

$$AlH_3 + LiPEt_2 \rightarrow Li[AlH_3PEt_2] \qquad (34)$$

The reactions of $AlCl_3$ and $H_2AlCl$ with $LiPEt_2$ are summarized in Schemes 2 and 3.



Scheme 2. Reactions of $AlCl_3$ with $LiPEt_2$.



Scheme 3. Reactions of $AlH_2Cl$ with $LiPEt_2$.

According to investigations by *Issleib et al.* [34], tetraalkyldiphosphines are cleaved by $LiAlH_4$, $Li[AlH(PR_2)_3]$ being formed *via* intermediate stages.

The compounds formed in accordance with Equations (30), (32), and (34) are very sensitive to hydrolysis and oxidation. Hydrolysis yields LiOH, $Al(OH)_3$, $HPEt_2$ and – except in the first example – $H_2$.

# Contributions to the Chemistry of the Binary Compounds of the Transition Elements

BY PROF. DR. HAAKON HARALDSEN

CHEMICAL INSTITUTE A, UNIVERSITY OF OSLO, BLINDERN (NORWAY)

*Dedicated to Professor W. Klemm on the occasion of his 70th birthday*

*Phase and structural relationships of the sulfur, selenium, and tellurium compounds of the 4d and 5d transition elements of groups IV to VII of the periodic system are discussed. Homologous elements behave very similarly with respect to the chalcogens, and this is particularly the case for niobium and tantalum, and for molybdenum and tungsten. However, zirconium, niobium, and molybdenum have a greater tendency towards formation of chalcogen-poor phases than their homologues hafnium, tantalum, and tungsten. Subchalcogenides are known only for zirconium and niobium. The number of phases and the tendency towards formation of solid solutions are considerably smaller among the tellurides than among the sulfides and selenides. The crystal structures of the telluride phases also differ from those of the sulfide and selenide phases of analogous composition. In addition, a review of the phase and structural relationships of the arsenic and antimony compounds of the 4d and 5d transition elements of groups V to VII is given.*

## I. Introduction

Previous investigations on the compounds of the transition elements with the chalcogens sulfur, selenium, and tellurium have shown that these substances show a very complex and, in many respects, unique behavior. Most thoroughly investigated are the chalcogenides of the 3d transition elements. Among them there exist, in addition to compounds of simple stoichiometric composition such as AX, $A_2X_3$, and $AX_2$, phases with extensive regions of homogeneity and compositions that can be expressed either by the formula $A_{1-x}X$ ($0 \leqslant x \leqslant 0.5$) or $A_{1+x}X_2$ ($0 \leqslant x \leqslant 1$).

Phases corresponding to various values of x have, in general, structures which can be derived from the NiAs or $Cd(OH)_2$ structure types by subtraction or addition of metal atoms, respectively. In the first-mentioned case, the composition of the phase can preferably be expressed by the formula $A_{1-x}X$, in the second by $A_{1+x}X_2$. The subtraction or addition of metal atoms is often accompanied by a lowering of crystal symmetry, leading to the formation of superstructures and structures in which the resulting vacancies or the additional metal atoms are distributed more or less regularly in the lattice.

More detailed investigations have shown that compounds with the exact stoichiometric composition AX are present only in a few cases. Thus a structure of the true NiAs-type rarely appears. This type of structure is, in a more or less modified form, usually associated either with a subtractive phase, as already mentioned, or, if an excess of metal atoms is present, with an interstitial phase $A_{1+x}X$.

Among the chalcogenides of the 3d transition elements structures of the $Cd(OH)_2$-type have been found mainly for the di-compounds of titanium and vanadium. Here again small deviations from the stoichiometric composition $AX_2$ apparently occur in most cases, corresponding to a slight excess of metal atoms. Of the remaining dichalcogenides of the 3d transition elements only the ditellurides of cobalt and nickel crystallize with the $Cd(OH)_2$ structure type. The other dichalcogenides of cobalt and nickel, and the dichalcogenides of manganese and iron, have structures either of the pyrite or the marcasite type. Chromium is exceptional as far as it does not form any di-compound with sulfur, selenium, or tellurium. For further details about the chalcogenides of the 3d transition elements, reference may be made to the comprehensive reviews [1–5].

Among the 4d and 5d transition elements, the platinum metals in many respects behave somewhat differently from the 3d transition elements towards the chalcogens, although many similarities can be found [11]. Just like the 3d transition elements, the platinum metals form relatively few compounds with the stoichiometric composition AX. The only compounds of this composition are two sulfides, PdS and PtS, one selenide, PdSe [6], and three tellurides, RhTe, PdTe, and PtTe. Only RhTe and PdTe possess structures of the NiAs-type. PdS, PdSe, and PtS have structures of tetragonal symmetry; PtTe crystallizes in the orthorhombic system.

[2] *H. Hahn*, Chemical Society Symposia, Bristol 1958 (chem. Soc., London), Special Publication No. *12*, 263 (1958).

[3] *J. Flahaut*, Bull. Soc. chim. France *1960*, 1282.

[4] *F. Jellinek*, Ark. Kemi *20*, 447 (1963).

[5] *A. Kjekshus* and *W. B. Pearson*, Solid State Chem. *1*, 83 (1964).

[6] *K. Schubert, H. Breimer, W. Burkhardt, E. Günzel, R. Haufler, H. L. Lukas, H. Vetter, J. Wegst*, and *M. Wilkens*, Naturwissenschaften *44*, 229 (1957).

The platinum metals form di-compounds with all three chalcogens sulfur, selenium, and tellurium. Only three platinum dichalcogenides, $PtS_2$, $PtSe_2$, and $PtTe_2$, and the ditellurides of palladium, rhodium, and iridium ($PdTe_2$, $RhTe_2$, and $IrTe_2$) possess structures of the $Cd(OH)_2$-type. Most of the other di-compounds of the platinum metals have structures of the pyrite type; a few of them have orthorhombic structures closely related to the pyrite or the marcasite type. Apparently no rhodium disulfide and no iridium diselenide with stoichiometric composition exist. Rhodium and iridium do, however, form compounds richer in chalcogen than the di-compounds. In the case of iridium the existence of even a triselenide ($IrSe_3$) has been shown [1,7]. These chalcogen-rich phases have, as already found by *Biltz et al.* [8], pyrite-like structures of low symmetry.

The platinum metal/chalcogen systems differ also from corresponding systems of the 3d transition elements in that phases with composition intermediate between AX and $AX_2$ exist only in the rhodium and iridium systems with sulfur and selenium. The structures of these phases are still unknown.

above 640 °C PdTe changes continuously into $PdTe_2$ [9–11].

With respect to their magnetic properties, the platinum metal chalcogenides differ considerably from the chalcogenides of the 3d transition elements. In the last-mentioned compounds, paramagnetism, ferromagnetism, antiferromagnetism, or ferrimagnetism is found, depending on composition and temperature. The platinum metal compounds are generally diamagnetic or only weakly paramagnetic.

## II. Chalcogenides of the 4d and 5d Transition Elements of Groups IV to VII

### 1. Sulfides

The chalcogenides of the 4d and 5d transition elements of groups IV to VII of the periodic system have recently been the object of several investigations. A survey of the phase and structural relationships in the sulfide systems is given in Table 1. The data originate mainly from *Jellinek*'s review [4].

Table 1. Sulfides of the 4d and 5d transition elements.

[a] *Jellinek* [4] also assumes the existence of phases of the approximate composition $MoS_{2.0-2.4}$ and $ReS_{2.0-2.4}$.

Moreover, no pronounced tendency towards the formation of phases with extended regions of homogeneity is found among the chalcogenides of the platinum metals. The same applies even to the rhodium/tellurium and the palladium/tellurium systems, in which phases both with NiAs-like and $Cd(OH)_2$-like structures are present. More recent investigations have shown, however, that

Many of the phases have extended regions of homogeneity, and some of them exhibit structures derivable from certain basic types in similar ways as for the chalcogenides of the 3d transition elements. Only in the zirconium/sulfur system, however, does a solid solution phase exist with a structure derived from a $Cd(OH)_2$-

type structure by addition of metal atoms [12]. There are no definite data on solid-solubility ranges in the hafnium/sulfur system [13]. The different lattice constants of hafnium disulfide found by *Haraldsen, Kjekshus, Røst,* and *Steffensen* [14] (a = 3.633 Å, c = 5.862 Å) on the one hand, and by *McTaggart* and *Wadsley* [13] (a = 3.635 Å, c = 5.837 Å) on the other may, however, indicate that hafnium disulfide is a phase of variable composition. The presence of a structure of the $Cd(OH)_2$-type for $HfS_2$ and of a $Cd(OH)_2$/NiAs-type structure in the case of hafnium sesquisulfide [13] supports this assumption.

The addition of metal atoms, which in hafnium sesquisulfide leads to a structure of the $Cd(OH)_2$/NiAs-type, does not proceed to the stage where all octahedral holes between the $AX_2$ layers in the $Cd(OH)_2$-type structure are occupied by metal atoms, resulting in a compound with composition HfS and a structure of NiAs-type. However, hafnium monosulfide has a different structure which is presently unknown [13].

So far no structure of the NiAs-type has been found in the zirconium/sulfur system. Instead, zirconium monosulfide belongs to a single-phase region which also includes the composition $Zr_2S_3$ and to which a cubic superstructure of the NaCl-type has been attributed [12]. For the subsulfide phase $ZrS_{0.5-0.8}$ *Hahn et al.* [12] proposed a structure of the WC-type. *Jellinek* [4], however, does not exclude the possibility that the phase has a disordered NiAs-like structure.

A structure of the NiAs-type has been found with certainty only for niobium subsulfide $NbS_{0.9}$ [4, 15]. This is another example of the tendency of the NiAs-type structure to occur with a somewhat lower chalcogen (X) content than required by the stoichiometric formula AX.

The structures of the $A_{1+x}X_2$ phases found in the niobium/sulfur and the tantalum/sulfur systems are derived not from the $Cd(OH)_2$ structure but from structure types designated by *Jellinek* [4] as the 2s-$Nb_{1+x}S_2$-type, the 3s-$Nb_{1+x}S_2$-type, and the 6s-$Ta_{1+x}S_2$-type. They are all typical layer structures and differ from the $Cd(OH)_2$-type mainly in that the six sulfur atoms surrounding each metal atom form a trigonal prism instead of an octahedron. The three structure types differ from each other in the stacking of the $AX_2$ layers in the direction of the c-axis. According to the way the layers are stacked upon each other, different structure types may arise [4, 16].

The disulfides are polytypic with exception of those of zirconium, hafnium, and technetium. *Jellinek* [4] reports five different structures for tantalum disulfide, of which one is of the $Cd(OH)_2$-type. In addition to the four structures in Table 1 there is also one in which the $TaS_2$ layers are stacked at random. For molybdenum, tungsten, and rhenium disulfides a rhombohedral structure of the 3s-$NbS_2$-type is known [15, 17–19] in addition to the hexagonal structure of the $MoS_2$-type (called the 2s-$MoS_2$-type by *Jellinek* [4]) which has been known for a long time. The former structure has recently also been observed in naturally occurring molybdenum disulfide [20–22].

Excepting technetium and possibly rhenium, all the metals mentioned in Table 1 form trisulfides. The trisulfides of molybdenum and tungsten have so far, however, been obtained only in X-ray amorphous form [4, 19]. The existence of rhenium trisulfide has not yet been ascertained.

Although no complete structure determination has been carried out, it is suggested that zirconium trisulfide [12] and hafnium trisulfide [13] are isostructural with monoclinic $ZrSe_3$, the structure of which has been determined by *Krönert* and *Plieth* [23]. Whether or not niobium trisulfide possesses this structure remains doubtful [24]. Tantalum trisulfide has a structure of orthorhombic symmetry [25]. The fact that rhenium forms a heptasulfide ($Re_2S_7$) was already recognized by *Biltz* and *Weibke* [26]. In the case of technetium, a disulfide of the $MoS_2$-type and a heptasulfide ($Tc_2S_7$) have been described [27].

Among the 3d transition elements titanium and vanadium form only sulfur-rich compounds. Thus a trisulfide of titanium, $TiS_3$, and a tetrasulfide of vanadium, $VS_4$, and possibly also a pentasulfide, $VS_5$ [28], are known. The structure of vanadium tetrasulfide has been determined by *Hellner et al.* [29]; it contains groups of two and two sulfur atoms, corresponding to a formula $V(S_2)_2$ with tetravalent vanadium.

### 2. Selenides

The selenides of the 4d and 5d transition elements of groups IV to VII of the periodic system have not been investigated in such detail as the sulfides. The results obtained so far are summarized in Table 2.

| Ta | | | $TaSe_{1.22-1.60}$ 2s-$Nb_{1+x}S_2$-type | $TaSe_{1.60-1.95}$ 6s-$Ta_{1+x}S_2$-type | $TaSe_{2.00}$ $Cd(OH)_2$-type 2s-$NbS_2$-type 3s-$NbS_2$-type 4s-$TaSe_2$-type 6s-$TaS_2$-type | | $TaSe_{3.00}$ $TaSe_3$-type | | |
| W | | | | | $WSe_2$ $MoS_2$-type | | $WSe_3$ amorphous | | |
| Re | | | | | $ReSe_2$ $ReSe_2$-type | | | $Re_2Se_7$ (?) | |

The picture is on the whole similar to that of the sulfides. It is particularly worth noting that no structure of NiAs or a related type seems to occur, unless zirconium subselenide $ZrSe_{0.6-0.8}$ possesses such a structure, in analogy with *Jellinek*'s proposal [4] for the corresponding sulfide. The WC-type given in Table 2 and the other data on the zirconium/selenium system are due to *Hahn* and *Ness* [30].

Niobium subselenide, $NbSe_{0.80}$, crystallizes in the tetragonal $Ti_5Te_4$-type [31]. The structure of $Ti_5Te_4$ itself was first determined by *Grønvold*, *Kjekshus*, and *Raaum* [32] and is shown in Fig. 1 in [001]-projection. The titanium and tellurium atoms are arranged in chains in the direction of the c-axis. The tellurium chains form square groups, with four chains in each. The titanium atoms form groups each containing five chains, one chain being surrounded by the four others at the corners of a square.

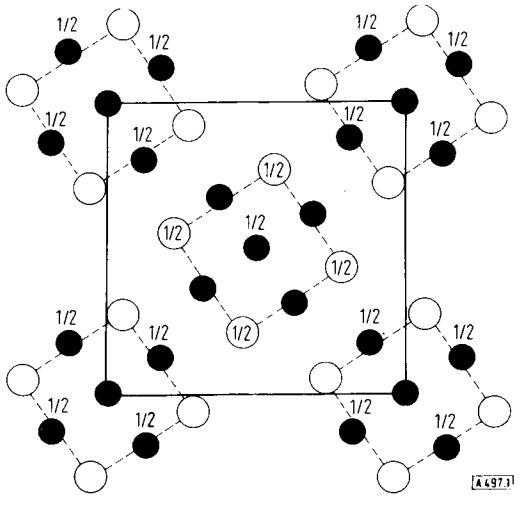

Fig. 1. [001] projection of the $Ti_5Te_4$ structure [32].
● Ti; ○ Te.

It is interesting to compare this structure with a NiAs-structure of the composition TiTe. Fig. 2 shows such a TiTe structure in [010]-projection. It follows from Figs. 1 and 2 that, apart from slight changes in the positions of the atoms, the most striking difference between the two structures is that the tellurium atoms

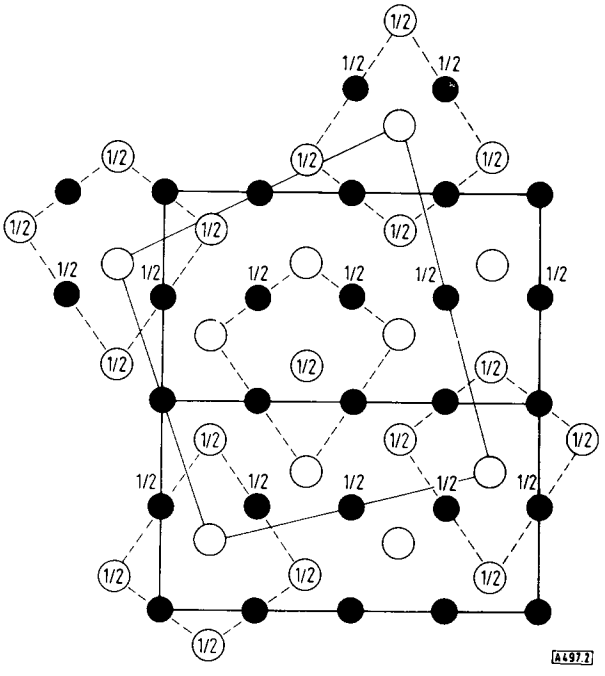

Fig. 2. [010] projection of the NiAs-type structure of TiTe [32].
● Ti; ○ Te.

within the quadrilateral of the TiTe structure (shown in broken lines) have been replaced by titanium atoms in the $Ti_5Te_4$ structure [32].

Not only the chalcogenides $Ti_5Te_4$, $V_5S_4$ [33], $V_5Se_4$ [34], $Nb_5Se_4$ [31], and $Nb_5Te_4$ [31] crystallize with the $Ti_5Te_4$-

type structure, but also the antimonides $Nb_5Sb_4$ [35, 36] and $Ta_5Sb_4$ [36, 37], as well as the arsenides $Mo_5As_4$ [36, 38] and $(W, Ti)_5As_4$ [36].

The diselenides of zirconium [30] and hafnium [13] have structures of the $Cd(OH)_2$-type, just like the corresponding sulfides. One of the five modifications of tantalum diselenide also belongs to this type of structure [39]. The other modifications of tantalum diselenide, the modifications of niobium diselenide, and the solid solutions derivable from the disulfides have structures corresponding to those of the analogous sulfides [16, 39–41]. Only the structures of the 4s-type are new. The compositions of the phases differ, however, to some extent.

More recent investigations indicate that the 2s-$NbS_2$-type is the only structure present in the $NbSe_{\approx 1.9-2.0}$ region, and that the other two structures occur only at still lower selenium concentrations [42]. It is therefore open to question whether the three structures given for the diselenide actually are polytypes of the same phase, or belong to phases of different composition.

A similar situation occurs in case of tantalum diselenides [39]. The only structures present for tantalum diselenide of stoichiometric composition apparently belong to the $Cd(OH)_2$- and the 4s-$NbSe_2$-types. Further structures given by *Kadijk*, *Huisman*, and *Jellinek* [41] and by *Brown* and *Beerntsen* [16] obviously appear only at lower concentrations of selenium. Thus, the 2s-$Nb_{1+x}S_2$-type has been found in the regions $TaSe_{\approx 1.22-1.60}$ and $TaSe_{\approx 1.95-2.00}$, and the 6s-$TaS_2$-type in the region $TaSe_{\approx 1.60-1.95}$. These results indicate that the solid solubility regions $NbSe_{1.55-2.00}$ and $TaSe_{1.22-2.00}$ given in Table 2 actually include several phases.

The molybdenum and tungsten diselenides have hexagonal structures of the $MoS_2$-type [43–45].

Rhenium diselenide has a structure of triclinic symmetry [46]. The similarity with the $Cd(OH)_2$ structure can be seen clearly from Fig. 3: both are typical layer structures. Each rhenium atom is surrounded by six selenium atoms at the corners of a somewhat distorted octahedron. Unlike the cadmium atoms in the $Cd(OH)_2$ structure the rhenium atoms are not situated exactly in the center of the octahedron, but are shifted towards one face leading to the presence of three shorter and three longer rhenium-selenium distances, and three significantly shorter rhenium-rhenium distances of 2.646,

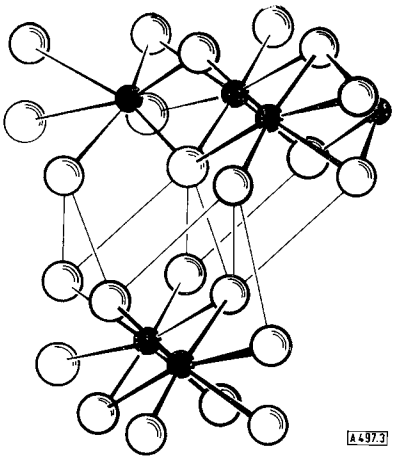

Fig. 3. The $ReSe_2$ structure [46].
● Re; ○ Se.

2.837, and 2.927 Å. The shortest of these distances is actually smaller than the rhenium-rhenium distance found in metallic rhenium (2.75 Å). This and other short rhenium-rhenium distances indicate that chemical bonds exist between the rhenium atoms in the $ReSe_2$ lattice. These bonds are probably the primary cause of the distortion of the $ReSe_2$ structure relative to the $Cd(OH)_2$ structure.

The niobium selenide $Nb_3Se_4$ has a hexagonal structure [47] in which each niobium atom is surrounded by six selenium atoms at the corners of a deformed octahedron (Fig. 4). The whole structure might be regarded as built up of such octahedra joined by common edges.

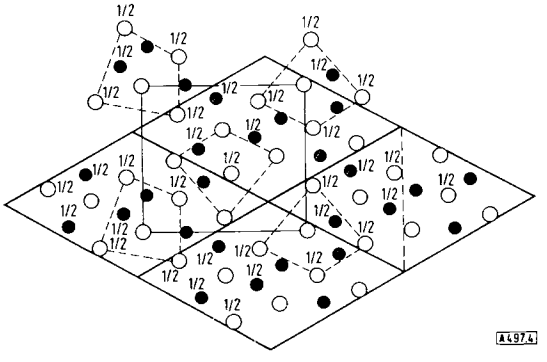

Fig. 4. [001] projection of the $Nb_3Se_4$ structure [74].
● Nb; ○ Se.

In analogy with the situation in the $ReSe_2$ structure, the niobium atoms are not located exactly in the centers of the octahedra, but are shifted from the center in such a manner that alternately longer and shorter niobium-niobium distances occur. The short metal-metal distances which are observed indicate that bonding exists between the niobium atoms.

Just as it is possible in the case of the $Ti_5Te_4$ structure to show certain similarities in the atomic arrangement of the NiAs and the $Ti_5Te_4$ structure by comparing corresponding groups of atoms, this can also be done for the $Nb_5Se_4$ and $Nb_3Se_4$ structures [47]. Such a comparison is possible on the basis of Fig. 4 and the $Ti_5Te_4$

structure shown in Fig. 1 if one replaces the titanium and tellurium atoms in Fig. 1 by niobium and selenium atoms, respectively. The rectangle outlined in Fig. 4 is then seen to correspond to the square in Fig. 1. The most notable difference is that the selenium atoms present in the quadrilaterals shown with broken lines in Fig. 4 are replaced by niobium atoms in Fig. 1. To convert the $Nb_5Se_4$ structure into the $Nb_3Se_4$ structure, it is necessary to replace these niobium atoms by selenium atoms, and, further, to remove some other atoms from the $Nb_5Se_4$ structure in combination with a fairly extensive rearrangement of the atoms.

As in the sulfide systems, several tri-compounds also exist in the selenide systems; only niobium and rhenium do not form any triselenide. Instead, these metals form compounds even richer in selenium, $NbSe_4$ [48] and $Re_2Se_7$ [49], respectively. Niobium tetraselenide occurs in two or three modifications with structures as yet unknown. Two of the modifications have tetragonal symmetry. Dirhenium heptaselenide is apparently analogous to dirhenium heptasulfide although its existence still cannot be regarded as certain.

The triselenides of molybdenum and tungsten are amorphous to X-rays [39,44]. Zirconium triselenide [30] and hafnium triselenide [13] are evidently isostructural, just like the sulfides, and have the monoclinic structure found by *Krönert* and *Plieth* [23] for $ZrSe_3$. The structure is a typical layer structure (Fig. 5), in which the metal

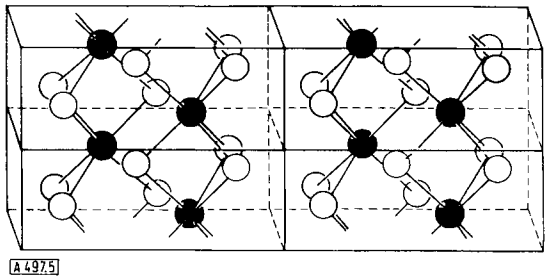

Fig. 5. The $ZrSe_3$ structure [23].
● Zr; ○ Se.

atoms are surrounded by four single selenium atoms and two $Se_2$ groups, resulting in a total of eight selenium atoms. The selenium-selenium distance in the $Se_2$ groups (2.34 Å) is twice the atomic radius of elemental selenium. Phases with structures of the $ZrSe_3$-type can therefore be regarded as partial poly-compounds $AX(X_2)$ with tetravalent metal atoms, divalent chalcogen atoms, and divalent, dimeric $X_2$ chalcogen groups.

In addition to the compounds already mentioned ($ZrS_3$, $ZrSe_3$, $HfS_3$, and $HfSe_3$) it is assumed that $TiS_3$ [50], ZrTe [51], $US_3$ [52–53], $USe_3$ [53,54], $UTe_3$ [53], and $ThTe_3$ [55] have structures of the $ZrSe_3$-type. On the other hand, it appears doubtful whether $NbS_3$ belongs to this structure type [24].

Tantalum triselenide also has a structure of monoclinic symmetry [25], but it is not of the $ZrSe_3$-type. In this respect, tantalum triselenide shows a similarity to tantalum trisulfide, which also has a different structure from that of $ZrSe_3$.

The structure of tantalum triselenide is characterized by a unit cell containing two crystallographically different tantalum atoms (I) and (II) and six crystallographically different selenium atoms, Se(I) to Se(IV) [56]. It follows from Fig. 6 that each tantalum atom is surrounded by

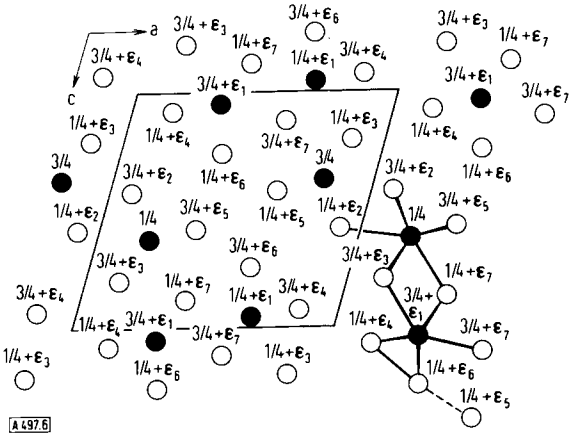

Fig. 6. [010] projection of the $TaSe_3$ structure [56].
● Ta; ○ Se.

eight selenium atoms. Six of the selenium atoms are at the corners of a trigonal prism, and two lie outside the rectangular faces of the prism. The two shortest selenium-selenium distances of 2.53 and 2.66 Å are somewhat greater than the selenium-selenium distances of 2.34 to 2.45 Å found in other compounds of similar type. However, they might still indicate the existence of selenium-selenium bonds in $TaSe_3$. Comparison with the $ZrSe_3$ structure shows that the coordiation of the metal atoms in the two structures is the same, but in the $ZrSe_3$ structure all the zirconium atoms are crystallographically equivalent.

Only preparative information is available about the molybdenum selenides $Mo_2Se_3$ and $Mo_2Se_5$ [57]. The hafnium selenides HfSe and $Hf_2Se_3$ have been prepared [13], but their crystal structures remain unknown.

### 3. Tellurides

Table 3 gives a survey of the phase and structural relationships in the telluride systems. The phase relationships are on the whole simpler than in the sulfide and

selenide systems. The only phases with extended regions of homogeneity are the two zirconium telluride phases $ZrTe_{0.5-0.75}$ and $ZrTe_{0.8-2.0}$ [51]. The broad regions of homogeneity attributed to the niobium and tantalum tellurides by some investigators [43,58,59] have not been confirmed by others [25,31,47,60].

The zirconium-rich phase $ZrTe_{0.5-0.75}$ and zirconium tritelluride correspond in compositions and structural types to the zirconium-richest and zirconium-poorest in the sulfide and selenide systems of this metal.

any compound with a greater content of tellurium than the sesquitelluride [13]. In this respect, the hafnium/tellurium system differs markedly from the zirconium/tellurium system and also from the other hafnium/chalcogen systems.

A structure of the $Cd(OH)_2$/NiAs-type has been found for hafnium sesquitelluride [13]. Whether or not this phase has a region of homogeneity is not known. Neither is any information available on the structure of hafnium monotelluride.

Table 3. Tellurides of the 4d and 5d transition elements.

| Elements | Subtellurides $A_{1+x}Te$ | Monotellurides $A_{1-x}Te$ | Sesquitellurides $A_{1+x}Te_2$-phases | Ditellurides $ATe_2$ | Tritellurides $ATe_3$ | Tetratellurides $ATe_4$ |
|---|---|---|---|---|---|---|
| Zr | $ZrTe_{0.5-0.75}$ WC-type | | $ZrTe_{0.8-2.0}$ NiAs/$Cd(OH)_2$-type | | $ZrTe_3$ $ZrSe_3$-type | |
| Nb | $NbTe_{0.80}$ $Ti_5Te_4$-type | | $NbTe_{1.33}$ $Nb_3Se_4$-type | $NbTe_{2.00}$ Type? | | $NbTe_{4.00}$ $NbTe_4$-type |
| Mo | | | $MoTe_{1.5}$ Type? | $MoTe_2$ $MoS_2$-type | | |
| Hf | | HfTe Type? | $HfTe_{1.5}$ $Cd(OH)_2$/NiAs-type | | | |
| Ta | | | | $TaTe_{2.00}$ Type? | | $TaTe_{4.00}$ $NbTe_4$-type |
| W | | | | $WTe_2$ orthorhomb. | | |
| Re | | | | $ReTe_2$ orthorhomb. | | |

The homogeneity region of the $ZrTe_{0.8-2.0}$ phase is so wide that it includes the composition of the ditelluride, the sesquitelluride, the monotelluride, and compositions of still lower tellurides as well [51]. Consequently, the $Cd(OH)_2$-like structure of zirconium ditelluride changes gradually into a structure of the NiAs-type by addition of zirconium atoms. The zirconium/tellurium system differs in this respect from the other two zirconium/chalcogen systems, in which a structure of the $Cd(OH)_2$/NiAs-type is present only in a comparatively narrow concentration range of $ZrX_{1.7-2.0}$. At the compositions $ZrS_{0.9-1.5}$ and $ZrSe_{1.0-1.4}$ phases with a cubic superstructure of the NaCl-type exist [12,30].

*Hahn* and *Ness* [51] do not exclude the existence of a superstructure of the NiAs-type between ZrTe and $ZrTe_{1.3}$. Further investigations are therefore needed in order to clarify the phase and structural relationships in the whole range from ZrTe to $ZrTe_2$. In other systems where similar broad regions of homogeneity with continuous transitions from structures of the $Cd(OH)_2$-type into the NiAs-type were first assumed, it has later been found that the extended phase regions actually include several phases with related, but not identical structures.

It is also remarkable that zirconium is the only metal discussed in Table 3 which forms a tritelluride. Among the other metals the compounds richest in tellurium are the ditellurides of molybdenum, tungsten, and rhenium, and the tetratellurides of niobium and tantalum. Hafnium occupies a special position since it does not form

The tellurium-poor niobium phases $NbTe_{0.80}$ [31] and $NbTe_{1.33}$ [47] correspond to the analogous niobium selenides with regard to composition and structure type. In other respects the phase and structural relationships of the niobium and tantalum tellurides differ considerably from those of the sulfides and selenides of these metals. One notes in particular the absence of the broad regions of homogeneity and the polytypic structures common to the disulfides, diselenides, and the $A_{1+x}X_2$-phases. In contrast to the disulfides and diselenides and to what is given in the literature [43,61], the probably isostructural niobium and tantalum ditellurides are not hexagonal but have a not yet elucidated structure of lower symmetry [62,63].

The tetratellurides of niobium and tantalum are isotypic and have structures of tetragonal symmetry [25,60,64]. *Novoselova, Grigoryan, Simanov*, and *Ukrainskii* [58,59] attributed the same symmetry to the phases $NbTe_{2.33-4.0}$ and $TaTe_3$, which they considered as the phases richest in tellurium. The unit cell of the tetratellurides of niobium and tantalum is derived from a structure for which the subcell is shown in Fig. 7. The a-axis of the real cell is twice that of the subcell, the c-axis is three times as long. Each metal atom is surrounded by eight tellurium atoms in form of a slightly distorted square antiprism. Each tellurium atom is coordinated to two metal atoms and eleven tellurium atoms. Five of the tellurium atoms form a planar, irregular pentagon, and six form a trigonal prism. The shortest tellurium-

● Nb; ○ Te

tellurium distance (2.867 Å for $NbTe_4$ and 2.790 Å for $TaTe_4$) allows the conclusion that tellurium-tellurium bonds exist in both tetratellurides. Although a certain similarity is present, the structure of the tetragonal modification of niobium tetraselenide [48] differs from the structures of the tetratellurides of niobium and tantalum.

## III. Arsenides and Antimonides of the 4d and 5d Transition Elements of Groups V to VII

Until recently the arsenides and antimonides of the 4d and 5d transition elements have received relatively little attention. However, this situation has now changed completely. Independently and almost simultaneously several research groups have carried out a number of investigations on the phase and structural relationships of the arsenides and antimonides of niobium, tantalum, molybdenum, and tungsten. The investigations have led to essentially consistent results.

A survey of the phases and structure types that can be regarded as established is given in Table 4. In addition to the systems mentioned, the tungsten/antimony system and the bismuth systems of niobium, tantalum, molybdenum, and tungsten have also been investigated [38]. No intermediate phases were detected in any of these systems. The existence of the phases MoAs, $MoAs_{1.04} \approx Mo_4As_5$, $W_2As$ and $W_4As_5$, described by *Boller* and *Nowotny* [36] has not been confirmed, neither by *Taylor*, *Calvert*, and *Hunt* [78], nor by *Jensen*, *Kjekshus*, and *Skansen* [38]. The $W_4As_5$ phase evidently is identical,

Unlike the other tungsten dichalcogenides and the molybdenum dichalcogenides, tungsten ditelluride, which is the only intermediate phase in the tungsten/tellurium system, does not have a structure of the $MoS_2$-type but an as yet not elucidated orthorhombic structure [43, 65, 66]. Like tungsten, rhenium forms a ditelluride $ReTe_2$ with an orthorhombic structure that also has not yet been determined [67].

Molybdenum ditelluride and molybdenum sesquitelluride were first described by *Morette* [65] whose results were confirmed by *Perotinen* and *Newnham* [68]. Molybdenum ditelluride has a structure of the $MoS_2$-type [68–70]; the structure of molybdenum sesquitelluride remains to be determined.

however, with the $W_2As_3$ phase of the last-mentioned authors. The same probably applies to the $Mo_4As_5$ phase, which should accordingly be regarded as $Mo_2As_3$.

Table 4 shows that niobium and tantalum form arsenides and antimodnies of identical compositions. The compounds have no detectable regions of homogeneity and can be regarded as stoichiometric[38]. All compounds of corresponding composition have structures of the same type.

A structure of the β-W-type, present for $Nb_3Sb$ and $Ta_3Sb$, has previously been found for about 40 to 50 different compounds. The structures are characterized, *inter alia*, by remarkably small metal-metal distances. This also applies to $Nb_3Sb$ and $Ta_3Sb$. Thus the shortest niobium-niobium distance is 2.632 Å in $Nb_3Sb$[35], while in metallic niobium it is 2.858 Å[81,82]. In $Ta_3Sb$ and metallic tantalum, the shortest tantalum-tantalum distances are 2.632 Å[37] and 2.863 Å[83], respectively.

The tetragonal structure of niobium monoarsenide has been determined independently by *Boller* and *Parthe*[71] and by *Furuseth* and *Kjekshus*[73a, b]. Each atom is surrounded at equal distances by six nearest neighbors of the other kind (Fig. 8). The structure may be considered as built up of almost regular, trigonal niobium prisms with an arsenic atom in the center. The prisms are rotated and displaced with respect to each other. A structure of the same type is found also for tantalum monoarsenide and for the monophosphides of niobium and tantalum[71,84].

All di-compounds of Table 4 have the structure type first found for $NbAs_2$[73a,73c]. The same type is suggested for $VP_2$, $VAs_2$, $NbP_2$, $TaP_2$, and α-$WP_2$[77]. A [010]-projection of the $NbAs_2$ structure is shown in Fig. 9. Each niobium atom is surrounded by six arsenic atoms at the corners of a trigonal prism and by two

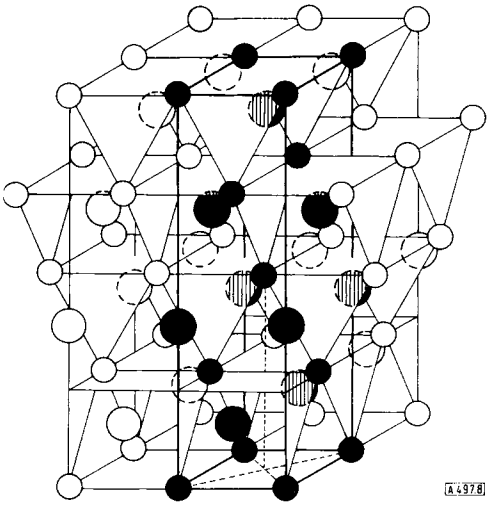

Fig. 8. The NbAs structure [71]. Small circles, Nb; large circles, As.

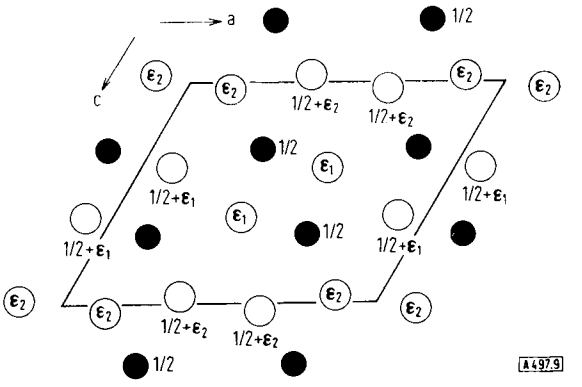

Fig. 9. [010] projection of the $NbAs_2$ structure [73c]. ● Nb; ○ As.

additional arsenic atoms and one niobium atom outside the rectangular faces of the prism. Two crystallographically different arsenic atoms, As (I) and As (II), are present. The arsenic atoms (I) have five niobium atoms as their nearest neighbors, forming a distorted square pyramid with one additional arsenic atom (I) outside the base of the pyramid. The arsenic atoms (II) are coordinated to three arsenic atoms (II) and three niobium atoms. The arrangement of the arsenic atoms (II) produces alternating longer and shorter arsenic (II)-arsenic (II) distances. In $NbAs_2$ the shorter distances are 2.446 Å, while in $NbSb_2$ the shorter antimony (II)-antimony (II) distances are 2.72 Å[73c]. The corresponding distances in $TaAs_2$ and $TaSb_2$ are 2.42 and 2.65 Å, respectively[37]. Compared to the shortest bond distances in metallic arsenic (2.507 Å) and antimony (2.904 Å)[85] indications are that half of the arsenic and antimony atoms in the diarsenides and diantimonides of niobium and tantalum are bound in pairs, corresponding to the formulae

$$\overset{+5\ -4\ -3}{Nb_2(As_2)As_2},\quad \overset{+5\ -4\ -3}{Nb_2(Sb_2)Sb_2},\quad \overset{+5\ -4\ -3}{Ta_2(As_2)As_2}\quad \text{and}\quad \overset{+5\ -4\ -3}{Ta_2(Sb_2)Sb_2}.$$

In agreement therewith, it has been shown that the compounds are diamagnetic. The mono-compounds NbAs and TaAs also are diamagnetic. On the other hand, the antimonide phases $Nb_5Sb_4$, $Ta_5Sb_4$, $Nb_3Sb$, and $Ta_3Sb$ with higher metal contents exhibit slight, almost temperature-independent paramagnetism, corresponding to a more metallic bond character[35,37].

Besides the diarsenides $MoAs_2$ and $WAs_2$ of the $NbAs_2$ type, molybdenum and tungsten form sesquiarsenides $Mo_2As_3$ and $W_2As_3$ of monoclinic symmetry[38,78,79]. Molybdenum also forms an arsenide $Mo_5As_4$, of the $Ti_5Te_4$-type, and an antimonide $Mo_3Sb_7$. This antimonide, and the rhenium arsenide of corresponding composition $Re_3As_7$, belong to a structure type first found for $Ir_3Ge_7$ by *Nial*[86].

# The Kinetics of Crystal Growth

BY DR. H. HEYER

FRITZ-HABER-INSTITUT DER MAX-PLANCK-GESELLSCHAFT, BERLIN (GERMANY)

*The fundamentals of the theory of crystal growth comprise the two concepts of growth via two-dimensional nuclei and growth with the aid of dislocations. Measurements of the relationship between rate of growth and supersaturation are particularly suitable for testing theoretical predictions. Experimental results are compared with predictions for crystal growth from the vapor phase, from solution, and from the melt. Depending on the experimental conditions, examples of both types of growth are met irrespective of the nature of the mother phase.*

## I. Introduction

Formation of a new crystalline phase from a supersaturated mother phase (supersaturated vapor, supersaturated solution, supercooled melt) requires the initial formation of a nucleus. This necessitates a fluctuation of the Gibbs free energy, the "work of nucleation." With regard to size and shape, the nucleus is in equilibrium with the surroundings. Spontaneous growth of the crystal becomes feasible only after it has grown to beyond the size of the nucleus. Additional growth thresholds can, however, determine the rate of growth.

Two stages can therefore be distinguished in the kinetics of crystal formation: nucleation, and growth of the nucleus. If many small crystals are formed during a crystallization process (rapid solidification of melts, formation of fine-grained precipitates), both steps are important in the kinetic treatment. In the formation of a few, larger crystals, the growth of the nuclei is the principal process. It is this process which forms the subject of this article.

A detailed picture of the growth mechanism has been developed since about 1925. Before then, work was concentrated largely on the interpretation of growth forms, for which purely geometric considerations (kinematic theory of crystal growth[1]), symmetry and structural properties of crystals (lattice plane density[2], principal bonding direction[3]), and thermodynamics (Gibbs condition[4], Wulff's theorem[5]) were utilized.

The basis for a molecular kinetic treatment was given by *Kossel*[6] and *Stranski*[7], who considered the deposition of single molecules in the formation of a crystal, and by *Volmer*[8], who derived an equation for the rate of growth. Basing his postulates on concepts due to *Gibbs*[9], *Volmer* assumed that nucleation was also necessary for the addition of each new lattice plane. The frequency of formation of these two-dimensional nuclei (cf. Fig. 1) determines the rate of growth. Subsequently, it was shown that two-dimensional nuclei are necessary only for the growth of certain types of crystal face[7]; but it is precisely these which determine the crystal growth form. The introduction of the average work of separation[10] led to a link between thermodynamic and statistical methods of treatment.

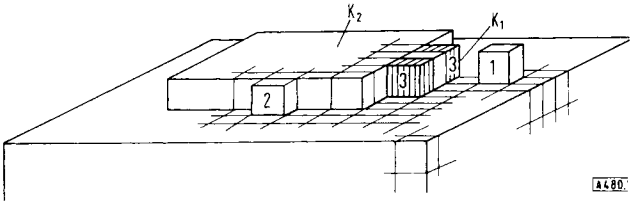

Fig. 1. Crystal face with two-dimensional nucleus ($K_2$), one-dimensional nucleus ($K_1$), an adsorption site on the face (1) and at the ledge (2), and kinks (3). Reproduced (with permission) from *B. Honigmann*: Gleichgewichts- und Wachstumsformen von Kristallen. Steinkopff, Darmstadt 1958 [22].

Sequences of growth rate for various types of face calculated from nucleation frequencies were in substantial agreement with experimental results. However, marked deviations were often encountered in the absolute values. These suggested that the simplifications adopted, such as the ideal lattice and spherically symmetrical bonding forces, as well as the neglect of adsorption, surface diffusion, and thermal roughening, were unjustified in many cases.

Initially, the influence of the structure of real crystals was considered in terms of the reduction in the work of nucleation at the concave edges of a mosaic structure[11]. *Burton, Cabrera,* and *Frank*[12,13] developed a new theory for the

growth of a real crystal on the basis of the screw dislocations introduced into the theory of plasticity by *Burgers*. Direct observation of dislocation lines and systems of growth steps, as well as determination of the theoretically required dependence of growth rate on the degree of supersaturation, enabled these postulates to be confirmed in many instances, but growth by dislocations by no means explains all the experimental results. Nucleation processes can become rate-determining, particularly during growth from highly supersaturated systems and from condensed or impure mother phases.

During the past few years allowance has been made for further factors such as adsorption and diffusion [14–20], and kinetically more complicated processes (growth from solution and melt, whisker and needle crystal growth, electrolytic growth, growth during recrystallization and chemical reactions) have been treated in detail. Only some of these types of growth can be dealt with here.

## II. Growth from the Vapor Phase

### 1. Equilibrium Form and Growth Form

The equilibrium form is the form of a crystal in thermodynamic equilibrium with its surroundings. Hence, the shape of a nucleus is always an equilibrium form. The faces of this equilibrium form and their size ratio are determined by the Gibbs condition that the surface free energy is a minimum for a constant number of structural units.

The growth form is determined by the rate of growth of the individual types of face. The slower the growth of a face, the faster is its extension in the growth form.

In an ideal crystal, faces are distinguished which require the formation of two-dimensional nuclei for the deposition of new lattice planes, and those which require merely one-dimensional nuclei or can grow without energy barriers. Only faces of the first type, which grow much more slowly than the others over a wide supersaturation range, participate in determining the growth form.

Because of lattice defects, *e.g.* screw dislocations, steps or ledges capable of growth are invariably present in the surface of real crystals. Formation of two-dimensional nuclei is therefore unnecessary even on faces of the first type. Their rate of growth is increased compared to corresponding faces of ideal crystals, but remains below the maximum corresponding to the frequency of impingement, since the units have to find their way to the growth sites by surface diffusion. Faces which in ideal crystals are able to grow without formation of two-dimensional nuclei are unaffected by defects in the crystals, since the distances between the kinks or the steps capable of growth have the same order of magnitude as the building unit spacing. Consequently, in real crystals also, only such faces contribute to the growth form which grow *via* two-dimensional nuclei in the case of ideal crystals.

It has been found that these faces controlled by two-dimensional nuclei correspond to those which arise from the equilibrium form [10]. This relationship still holds when the equilibrium conditions are altered by a high supersaturation or additional factors such as adsorption [10, 16]. For this reason, determination of the equilibrium form makes possible a theoretical elucidation of the faces making up the growing crystal.

### 2. Growth Rate Theory

Work of nucleation has to be expended on the faces of the equilibrium form of an ideal crystal for each new lattice plane (Fig. 1) [*]. To determine the growth rate of these faces, it is initially necessary to consider equilibrium conditions, since both the shape and the size of the two-dimensional nucleus must be known if the work of nucleation is to be evaluated. The shape is obtained from the Gibbs condition, with the Helmholtz free energy of the edge being a minimum. The size is obtained from the Gibbs-Thomson equation for the two-dimensional case [cf. Equation (5)], which relates nucleus size and supersaturation. Presupposing that the growth of two-dimensional nuclei is sufficiently rapid, the growth rate R is found to be [8, 14, 23–26]:

$$R = d \cdot I = d \cdot H \cdot e^{-\Delta G_n'/kT} \qquad (1)$$

where d is the step-height of the nucleus, I the nucleation frequency, H a frequency factor, and $\Delta G_n'$ the work of nucleation or, more accurately, the change in Gibbs free energy when a two-dimensional nucleus is formed; it is given by

$$\Delta G_n' = \frac{(\Sigma \rho_i r_i A_i)^2}{4kT \ln(p_h/p_\infty)} \qquad (2)$$

wherein $\rho$ is the specific Gibbs free ledge energy, r the spacing of structural units, A a geometric factor, i a subscript for the respective type of face, and $p_h/p_\infty$ the supersaturation ratio ($p_\infty$ is the vapor pressure of a sufficiently large crystal, and $p_h$ that of a micro-crystal of radius h). The *relative* supersaturation, $\Omega$, is defined by $\Omega = p_h/p_\infty - 1$.

Several derivations exist for Equation (1) (cf. [8, 14]) and give diverse expressions, particularly for the factor H, for which values between $10^{20}$ and $10^{28}$ are obtained [12, 14, 26].

[*] During growth of the nucleus, the addition of each new layer requires performance of the work necessary for a one-dimensional nucleus. At the temperatures generally used for crystal growth, this work factor does not represent a significant energy barrier.

[23] *I. N. Stranski* and *R. Kaischew*, Z. physik. Chem. *B 26*, 317 (1934).

According to Equations (1) and (2), the rate of growth and the supersaturation are related exponentially (see Fig. 4). Equation (1) shows that R must become practically zero even at finite degrees of supersaturation. For the critical supersaturation, $\Omega_{cr}$, at which growth commences, values between 0.25 and 0.5 have been calculated for molecular crystals [13, 21, 27]. For metals, $\Omega_{cr}$ may be substantially greater [14].

The growth of real crystals is influenced above all by lattice defects which maintain existing growth steps or continuously form fresh ones. Screw dislocations are particularly significant. In contrast, point defects play only an indirect role in the growth kinetics, in that the formation or multiplication of dislocations can be affected by impurity or vacancy accumulations. A brief description of growth phenomena in the presence of screw dislocations will now be given. (A mathematically more rigorous treatment can be found in [13–15].)

Where a screw dislocation penetrates a crystal face, the crystal can grow without formation of two-dimensional nuclei. Further addition of units leads to the formation of a circular or polygonal spiral (see Fig. 2).

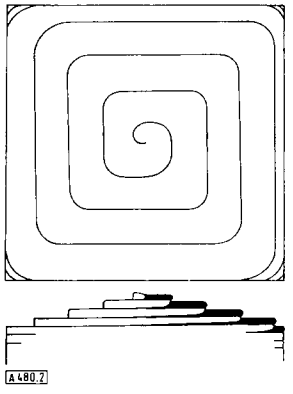

Fig. 2. Crystal face with a growth spiral (taken from [12]). Reproduced (with permission) from Transactions of the Faraday Society.

The growth rate of such a surface is determined by the step height of the growth front $d_0$, the distance between the steps s, and the lateral rate of advance of the steps, w.

$$R = d_0 w/s \qquad (3)$$

For the general case of a round spiral, the latter "rotates" at constant angular velocity about the point of penetration of the dislocation. When the rate of advance, w, is independent of the distance from the center, the Archimedean spiral fulfils the condition of a radius-independent angular velocity. The distance between the steps depends on the length of the edge of the two-dimensional nucleus corresponding to the relevant degree of supersaturation. If the initial radius of curvature of the spiral is taken to be the radius $r_n$ of a nucleus assumed to be circular (a greater step curvature cannot be stable), the distance between the steps is given by [*]:

$$s = 4\pi r_n \qquad (4)$$

$r_n$ is obtained from the Gibbs-Thomson equation for the two-dimensional case [8]:

$$kT \ln(p_h/p_\infty) = \rho f_0/r_n \qquad (5)$$

where $f_0$ is the area occupied by a structural unit.

The rate of advance w, which is determined essentially by the mean diffusion path $x_s$ of the surface molecules and the difference $\Delta\dot{N}$ between the number of molecules striking the surface per unit time at the temperature of the evaporating sample and at the temperature of the growing crystal, is given by

$$w_I = 2 x_s \alpha_K \alpha_H f_0 \Delta\dot{N} \qquad (6)$$

where $\alpha_K$ and $\alpha_H$ are two partial condensation coefficients [see Equation (12)]. Equations (3)–(6) and the approximations $\ln p_h/p_\infty \approx \Omega$ and $\Delta\dot{N} \approx \dot{N}\Omega$ together lead to the rate equation

$$R_I = d_0 x_s \dot{N} \alpha_K \alpha_H kT\Omega^2/2\pi\rho. \qquad (7)$$

Accordingly, $R_I$ is proportional to the square of the degree of supersaturation. Figure 3 illustrates this relation.

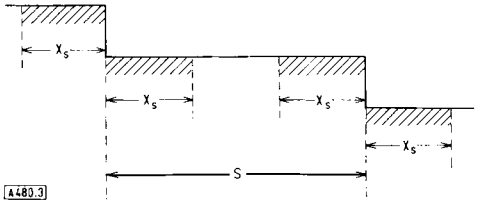

Fig. 3. Cross-section through a growing face. $x_s$: mean diffusion path; s: distance between steps.

The hatched regions on either side of the step represent the catchment area for molecules able to reach the step. Only this part of the total surface contributes to growth. Molecules which impinge on the blank part of the surface on the average re-evaporate before they reach a step. However, Equation (7) is valid only for low degrees of supersaturation, *i.e.* as long as the hatched regions in Fig. 3 do not intersect.

At higher degrees of supersaturation, s in Equation (4) becomes very small. The number of structural units reaching a step then no longer depends on $x_s$, since all impinging units do so. Equations (6) and (7) become

$$w_{II} = s f_0 \alpha_K \alpha_H \Delta\dot{N}/2 \qquad (8)$$

$$R_{II} = d_0 f_0 \dot{N} \alpha_K \alpha_H \Omega \qquad (9)$$

At higher degrees of supersaturation, R is proportional to $\Omega$.

[26] *I. N. Stranski* and *L. Krastanow*, S.-B. Akad. Wiss. Wien, math.-naturwiss. Kl., Abt. IIb, *146*, 797 (1938).

[27] *M. Volmer* and *W. Schultze*, Z. physik. Chem. *A 156*, 1 (1931).

[*] For a mathematically more complicated spiral, $s = 19\, r_n$ [28].

[28] *N. Cabrera* and *M. M. Levine*, Philos. Mag. [8] *1*, 450 (1956).

Equations (7) and (9) represent the limiting cases for low and high degrees of supersaturation, respectively, of the equation given by *Burton, Cabrera,* and *Frank* [13]:

$$R_{I,II} = d_0 f_0 \dot{N} \alpha_K \alpha_H (\Omega^2/\Omega_*) \tanh (\Omega_*/\Omega) \text{ [*]} \quad (10)$$

$\Omega_*$ is the characteristic degree of supersaturation at which the quadratic relationship is transformed into the linear one:

$$\Omega_* = 2\pi\rho f_0/x_s kT \quad (11)$$

For a real crystal, R can be formally expressed by

$$R = \alpha R_{max} = \alpha_F \alpha_K \alpha_H R_{max} \quad (12)$$

where $\alpha$ is the overall condensation coefficient given by the ratio of the experimentally or theoretically determined rates of growth to the gas-kinetically maximum possible rate $R_{max} = f_0 d_0 \Delta\dot{N}$. The factor $\alpha$ can be resolved into partial condensation coefficients which allow for the following retardations during growth [**]: surface diffusion ($\alpha_F$), diffusion at the growth step ($\alpha_K$), and possible obstructions during incorporation in the kink ($\alpha_H$). The factor $\alpha_F$ is obtained from Equations (10) and (12) as $(\Omega/\Omega_*) \tanh (\Omega_*/\Omega)$. For $\Omega < \Omega_*$,

$$\alpha_F = \Omega/\Omega_* = 2 x_s/s \quad (13)$$

For $\Omega > \Omega_*$, $\alpha_F$ reaches the value 1. For simple metal and molecular lattices, $\alpha_K \approx 1$ [13,29]. For $\alpha_H$ we may write [13]:

$$\alpha_H = (1 + x_s \tau/r \tau_F)^{-1} \quad (14)$$

where $\tau_F$ is the residence time of a building unit on the face before it re-evaporates, r is the distance between the units in the step, and $\tau$ is the relaxation time, *i.e.* the time required to re-establish $\Omega = 0$ at the kink after incorporation of a unit. $\alpha_H$ becomes less than unity when the entropy of rotation of the adsorbed molecules is much greater than that of the molecules inside the solid.

The mean diffusion path $x_s$ which appears in Equations (6) to (14) can be related to the surface diffusion coefficient $D_F$ and to $\tau_F$ by means of the Einstein equation

$$x_s^2 = D_F \tau_F \quad (15)$$

with the following values for $D_F$ and $\tau_F$ [13,15]:

$$D_F = r^2 \nu e^{-(\varphi_{ads} - \varphi_{saddle})/kT} \quad (16)$$

$$\tau_F = (1/\nu') e^{\varphi_{ads}/kT} \quad (17)$$

$\nu$ and $\nu'$ are two frequency factors, of the order of $10^{-13}$ sec$^{-1}$, which as an approximation can be equated; $\varphi_{ads}$ and $\varphi_{saddle}$ denote the work of separation of a building unit from the adsorption site in the surface or from a saddle position between two adsorption positions. $x_s$ is then given by

$$x_s = r e^{\varphi_{saddle}/2kT} \quad (18)$$

Estimates for the close-packed faces of simple lattices lead to values of $10^2$ r to $10^3$ r [13,15] for the mean diffusion path.

## 3. Consideration of Further Factors Affecting Growth of Real Crystals

The equations for the rate of growth given in the previous section contain several simplifying assumptions. For comparison with results obtained under experimental conditions, these equations have to be modified. The principal considerations are:

(a) When the step spacing s is smaller than the mean diffusion path $x_s$ on the surface, the spiral may become unstable.

(b) Numerous dislocations are generally present.

(c) The surrounding gas phase usually contains foreign gases.

(d) High growth steps may form.

(a) According to *Hirth* and *Pound* [14,30,31], at $\Omega > \Omega_*$, *i.e.* when $s < x_s$ according to Equations (4), (5), and (11), the growth steps have a tendency to accelerate their advance. Since the outer spiral turns run ahead, s increases until the value 6 $x_s$ is reached asymptotically. $\alpha_F$ then becomes $1/3$ according to Equation (13). Within a limited region in the vicinity of the point of penetration of the dislocation, the smaller distance given by Equation (4) remains valid. The proportion of these regions increases with increasing dislocation density so that $\alpha_F$ varies between $1/3$ and 1 [14].

(b) The influence of the number of dislocations is governed by the ratio of the spacing $d_V$ between them and the radius of the nucleus $r_n$. Four possibilities arise already in the case of two screw dislocations [13,14]:

($\alpha$) Dislocations of opposite sign and $d_V > 2\pi r_n$. The two spiral systems unite to form circular terraces whose spacing corresponds to that between the individual spirals.

($\beta$) Dislocations of opposite sign but with $d_V < 2r_n$. Here the step joining the two centers is unable to grow because it is shorter than the nucleus. The effects of the two dislocations cancel.

($\gamma$) Dislocations of the same sign, $d_V > s/2 = 2\pi r_n$. Joining together of the parts of the two spirals leads to a spiral with a spacing between turns corresponding to that of the individual spiral.

($\delta$) Dislocations of the same sign but with $d_V < 2\pi r_n$. The two spirals do not intersect. Since s has only half its former magnitude, R is doubled.

In the general case of numerous dislocations, the growth rate is different from that found in the presence of a single screw dislocation when non-compensating screw dislocations of the same sign with a spacing smaller than $2\pi r_n$ are present on the surface. The arrangement with the largest number of such dislocations determines the rate of growth. If $\varepsilon$ is the number of these dislocations, R increases approximately by a factor $\varepsilon$. The increase is possible only as long as the distance between the growth steps is sufficiently large compared with $x_s$. Suitable dislocation groups therefore

[*] Here, the factor $\nu e^{-w/kT}$ used in [13] ($\nu$ = vibration frequency, w = molar heat of vaporization) is replaced by $f_0\dot{N}$.

[**] If not all impinging molecules enter the adsorbed layer, an additional partial condensation coefficient must be introduced.

[29] *H. Heyer*, Dissertation, Freie Universität Berlin, 1962.

[30] *J. P. Hirth* and *G. M. Pound*, J. physic. Chem. *64*, 619 (1960).

[31] *J. P. Hirth* and *G. M. Pound*, Acta metallica *5*, 649 (1957).

transform the quadratic law (7) into the linear one (9) for degrees of supersaturation smaller than $\Omega_*$ (cf. Equation 11). The formation of dislocation groups is related to the degree of supersaturation $\Omega$ in accord with the above criteria. As the degree of supersaturation grows, a splitting into individually effective dislocations ensues.

(c) Foreign substances contained in the mother phase can influence growth in various ways. Adsorption causes the specific free surface energy $\sigma$ and the specific free ledge energy $\rho$ to be reduced[*]. In the case of growth *via* two-dimensional nuclei, $\Delta G'_n$ and hence $\Omega_{cr}$ are lowered. At the same time, a frequency factor introduced in the statistical thermodynamic derivation of $\Delta G'_n$ decreases[14]. This causes the values of $\Delta G'_n$ and $\Omega_{cr}$ to increase, but in general the first-mentioned effect predominates.

During growth by a dislocation mechanism, a lowering of $\rho$ effects a decrease in the step spacing and a consequent acceleration of growth. Reduction in $x_s$, however, retards the growth. The most important factor is the decrease in concentration of structural units in the adsorbed layer[14], leading to a retardation of growth.

When relatively immobile foreign molecules or aggregates are present on the surface, these obstruct the advance of the steps when their spacing is smaller than $2r$[32]. The concentration of these particles depends on the growth rate and the number of foreign molecules $\dot{N}_F$ striking a unit area per unit time. Assuming uniform distribution, the limiting degree of supersaturation below which the steps no longer advance is given by

$$\Omega_{w=0} = \text{const}\,(\dot{N}_F)^{1/3} \qquad (19)$$

(d) If the height of a growth step is a multiple of that of a monomolecular step, w is given by

$$w_d = (d_0/d)\, w_{d_0}\,(1 + d/x_s) \qquad (20)$$

where $d_0$ and d denote the heights of the mono- and polymolecular steps, respectively, and $w_{d_0}$ is given by Equation (6). The second term in the brackets allows for the direct condensation on the front face of the step. Also s will change, and $\rho$ in Equation (5) must be replaced by

$$\rho_d = (d/d_0)\, a\, \rho_{d_0} \qquad (21)$$

where $\rho_d$ is the specific free ledge energy for a step of height d and $\rho_{d_0}$ that for a monomolecular step. For simple nonpolar lattices $a \approx 2$[29], but it can assume values of less than 1 for ionic lattices. When it is further considered that $f_0$, the area occupied by a building unit, must be divided by $d/d_0$ in the case of high steps, the value of s for high steps corresponding to Equation (4) is

$$s_d = a\, s_{d_0} \qquad (22)$$

According to *Chernov*[15, 33], the frontal area of high steps is not plane because of the preferential addition on the base and at the upper edge.

Various causes for formation of high steps have been put forward. According to *Frank*[34] and *Forty*[35], the height of the step is determined by the component of the Burgers vector[*] normal to the surface. Its magnitude can be determined by the substrate on which the crystal has formed or by "accidents" during growth[36].

If the line of dislocation progresses in the form of a spiral, the center of the latter "rotates" during growth. In this way, a macroscopic spiral is formed[37] (cf. also[38]).

If a time-dependent impurity adsorption is postulated[14, 39], the velocity of a step will depend on the distance from the preceding one. This causes an equidistant sequence of steps to become unstable. Where a step has assumed a position somewhat remoter from the preceding one, its velocity will be reduced further because adsorption has increased. It is therefore readily caught by the next step whose velocity increases as it approaches its predecessor.

Because of (a) to (d) the growth of a real crystal will generally be retarded. For $\Omega < \Omega_*$, the formal relationship

$$R_I' = (d_0\, \varepsilon/d\, a\, b) R_I \qquad (23)$$

may be written, where $\varepsilon$ allows for the increase in $R_I$ caused by groups of dislocations, while $d/d_0$, a, and b allow for the decrease in $R_I$ caused by high steps, the reduction in $\rho$, and the effect of adsorption on w.

Fig. 4 shows the relationship between the rate of growth and the degree of supersaturation in schematic form. It demonstrates that in the case of real crystals the degree of supersaturation can give rise to different growth mechanisms, whose ranges of validity are defined by $\Omega_*$ and $\Omega_{cr}$. For the different substances and the special growth conditions discussed above, $\Omega_*$ and $\Omega_{cr}$ can differ widely. During growth in less pure surroundings (*e.g.* with foreign gases in the mother

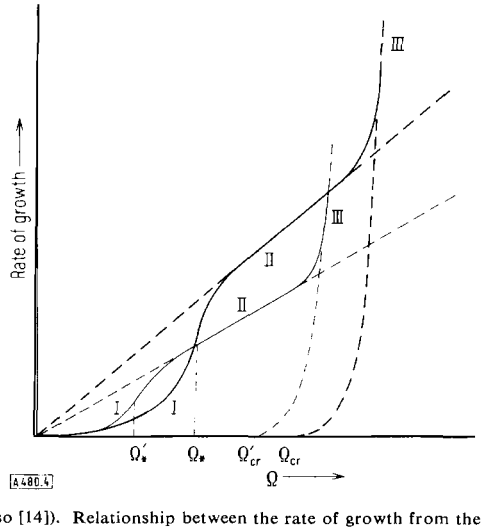

Fig. 4 (cf. also [14]). Relationship between the rate of growth from the vapor and the degree of supersaturation. The thick solid curve is the growth rate of real crystals according to Equations (7) (range I), (9) (range II), and (1) (range III).

Where no dislocations are present, growth can only commence at $\Omega = \Omega_{cr}$. The transition from the quadratic to the linear relationship is indicated by $\Omega_*$ [see Equation (11)]. The thinner curve gives a possible course of $R'_I = f(\Omega)$ [Equation (23)] with $\Omega'_*$ and $\Omega'_{cr}$ as transition points between the three ranges.

phase) the values are generally smaller. This behavior explains the different mechanisms observed for approximately the same degrees of supersaturation.

## 4. Experimental Studies

For growth from the vapor phase, the values of $\Omega_{cr}$ will hardly ever be less than 0.5. At the lower degrees of supersaturation employed for growing single crystals, therefore, growth takes place according to the quadratic Equation (7) or the linear relationship (9). The presence of dislocations is almost invariably required during growth from the vapor phase (only whisker growth provides exceptions). Evidence for a nucleation mechanism has been observed only in the case of dendritic growth and growth of whiskers at degrees of supersaturation above $\Omega_{cr}$.

*Volmer* and *Schultze*[27] have investigated the growth of iodine, naphthalene, and white phosphorus at 0 °C and supersaturations between 0.004 and 0.08[*]. For naphthalene and phosphorus, they found only a linear growth relationship, but for iodine the rate of growth decreased below $\Omega = 0.04$ faster than expected from the linear relationship, and at $\Omega = 0.004$ the growth rate was practically zero. The authors interpret this result as a confirmation of the nucleation theory, while *Burton*, *Cabrera*, and *Frank*[13] subsequently carried out an evaluation according to the quadratic relation.

*Bradley* and *Drury*[40] studied the growth of iodine and carbon tetrabromide crystals. For iodine, the measurements were carried out between 0 and 25 °C and at supersaturations between 0.002 and 0.07. The monoclinic modification of $CBr_4$, stable up to 47 °C, was studied at 40 °C for supersaturations between 0.0004 and 0.03, and the cubic structure at 50, 55, and 59 °C for Ω-values between 0.0001 and 0.04. A quadratic relationship between R and Ω was found for iodine and cubic $CBr_4$, while a linear change was observed for monoclinic $CBr_4$ down to the lowest supersaturation employed.

*Parker* and *Kushner*[41] studied the condensation of zinc at 390 °C and Ω-values between 0.009 and 0.09. These authors found an only approximately linear relationship with $\alpha \approx 0.1$. In contrast, *Rapp*, *Hirth*, and *Pound*[42] obtained $\alpha \approx 1$ at 70 °C and higher values of Ω.

For β-methylnaphthalene and *p*-toluidine, *Chernov* and *Dukova*[33] found a relationship between the growth rate and Ω which corresponds approximately to regions I and II in Fig. 4 (see Fig. 5).

The characteristic degree of supersaturation $\Omega_*$ [see Equation (11)] was greater for higher ($d = 60\ d_0$) than for lower steps ($d$ = several $d_0$). As Ω increased, the spirals disappeared and a circular step surrounding the point of origin of the dislocation remained. This behavior was interpreted by postulating a splitting of the original spiral with a high Burgers vector into separate dislocations.

*Kitchener* and *Strickland-Constable*[43] determined the growth and evaporation rates on the (111) faces of orthorhombic sulfur and the (110) and (111) faces of orthorhombic benzophenone, as well as on polycrystalline benzophenone,

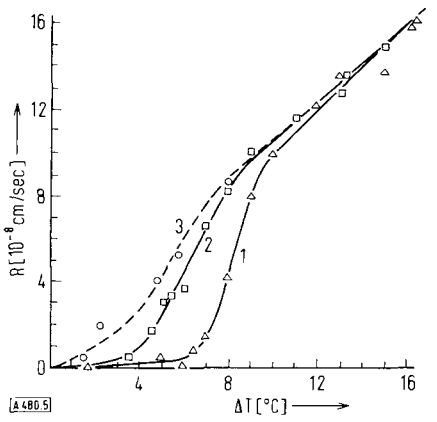

Fig. 5. Growth rate of β-methylnaphthalene in relation to the height of the step. 1: $d = 4d_0$; 2: $d = 40d_0$; 3: $d = 60d_0$ (from [33]).

as a function of Ω between 15 and 60 °C. During growth, Ω was varied between 0.07 and 0.20 and during evaporation between 0.05 and 0.15. The resulting curves (Fig. 6) are linear for the larger values of Ω. Here $\alpha < 0.1$. The bent portion was treated according to Equation (7).

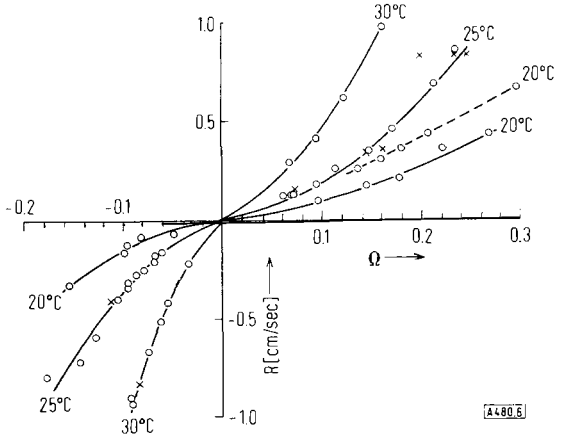

Fig. 6. Growth rate and evaporation rate of the (110) faces of benzophenone at 20, 25, and 30 °C (taken from [43]). - - - Measurements made immediately after those at 30 °C; × control values.

Investigations on ice crystals by *Shaw* and *Mason*[44] gave a quadratic relationship between Ω and R. In addition, R was strongly dependent on the size of the crystal. The derivative $d(2h)^2/dt$ (2h is the distance between opposite faces) was found to be constant for a given value of Ω.

Measurements of the growth rate of individual (110) faces of urotropine and (111) faces of arsenolite crystals[29,45] indicated an approximately quadratic relationship between Ω (0.004–0.4) and R for microscopically smooth faces, while a defective face in the same Ω range gave an approximately linear relationship (Fig. 7).

The increase in R related to the change-over to the linear relationship was explained by an increase in the dislocation density.

The dependence of the rate of advance of the growth steps w on the ratio $d/d_0$ (d = step height) was measured for naphthalene, biphenyl, and *p*-toluidine crystals at $\Omega = 0.01$ by *Lemmlein*, *Dukova*, and *Chernov*[46,47]. The resulting curves are reproduced in Fig. 8 and obey Equation (20).

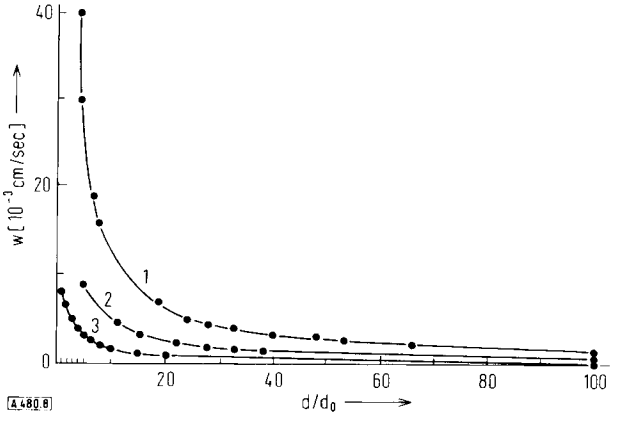

Fig. 8. Relationship between the rate of advance w of the growth steps and the ratio $d/d_0$ (d = step height).
1: *p*-toluidine; 2: biphenyl; 3: naphthalene (from [47]).

*Hallett*[48] investigated the growth of ice crystals at atmospheric pressure in relation to the temperature and the degree of supersaturation. The rate of advance of the steps on the basal face was found to be inversely proportional to the step height, in accordance with Equation (20).

Numerous other papers furnish information about the mechanism of crystal growth without giving growth rate figures. Let us mention only two experimental techniques which give details about the surface structure at atomic dimensions. The first concerns studies with the field electron and the field ion microscopes[49–51], the second deals with electron microscopic studies of gold decorated NaCl surfaces[52].

[48] *J. Hallett*, Philos. Mag. [8] *6*, 1073 (1961).

The presence of pure solvent is enough to reduce appreciably the value of the specific free ledge energy ρ. This leads to a decrease in the work of two-dimensional nucleation and a displacement of $\Omega_{cr}$ toward small values. In addition, diffusion in the solution can become the rate-determining factor. Since surface diffusion is also decreased, direct addition on the step or on the kink begins to compete with the route mother phase → surface → step → kink.

### 1. Growth Rate Theory

The nucleation theory yields an equation for the rate of growth differing from Equation (1) by a factor $e^{-\Psi_{L/k}}$, which makes allowance for the activation energy $\Psi_L$ for the transfer of a molecule from solution into the crystal.

For real crystals, a sequence of growth steps brought about by screw dislocations is again made the basis of the theory[15]. The rate of advance w is now given by:

$$w = \pi\, v_0\, \beta\, (c_\sigma - c_e) = \pi v_0 \beta c_e \Omega (1 + \frac{\beta r}{D} \ln \frac{s}{\pi r} \sinh \frac{\pi}{s} \delta)^{-1} \qquad (24)$$

where $v_0$ is the volume of the molecule, $c_\sigma$ the concentration of the solution, $c_e$ the saturation concentration, and β a factor which allows for the rate of exchange of building units between step and solution. D is the diffusion coefficient and δ the thickness of the diffusion layer. The factor β diminishes when the number of kinks in the step is reduced. Using Equation (3), the rate of growth becomes

$$R_I = dw/s = f_0 \beta k T c_e \Omega^2 \left[4\rho\,(1 + \frac{\beta r}{H} \ln \frac{\delta \Omega_*}{r\Omega} \sinh \frac{\Omega}{\Omega_*})\right]^{-1} \qquad (25)$$

In this equation, the expression in parentheses represents the relationship between the condensation coefficient and the supersaturation. In Equations (24) and (25) $\Omega = (c_\sigma - c_e)/c_e$, and $\Omega_*$ is given by

$$\Omega_* = 4\, f_0\, \rho / kT\delta \qquad (26)$$

For $\Omega \ll \Omega_*$, the growth steps are so far apart that the diffusion fields do not overlap. As in growth from the vapor phase, R is proportional to $\Omega^2$. As Ω increases, s becomes less than δ. Equation (25) is then transformed into

$$R_{II} = \frac{D\, v_0 c_e}{\delta} \Omega - \left(1 + \frac{\beta r}{D} \ln \frac{\Omega_* \delta}{2\Omega r}\right) \frac{D^2\, v_0\, c_e\, \Omega_*}{\beta\, r\, \delta} \qquad (27)$$

This almost linear function of Ω cuts the ordinate below the origin when extrapolated. An approximation for the range $0.01 < \Omega < 0.2$ is

$$R = (\beta\, r\, k\, T\, c_e / 4\sigma)\, K\, \Omega^L \qquad (28)$$

The values of the constants K and L are determined by those of the parameters in Eqs. (25) and (27). Fig. 9 shows the relationship between the growth rate and the degree of supersaturation.

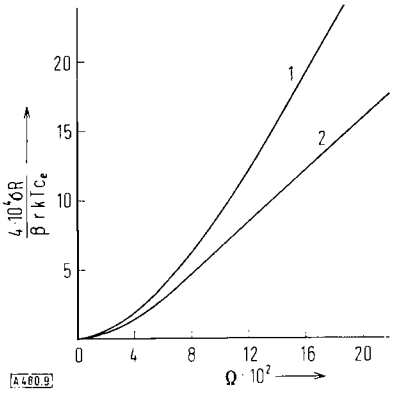

Fig. 9. Normalized growth rate from solution as a function of supersaturation (according to Equation (28); from [15]).
Curve 1: K = $4\times10^{-2}$, L = 1.65, $\delta$ = $3.5\times10^{-5}$ cm; curve 2: K = $1.7\times10^{-2}$, L = 1.42, $\delta$ = $7\times10^{-5}$ cm.

## 2. Experimental Investigations

*Booth* and *Buckley*[53] measured the growth rates of individual faces of ethylenediamine L-tartrate crystals and obtained the relationship shown in Fig. 10. The curves match the theoretical ones in Fig. 9. The presence of impurities reduces the growth rate and causes a displacement of $\Omega_*$ to smaller values.

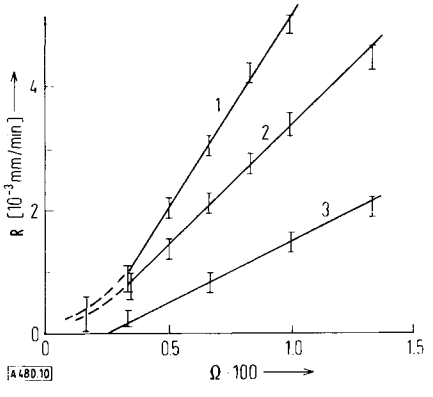

Fig. 10. Growth rate of ethylenediamine L-tartrate crystals from solution. 1: at 52 °C; 2: at 42 °C; 3: at 42 °C with 0.5 g/l added boric acid (from [53]).

*Bennema*[54] observed a linear relationship between R and $\Omega$ for the growth of potassium alum from aqueous solution, with $\Omega$ lying between 0.0001 and 0.01.

Studies of the layer-growth of β-methylnaphthalene crystals from alcoholic solution by *Kozlovskii* and *Lemmlein*[55] confirmed the relationship given by Equation (20).

In contrast, several observations can be interpreted by a nucleation mechanism. *Spangenberg* and *Nitschmann*[56] found that NaCl crystals obtained from aqueous solution begin to grow only above $\Omega_{cr}$ = 0.00045. A supersaturation region which is ineffective for growth is, however, found only when the crystal is bounded by (100) faces. Crystals with artificially created (011) and (111) faces start growing as soon as supersaturation is reached. This is important because it makes the interpretation of the cessation of growth as an adsorption effect very unlikely. *Neuhaus*[57] also found a critical degree of supersaturation of $\Omega_{cr}$ = 0.0028 for $CuCl_2 \cdot 2H_2O$. However, the observed linear rise of R with increasing supersaturation in the adjacent region of $\Omega$ values between 0.0028 and 0.007 is in conflict with a two-dimensional nucleation mechanism.

*Michaels* and *Colville*[58] studied the growth of adipic acid crystals at 25–45 °C from pure aqueous solutions and after the addition of anionic and cationic surface-active substances, and found an exponential relationship between R and $\Omega$ for values of $\Omega$ between 0.16 and 1.20 for the (110), (010), and (001) faces of the orthorhombic crystals. Anionic additives slow down growth markedly, cationic ones only slightly.

## IV. Growth from the Melt

Growth from the melt is subject to the same rules which govern growth from solution, but in addition, the effect of thermal conductivity is significant since there is much less difference between the coefficients of thermal conductivity of the crystals and the melt than between those of the crystal and the solution. New growth-form criteria are thereby created. Where the heat is taken up by the crystal, as in most pulling and solidification processes, rounded crystals are generally formed, since the growth front is now determined by the position of the isothermal surface at the melt temperature and not by kinetic processes[27]. Only where stronger supercooling or greater differences in thermal conductivity cause the removal of sufficient heat through the crystal to lead to the formation of a region of supercooled melt in front of the crystal, is the kinetic process again able to compete, with possible appearance of polyhedral shapes. Where the heat is taken up by the melt, only polyhedral shapes will be formed.

The experimental study of growth kinetics is made difficult above all by the fact that the temperature of the melt in the immediate vicinity of the phase boundary and therefore the effective degree of supercooling is not known accurately.

### 1. Growth Theory

The nucleation theory again supplies an expression analogous to Equation (1) with an additional term $e^{-\Psi_s/kT}$ where $\Psi_s$ is the activation energy for the transition of a molecule from the melt into the crystal[8,23,59–61]. Using

$$\Delta G'_n = A\, M\, \rho^2\, T_s/2\, d_0\, \gamma\, \Lambda_s\, \Delta T \qquad (29)$$

[57] *A. Neuhaus*, Angew. Chem. *71*, 678 (1959).

[58] *A. S. Michaels* and *A. R. Colville Jr.*, J. physic. Chem. *64*, 13 (1960).

[59] *M. Volmer* and *M. Marder*, Z. physik. Chem. *A 154*, 97 (1931).

[60] *W. I. Danilov* and *W. I. Malkin*, Zh. fiz. Khim. *28*, 1837 (1954).

[61] *D. Turnbull*, Solid State Physics *3*, 225 (1956).

where A is a geometric factor, M the molecular weight, $T_s$ the temperature of the melt, $\gamma$ the density, $\Lambda_s$ the molar heat of fusion and $\Delta T = T_s - T$ is the degree of supercooling, R is obtained as

$$R = d\, He^{-\Psi_s/kT}\, e^{-\Delta G'_n/kT} \qquad (30)$$

Although our knowledge of the melt-crystal interface is as yet very incomplete – both a step structure and a more or less uniform distribution of the kinks have been proposed for the growing face [15] – direct observations of the growth of spirals in phenyl salicylate [62] and in β-methylnaphthalene [63] as well as observations of growth steps after removal of the melt [64–66] appear to indicate that treatment by the theory of dislocations is justified. The following expression for R [15] is analogous to Equation (25):

$$R = f_0 \beta_T \lambda_s T_s \Omega^2 \left[ 4\rho \left(1 + \frac{\beta_T r \lambda_s}{\varkappa} \ln \frac{\delta\Omega}{r\Omega}\right) \sinh \frac{\Omega}{\Omega_*} \right]^{-1} \qquad (31)$$

where $\Omega$ is the relative degree of supercooling $(T_s - T)/T_s$, $\lambda_s$ is the molecular heat of fusion, and $\varkappa$ the thermal conductivity. $\beta_T$, like $\beta$ in Equation (25), denotes the rate of particle exchange between the melt and the step, and is given approximately by

$$\beta_T = D\, \lambda_s / v_0\, r\, k T_s^2 \qquad (32)$$

where D is the coefficient of diffusion through the melt.

The existence of either a linear or a quadratic relationship between R and the degree of supercooling depends not only on the ratio $\Omega/\Omega_*$ but also on $\varkappa$. A high thermal conductivity tends to make the factor $r\beta_T\lambda_s/\varkappa$ zero, and favors the quadratic relationship. As in the case of the solutions, R can be written as the following function of $\Omega$ for small values of $\Omega$:

$$R = (f_0 \beta_T \lambda_s T_s / 4\rho)\, K\, \Omega^L \qquad (33)$$

When plausible values of r, $v_0$, $\rho$, $\beta_T$, D, and $T_s$ are introduced, one obtains $K \approx 0.1$ and $L \approx 1.7$. L depends weakly and K strongly on the assumed values.

## 2. Experimental Investigations

Numerous investigations confirm the relationship (33). The equations obtained for R are shown in Table 1 in the form $R = K' (\Delta T)^L$.

Other work points to growth *via* two-dimensional nuclei. This is true also for some of the substances listed in Table 1, for which Equation (33) applies only during the initial stages, so that the references quoted can be taken only partially as confirmation of the dislocation growth mechanism.

The curve found by *Volmer* and *Marder* [59] for glycerol fits Equation (30) over the measured supersaturation range.

Table 1. Growth from the melt; experimental values of the parameters in the equation $R = K'(\Delta T)^L$ (cf. [15, 61]).

| Substance | K' [cm/sec °K] | L |
|---|---|---|
| Water [67] | $1.6\times10^{1}$ | 1.7 |
| Water [68] from −2 to −3.1 °C | $1.3\times10^{2}$ | 2.9 |
| from −3 to −6.5 °C | $7.55\times10^{2}$ | 2.32 |
| Glycerol [59] | $8\times10^{6}$ | 1.7 |
| Phenyl salicylate [69] ($\Delta T < 6$ °C) | $4\times10^{4}$ | 1.7 |
| Phenyl salicylate [69] ($\Delta T > 6$ °C) | $1.56\times10^{5}$ | 2.3 |
| Tin [70] | 0.7 | 1.8 |
| Phosphorus [71, 72] | 1.0 | 1.7 |

*Hillig* [67] found an exponential relationship between R and the degree of supercooling for the growth of microscopically smooth basal planes of ice:

$$R = 0.03\, e^{-0{,}35/\Delta T}\ \text{cm/sec} \qquad (34)$$

Defective faces exhibited a higher growth rate (*ca.* 300 times as great at $\Delta T = 0.03$ °C) proportional to $\Delta T^{1.3}$.

*Danilov* and *Malkin* [60] also found an exponential relationship for phenyl salicylate up to a supercooling of 2.6 °C. The latent region extending up to 1.6 °C supercooling is particularly noteworthy (cf. Fig. 11).

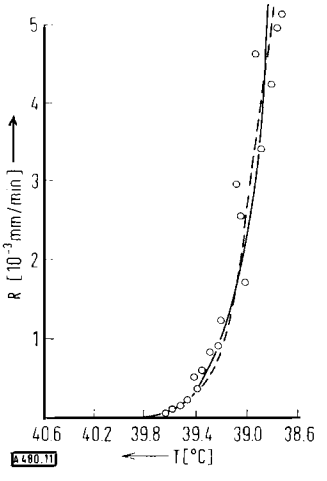

Fig. 11. Growth rate of phenyl salicylate from the melt (taken from [60]). – – – –: calculated curve.

## V. Growth of Platelets, Whiskers, and Proper Whiskers

A special form of growth is the formation of either platelets or acicular crystals which are generated during preferential growth in either two or only one direction. The acicular crystals are divided into whiskers and proper whiskers (or squeezed whiskers), according to whether their growth takes place at the tip or the base, though the term "whisker" is mostly applied to both forms. Literature surveys are given, *e.g.*, in [73–75].

## 1. Whisker Growth

The growth process during the formation of whiskers is characterized by an initially high velocity in the longitudinal direction with simultaneous cessation of growth of the side faces. At a critical length the rapid growth suddenly stops. End and side faces now grow at normal rates, or the growth ceases entirely. The axis of the whiskers always follows crystallographic directions of low indices. Occasionally, changes in orientation occur so that kinked whiskers are formed [76,77]; spiral forms are less common [77].

Adsorption processes are evidently important factors in the growth of platelets and whiskers; whisker growth from the vapor phase is observed only when foreign gases are present. For instance, zinc whiskers are formed from the vapor [78] at partial pressures of He or $H_2$ between 10 and 600 mm. As the partial pressure increases, the whiskers become longer and thinner. In contrast, very high foreign gas pressures, especially of non-inert gases, lead to clusters and shorter whiskers or to dendritic forms. The conditions for whisker formation lie therefore halfway between those for isometric crystals and for dendrites.

*Sears* [79] postulated a preferential orientation of the screw dislocations in the crystal to explain the growth mechanism. Whiskers are supposed to contain one or more dislocations parallel to the long axis, while platelets have a two-dimensional network of dislocations. Accordingly, the end faces grow *via* a dislocation mechanism while the dislocation-free side faces require the formation of two-dimensional nuclei.

The structural units striking the side faces reach the tip by diffusion along the surface and are there incorporated into the lattice. This explains why whiskers are able to grow substantially more quickly than is indicated by the gas-kinetic impingement rate.

A theoretical treatment of the diffusion rate for the growth of whiskers from the vapor phase is contained in references [80–83]. According to these, the rate of growth of a whisker is given by

$$R = \Delta\dot{N}\, x_s\, (2\, m_0/r_N\gamma)\, \tanh\,(l/x_s), \qquad (35)$$

where $l$ and $r_N$ are the length and radius of the whisker, $m_0$ is the mass of a building unit, and $\gamma$ the density. For $l < x_s$, R is given by

$$R = \Delta\dot{N}\, l\, (2\, m_0/r_N\gamma), \qquad (36)$$

while for $l > x_s$

$$R = \Delta\dot{N}\, x_s\, (2\, m_0/r_N\gamma). \qquad (37)$$

Shorter whiskers therefore obey an exponential and longer whiskers a linear growth law. $x_s$ was found to be 65 $\mu$ (at 53 °C) for potassium and 50–122 $\mu$ for mercury (at −51 to −68 °C.).

Whisker and platelet growth from the vapor phase has been studied above all for mercury [79,82,84,85,90] and for potassium [80–82,86–88,91]. A linear dependence of the growth rate on supersaturation was found by *Dittmar* and *Neumann* [80] for potassium, and by *Sears* [79] for mercury. The exponential relationship was observed by *Gomer* [90] and by *Parker* and *Hardy* [91] during studies on mercury and potassium with the field electron microscope. *Parker*, *Anderson*, and *Hardy* [82] found both relationships with both these substances. Fig. 12 shows the longitudinal growth rate of potassium whiskers [89].

These experiments confirm the concept according to which the rapid whisker growth ceases when $\Omega > \Omega_{cr}$, because under this condition the side faces can grow *via* two-dimensional nuclei.

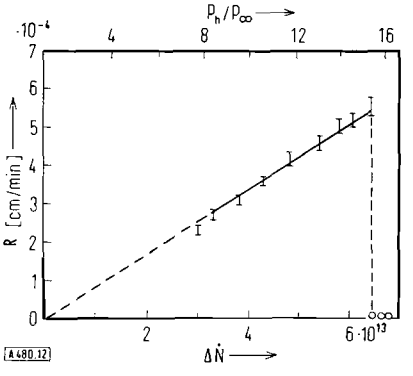

Fig. 12. Longitudinal growth rate of potassium needles at 55.8 °C $\Delta\dot{N}$ is the difference between the number of impingements obtained from the kinetic theory of gases at the temperature of the vapor and the temperature of the crystal. $p_h/p_\infty$ is the supersaturation ratio. The rate of growth R decreases sharply when the critical supersaturation for the side faces is rached (from [89]).

Objections to the above growth mechanism are provided by the dislocation content of the whiskers [92], since whiskers with and without axial dislocations have been found.

Whiskers are also formed during growth from solution, from the melt, and from solid phases [73].

## 2. Growth of Proper Whiskers

Spontaneous growth of proper whiskers occurs during the annealing of thin metal layers deposited on metal or glass substrates.

Examples are layers (*ca.* 1 μ thick) of Sn, Sb, Bi, Zn, Cd, and of Sn–Al and Pb–Cu alloys on copper, tombac, steel, and glass substrates [93–99]. The surrounding vapor phase has no effect on the progress of growth. The whiskers produced generally have a diameter equal to the layer thickness, and grow to a length of several millimeters. They consist of material of the respective layer or in the case of alloys generally of one of the components. Growth ensues by building up at the base of the whisker, so that the often irregularly shaped head remains unaltered. The longitudinal axis lies in a low-index direction.

It is postulated that the growth of proper whiskers represents a special form of recrystallization [73, 100]. The normal recrystallization which initially occurs during tempering after deposition of the layer is inhibited by stationary grain boundaries when the grain size reaches the order of magnitude of the layer thickness [101]. Growth of whiskers with a diameter equal to this grain size then takes place out of the layer. The driving force consists of stresses generated in the layer by the strongly anisotropic thermal expansion of the crystals [96]. Temperature changes of a few degrees are sufficient to bring this about. The material transport presumably takes place by grain boundary diffusion. When all stresses have been eliminated, longitudinal growth and formation of fresh whiskers cease almost at once and at the same time. At higher temperatures (above about 200 °C) the activation energy for the movement of the inhibited grain boundaries is available, making possible normal recrystallization.

Growth of proper whiskers can be produced also by mechanical deformation. One example is the formation of tin whiskers on tinned steel [99]. Application of pressure enabled the rate of growth to be increased by a factor of $10^4$ [102]. It is assumed that dislocation rings move out from the substrate during growth [103–107].

At more rapid growth rates, crystal forms often arise which, because of their appearance, are designated as dendrites. The dendritic branches represent preferred growth directions which correspond to lower-index crystallographic directions of the respective lattice. Dendritic growth occurs when $\Omega \gg \Omega_{cr}$ and when the development of the nuclei is retarded by diffusion or by heat conduction processes.

Information about the growth process is provided by observations of the alteration of the dendritic axes with increasing degree of supersaturation during crystallization of NaCl from pure and impure solutions [108]. As the degree of supersaturation increases, the dendritic direction changes in the sequence (111) → (110) → (100). An explanation for this change was found in the difference between the work of nucleation at the corner, edge, and face of ionic crystals [26, 108, 109]. Both the pre-exponential factor H and the work of two-dimensional nucleation $\Delta G'_n$ in Equation (1) have maximum values in the center of the face, fall off at the edges, and are a minimum in the corners. All nucleation work factors decrease as the degree of supersaturation is increased, so that the frequency factor H becomes the decisive quantity in determining the nucleation frequency. The same change in dendritic direction with rising degree of supersaturation occurs when the work of nulceation is reduced by adsorption. Addition of increasing concentrations of formamide, urea, and aminoacetic acid led to a shift of the dendritic growth from (111) to (100) [110, 111].

Experiments from the melt and with other NaCl-type crystals gave the same result. Analogous studies with CsCl, CsI, and TlCl showed [108] a shift of the dendritic axis in the order (100) → (111) → (110).

# Kinetic Relationships between Reactions in the Gas Phase and in Solution

BY PROF. DR. H. MARTIN

INSTITUT FÜR PHYSIKALISCHE CHEMIE DER UNIVERSITÄT KIEL (GERMANY)

*Dedicated to Professor W. Klemm on the occasion of his 70th birthday*

*Some recent examples of reactions proceeding both in the gas phase and in solution have been investigated to determine their kinetics and mechanisms. The ratio of the corresponding rate constants, $k_G$ and $k_L$, of the elementary processes studied has been found to be about unity for unimolecular reactions and between 1 and 10 for bimolecular reactions. The mechanisms, overall rates, rate constants, and activation energies have been determined for the homogeneous gas reaction $NOCl + Cl_2O = NO_2Cl + Cl_2$ and the reaction $NOCl + N_2O_5 = NO_2Cl + 2\ NO_2$, carried out in $C_2F_3Cl_3$.*

## I. Introduction

Of the thousands of reactions that have been studied in solution, hardly ten have also been investigated in the gas phase. This is very surprising since it is of general theoretical interest to compare the kinetics of a reaction occurring in solution with those of a gas-phase reaction. Moreover, from a molecular point of view it is easier to describe the reaction in the gas than in a condensed phase, since in the latter the reacting entities are constantly in contact with four, six, or more surrounding particles.

The reason why so few solution reactions have also been studied in the gas phase is that a great number of reactions taking place in different solvents with various degrees of ease proceed *via* ionic mechanisms featuring polar or charged species. Polar solvents promote ionic reactions – the more polar the solvent the faster is the reaction. Ionic processes do not occur in the gas phase, except on a surface or at very high temperatures. Thus alkyl halides and esters are not hydrolysed in the gas phase to any measurable extent, and when we attempt to force the reaction by increasing the temperature, competing reactions become predominant.

It follows, therefore, that a reaction can be carried out in both the gas phase and in solution only if the interaction between the reacting molecule and the solvent molecules is so small that the non-ionic mechanism of the gas-phase reaction can equally well proceed in solution. In principle, this should be possible by the use of a non-polar, inert solvent.

For our kinetic investigations we selected reactions which had been studied in the gas phase and tried to carry them out in solution, in order to test the validity of the mechanisms determined for the gas-phase reactions. The reactions in question, *i.e.* those of $ClO_2$ and $Cl_2O$ with NOCl, $NO_2/N_2O_4$, and $N_2O_5$, are generally characterized by complicated kinetics. Our basic approach was as follows: provided that the elementary steps of the process do not change when the reaction, first carried out as a truly homogeneous gase-phase reaction, is performed in solution, the kinetic features found in the first case should also be valid (at least qualitatively) in the second case, particularly since the sequence of steps is assumed to be non-cyclic. When in fact the same overall stoichiometry and rate equation are found in both phases, we can infer that the elementary steps and their sequence also are the same, and the proposed mechanism of the gas reaction is then confirmed. When, however, the overall reaction and/or the rate equation are different for the reaction in solution, there are two possibilities: either the mechanism of the gas-phase reaction has been replaced by an ionic process in solution, or what we assumed to be a homogeneous gas reaction really has some heterogeneous character owing to wall effects. When the gas reaction is not homogeneous, we cannot expect to find the same kinetics in solution, since the latter process is not affected by the walls of the vessel.

## II. Survey of the Inorganic Reactions Investigated

The gas-phase reactions that have so far also been investigated in solution are listed in Table 1. Reactions (I) to (V) proceed in the non-polar, inert solvent 1,1,2-trichloro-1,2,2-trifluoroethane (denoted here by $C_2F_3Cl_3$) in the same way as they do in the gas phase:

Table 1. Reactions carried out in different phases.

| Overall reaction [a] | Phase [b] |
|---|---|
| (I) $ClO_2 + 3\,NO_2 = NO_3Cl + N_2O_5$ | Gas [1, 2] |
| | Solution [3, 8] |
| | Melt [4] |
| (II) $Cl_2O + 2\,NO_2 = NO_3Cl + NO_2Cl$ | Gas [5] |
| | Solution [6] |
| (IIa) $2\,Cl_2O + 2\,NO_2 = 2\,NO_3Cl + Cl_2$ | Melt [5] |
| (III) $ClO_2 + 2\,NOCl = NO_2Cl + NO_2 + Cl_2$ | Gas [7] |
| | Solution [8] |
| (IV) $4\,ClO_2 + 2\,N_2O_5 = 4\,NO_3Cl + 3\,O_2$ | Gas [1, 2] |
| | (Solution, melt) [9] |
| (V) $2\,Cl_2O + 2\,N_2O_5 = 2\,NO_3Cl + 2\,NO_2Cl + O_2$ | Gas [1] |
| | Solution [6] |
| (Va) $Cl_2O + N_2O_5 = 2\,NO_3Cl$ | Melt [5] |
| (VI) $Cl_2O + NOCl = Cl_2 + NO_2Cl$ | Gas [11] |
| | Solution [3] |
| (VIa) $Cl_2O + NOCl = 3/2Cl_2 + NO_2$ | Melt (−78 °C) [11] |
| (VII) $N_2O_5 + NOCl = 2\,NO_2 + NO_2Cl$ | Gas [12] |
| | Solution [13] |

[a] The formula $NO_2$ is used here to denote the mixture $NO_2/N_2O_4$ in the rapidly established equilibrium $2\ NO_2 \rightleftharpoons N_2O_4$. However, in some cases, particularly in condensates, practically only $N_2O_4$ is present.
[b] Solvent: $C_2F_3Cl_3$.

[1] *Th. Jacobsen*, Dissertation, Universität Kiel, 1955.

the stoichiometry and the rate equation are the same. Under otherwise the same conditions, reactions (I) to (III) are about three times as fast in solution at room temperature as in the gas phase. For the reactions (IV) and (V) even the rates are the same for the two phases. This is not surprising, since these reactions are governed by the dissociation of dinitrogen pentoxide [6, 10].

That each of reactions (I) to (V) is characterized by the same overall equation in the two phases has been proved, *inter alia*, by extinction measurements on the solutions after the reaction has reached completion (for references, see Table 1). The kinetics of these reactions will be briefly described in Section III. The fact that the kinetics remain the same in solution confirms the mechanisms proposed for the gas reactions.

The following bimolecular processes occur in reactions (I) to (IV):

$$NO_2 + ClO_2 \rightarrow NO_3 + OCl \quad (1)$$

$$NO_2 + Cl_2O \rightarrow NO_2Cl + OCl \quad (2)$$

$$NO_2 + NOCl \rightarrow NO_2Cl + NO \quad (3)$$

The rate constants and the activation energies of these steps can be found by studying the overall reactions in the gas and the liquid phase (cf. Table 2).

In the formation of nitryl chloride and chlorine from nitrosyl chloride and chlorine monoxide in the gas phase [reaction (VI), Table 1], it has recently been possible to eliminate the wall effect almost entirely and to interpret the kinetics of the reaction. Unlike reactions (I)–(V), this reaction seems to be a single elementary step whose rate is given by

$$3.98 \times 10^9 \exp(-9100/RT)[Cl_2O][NOCl]\ \text{l mole}^{-1}\ \text{sec}^{-1}. \quad (4)$$

The reaction in $C_2F_3Cl_3$ is still to be investigated.

It has not yet been possible to carry out the formation of nitryl chloride and nitrogen dioxide from nitrosyl chloride and dinitrogen pentoxide [reaction (VII)] as a homogeneous gas reaction. The overall reaction has been carried out in $C_2F_3Cl_3$; its rate is well reproducible. The rate equation and the mechanism are discussed in Section III, 4.

Table 1 also contains some qualitative data on the reactions in the solvent-free, liquid condensate of the reacting gases. Under these conditions, the course followed in the gas phase can sometimes be repeated in qualitatively the same form, whereas in other cases different end-products are obtained, as in reactions (IIa), (Va), and (VIa), in which chlorine monoxide is invariably one of the reactants. No kinetic measurements were carried out on these reactions.

## III. Description of the Reactions Investigated

### 1. Reactions (I) and (IV) and the Bimolecular Process (1)

The overall reactions

$$ClO_2 + 3\ NO_2 = NO_3Cl + N_2O_5 \quad (I)$$

$$4\ ClO_2 + 2\ N_2O_5 = 4\ NO_3Cl + 3\ O_2 \quad (IV)$$

always occur side by side, since a mixture of $ClO_2$ and $NO_2$ gives rise to $N_2O_5$ which participates in reaction (IV), and the $NO_2$ formed as an intermediate in the reaction of $ClO_2$ with $N_2O_5$ cannot be fully consumed in the reaction (I). Although reactions (I) and (IV) proceed simultaneously in the same reaction mixture, two or three separate steps can still be clearly observed, at least in the gas phase (cf. Fig. 1) [14].

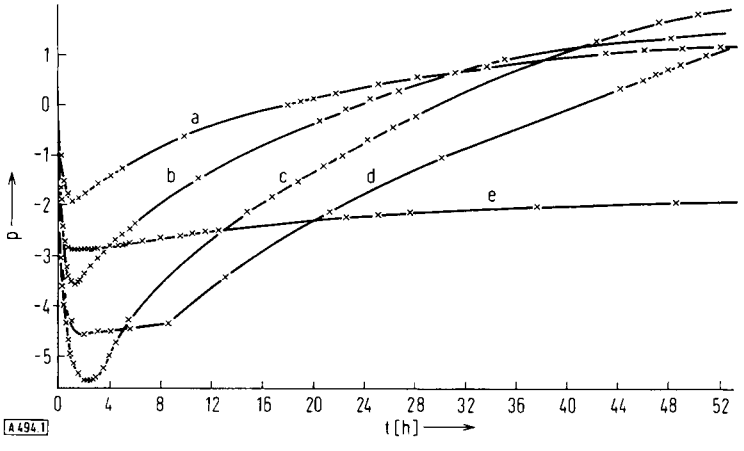

Fig. 1. Change in the pressure with time of the gaseous system $ClO_2/NO_2/N_2O_4$ at 25 °C.

| Curve | Initial pressure [mm Hg] $ClO_2$ | $NO_2 + N_2O_4$ | Formula units $NO_2/ClO_2$ |
|---|---|---|---|
| a | 43.7 | 202.0 | 6.85 |
| b | 60.0 | 200.3 | 4.95 |
| c | 79.1 | 198.0 | 3.70 |
| d | 79.7 | 116.3 | 2.02 |
| e | 79.7 | 64.6 | 1.05 |

Ordinate: Pressure (graduations of a spiral manometer, 1 unit = 11.76 mm Hg; initial scale reading set to zero).

The pressure drop in the first 1 to 2 hours (first stage) is caused almost exclusively by reaction (I). In mixtures a, b, and c, containing an excess of $NO_2$, the rise in pressure beyond the minimum is due to the dissociation of $N_2O_5$. In mixtures d and e, containing an excess of $ClO_2$, this pressure increase is only gradual. It is in the course of this second stage that the $N_2O_5$ formed in (I) reacts with excess $ClO_2$ to give chlorine nitrate [15] and oxygen according to

reaction (IV). When the excess of $ClO_2$ is small (curve d) and is consumed in reaction (IV) ($N_2O_5$ being still present), the second stage gives rise abruptly to a third stage also constituted by the dissociation of $N_2O_5$.

Fig. 2 shows a kink in the pressure curves for a mixture of $N_2O_5$ with a stoichiometric deficiency of $ClO_2$, plotted against the overall time of the reaction (IV) (the initial mixture was composed of pure components)[1]. It can be seen from Fig. 2

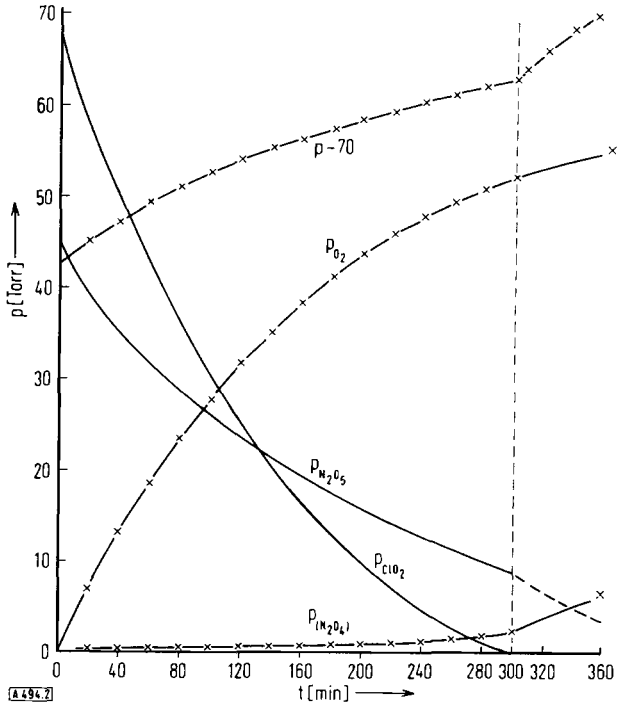

Fig. 2. Change in the total pressure p (given as p−70 mm Hg) of the system $ClO_2/N_2O_5$ and in the partial pressures of $ClO_2$, $N_2O_5$, $O_2$, and $N_2O_4$ at 40.5 °C; $p(N_2O_4) = pN_2O_4 + 1/2\ pNO_2$; initial pressures 67.4 mm Hg ($ClO_2$) and 45.2 mm Hg ($N_2O_5$).

that a small amount of $NO_2/N_2O_4$ is formed besides $NO_3Cl$ and $O_2$ during reaction (IV)[16]. The curve of the partial pressure of $O_2$ shows no kink at the moment of disappearance of the $ClO_2$, and the rate of formation of $O_2$ is not affected by the concentration of $ClO_2$, but obeys the equation

$$d[O_2]/dt = (1/2)\, k_{N_2O_5}\, [N_2O_5] \qquad (5)$$

where $k_{N_2O_5}$ is the rate constant for the dissociation of $N_2O_5$. The absence of a kink in the $p_{O_2}$ curve proves that reaction (IV) is governed by the dissociation of $N_2O_5$, more precisely, by step (7) in the following set of reactions[1,2].

$$N_2O_5 \underset{k_{-6}}{\overset{k_6}{\rightleftharpoons}} NO_3 + NO_2 \qquad (6, -6)$$

$$NO_3 + NO_2 \xrightarrow{k_7} NO_2 + NO + O_2 \qquad (7)$$

$$NO + NO_3 \xrightarrow{k_8} 2\ NO_2 \qquad (8)$$

$$NO + ClO_2 \xrightarrow{k_9} NO_2 + OCl \qquad (9)$$

$$NO_2 + ClO_2 \xrightarrow{k_1} NO_3 + OCl \qquad (1)$$

$$NO_2 + OCl \xrightarrow{k_{10}} NO_3Cl \qquad (10)$$

This reaction sequence gives a quantitative account of the processes taking place in mixtures of $ClO_2$, $NO_2$, $N_2O_4$, and $N_2O_5$. The fast bimolecular step (8) has been included because it plays a part in the dissociation of pure $N_2O_5$. In mixtures containing $ClO_2$, step (8) is suppressed by the bimolecular step (9). The above reaction scheme leads to the following rate equation:

$$-d[ClO_2]/dt = (k_6k_7/k_{-6})\,[N_2O_5] + k_I\,[NO_2]\,[ClO_2] = k_{IV}\,[N_2O_5] + k_I\,[NO_2]\,[ClO_2] \qquad (11)$$

where constants $k_{IV}$ and $k_I$ can be determined experimentally and their values in the gas phase and in solution ($C_2F_3Cl_3$) are as follows:

$(k_I)_G = 2.25\times 10^7 \exp(-11000/RT)$ l mole$^{-1}$ sec$^{-1}$ [8],
$(k_{IV})_G = 1.8\times 10^{13} \exp(-24600/RT)$ sec$^{-1}$ [6],
$(k_I)_L = 4\times 10^8 \exp(-12000/RT)$ l mole$^{-1}$ sec$^{-1}$ [8],
$(k_{IV})_L = 2.0\times 10^{13} \exp(-24500/RT)$ sec$^{-1}$ [6].

The rate equation (11) encompasses the limiting overall reactions (I) and (IV), *i.e.* the reaction rates for mixtures containing no $N_2O_5$ or no $NO_2$.

The rate constant for the dissociation of $N_2O_5$, $k_{N_2O_5}$, obtained as $2\,k_6k_7/k_{-6}$ from steps (6) to (8), is twice as high as $k_{IV}$, for which Equation (11) gives $k_6k_7/k_{-6}$. This relationship has been confirmed experimentally by *Jacobsen*[1] for the gas reaction[17].

## 2. Reactions (II) and (V) and the Bimolecular Process (2)

The formation of chlorine nitrate and nitryl chloride in accordance with

$$Cl_2O + 2\ NO_2 = NO_3Cl + NO_2Cl \qquad (II)$$

is governed in both phases by the rate equation

$$-d[Cl_2O]/dt = k_{II}\,[Cl_2O][NO_2] \qquad (12)$$

where

$(k_{II})_G = 4.35\times 10^7 \exp(-11600/RT)$ l mole$^{-1}$sec$^{-1}$ [5]

and

$(k_{II})_L = 3.5\times 10^7 \exp(-10400/RT)$ l mole$^{-1}$sec$^{-1}$ [6].

Reaction (II) may be considered to consist in the following steps:

$$NO_2 + Cl_2O \xrightarrow{k_2} NO_2Cl + OCl \qquad (2)$$

$$NO_2 + OCl \xrightarrow{\text{fast}} NO_3Cl \qquad (13)$$

where the rate-determining step is (2). Thus $k_2$ can be determined by measuring the constants $k_{II}$.

Fig. 3 shows that the gas-phase reaction is subject to the wall effect: the decomposition of the end-product is strongly accelerated even by a quartz wall, which exerts a much lower catalytic action than a glass wall. The fact that the same reaction can be carried out in the liquid phase proves, however, the validity of the interpretation of the gas reaction[6].

[16] Therefore, strictly speaking, the overall reaction is $4\ ClO_2 + (2 + 2x)N_2O_5 = 4\ NO_3Cl + (3 + x)O_2 + 2x\ N_2O_4$ (IV') However, the value of x deviates noticeably from zero only in mixtures containing a deficiency of $ClO_2$ [1].

[17] Since $k_{N_2O_5} = 15.8\times 10^{-3}$ min$^{-1}$ (40.5 °C), the value of $k_{IV}$ should be $k_{IV} = 7.9\times 10^{-3}$ min$^{-1}$. The measurements on the systems $ClO_2/NO_2/N_2O_4$ and $ClO_2/N_2O_5$ gave $k_I = 1.62\times 10^{-3}$ mm Hg$^{-1}$ min$^{-1}$ (40.5 °C) and $k_{IV} = 8.2\times 10^{-3}$ min$^{-1}$ (40.5 °C) [1].

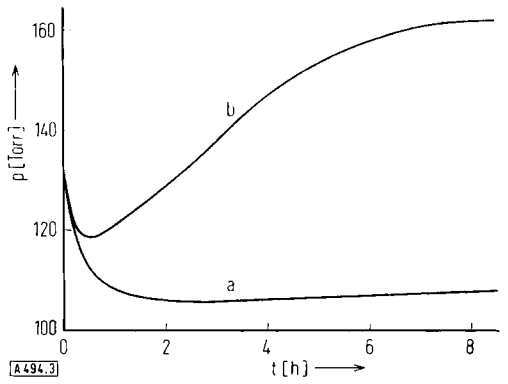

Fig. 3. Change in pressure of the gaseous system $Cl_2O/NO_2/N_2O_4$ in a 1000 ml quartz flask at 40 °C. Curve a: no packing; curve b; packed with quartz Raschig rings. Initial pressures 50 mm Hg ($Cl_2O$), 68.5 mm Hg ($NO_2$), and 14 mm Hg ($N_2O_4$).

The formation of chlorine nitrate and nitryl chloride from $Cl_2O$ and $N_2O_5$ (instead of $NO_2$) according to

$$2\,Cl_2O + 2\,N_2O_5 = 2\,NO_3Cl + 2\,NO_2Cl + O_2 \qquad (V)$$

is characterized in both phases by the rate equation:

$$-\,d[Cl_2O]/dt = k_{N_2O_5}\,[N_2O_5] \qquad (14)$$

The rate constant has virtually the same value in both cases:

$(k_{N_2O_5})_G = 3.6\times10^{13}\exp(-24600/RT)\ sec^{-1}$
and
$(k_{N_2O_5})_L = 4.0\times10^{13}\exp(-24500/RT)\ sec^{-1}$ (in $C_2F_3Cl_3$) [6].

In contrast to the system $ClO_2/N_2O_5$, no measurable amount of $NO_2$ is formed during the reaction in the system $Cl_2O/N_2O_5$. Consequently, the reaction is described satisfactorily by Equation (14). It is still uncertain whether the $NO_2$ formed eventually in the dissociation of $N_2O_5$ reacts further with $Cl_2O$ according to (II), or whether $Cl_2O$ is intercepted earlier in the dissociation of $N_2O_5$, possibly in the fast reaction $NO + Cl_2O \rightarrow NOCl + OCl$.

### 3. Reaction (III) and the Bimolecular Process (3)

The reaction of chlorine dioxide with nitrosyl chloride according to:

$$ClO_2 + 2\,NOCl = NO_2Cl + NO_2 + Cl_2 \qquad (III)$$

in both phases obeys the rate equation

$$-\,d[ClO_2]/dt = k_{III}\,[NOCl]\,[NO_2] + k_I\,[ClO_2]\,[NO_2] \qquad (15)$$

with
$(k_{III})_G = 1.9\times10^7\ \exp(-10000/RT)\ l\ mole^{-1}sec^{-1}$ [7]
and
$(k_{III})_L = 2.3\times10^8\exp(-10700/RT)\ l\ mole^{-1}sec^{-1}$
in $C_2F_3Cl_3$ [8]. The values for $k_I$ are given in Section III, 1.

The rate of reaction (III), which is autocatalysed by $NO_2$, is explained by the two concurrent reaction sequences (3), (16), and (17), and (1), (18), and (17), if the constants $k_3$ and $k_1$ of the rate-determining steps (3) and (1) are identified with the empirical constants $k_{III}$ and $k_I$.

$$NO_2 + NOCl \xrightarrow{k_3} NO + NO_2Cl \qquad (3)$$
$$NO + ClO_2 \rightarrow NO_2 + OCl\ (fast) \qquad (16)$$
$$OCl + NOCl \rightarrow NO_2 + Cl_2\ (fast) \qquad (17)$$
$$NO_2 + ClO_2 \xrightarrow{k_1} NO_3 + OCl \qquad (1)$$
$$NO_3 + NOCl \rightarrow NO_2 + NO_2Cl\ (fast) \qquad (18)$$
$$OCl + NOCl \rightarrow NO_2 + Cl_2\ (fast) \qquad (17)$$

The rather unusual course of this reaction is shown in Fig. 4.

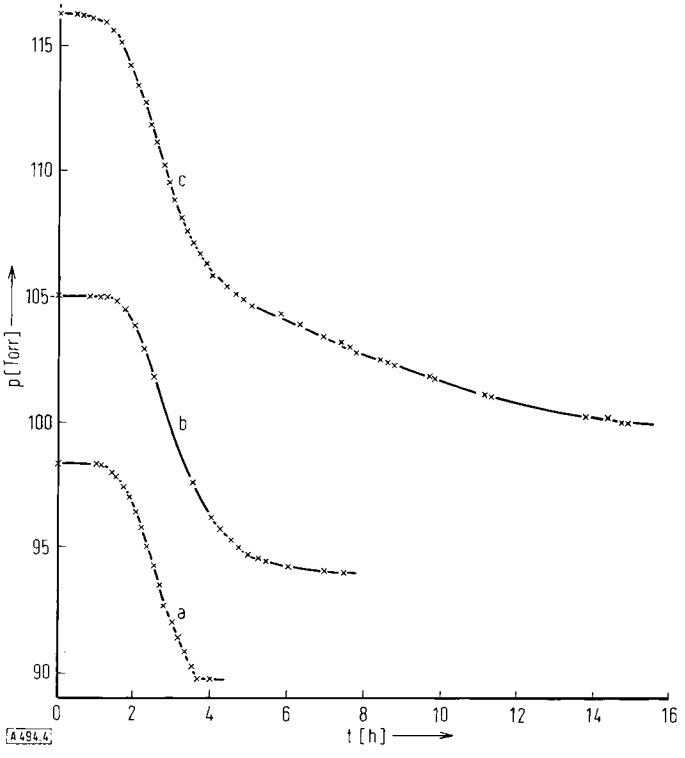

Fig. 4. Change in pressure of the gaseous system $ClO_2/NOCl$ at 0 °C.

| Curve | Initial pressure [mm Hg] $ClO_2$ | NOCl | Initial $p_{NOCl}/p_{ClO_2}$ |
|---|---|---|---|
| a | 28.1 | 70.2 | 2.5 |
| b | 35.0 | 70.0 | 2.0 |
| c | 46.6 | 69.7 | 1.5 |

The salient features of the reaction are the hesitant initiation (autocatalysis), the sharp decline of the reaction of a starting mixture deficient in $ClO_2$ (case a), normal decay in the stoichiometric starting mixture (case b), and the delayed decay with excess of $ClO_2$, owing to a transition to the slower reaction (I) between $NO_2$ and excess of $ClO_2$ (case c). All these features recur in solution [8].

Although the overall reaction can also be explained by a chain mechanism, the steps to be included are much less feasible than those mentioned above [7]. The fact that the reaction can be repeated in solution proves the validity of the above open reaction sequences.

### 4. Reaction (VII) in Solution

The reaction of dinitrogen pentoxide with nitrosyl chloride according to

$$N_2O_5 + NOCl = N_2O_4 + NO_2Cl \qquad (VII)$$

leads to nitrogen dioxide and nitryl chloride. When the reaction is carried out in $C_2F_3Cl_3$ [13] at −10 to −35 °C, the former product is present almost entirely in the form of $N_2O_4$. The initial reaction rate is given by

$$-(d[NOCl]/dt)_0 = k_0 [N_2O_5]_0^2 [NOCl]_0 \quad (19)$$

with $k_0 \approx 0.7$ l² mole$^{-2}$ min$^{-1}$ (at −10 °C). The reaction is thus of third order. After time t, however, the rate is expressed by

$$-d[NOCl]/dt = k_{20} [N_2O_5] [NOCl] \quad (20)$$

*i.e.* the reaction becomes second-order.

The two rate equations can be explained by assuming that, similarly to $N_2O_5$, the resulting $N_2O_4$ acts as a catalyst, possibly in accordance with the following scheme:

$$N_2O_5 + NOCl \underset{k_{-21}}{\overset{k_{21}}{\rightleftharpoons}} N_2O_5 \cdot NOCl \quad (21, -21)$$

$$N_2O_5 \cdot NOCl + N_2O_5 \xrightarrow{k_{22}} NO_2Cl + N_2O_4 + N_2O_5 \quad (22)$$

$$N_2O_5 \cdot NOCl + N_2O_4 \xrightarrow{k_{23}} NO_2Cl + N_2O_4 + N_2O_4 \quad (23)$$

This leads to the rate equation:

$$\frac{d[NOCl]}{dt} = \frac{k_{21}k_{22}[N_2O_5]^2[NOCl] + k_{21}k_{23}[N_2O_5][N_2O_4][NOCl]}{k_{22}[N_2O_5] + k_{23}[N_2O_4] + k_{-21}} \quad (24)$$

This in turn leads to Equation (25) if we put $[N_2O_5] + [N_2O_4] = [N_2O_5]_0$ and make the plausible assumptions $k_{22} \approx k_{23} = k'$ and $k'[N_2O_5]_0 \ll k_{-21}$.

$$-d[NOCl]/dt = (k_{21}k'/k_{-21})[N_2O_5]_0[N_2O_5][NOCl] \quad (25)$$

If we put $k_{21}k'/k_{-21} = k_0$ and $k_{21}k'[N_2O_5]_0/k_{-21} = k_{20}$, this rate equation is seen to be identical with Equations (19) and (20) constructed on an experimental basis.

The reaction has also been investigated in the gas phase, and *Weston* [12] has postulated a wall reaction with the rate equation $-d[N_2O_5]/dt = k[N_2O_5][NOCl]$. He found, however, that the results are difficult to reproduce. A mechanism for a homogeneous gas reaction could not be proposed.

A small, negative temperature coefficient has been obtained for the second-order rate constants in both phases [12, 13]. This can be explained by the rate equation (25), if we assume that the equilibrium (21, −21) is displaced to the left as the temperature increases, and that processes (22) and (23) have low activation energies.

Since the reaction has a negative activation energy both in the gas phase and in solution, we may assume that the mechanisms are similar in both phases and that we would also find rate equations of the type of (19) and (20) for the gas reaction if the wall effect were eliminated.

## IV. Theoretical Interpretation of $k_L/k_G$

Both the classical collision theory and the transition-state theory have been applied to studying the effect on the rate of a gas-phase reaction of filling the space between the reacting particles with an inert medium (assumed not to interact strongly with the reactants or the activated complex and to leave the activation energy unchanged). Owing to the lack of an exact theory of liquids, it is not surprising that the results are discordant and represent only approximations.

### 1. Bimolecular Processes

On the basis of the theories of *Debye* and *Menke* concerning the spatial structure of liquid mercury, *Rabinowitch* [18] derived values for bimolecular collision factors in solution, which are only a few times as great as those for the corresponding gas reactions. Thus, according to the collision theory, a reaction carried out in solution (under otherwise the same conditions) should be somewhat faster than the same reaction in the gas phase. Using the theory of the transition state, *Evans, Polanyi, Bell, et al.* [19] came to a similar conclusion. On the basis of an empirical linear relationship between heat and entropy of solution, they found that $A_L/A_G = \exp(650/RT)$, where $A_L$ and $A_G$ are the frequency factors in the liquid and the gaseous phase, respectively. It follows, therefore, that the relationship

$$k_L/k_G = A_L/A_G \approx 2 \text{ to } 3 \quad (26)$$

(at room temperature) should hold, provided that the activation energy is the same in the two phases.

However, the transition state theory leads to higher values when we use the free volumes $V_{f,i} = RT_i \exp(-\Delta S_i^V/R)$, where $\Delta S_i^V$ is the entropy of vaporization at the boiling point $T_i^\circ$, and the vapor pressures $p_i^\circ$ of the reactants A, B, . . . and the activated complex $X^\ddagger$ [20]. In this case we obtain for the ratio between the reaction rate in solution and that in the gas phase

$$k_L/k_G = (p_A^\circ \cdot p_B^\circ \cdot \cdots / p_{X^\ddagger}^\circ)(RT/V_o)^{\Delta n}(\gamma_A \cdot \gamma_B \cdots / \gamma_{X^\ddagger})$$

$$= e^{\Sigma \Delta H_i^V/RT} \cdot \left(\frac{T_A}{V_{f,A}} \cdot \frac{T_B}{V_{f,B}} \cdots \Big/ \frac{T_{X^\ddagger}}{V_{f,X^\ddagger}}\right) \cdot \left(\frac{T}{V_o}\right)^{\Delta n} \cdot \left(\gamma_A \cdot \gamma_B \cdots / \gamma_{X^\ddagger}\right) \quad (27)$$

or with the approximations $V_{f,A} \approx V_{f,B} \approx \cdots \approx V_f$ and $T_A \approx T_B \approx \cdots \approx T_{X^\ddagger} \approx T$

$$k_L/k_G = e^{\Sigma \Delta H_i^V/RT}(V_f/V_o)^{\Delta n}(\gamma_A \cdot \gamma_B \cdots / \gamma_{X^\ddagger})$$

in which $V_0$ is the volume of 1 mole of solvent plus solute, $\Delta n$ is the difference in the number of moles, the $\gamma_A$, $\gamma_B$, $\cdots$ $\gamma_{X^\ddagger}$ are the activity coefficients, and the $\Delta H_i^V$ are the enthalpies of vaporization.

When the bimolecular processes,

$$A + B \rightleftarrows X^\ddagger \rightarrow \text{products} \quad (28)$$

in which $\Delta n = -1$ for the formation of the activated complex $X^\ddagger$, are carried out in an ideal solution, in which the activity coefficients are unity, Equation (27) can be written in the form:

$$k_L/k_G = \exp\left[\left(\Delta H_{X^\ddagger}^V - \Delta H_A^V - \Delta H_B^V\right)/RT\right](V_f/V_o) \quad (29)$$

[18] *E. Rabinowitch*, Trans. Faraday Soc. *33*, 1225 (1937).

[19] See, *e.g.*, [10], p. 120.

[20] See, *e.g.*, *A. A. Frost* and *R. G. Pearson*: Kinetics and Mechanism. Wiley, New York-London 1961. See there for further literature.

If, in addition, the activation enthalpies are the same in the two phases, *i.e.* $(\Delta H^{\neq})_L = (\Delta H^{\neq})_G$, it follows from the general relationship

$$(\Delta H^{\neq})_L - (\Delta H^{\neq})_G \quad \Sigma \Delta H_i^V \tag{30}$$

that the stoichiometric sum $\Sigma \Delta H_i^V = \Delta H_X^V{}^{\neq} - \Delta H_A^V - \Delta H_B^V - \cdots$ of the enthalpies of vaporization disappears from the exponential terms of Equations (27) and (29), leading with the approximation $V_f \approx 0.5$ ml/mole to:

$$k_L/k_G = V_o/V_f \approx 100 \tag{31}$$

Table 2 shows the experimental values of $k_L/k_G$ for bimolecular processes investigated quantitatively so far in the gas phase and in solution. The value of this ratio is seen to vary between 0.9 and 10. The disagreement with the prediction of Eq. (31) may be due partly to the non-ideal nature of the liquid mixtures and partly to the fact that the reactants have different free volumes. Further, the exponential term in Equation (29) may be less than unity, *i.e.* the stoichiometric sum of the enthalpies of vaporization is negative. This possibility is supported by the experimental values of the activation energies. With the exception of the two reactions in which the value of $k_L/k_G$ is comparatively high (cyclopentadiene + acrolein and $NO_2 + Cl_2O$), the activation energies are larger in solution than in the gas phase (within the limits of error, which are considerable). Moreover, it is not the experimental activation energies, but the $\Delta H^{\neq}$ values that are to be equated in the determination of the stoichiometric sum of the enthalpies of vaporization ($\Sigma \Delta H_i^V$) according to Equation (30). In the case of bimolecular processes in solution and in the gas phase, the following relations hold for these $\Delta H^{\neq}$ values:

$$(\Delta H^{\neq})_L = E_L - RT \tag{32}$$

$$(\Delta H^{\neq})_G = E_G - 2\,RT \tag{33}$$

The values of $\Delta H^{\neq}$ obtained in this way are also listed in Table 2. When these values are used to calculate $\Sigma \Delta H_i^V$ with the aid of Equation (30) and when the resulting values are inserted in (29), the exponential function in the latter equation is in fact seen to be less than unity, being about 0.3 for the dimerization of cyclopentadiene, about 0.07 for reaction (1), and about 0.11 for reaction (3). For these three reactions, the ratios predicted by Equation (29) (in conjunction with $V_o/V_f = 100$) are $k_L/k_G \approx 30$, 7, and 11 respectively, these values being closer to the experimental results than those predicted by Equation (31).

Table 2. Bimolecular processes capable of proceeding in different phases.

| Bimolecular process | Phase | E [kcal] | $\Delta H^{\neq}$ [kcal] | k (20 °C) [l mole$^{-1}$ sec$^{-1}$] | $k_L/k_G$ (20 °C) |
|---|---|---|---|---|---|
| $pH_2 + O_2 \rightarrow oH_2 + O_2$ [21] | $H_2O$ | — | | 0.175 | 1.1 |
| | Gas | ≈ 0 | | 0.153 | |
| 2 Cyclopentadiene → dicyclopentadiene [22] | $CS_2$ | 16.9 | 16.3 | $4.0\times10^{-7}$ | 0.9 |
| | $C_6H_6$ | 16.4 | 15.8 | $7.6\times10^{-7}$ | 1.7 |
| | $CCl_4$ | 17.1 | 16.5 | $8.9\times10^{-7}$ | 2.0 |
| | Paraffin | 17.4 | 16.8 | $13.2\times10^{-7}$ | 3.0 |
| | Melt | 16.2 | 15.6 | $5.1\times10^{-7}$ | 1.1 |
| | Gas | 16.7 | 15.5 | $4.5\times10^{-7}$ | |
| Cyclopentadiene + Acrolein → 5-Norbornene-2-carbaldehyde [23] | $C_6H_6$ | 13.7 | 13.1 | $7.8\times10^{-5}$ | 10 |
| | Gas | 15.2 | 14.0 | $0.76\times10^{-5}$ | |
| $NO_2 + ClO_2 \rightarrow NO_3 + OCl$ (1) | $C_2F_3Cl_3$ | 12.0 | 11.4 | 0.42 | 2.8 |
| | Gas | 11.0 | 9.8 | 0.15 | |
| $NO_2 + Cl_2O \rightarrow NO_2Cl + OCl$ (2) | $C_2F_3Cl_3$ | 10.4 | 9.8 | 0.57 | 6.0 |
| | Gas | 11.6 | 10.4 | 0.095 | |
| $NO_2 + NOCl \rightarrow NO_2Cl + NO$ (3) | $C_2F_3Cl_3$ | 10.7 | 10.1 | 2.3 | 3.7 |
| | Gas | 10.0 | 8.8 | 0.62 | |

In the bimolecular processes (1) to (3), in which A is invariably $NO_2$ while B is, respectively, $ClO_2$, $Cl_2O$, and NOCl, the ratio of the rate constants $k_L/k_G$ can also be estimated from the solubilities of the reactants in the solvent. In the gas and the liquid phases, Equations (34) and (35) should hold for the activation equilibrium (28):

$$K_G^{\neq} = [X^{\neq}]/([A]\cdot[B]) \tag{34}$$

$$K_L^{\neq} = ([X^{\neq}]\cdot l_X{}^{\neq})/([A]\, l_A \cdot [B]\, l_B) = K_G^{\neq}\cdot l_X{}^{\neq}/(l_A \cdot l_B) \tag{35}$$

where $l_X{}^{\neq}$, $l_A$, and $l_B$ are the Ostwald solubility coefficients. Since k is proportional to $K^{\neq}$ (T = const.), the relationship

$$k_L/k_G = K_L^{\neq}/K_G^{\neq} = l_X{}^{\neq}/(l_A\cdot l_B) \tag{36}$$

should also hold. We should therefore be able to calculate $k_L/k_G$ from the solubilities. The solubilities of the activated complexes $X^{\neq} = NO_2\cdot B^{\neq}$ are admittedly unknown, but we may try to estimate them by correlating them with the solubility of $N_2O_4$, whose structure is likely to be similar to that of the activated complex. We then assume that the solubility is increased by a certain factor when one $NO_2$ group in $N_2O_4$ is replaced by component B (more soluble in $C_2F_3Cl_3$) and that this factor is half of that connecting the solubilities of pure $NO_2$ and of pure B. We thus put

$$l_{NO_2B}{}^{\neq} \approx l_{N_2O_4}\cdot l_B/2\, l_{NO_2} \tag{37}$$

Substitution in Equation (36) leads to the estimate:

$$k_L/k_G = l_{NO_2B}{}^{\neq}/(l_{NO_2}\cdot l_B) = l_{N_2O_4}/2\, l_{NO_2}^2 \tag{38}$$

Using the values $l_{N_2O_4} = 180$ and $l_{NO_2} = 3.6$ to 5, we obtain $k_L/k_G = 3.6$ to 6.9 for reactions (1) to (3). These values are seen to be in good agreement with the experimental results listed in Table 2.

### 2. Unimolecular Processes and the Dissociation of $N_2O_5$

For unimolecular processes, the theoretical rate in the gas phase is found to be about the same as that in solution, *i.e.*

$$k_L/k_G \approx 1 \tag{39}$$

[21] *L. Farkas* and *H. Sachsse*, Z. physik. Chem. *23*, 1, 19 (1933).

[22] *A. Wassermann*, Mh. Chem. *83*, 543 (1952). The values of k listed in Table 2 were calculated from the values for A and E given there.

[23] *A. Wassermann*, Trans. Faraday Soc. *34*, 128 (1938).

provided that the activation energy E is the same in the two phases. For such processes, Equation (27) can be simplified to

$$k_L/k_G = \left(p_A^\circ/p_{X^\ddagger}^\circ\right)\cdot\left(\gamma_A/\gamma_{X^\ddagger}\right) = e^{\Sigma\Delta H_i^V/RT}\gamma_A/\gamma_{X^\ddagger} \qquad (40)$$

When the activation energies are the same, which in this case means $(\Delta H^\ddagger)_G = (\Delta H^\ddagger)_L$, the exponent $\Sigma\Delta H_i^V = \Delta H_X^{V\ddagger} - \Delta H_A^V$ also disappears by virtue of Equation (30) and $k_L/k_G$ is given simply by the ratio of the activity coefficients of the reactant A and of the activated complex $X^\ddagger$ in the solution. Moreover, when the polarity of $X^\ddagger$ is not very different from that of A, the two activity coefficients will be approximately the same.

With the exception of the racemization of diaminodimethylbiphenyl, the experimental values are in reasonably good agreement with Equation (39) (see Table 3). When $E_G$ is greater than $E_L$, $k_L/k_G$ is seen to be greater than unity. Conversely, when $E_G < E_L$ (the dissociation of acetyl peroxide), $k_L/k_G < 1$. This behavior is expected on the basis of Equations (40) and (30), provided that $\gamma_A = \gamma_{X^\ddagger}$. In the first of the above two cases the exponent in (40) is positive and in the second it is negative. Admittedly, not even a semiquantitative confirmation can be offered for Equation (40), with the possible exception of the dissociation of dicyclopentadiene.

The dissociation of $N_2O_5$ has been investigated extensively, in the gas phase and in solution[10] in several solvents, *e.g.* $C_2F_3Cl_3$[6], $CCl_4$, $CHCl_3$, $H_2ClC-CH_2Cl$, $H_3C-CHCl_2$, $HCl_2C-CCl_3$, $H_3C-NO_2$, $Br_2$, $N_2O_4$, and $HNO_3$. Except in the last-mentioned solvent, in which a higher E and a correspondingly smaller k have been found, the activation energies and the rate constants of this reaction do not vary significantly with the medium, and excellent agreement is found with Equation (39).

It should be pointed out that the dissociation of $N_2O_5$ is not unimolecular, but is a complicated process involving the steps (6), (−6), (7), and (8) (cf. Section III, 1). Its first-order rate constant is given by $k_{N_2O_5} = 2k_6k_7/k_{-6}$, *i.e.* it is composed of three rate constants of which only $k_6$ refers to a unimolecular reaction. Thus, if we find that $(k_{N_2O_5})_L/(k_{N_2O_5})_G = 1$, this merely proves that the expected ratio $(k_6)_L/(k_6)_G = 1$ holds if, furthermore, the relationship $(k_{-6})_L/(k_{-6})_G = (k_7)_L/(k_7)_G$ is valid for the two bimolecular steps (−6) and (7). Since these steps are very similar, the above relationship between $k_{-6}$ and $k_7$ is very likely to be valid. This is further supported by the observation that the experimental values of $k_L/k_G$ listed in Table 2 differ only slightly from each other for other bimolecular reactions of $NO_2$ [reactions (1) to (3)].

Table 3. Unimolecular processes capable of proceeding in different phases.

| Unimolecular process | Phase | E [kcal] | k [sec$^{-1}$] | Temp. [°C] | $k_L/k_G$ |
|---|---|---|---|---|---|
| (+)-α-Pinene → (±)-limonene [24] | Melt | — | $5.0\times10^{-7}$ | 184 | 1.4 |

| | Toluene | 32.0 | $1.59\times10^{-4}$ | 85.2 | 0.7 |
| | Acetic acid | 30.2 | $1.30\times10^{-4}$ | 85.2 | 0.6 |
| | Propionic acid | — | $1.66\times10^{-4}$ | 85.2 | 0.7 |
| | $CCl_4$ [28] | 33.4 | $1.2\times10^{-4}$ | 85.2 | 0.5 |
| | Gas | 29.5 | $2.24\times10^{-4}$ | 85.2 | |

The experimental data listed in Tables 2 and 3 are insufficient to test the quantitative validity of the theoretical postulates concerning the change occurring in the rate constants of elementary processes when a gas-phase reaction is changed into a reaction in solution. There is, however, no doubt that the transition-state theory leads to a useful correlation between the rate of reactions in the gas phase and in solution.

# Color Centers in Alkali Borate Glasses Containing Cobalt, Nickel, or Copper

BY PROF. DR. R. JUZA, DR. H. SEIDEL, AND DIPL.-CHEM. J. TIEDEMANN

INSTITUT FÜR ANORGANISCHE CHEMIE DER UNIVERSITÄT KIEL (GERMANY)

*Dedicated to Prof. W. Klemm on the occasion of his 70th birthday*

*The absorption spectra and the magnetic moments of $Co^{2+}$, $Ni^{2+}$, and $Cu^{2+}$ in alkali borate glasses of various compositions and in halide-containing glasses have been explained from the point of view of the ligand field theory. Spectra and magnetic moments are highly dependent on the composition of the base glass; this must be ascribed to the change in the coordination of the transition-metal ions. There are far-reaching analogies with corresponding complexes in solution or in the crystalline state.*

## 1. Introduction

Earlier investigations on borate glasses containing $Co^{2+}$, $Ni^{2+}$, or $Cu^{2+}$ as coloring transition-metal ions were designed to give further information on the color centers in these glasses [1,2]. It is just these transition-metal ions which appeared suitable, since glasses can be prepared with only one oxidation state of the metal, and therefore no complications due to a second oxidation state can arise. Moreover, many complexes of these ions have been investigated in detail. Their magnetic behavior, and particularly their spectra, have been interpreted from the viewpoint of ligand field theory, and this facilitated the interpretation of the spectra and of the magnetic susceptibilities of the colored glasses.

It has long been known that a transition-metal ion can exhibit different colors in different glasses, even when its valence remains unchanged [3]. Since the color changes in the glasses considered here cannot be ascribed to a change in the oxidation state, they must be due to the change in the environment of the transition-metal ion. The magnetic moment of the transition-metal ion changes largely parallel with the color; this phenomenon can be explained by the different orbital contributions when the coloring ion is in states of octahedral or tetrahedral coordination. It will be shown below that the laws which follow from the ligand field theory for transition-metal complexes in solution or in the crystalline state apply also to the color centers present in glasses.

## 2. Alkali Borate Glasses

The base glasses used were alkali borate glasses with different kinds and amounts of alkali-metal oxides. These glasses were selected since their structure is comparatively well known.

According to the network theory proposed by *Zachariasen* [4], $B_2O_3$ glass is built up of a two- or three-dimensional network of plane $BO_3$ groups. Each oxygen atom ("bridging oxygen") is common to two structural groups. This can be written as $\rangle B-O-B\langle$ (the B–O–B angle being less than 180 °). When a metal oxide, *e.g.* $Na_2O$, is fused with $B_2O_3$, the oxygen of the added oxide is completely incorporated into the network, with the formation of tetrahedral $BO_4$ groups, an equivalent amount of $Na^+$ ions being present in the interstices of the three-dimensional network. This process takes place up to about 16.7 mole-% of $Na_2O$, which corresponds to $Na_2O \cdot 5B_2O_3$. When the glass contains this amount of an alkali-metal oxide, every tenth $BO_3$ group in the network becomes converted into a $BO_4$ group.

At higher contents of alkali-metal oxide no further $BO_4$ tetrahedra are formed, but the network is disrupted and at the same time non-bridging oxygen appears:

$$Na_2O + \rangle B\text{-}O\text{-}B\langle \longrightarrow 2\ Na^{\oplus} + 2\ {}^{\ominus}O\text{-}B\langle$$

This difference in the behavior of the $B_2O_3/Na_2O$ system at small and large contents of alkali-metal oxide has been investigated frequently. This "boric acid anomaly" occurs not only in binary alkali-metal borate glasses, but also in the borosilicate glasses.

The network theory, applied *e.g.* to silicate glasses, has accounted correctly for many observed properties of various glasses. It is supported, *inter alia*, by X-ray investigations [5]. However, in $B_2O_3$ glass and the alkali-borate glasses, the coordination relationships are obviously very much more complicated than the network theory would indicate. A comparison of the network in vitreous $B_2O_3$ with that in crystalline $B_2O_3$ is clearly indicated.

The infrared spectrum of $B_2O_3$, which crystallizes in the hexagonal system, agrees closely with that of $B_2O_3$ glass [6], but not with that of a modification of $B_2O_3$

formed under high pressure. Without doubt the coordination relationships in $B_2O_3$ glass and in the hexagonally crystalline $B_2O_3$ are very similar. The structure of the latter has been determined by *Berger*[7], although only from powder photographs. The mean coordination number of the boron is between three and four. The hexagonal $B_2O_3$ is constructed of two types of highly deformed $BO_4$ tetrahedra. In type b, the $BO_4$ group contains a shallow trigonal $BO_3$ pyramid (O–O distance 2.39 Å; B–O 1.45 Å; height of the pyramid 0.4 Å); in type a, the shallow $BO_3$ pyramid is still more irregular than in type b.

Detailed X-ray investigations[8] on $B_2O_3$ glass show a far more regular arrangement of the atoms than is proposed by the classical model of *Zachariasen* and of *Warren*. Shallow $BO_3$ pyramids are again present; they take the place of the plane $BO_3$ groups of *Zachariasen* and *Warren's* model. Nevertheless, the $B_2O_3$ glass does not contain the three-dimensional lattice structure of hexagonal $B_2O_3$, even in small regions, required by the crystallite hypothesis of the vitreous state. The $BO_3$ groups are in layers having a substantially regular arrangement and these, in turn, form thin bundles of layers. Such bundles are arranged in unordered fashion and are linked statistically to one another through individual $BO_3$ chains or irregular layers.

Unfortunately, there are no corresponding X-ray investigations of alkali-metal borate glasses. From NMR measurements on potassium borate glasses[9] it has been concluded that the proportion of $BO_4$ groups increases up to about 17 mole-% of $K_2O$ in the sense of *Warren*'s assumptions[5]. While, however, according to *Warren*[5] the proportion of $BO_4$ groups tends to decrease again with increasing amounts of alkali-metal oxide added, according to *Svanson*[9] this proportion tends to increase. However, there is probably no necessity for a fundamental change in the basic assumptions on the incorporation of alkali-metal oxide that have been described above.

## 3. $Co^{2+}$, $Ni^{2+}$, and $Cu^{2+}$ Ions in the Ligand Field

### a) The One-Electron Orbital Scheme of $Co^{2+}$

Free bivalent ions of cobalt, nickel, or copper possess five degenerate 3d one-electron orbitals. According to Pauli's principle, these are occupied by electrons as shown in the center of Fig. 1 for an isolated $Co^{2+}$ ion. In complexes, these ions frequently form centers of regular coordination polyhedra, in which they are surrounded by identical ligands at the same distance. For this reason, additional forces in the form of a ligand field with the symmetry of the corresponding coordination polyhedra act on the five 3d orbitals so that their original degeneracy is cancelled. If the field has octahedral or tetrahedral symmetry, one triply degenerate group ($d_{xy}$, $d_{xz}$, $d_{yz}$) and one doubly degenerate group ($d_{x^2-y^2}$, $d_{z^2}$) of orbitals arise[10,11].

The splitting for the octahedral case is shown on the right of Fig. 1; the triply degenerate state is denoted by the symmetry symbol $t_{2g}$, and the doubly degenerate by the symbol $e_g$. In this

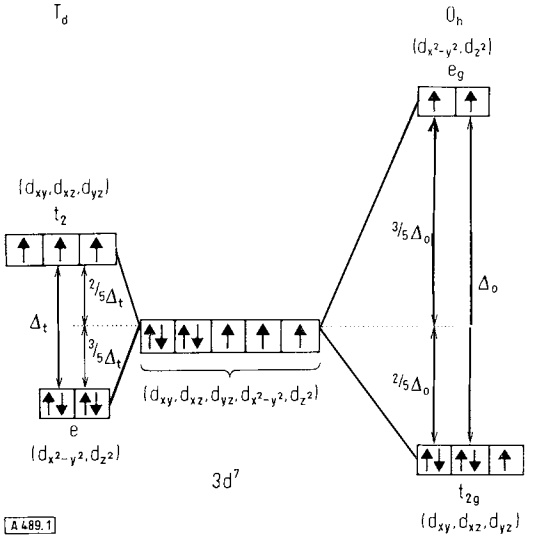

Fig. 1. One-electron orbital scheme of $Co^{2+}$ in octahedral (right) and tetrahedral (left) ligand fields. $\Delta_o$, $\Delta_t$ = energy differences (ligand field strengths) between the $t_{2g}$ and $e_g$ and between the $t_2$ and e levels (not to scale).

case, the electron configuration of the $Co^{2+}$ is $t_{2g}^5 e_g^2$ (that of $Ni^{2+}$ is $t_{2g}^6 e_g^2$, and that of $Cu^{2+}$ $t_{2g}^6 e_g^3$). The $e_g$ orbitals $d_{x^2-y^2}$ and $d_{z^2}$ are destabilized, since they point to the ligands located in the direction of the x-, y-, and z-axes. This does not apply to the $t_{2g}$ orbitals; they are stabilized in the field. The difference between energies of the $t_{2g}$ and the $e_g$ levels, which gives the field strength in the case of cubic symmetry of the ligand field, is denoted by $\Delta_o = 10\ Dq$[12].

In the tetrahedral field (Fig. 1, left), the doubly degenerate state is given the symmetry symbol e and the triply degenerate state the symbol $t_2$. Here the electron configuration of $Co^{2+}$ is $e^4 t_2^3$ (that of $Ni^+$ is $e^4 t_2^4$, and that of $Cu^{2+}$ $e^4 t_2^5$). In the tetrahedral field the $t_2$ orbitals are destabilized; they come closer in space to the tetrahedrally arranged ligands than the stabilized e orbitals. For the energy difference between e and $t_2$ levels we have, assuming the same distances and same ligands, $\Delta_t = 4/9\Delta_o$. The tetragonal deformation of an originally octahedral field will be discussed in connection with the copper containing glasses (Section 6).

With constant coordination of the central ion, the ligand field strength $\Delta = 10\ Dq$ depends on the type of ligands. Ligands with weak fields lead to a small value of Dq, and ligands with strong fields to a large one. The following sequence applies to the field strengths of the ligands of interest in this paper: $I^- < Br^- < Cl^- < F^- < H_2O$[13] (see also Section 8).

All complexes discussed here are high-spin complexes: in accordance with the rule of maximum multiplicity, one electron first enters each orbital with the formation of the greatest possible total spin angular momentum. "Low-spin complexes", which can in principle arise with $Co^{2+}$, are not formed by the ligands under discussion here (oxygen and chloride, bromide, and iodide) since their ligand fields are too small.

b) Energy-Level Diagram of $Co^{2+}$

With its seven electrons in the 3d shell, the $Co^{2+}$ ion in the ground state has a spin angular momentum of S = 3/2 and an orbital angular momentum of L = 3; consequently, the ground state is given as $^4F$ (cf. Fig. 2). At a fairly large distance (14500 $cm^{-1}$ for the gaseous ion) there is another

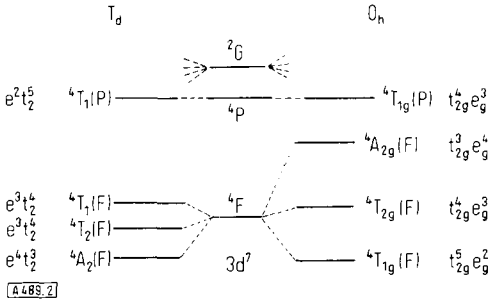

Fig. 2. Energy-level diagram of $Co^{2+}$. Left, splitting in the tetrahedral ligand field; right, that in the octahedral ligand field.

quartet level, $^4P$, then the levels $^2G$, $^2H$, $^2P$ ... follow in quick succession. All transitions relate to electron transitions within the 3d level.

When $Co^{2+}$ is incorporated in the center of tetrahedral or octahedral coordination polyhedra, the levels are changed under the influence of the ligand field; some of the levels are split and some displaced. The electron configurations given in the one-electron orbital scheme (Fig. 1) correspond to the ground states in the octahedral field ($^4T_{1g}$) and in the tetrahedral field ($^4A_2$).

The transition from the $^4F$ level, which applies to the free ion, to the subsequent level of the same multiplicity in the octahedral or the tetrahedral ligand field is shown schematically in Fig. 3 (after *Orgel*[11]) as a function of the field. Starting from a ligand field strength 0 for the free ion, $^4F$ is split into three subsequent levels of the same multiplicity, the electron configurations of which are given at the edge of the figure. The symbols also give the degeneracy: triple for T, double for E, and single for A and B levels[14].

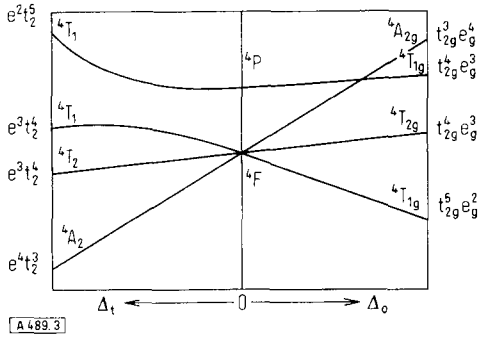

Fig. 3. Orgel diagram of the quartet levels for $Co^{2+}$ according to [11]. Abscissa: ligand field strength.

## 4. Alkali Borate Glasses Containing Cobalt

### a) Optical Investigations

The base glasses were made by fusing $B_2O_3$ and alkali-metal carbonate at 850 to 960 °C in a platinum crucible. CoO was melted into these glasses under protective gas; the oxidation number of +2 of cobalt in the glass was checked analytically.

[14] *R. S. Mulliken*, Physic. Rev. *43*, 279 (1933).

The classes used for the optical investigations contained an average of 0.2% by weight of Co. The glasses were ground to plane-parallel plates whose absorption between 50000 and 4000 $cm^{-1}$ was measured with a Zeiss PMQ II spectrophotometer[15] [*].

As already known, the content of alkali-metal oxide affects the color of the glasses. Glasses with a low content of $Na_2O$ are bright red-purple, those rich in $Na_2O$ intensely blue[16]. The bands of the purple glass with a low alkali content can be ascribed to $Co^{2+}$ in an octahedral environment, and that of the alkali-rich blue glass to $Co^{2+}$ in a tetrahedral environment.

The spectrum of the alkali-poor red-purple cobalt sodium borate glass (base glass $Na_2O{\cdot}7B_2O_3$) is shown in Fig. 4. The absorption bands with the assigned transitions are given in Table 1. The Orgel diagram of $Co^{2+}$ (Fig. 3) also gives the electron configurations of the

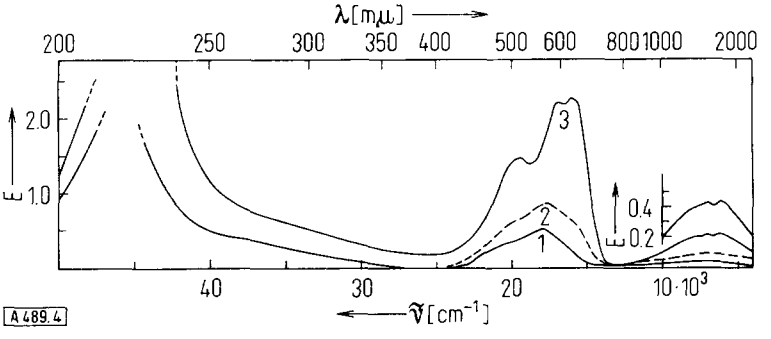

Fig. 4. Spectra of cobalt sodium borate glasses with the base glass compositions $Na_2O{\cdot}7B_2O_3$ (red-purple, curve 1), $Na_2O{\cdot}4.6B_2O_3$ (blue-purple, curve 2), and $Na_2O{\cdot}3\ B_2O_3$ (blue, curve 3). Ordinate: extinction.

Table 1. Band assignment in the spectrum of an alkali-poor, purple cobalt, sodium borate glass (base glass $Na_2O{\cdot}7\ B_2O_3$) and comparative spectra. (sh) = shoulder.

| Co-glass $\tilde{\nu}$ ($cm^{-1}$) | $[Co(H_2O)_6]^{2+}$ $\tilde{\nu}$ ($cm^{-1}$) [17] | CoO/MgO $\tilde{\nu}$ ($cm^{-1}$) [18] | Assignment |
|---|---|---|---|
| 7500 | 8000 | 8470 | $^4T_{1g} \rightarrow {}^4T_{2g}(F)$ |
| 18000 | 16000 | 18000 | $^4T_{1g} \rightarrow {}^4A_{2g}(F)$ |
| 21000 (sh) | 20200 | 19800 | $^4T_{1g} \rightarrow {}^4T_{1g}(P)$ |
| *ca.* 46000 | — | — | Charge-transfer |

ground state and the excited states. The spectra of $[Co(H_2O)_6]^{2+}$ [17] and of $Co^{2+}$ in MgO [18] are also given for comparison. According to this, the $Co^{2+}$ in the glass is present in an octahedral environment. A similar gradation of the wave numbers as for the three $Co^{2+}$ complexes shown in the table is found for the corresponding $Ni^{2+}$ compounds; it depends on the strength of the ligand field (cf. Section 8). The charge-transfer bands appearing in the diagrams are also described in Section 8.

[*] The extinctions given in this paper refer to a layer thickness of 1 mm and to 1 g of the transition metal per 100 g of glass; the absorption of the base glass has been taken into account.

[15] Experiments at wave numbers below 4000 $cm^{-1}$ are still in progress, since here a new preparative and measuring technique is required.

[16] For a spectroscopic analysis primarily of colored silicate glasses, see *C. R. Bamford*, Physics Chem. Glasses *3*, 189 (1962).

[a] Calculated by the method given in [22].
[b] Calculated [19].

with the spectrum of tetrahedrally coordinated $Co^{2+}$ ions in $Zn_{0.99}Co_{0.01}O$ and $Co_{0.1}Mg_{0.9}Al_2O_4$ [20] shows that the $Co^{2+}$ in the alkali-rich glass is present in tetrahedral coordination.

In principle, three quartet-quartet transitions are to be expected (cf. Fig. 2):

$^4A_2 \rightarrow {}^4T_2(F)$, $^4A_2 \rightarrow {}^4T_1(F)$, $^4A_2 \rightarrow {}^4T_1(P)$.

All three $^4T$ states should be split by spin-orbit coupling, so that a multiplet structure of the corresponding absorption bands is to be expected [21]. The lowest transition $^4A_2 \rightarrow {}^4T_2$ (which occurs at about 4200 $cm^{-1}$ in $Zn_{0.99}Co_{0.01}O$) could not be observed, since it lies near the limit of the range of the instrument employed (Zeiss PMQ II). In the visible region, there is a system of three bands with two strong and one medium component. It is not likely that these bands are based only on the transition to the $^4T_1(P)$ level, since there is a $^2G$ state just above the $^4P$ state of the free $Co^{2+}$ ion. Two of its subsequent levels, namely $^2E(G)$ and $^2T_1(G)$, cross the level $^4T_1(P)$ even at small ligand field [19]. Consequently, the energetically highest band (19500 $cm^{-1}$) may be assigned to a $^4A_2 \rightarrow {}^2G$ subsequent level transition and the other two bands to the $^4A_2 \rightarrow {}^4T_1(P)$ transition.

### b) Magnetic Investigations

According to the ligand field theory, the magnetic behavior of transition-metal ions is also connected with their spatial environment [23,24]. Consequently, it was necessary to determine whether changes occur in the magnetic moments of the transition-metal ions in the glasses, for example, with a varying content of alkali, and whether these changes can be explained in agreement with the optical findings. The glasses used for magnetic measurements contained an average of ten times as much transition metal as those for the optical measurements, *i.e.* 2% by weight, so that the moment of the transition ion could be determined with sufficient accuracy [*].

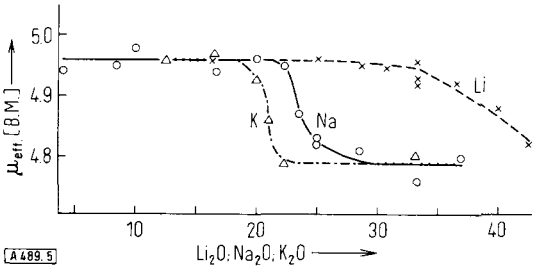

Fig. 5. Magnetic moment of $Co^{2+}$ in lithium, sodium, and potassium borate glasses as a function of the content of the alkali-metal oxide. Left, purple glasses, octahedral arrangement; Right, blue glasses, tetrahedral arrangement. Abscissa: Alkali-metal oxide content, mole-%.

As can be seen in Fig. 5, the effective magnetic moment ($\mu_{eff}$) of the $Co^{2+}$ ion decreases at low contents of the alkali-metal oxide in potassium glasses and at high contents of the alkali-metal oxide in sodium and in lithium glasses [1]. The decrease in the moment takes place at about the same content of the alkali-metal oxide as the color change of the glass, and thus is related to the change in the coordination number.

The high moment in the alkali-poor glass is explained below by a comparatively large component of the orbital angular momentum, *i.e.* by comparatively weak spin-orbit coupling; the opposite applies to the alkali-rich glass.

When only the spin moment is active for the $Co^{2+}$ ion with the electron configuration $3d^7$, we obtain

$$\mu_{eff} = \sqrt{4S(S+1)} = 3.87 \text{ B. M.}$$

When, in addition, there is full orbital contribution, we have

$$\mu_{eff} = \sqrt{4S(S+1) + L(L+1)} = 5.20 \text{ B. M.}$$

The experimental values for high-spin $Co^{2+}$ complexes lie between these limits. The magnetic behavior to be expected in an octahedral or a tetrahedral environment can be deduced qualitatively from the energy-level diagram of the $Co^{2+}$ ion (Fig. 2). Here only these two cases will be mentioned, since the octahedral or tetrahedral arrangement of the oxygen environment of the ions in the alkali-poor and alkali-rich glasses, respectively, follows from the optical measurements.

Since the magnetic behavior is determined predominantly by the ground state of the ion, only the levels succeeding $^4F$ will be considered. The electron configu-

[*] To determine the magnetic moments, the susceptibilities were measured between 90 and 373 °K with the "Magnet Binder E 20 E 1" with current stabilization. The susceptibilities of the base glasses were taken into account.

ration in the 3d shell in the octahedral field is described by $t_{2g}^5 e_g^2$, *i.e.* by a triply degenerate T level, while in the tetrahedral field it is described by $e^4 t_2^3$, and therefore by a nondegenerate A state. *Penney* and *Schlapp* [12] showed that a contribution from the orbital moment can appear only when the ground state is a T state. If these considerations are applied to the $Co^{2+}$ ion in the sodium borate glass, we obtain a higher effective moment for the octahedrally surrounded ion in the alkali-poor glass than for the tetrahedrally surrounded ion in the alkali-rich glass. As Fig. 5 shows, this is in fact the case: in the alkali-poor glasses the coloring ion has an effective moment of about 4.95 and in the alkali-rich glasses of about 4.80 B. M.

However, even with tetrahedrally surrounded $Co^{2+}$ a higher moment is found than would be expected from the spin-only equation. The reason for this is the participation of the higher, triply degenerate T levels, which are energetically not far from the A level and which permit an orbital contribution to be expected. In the one-electron orbital scheme (Fig. 1), therefore, the electron configuration of the $Co^{2+}$ ion should not be described by $e^4 t_2^3$ alone but partly by $e^3 t_2^4$ as well.

## 5. Alkali Borate Glasses Containing Nickel [2]

In the ground state, the $Ni^{2+}$ ion possesses a spin angular momentum S = 1 and an orbital angular momentum L = 3; consequently, the ground state is $^3F$. The levels above are $^1D$ and $^3P$, as shown schematically in Fig. 6. The splittings under the influence of an octahedral field (right) [25–27] and a tetrahedral field (left) [27, 28] are also shown.

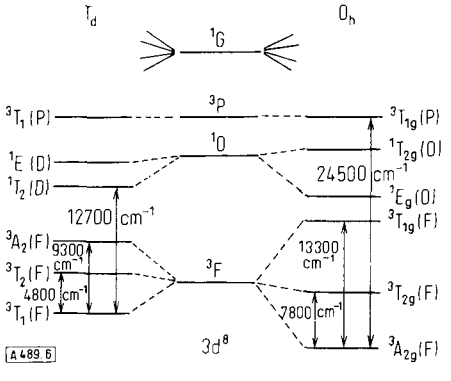

Fig. 6. Energy-level diagram of $Ni^{2+}$. Left, splitting in the tetrahedral ligand field; right, splitting in the octahedral ligand field.

### a) Optical Investigations

The spectrum of the yellow-green alkali-poor nickel potassium borate glasses (base glass $K_2O{\cdot}10B_2O_3$) shows three absorption bands (cf. Fig. 7) whose maxima are assigned to transitions in the energy-level diagram of $Ni^{2+}$ for an octahedral environment (Fig. 6). The spectra of $[Ni(H_2O)_6]^{2+}$ [25, 26] and of $Ni^{2+}$ in MgO [29] can be used for comparison.

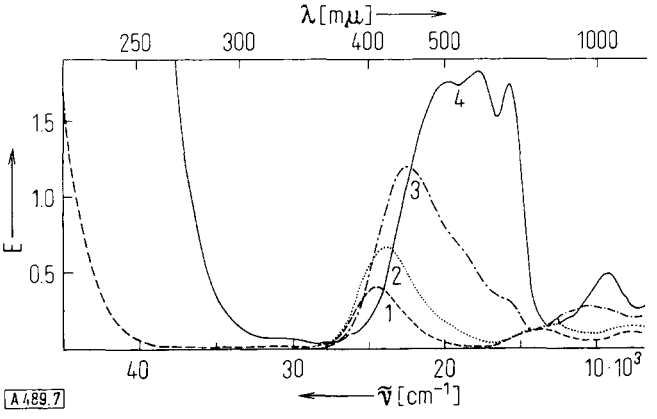

Fig. 7. Spectra of nickel potassium borate glasses with the base glass compositions $K_2O{\cdot}10\ B_2O_3$ (yellow-green, curve 1), $K_2O{\cdot}4\ B_2O_3$ (amber yellow, curve 2), $K_2O{\cdot}3\ B_2O_3$ (amber brown, curve 3), and $K_2O{\cdot}2\ B_2O_3$ (deep purple, curve 4).

The ligand field splitting $\Delta = 10$ Dq can be estimated from the band at 7800 $cm^{-1}$, since this is based on the transition $^3A_{2g} \rightarrow {}^3T_{2g}$ (F), which corresponds to 10 Dq. Consequently, the ligand field in the nickel potassium borate glass (7800 $cm^{-1}$) would be weaker than in the $[Ni(H_2O)_6]^{2+}$ complex (8300–8500 $cm^{-1}$) or in the $NiO_6$ octahedra ($Ni^{2+}$ incorporated in MgO) (8600 $cm^{-1}$).

Whether, in addition to the band at 13300 $cm^{-1}$, a band exists between 13000 $cm^{-1}$ and 15000 $cm^{-1}$ with the participation of a $^3A_{2g} \rightarrow {}^1E_g$ (D) multiplicity-forbidden transition, cannot be decided from our measurements on nickel-containing potassium borate glasses; in the corresponding sodium borate glasses (cf. Fig. 8) it is found at 14600 $cm^{-1}$.

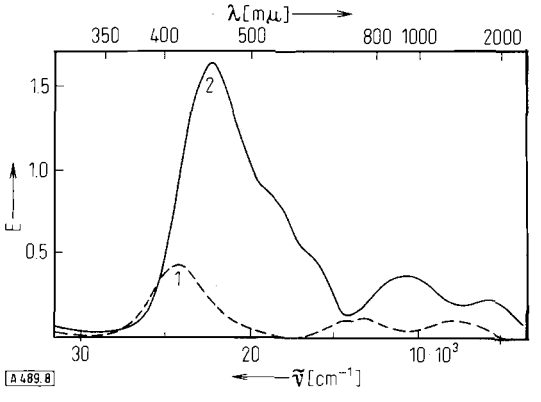

Fig. 8. Spectra of nickel sodium borate glasses with the base glass compositions $Na_2O{\cdot}10\ B_2O_3$ (yellow-green, curve 1) and $Na_2O{\cdot}2\ B_2O_3$ (amber brown, curve 2).

The spectrum of the deep purple alkali-rich nickel-containing potassium borate glass (base glass $K_2O{\cdot}2B_2O_3$) differs strongly from that of the glass with octahedrally coordinated $Ni^{2+}$ (cf. Fig. 7). The spectrum can be assigned to the transitions in the energy-level

[25] *C. K. Jørgensen*, Acta chem. scand. *9*, 1362 (1955).
[26] *C. Furlani*, Z. physik. Chem. N. F. *10*, 291 (1957).
[27] *A. D. Liehr* and *C. J. Ballhausen*, Ann. Physics *2*, 134 (1959).
[28] *H. Hartmann* and *H. Fischer-Wasels*, Z. physik. Chem. N. F. *4*, 297 (1955).
[29] *W. Low*, Physic. Rev. *109*, 247 (1958).

diagram of $Ni^{2+}$ in a tetrahedral environment (cf. Fig. 6) and agrees approximately with the spectrum of tetrahedrally coordinated $Ni^{2+}$ in $Ni_{1.9}Zn_{0.1}SiO_4$ [30].

A particularly important indication of the presence of a $NiO_4$ coordination tetrahedron is the occurrence of the band at 4800 $cm^{-1}$, which we have assigned to the $^3T_1 \rightarrow {}^3T_2(F)$ transition. For $Ni^{2+}$ coordinated octahedrally by oxygen in the glass, the ligand field band of lowest energy occurs at 7800 $cm^{-1}$.

As in the alkali-poor glass, here again the ligand field splitting can be estimated from the $^3T_1 \rightarrow {}^3T_2(F)$ (4800 $cm^{-1}$) transition. The multiplicity-forbidden triplet-singlet transition (12700 $cm^{-1}$) is observed with many tetrahedral metal complexes. However, because it is forbidden, the band is only weak. The three bands (15700, 17800, and 19700 $cm^{-1}$) in the region of the transition $^3T_1 \rightarrow {}^3T_1(P)$ have so far not been interpreted unambiguously [31, 32].

The spectrum of a yellow green alkali-poor nickel sodium borate glass (base glass: $Na_2O \cdot 10\ B_2O_3$) agrees completely with that of the corresponding potassium glass (cf. Fig. 8). On the other hand, the spectrum of the amber-brown alkali-rich nickel sodium borate glass (base glass $Na_2O \cdot 2\ B_2O_3$) is very different from that of the purple potassium glass of the corresponding composition. The alkali-rich sodium glass shows a mixed color like a potassium glass of medium alkalinity (base glass approximately $K_2O \cdot 3\ B_2O_3$); octahedrally and tetrahedrally coordinated $Ni^{2+}$ ions are present.

### b) Magnetic Investigations

Fig. 9 shows the change of the magnetic moments of the $Ni^{2+}$ ion in sodium and potassium borate glasses as a function of the content of the alkali-metal oxide. For the $Ni^{2+}$ ion, with the electron configuration $3d^8$, one would expect an effective moment of 2.83 B. M. for the spin-only case, or $\mu_{eff}$ = 4.47 B. M. with complete orbital contribution. It can be seen from the energy-level diagram (Fig. 6) that here, in contrast to the cobalt glasses, a lower moment is to be expected for the octahedral coordination (A ground state) than for the tetrahedral coordination (T ground state). In the series of the nickel potassium borate glasses, values of 3.30 B. M. have been found for $Ni^{2+}$ in the $NiO_6$ octohedra and 3.65 for $Ni^{2+}$ in the $NiO_4$ tetrahedra.

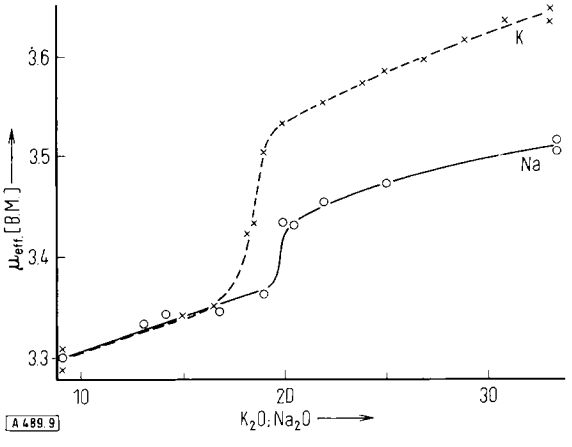

Fig. 9. Magnetic moment of $Ni^{2+}$ in the sodium and potassium borate glasses as a function of the content of the alkali oxide. Left, yellow-green glasses, octahedral arrangement; right, purple glass (with K), tetrahedral arrangement, and amber-brown glass (with Na), tetrahedral and octahedral arrangements. Abscissa: content of alkali oxide in mole-%.

In the nickel sodium borate glasses, the values for the alkali-poor glass are 3.30 B. M. ($NiO_6$ octahedra) and that for the alkali-rich glass 3.50 B. M.: the last figure is, however, a statistical average over $NiO_6$ and $NiO_4$ polyhedra simultaneously present, as expected on the basis of the spectra.

In the case of nickel glasses, the magnetic moment is more suitable than in the case of cobalt glasses as an indicator of the tetrahedral or octahedral coordination of the color center in the glass. This may be due to the fact that – as can be seen from the energy-level diagrams of $Ni^{2+}$ (Fig. 6) and $Co^{2+}$ (Table 2) – the distance between the A level and the first T level in octahedrally coordinated nickel, at 7800 $cm^{-1}$, is almost twice as great as in the tetrahedrally coordinated cobalt at 4060 $cm^{-1}$. Consequently, with the octahedrally coordinated $Ni^{2+}$ ion attainment of the triply degenerate T level, which leads to orbital contribution, requires a greater energy than for the tetrahedrally coordinated $Co^{2+}$ ion. Hence, the difference between the effective "spin-only moment" found and the moment to be expected from the spin-only formula for octahedrally coordinated $Ni^{2+}$ (*ca.* 0.5 B. M.) is also substantially smaller than with tetrahedrally coordinated $Co^{2+}$ (*ca.* 0.9 B. M.).

## 6. Alkali Borate Glasses Containing Copper

With S = $^1/_2$ and L = 2, the $Cu^{2+}$ ion has the ground state $^2D$; there are no other levels for the $3d^9$ configuration. When the $Cu^{2+}$ ion is incorporated in the center of octahedral or tetrahedral coordination polyhedra, two subsequent levels arise in each case by the splitting of the ground state in the ligand field (cf. Fig. 10). On the right of Fig. 10 is shown the splitting in the case of tetragonal-bipyramidal symmetry of the ligand field [33].

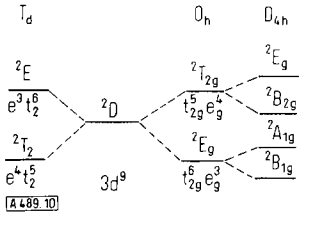

Fig. 10. Energy-level diagram of $Cu^{2+}$. Left of $^2D$ term, the splitting in the tetrahedral ligand field; right, that in the octahedral and in the tetragonal-bipyramidal ligand field.

[30] *O. Schmitz-DuMont, H. Gössling*, and *H. Brokopf*, Z. anorg. allg. Chem. *300*, 159 (1959).

[33] *C. J. Ballhausen*: Introduction to Ligand Field Theory. McGraw-Hill, New York 1962.

This case is important with the $Cu^{2+}$ ion because no undistorted octahedral $Cu^{2+}$ complex is known [34].

### a) Optical Investigations

The spectrum of the blue-green alkali-poor copper sodium borate glass (base glass $Na_2O{\cdot}12\ B_2O_3$) is shown in Fig. 11. It has a weak broad absorption band in the visible region, and a strong band in the ultraviolet. Comparison with the spectrum of the $[Cu(H_2O)_6]^{2+}$ ion [35] shows that the $Cu^{2+}$ must be present in the glass in approximately octahedral coordination. Only one ligand field band appears, as expected for octahedral coordination according to the energy-level diagram. Since there is no other transition in the neighborhood the band should be a Gaussian curve [36]. Closer inspection shows, however, that the observed band consists of two superposed bands (cf. Table 3). The assignment was therefore carried out on the basis of the tetragonally distorted ligand field which should occur with $Cu^{2+}(lig)_6$ coordination polyhedra on the basis of the strong Jahn-Teller effect occurring in the case of a $3d^9$ electron configuration [34].

The dark blue alkali-rich glass containing copper (base glass $Na_2O{\cdot}2\ B_2O_3$) shows, like the alkali-poor glass, a broad absorption band in the visible region and one band in the ultraviolet. However, the spectra of the two glasses differ from one another in two points, which possibly indicate a partial tetrahedral coordination: the band in the visible has a higher intensity and the charge-transfer band rises more steeply and at lower energy; this shift has also been observed in the transition of cobalt (cf. Fig. 2) and of nickel (cf. Fig. 7) from a coordination number of 6 to one of 4.

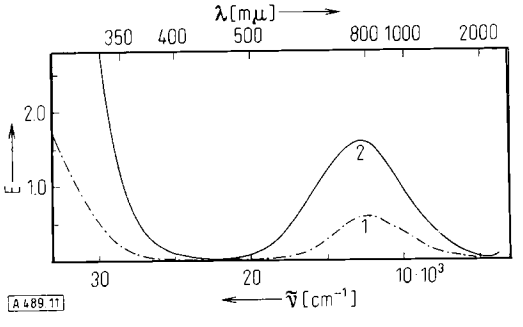

Fig. 11. Spectra of copper sodium borate glasses with the base glass compositions $Na_2O{\cdot}12\ B_2O_3$ (blue-green, curve 1), and $Na_2O{\cdot}2\ B_2O_3$ (dark blue, curve 2).

Table 3. Band assignment in the spectrum of the alkali-poor, blue-green copper sodium borate glass (base glass $Na_2O{\cdot}12\ B_2O_3$) and in a comparative spectrum.

| Cu-glass $\tilde{\nu}$ ($cm^{-1}$) | $[Cu(H_2O)_6]^{2+}$ $\tilde{\nu}$ ($cm^{-1}$) [35] | Assignment |
|---|---|---|
| 9300 | 9300 | $^2B_{1g} \rightarrow {}^2B_{2g}$ |
| 12300 | 12700 | $^2B_{1g} \rightarrow {}^2Eg$ |

### b) Magnetic Investigations

The results of the magnetic investigation may help to elucidate the coordination relationships. Up to a base glass composition of $Na_2O{\cdot}7\ B_2O_3$ the alkali-poor copper glasses (cf. Fig. 12) show an effective moment of 1.95 B. M. for the $Cu^{2+}$ ion. The moment rises to 2.10 B.M. in the glass richest in alkali ($Na_2O{\cdot}2\ B_2O_3$) [37].

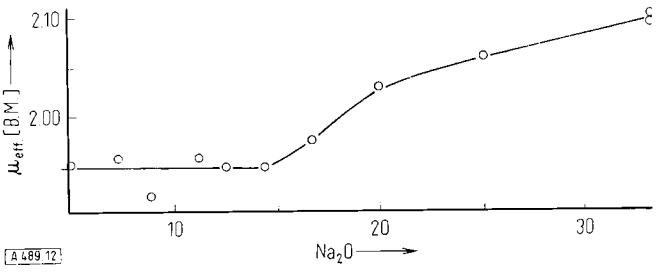

Fig. 12. Magnetic moment of $Cu^{2+}$ in sodium borate glasses as a function of the content of sodium oxide. Left, blue-green glass, tetragonal-bipyramidal structure; right, blue glass; for structure see text. Abscissa: Content of sodium oxide in mole-%.

According to theoretical investigations [38, 39] on the magnetic moment of $Cu^{2+}$ complexes in ligand fields of various symmetries, the $Cu^{2+}$ ion in octahedral or tetragonal-bipyramidal fields should have a moment of 1.73 to 1.9 B. M., *i.e.* near the spin-only value of 1.73. In a tetrahedral environment, a substantially higher value of 2.2 B. M. should appear. This stronger orbital contribution in the tetrahedral field is based on the triply degenerate ground state $^2T_2$ (cf. Fig. 10), while with the only doubly degenerate $^2Eg$ ground state or the non-degenerate $^2B_{1g}$ ground state in fields of symmetry $O_h'$ or $D_{4h}$ the orbital contribution should scarcely be involved. The values found (1.95 and 2.10 B. M., respectively) may indicate that the transition-metal ion is present in octahedral coordination in the alkali-poor glass, and already to some extent in tetrahedral coordination in the alkali-rich glass.

It cannot, however, be decided with certainty from the spectra and magnetic moments whether only distorted octahedral or, in addition, tetrahedral structural groups are present in the alkali-rich glass; there may be a superposition of both, as is observed in nickel-containing sodium borate glasses (cf. Fig. 8). A decision as to whether glasses with $Cu^{2+}$ ions surrounded only tetrahedrally by oxygen can be prepared will probably be provided by measurements on analogous copper potassium or, better, copper cesium borate glasses.

## 7. Transition-Metal Complexes and Glass Structure

The extent of correspondence of $MX_6$ or $MX_4$ structural groups in glass and in crystalline compounds is striking. The immediate environment of the transition-metal ion in glass has, according to the optical results, the same

[37] The magnetic investigations on copper-containing glasses were carried out by Dr. *H. Printzen*.

[38] *K. Ito* and *T. Ito*, Austral. J. Chem. *11*, 406 (1958).

[39] *N. Figgis*, Nature (London) *182*, 1568 (1958).

high symmetry as in the corresponding dissolved or solid compounds. In glass – the comparison can be carried furthest in the halogen complexes to be described in Section 8 – no additional band splitting, which would show a reduction in symmetry, can be observed either. The tetragonal symmetry of the $CuO_6$ polyhedron in glass is also found in crystalline materials, *e.g.* in copper ferrite [40]. The spatial arrangement of the oxygen atoms is determined by the direction and occupancy of the d-orbitals responsible for the bond. The spatial arrangement of the ligands, which evidently remains after solidification, is made possible by the high mobility of the ions in the glass melt.

Boric oxide glass itself dissolves heavy metal oxides to only a small extent. This is probably due to the very firm bond between oxygen and boron. Each oxygen atom is shared by two shallow $BO_3$ pyramids. The polarizing action of the transition metal ions on the oxygen is of great importance for the formation of complexes. However, it is low in the case of a $B_2O_3$ bridging oxygen, since this atom is under the highly contrapolarizing action of the two borons to which it is bound.

The addition of an alkali-metal oxide increases the solubility of transition-metal oxides in the glass. The spectrum remains constant over a comparatively wide range: thus, the spectrum of nickel in glass of composition $K_2O{\cdot}5B_2O_3$ coincides with that in the glass $K_2O{\cdot}10\ B_2O_3$, shown in Fig. 7. In this range of compositions, as shown in Section 2, the $BO_3$ groups are converted increasingly into $BO_4$ groups. The oxygen in the tetrahedral $BO_4$ groups is also bridging oxygen: it is also contrapolarized by two boron atoms, but less strongly than the bridging oxygen in the $BO_3$ groups. In crystalline polyborates, the B–O distance in the plane structural groups is 1.38 Å, and in the tetrahedral groups 1.48 Å [41]. The increase in the distance requires a smaller contrapolarizing action of the boron. It must be assumed that the associated increase in the polarizability of the oxygen due to the transition-metal ions is responsible for the increase in the solubility of the metal oxides and for the formation of $MO_6$ complexes. The metal-oxygen bond should here be regarded as strongly polar.

Borate glasses with more than 17 mole-% of sodium oxide contain "non-bridging" oxygen, which is associated with an excess of negative charge but which is substantially less contrapolarized by boron. Consequently, the requirements of the formation of the $MX_4$ complexes, in which the proportion of covalent bonding is greater, are satisfied. A short discussion of the ligand fields of bridging and non-bridging oxygen is given at the end of Section 8.

The ideas on the coordination of color centers in glasses are supported by the magnetic behavior, but the conclusions drawn from the latter are less stringent. However, this is not due to the vitreous state of the samples investigated; with crystalline complexes, too, the magnetic behavior is frequently complicated to such an extent by different orbital contributions that convincing conclusions can be drawn only with difficulty. On the other hand, a particularly simple magnetochemical situation exists in the glasses investigated, at least with the contents of transition-metal ions considered here. Very low values of the constant $\Theta$ in the Curie-Weiss law are always found; they are generally between $-5$ and $-20\,^{\circ}K$. Thus practically no interactions occur between the 3d electrons of neighboring metal ions; it is prevented by the great distance in the boron-oxygen network.

The change in color of the glasses and the change in the magnetic moment depend not only on the content of alkali but also on the natures of the transition metal and of the alkali-metal oxide used.

Of the ions $Co^{2+}$, $Ni^{2+}$, and $Cu^{2+}$, when incorporated into sodium borate glasses, the transition to tetrahedral coordination takes place completely with $Co^{2+}$. In the case of $Ni^{2+}$, both types of coordination are present, and with $Cu^{2+}$ only a very low fraction is converted to tetrahedral coordination. This is due to the decrease of crystal field stabilization in a tetrahedral environment in the sequence $Co^{2+}$, $Ni^{2+}$, $Cu^{2+}$ [34].

An influence of the type of alkali-metal oxide ($Li_2O$, $Na_2O$, and $K_2O$) on the position and width of the transition region is also found, as can be seen best from the change in the magnetic moments of cobalt (cf. Fig. 5). With $Li_2O$, the tetrahedral coordination is evidently no longer achieved completely in the cobalt glass, whereas this is the case with $Na_2O$ and $K_2O$. Similarly, the tetrahadral coordination is achieved in the nickel-containing $K_2O$ glasses, but not with $Na_2O$. This difference in the behavior of the alkali-metal oxides is in our opinion connected with the importance of nonbridging oxygen atoms for the formation of the tetrahedral complexes. The concentration of the non-bridging oxygens is, however, difficult to measure. The concentration of oxygen ions has been determined in glass melts by EMF measurements; it is higher in potassium borate melts than in sodium and lithium borate melts of the same alkali content [42]. This result undoubtedly also gives a point of reference for the situation in the glasses; it explains the occurrence of tetrahedral coordination polyhedra in glasses of the heavy alkali metals. Regarded from the point of view of polarization of the oxygen, the polarizing action of the small alkali-metal ion in lithium borate glasses competes with that of the transition metal, while in the glasses with larger alkali-metal ions, having a smaller polarizing action, this competition takes place to a smaller extent.

## 8. Halide-Containing Cobalt and Nickel Glasses

The color of a glass can be changed by the addition of alkali-metal halides in the melt [1,2,43]. We wished to determine under what circumstances such changes in

[40] *E. Prince* and *R. G. Treutling*, Acta crystallogr. *9*, 1025 (1956).

[41] *J. Krogh-Moe*, Acta crystallogr. *13*, 889 (1960); Ark. Kemi *14*, 439 (1959).

[42] *W. Stegmaier* and *A. Dietzel*, Glastechn. Ber. *18*, 297 (1940).

[43] *W. C. Taylor*, Glass Ind. *7*, 90 (1925).

the color and possibly also in the magnetic moment of the transition metal ion occurred in cobalt- and nickel-containing glasses, whether the changes could be related to the ideas on color centers, and whether the ligand field theory can be applied.

We shall discuss first those cases in which the incorporation of alkali-metal halides has no influence on the color of the glasses. Table 4 gives a survey; on the average, 10 moles of halide were added per mole of the transition

Table 4. Survey of the color, magnetic moment, and coordination of the transition-metal ion in halide-containing alkali borate glasses with cobalt and nickel.

| Glass | Additive | Color | $\mu_{eff}$ (B. M.) | Coordination |
|---|---|---|---|---|
| Alkali-poor cobalt glass ($Na_2O{\cdot}7\ B_2O_3$) | — | Red-purple | 4.95 | $O_6$ |
| | F | Red-purple | 4.94 | $O_6$ |
| | Cl | Blue | 4.89 | $Cl_4$ |
| | Br | Blue | 4.91 | $Br_4$ |
| | I | Green | 5.09 | $I_4$ |
| Alkali-rich cobalt glass ($Na_2O{\cdot}3\ B_2O_3$) | — | Blue | 4.80 | $O_4$ |
| | F | Blue | 4.79 | $O_4$ |
| | Cl | Blue | 4.84 | $O_4$ |
| | Br | Blue | 4.85 | $O_4$ |
| | I | Blue | 4.89 | $O_4$ |
| Alkali-poor nickel glass ($K_2O{\cdot}8\ B_2O_3$) | — | Yellow-green | 3.29 | $O_6$ |
| | Cl | Blue | 3.65 | $Cl_4$ |
| Alkali-rich nickel glass ($K_2O{\cdot}2\ B_2O_3$) | — | Purple | 3.65 | $O_4$ |
| | Cl | Purple | 3.65 | $O_4$ |

metal. The color of the alkali-rich cobalt- and nickel-containing glasses remained unchanged. The absorption bands in the near infrared and in the visible agree with those of the halide-free glasses. Since these are the regions of the ligand field bands, the same assignment applies as for the corresponding halide-free glass. The magnetic moments of $Co^{2+}$ and $Ni^{2+}$ also remain constant. The ligand field in the $CoO_4$ coordination polyhedra is obviously stronger than in the $Co(Hal)_4$ polyhedra, so that $Co(Hal)_4$ structural groups cannot form in alkali-rich glasses. However, slight differences in the spectra occur in the charge-transfer region.

Alkali-poor glasses (base glass $Na_2O{\cdot}7B_2O_3$) behave quite differently: when an alkali-metal chloride, bromide, or iodide is incorporated with the melt, their colors change. Comparison of the spectra of these glasses (Fig. 13) with the spectra of $[Co(Hal)_4]^{2-}$ compounds [19] shows that tetrahedral cobalt-halogen coordination polyhedra must be present. Table 5 gives the bands and the proposed assignments of the three glasses. The band discussion is based on that for the alkali-rich, halide-free, cobalt-containing sodium borate glasses (cf. Fig. 2 and Table 2). The first transition $^4A_2 \rightarrow {}^4T_2(F)$ for all three $Co(Hal)_4$ polyhedra occur below 4000 $cm^{-1}$ [43a].

The splitting into three bands in the near infrared [the $^4A_2 \rightarrow {}^4T_1(F)$ transition] has the same causes as the splitting for the same transition in the alkali-rich halide-free glass.

[43a] Note added in proof: Subsequent measurements with a Beckman IR 9 spectrophotometer yielded 3100 $cm^{-1}$ for the glass containing chloride. There is a shift to lower wave numbers in the glasses containing bromide and iodide.

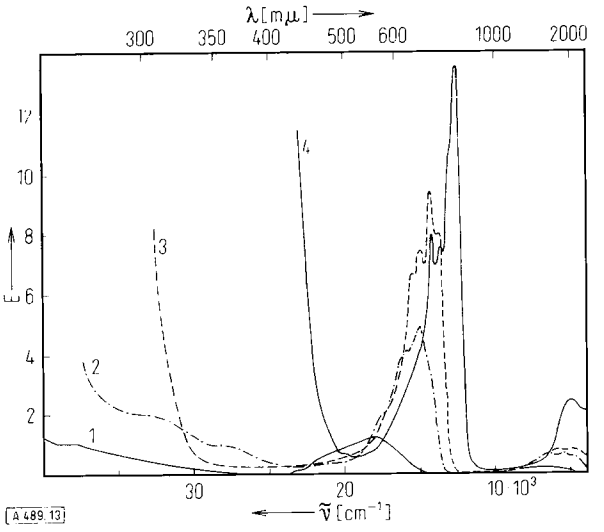

Fig. 13. Spectra of alkali-poor cobalt sodium borate glasses with added NaF (red-purple, curve 1), NaCl (blue, curve 2), NaBr (blue, curve 3), NaI (green, curve 4). Base glass $Na_2O{\cdot}7\ B_2O_3$.

Table 5. Band assignment in the spectra of alkali-poor halide-containing cobalt sodium borate glasses (base glass $Na_2O{\cdot}7\ B_2O_3$). (sh) = shoulder.

| from *ca.* 37000 | from *ca.* 32000 | from *ca.* 22000 | Charge-transfer |

A very complex system of bands is found in the visible region. It is difficult to say which bands from the central part of this system are due to $^4A_2 \rightarrow {}^4T_1(P)$ transitions and which to $^4A_2 \rightarrow {}^2G$ subsequent level transitions, since according to calculations by *Cotton*, *Goodgame*, and *Goodgame* the levels $^2E(G)$ and $^2T_1(G)$ cross $^4T_1(P)$ even in the weak field with Dq = 300 or 320 $cm^{-1}$, in which, moreover, a multiplet splitting must also be taken into account [19].

The alkali-poor nickel potassium borate glass (base glass $K_2O{\cdot}8\ B_2O_3$) into which KCl was incorporated (blue) again shows an absorption spectrum (cf. Fig. 14) completely different from that of the halide-free glass (yellow-green): it is the spectrum characteristic of $NiCl_4$ coordination polyhedra. Table 6 gives the bands and the assignment proposed by the use of the energy-level diagram (Fig. 5). The $[NiCl_4]^{2-}$ complex has been thoroughly investigated both theoretically and experimentally in solution, in the solid state, and in melts. Nevertheless, the occurrence of three bands in the $^3T_1 \rightarrow {}^3T_1(P)$ region has not yet been finally explained [31,32,44].

[44] *D. M. L. Goodgame*, *M. Goodgame*, and *F. A. Cotton*, J. Amer. chem. Soc. *83*, 4161 (1961).

The fluoride containing alkali-poor cobalt glass occupies a special position. The spectrum agrees with that of the fluoride-free glass (cf. Fig. 13, curve 1), and from this it can be deduced that the $CoO_6$ octahedra are not destroyed by the addition of fluoride. The band assignment is the same as in the fluoride-free glass.

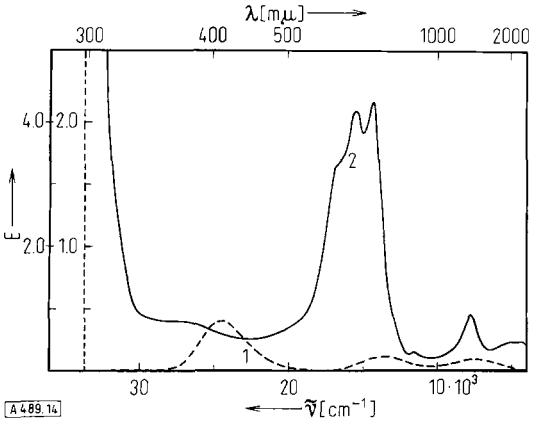

Fig. 14. Spectra of the alkali-poor nickel potassium borate glass (yellow-green, base glass $K_2O{\cdot}8\ B_2O_3$) without (curve 1) and with the addition of KCl (blue, curve 2).

Table 6. Band assignment in the spectrum of an alkali-poor, blue KCl-containing nickel potassium borate glass (base glass $K_2O{\cdot}8\ B_2O_3$).

| Ni-glass $\tilde{\nu}$ ($cm^{-1}$) | Assignment |
|---|---|
| 7700 | $^3T_1 \rightarrow {}^3A_2(F)$ |
| 11600 | $^3T_1 \rightarrow {}^1T_2(D)$ |
| 14200 | Region of $^3T_1 \rightarrow {}^3T_1(P)$ |
| 15300 | |
| 16400 (sh) | |

A further proof of the existence of cobalt-halogen bonds is offered by the charge-transfer bands (cf. Fig. 13 and Table 5), the rise of which in the sequence of the glasses with $Cl^-$, $Br^-$ and $I^-$ is displaced strongly to longer wavelengths. This shift corresponds to the law according to which "electron transfer" from $Hal^-$ to $Co^{2+}$ takes place more easily, and therefore at smaller wavelengths, with increasing oxidizability of the ligands ($Cl^- < Br^- < I^-$). There must be a comparatively high proportion of covalent bonding in the $Co(Hal)_4$ polyhedra, highest in the $CoI_4$ polyhedra. In these, therefore, the electrons coming from the ligands must be most strongly transferred into a molecular orbital that is predominantly concentrated on the metal ion.

The magnetic properties of the $Co^{2+}$ and $Ni^{2+}$ ions in the halide-containing glasses (cf. Table 4) also fit into the pattern obtained from the optical measurements. While in the alkali-rich glasses the moments are not changed by the incorporation of alkali-metal halides in the melt, the moment for the octahedral coordination changes into that for the tetrahedral coordination in the alkali-poor nickel-containing glass after the addition of halide. In the cobalt-containing glasses, a weak rise in the moments of the $Co^{2+}$ ion is found, in the sequence of $CoO_4$, $CoCl_4$, $CoBr_4$, and $CoI_4$ structural groups. This can be explained qualitatively by the fact that the distance between the non-degenerate $^4A_2$ ground terms of the $Co^{2+}$ ion (cf. Fig. 2) and the nearest triply degenerate $^4T_2$ state decreases because of the weakening of the ligand field in the direction of the $CoI_4$ complex, *i.e.* the $^4A_2 \rightarrow {}^4T_2$ excitation will occur more readily and therefore the participation of the triply degenerate T state in the state of the $Co^{2+}$ ion becomes greater.

The experiments with the halide-containing glasses are a good example of the influence of the ligand field. Thus it can be shown that, in the sense of *Tsuchida*'s sequence [13], $I^- < Br^- < Cl^- < H_2O$, an iodide-containing alkali-poor cobalt glass (green) becomes blue when chloride is incorporated in the melt, while the color of a chloride-containing glass does not change when iodide is added. In the same way, the $CoO_4$ complex cannot be destroyed by halide; the oxygen of the borate glass must therefore be inserted between $H_2O$ and $Cl^-$ in the above sequence. However, this comparison applies only if the coordination number is retained; when it changes, even the oxo complex $CoO_6$ can be converted into the halogeno complex $Co(Hal)_4$.

The spectroscopic results also permit a calculation of the ligand field strength $\Delta_t$ by Cotton and Goodgame's method [22] (Table 7).

Table 7. Ligand field strength $\Delta_t$ in some coordination polyhedra.

| Polyhedron | $CoI_4$ | $CoBr_4$ | $CoCl_4$ | $CoO_4$ | $Co(OH)_4$ |
|---|---|---|---|---|---|
| $\Delta_t$ ($cm^{-1}$) | 2750 | 2920 | 3190 [*] | 4060 | 4230 |

[*] Added in proof: Experimental value 3100 $cm^{-1}$ [transition $^4A_2 \rightarrow {}^4T_2(F)$].

The four values applying to the glasses are supplemented by the value calculated for $Co(OH)_4$ [19]. The non-bridging oxygen $^{\ominus}O-B\langle$ in the $CoO_4$ polyhedron therefore has a smaller field than the $OH^-$ ion. Similarly, the bridging oxygen $\rangle B-O-B\langle$ has a smaller ligand field than H–O–H, since the ligand field strength is calculated to be 7800 $cm^{-1}$ from the nickel-containing glass with $NiO_6$ polyhedra (transition $^3A_{2g} \rightarrow {}^3T_{2g}(F)$; cf. Fig. 6), while the $Ni(H_2O)_6$ polyhedra give the larger value of 8400 $cm^{-1}$ [25,26].

*We thank the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie for their generous support of these investigations.*

# Madelung Constants

BY PROF. DR. R. HOPPE

INSTITUT FÜR ANORGANISCHE UND ANALYTISCHE CHEMIE DER UNIVERSITÄT GIESSEN (GERMANY)

*Dedicated to Prof. Wilhelm Klemm on the occasion of his 70th birthday*

*Madelung constants are simple numbers which depend on the type of structure investigated. They are needed for the calculation (using the Born-Haber cycle) of lattice energies and enthalpies of formation of ionic compounds. Each Madelung constant is the sum of partial Madelung constants which represent the contributions of the individual ions to the total lattice energy. The partial Madelung constants depend on the ionic charge and, clearly though not stringently, on the coordination number. On the other hand, each Madelung constant can be represented by a sum of Madelung constants for related simple primitive AB structures. Surprisingly, these Madelung constants are numerically interrelated in a simple manner, and are related to the partial Madelung constants of interstitial sites. – Madelung constants of parameter-dependent structures (e.g. of the rutile or anatase type) and their variations with the structure-determining quantities are of particular interest. Madelung constants also yield information in the case of complex compounds and – surprisingly – of non-metal compounds (e.g. $XeF_2$, $XeF_4$, $XeF_2 \cdot XeF_4$).*

For many problems both inside and outside the realm of inorganic chemistry, it is necessary or desirable to obtain reasonably reliable information about the free energy of formation of unknown compounds or of compounds that have not yet been subjected to thermochemical investigation. A very recent example of such a problem is that of the thermodynamic stability of xenon fluorides [1, 1a].

Entropies can nearly always be found with a high degree of accuracy from thermochemical data for analogous compounds. The calculation of enthalpies of formation, on the other hand, is difficult even today. An important aid to the calculation of enthalpies of formation, and one that is often used because of its fundamental simplicity, is the Born-Haber cycle. It can be seen from Fig. 1 that the two simple steps I and II, *i.e.* the formation of single atoms of the gaseous substances and the formation, from these atoms, of isolated gaseous ions, are followed by a third, more complicated step, in which all the ions combine to form the crystal structure

Even for compounds which can be considered as consisting largely of ions, it is difficult to calculate the enthalpy of formation $\Delta H^\circ$ corresponding to step IV (Fig. 1) with sufficient accuracy. There are several reasons for this. In the first place (and this is a fundamental weakness of the Born-Haber cycle), $\Delta H^\circ$ is a relatively small difference of values that are often very large (ionization potential $I_{Sp}$, electron affinity $E_A$, enthalpy of sublimation $\Delta H^\circ_{subl}$, dissociation energy $D_o$, lattice energy $U_g$), so that small individual errors can lead to a considerable absolute error. Secondly, the calculation of the lattice energy associated with step III (cf. Fig. 1) is not simple. This lattice energy can be broken down into three terms as shown in Equation (1),

$$U_g = [MF \times f(z_i) \times N_L \times e^2]/r_{KA} + E_{nC} + E_{corr} \qquad (1)$$

where $N_L$ is the Avogadro number, e is the unit charge, $r_{KA}$ is the shortest distance between cations and anions, and $f(z_i)$ is a function of the ionic charge, which is often written out in full for binary compounds [$f(z_i) = z_1 \times z_2$], but is better included in the Madelung constant MF in the case of more complicated compounds. (For the sake of simplicity, it is always assumed that T = 0 °K.)

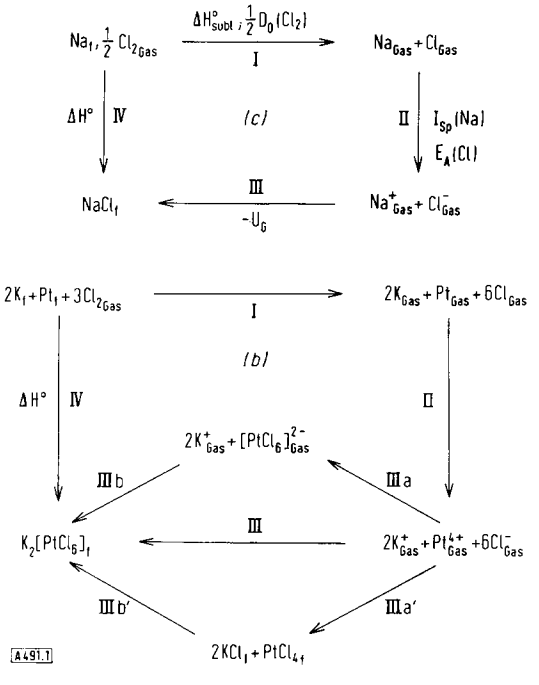

Fig. 1. Born-Haber cycle for NaCl (c) and $K_2[PtCl_6]$ (b). The index f denotes the solid state.

[1] *R. Hoppe, H. Mattauch, K.-M. Rödder,* and *W. Dähne,* Z. anorg. allg. Chem. *324,* 214 (1963); *N. Bartlett,* Endeavour *23,* 3 (1964).

[1a] *R. Hoppe,* Fortschr. chem. Forsch. *5,* 213 (1965).

In order to calculate the first term in Equation (1), *i.e.* the "Madelung component of the lattice energy", we must know the Madelung constant. This is determined by the charge on the ions and by their positions in the unit cell; in the remainder of this paper it will for binary compounds always be based on the shortest distance between cations and anions. The calculation of the Madelung constants is laborious without the aid of modern computers; consequently, Madelung factors have so far been calculated only for about 50 types of structures (most of which are very simple, often parameter-free structures) (cf. list in [3]).

The term $E_{nC}$, which takes into account the Born repulsion between the electron clouds that is due to non-Coulombic forces, must be present to explain the finite value of the equilibrium distances $r_{KA}$. Thus if we were to consider only the Madelung component of the lattice energy, this would reach its "optimum" value at $r_{KA} = 0$! Further correction takes into account the mutual polarization of the ions, the zero-point energy, lattice-energy components due to additional bonding forces (*e.g.* bonds within complex ions), *etc.* (cf. [2, 3]); these correction terms are combined in the term $E_{corr}$ in Equation (1). As can be seen from the review by *Waddington* [3], satisfactory accuracy in the calculation of lattice energies by means of Equation (1) can at present be achieved only for relatively few inorganic compounds, *e.g.* the alkali metal halides and alkaline earth metal chalcogenides. Impressive calculations have recently also led to the lattice energies of the higher alkali metal oxides [4].

## A. General

### I. The Madelung Constant and the Lattice Energy

Equation (1) can be used for the calculation of enthalpies of formation only if sufficient Madelung constants are known and if the uncertainty associated with the terms $E_{nC}$ and (in particular) $E_{corr}$ can be minimized. This makes the calculation of more Madelung constants desirable. The knowledge of Madelung constants is even more important in cases where the Madelung component of the lattice energy can be used alone, *e.g.* for investigating which modification of a compound (*e.g.* $TiO_2$) is thermodynamically stable under normal conditions, or why a parameter-dependent structure [*] (*e.g.* the rutile type) favors certain parameters (*e.g.* c/a $\approx \sqrt{2}/2$ and $x_O = 0.3$), instead of other "adjacent" values.

It can often be assumed in such cases that the terms $E_{Cn}$ and $E_{corr}$ are practically the same for "adjacent" modifications [**] of the same compound, so that differences in the enthalpies of formation are essentially due to differences in the Madelung components of the lattice energies. A similar argument applies to the variation of c/a or of the oxygen coordinates in isotypic compounds of the same structural type, such as $NaScO_2$, $NaYO_2$, $NaInO_2$, and $NaTlO_2$ [5].

### II. Partial Madelung Constants

It follows implicitly from *Ewald*'s method [6] for the calculation of Madelung constants that the Madelung constant, and hence the Madelung component of the lattice energy, can be expressed as a sum of terms which are due to the different ions in the unit cell [7]. We shall call these terms partial Madelung constants (PMF) [8, 9]. If in a compound $A_mB_n$ all the A particles occupy equivalent positions and if the same holds for all the B particles, Equation (2a) is valid:

$$MF(A_mB_n) = m \times PMF(A) + n \times PMF(B) \qquad (2a)$$

For example, for the NaCl type [$O_h^5$ – Fm3m, Z = 4, with $Na^+$ in 4(a) and $Cl^-$ in 4(b)], we have Equation (3),

$$MF(NaCl) = PMF(Na^+) + PMF(Cl^-) \qquad (3)$$

and similarly, for the $CaF_2$ type [$O_h^5$ – Fm3m, Z = 4, with $Ca^{2+}$ in 4(a) and F in 8(c)], we have Equation (4).

$$MF(CaF_2) = PMF(Ca^{2+}) + 2 \times PMF(F^-) \qquad (4)$$

If, on the other hand, the particles A occupy j different types of positions (multiplicity $z_j$), while the particles B occupy r different types of positions (multiplicity $z_r$), the general equation is (2b), where the factors $m_j = z_j/Z$

$$MF(A_mB_n) = \sum_{j=1}^{j} m_j \times PMF(A_j) + \sum_{r=1}^{r} n_r \times PMF(B_r) \qquad (2b)$$

and $n_r = z_r/Z$ ensure that the individual PMF values are correctly weighted (Z = number of formula units per unit cell). Thus for $Mn_2O_3$ [$T_h^7$ – Ia3, Z = 16, with $Mn_I$ in 8(a), $Mn_{II}$ in 24(d), and O in 48(e)], we obtain

$$MF(Mn_2O_3) = 1/2\, PMF(Mn_I) + 3/2\, PMF(Mn_{II}) + 3\, PMF(O) \qquad (5)$$

In contrast to the Madelung constants themselves, which offer only an overall picture of the energy relationships of a structural type, the partial Madelung constants provide information about the potential energies of the individual ions. For the calculation of partial Madelung constants, see [7–9].

## III. Partial Madelung Constants as Structural Arguments [9,10]

The partial Madelung constants of the various ions can also be used as structural arguments:

Using modern Fourier methods, very accurate information about the position of the center of gravity of the particles in a crystal can be obtained by X-ray analysis of single crystals, often with an average error of only ±0.005 Å. It is only in special cases, however, that electron density distributions can be found from precision measurements and used as a basis for conclusions regarding the type of chemical bonding [10a].

It is therefore still useful to employ concepts such as ionic radius, sum of the radii, ratio of the radii, coordination number, *etc.*, in the interpretation of crystal structures (which are described only geometrically by the positions of the particles). Of course, there is a remarkable discrepancy between these concepts, which are often only vaguely defined, and the accuracy of modern methods of structural analysis. Thus in addition to attempts to obtain improved definitions of these fundamental crystal-chemical quantities (cf. *e.g.* [11]), every possibility of obtaining further information from the structural geometry should be examined. Such a possibility seems to be offered by the partial Madelung constants: A three-dimensional description of the potentials and potential energies of the individual particles corresponding to the three-dimensional network of the centers of gravity is obtained by calculation of the partial Madelung constants. This discontinuous "grid" of partial Madelung constants may then be made as "dense" as required by the calculation of partial Madelung constants for interstitial sites.

It has been found that even in the case of compounds with considerable non-ionic character, a better understanding of the reasons for the occurrence of certain structures is obtained by comparison of the partial Madelung constants with those of chemically related compounds (*e.g.* $BrF_3$, $XeF_4$, and $XeF_2$) [11a].

It has been known for some time that the Born-Haber cycle can also be applied in the case of compounds that do not consist of ions. Thus *Kapustinskii* [12] demonstrated that the lattice energies of non-ionic compounds can often be calculated with reasonable accuracy with the aid of the effective Madelung constants (cf. Section A.IX), which were introduced by *Klemm* [13]. (In favorable cases, the lattice energies of covalent compounds are found with an accuracy of about ±10 kcal/mole.)

## IV. Madelung Constants of AB Types with Single Primitive Unit Cells [8,10,13a]

Simple relationships exist between Madelung constants of some compounds [7,14], for example:

$$MF(CaF_2) = MF(CsCl) + 2 \times MF(ZnS) \qquad (6)$$

In spite of reports to the contrary [15], there is an infinite number of such relationships for a given structure, since the Madelung constant represents the sum of all attractive and repulsive interactions of the ions in the crystal and can be broken down in an infinite number of ways into partial sums.

The Madelung constants of AB compounds with simple primitive unit cells (*e.g.* the CsCl type) are particularly important, since the Madelung constant of any structural type can be expressed as a sum of Madelung constants of single primitive (not necessarily isometric) AB types [*]. This follows from the fact that any structure can be derived by superposition of suitable, not necessarily isometric single primitive AB types. The Madelung constants of single primitive AB types are therefore "building units" for all other Madelung constants; they will be denoted in the remainder of this article by °MF.

For the sake of simplicity, we shall discuss only Madelung constants of single primitive AB types with cubic unit cells. However, similar relationships exist for non-cubic single primitive AB types.

For AB types with single primitive cubic unit cells, we shall always use the arrangement $A^+$ in 0,0,0 and $B^-$ in x,y,z, the corresponding Madelung constant being denoted by $^\circ MF(x,y,z)_k$; for example

$$MF(CsCl) \equiv {}^\circ MF(1/2,1/2,1/2)_k$$

When based on the shortest distance A–B, these Madelung constants all lie between 1 (the "Madelung constant" of the gaseous molecule AB) and MF(CsCl) = 1.76267... (cf. Table 1).

Table 1. $^\circ MF(x,y,z)_k$ for special values of x, y, z [8].

| x | y | z | $^\circ MF(x,y,z)_k = 2 \times PMF(x,y,z)_k$ |
|---|---|---|---|
| 1/2 | 1/2 | 1/2 | 1,7626747730... |
| 1/2 | 1/2 | 1/4 | $1{,}60742_5$... |
| 1/2 | 1/2 | 0 | $1{,}594367$ |
| 1/2 | 1/4 | 1/4 | $1.41251_3$... |
| 1/2 | 1/4 | 0 | $1.38825_9$ |
| 1/2 | 0 | 0 | $1.37068_1$ |
| 1/4 | 1/4 | 1/4 | $1.14177_4$... |
| 1/4 | 1/4 | 0 | $1.08778_1$... |
| 1/4 | 0 | 0 | $1.03580_8$... |

The variations of °MF(x,0,0), °MF(x,1/2,0), °MF(x,1/2,1/2) and °MF(x,x,x) in the range $0 \leqslant x \leqslant 1/2$ are shown in Figure 2. It can be seen that the variations follow roughly the same pattern, and are all characterized by the rapid fall-off from the maximum. The

[*] The dimensions of the unit cells of these AB types need not be the same as those of the structural type, the Madelung constant of which is to be expressed as a sum.

Madelung constants of single primitive $A^+B^-$ types with non-cubic unit cells are also smaller than 1.76267..., but some are smaller than 1.0, and they may even be negative (cf. Section X).

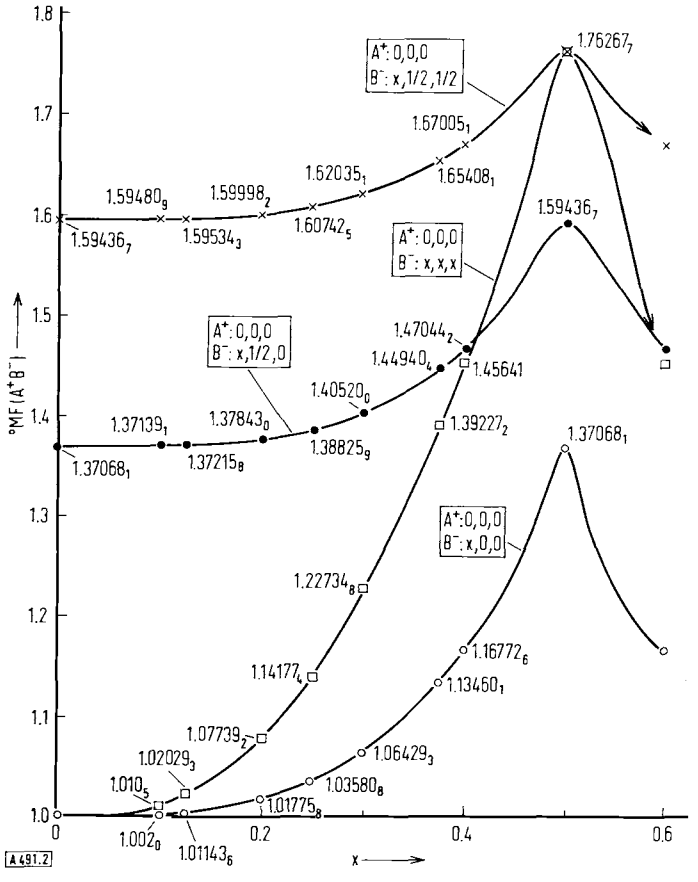

Fig. 2. Madelung constants (°MF) of cubic AB types with single primitive unit cells [arrangement: $A^+$ in (0,0,0) and $B^-$ in (x,y,z)].

## V. Partial Madelung Constants of Single Primitive AB Types

Single primitive AB types, irrespective of size and/or symmetry of their unit cell have commutative sub-lattices [7]. The partial Madelung constants of $A^+$ and $B^-$ are then numerically equal, each being half of the total Madelung constant. Where the ions are monovalent, $PMF(x,y,z)_k$ is between 0.5 and 0.88 (cf. Table 1). Moreover, some non-primitive AB structures, such as the rock salt, sphalerite and wurtzite types, also have commutative sub-lattices. In these cases the partial Madelung constants of the $A^+$ and $B^-$ particles are again numerically equal, each again being half of the total Madelung constant. An important example of a simple AB type with non-commutative sub-lattices is the NiAs type, in which the Madelung constant, as calculated by *Zemann* [16], is not a simple function of the partial Madelung constants of $A^+$ and $B^-$, which differ in their numerical values [*].

The partial Madelung constants of polyvalent ions in single primitive AB types are $z_i^2$ times as great as those of monovalent ions in the same lattice type ($z_i$ = number of unit charges on the ion in question).

[16] *J. Zemann*, Acta crystallogr. *11*, 55 (1958).

[*] They were recently calculated as functions of c/a; see [13a].

## VI. Relationships between the Madelung Constants of Single Primitive AB Types [17]

The Madelung constants of more complex structural types can all be expressed (cf. Section IV) as the sum of the Madelung constants of single primitive cells of the same size. It was assumed, therefore, that the Madelung constants of primitive AB types are not mutually related ("independent" Madelung constants) [8]; however, this assumption is wrong [17]:

Any single primitive AB structure, irrespective of the size and symmetry of its unit cell, can be described by a non-primitive pseudo-cell obtained by multiplication of one, two, or all three of the principal axes; this naturally does not change the Madelung constant, which can therefore be expressed as the sum of the Madelung constants of other single primitive AB types. If the non-primitive pseudo-cell is based on m times the a-axis, n times the b-axis, and p times the c-axis, we have

$$^{\circ}MF(x,y,z) = \sum_{r=0}^{m-1}\sum_{s=0}^{n-1}\sum_{t=0}^{p-1} \alpha_{rst}\ {}^{\circ}MF\left(\frac{x+r}{m},\frac{y+s}{n},\frac{z+t}{p}\right) - \sum_{r'=0}^{m-1}{\sum_{s'=0}^{n-1}}'{\sum_{t'=0}^{p-1}}' \alpha_{r's't'}\ {}^{\circ}MF\left(\frac{r'}{m},\frac{s'}{n},\frac{t'}{p}\right) \quad (7)$$

In this equation, the primes in $\Sigma'$, r', s', and t' indicate that the relationship r' = s' = t' = 0 must not be valid. The factors $\alpha_{rst}$ and $\alpha_{r's't'}$ are simple numbers depending on the geometry of the structure, and ensuring that the values of °MF are correctly weighted and normalized in the summation.

For example, if we describe the CsCl structure by eight times the primitive cell, we obtain

$$MF\left(\tfrac{1}{2},\tfrac{1}{2},\tfrac{1}{2}\right)_k = \tfrac{16}{3} \times MF\left(\tfrac{1}{4},\tfrac{1}{4},\tfrac{1}{4}\right)_k - \sqrt{3} \times MF\left(\tfrac{1}{2},0,0\right)_k - \frac{\sqrt{3}}{\sqrt{2}} \times MF\left(\tfrac{1}{2},\tfrac{1}{2},0\right)_k \quad (8)$$

These unexpected and surprising relationships between the Madelung constants of single primitive AB types, which exist in every case irrespective of size and symmetry of the unit cell, indicate that we are still far from a real understanding of the Madelung constants. They also suggest that other numerical relationships may exist between the Madelung constants of single primitive AB types with isometric unit cells.

## VII. Relationships between the Partial Madelung Constants of Primitive AB Types and of Interstitial Sites [17]

If we consider an infinitely large crystal of a primitive AB structure, and assume that only one interstitial site is occupied by an additional ion, the partial Madelung constant of this ion can be expressed as a sum of partial Madelung constants of single primitive AB types, and can then provide information about the energy of interstitial sites; defects can also be taken into account in this calculation by the use of additional terms.

For example, the partial Madelung constant of a cation $X^+$ occupying the position $^1/_2, ^1/_2, 0$ in one unit cell only of a CsCl-type crystal ($A^+$ in 0,0,0 and $B^-$ in $^1/_2, ^1/_2, ^1/_2$) is:

$$PMF(X^+) = PMF\left(\tfrac{1}{2},0,0\right) - \frac{\sqrt{2}}{2} \times PMF\left(\tfrac{1}{2},\tfrac{1}{2},0\right) = 0.2432946_6 \quad (9)$$

[17] *R. Hoppe*, unpublished work.

## VIII. Reduced Partial Madelung Constants

In isotypic compounds of the same formula type, but with different valences (*e.g.* $Cu^{+}Cl^{-}$, $Zn^{2+}S^{2-}$, $Ga^{3+}As^{3-}$), the partial Madelung constants of the "cations" are related as the squares of the valences $z_i^2$, if the valence factor $f(z_i)$ from Equation (1) is included in the Madelung constant. Similar relationships exist for more complex structures. In addition to the partial Madelung constants $PMF(A^{m+})$ and $PMF(B^{n-})$, it is therefore convenient to define reduced partial Madelung constants [10,18] as the partial Madelung constants divided by $z_i^2$, *i.e.*

$$*PMF(A^{m+}) \equiv \frac{PMF(A^{m+})}{m^2} \quad \text{and} \quad *PMF(B^{n-}) \equiv \frac{PMF(B^{n-})}{n^2}$$

These quantities enable us to compare the potentials in compounds of different types and with different ionic charges.

The reduced partial Madelung constants are strongly affected by the peculiarities of the crystal structures, and (unfortunately) are by no means constant. A number of typical values are given in Table 2, and Figure 3 shows how the reduced partial Madelung constants of cations vary with the coordination number and the ionic charge.

The reduced partial Madelung constants as found from Figure 3 are maximum values, and the values found for real structures are usually lower. For the "coordination number" in such cases, see Section IX.

Table 2. Reduced partial Madelung constants *PMF of the cations in typical binary crystal structures.

| Ion | Compound | Type | *PMF($A^{m+}$) |
|---|---|---|---|
| $Na^{+}$ | NaCl | NaCl | 0.874... |
| $Ca^{2+}$ | $CaF_2$ | $CaF_2$ | 0.819... |
| $Bi^{3+}$ | $BiF_3$ | $Li_3Bi$ | 0.797... |
| $Sc^{3+}$ | $ScF_3$ | $ReO_3$ | 0.685... |
| $Sn^{4+}$ | $SnF_4$ | $SnF_4$ | 0.657... |
| $A^{4+}$ | $AB_4$ | 8 B in: 0,0,0 | 0.701... |
| | 2 A in: $^1/_4, ^1/_4, ^1/_4$ | $^1/_2, 0, 0$ | |
| | $^3/_4, ^3/_4, ^3/_4$ | $0, ^1/_2, 0$ | |
| | | $0, 0, ^1/_2$ | |
| | | $^1/_2, ^1/_2, 0$ | |
| | | $^1/_2, 0, ^1/_2$ | |
| | | $0, ^1/_2, ^1/_2$ | |
| | | $^1/_2, ^1/_2, ^1/_2$ | |
| $Nb^{5+}$ | $NbCl_5$ | $NbCl_5$ | 0.551... |

## IX. The Madelung Constant as a Function of Structure-Determining Factors such as Composition and Coordination Number

Many attempts have been made to estimate Madelung constants. *Klemm* [13], in his simplified expression (10) for the lattice energy, introduced an "effective" Madelung constant a'.

$$-U_{g(exp)} = \frac{a' \times N_L \times e^2}{r_{KA}} \qquad (10)$$

He showed that a' is practically constant for chemically similar compounds of analogous composition, but depends strongly on the formula type and on the bonds present. (The terms $E_{nC}$ and $E_{corr}$ of Equation (1) are here included in a').

*Kapustinskii* [12] then showed that the lattice energies of many compounds can be calculated from Equation (11), often with good accuracy.

$$U_g = \left[\frac{287.2 \times Z \times z_A \times z_B}{r_{KA}}\right]\left[1 - \frac{0.345}{r_{KA}}\right] \text{[kcal/mole]} \qquad (11)$$

($z_A$ and $z_B$ are the ionic charges of A and B, and Z is the number of atoms per formula unit.) In this case the Madelung constant is considered as independent of the coordination numbers of the particles A and B in the binary compound $A_mB_n$, since Equation (11) is based on Equation (12):

$$MF(A_mB_n) = \frac{z_A \times z_B \times Z \times \text{const.}}{2} \equiv \frac{z_A \times z_B \times Z \times MF(NaCl)}{2} \qquad (12)$$

It is surprising to find that (contrary to the results of calculations, which give a different Madelung constant for each structural type) MF(NaCl) may be used for all possible AB structures. For other binary structural types, a simple calculation with the aid of Equation (12) gives effective Madelung constants that should depend only on the composition, *i.e.* on the formula type, and not on structural pecularities! The explanation for this is as follows:

In binary compounds, we have:

$$z_A \times z_B \times Z \equiv \sum z_i^2. \qquad (13)$$

Thus, according to *Kapustinskii* [Equations (11) and (12)]:

$$MF(A_mB_n) = \sum z_i^2 \times \frac{MF(NaCl)}{2} = \sum z_i^2 \times PMF(Na^{+}_{NaCl}). \qquad (14)$$

It can be seen that, although *Kapustinskii* himself failed to notice it, this expression implicitly represents any Madelung constant as the sum of partial Madelung constants [10].

*Kapustinskii* also assumed that all compounds can be regarded as "NaCl derivatives" [in Equation (11) the shortest interionic distance $r_{KA}$ is assumed for the coordination number 6], a view that has also been expressed by other authors (cf. *e.g.* [19]).

To understand this apparently bold simplification, it must be remembered that a deviation from the coordination number 6

[19] *T. C. Waddington*, Trans. Faraday Soc. *56*, 305 (1960).

in a real structure rather frequently leads to *lower* coordination numbers, and nearly always results in lower partial Madelung constants, and hence in smaller Madelung components of the lattice energy. However, such a deviation can occur only if additional (*e.g.* covalent) bonds ensure that the decrease in the Madelung component of the lattice energy is overcompensated in some other way. If the overcompensation is comparatively slight, *Kapustinskii*'s equation (14) is applicable, even for compounds that cannot be considered as consisting predominantly of ions. For coordination numbers above 6, the Madelung component of the lattice energy again changes only slightly, as can be seen from a comparison of the Madelung constants of the NaCl and CsCl types. Moreover, the shortest distance $d_{KA}$, too, depends on the coordination number and always changes in the same direction as the Madelung constant. Thus alterations of the Madelung constant are in part "internally" compensated.

If one does not wish to calculate lattice energies from Equation (11), but to estimate Madelung constants from Equation (12), it is more convenient in the case of binary compounds [7] to use Equation (15)

$$MF(A_mB_n) = \frac{1}{2} \times \sum z_i^2 \times \beta \qquad (15)$$

in which $\beta$ = MF(NaCl) is replaced by the more accurate:

$$\beta + (\beta/p)^2 = 1.81 \qquad (16)$$

In Equation (16), $\bar{p}$ is the "average" coordination number of A and B [*i.e.* $^1/_3(8+2\times4)=5.33$ for the $CaF_2$ type].

*Templeton* [18] later also attempted to represent Madelung constants of binary compounds as functions of the coordination number; he used the empirical equation (17)

$$MF = 1.89 - 1/p_h \qquad (17)$$

in which $p_h$ is the weighted harmonic mean of the coordination numbers of A and B. The fact that all the straight lines in Fig. 3 meet at 1.89/2 is probably closely connected with Equation (17). The approximations used by *Hoppe* [Eq. (15)] and by *Templeton* give practically the same results, as can be seen from the examples in Table 3.

Table 3. Madelung constants MF of the CsCl, NaCl, and ZnS types.

| | *Hoppe* [7] | *Templeton* [18] | Exact value |
|---|---|---|---|
| CsCl | 1.761 | 1.765 | 1.7626... |
| NaCl | 1.727 | 1,723 | 1.7475... |
| $Zn^+S^-$ | 1.638 | 1.640 | 1.6380... |

However, there is no strict relationship between the Madelung constant and the coordination number! Such a functional relationship does not exist even in the case of the Madelung constants °MF of single primitive AB structures. The reason is the simplicity of the concept of the coordination number, *i.e.* the fact that only the nearest neighbors (with opposite charges) are counted for compounds considered as consisting of ions, whereas the partial Madelung constants take into account the interactions of one ion with all the others, however far away and whatever the sign of their charge. Furthermore, in the case of more complex structures (*e.g.* crystal structures of the NaSi type [20]), it is impossible to be completely objective in deciding

[20] *W. Klemm, J. Witte*, and *H. G. v. Schnering*, Z. anorg. allg. Chem. *327*, 260 (1964).

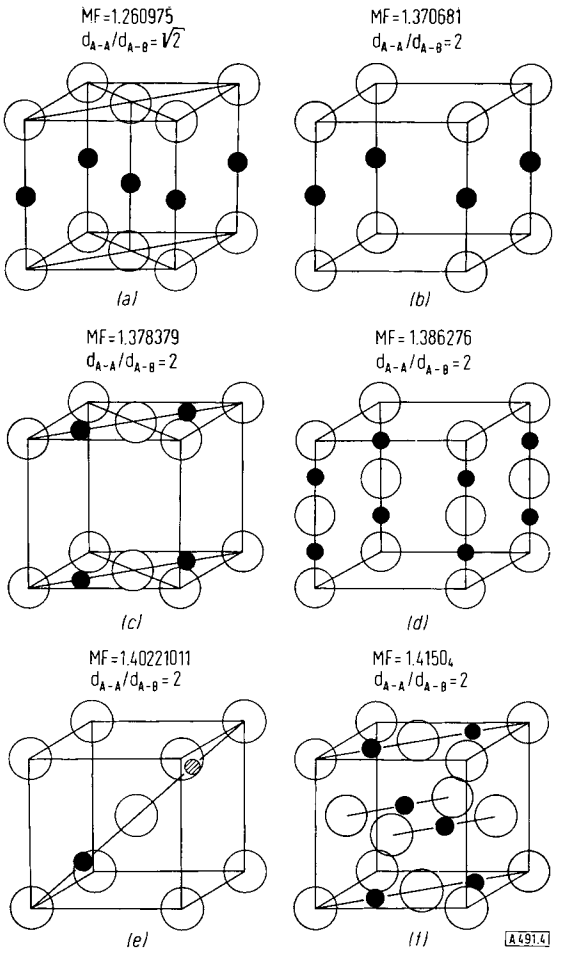

Fig. 4. Simple AB structures with the same "simple" coordination number, and the corresponding Madelung constants (sizes of the particles chosen arbitrarily).

which are the "nearest" neighbors. To illustrate this, Figure 4 shows some simple AB structures the coordination numbers of which, when counted on the basis of the simple definition, are the same. The Madelung constants [17] of these structures, on the other hand, show the influence of the arrangements of the A and B sub-lattices. From Figure 5 it can be seen how the Madelung constant is affected by the nature of the A and B sub-lattices (as a function of the coordination number) (cf. also Table 4).

Table 4. Madelung constants of simple cubic AB types. — C.N. = coordination number.

| C.N. | cubic primitive | cubic body-centered sub-lattices start in | cubic face-centered |
|---|---|---|---|
| 2 | $A^+$: 0,0,0<br>$B^-$: $^1/_2$,0,0<br>MF = 1.37068... | 0,0,0<br>$^1/_4$,$^1/_4$,$^1/_4$<br>MF = 1.40221... | 0,0,0<br>$^1/_4$,$^1/_4$,0<br>MF = 1.41504... |
| 3 | | $A^+$: 0,0,0<br>$B^-$: $^1/_2$,$^1/_8$,$^1/_8$<br>MF = 1.56968... | |

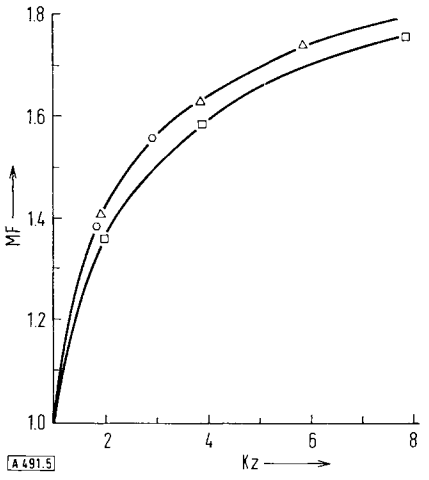

Fig. 5. Madelung constants and "simple" coordination numbers of simple cubic AB types with commutative sub-lattices. Primitive (□), face-centered (△), and body-centered (○) sub-lattices. Kz = coordination number.

The estimation of Madelung constants or the deduction of "effective coordination numbers" from calculated partial Madelung constants will always raise difficulties, since the precisely defined Madelung constant cannot be readily related to the rather vague though useful concept of the "coordination number".

Estimations of this nature are best carried out with the aid of Equation (18), in which $*PMF_i$ is the reduced partial Madelung constant and $z_i$ is the charge; $p_i$ corresponds to $m_j$ or

$$MF = \sum z_i^2 \cdot p_i \cdot *PMF_i \qquad (18)$$

$n_r$ of Equation (2b), and the summation is carried out as in Equation (2b). The $*PMF_i$ are found from comparable structures, or from graphs as in Figure 7.

## B. Special Part

The Madelung constant of a structural type is of interest for the discussion of enthalpies of formation. However, it acquires a more general importance only when considered in relation to other Madelung constants. An "observed" crystal structure is only one of many, since it is "surrounded" by a large number of other structures (*e.g.* thermodynamically less stable modifications) which are fundamentally possible, but which do not occur at thermodynamic equilibrium or have not so far been found.

It is particularly interesting in this connection to find how the Madelung constant of a structural type changes:

(a) when greater or smaller changes in the size and/or in the symmetry of the unit cell occur, while the coordinates of the particles remain constant in relation to the new axes, *i.e.* when the unit cell undergoes homogeneous affine transformations,

(b) when the coordinates of the particles change in parameter-dependent structural types, while the size of the unit cell remains unaltered, or

(c) when the changes described under (a) and (b) occur simultaneously.

In the following sections, therefore, we shall discuss, not only individual Madelung constants, but mainly their dependence on the variations mentioned.

### I. Madelung Constants of AB Types [10,17]

Homogeneous affine transformations lead to changes in the lengths of the axes and in the angles formed by them. For the sake of simplicity, the following examples are confined to special transformations in which the angle remains unchanged, and in which the changes in the principal axes can be expressed by one figure (the axial ratio c/a).

#### 1. Changes in the Madelung Constants on Tetragonal Compression or Elongation of a Cubic Unit Cell [8]

The following general rule is valid here, as for any other structure:

Any affine transformation of a structural type with a finite Madelung constant gives a new structure which also has a finite Madelung constant if the shortest distance $d_{A-B}$ remains smaller than the shortest distances $d_{A-A}$ and $d_{B-B}$. On the other hand, when the ratio $d_{A-A}/d_{A-B}$ or $d_{B-B}/d_{A-B}$ approaches zero, the Madelung constant approaches $-\infty$. It is assumed here that the Madelung constant is always based on the shortest distance $d_{A-B}$.

Table 5 contains some typical examples of Madelung constants of AB structures with single primitive unit cells derived from cubic unit cells by tetragonal compression or elongation. A characteristic feature is that

Table 5. Changes in the Madelung constants MF of cubic AB structures on tetragonal affine transformation of the unit cell [8]. $A^+$ in: 0,0,0; $B^-$ in: x,y,z [8].

| x,y,z \ c/a | 0 | 1/2 | 1 | 2 | ∞ |
|---|---|---|---|---|---|
| 0,0,1/2 | 1.386... | 1.386... | 1.770... | 0.774... | −∞ |
| 1/2,0,0 | −∞ | 1.127... | 1.370... | 1.378... | |
| 1/2,1/2,0 | −∞ | 1.095... | 1.594... | 1.615... | 1.615... |
| 1/2,1/2,1/2 | −∞ | 1.158... | 1.762... | 0.911... | −∞ |
| 1/2,0,1/2 | −∞ | 1.244... | 1.594... | 0.848... | −∞ |
| 1/4,1/4,0 | −∞ | 0.934... | 1.087... | | |
| 1/4,0,0 | −∞ | 0.971... | 1.035... | | |

the Madelung constant of the CsCl type falls off rapidly towards $-\infty$ on compression or elongation. That of the NaCl structure, on the other hand, remains finite, as can be seen from Table 6.

Table 6. The Madelung constant of the NaCl type on tetragonal affine transformation of the unit cell [8].

| c/a | MF |
|---|---|
| 0 | 1.3862... |
| 1 | 1.7475... |
| ∞ | 1.615... |

#### 2. Changes in the Madelung Constants on Hexagonal Compression or Elongation of a Cubic Unit Cell [10]

The CsCl and NaCl structures, which are fundamentally different in their cubic arrangements, are found to be

affinely transformed in the hexagonal arrangement (cf. Table 7).

Table 7. NaCl and CsCl types as affine transformations of the same structure. The letters A, a, B, b, C, c denote the positions of the particles with the coordinates given. The cation sites are denoted by capital letters and the anion sites by small letters.

| z | | |
|---|---|---|
| 1 | o o o o o o A | A (and a): 0,0,z |
| 5/6 | + + + + + + b | B (and b): 1/2, 2/3, z |
| 4/6 | o o o o o o C | C (and c): 2/3, 1/3, z |
| 3/6 | + + + + + + a | c/a = $\sqrt{6}$ : NaCl-type |
| 2/6 | o o o o o o B | c/a = $\sqrt{3/2}$ : CsCl-type |
| 1/6 | + + + + + + c | |
| 0 | o o o o o o A | |

As we pass from the CsCl type (c/a = $\sqrt{6}/2$) to the NaCl type (c/a = $\sqrt{6}$), the simple coordination number changes continuously from 8 to 6. If there were a direct relationship between the simple coordination number and the Madelung constant, the latter should change in the same direction as the coordination number, *i.e.* $\partial(MF)/\partial(c/a) \neq 0$ between the values given for c/a. However, it can be seen from Figure 6 that this is not the case. The two Madelung constants MF(CsCl) and MF(NaCl) are, in fact, separated by a minimum.

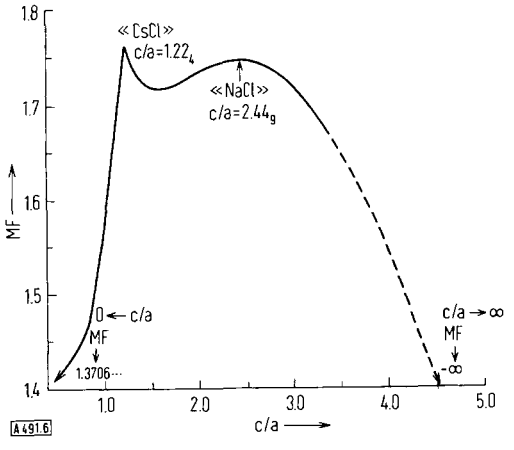

Fig. 6. Dependence of the Madelung constants of the CsCl and NaCl types on the ratio c/a in the hexagonal arrangement[10].

The change in the Madelung constants is also affected by the fact that during hexagonal elongation along [001], the shortest distance $d_{A-B}$ in the CsCl type increases rapidly for two (or six on analogous compression) of the original eight equally distant neighbors. The steep fall in MF(CsCl) for both larger and smaller values of c/a is directly related to this effect. Conversely, the relatively small decrease in MF(NaCl) on both sides of c/a = $\sqrt{6}$ is due to the fact that the six nearest neighbors do *not* split up into non-equivalent groups.

The characteristic changes in the Madelung constants of these two binary structural types are related to the fact that, although the structures of many ternary compounds (double oxides, double fluorides) are variants of the NaCl type (*e.g.* the important α-$NaFeO_2$ type), no corresponding variants of the CsCl type have so far been found.

The sphalerite type, in which the A and B sub-lattices are arranged somewhat differently (Table 8) also belongs to this group. Here the Madelung constant MF(ZnS) decreases monotonically on both sides of c/a = $\sqrt{8}/3$,

Table 8. Schematic representation of the ZnS structure. (For explanation of the symbols, see Table 7.)

| z | | |
|---|---|---|

| 0 | o o o o o o o o o o A | |

approaching 1 for c/a → 0, and $-\infty$ for c/a → ∞ (cf. Figure 7). The Madelung constant of the wurzite type shows a similar dependence on c/a, although (as can be seen from Table 9) this type consists of hexagonally close-packed sequences of A and B particles.

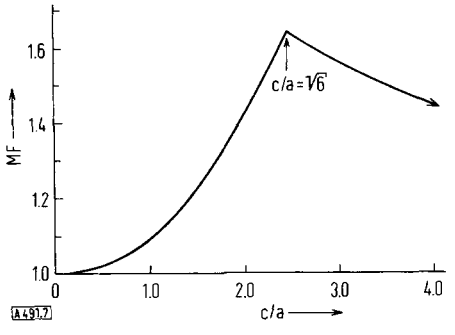

Fig. 7. Dependence of the Madelung constant of the sphalerite type on the ratio c/a in the hexagonal arrangement.

An example of an AB structure with non-commutative sub-lattices is the NiAs type (cf. Table 10), the Madelung constant of which (Fig. 8) also passes through a maximum[16], and approaches $-\infty$ for c/a → 0 and for c/a → ∞.

## II. Madelung Constants of Complicated Structural Types

Recently calculated Madelung constants of some important structural types are listed in Table 11 (see below).

### 1. The Madelung Constant of the Rutile Structure

In the rutile type $AB_2$, each cation A has only six equally distant neighbors B if the axial ratio c/a and the parameter x of the anion are related as

$$x = 1/4 + c^2/8a^2 \qquad (19)$$

*Bollnow*[21] has calculated MF(rutile) for a number of values of c/a and x that satisfy Equation (19). A recent detailed publication[22] suffers from the disadvantage that MF(rutile) is based, not on the shortest A–B distance (or some other simple difference), but on an undefined average of the distances to the six neighbors 4+ 2!), which are generally not all equal; the nature of this average cannot be deduced from the values given, but it is obviously not a simple mean. Moreover, since the difference between the Madelung constant and the Madelung component of the lattice energy is overlooked, some of the conclusions drawn are incorrect.

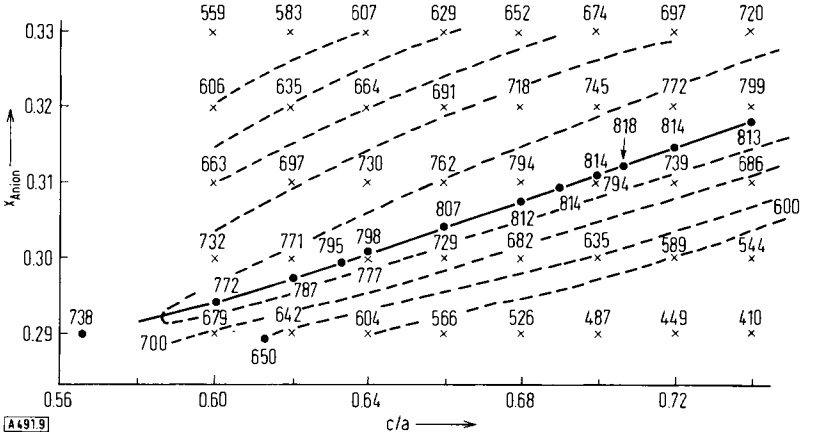

Fig. 9. Two-dimensional diagram of a three-dimensional representation of the Madelung constants of rutile as a function of $x_{anion}$ and c/a in accordance with Equation (19). The figures beside the curves are [MF(rutile)−4]× $10^3$.

Figure 9 shows MF(rutile) as a function of c/a and x[10]. The following points can be observed:

1. The Madelung constant has a maximum for c/a = $\sqrt{2}/2$ and x = 5/16 [in accordance with Equation (19)].

It became known only recently that this maximum is due to the structural geometry of the rutile type[17]. Thus if we start with a body-centered arrangement of the anions with regularly occupied quasi-octahedral holes (cf. Figure 10) the significance of the ratio c/a = $\sqrt{2}/2$ becomes immediately obvious: For this ratio the cubic sub-lattice (as indicated in Figure 10) and the favorable arrangement of the cations (with the charges +2 or +4) remain unchanged.

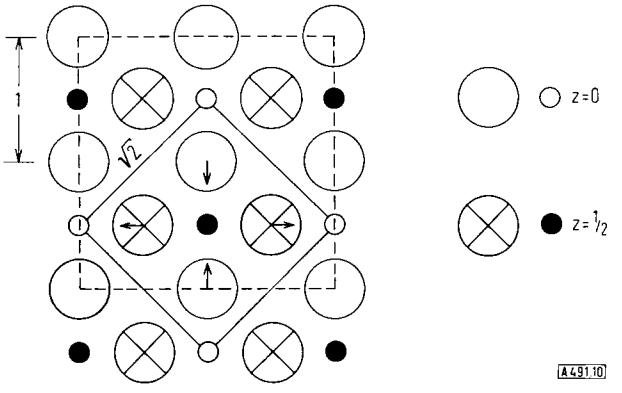

Fig. 10. Structural geometry of the rutile type. The lengths and directions of the arrows show the displacement of the anions to the true positions (sizes of the particles chosen arbitrarily).

2. No known compound with a rutile structure corresponds to this ideal case. This is at least partly due to the fact that the "grid" of Madelung factors (Figure 9) is calculated for point-shaped ions and does not take into account finite and even fixed ionic radii.

In typical rutile-type compounds $AB_2$, such as difluorides (*e.g.* $ZnF_2$) and dioxides (*e.g.* $SnO_2$), the ratio of the distances $d_{A-B}$ (1.9 to 2.1 Å) and $d_{B-B}$ (2.6 to 2.7 Å) is expected to be between 0.7 and 0.8. From the maximum of the Madelung constant at c/a = $\sqrt{2/2}$ and x = 5/16, it follows that $d_{A-B}/d_{B-B} = 0.83$ [by comparison, for c/a = 0.6 and x = 0.295, we find $d_{A-B}/d_{B-B} = 0.72$]; the deviations towards c/a < $\sqrt{2/2}$ are therefore understandable to some extent.

3. Even with a knowledge of the Madelung constants, it is not possible to discuss the question of why the parameters of a given rutile-type compound (*e.g.* $ZnF_2$) have the observed values (c/a = 0.666, x = 0.303: cf.[23]) instead of other values close to these.

Thus if these parameters are slightly changed, it can be assumed that the shortest distance $d_{A-B}$ [2.01$_5$ Å (2×) for $ZnF_2$] will remain constant as is required by the concept of

[21] *O. F. Bollnow*, Z. Physik *33*, 741 (1925).

[22] *W. H. Baur*, Acta crystallogr. *14*, 209 (1961).

[23] *W. H. Baur*, Acta crystallogr. *9*, 515 (1956); *11*, 488 (1958).

fixed ionic radii, or that the molar cell volume [20.87 cm³ for $ZnF_2$] will remain unchanged, as is to be expected if the volume increments of the various ions are constant. Examples are known which show that neither of these two concepts (which are mutually exclusive, cf. [24]) is strictly correct. This means that in the Madelung component of the lattice energy [Equation (1)] of "adjacent" rutile-type compounds, the numerator can be given accurately, but not the denominator (the shortest distance $d_{A-B}$). This difficulty is encountered with all parameter-dependent structures.

4. Finally it should be borne in mind that abnormally short distances $d_{B-B}$ are found in dioxides with rutile structures, such as $SnO_2$ and $TiO_2$ (the shortest O–O distance in $TiO_2$ is 2.53 Å). The only other cases in which such short distances are found are complex anions, *e.g.* $SO_4^{2-}$, $PO_4^{3-}$, or where strong hydrogen bonding occurs. These short distances are due to the strong polarization of the $O^{2-}$ particles by the highly charged cations ($Ti^{4+}$ *etc.*); they show that the picture of a compound consisting of rigid ions must be modified for these dioxides.

## 2. The Madelung Constant of the Anatase Structure

The anatase structure also depends on two parameters, namely the ratio c/a of the tetragonal unit cells (cf. Figure 11) and the parameter $z_O$ of the anions. For c/a = 2.0 and $z_O = 1/4$, we have a variant of the NaCl type in which half of the cation sub-lattice has been removed

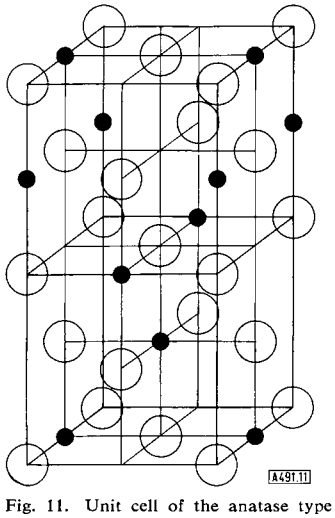

Fig. 11. Unit cell of the anatase type (sizes of the particles chosen arbitrarily).

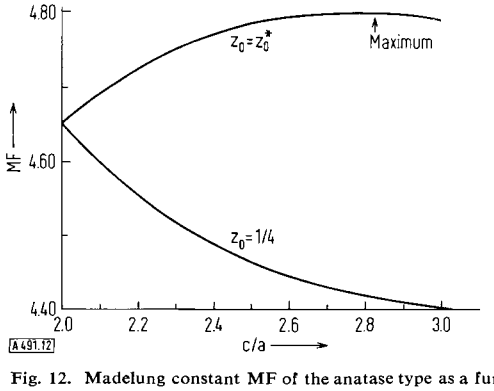

Fig. 12. Madelung constant MF of the anatase type as a function of c/a and $z_O$ [13a].

[24] *W. Biltz*: Raumchemie der festen Stoffe. W. de Gruyter, Leipzig 1934.

systematically. Figure 12 shows the variation of the Madelung constant MF(anatase), and Figure 13 shows the variation of the partial Madelung constants for two limiting cases: in the first case, c/a varies while $z_O$ (=1/4) remains constant [six originally equally distant B neighbors of each A particle become unequally distant (4+2) as c/a increases], and in the second case $z_O$ changes with c/a in accordance with Equation (20)

$$z_O^* = 1/8 + a^2/2c^2 \qquad (20)$$

(in this case, each A particle remains surrounded by six equally distant B particles). It is interesting to note that in compounds of the "filled-up" anatase type ($\alpha$-$LiFeO_2$ type), that have been studied so far, $z_O \approx z_O^*$, *i.e.* for any given c/a the arrangement of the O particles is such as to give the optimum Madelung constant [5, 24a].

## 3. Madelung Constants of Complex Structures

It can be seen from Figure 1b that in the case of coordination compounds, the Born-Haber cycle can be applied in various ways; the term "complexing energy" is also used with various meanings (it can be defined by steps IIIa or IIIb′ in Figure 1b [25]). In stating the Madelung constants of complex structures, therefore, it is particularly important to specify the reference distance. The values in Table 11 are based on the shortest central ion-ligand distance in each case.

Table 11. Madelung constants of other structural types.

| Compound | Type | Type | MF | Ref. |
|---|---|---|---|---|
| $SiO_2$ | High cristobalite | $A^{2+}B_2^-$ | $4.453_4$.. | [9] |
| | Low cristobalite | $A^{2+}B_2^-$ | 4.428 | [9] |

## III. Madelung Constants of Molecular Lattices

Compounds such as $BrF_5$, $SiF_4$, $SbCl_3$, and $XeF_2$ form solids with structures in which the building units are individual molecules. Typical covalent bonds seem to

[24a] *R. Hoppe, B. Schepers, H. J. Röhrborn*, and *E. Vielhaber*, Z. anorg. allg. Chem. *339*, 130 (1965).

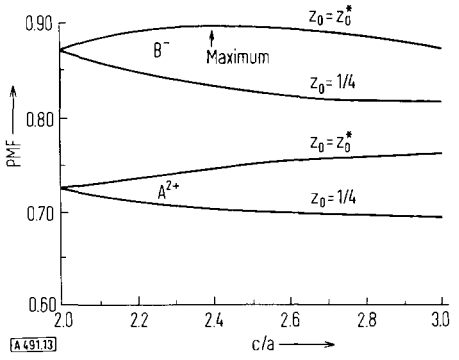

Fig. 13. Partial Madelung constants PMF of the anatase type as functions of c/a and $z_0$ [13a].

be present here. With the exception of *Klemm*'s effective Madelung constants [13], little was previously known about the Madelung constants of such structures. It is of interest, however, how these Madelung constants are related to those of typically ionic compounds. The Madelung constants of $XeF_2$, $XeF_2 \cdot XeF_4$, and $XeF_4$ are therefore briefly discussed in the following sections.

## 1. The Madelung Constant of the $XeF_2$ Structure [1a]

Linear F–Xe–F molecules are present in the tetragonal unit cell of xenon difluoride (cf. Figure 14). The PMF values and the Madelung constant of this structure are given in Table 12. PMF($Xe^{2+}$) for the coordination number 2 fits readily into the pattern of PMF($A^{2+}$) values for higher coordination numbers, as does the Madelung constant MF($XeF_2$) itself [*]. Thus $XeF_2$ is distinctly polar, in agreement with spectroscopic findings (cf. [1a]). This explains the apparently large enthalpy of sublimation (12.3 kcal/mole).

## 2. The Madelung Constant of the $XeF_2 \cdot XeF_4$ Structure

The composition of the double fluoride $XeF_2 \cdot XeF_4$, which still seems not to have been confirmed by analysis, was deduced from X-ray analysis (cf. Figure 15). Table 12 shows the individual PMF values and the Madelung constants for the components $XeF_2$ and $XeF_4$ in the addition compound. All values are of the expected magnitude.

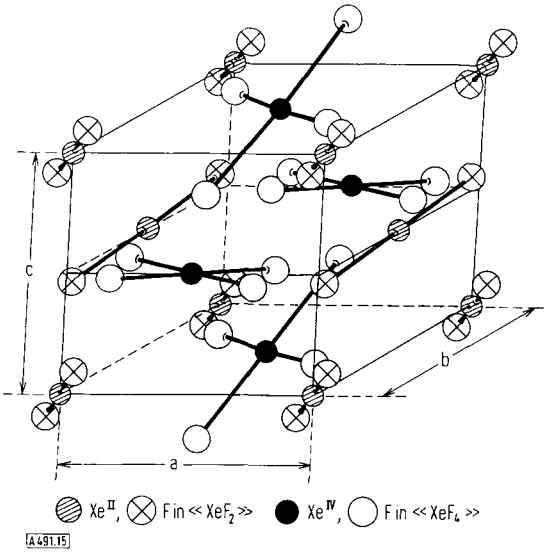

Fig. 15. Crystal structure of $XeF_2 \cdot XeF_4$ (a = 6.64 Å, b = 7.33 Å, c = 6.40 Å, β = 92°40') (sizes of the particles chosen arbitrarily).

Table 12. Comparison of Madelung constants and partial Madelung constants of $XeF_2$, $XeF_2 \cdot XeF_4$, and $XeF_4$ [1a].

| | $XeF_2 \cdot XeF_4$ | $XeF_2$ | "$XeF_2$" in $XeF_2 \cdot XeF_4$ | $XeF_4$ | "$XeF_4$" in $XeF_2 \cdot XeF_4$ | $SiF_4$ |
|---|---|---|---|---|---|---|
| Reference distance Xe–F[Å] | 1.909 | 1.983 | 1.995 | 1.932 | 1.909 | Si–F |
| PMF ($Xe^{2+}$) | 2.49848 | 2.4494 | 2.61051 | 9.4138 | | PMF($Si^{4+}$) = |
| PMF ($Xe^{4+}$) | 9.03938 | | | | 9.03938 | 8.8262 |
| PMF ($F_I^-$) | 0.60535 | 0.6749 | 0.63250 | | | PMF($F^-$) = |
| PMF ($F_{II}^-$) | 0.86372 | | | 0.8233 | 0.86372 | 0.9157 |
| PMF ($F_{III}^-$) | 0.86209 | | | 0.8184 | | |
| MF | 16.200 | 3.7992 | 3.87550 | 12.6972 | 12.4910 | 12.4889 |

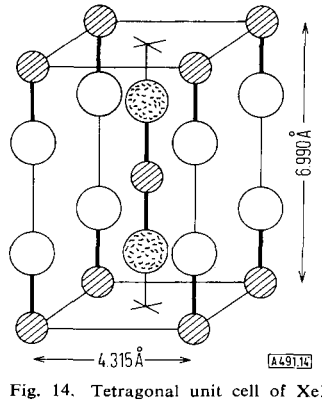

Fig. 14. Tetragonal unit cell of $XeF_2$ (sizes of the particles chosen arbitrarily).

[*] For details, see [1a].

## 3. The Madelung Constant of the $XeF_4$ Structure

The monoclinic unit cell of $XeF_4$ contains discrete, practically square $XeF_4$ groups (cf. Figure 16); the PMF values and the Madelung constant are given in Table 13. Comparison with the data for $XeF_2 \cdot XeF_4$

Table 13. Madelung constants and partial Madelung constants of a number of tetrahalides with respect to the shortest distance A–B=1 [1a, 9, 10].

| | [Xe[4]$F_4$] | $\frac{1}{\infty}$[Sn[6]$F_4$] | $\frac{2}{\infty}$[Nb[6]$Cl_4$] | [Si[4]$F_4$] |
|---|---|---|---|---|
| PMF ($A^{4+}$) | 9.4138 | 10.5153 | 8.9515 | 8.8262 |
| PMF ($F_I^-$) | 0.8233 | 1.0364 | 1.1102 | 0.9157 |
| PMF ($F_{II}^-$) | 0.8184 | 0.7480 | 1.0141 | |
| PMF ($F_{III}^-$) | | | 0.7874 | |
| MF | 12.6972 | 14.0841 | 12.6505 | 12.4889 |

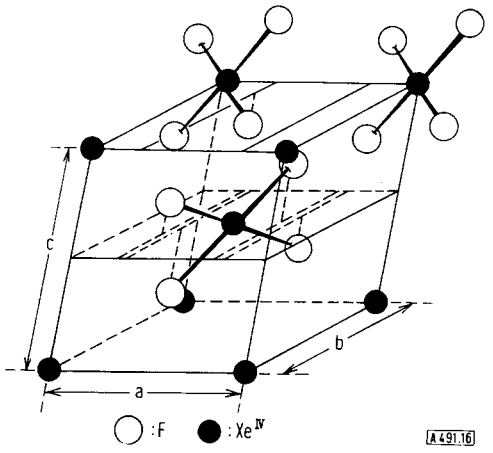

Fig. 16. Crystal structure of $XeF_4$ (a = 5.05 Å, b = 5.92 Å, c = 5.77 Å, $\beta$ = 99.6 °). For the sake of clarity, only some of the F atoms are shown (sizes of the particles chosen arbitrarily).

shows that the $PMF(F^-)$ values and the Madelung constant are of the expected magnitude. Comparison with the data for $SiF_4$ shows that the $PMF(F^-)$ values for $XeF_4$ are smaller than those for $SiF_4$. The reason is the electrostatically unfavorable planar shape of the $XeF_4$ unit. The smaller value of $PMF(Si^{4+})$ as compared with $PMF(Xe^{4+})$ indicates the more intimate entanglement of the $XeF_4$ groups. From the heats of sublimation ($SiF_4$: 6.15 kcal/mole, $XeF_4$: 15.3 kcal/mole) the Madelung constant of the $XeF_4$ type would be expected to be larger than that of the $SiF_4$ type. Table 13 shows that this is indeed the case. However, in considerations of this kind one has to be satisfied with modest accuracy.

# Structure Formation and Molecular Mobility in Water and in Aqueous Solutions

BY PROF. DR. E. WICKE

INSTITUT FÜR PHYSIKALISCHE CHEMIE DER UNIVERSITÄT MÜNSTER (GERMANY)

*Dedicated to Prof. W. Klemm on the occasion of his 70th birthday*

*The study of the structure of water and of aqueous solutions has recently received new impetus from the efforts at commercial desalineation of sea water and from developments in molecular biology. The current view that, apart from single molecules, water contains only one type of structural element, namely „flickering "network structures with tetrahedrally hydrogen-bonded water molecules (two-states model) is proving inadequate in the interpretation of new experimental data and in the calculation of thermodynamic functions. After a critical discussion of the basis of this model and of the concept of hydrogen bonds, a second kind of structural element, i.e. a third state, is suggested: small aggregates of molecules containing mainly non-tetrahedral hydrogen bonds as well as some tetrahedral ones, and packed more densely than allowed by the lattice-like structure. These aggregates – dimers to hexamers – can be regarded as the primary products of disruption of the network structures, and displace the latter as structural components in water with increasing temperature or concentration of solutes. This "combined" model allows a consistent interpretation of the properties of water and of the various effects of dissolved substances.*

## Introduction

Intermolecular structures have long been held responsible for the anomalies in the physicochemical properties of water, and are also used to explain its behavior as a solvent. The most important method up to a few years ago of detecting these structures was based on the radial distribution function of the intermolecular distances as found from X-ray diffraction photographs of liquid water. The development of microwave and in particular NMR spectroscopy now enables us to take a closer look at the interactions between neighboring $H_2O$ molecules and between dissolved particles and $H_2O$ molecules. Information about the mobility of $H_2O$ molecules, particularly with regard to rotary motion (reorientation), provides a better picture of the "structure", as well as a more sensitive means of determining the effect of solute particles on the short-range order of the $H_2O$ molecules.

In the following pages the development of current views will be discussed systematically and critically. It appears that we have been too ready to assume that the liquid structure of water is due to an intermolecular linkage of the same type as in ordinary ice (this will be referred to below as linkage by "tetrahedral" hydrogen bonds). Thus in addition to the larger structural units, *i.e.* the fluctuating networks or clusters, in which linkage is in fact mainly due to tetrahedral H bonds, too little attention has been paid to the possibility of a second, smaller type of aggregate, in which the molecules are held together by more dipolar non-tetrahedral hydrogen bonds.

## The Molecular Structure of Water

### 1. Structure of the $H_2O$ Molecule and of Ice

The geometrical structure of and the charge distribution in $H_2O$ are shown schematically in Fig. 1. In a free oxygen atom, in which the eletronic configuration of the L shell is $(2s)^2$ $(2p_z)^2$ $(2p_y)$ $(2p_x)$, the charge density of the $(2s)^2$ pair of electrons has a spherically symmetrical distribution about the inner-shell electrons; the charge densities of the $(2p_z)^2$ pair of electrons and of the two valence electrons $2p_y$ and $2p_x$ have rotationally symmetrical distributions about the three mutually perpendicular axes z, y and x. Two hydrogen atoms bound by $2p_y$ and $2p_x$ tend to widen the 90° angle owing to electrostatic repulsion. The electron configuration of the oxygen can accomodate this tendency to some extent by changing from pure p and s states to mixed electronic states (hybridization). As the s contribution to the states of the valence electrons increases, so also does the angle between the axes of maximum charge density; when this contribution reaches a certain level, the potential energy of the $H_2O$ molecule reaches a minimum (corresponding to a maximum in the bond energy), and the valence angle is the angle between the axes at this point. However, the hybridization of p and s states also leads to a change in the charge distributions of the two pairs of non-bonding electrons on the oxygen. Their charge clouds project unsymmetrically from the oxygen molecule on the side remote from the protons, so that the charge distribution in the $H_2O$ molecule can be described by an approximately tetrahedral four-point model (see Fig. 1a).

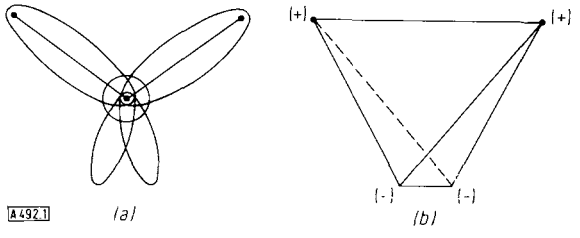

Fig. 1. Charge distribution in the $H_2O$ molecule according to *Bjerrum* [1]. (a) Electron distribution about the nuclei; (b) tetrahedral model of the $H_2O$ molecule.

For $H_2O$ molecules in the vapor state, where there is no interaction with neighbors, the valence angle is 104.5°, the O–H distance 0.96 Å, and the electrical dipole moment 1.84 D. It follows that in the isolated $H_2O$ molecule, each of the four centers of high charge density (see Fig. 1b) carries only 0.17 electronic charge; the protons are therefore largely surrounded and screened by electron clouds. If external influences cause the valence angle to increase beyond 104.5°, the accompanying increase in hybridization leads, within certain limits, to a further increase in the magnitudes of the four "point charges", and hence in the polarity and dipole moment of the molecule.

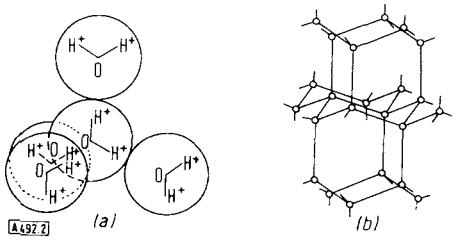

Fig. 2. Four-coordination of the $H_2O$ molecules with tetrahedral hydrogen bonds (a) and arrangement of the oxygen atoms in the ice structure (b). From *Samoilow* [2].

In the normal ice lattice, each proton forms a H-bond by interacting with a center of negative charge of a neighboring $H_2O$ molecule (cf. Fig. 2). This leads to the tetrahedral arrangement of the oxygen atoms found in ordinary, hexagonal ice, which corresponds to the silicon sub-lattice in β-tridymite (Fig. 2b). The bulkiness of the ice structure with its large, cage-like cavities is due to the low coordination number of 4. The distance between adjacent oxygen atoms linked by a hydrogen bond is 2.76 Å; the O–H distance (about 0.99 Å) is slightly greater than in isolated $H_2O$ molecules in the gas phase. There are two limiting possibilities for the H–O–H valence angle in the ice structure: (a) the H atoms lie on the lines joining the nuclei of the oxygen atoms, in which case the valence angle is increased from the value of 104.5° for the isolated water molecule to the tetrahedral angle of 109.5°; (b) the H–O–H angle in ice remains 104.5°, the hydrogen atoms lying to the side of the lines joining the oxygen atoms, *i.e.* the H-bonds are angular (bent). No definite conclusion can be reached on the basis of neutron diffraction measurements on solid $D_2O$, since the results are compatible with both possibilities [3]. It is possible, therefore, that the H–O–H valence angle in ice is slightly smaller than the tetrahedral angle and lies between the two limiting cases, *i.e.* the hydrogen bonds in the ice structure may be slightly "curved". However, since the valence angle is greater than 104.5°, the polarity of the $H_2O$ molecule in the ice structure should be greater than in the isolated state. From the high dielectric constant of ice (92 at the melting point), it is estimated that the dipole moment of the 4-coordinated water molecule in the ice structure is 2.5 D, compared to 1.84 D in the vapor [4]. These relationships, together with the fact that the O–H distance is greater in ice than in the gas phase, suggest that the hydrogen bonding in ice leads to considerable withdrawal of the protons from the screening electron cloud. Thus the "point charges" of the water molecules at the vertices of the tetrahedra in the ice structure are stronger than in "single" $H_2O$ molecules, *i.e.* molecules that are not involved in H bonding.

The well-known peculiarities of water, *i.e.* its density maximum at 4 °C, high heat of vaporization, surface tension, and specific heat in comparison with those of other liquids, and other anomalies such as those in the viscosity, thermal conductivity, and sonic absorption, led a long time ago to the view that bulky hydrogen-bonded structures also exist in the liquid state. Thus *Röntgen* and *Tammann* referred to "ice-like molecules", which they regarded as residual ice structure still present in water above the melting point. As the temperature increases, these "ice-like structures" dissociate into smaller aggregates and single molecules, and the resulting increase in the coordination number causes a decrease in volume. The density maximum at 4 °C can be explained by this tendency to closer packing, together with the opposing tendency of thermal expansion. With

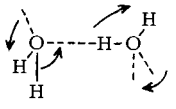
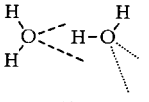
increasing thermal breakdown of the ice-like structure, the behavior of water approaches that of normal liquids. Similar "normalization" is observed under the influence of high pressures ($10^3$ to $10^4$ atm) and increasing electrolyte concentrations.

## 2. Types of Hydrogen Bonds

The breaking up of structures and of hydrogen bonds referred to below does not imply that the bonded atoms move away from each other along their center line, with the result that a hydrogen bond is stretched and ultimately broken; instead, in view of the close packing in the liquid state, we must imagine the rotation of $H_2O$ molecules out of the range of mutual orientation in which their interaction potential passes through a relative minimum [see Formula *(1)*]. This is generally



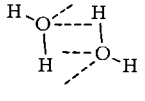
*(1)*



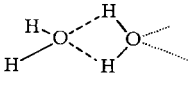
*(2)*

accompanied by an increase in the distance between the centers of gravity of adjacent molecules. Thus a hydrogen bond is regarded as broken or dissociated if the mutual orientation of the two $H_2O$ molecules is such that their interaction potential passes through a (relative) maximum. In general, an $H_2O$ molecule can get free from all hydrogen bonds to its neighbors only if it passes to practically free rotation.

Type *(1)*, which is suggested by the structure of ordinary hexagonal ice, is not the only orientation of two adjacent $H_2O$ molecules that gives a potential minimum; other orientations for which a minimum occurs include an open-chain structure *(2)*, a planar ring *(3)*, and a



*(3)*



*(4)*

"bifurcated" structure *(4)*. In these orientations, in contrast to type *(1)*, two negative charge centers of one $H_2O$ molecule are used to bind an adjacent molecule. Hence the total number of hydrogen bonds is lower, but the smaller aggregates with chain or ring structures, which are built up in this way, enable a closer packing of the molecules than in ordinary ice or in tetrahedrally constructed "clusters". The arrangements *(2)–(4)* have been repeatedly discussed as possible structures of $H_2O$ dimers [5]; type *(4)*, however, seems to be unfavorable for steric reasons.

Hydrogen bonds of type *(1)* will be referred to as "tetrahedral", and the types *(2)*, *(3)*, and *(4)* as "non-tetrahedral". In the types *(2)* and *(3)*, the polarity of the $H_2O$ molecules is not increased by spreading of the H–O–H valence angle. Moreover, the bridging protons are more strongly enveloped by the lone electron pair from the oxygen in types *(2)* and *(3)* than in type *(1)*. Thus with regard to their polarity, and above all to the electrostatic screening of their protons, non-tetrahedrally bound $H_2O$ molecules are between tetrahedrally bound $H_2O$ molecules and $H_2O$ molecules not involved in hydrogen bonding. The characteristic differences between these three types of $H_2O$ molecule and between the two types of hydrogen bond provide an interpretation for experimental findings that would otherwise be difficult to explain.

The bulky lattice of ordinary ice (ice I), which is characterized by straight or at most slightly bent tetrahedral bonds, changes at even moderate pressures into denser modifications. It exists in equilibrium with the much denser tetragonal ice III at 2050 atm and −22 °C, and with the still denser cubic ice II at 2100 atm and −34.5 °C. Altogether six denser modifications stable at high pressures are known [6]. The melting point-pressure curve of the so-called high-temperature modification, ice VII, has recently been measured up to 442 °C (200000 atm) [7].

This diversity of solid states suggests that the loose structure with the straight hydrogen bonds in ice becomes unstable at high pressure and rearranges to other ways of packing of the $H_2O$ molecules with higher coordination numbers and possibly shorter O···O distances, and hence with closer packing. Hydrogen bonds with remarkably short O···O distances (as short as 2.5 Å) have, in fact, been observed in a number of crystals containing OH groups [5, 6]. A number of cases of distinctly "curved" hydrogen bonds are also known, with O–H···O angles as small as about 165 ° [5]. Thus high pressures can lead to a closer packing in ice by bending and possibly compression of the hydrogen bonds. This is indicated, *e.g.*, by the results of an X-ray analysis of ice III, according to which the structural units are distorted oxygen tetrahedra [6, 8]. It is possible that other types of linkage, such as the non-tetrahedral hydrogen bonds described above, can also occur with further modification of the ice [*].

The arrangement in the structured regions (*i.e.* the "ice-like molecules") of liquid water need not be similar to that of ordinary ice, as has recently also been pointed out by *Frank* [9]. Arrangements such as that of ice III or cage structures of the type present in gas hydrates (Fig. 8) have been suggested (see also below); structures of this type cannot be ruled out as long as they agree with the results of the X-ray analysis of liquid water.

[*] Note added in proof: Recent X-ray structure analysis of ice VI resulted in chains of distorted oxygen tetrahedra with some strongly bent hydrogen bonds (*B. Kamb*, Science *150*, 205 (1965)). Two structures having their chains mutually displaced by 90 ° fit into each other ("self-clathrate structure"), without being linked by H-bonds. The short distance between next-nearest neighbors (3.5 Å) leads to a high packing density (1.33 g/cm³).

## 3. Models for the Structure of Water

The concept of "ice-like molecules" was first treated quantitatively by *Eucken* in 1946[10]. This author regarded water as a mixture of different associates of definite stoichiometries, and set out to derive a quantitative description of the thermodynamic properties of water in extended ranges of state on the basis of the simplest possible assumptions about these associates. To compare the results of his calculations with experimental results, he chose parameters that are strongly influenced by association, *i.e.* the density (between −20 and about +100 °C, at 1 to 12000 atm) and the molar heat capacity (between 0 and 200 °C, at normal pressure). For the "ice-like molecules" postulated by *Röntgen* and *Tammann*, he took the smallest possible grouping, *i.e.* an associate of eight molecules forming a structure which, as shown in Fig.3, contains a cavity such as those occurring in the tridymite structure of ice (Fig. 2). *Eucken* assumed the volume occupied by these associates of eight molecules to be about 10 % greater, on average, than that occupied by the other components of water. He explained the anomalies in the equation of state of water by dissociation of these associates with increasing temperature and with increasing pressure.

Fig. 3. Model of an "ice-like" octamer with a cavity similar to that in tridymite, after *Eucken* [10].

In order to obtain a correct representation of the heat capacity of water as a function of temperature, it is necessary to postulate thermal changes in structure extending over wide temperature ranges. According to *Eucken*, the associates of eight molecules dissociate *via* two intermediates, one containing four molecules and the other containing two. He did not exclude the possibility that other associates (*e.g.*, one containing three molecules) exist, but neglected these in the calculations in order to keep the model as simple as possible; associates containing more than eight molecules were thought to be improbable. *Eucken*'s picture of individual associates was based on the assumption that the tendency of the $H_2O$ molecules to form hydrogen bonds and structures in liquid water could be saturated to some extent. In this model there is no differentiation between the various types of H-bonds, and it is not restricted to one distinct type.

For the above model it was necessary to use empirical values for seven quantities, *i.e.*, the molar fractions of the three types of associates in water at one given temperature (*e.g.* 0 °C), their heats of dissociation, and the increased volume of the associates containing eight molecules. These seven values permit the calculation of the proportions of the different species in water as a function of temperature and pressure, if the mixture is assumed to be ideal.

Figure 4 shows how the fractional amounts of these species vary with temperature between 0 and 100 °C and at normal pressure, as found by *Eucken*. Appreciable quantities of the two-molecule associates are still present at relatively high temperatures, and these may be responsible for the anomalous behavior of water at the critical point.

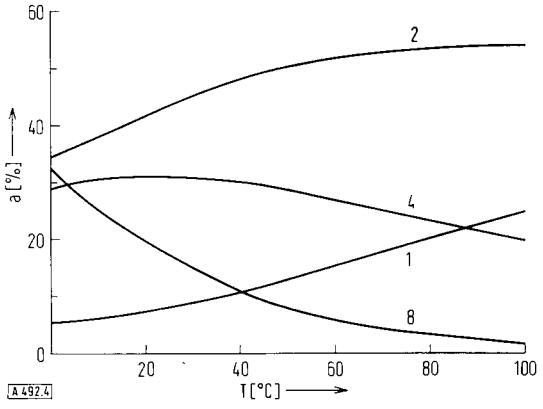

Fig. 4. Relative proportions a of octamers (8), tetramers (4), dimers (2), and single molecules (1) as a function of temperature, after *Eucken* [10].

Developments in England and in the United States took an entirely different course. The starting point for this development was *Bernal* and *Fowler*'s interpretation of the first reliable X-ray diffraction diagrams for liquid water[11].

Fig. 5 shows the radial distribution function of liquid water, *i.e.* the frequency distribution of the distances

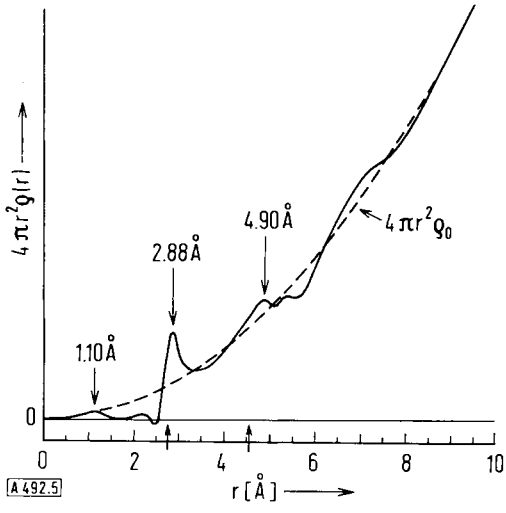

Fig. 5. Radial distribution function of the $H_2O$ molecules in liquid water from X-ray diffraction at 25 °C, after *Danford* and *Levy* [12]. The arrows on the abscissa at 2.75 and 4.50 Å indicate the distances of the nearest and next-nearest neighbors in the ice structure. The maximum at 1.10 Å is attributed by the authors to the O—H distance in the $H_2O$ molecules ($\varrho$ = number density of $H_2O$ molecules at distance r from a central molecule [Å$^{-3}$]; $\varrho_0$ = averaged number density of molecules in water [Å$^{-3}$].

between an arbitrarily chosen central molecule and the $H_2O$ molecules surrounding it, averaged over all directions in space. The maximum of the smallest average distance between adjacent molecules is remarkably sharp, and occurs at 2.88 Å, corresponding to a slightly elongated hydrogen bond of the type that occurs in the ice structure. A second maximum at 4.90 Å can be related to the distance between the second-nearest neighbors in ice.

From such and other analogies between the radial distribution functions of liquid $H_2O$ and of tridymite-like and quartz-like structures, *Bernal* and *Fowler* concluded that the $H_2O$ molecules in liquid water must be largely arranged in a four-coordinate pattern. The idea that water has a "loose" lattice structure was supported by considerations arising in the explanation of the high and very similar values found for the static dielectric constants of ice and water (92 and 88.5 at 0 °C, according to recent measurements). Thus according to *Bernal* and *Fowler*, the structure of supercooled water is essentially similar to the tridymite structure of ice, while at temperatures up to 200 °C, this gives way to a more densely packed quartz-like structure (in which however, the O–H···O bridges would have to be strongly bent [13a, 13b]). The density maximum of water at 4 °C is attributed to the transition to this quartz-like structure. Random close packing, as in normal liquids, is thought to predominate only at temperatures above 200 °C.

In this model of a tetrahedrally-coordinated, three-dimensional network, *Bernal* and *Fowler* provided the basis for the predominant view that the structure of water is due entirely to tetrahedrally oriented hydrogen bonds between adjacent $H_2O$ molecules. At the same time, by assuming that only one type of molecule, corresponding to the average of all the molecules, need be considered, they laid the foundations for the theories that *Frank* described as "uniformistic" [9] (to distinguish them from theories that regard the presence of different structural units as an essential characteristic of the structure of water).

It soon became clear, however, that the radial distribution function had been greatly overrated as a source of detailed information about the lattice-like arrangement of the $H_2O$ molecules in liquid water, particularly since the distances are averaged over all directions. This was demonstrated in 1938 by *Morgan* and *Warren* in the discussion of their new X-ray diffraction results for liquid water [14]. These authors also drew attention to a previously disregarded region of almost uniformly distributed distances (between 3 and 4 Å in Fig. 5) which have no correspondence in ordinary ice-like structures. From this they concluded that only part of the $H_2O$ molecules in liquid water can be linked tetrahedrally, that is a considerable part of the tetrahedral structure of ice should collapse immediately on melting; the contraction that accompanies melting is attributed to the filling of the cavities with $H_2O$ molecules that have broken away from the structure.

This criticism of *Bernal* and *Fowler*'s views was one of the factors that induced *Eucken* to set up a model with smaller molecular aggregates in which each $H_2O$ molecule forms only two or three hydrogen bonds, and which is consistent with the X-ray diffraction results.

The models subsequently developed in England and in the U.S.A., on the other hand, are still essentially based on *Bernal* and *Fowler*'s ideas, but further assumptions and corrections have been introduced to obtain agreement with the radial distribution function of *Morgan* and *Warren*.

On the basis of a purely electrostatic theory of (tetrahedral) hydrogen bonding, *Lennard-Jones* and *Pople* (1951) concluded that the angular orientation of two $H_2O$ molecules should be relatively flexible (small torsional forces for the transition from straight to bent O–H···O linkages; cf. *(I)*). The authors used this flexibility to fit the theory to experimental results, as mentioned above, and in this way developed a uniformistic model [15]. According to this model, the H-bridges even in ice bend as the temperature is raised, until the long-range lattice orientation breaks down, *i.e.* the ice melts. It is postulated that in liquid water, the four hydrogen bonds on each $H_2O$ molecule can bend or twist independently of one another. Thus the real difference between ice and water, according to this theory, is the mutual independence of the flexible orientations of the H-bonds. This would also explain how the cavities of the ice structure can become filled with $H_2O$ molecules in liquid water, without breakage of an appreciable fraction of the hydrogen bonds. Owing to the opposing effects of the thermal motion and the torsional strain of bending, the mean deflection of the H-bonds increases with temperature. By a suitable choice of values for the torsional force constants and for the numbers of nearest, second-nearest, and third-nearest neighbors ($N_1 = 4$, $N_2 = 11$, $N_3 = 22$) *Pople* obtained good agreement with *Morgan* and *Warren*'s radial distribution function, including the tendency of the frequency maxima to broaden with rising temperature. However, values found for the average bending angle were rather high (26 ° at 0 °C increasing to 30 ° at 100 °C). With this model, calculation of the dielectric constant of water by *Kirkwood*'s method [16] gave the correct temperature-dependence between 0 and 83 °C, but the absolute values were too low by about 20%.

Mixture models of the structure of water, with the exception of *Eucken*'s associate model, can be sub-divided into network or cluster models and cell or cage models. In the first type, liquid water is regarded as a mixture of "clusters" of $H_2O$ molecules, each molecule being linked to four others, and single $H_2O$ molecules, which occupy the spaces between the clusters (see Fig. 6). The clusters are continuously being built up and broken down, and single molecules are added on and split off in a rapid interchange (*ca.* $10^{-11}$ sec). However, this model

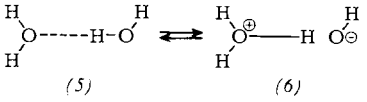
involves, not only two types of $H_2O$ molecules (single and four-coordinate), but five types, since $H_2O$ molecules with one, two, or three hydrogen bonds are also present at the surfaces of the clusters, although only as short-lived intermediate states.

The first model of this type was proposed by *Hasted et al.* in connection with dielectric relaxation measurements [4]. With such a model, they were able to explain the occurrence of a single, uniform, and remarkably fast relaxation process in water ($\tau_{liq} \approx 10^{-11}$ sec, as compared with $\tau_{solid} \approx 10^{-5}$ sec at the melting point). Assuming that only 9 % of the H-bonds in ice are broken on melting, and using a very rough estimate of the further breakdown with rising temperature, they obtained satisfactory results for the dielectric constant of water by *Kirkwood*'s method. The single molecules in the regions between the clusters were assumed to rotate almost freely.

Ten years later, *Némethy* and *Scheraga* attempted to obtain a more accurate picture of the breakdown of the clusters with rising temperature by means of statistical thermodynamics. Like *Eucken*, these authors used the thermodynamic data for water (instead of the dielectric constants) as a basis for comparison [17]. According to their calculations, the proportion of the H-bonds in ice that break during melting is not 10 %, but about 50 %. For regions with four-coordinated structures such as that in Fig. 6, they found an average of 90 $H_2O$ molecules per cluster at 0 °C, decreasing to about 25 at 70 °C. For less than 25 molecules per cluster, this model no longer has physical significance.

The development of the "flickering cluster" concept has been greatly aided by the fact that covalent as well as electrostatic bonding components must be taken into account for the (tetrahedral) hydrogen bonds. These covalent components can be approximately represented by the contribution made by the limiting resonance structures *(6)* to the hydrogen bonding. Theory shows that these limiting structures participate to the extent of a few per cent in hydrogen bonds of normal length (2.8 Å) [5], with the result that the tetrahedral orientation of the hydrogen bonds in the clusters is more rigid than had been assumed by *Lennard-Jones* and *Pople*.

*Frank* pointed out a special effect due to the covalent contributions [18, 19]: the charge separation associated with the limiting structure *(6)* increases the tendency of both $H_2O$ molecules to form hydrogen bonds with other neighbors, and these further hydrogen bonds then increase the energy of the original hydrogen bond by a kind of feedback effect. This possibility of co-operative behavior in the formation and breakdown of bridge structures is regarded as characteristic of tetrahedral



*(5)* *(6)*

hydrogen bonds and "flickering" clusters. In this connection, *Némethy* and *Scheraga* [17] emphasize that although the single $H_2O$ molecules shown in Fig. 6 exert strong dipole forces as well as van der Waals forces on one another, they are nevertheless "monomeric, unbonded water". Small aggregates such as dimers are unlikely to be present, and were disregarded in the calculations. In contrast to this cooperative behavior, the non-tetrahedral hydrogen bonds will to a certain extent be capable of saturation and therefore preferentially lead to the formation of smaller aggregates.

It is interesting to compare the above two cluster models with *Eucken*'s associate model. Fig. 7 shows the temperature-dependence of the average number of hydrogen bonds per $H_2O$ molecule for the three models. In the cluster and cage models, the ordinate values divided by 2 give the average "degree of cross-linking" of the $H_2O$ molecules (by tetrahedral hydrogen bonds). The Némethy-Scheraga cluster model and *Eucken*'s associate model differ remarkably little in the absolute values and temperature-dependence of the average number of H-bonds, the differences being much smaller than those between the two cluster models. This result is surprising at first, in view of the fundamentally different concepts on which the models are based; however, the Némethy-Scheraga cluster model is the only model, apart from *Eucken*'s, that gives reasonably good results for the molar heat capacity of water, though the values decrease a little too fast with rising temperature (from 21.5 to 13.7 cal mole$^{-1}$ deg$^{-1}$ between 0 and 70 °C, compared to experimental values of 18.1 to 16.9 cal mole$^{-1}$ deg$^{-1}$).

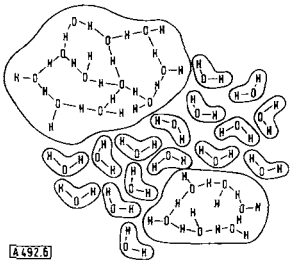


Fig. 6. Model of the structure of water as a mixture of clusters and single molecules. The $H_2O$ molecules in the clusters are assumed to be linked by tetrahedral hydrogen bonds and to have a coordination number of four. After *Némethy* and *Scheraga* [17].

In the second type of mixture model, *i.e.* the cell or cage type, the mixture contains only two components. One of these components, in keeping with the views of *Bernal* and *Fowler*, is a bulky framework of tetrahedrally coordinated $H_2O$ molecules. The other component consists of single water molecules in the cavities of this framework, where they rotate without restraint, since they do not participate in hydrogen bonding. The structural parameters of the framework and the extent to which the cavities are filled can be chosen to give the correct density, dielectric constant, *etc.* of water. The first model of this type was proposed in 1946 by *Samoilov*, and consists of an ice-like structure with monomeric $H_2O$ molecules in interstitial sites (ref. 2, p. 44).

*Pauling* suggested a cage model for the structure of water in 1957 [13a, 13b]. The structural units in this model are two $H_2O$ polyhedra known from the gas hydrates (Fig. 8); one is a pentagonal dodecahedron comprising 20 $H_2O$ molecules with a cavity diameter of 5.2 Å, the other a polyhedron with fourteen faces containing 24 $H_2O$ molecules and with a cavity diameter of 5.9 Å. According to *Pauling*, these polyhedra can combine in various ways to give the framework structure of liquid water. For example, combination as in the methane hydrate illustrated in Fig. 8 (46 $H_2O$ molecules in the framework of the cubic unit cell, 8 $H_2O$ molecules in the cavities) gives a density (0.98 g/cm$^3$) close to that of water. *Pauling*'s choice of the gas hydrate polyhedra as models for the "cage" is based on the remarkable stability of these structural units: a pentagonal dodecahedron with one free $H_2O$ molecule in the cavity contains 21 $H_2O$ molecules and 30 (tetrahedral) hydrogen bonds, *i.e.* 71.5 % of the maximum possible (42); however, it is impossible to cut out a complex of 21 molecules with even 60 % of this maximum number of hydrogen bonds from the structure of ice. The cage model requires relatively high degrees of cross-linking; *Pauling* gives a value of 85 % at 0 °C, corresponding to the above example of methane hydrate. The author seems not to have published either calculations on the change in the degree of cross-linking or comparisons with the thermodynamic properties of water; however, *Frank* and *Quist* subsequently carried out calculations of this nature [21], and we shall return to these in the next Section.

The latest model for the structure of liquid water is the cage model proposed by *Marchi* and *Eyring* [20]. It assumes that when ice melts, the $H_2O$ molecules of the ordinary ice structure rearrange themselves into a new structure, which is about 20 % more dense than the ice structure, but in which the coordination is still tetrahedral; this new structure may resemble the tetragonal structure of ice III [8], or it may be similar to the cage models proposed by *Pauling* or *Danford* and *Levy* [12]. At the same time, "holes" characteristic of *Eyring*'s theory of liquids are formed in the liquid structure, leading to a 10 % increase in volume, so that the overall change in volume is a decrease of 10 %. The cavities in the framework contain freely rotating molecules, the proportion of which increases from about 2.5 % of all the $H_2O$ molecules present at the melting point to about 40 % at the boiling point (Fig. 7). Thus the structure of the framework must change within this temperature range, in order to accomodate the larger number of single molecules in its cavities; this change is thought to be related with the minimum in the heat capacity of water at 35 °C. Even with such a marked thermal dissociation of the H-bond structures (as demonstrated by the steeply descending curve in Fig. 7), however, the value obtained by the authors for the molar heat capacity of water is only about half (10 cal mole$^{-1}$ deg$^{-1}$) of the true value.

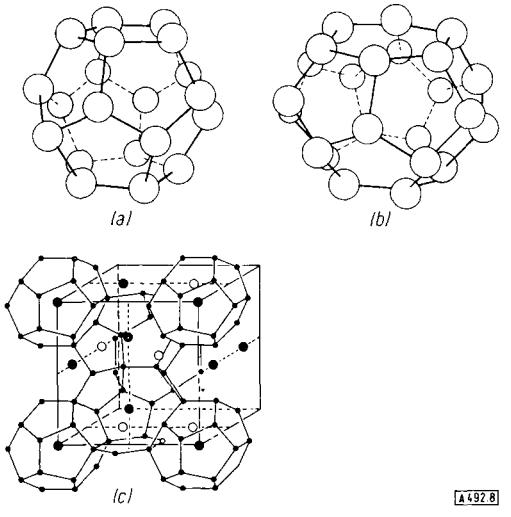

Fig. 8. Structure of solid methane hydrate, $(CH_4)_8(H_2O)_{46}$. Pentagonal dodecahedra (a) and polyhedra with 14 faces (b) consisting of tetrahedrally linked $H_2O$ molecules, and each containing one $CH_4$ molecule. (c) shows the arrangement of the polyhedra in the overall structure of the gas hydrate, illustrated by the front half of the cubic unit cell. After *von Stackelberg* and *Müller* [40].

### 4. Discussion of the Structural Models. — A Combined Structural Model

The models outlined above, with few exceptions, are characterized by the fact that only one type of structural element (*i.e.* networks of tetrahedrally coordinated $H_2O$ molecules) is considered in each case, and the elements of this type are assumed to exist in liquid water together with unbonded single molecules, the whole having a relatively high degree of cross-linking. Three arguments are used to support this assumption:

a) According to *Pauling* [13b], the sublimation energy of ice (12.2 kcal/mole) includes a contribution of 2.5 kcal/mole due to van der Waals forces. Thus each of the two hydrogen bonds formed by each $H_2O$ molecule in ice has a bond energy of about 5 kcal/mole. Thus the enthalpy of fusion of ice (1.44 kcal/mole) is sufficient to break only 0.3 hydrogen bond per molecule, so that the degree of cross-linking of water at the melting point must still be at least 85 %.

b) Relaxation processes in water, particularly dielectric relaxation, have been found to be uniform, one-step processes, indicating that water contains only one type of relaxing structural element.

[20] *R. P. Marchi* and *H. Eyring*, J. physic. Chem. *68*, 221 (1964).
[21] *H. S. Frank* and *A. S. Quist*, J. chem. Physics *34*, 604 (1961).

c) The fact that the dielectric constant of water at the melting point (88.5) differs only slightly from that of ice indicates that the degree of cross-linking in water is almost as high as that in ice.

Against point (a) it may be argued that the van der Waals contributions should be higher in water than in ice, owing to the higher average coordination numbers in water; thus the quantity of energy available for breaking hydrogen bonds is greater than the enthalpy of fusion. With regard to argument (b), uniform relaxation processes would also be expected if water contained several types of structural elements, the average lifetimes of which are so similar that they cannot be distinguished experimentally. Finally, while it is likely from argument (c) that the degree of cross-linking, at least at the melting point, is in fact high, it is possible that this is partly due to ordered states other than tetrahedrally coordinated frameworks or clusters.

*Frank* and *Quist* [21] have shown particularly clearly that it is necessary to consider a "third state" of $H_2O$ molecules in liquid water, in addition to the tetrahedrally coordinated networks and freely rotating single molecules. When these authors tried to reproduce the behavior of water with respect to density, compressibility, and molar heat capacity with the aid of *Pauling*'s cage model, they found that it was impossible to obtain a value higher than 12 kcal $mole^{-1}$ $deg^{-1}$ for the molar heat capacity. They concluded that there must be another state or group of states as intermediates between the $H_2O$ molecules in the cage structure and the monomers [*]. These states may only be present in small amounts at the melting point, but their concentration must increase with rising temperature in order to provide the required contribution to the heat capacity and to diminish other difficulties that generally arise with cage models as a result of their rigidity and insufficient adaptability to dissolved particles.

Some information about such a "third state" can be gained from results obtained by *Pimentel et al.* [22]. These authors condensed mixtures of nitrogen and water vapor at 20 °K on AgCl plates; the presence of a very large excess of nitrogen (1000:1 to 10:1) ensured that any $H_2O$ aggregates formed would be small (matrix isolation technique). They used the infrared absorption of the condensed layers in the regions of the $H_2O$ bending and stretching vibrations as a basis for conclusions as to the nature of the (smaller) aggregates $(H_2O)_n$ occurring in the condensed mixture at increasing water contents. The results indicate that the planar ring structure *(3)* is more likely under these conditions for the $H_2O$ dimer than the other types of dimers *(2)* and *(4)* mentioned in Section I.2. The authors also concluded from the infrared spectrum that the layers contained trimers and tetramers with non-tetrahedral hydrogen bonds, as well as higher polymers.

It seems reasonable to assume that aggregates of this type containing two, three, four and possibly up to six $H_2O$ molecules are the "third state" expected by *Frank* in liquid water. This "combined" model of the structure of water once more approaches *Eucken*'s views. However, instead of the "ice-like" octamers, it contains tetrahedrally coordinated networks; moreover, the average number of hydrogen bonds per $H_2O$ molecule is to be expected appreciably higher than in *Eucken*'s model. The correct curve in Fig. 7 should probably lie between those for the cluster models of *Scheraga* and *Hasted*. The structure of water accordingly is more complicated than assumed in the models concepted so far. Our knowledge of the water structure is in fact insufficiently detailed for a quantitative treatment. The following qualitative statements may, however, be made:

The networks with tetrahedral hydrogen bonds probably contain about 100 $H_2O$ molecules each in the neighborhood of 0 °C. The numerous molecules in the "surfaces" of these clusters already belong in part to the boundary regions between the clusters, in which the molecules are more closely packed (higher coordination numbers); in contrast to Fig. 6, however, the molecules of these regions are irregularly linked to one another, an appreciable proportion of the linkages being nontetrahedral hydrogen bonds. Both types of H-bonds have lifetimes of the order of $10^{-11}$ sec (the time taken for about 1000 OH stretching vibrations), and these lifetimes determine the frequencies of the fluctuations within and between the different structural elements. As the temperature is increased, the networks disintegrate rapidly; the number of smaller molecular aggregates at first increases with increasing temperature. The thermal breakdown of clusters, which are the main cause of the density anomalies, compressibility, and viscosity of water, is practically complete at 100 °C. This decay of the clusters is accompanied by cleavage of the larger molecular aggregates to form smaller ones; the shallow minimum in the heat capacity of water at about 35 °C may be related to the overlap of the thermal breakdown of the two types of structural units. It must be assumed that the thermal decay of the molecular aggregates takes place in several steps, which overlap to a considerable extent; this gives the high contributions of dissociation enthalpy, which are little dependent on temperature and which are required to explain the experimental values obtained for the heat capacity of water.

This concept of several thermal breakdown ranges, which are coupled together in such a way that no stages can be distinguished, follows the line developed by *Eucken* (Fig. 4).

Not only does this model allow for a replacement of the clusters that predominate at low temperatures by "molecular aggregates" as the temperature increases but, since these molecular aggregates contain a considerable proportion of non-tetrahedral hydrogen bonds, it also postulates a continuous increase in the relative amount of non-tetrahedral H-bonds with rising temperature.

**Addendum in Proof**

Since completion of the manuscript a number of publications on the structure of water have appeared, evaluating predominantly Raman and infrared spectroscopic results. In view of Raman spectra in the range of OH stretching bands

[*] The same conclusion has been drawn from difficulties encountered in the interpretation of "hydration of the second kind" on the basis of this model.

[22] *M. van Thiel, E. D. Becker*, and *G. C. Pimentel*, J. chem. Physics *27*, 486 (1957).

and of the radial distribution function from X-ray diffraction, a special "two-states model" was developed [23a]: puckered rings containing six $H_2O$ molecules (with tetrahedral H- bonds) forming an ice-like structure (structure I) or a more tightly packed structure (structure II). The relative proportions (structure I: 60 % at 0 °C; 30 % at 100 °C) can be chosen to fit the coefficient of thermal expansion and the compressibility of water. The model fails to explain the temperature dependence of the heat capacities; the authors remark that a further breakdown of structure II to a "third state" would be required. This is further confirmation of the inadequacy of a "two-states model".

With the treatment of a three-states model, *Vand* and *Senior* [23b] extended infrared studies of *Buijs* and *Choppin* [23c]. The latter authors divided the water band between 1.1 and 1.3 $\mu$, which is assigned to a combination $\nu_1 + \nu_2 + \nu_3$ of stretching frequencies and the bending vibration, into 3 sub-bands corresponding to $H_2O$ molecules the OH groups of which are involved in no, one, or two (tetrahedral) H-bonds. The change of concentration with temperature of the 3 molecular states was estimated from the temperature dependence of the intensities between 6 and 72 °C; the mean number of H-bonds per $H_2O$ molecule is close to the results of *Nemethy* and *Scheraga* [17] (cf. Fig. 7). (Size of the "flickering clusters": about 90 $H_2O$ molecules at 20 °C). The assignment of the absorption band and the analysis have, however, led to contradiction [23d] and controversy [23e]. *Vand* and *Senior* conclude that the thermodynamic properties of water cannot be computed, when discrete energy levels are assumed for the three molecular states suggested by *Buijs* and *Choppin*, but that Gaussian distributions of energy with correspondingly more adjustable parameters lead to reasonable results. Since, however, the three energy bands overlap strongly, the connection with the model is lost

From Raman spectra in the region of fundamental OH and OD stretching vibrations, *Wall* and *Hornig* [23f] also arrived at a continuous distribution of molecular states. In order to reduce the intramolecular coupling responsible for the broadening of the bands, they studied the OH band in a 10 % solution of HDO in $D_2O$ and the OD band in 10 % HDO in $H_2O$. Since under these conditions the bands also show no fine structure, the authors hold mixture models in which ordered lattice regions are the only structural units, apart from "monomeric" $H_2O$, to be unrealistic. The concept of mixture models in general has been reviewed by *Frank* [23g].

*Walrafen* [23h] studied the Raman and infrared spectra of $H_2O$ and $D_2O$, particularly in the range below 900 $cm^{-1}$. He assigned the bands in this long -wavelength region to intermolecular stretching and deformation vibrations, assuming $(H_2O)_5$ complexes with tetrahedral arrangement (symmetry $C_{2v}$). With increasing temperature the intensities of the bands decrease rapidly, particularly that of a band at 175 $cm^{-1}$, assigned to the stretching vibration (libration) of two $H_2O$ molecules linked by a hydrogen bond. Only a few tetrahedral bonds should thus remain in water at 100 °C.

The problem of the interpretation of the infrared bands of water has recently been resumed in detail by *Luck* [23i]: The sub-bands of the various species overlap almost completely, and the extinction coefficients, as well as their temperature dependence (influence of medium, dipole and dispersion forces) can only be estimated roughly. According to *Luck*, the combination band between 1.1 and 1.3 $\mu$ can be regarded as due to superposition of four vibrations: those of "free" OH groups in $H_2O$ molecules in which the other OH group also is free (1) or is part of a hydrogen bond (2), and those of OH groups in angular (3) or linear (4) H-bonds. Because of the difficulties mentioned, *Luck* makes use of the species (1) and (4) only to interprete his results (which extend to beyond the critical point). The average number of H-bonds follows the curve of *Hasted et al.* (Fig. 7) between 0 and 100 °C, in contrast to the results of *Buijs* and *Choppin*. In view of the approximations made, these values and the cluster sizes derived from them should be regarded as upper limits.

Most of the new experimental results confirm the "combined" structure model of water proposed in this article; no result in fundamental contradiction has been reported.

## II. The Influence of Dissolved Substances on the Structure of Water

### 1. General

The solvent properties of water depend on the interactions between the dissolved particles and the $H_2O$ molecules in the water structure. The diversity of the substances that dissolve in water indicate that this structure is sufficiently complex to be able to adapt itself in a characteristic manner to different types of solutes (non-polar, polar, or electrically charged).

The most familiar interaction of this type is the hydration of ions. The $H_2O$ molecules in the vicinity of the charged particles are kept in the potential trough of the ion-dipole interaction, and the depth of this trough corresponds to the hydration energy. The electric field of the ions decouples the H-bonds between the $H_2O$ molecules, and if its readjusting power is high enough, it may give rise to the formation of ordered hydration shells (cf. Fig. 9). It is not yet possible to determine the structures of such ordered regions by direct methods,

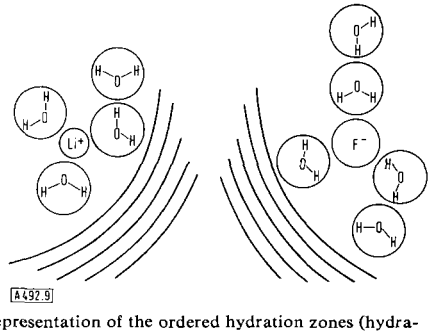

Fig. 9. Schematic representation of the ordered hydration zones (hydration shells) of the $Li^+$ and $F^-$ ions and fault zones of the water structure.

but this may become possible as a result of further development of X-ray diffraction methods, which may be applied to very concentrated electrolyte solutions [24]. Indirect information can be obtained from the viscosity and from relaxation times for the reorientation in space of $H_2O$ molecules. If the values of these parameters are higher for solutions than for pure water, it may be concluded that the solutions contain regions

in which the $H_2O$ molecules are more rigidly oriented with respect to one another than in pure water, *i.e.* in which the distances and angles between the molecules remain fixed for longer periods. These regions that are "rigid" in comparison with pure water are referred to as "ordered" or "structured" regions. At greater distances from the ions, the electric field is just strong enough to prevent the mutual orientation of the $H_2O$ molecules, and hence also the formation of the structural units of water. This region in which the water structure is broken down is shown in Fig. 9 as a fault zone. The average number of H-bonds between $H_2O$ molecules in this zone is smaller than that in pure water, and the $H_2O$ molecules are consequently more mobile. These relatively "fluid" regions are known as regions of "structure breaking".

This characterization of the hydration of ions by two concentric domains of water molecules in which the degree of order is higher and lower, respectively, than in pure water corresponds to the currently accepted picture, the development of which is due mainly to *Frank* and *Wen* [18]. One apparent deficiency of this picture is that although it takes into account the influence of the electric field, it ignores all other interactions between the ions and the $H_2O$ molecules in the water structure, *e.g.* volume or displacement effects, which also occur with neutral particles.

The simplest interaction of this kind, which can be imagined, is the separation of $H_2O$ molecules by dissolved particles, leading to reduced H-bond formation between the $H_2O$ molecules. This interaction should affect the association equilibria of the water in such a way as to give lower degrees of association. *Eucken* referred to this as (pure) "dilution effect" [25]. Here we shall use the terms boundary effect or break-off effect, since the phenomenon is due to the break off of the structure-forming elementary processes of pure water at certain positions; similar effects should also occur at macroscopic boundaries, such as the walls of a container or the surface of the liquid. However, this largely non-specific interaction does not generally occur alone, but is masked by other, more specific effects. There are two particularly important cases to considered:

(a) Loosening of the water structure as a result of break-off effects is to be expected mainly at the "surfaces" of non-polar or weakly polar dissolved particles. However, $H_2O$ molecules adjacent to these surfaces will try to screen their charge centers as much as possible in order to minimize the electric field extending into the non-polar environment, since relatively large amounts of electrostatic energy would otherwise have to be introduced into these regions of low dielectric constant. Particularly effective screening can be achieved by charge compensation of neighboring $H_2O$ molecules with formation of non-tetrahedral hydrogen bonds, as described in Section I.2. The nonpolar particles or groups are then surrounded, not by the expected loose "fluid" regions, but by a zone of more intense structure formation in which the orientation of the $H_2O$ molecules is relatively rigid. This phenomenon is known as hydration of the second kind [46b], and will be described in greater detail below.

[25] *A. Eucken*, Nachr. Akad. Wiss. Göttingen, math.-physik. Kl., math.-physik.-chem. Abt. *1947*, 33.

(b) The opposite behavior is to be expected where the $H_2O$ molecules are adjacent to strongly polarizable "surfaces" of dissolved particles, such as are formed by ions with an extended charge distribution. This is found mainly with large anions such as $Br^-$, $I^-$, $NO_3^-$, and $ClO_4^-$, the charge clouds of which screen $H_2O$ molecules in contact with them or (with their protons) "immersed" in them, so that the break-off effect can be fully active. Particularly strong structure-breaking effects are observed with these ions, and the fault zones indicated in Fig. 9 extend almost to the "surfaces" of the ions, *i.e.* ordered hydration shells are no longer formed ("ordered" in relation to water).

These break-off effects, which are due to displacement, are accompanied by the above-mentioned decoupling of hydrogen bonds by the electric field of the ions. Owing to the concerted action of these two effects, large cations such as $Rb^+$ and $Cs^+$ also have strong structure-breaking influences. Thus the $H_2O$ molecules adjacent to singly charged large anions and cations are, on average, more "mobile" in the potential troughs of the hydration regions (*i.e.* they can rotate and be displaced more easily) than in pure water. This type of hydration of ions has been pointed out mainly by *Samoilow* [26], who suggested that it should be called "negative hydratation". We shall refer in the present paper to "predominantly disordered" hydration of ions, and the $H_2O$ molecules in this case will be described as relatively "fluid".

In the case of LiF (Fig. 9), the ordering effects predominate over the structure-breaking effects. The same is true of practically all ions with multiple charges. The hydration of these ions is "predominantly ordered"; the orientation of the $H_2O$ molecules, averaged over the entire surroundings of the ion, is relatively "rigid" in comparison with pure water.

Thus the interactions discussed above can be summarized as follows:

*Structure forming*: formation of structured ion hydration shells; hydration of the second kind;

*Structure breaking*: decoupling of H-bonds in the electric field of the ions; break-off effects; fault zones; negative hydration.

In the above context "structure breaking" by solutes means the breakdown of the water structure from the flickering clusters, *via* the higher aggregates, to the dimeric and single molecules, as described in Section I for the thermal breakdown of the structure of pure water. "Structure forming", on the other hand, is simply the formation of ordered regions with relatively "rigid" dynamic behavior of the $H_2O$ molecules; this ordering need not obey the rules governing the structure of liquid water.

## 2. Experimental Results

Results of studies on the heat capacities and infrared absorption spectra of electrolyte solutions will now be discussed, as well as those of microwave and nuclear magnetic resonance spectroscopy, which have made an important contribution to the development of the combined model of the structure of water and to the development of the above views on the effects of dissolved particles on this structure.

### a) Heat Capacities and the Hydration of Ions

On the basis of *Eucken*'s views on the hydration of ions [26a] the heat capacities of many electrolyte solutions at various concentrations were measured between about 10 and 130 °C by precision calorimetric methods [27–30]. The results were extrapolated to infinite dilution to find the partial molar heat capacities of the dissolved electrolytes in the standard state. This eliminates the influence of ion-ion interactions, whereas the extrapolated values contain the influence of the ion-water interactions, because they include the total difference between the molar heat capacity of the water in the solution and that of pure water.

Figures 10 and 11 show the (extrapolated) partial molar heat capacities of alkali halides and of HCl and NaOH in aqueous solution. If influence of the ions on the structure of water could be neglected, these electrolytes would have practically the same partial molar heat capacity at infinite dilution, *i.e.* about +12 cal mole$^{-1}$ deg$^{-1}$. The values obtained, however, are all negative and generally become more negative as the radius of the cation (Fig. 10a) or of the anion (Fig. 10b) is increased. At higher temperatures, this trend apparently is reversed, as is clearly shown by the fact that the curves intersect, even though the error in the (extrapolated) points may be up to ±3 cal/mole·degree. With increasing temperature, the partial molar heat capacities pass through a maximum, which for all electrolytes falls within the remarkably narrow range of 50 to 80 °C.

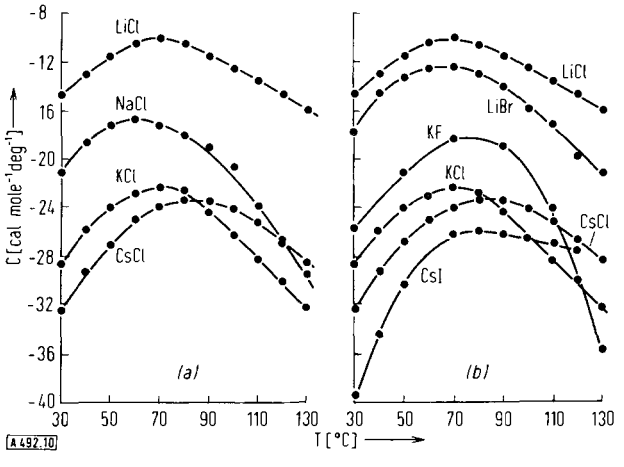

Fig. 10. Partial molar heat capacities C of alkali metal chlorides in aqueous solution (in the standard state), for demonstration of the influence of various cations (a) [27, 29, 30] and anions (b) [27, 30].

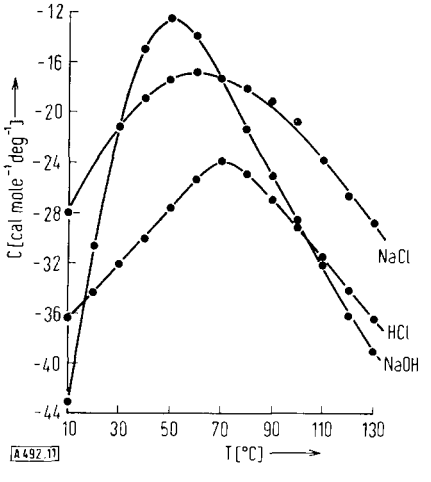

Fig. 11. Partial molar heat capacities C of HCl, NaOH, and NaCl in aqueous solution (standard state) [27–29].

The negative partial molar heat capacities of the dissolved electrolytes show that the heat capacity of water is much lower in these electrolyte solutions than in the pure state. Since the abnormally high heat capacity of water is due to the thermal decay of hydrogen bonds, this means that there are fewer hydrogen bonds present in the electrolyte solution, *i.e.*, that a large number of hydrogen bonds have already been broken during the dissolution of the electrolyte.

This is not due only to structure breaking. Many hydrogen bonds are also removed during the formation of ordered hydration shells, since the $H_2O$ molecules used must be withdrawn from the water structure. This process is important in the case of univalent ions, particularly $Li^+$, $F^-$, and the water ions $H^+$ and $OH^-$. The partial molar heat capacities of HCl and NaOH in Fig. 11 are at some temperatures much more negative than those of NaCl; this is mainly due to the fact that the protons and the hydroxide ions form special hydration structures in water (Fig. 12).

Several factors are responsible for the decrease in the partial molar heat capacities with increasing ionic radii of the alkali metal and halide ions. The relatively large differences between the LiCl and NaCl curves in Fig. 10a and between the KF and KCl curves in Fig. 10b are probably due mainly to the fact that the thermal splitting-off from the ordered hydration shells of $Li^+$ and $F^-$ in this temperature range makes a higher dissociation contribution to the molar heat capacity than in the case of $Na^+$ and $Cl^-$. On the other hand, the steps from $K^+$ to $Cs^+$ and from $Cl^-$ to $Br^-$ and $I^-$ are due to the increase in the structure-breaking action with increasing ionic radius, the principal factor in this case being the break-off effect (see Section II.1.).

The maximum in the curve of partial molar heat capacity against temperature can be correlated with the breakdown ranges of the two types of structural unit in water, *i.e.* the clusters and the molecular aggregates. Near room temperature, the structure-breaking action affects mainly the clusters; this explains the strongly negative molar heat capacities in this temperature range. When the temperature is increased, this effect decreases parallel with the number and size of clusters still present in pure water. Above about 60 °C, the breakdown of molecular aggregates by the electric fields of the ions becomes more important, and the partial molar heat capacities again become more negative, the steepness of the decrease depending on the size of the ion. Thus the molecular aggregates are more strongly broken down by smaller ions with their higher field strengths, *i.e.*, the order of the curves is reversed above 100 °C. The lithium ion behaves exceptionally, since in this case the thermal decay of the ordered hydration shell still makes an appreciable positive contribution to the partial molar heat capacity even at 130 °C.

[30] *Th. Ackermann et al.*, unpublished work.

The heat capacities of aqueous solutions of simple electrolytes can be understood in this way. Many of the details still remain to be clarified, but it can already be seen that a combined model is required for the structure of water, and that the ion-water interactions considered in Section II.1 must be taken into account.

From the partial molar heat capacities of HCl shown in Fig. 11, and from the densities of aqueous hydrochloric acid solutions, it was concluded about ten years ago that the proton is primarily hydrated with four $H_2O$ molecules. The model shown in Fig. 12 was then proposed for this hydration shell. According to this model, the hydronium ion $H_3O^+$ and three $H_2O$ molecules form a complex $[H_9O_4]^+$, which can add on further $H_2O$ molecules to form an outer hydration layer [28]. Within the $[H_9O_4]^+$ complex, the proton can move (or jump) rather freely along the hydrogen bonds, the resulting fluctuations giving rise to a strong continuous absorption in the infrared spectra of aqueous solutions of acids. *Ackermann* has measured the absorption in the fundamental vibration range of $H_2O$ with the aid of special cells [31]. Fig. 13 shows the strong additional continuous absorption of 5 N hydrochloric acid, which extends from the broad double band of the OH stretching vibration to beyond the deformation band at 1640 $cm^{-1}$. Since then, various other authors have observed $[H_9O_4]^+$ complexes under different conditions. *Beckey* found $[H_9O_4]^+$ complexes in the course of mass-spectroscopic studies with a field-emission ion source operated in the presence of water vapor [32]. *Rudolph* and *Zimmermann* recently measured the infrared absorption of solid hydrogen bromide tetrahydrate at −170 °C, and concluded from the analysis of the spectrum that the substance has the structure $[H;O_4]^+Br^-$, with $[H_9O_4]^+$ as shown in Fig. 12 [33].

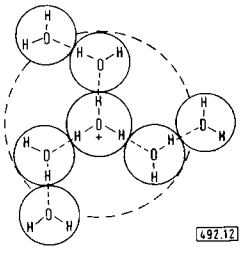

Fig. 12. Hydration of the proton in aqueous solution with formation of the $[H_9O_4]^+$ complex [28].

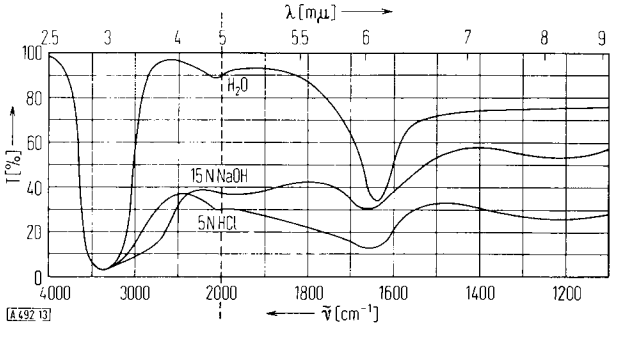

Fig. 13. Infrared absorption of aqueous 5 N HCl and 15 N NaOH in comparison with pure water in the fundamental vibration region of $H_2O$ [31].

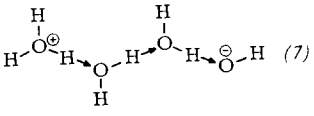
Analogously it has been shown that the hydration shell of the hydroxide ion probably has a similar structure [34], again involving fluctuation of protons along hydrogen bonds. Concentrated aqueous NaOH solutions have been found to give a continuous additional absorption similar to that found for hydrochloric acid (cf. Fig. 13) [31]. The mobility of the protons in these hydrate structures contributes to the extreme rapidity of neutralizations. Thus when $H^+$ and $OH^-$ ions approach each other so closely that the structures of their hydration shells coalesce, the proton spontaneously closes the remaining gap by jumping along hydrogen bonds. *Eigen* and *De Maeyer* measured the rate of neutralization with the aid of the dissociation field effect [35], and found that the last 5 to 8 Å (*i.e.* two to three H-bond lengths) between the proton and the hydroxide ion are covered by proton jumps as described above [see formula *(7)*].



(7)

Structure formation and transport mechanisms of this nature are generally of considerable importance to protolytic reactions in aqueous media; they are particularly important to the influence of the pH on rates of reaction in biological systems (acid-base and enzyme catalysis [36]).

### b) Heat Capacities and Hydration of the Second Kind

The (extrapolated) partial molar heat capacities of a number of organic salts are shown in Fig. 14 [37]. Most of the values are positive, unlike those of simple electrolytes (Figs. 10 and 11). This is chiefly due to the con-

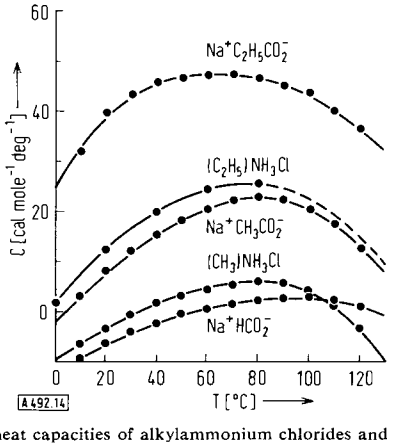


Fig. 14. Partial molar heat capacities of alkylammonium chlorides and of sodium salts of fatty acids in aqueous solution (standard state) [37].

tributions of the vibrations and internal rotations in the organic ions. However, the increment of 15 to 20 cal $mole^{-1}$ $deg^{-1}$ resulting from the introduction of one additional $CH_2$ group into the alkylammonium or fatty acid ion is surprisingly large; the same increment per $CH_2$ group was found by measurements on aqueous solutions of the free fatty acids [37]. In the corresponding hydrocarbons, or in the pure liquid acids, one additional $CH_2$ group contributes with its thermal degrees of freedom only 5 to 10 cal/mole degree to the molar heat capacity. In aqueous solution, therefore, the greater part of the increment observed, corresponding to about 10 cal/$mole^{-1}$ $deg^{-1}$, must be due to other causes. It is, in fact, due to "hydration of the second kind", *i.e.*, an intensified hydrogen-bond structure in the vicinity of the hydrocarbon groups; the extra contribution to the heat capacity comes from the thermal decay of this structure with rising temperature. The maximum in the curve of the partial molar heat capacity of the dissolved organic electrolytes against temperature (Fig. 14) is due to the contributions of the ions, as explained earlier for monatomic ions.

The structure formation of water in the vicinity of non-polar groups, *i.e.*, the greater rigidity of the mutual orientation of adjacent $H_2O$ molecules (short-range order) provides an explanation for the fact that non-polar gases such as hydrocarbons dissolve exothermically in water, the entropy of the system simultaneously undergoing an abnormally large decrease. This explanation was first offered by *Frank* and *Evans* [38]; however, the term "iceberg formation" coined by these authors has often led to the view that the structure formation in the vicinity of non-polar particles consists in the enlargement and stabilization of the flickering clusters with their framework of tetrahedral hydrogen bonds (see, *e.g.*, *Némethy* [17]) [*]. In reality, however, the chemical shift of the proton resonance of water (Section II.4d) indicates that the structure in this case is not one with tetrahedral hydrogen bonds, but involves predominantly non-tetrahedral linking of neighboring $H_2O$ molecules.

Structure formation in the vicinity of non-polar dissolved particles has also been correlated with the structure of gas hydrates, in which $H_2O$ molecules form crystalline cages around non-polar and weakly polar molecules such as hydrocarbons or halogenated hydrocarbons (cf. Fig. 8). These hydrogen-bond structures, which were elucidated by *Claussen* [39] and *v. Stackelberg* [40], resemble a particularly bulky modification of ice. Water molecules can be separated from salt solutions by the formation of solid hydrates with gases (*e.g.* propane) under pressure, even above the normal freezing-out temperature; this procedure, termed gas hydrate process, has been suggested for the desalineation of sea water [41]. However, these strictly ordered cage structures in the solid state have relatively little connection with hydration of the second kind in the case of dissolved non-polar particles. On the other hand, an intensified short-range order analogous to hydration of the second kind can be assumed to occur at water surfaces. It is due to similar electrostatic factors (boundary effects) and is responsible for the anomalously high surface tension of water. Thus structure formation in the vicinity of non-polar groups may be regarded as the origin on a molecular scale of the development of an interface between water and a non-polar medium [37].

If two non-polar groups (*e.g.*, alkyl side-chains) surrounded by $H_2O$ molecules with an intensified short-range order approach each other, the regions of short-range order tend to coalesce to form a hydration zone of the second kind surrounding both groups (this reduces the number of $H_2O$ molecules involved in this ordered zone, and so leads to a gain in entropy). The result is an effect similar to surface tension: the non-polar groups tend to form micelles, and behave as if the strength of the attractive forces between them were increased.

This effect is often discussed in connection with the stabilization of the tertiary structure of proteins in aqueous solution; the so-called "hydrophobic bonds" between non-polar side groups of the polypeptide chains are thought to assist the hydrogen bonds in maintaining the protein structures [42].

### c) Microwave Spectroscopy. Dielectric Relaxation

The close agreement between the dielectric constant of water at 0 °C and that of ice is an important argument in favor of the assumption that regions of order similar to that in ice still exist in the liquid state. The rapid reorientation of the $H_2O$ dipoles in the electric field (which, according to *Hasted*, has a relaxation time of $0.8 \times 10^{-11}$ sec in water at 25 °C [4,42a]) suggest that these zones are not very large, and that they are constantly being broken down and re-formed in a rapid sequence of thermal-statistical fluctuations, *i.e.* they are "flickering clusters". The decrease in the dielectric constant with increasing temperature up to about 100 °C can be correlated with the thermal breakdown of the clusters. Since the molecular aggregates with predominantly non-tetrahedral H-bonds replacing these clusters also are strongly polarizable, the dielectric constant and its temperature coefficient remain remarkably large (55.5 at 100 °C; 34.5 at 200 °C) even at higher temperatures.

Aqueous solutions exhibit a region of dielectric dispersion at wavelengths between 1 and 10 cm in the same region as pure water (characteristic wavelength for pure

[38] *H. S. Frank* and *M. W. Evans*, J. chem. Physics *13*, 507 (1945).

[*] Note added in proof: *A. Ben-Naim*, J. phys. Chem. *69*, 1922 (1965) has shown that a preference for larger clusters in the vicinity of non-polar molecules results from calculations of the energetic interaction if it is assumed that the clusters are "compact", *i.e.* that they do not incorporate the non-polar groups – as is assumed by *Nemethy* and *Scheraga* – but interact with these groups only at their "surfaces". The calculation shows a stabilization of larger at the expense of smaller clusters because in the former the surface/volume ratio is lower.

water: $\lambda_w$ = 1.56 cm at 25 °C). *Hasted et al*[4, 42a] showed the existence of groups of substances (see Table 1) whose solutions give dispersion curves that can be regarded (as in the case of pure water) as a uniform relaxation process with a single relaxation time. The dipole molecules listed in Table 1, the smallest of which is propionic acid, are aligned relatively slowly with the field direction; the dielectric dispersion range due to this reorientation process, is situated at considerably longer wavelengths. Thus in the microwave region, *i.e.* from 1 to 10 cm, there is no dipole contribution from the solute molecules to the dielectric constant of the solution. Since the effect of displacement polarization of the solute can be readily estimated, it is possible to study the dielectric behavior of the water alone. This is an advantage of dielectric relaxation methods in the study of the effects of solutes on the structure of water.

The measurements yield the limiting value of the dispersion stage towards long wavelengths, *i.e.* the "static" dielectric constant $\varepsilon_{st}$, which, as described above, contains no dipole component due to the solvent. On the other hand, the frequency of the maximum of absorption can be determined, and hence the characteristic wavelength $\lambda_s$, which is related to the relaxation time by: $\lambda_s/2\pi c = \tau$, where $c$ is the speed of light. This dielectric relaxation time $\tau$ is closely related to the reorientation of the $H_2O$ molecules as a result of thermal motion of the molecules, and can be approximately (*i.e.* disregarding the effects of the local fields) identified with the average reorientation time, which is found by averaging over all the states of $H_2O$ molecules that exist in the solution. $\varepsilon_{st}$ and $\lambda_s$ vary linearly with the concentration c of the solutions up to c = 1 to 2 mole/*l*. Table 1 shows the gradients of the experimental curves for a representative selection of solutes. The negative values of $[\varepsilon_{st}(c) - \varepsilon_w]/c$ in the second column of the Table show that the static dielectric constant is reduced by the solutes studied.

Table 1. Influence of solutes on the static dielectric constant, $\varepsilon_{st}(c)$, and on the characteristic wavelength, $\lambda_s(c)$, of water in solutions of molarity c at 25 °C [4]. $\varepsilon_w$, $\lambda_w$ are reference values for pure water.

[*] For pure water at 25 °C: $\lambda_w = 1.56$ cm; $\tau_w = 0.83 \times 10^{-11}$ sec. A value of +10 corresponds to an increase of $0.05 \times 10^{-11}$ sec in the relaxation time of a 1 M solution over that in pure water.

This is due to three effects, all of which act in the same sense: (a) when the solution is formed, regions that previously contained a strongly polarizable water structure are occupied by the much less polarizable particles of the solute; (b) strong electrostatic fields fix the orientations of the water dipoles in ordered hydration shells; (c) structure-breaking effects preferentially break down the clusters, which make a large contribution to the dielectric polarization. Since several effects are simultaneously present, it is difficult to draw definite conclusions from the results. It can be stated, however, that the results show no evidence of effects that increase the dielectric constant, such as formation or stabilization of frameworks with tetrahedral H-bonds (*e.g.* clusters).

It can be seen from Table 1 that the differences in the relaxation times are more specified than the differences in the static dielectric constants. The values in the third column of the Table can be divided into three groups. The first group comprises weakly polar neutral substances and weak organic electrolytes, which retard reorientation relatively strongly; the orientation of the $H_2O$ molecules in the vicinity of these dissolved particles is more rigid, on average, than in pure water (hydration of the second kind). This effect also prevails (as expected) in the third group, which includes salts of fatty acids and alkylammonium salts. Owing to the influence of the ionic charge, however, the effect is weaker in this case. In the second group (alkali metal halides), on the other hand, the average relaxation time is reduced, *i.e.* the $H_2O$ dipoles can reorient themselves more easily; the value obtained for hydrochloric acid was the same as that for pure water.

The fact that in these cases the structure formation in the ordered hydration shells of $H^+$, $Li^+$, $Mg^{2+}$, and $F^-$ does not outweigh the structure-breaking effect, so leading to an increase in the average relaxation time, probably is due to the method of averaging inherent in the relaxation measurements. The various states of the $H_2O$ molecules are assigned weighting factors that increase with the contribution made by the state in question to the total dielectric polarization. The contribution made by $H_2O$ molecules in ordered ion-hydration shells decreases as the molecules become more firmly fixed so that their relatively long relaxation times have no marked influence on the average.

The order in which the electrolytes listed in Table 1 facilitate the reorientation of the $H_2O$ molecules (HCl < NaF, LiCl < RbCl, NaI) is the same as the order in which their structure-destroying action increases. However, the "origin" of the structure forming-structure breaking scale is displaced here towards the side of structure breaking compared to other methods.

### d) Chemical Shift of the $H_2O$ Proton Resonances in Aqueous Solutions

The most important advances of recent years on the problem of the structure of water and aqueous solutions have been achieved with the aid of nuclear magnetic resonance spectroscopy. Only a representative selection of the results obtained will be discussed here. The chemical shift is a measure of the difference in polarity of the $H_2O$ molecules in various bonding states, *i.e.* a measure of the extent to which the proton is shielded. The relaxation measurements mentioned below give the most reliable information available at present about the dynamic behavior of the $H_2O$ molecules (reorientation times)[*].

[*] For the principles and the methods of measurement of nuclear magnetic resonance, see *H. Strehlow* [43].

[43] *H. Strehlow*: Magnetische Kernresonanz und chemische Struktur. Steinkopff, Darmstadt 1962; Ber. Bunsenges. physik. Chem. 67, 250 (1963).

The chemical shift of the proton resonances of the water in various diamagnetic electrolyte solutions in relation to pure water was first studied by *Hertz* and *Spalthoff*[44, 45], by means of the "internal standard" method. A little tert.-butyl alcohol was added to the solutions or to the pure water, and the methyl protons of the alcohol were used as internal standard. The results are shown in Figs. 15 and 16. Only one resonance line was obtained

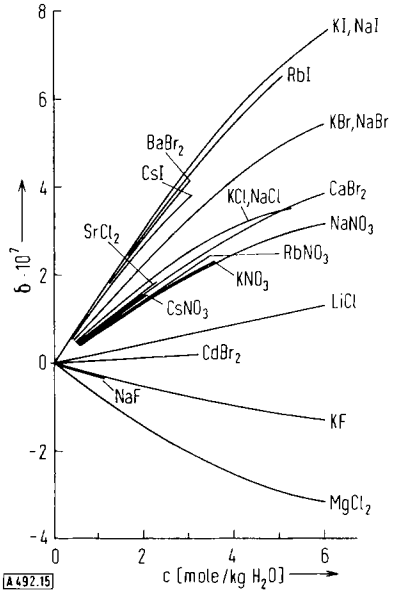

Fig. 15. Chemical shift $\delta$ relative to pure water of the $H_2O$ protons in aqueous solutions of inorganic electrolytes, as a function of concentration at 25 °C. $\delta = (H_c - H_0)/H_0$ ($H_c$ = resonance field of the $H_2O$ protons in a solution of concentration c; $H_0$ = resonance field in pure water) [44].

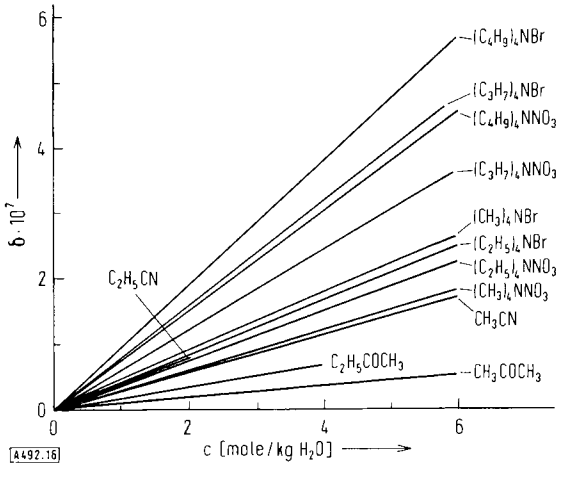

Fig. 16. Chemical shift of the $H_2O$ protons in aqueous solutions of substances containing hydrocarbon groups, at 25 °C [44].

for the $H_2O$ protons in every case. It may therefore be concluded that the $H_2O$ molecules change so rapidly from one state to another that the chemical shift obtained is an average for all these states (exchange takes less than $10^{-7}$ sec even in the ordered hydration shells of the alkaline earth ions).

It can be seen from Figs. 15 and 16 that in nearly all the solutions studied, these average chemical shifts are positive in relation to pure water, *i.e.* a higher external magnetic field is required for resonance of the $H_2O$ protons than in the case of pure water. This means that in these solutions, the contribution of such molecules to the chemical shift predominates in which the diamagnetic screening of the protons by the electron clouds is stronger than in pure water. A negative chemical shift, on the other hand, would indicate that the contributions of $H_2O$ molecules predominate whose protons are less strongly shielded and which are therefore more polar than in pure water. This is the type of behavior expected in $H_2O$ molecules that are built into the ordered hydration shell of ions, and should therefore be particularly noticeable in solutions containing $Li^+$, $F^-$, and alkaline earth ions.

In fact, the only solutions studied that give negative chemical shifts (see Fig. 15) are those of NaF, KF, and $MgCl_2$. Even LiCl solutions give positive chemical shifts, while the positive shifts are still stronger for solutions of $SrCl_2$, $CaBr_2$, and $BaBr_2$. In these cases the influence of the ordered hydration shell around the cations is evidently outweighed by opposing effects. The only effects of this type that could be involved are those of the halide ions $Cl^-$, $Br^-$, and $I^-$, so that these must cause a strong positive shift of the resonances of neighboring water protons. This positive shift increases stepwise in the above order, as can be seen from the values for the alkali metal chlorides, bromides, and iodides in Fig. 15 (the behavior of the nitrates is almost the same as that of the chlorides). The effects of the alkali metal ions from $Na^+$ to $Cs^+$ differ only slightly. The phenomenon is therefore characteristic of large, highly polarizable anions, and is obviously the same as the effect discussed in Section II.1 in connection with the break-off of the water structure; thus protons of adjacent $H_2O$ molecules are embedded in and shielded by the charge cloud of the ions, and the positive chemical shift is due to the (internal) diamagnetism of the shielding electronic charges.

A positive proton resonance shift has also been observed for pure water with increasing temperature; the chemical shift increases linearly with temperature, at 100 °C it is $\delta = 7 \times 10^{-7}$ relative to pure water at 25 °C [44]. This shows that the water molecules, on average, become less polar as the temperature is raised, *i.e.* as the thermal dissociation of the structural units in the order clusters – molecular aggregates – single molecules progresses. Since the molecular aggregates contain many non-tetrahedral hydrogen bonds, the $H_2O$ molecules in this state are less polar (*i.e.* their protons are more strongly shielded) than in the tetrahedral hydrogen bonds of the flickering clusters; in the unbonded state, *i.e.* as monomers, the $H_2O$ molecules are even less polar than in the molecular aggregates. (Measurements on water vapor and on very dilute solutions of $H_2O$ in carbon tetrachloride indicated a strong positive shift ($\delta = 4.3 \times 10^{-6}$) relative to pure water at 25 °C.)

The surprising linearity of the changes in the proton resonance shift with temperature in the case of pure water

[44] *H. G. Hertz* and *W. Spalthoff*, Z. Elektrochem., Ber. Bunsenges. physik. Chem. *63*, 1096 (1959).

[45] *H. G. Hertz*, Ber. Bunsenges. physik. Chem. *67*, 311 (1963).

is probably connected with the superposition of these two effects. Thus ice, in which the number of tetrahedral hydrogen bonds is a maximum (two per $H_2O$ molecule), should give a relatively strong negative shift in relation to liquid water. This cannot be verified by measurement, since the resonance signals for ice (as for most solids) are so broad that it is impossible to determine the resonance frequencies with the required accuracy (±1 c/s for the examples in Fig. 15). However, if the number and stability of the "ice-like" clusters in water were increased by solutes, this would lead to a negative chemical shift of the proton resonance of water in the solutions in question. *Hertz* and *Spalthoff*[44] carried out measurements on quaternary ammonium salts and on organic substances that give neutral solutions in water in an effort to detect this "iceberg formation" (*Frank* and *Evans*[38]).

It can be seen from Figure 16 that the shifts obtained are always positive in relation to pure water, and increase with the length of the alkyl group. This indicates that the intensified structure of water in the neighborhood of non-polar groups, *i.e.* hydration of the second kind, does not involve ice-like structures. Instead, the adjacent $H_2O$ groups must be joined by linkages with stronger electrostatic screening of the protons, *i.e.* linkages such as the non-tetrahedral hydrogen bonds described in Section I.2.

### e) Nuclear Magnetic Relaxation Rate

When the thermal equilibrium distribution of the nuclear spins over the energy states in a magnetic field is temporarily disturbed, the disturbance decays with a time constant $T_1$. The reciprocal $1/T_1$ is known as the relaxation rate. *Hertz* and *Zeidler*[46a] have shown that the relaxation rate for the proton nuclear spins of the $H_2O$ molecules in water and in aqueous solutions and provide information about the average time required for the $H_2O$ molecules to execute one (hindered) rotation. These "reorientation times" are approximately proportional to the measured relaxation rates for the proton nuclear spins. The values obtained as a result of this averaging over states of $H_2O$ molecules with different "mobilities" are more reliable with regard to structure forming and breaking in electrolyte solutions than the values obtained by the dielectric method involving the average reorientation times of $H_2O$ dipoles. It can be seen from Fig. 17 that the relaxation rates, and hence the reorientation times, are lower on average in the solutions of the chlorides, bromides, iodides (also nitrates) of potassium, rubidium, and cesium than in pure water. Thus breakdown of structure predominates in these cases; the hydration of the ions is predominantly disordered, and the dynamic behavior of the solvent water is relatively "fluid". On the other hand, the average reorientation times of the $H_2O$ molecules in the solutions of the Li and Na salts, of KF, and of the alkaline earth halides are greater than in pure water,

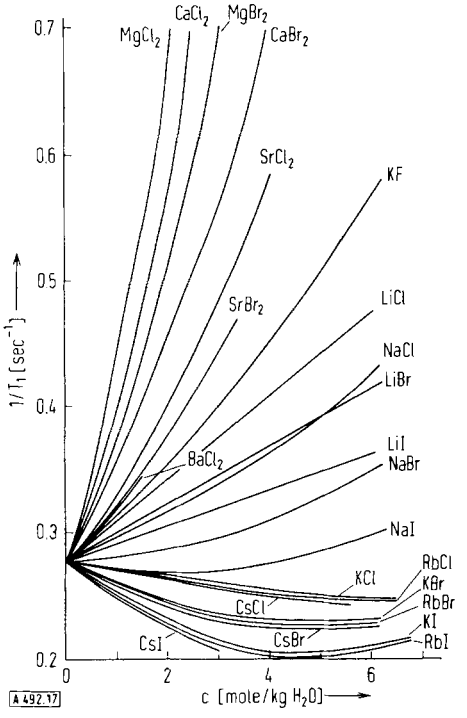

Fig. 17. Relaxation rate $1/T_1$ of the nuclear resonance of the $H_2O$ protons in aqueous solutions of inorganic electrolytes as a function of concentration at 25 °C ([45] and personal communication from *H. G. Hertz* and *M. D. Zeidler*).

indicating that the hydration of the ions in these cases is predominantly ordered, and the dynamic behavior of the water is relatively "rigid" [*].

This method was specially adapted by *Hertz* and *Zeidler* for the study of the hydration of non-polar groups in aqueous solution[46b]. To avoid interference due to the protons of solutes, only deuterated solutes were used in one method; the results are illustrated in Fig. 18 for dimethyl sulfoxide, potassium acetate, and tetramethylammonium nitrate. The average reorientation time of the $H_2O$ molecules increases steadily with the concentration of these substances (similar behavior is found with potassium oxalate).

Another method for solutes containing hydrogen involves the use of deuterium oxide as solvent; the reorientation times of the $D_2O$ molecules are then studied by means of the deuteron nuclear quadrupole resonance signal. Experimental results obtained with quaternary ammonium salts are shown in Fig. 19. It can be seen that the orientation of the $D_2O$ molecules becomes increasingly rigid on passing from methyl through ethyl to propyl groups. With butyl groups, the effect decreases again, probably owing to coiling or

[46a] *H. G. Hertz* and *M. D. Zeidler*, Ber. Bunsenges. physik. Chem. *67*, 774 (1963); *M. D. Zeidler*, Dissertation, Universität Münster, 1963.

[*] Note added in proof: *D. W. McCall* and *D. C. Douglas*, J. phys. Chem. *69*, 2001 (1965), using the NMR spin-echo method, have studied the self-diffusion of $H_2O$ in pure water and in electrolyte solutions at 23 °C. The measured (average) self-diffusion coefficient generally decreases with increasing electrolyte concentration; an increase was found, however, for KBr, KI, CsI, and $KNO_3$. The concentration dependence is essentially analogous to that of the solution viscosity. The authors correlate their results with the proton chemical shifts (Fig. 15); they agree much better, however, with the concentration dependence of the relaxation rates in Fig. 17.

[46b] *H. G. Hertz* and *M. D. Zeidler*, Ber. Bunsenges. physik. Chem. *68*, 821 (1964).

micelle formation. The same qualitative results were obtained in the homologous series of fatty acids and their salts in deuterium oxide [46b]. Further, from the increase of the relaxation rates with temperature (which was studied up to 80 °C), it can be concluded

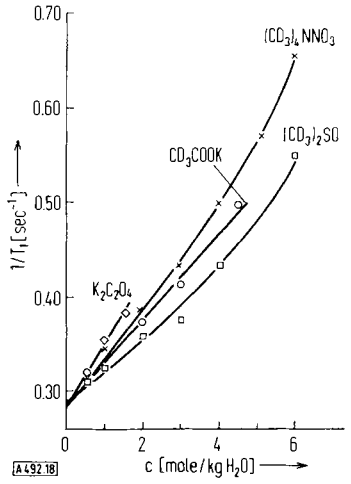

Fig. 18. Relaxation rate $1/T_1$ of the nuclear resonance of the $H_2O$ protons in aqueous solutions of organic substances that contain no protons, as a function of the molal concentration at 25 °C [46b].

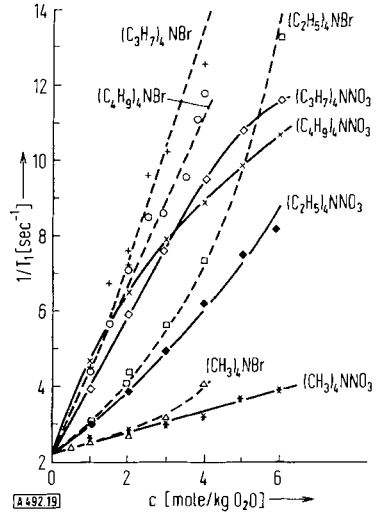

Fig. 19. Relaxation rate $1/T_1$ of the nuclear quadrupole resonance of the $D_2O$ deuterons in solutions of tetraalkylammonium salts in $D_2O$ at 25 °C [46b].

that these solutions contain $H_2O$ molecules whose reorientation is much more strongly restricted than in pure water. These measurements have given the most direct evidence so far obtained for structure formation by $H_2O$ molecules in the neighborhood of non-polar groups [47].

Some typical results of nuclear magnetic relaxation measurements are given in Fig. 20 for an aqueous solution of tetraethylammonium bromide. The hydration zone of the ions is indicated in every case. The values beside the curved arrows show the reorientation times of the particles in question, while those near the straight arrows are the average times spent by the particles at a given site between two jumps. These residence times were found from the self-diffusion of the particles. Both the reorientation time and the residence time can be taken as $10^{-11}$ sec in pure water. In the hydration sphere of the bromide ions, the reorientation and transposition take $7 \times 10^{-12}$ sec, *i.e.* the $H_2O$ molecules are more mobile than in pure water; in the neighborhood of the tetraethylammonium ion, the molecules take $2 \times 10^{-11}$ sec for one reorientation, *i.e.* they are rather more

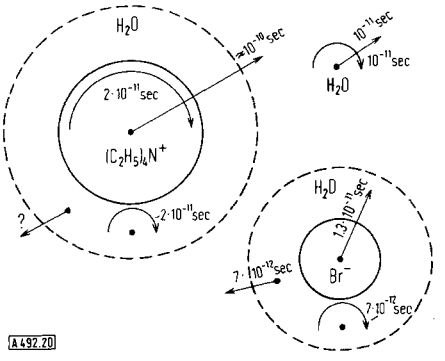

Fig. 20. Reorientation and residence times of the $H_2O$ molecules in various zones and of the ions in an aqueous solution of tetraethylammonium bromide at 25 °C. Concerning the division into zones and the time values, cf. *H. G. Hertz* and *M. D. Zeidler* [46a, 46b].

rigidly bound than in pure water. The same reorientation time is found for the quaternary ammonium ion itself. This remarkably low value for such a large, bulky particle shows that the ion experiences little hindrance to rotation inside its "hydration sphere of the second kind"; this is expected, since there are no specific (orientation-dependent) interactions between the alkyl groups and the adjacent $H_2O$ molecules. The residence time of the bromide ion inside its hydration zone ($1.3 \times 10^{-11}$ sec) is remarkably short, obviously owing to the increased mobility of the $H_2O$ molecules in this zone.

It follows from Fig. 20 that it is only a crude approximation to describe the interactions between dissolved particles and $H_2O$ molecules in water by regions of "structure breakdown" and "structure formation". Beyond this the physicochemical properties of the solutions are strongly dependent on the dynamic behavior of the $H_2O$ molecules within the various structure regions, *i.e.* their mobility in reorientation and transposition. Some apparent contradictions reported in the literature may be explained by the different ways of averaging – which are inherent in different experimental methods – the short-lived intermediate states.

## Reaction of Alkyldichloroamines with Nickel Tetracarbonyl [1]

By Dr. H. Bock and Dr. K. L. Kompa

Institut für Anorganische Chemie
der Universität München (Germany)

On reaction with *N,N*-dichloro-t-butylamine or -cyclohexylamine in benzene at 0 °C, nickel tetracarbonyl evolves three moles of carbon monoxide per mole. A colorless precipitate *(1)* is formed that has a Ni:N ratio of 1:1 and is insoluble in the usual solvents.

$$2\ RNCl_2 + 2\ Ni(CO)_4 \rightarrow 2\ [RNCl_2Ni(CO)] \quad (1)$$

$$H_2O \xrightarrow{\text{excess of } H_2O} 2\ RNH_2 + 2\ NiCl_2 + 2\ CO_2$$

$$\xrightarrow{1\ \text{mole } H_2O} RHN{-}CO{-}NHR + 2\ NiCl_2 + CO_2$$

Addition of the complex *(1)* to water gives equimolar amounts of the original amine and nickel(II) chloride (carbon dioxide was determined qualitatively). However, cautious hydrolysis of *(1)* with moist benzene or moist diethyl ether permits isolation of the *N,N'*-dialkylurea in yields of 80 % calculated on the amount of nickel carbonyl that reacted; the stoichiometric amount of nickel(II) chloride remains on evaporation of the reaction mixture. Cautious deuteriolysis of the complex *(1)*, $R = C(CH_3)_3$, gives the *N*-deuteriated urea, whose $^1$H-NMR spectrum shows, as expected, only one type of proton.

## Conformational Analysis of Bicyclopropyl by Vibrational Spectroscopy

By Prof. Dr. W. Lüttke and Dipl.-Chem. A. de Meijere

Organisch-Chemisches Institut der Universität Göttingen (Germany), and

Prof. Dr. H. Wolff and Dr. H. Ludwig

Institut für Physikalische Chemie der Universität Heidelberg (Germany) and

Dr. H. W. Schrötter,

Physikalisches Institut der Universität München (Germany)

A large number of conformational analyses of open-chain and cyclic aliphatic compounds have been carried out, especially on derivatives of ethane and cyclohexane [1]. However, no studies have been carried out on molecules in which two aliphatic rings are linked by a single bond. We have therefore commenced a systematic investigation of the conformations of the compounds in the homologous series

$$(H_2C)_n\ CH\text{-}CH\ (CH_2)_n \qquad n = 1, 2, \ldots 5$$

*(1)*

in order to find out whether these compounds show rotational isomerism around the central C–C single bond and to determine the extent to which this isomerism depends on the strain in the rings, the spatial requirements of the rings, and the hybridization of the two central carbon atoms.

The following observations on bicyclopropyl were made:

1. The infrared spectra of the gas and liquid contain the same number of bands.

2. The number of bands in the infrared and Raman spectra is approximately halved on transition from the liquid to the solid state.

3. Most of the vibrational frequencies in the infrared and Raman spectra of liquid bicyclopropyl agree, but there is no such coincidence of spectral bands in the crystalline state (see Fig. 1).

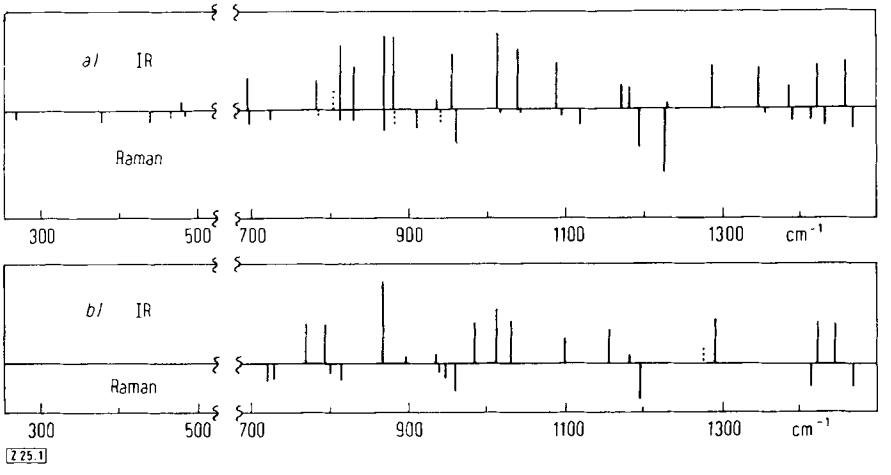

Fig. 1. Infrared and Raman spectra of (a) liquid and (b) crystalline bicyclopropyl.

Hence the solid strictly obeys the rule of mutual exclusion, *i.e.* in the crystal lattice the molecule occurs in a form with a center of symmetry. Of all the conformational isomers possible, this can only be the s-*trans*-form (see Fig. 2) which belongs to the $C_{2h}$ point group. Accordingly, all the bands in the spectra of the crystalline form can be assigned without difficulty to the normal vibrations of the s-*trans*-form and can be included in the series of spectra of cyclopropane monoderivatives ("spectral sequence" [2]).

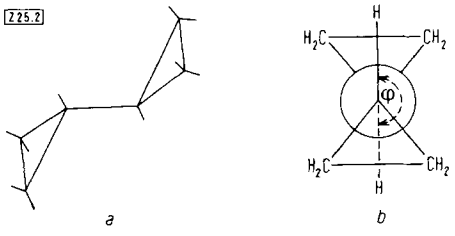

Fig. 2. s-*trans*-Conformation of bicyclopropyl.
a) Perspective; b) Newman projection (φ = angle of torsion).

When the substance is melted, numerous other bands appear in its spectra; hence there must be a rotationally isomeric form in equilibrium with the s-*trans*-form in the *liquid* phase. Preliminary measurements of the intensities revealed that both forms are present in comparable concentrations and that the position of the equilibrium changes only slightly with temperature. The coincidence of most of the infrared and Raman absorptions indicates that the rotational isomer does not have a center of symmetry.

We have also prepared 1-methyl- and 1,1'-dimethylbicyclopropyl and examined them analogously. The infrared and Raman spectra of the monomethyl derivative did not permit a definite decision as to the nature of the rotational isomers because this compound has only low symmetry (s-*trans*- and s-*cis*-forms have $C_s$, other forms have $C_1$ symmetry). The dimethyl derivative has a symmetry corresponding to that of the unsubstituted compound and gives infrared spectra in the liquid and crystalline states containing the same number of bands (apart from crystal field splittings). The infrared and Raman spectra of the liquid dimethyl derivative obey the rule of mutual exclusion. Consequently dimethylbicyclopropyl also occurs in the s-*trans*-form ($C_{2h}$); here intramolecular rotation is restricted by steric hindrance.

Similar spectroscopic measurements with 1,3-butadiene, which is formally the first member of the series *(1)*, showed that it behaves exactly like dimethylbicyclopropyl. Within the accuracy of our concentration measurements (3–4 %), there is no s-*cis*-butadiene present in any of the three states of aggregation of the compound between −160 and 30 °C; this is in agreement with findings from another approach [3].

## Conformations of Bicyclopropyl and Bicyclobutyl by Electron Diffraction

By Prof. Dr. O. Bastiansen and Dipl.-Chem. A. de Meijere

Chemical Institute of the University Oslo (Norway) and
Organisch-Chemisches Institut
der Universität Göttingen (Germany)

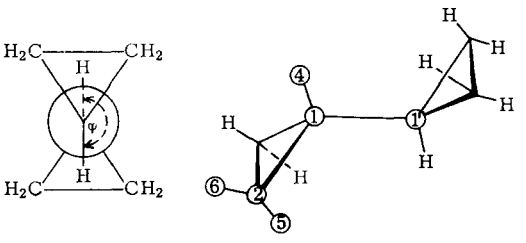
The problem of the shapes of the rotational isomers of bicyclopropyl[1] can be solved by a study of the electron diffraction of the substance in the gaseous state.

The diffraction diagrams were obtained by the sector microphotometer method and were treated in the usual way[2, 3]. All the bond lengths and valence angles (Table 1) were obtained from the experimental radial distribution curves. The forms of the rotational isomers were determined from the same data. For this purpose radial distribution curves were calculated for numerous models having various torsion angles and for mixtures thereof, and compared with the experimental curve. The best agreement was obtained for a mixture of 60 % of a non-rigid *gauche* form with 40 % of a non-rigid *s-trans*-form *(1)*; a torsion amplitude of ± 18 ° about the equilibrium angle φ was assumed for the non-rigid

Table 1. Bicyclopropyl.

| Bond | Length [Å] | u [Å] [a] |
|---|---|---|
| C–C (in the ring) | 1.517 ± 0.005 | 0.048 ± 0.002 |
| C–C (between rings) | 1.517 ± 0.01 | 0.048 ± 0.004 |
| C–H | 1.094 ± 0.02 | 0.089 ± 0.006 |
| C(2)–C(1') | 2.634 ± 0.02 | 0.070 ± 0.005 |
| C(1)–H(5) = C(1)–H(6) | 2.235 ± 0.03 | 0.118 ± 0.008 |
| ∢ H–C–H | 117.3 ± 1.5 ° | |
| ∢ H(4)–C(1)–C(1') | 115.2 ± 1.5 ° | |
| ∢ C(2)–C(1)–C(1') | 120.5 ± 1.5 ° | |

[a] u = root mean square amplitude of vibration. The values were refined by matching the theoretical to the experimental intensity curve by the least squares method.



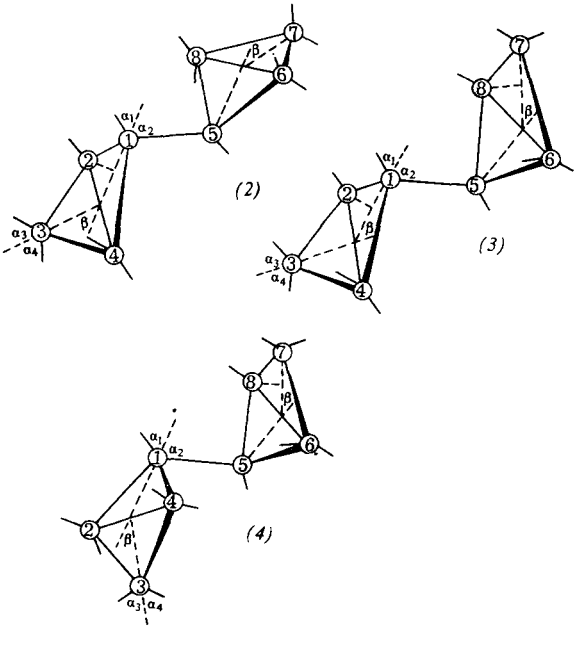
*(1a)* *(1b)*, φ = 180°

*gauche* form, the angle φ being between 35 and 40 ° because of the unusual geometry of the molecule. For the non-rigid *s-trans*-form an amplitude of ± 80 ° about the equilibrium angle φ = 180 ° had to be assumed, *i.e.*, rotation about the central C–C bond of bicyclopropyl is almost unhindered in the region 100 to 260 °. This behavior can be understood if the potential curve V(φ) of internal rotation is calculated with consideration merely of the H···H interaction[4].

The same procedure was applied for bicyclobutyl. Table 2 shows the structural parameters obtained. In this case, as the cyclobutyl ring is not planar[5], three conformations must be considered, independent of the rotational isomerism about the central C–C bond: dependent on the folding of the cyclobutane ring an equatorial (*e*) and an axial (*a*) position

Table 2. Bicyclobutyl.

| Bond | Length [Å] | u [Å] (cf. Table 1) |
|---|---|---|
| C–C (in the ring) | 1.548 ± 0.004 | 0.052 ± 0.003 |
| C–C (between rings) | 1.536 ± 0.016 | 0.051 ± 0.005 |
| C–H | 1.104 ± 0.01 | 0.085 ± 0.006 |
| C(4)–C(5) | 2.625 ± 0.02 | 0.075 ± 0.005 |
| ∢ H–C–H = $\alpha_3 + \alpha_4$ | 110.0 ± 4.0 ° | |
| $\alpha_3 = \alpha_4$ | 55,0 ± 2.0 ° | |
| $\alpha_2$ | 51.6 ± 2.0 ° | |
| $\alpha_1$ | 58.5 ± 2.0 ° | |
| β | 33.0 ± 2.0 ° | |



can be distinguished for the C(1)–C(5) and the C(5)–C(1) linkages relative to the two rings. The existence of the three forms, *ee-s-trans* ($\varphi$ = 180°) *(2)*, *ea-s-trans* ($\varphi$ = 180°) *(3)*, and *ee-gauche* ($\varphi$ = 60°), can be proved from the experimental radial distribution curve. The contribution from the *ea-gauche* form ($\varphi$ = 60 °C) is only just observable, whereas the presence of small amounts of the *aa-s-trans* ($\varphi$ = 180 °C) *(4)* and the *aa-gauche* form ($\varphi$ = 77 °C) can only be justified by statistical considerations. The best agreement between the theoretical and the experimental curve was obtained for the following composition (the amounts in brackets were not directly determinable): *ee*-form ($\varphi$ = 180 °C) 31 %, *ee*-form ($\varphi$ = 60 °C) 26 %, *ea*-form ($\varphi$ = 180 °C) 24 %, *ea*-form ($\varphi$ = 63°)[6] 12 %, [*aa*-form ($\varphi$ = 180°) 5 %], [*aa*-form ($\varphi$ = 77°) 2 %][6].

Although the relative error in the percentages is estimated as ± 10 %, the relative proportions give provisional values for the energy differences between the forms. From such calculations the non-rigid *s-trans*-form of bicyclopropyl is favored over the non-rigid *gauche* form by less than about 500 cal/mole. For bicyclobutyl the *ee-s-trans*-form is energetically the most favored, the energy difference from the *ee-gauche* and the *ea-s-trans*-form being about 550 cal/mole, and from the *ea-gauche* form about 1400 cal/mole.

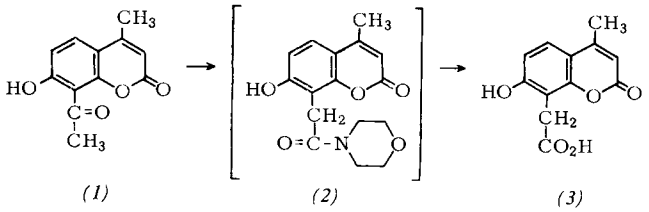
## Synthesis of 4-Methylosthenolic Acid by the Willgerodt-Kindler Reaction[1]

By Dr. K.-H. Boltze and Dr. H.-D. Dell

Chemische Abteilung der Troponwerke,
Köln-Mülheim (Germany)

The Willgerodt-Kindler reaction (conversion of ketones into ω-carboxamides of the same chain length[2]) has previously not been used for the preparation of carboxylic acid derivatives of coumarin. Such derivatives of umbelliferone have, however, been obtained by degradation of natural products.

We have prepared 4-methylosthenolic acid *(3)* from 8-acetyl-4-methylcoumarin *(1)*[3] by a Willgerodt-Kindler reaction.



*(1)* *(2)* *(3)*

A mixture of 0.03 mole of *(1)*, 0.045 mole of morpholine, and 0.06 g-atom of sulfur was heated at 140 °C for 4 h. After addition of 32 ml of a mixture of glacial acetic acid, concentrated $H_2SO_4$, and water (80:12:18 v/v) the whole was heated for 4–6 h at the boiling point, poured while hot into 500 ml of hot water, boiled, and filtered hot. The acid *(3)* separated on cooling (crude yield: 81 %). After repeated recrystallization from water the yield of pure product was about 50 %. The acid *(3)* crystallizes as pale pink needles of m.p. 240–242 °C.

If the synthesis is carried with the 7-*O*-methyl derivative instead of *(1)*, the same acid *(3)* is formed and not its 7-*O*-methyl derivative, owing to ether cleavage.

4-Methylumbelliferone-8-propionic acid, m.p. 167–170 °C, can be obtained analogously from 8-allyl-4-methylumbelliferone[4]. In accordance with *Mansfield*'s modification[5] of the Kindler reaction of aminomethylated phenols, 8-dimethylaminothiocarbonyl-4-methylumbelliferone [needles of m.p. 250–260° (decomp.)] was obtained from 8-dimethylaminomethyl-4-methylumbelliferone, and thence 4-methylumbelliferone-8-carboxylic acid, m.p. 254–257 °C (from ethanol/dimethylformamide).

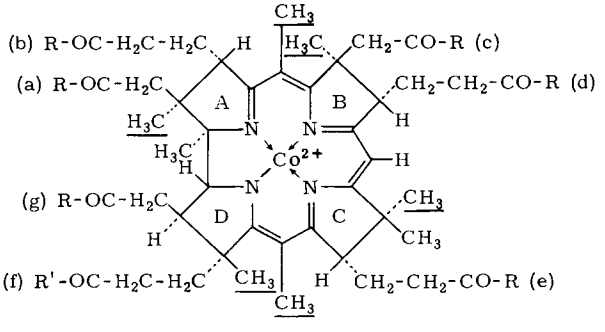
## Conversion of Cobinamide into Cobyric Acid

By Dr. Gerhard Müller and Priv.-Doz. Dr. Otto Müller

Isotopenlaboratorium der Abteilung für Chemie,
Geologie, und Biologie
der Technischen Hochschule Stuttgart (Germany)

Cobyric acid *(1)*[1] is a valuable starting material for the preparation of potent antagonists of vitamin $B_{12}$[2], but so far has been isolated in substantial amounts only from a corrinoid mixture found in sewage sludge[1].

We have found that cobinamide *(2)* or vitamin $B_{12}$ obtained from fermentation mixtures can also be converted into cobyric acid.



*(1)*, R = $-NH_2$, R′ = $-OH$
*(2)*, R = $-NH_2$, R′ = $-NH-CH_2-CH(OH)-CH_3$
*(3)*, R = $-NH_2$, R′ = $-O-CH(CH_3)-H_2-NH_2$

In anhydrous hydrofluoric acid the amide group f of cobinamide rearranges, by way of the hydroxyoxazolidine derivative, to yield the cobyric ester *(3)* of 1-aminopropan-2-ol. After acylation of the amino group by acetic anhydride, the ester *(3)* is hydrolysed to cobyric acid *(1)* by piperidine/water. Vitamin $B_{12}$ is also suitable as starting material since it is rapidly degraded to cobinamide *(2)* by hydrofluoric acid. The ester *(3)* regenerates the amide *(2)* when kept in an alkaline reaction medium (*e.g.* 0.05 M $Na_2HPO_4$).

*Cobyric Acid from Cobinamide*: A solution of 1 g of cyanocobinamide (dried for 24 h at 80° over $P_2O_5$) in a mixture of 15 ml of anhydrous hydrofluoric acid and 5 ml of absolute methanol is set aside at 30 °C for 3 days. The solvent

is removed in a vacuum and the residue is taken up in 200 ml of 0.1 % aqueous hydrocyanic acid and added to a column (40 mm diameter by 100 mm) of carboxymethylcellulose.

Most of the unchanged cyanocobinamide runs through the column; the rest is eluted with 2 % acetic acid, and immediately thereafter the cobyric ester *(3)* of 1-aminopropan-2-ol is eluted with a 1:1 mixture of 2 % acetic acid and 2 % ammonium acetate solution. This ester is purified by extraction with phenol[3], taken up in 100 ml of water, and acetylated by slow, dropwise addition to 5 ml of acetic anhydride at 0 to 2 °C with stirring. After an hour the product is washed twice with 10 ml of chloroform, and the corrinoid is purified by extraction with phenol. For cleavage, the ester is kept at 0 °C for 2 h in 200 ml of 1 M aqueous piperidine solution. The mixture is washed three times with 30 ml of 2:1 isopropyl ether/1-butanol and brought to pH 5.5 by dilute hydrochloric acid. After a further phenol extraction and cellulose-column-chromatography with sec-butanol/water (10:3) the cobyric acid is obtained in pure form; yield 20–22 %.

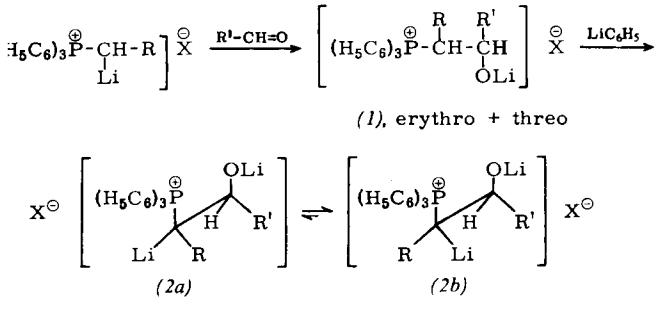
## Trans-Selective Olefin Syntheses

By Dr. M. Schlosser and K. F. Christmann

Organisch-Chemisches Institut
der Universität Heidelberg (Germany)

Usually only mixtures of *trans*- and *cis*-olefins can be obtained by the Wittig reaction. A few examples are known yielding predominantly *trans*-[1] or *cis*-[2] olefins. *trans*-Selective olefination can be expected if equilibration of the *erythro*- and *threo*-betaines *(1)*[1c] can be accelerated.

We have now found that interconversion of the diastereoisomeric betaine ylides *(2)*[3] is extremely rapid[4]. These ylides are formed if the betaine-LiX adduct *(1)* is treated with phenyl-lithium or n-butyl-lithium in ether/tetrahydrofuran (1:1) at −30 °C, and with proton donors (*e.g.*, hydrogen chloride or t-butyl alcohol) they regenerate the betaine-LiX adducts *(1)*.



*(1)*, erythro + threo

*(2a)* *(2b)*

The equilibrium between the diastereoisomeric betaine ylides lies far to the side of form *(2b)*, so that protonation gives mainly the *threo*-betaine [*threo*-*(1)*]. Subsequent treatment with potassium t-butoxide then liberates almost pure *trans*-olefin (cf. Table).

| Olefin | R | R' | Yield [%] | *trans*: *cis* |
|---|---|---|---|---|
| 2-Octene | $CH_3$ | n-$C_5H_{11}$ | 70 [b] | 99: 1 |
| 2-Octene | n-$C_5H_{11}$ | $CH_3$ | 60 [b] | 96: 4 |
| 4-Octene | n-$C_3H_7$ | n-$C_3H_7$ | 72 [b] | 98: 2 |
| 1-Phenyl-1-propene | $CH_3$ | $C_6H_5$ | 69 [a] | 99: 1 |
| 1-Phenyl-1-butene | $C_2H_5$ | $C_6H_5$ | 72 [a] | 97: 3 |
| 1-Phenyl-1-hexene | n-$C_4H_9$ | $C_6H_5$ | 75 [a] | 96: 4 |
| 1-Phenyl-1,3-pentadiene | $CH_3$ | *trans*-$C_6H_5$–CH=CH | 63 [b] | 97: 3 |
| 2-Phenyl-2-butene | $CH_3$ | [c] | 55 [a] | 89:11 |

[a] Determined gas-chromatographically.

[b] Isolated in substance.

[c] With acetophenone as carbonyl component, *i.e.*, R' = $C_6H_5$, and with $CH_3$ in place of H.

*Procedure*

The phosphonium salt (30 mmole) is suspended in 50 ml of tetrahydrofuran and 30 ml of ether and stirred with 30 mmole of ethereal phenyl-lithium solution until the Gilman test is negative (about 10 min). The solution is cooled to −70 °C and 30 mmole of aldehyde (dissolved in 20 ml of ether) is added; the mixture is stirred vigorously. As soon as decolorization is complete (5 min at −70 to −40 °C), a further 30 mmole of phenyllithium solution is added and the whole kept at −30 °C until the Gilman test is again negative (about 5 min). This solution is treated with 33 mmole of ethereal hydrogen chloride and with 45 mmole of potassium t-butoxide (as 1:1 complex with t-butyl alcohol). The mixture is stirred at room temperature for 2 h, centrifuged, and the clear supernatant liquor is poured off, washed with water until neutral, and dried. After evaporation of the solvent, the olefin is fractionated in a vacuum.

For comparison the olefins listed were prepared in parallel experiments by the conventional Wittig reaction. The *trans*:*cis* ratio (determined gas-chromatographically) varied between 75:25 (phenylhexene) and 20:80 (2-octene).

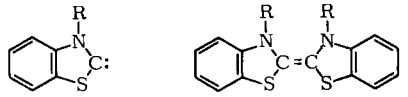
## Elimination of Hydrogen Halide from Benzo- and Naphtho-thiazolium Halides [1]

By Prof. Dr. H.-W. Wanzlick, Dr. H.-J. Kleiner, Dipl.-Ing. I. Lasch, and Dipl.-Chem. H. U. Füldner

Organisch-Chemisches Institut
der Technischen Universität Berlin (Germany)

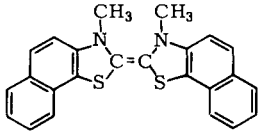
Hydrogen halide can be removed from benzothiazolium halides by heating them with triethylamine[2] or by treating them with triethylamine (or other tertiary amine) in polar solvents at room temperature[3,4], with sodium in dioxane[4], or with triethylamine in boiling acetone[5]. This leads to dimers *(2)*, of as yet unknown configuration, by way of the short-lived nucleophilic carbenes *(1)*[6]. Contrary to our pre-

vious assumption[3], the carbene moieties *(1)* cannot be isolated in substance.



*(1)* *(2)*

*N*-Methylnaphtho[2,1-*d*]thiazolium iodide (obtained from naphtho[2,1-*d*]thiazole and methyl iodide in dimethylformamide in 92 % yield, m.p. 203–204 °C), when treated with triethylamine in dimethylformamide (preferably under nitrogen) gives the brilliant red dimer *(3)* (87 %; decomp. above *ca.* 195 °C; configuration not yet known) within a few seconds even at 0 °C.



*(3)*

Like *(2)* and related systems, the compound *(3)* reacts as a "half-molecule" (cf.[1]). Thus with diazo compounds they give azines.

Whereas the compounds of type *(2)* studied so far do not show evidence of dissociation in mass spectroscopy[7], the mass spectrum of the dimer *(3)* shows the peak due to the half-molecule (m/e = 199) as well as the comparably intense peak of the molecule-ion (m/e = 398)[8].

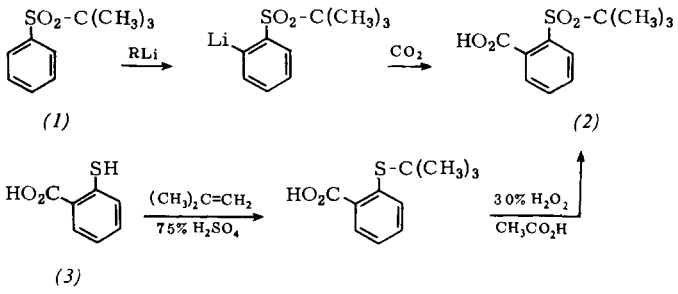
## Synthesis of 2-Alkyl-1,3-dilithiobenzenes and 2-Alkylisophthalic Acids

By Dr. F. M. Stoyanovich and Prof. Dr. B. P. Fedorov

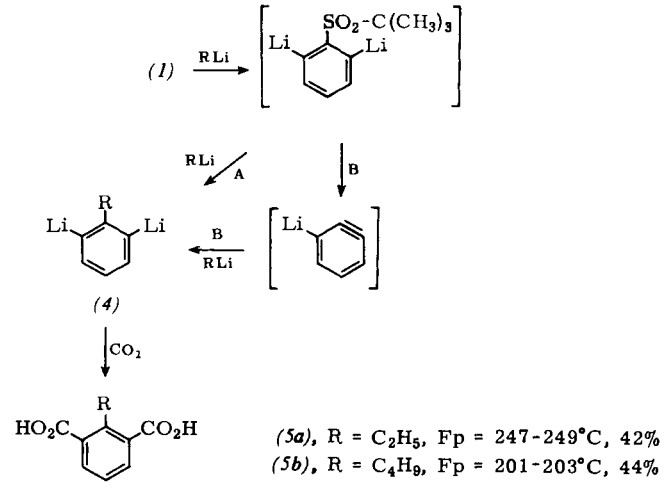
N. D. Zelinskii Institute for Organic Chemistry of the Academy of Sciences of the U.S.S.R., Moscow

When t-butyl phenyl sulfone *(1)* is metalated in ether/tetrahydrofuran (1:1) at −60 °C for 8–10 h with an excess of an alkyl-lithium or at −10 °C for 3 h with 1 mole of the alkyl-lithium and then carbonated, *o*-(t-butylsulfonyl)benzoic acid *(2)* is formed in 40–45 % yield. The structure of the acid was proved by synthesis from thiosalicylic acid *(3)*.



*(3)*

If the reaction is carried out with an excess (3 moles or more) of the alkyl-lithium (alkyl = ethyl or butyl) for 15–20 h at 20 °C, the t-butylsulfonyl group is removed from *(1)* and the 2-alkyl-1,3-dilithiobenzene is formed, which can be recognized by formation of the previously unknown 2-alkylisophthalic acids *(5)* on carbonation. The acids *(5)* are



*(4)*

*(5a)*, R = $C_2H_5$, Fp = 247–249 °C, 42 %
*(5b)*, R = $C_4H_9$, Fp = 201–203 °C, 44 %

very stable and can be recrystallized from hot concentrated $HNO_3$ and sublimed without decomposition at 200–220 °C/1 mm. Their structure is proved by oxidation of *(5a)* with concentrated $HNO_3$ (sealed tube, 160–180 °C, 5 h) to hemimellitic acid[1].

The formation of the acids *(5)* can be explained by nucleophilic substitution of the t-butylsulfonyl group (route A) or intermediate occurrence of 3-lithiobenzyne (route B).

## Synthesis of Bicyclo[3.1.1]heptane

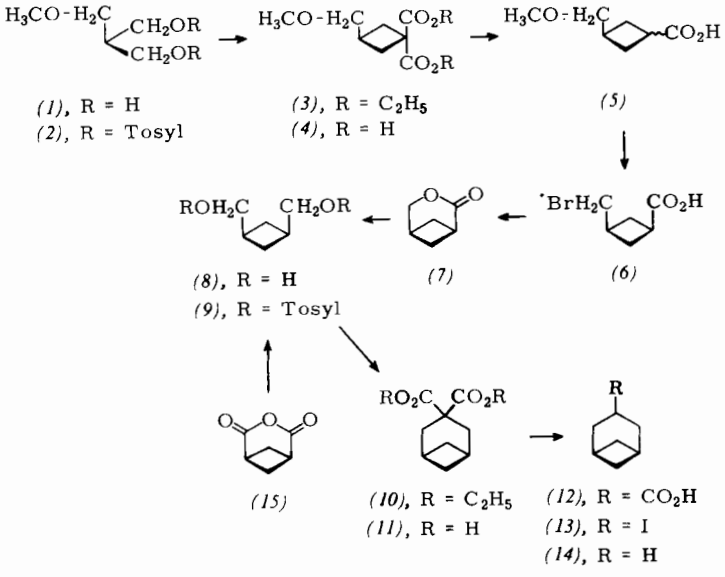
By Prof. Dr. H. Musso and Dipl.-Chem. K. Naumann

Chemisches Institut der Universität Marburg and Chemisches Institut der Ruhr-Universität Bochum[11] (Germany)

Attempts to synthesise bicyclo[3.1.1]heptane (norpinane) *(14)* have previously failed[2]. We have now prepared this compound by the following method, in order to study the 1,4 interaction in the boat form of cyclohexane.

Ethyl (methoxymethyl)malonate was reduced with $LiAlH_4$ to 2-methoxymethyl-1,3-propanediol *(1)* (b.p. 139 °C/12 mm, 59 %), whose di-*p*-toluenesulfonate *(2)* (m.p. 166 °C, 81 %) was condensed with ethyl malonate by *Buchta*'s method[3], giving diethyl (3-methoxymethyl)-1,1-cyclobutanedicarboxylate *(3)* (b.p. 97–99 °C/0.7 mm, 63 %). The acid *(4)* (m.p. 123 °C, 100 %) obtained therefrom on hydrolysis was de-

carboxylated when heated at 160 °C, yielding a mixture of *cis*- and *trans*-3-(methoxymethyl)-1-cyclobutanecarboxylic acids *(5)* (b.p. 140 °C/11 mm, 93 %) in which, according to the gas-chromatogram of the methyl esters, the *cis*-acid was present in excess (55 %). Treatment with hydrogen bromide converts *(5)* into a mixture of *cis*- and *trans*-3-(bromomethyl)-1-cyclobutanecarboxylic acid *(6)* (b.p. 100 °C/0.8 mm, 65 %) [4]. Silver oxide readily converts the *cis*-component of the acids *(6)* into the bicyclic lactone *(7)* (m.p. 75 °C), which can be isolated in 63 % yield. Reduction of the lactone *(7)* with $LiAlH_4$ affords *cis*-1,3-cyclobutanedimethanol *(8)* [5a] (b.p. 92 °C/1 mm, 79 %), which can also be prepared analogously from *cis*-1,3-cyclobutanedicarboxylic anhydride *(15)* [5]. The di-*p*-toluenesulfonate *(9)* (m.p. 79 °C, 71 %) of *(8)* is treated again with malonic ester, yielding diethyl norpinane-3,3-dicarboxylate *(10)* (b.p. 98 °C/1 mm, 54 %), and the derived



acid *(11)* (m.p. 172 °C, 89 %) was decarboxylated to norpinane-3-carboxylic acid *(12)* (m.p. 48 °C, 99 %). This acid *(12)* was converted by lead tetraacetate, iodine, and light [6] into 3-iodonorpinane *(13)* (b.p. 210 °C, crude yield 90 %), from which the iodine was removed by reduction. Dehalogenation by $LiAlH_4$ in boiling tetrahydrofuran is incomplete, but lithium in t-butyl alcohol or hydrogen in presence of Raney nickel and triethylamine affords an iodine-free product from which bicyclo[3.1.1]heptane (norpinane) *(14)* was separated as pleasant-smelling, colorless crystals (m.p. 54 °C) by gas chromatography [7].

Retention times on the gas chromatogram at 95 °C were: n-pentane 3.5, norbornane 5.3, *(14)* 5.7 min [8].

All the new compounds gave satisfactory elemental analyses and infrared and NMR spectra.

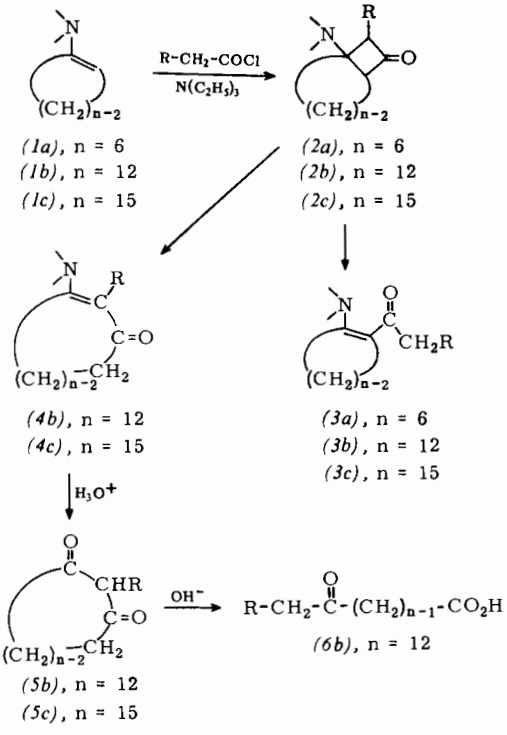
## Synthesis of 1,3-Cyclotetradecanediones by Ring Enlargement [1]

By Dr. H. J. Buysch and Prof. Dr. S. Hünig

Institut für Organische Chemie
der Universität Würzburg (Germany)

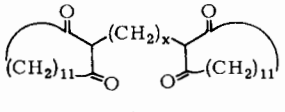
The acylation of tertiary enamines by aliphatic acid chlorides in presence of triethylamine proceeds by way of ketenes, which in the case of enamines derived from aldehydes lead, by addition, to isolable cyclobutanone derivatives [2]. Easy opening of the cyclobutane ring gives acylenamines [2]. The intermediate *(2a)* from 1-morpholinocyclohexene *(1a)* can be detected ($\nu_{C=O}$ = 1770 to 1780 $cm^{-1}$) in the reaction medium for a short time, but only the product *(3a)* [3] can be isolated [2a].

We have now found that the intermediate *(2b)* for med from 1-morpholinocyclododecene *(1b)* isomerizes spontaneously in two ways: products *(3b)* and, by ring expansion by two carbon atoms, *(4b)* are obtained. Acid hydrolysis of the latter gives 1,3-cyclotetradecanediones *(5)* (yields: R = H, *ca.* 20 %, R = alkyl, *ca.* 80 %), which can be purified through their Cu chelates.



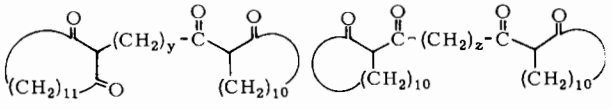
"Acid cleavage" of the diketones *(5)* by alkali affords the keto acids *(6)*, whereas loss of the acyl group is the preponderant reaction of the 2-acylcyclododecanones [4].

The ring expansion in reaction of the enamine *(1b)* with acyl chlorides explains why this reaction is suitable for extension



*(7)*

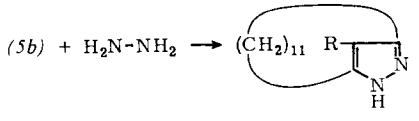
x = 4, m. p. = 183-184 °C



*(8)* *(9)*

of the chain of monocarboxylic acids by 12 carbon atoms (yields 70 to 75 %) and of dicarboxylic acids from $C_8$ onwards by 24 carbon atoms (yields 40 to 50 %)[5]. From the enamine *(1b)* and dicarboxylic acid dichlorides [$C_8$, $C_{10}$, $C_{22}$, $C_{32}$] we obtained 50 to 60 % yields of the tetraketones *(7)* corresponding to *(5)* [x = 4, 6, 18, 28], their structures following from homogeneous alkaline ring fission to diketo dicarboxylic acids. Compounds *(8)* and *(9)* were by-products in the formation of *(7)*. Alkaline fission of product *(8)* affords a keto acid mixture and cyclododecanone (> 10 % yield), whereas the tetraketone *(9)* gives cyclododecanone in about 70 % yield.

Compounds *(5)* and *(7)–(9)* are suitably characterized by reaction with hydrazine to give pyrazoles, *e.g. (10)*.



*(10)*

Experiments are in progress to test the generality of the ring expansion reaction. The reaction sequence has meanwhile been reproduced for *(5b)*, R = H and $CH_3$, and applied to *(1c)* whose ring is thereby expanded to cycloheptadecanedione *(5c)*[6].

Results of the various methods of investigation are not immediately comparable for the two series of compounds; in order to test the results for the *P*-substituted dimethylanilines *(1)* to *(4)* by an independent method, and to relate them to those for the compounds *(5)* to *(7)*, we determined the half-neutralisation potential (HNP)[6] of the dimethylamino groups of compounds *(1)* to *(4)* by potentiometric titration in chloroform/glacial acetic acid at 20 ± 1 °C with 0.02 N $HClO_4$ in glacial acetic acid; therefrom we calculated the Hammett σ′ constants of the phosphorus-containing *para*-substituents (cf. Table) by using Eq. (a), which was obtained from the half-neutralisation potentials (determined under the same conditions) of reference substances of known σ′[10] by the method of least squares.

$$\sigma' = 3.47 + (5.30\times10^{-3})\mathrm{HNP} \qquad (a)$$

When several $(CH_3)_2N$ groups were present in one molecule, they gave rise to only one potential jump; protonation of the phosphorus did not interfere in the titration of the phosphines *(4)*[7]. Values of σ′ for comparison exist for three P substituents, obtained by alkali cleavage of substituted benzyltrimethylsilanes[8]; for two substituents [$(C_6H_5)_2$OP- and $(CH_3)_2$OP-] the σ′ values of +0.845 and +0.725, respectively, agree well with our results; the value for $(CH_3)_3P^{\oplus}$-, σ′ = +1.14, diverges considerably, but in view of the instability of phosphonium salts in an alkaline medium this may be due to decomposition of the trimethylphosphonium group.

As expected[1,3,5], phosphorus is a fairly strong electron acceptor in all cases; the σ′ values depend on the electron density at the phosphorus: $(\sigma'_{NO_2}>)\ \sigma'_{Phosphonium} > \sigma'_{Phosphinyl} \geqslant \sigma'_{Thiophosphinyl}$ $(> \sigma'_{COOCH_3})$; for *(1)* and *(2)*, n = 1, $\sigma'_{R^1=C_6H_5} > \sigma'_{R^1=CH_3}$[3]; for *(2)* and *(3)* [and for *(4)*, n = 2 or 3], $\sigma'_{n=1} > \sigma'_{n=2} > \sigma'_{n=3}$. The phosphines *(4)*, n = 2 or 3, behave analogously to the phosphine oxides *(2)*, n = 2 or 3, and thus, as in the u.v. spectra show no participation of the phosphorus 3p orbital; however, the compound *(4)*, n = 1, in which the donor effect exerted on the phosphorus is smaller resembles the phosphines *(5)* in having a smaller σ′ value[5]. The decrease in σ′ for the series where n = 1 is qualitatively similar to the decrease in Hammett constants calculated from dissociation constants of the benzoic acids *(5a)* to *(7a)* ($\sigma_{(C_6H_5)_2OP-}$ = +0.71; $\sigma_{(C_6H_5)_2SP-}$ = +0.70; $\sigma_{(C_6H_5)_2P-}$ = +0.31)[4,5], but, as is typical for a mesomeric effect[9], the numerical values are higher for the dimethylanilines. A similar dependence on the nature of the reaction center Y is known also for the substituent constants of a $p$-$(C_2H_5O)_2OP$- group in the series $(C_2H_5O)_2OP$–$C_6H_4$–$p$-Y, where Y = $NH_2$, OH, or COOH[9].

## The Electronic Effect of Phosphorus in para-Phosphorus-Substituted Dimethylanilines

By Dr. G. P. Schiemenz

Institut für Organische Chemie
der Universität Kiel (Germany)

Phosphorus-containing substituents are held to have electron-acceptor properties in respect of an aromatic ring when there is 3d-orbital participation. We have found such an effect, of surprising strength[1], for dimethylanilines with phosphonium *(1)*, phosphinyl *(2)*, thiophosphinyl *(3)*, and phosphino groups *(4)* as *para*-substituents[2,3]; it is shown in the ultraviolet spectra by a bathochromic shift of the 1st primary dimethylaniline band; for the phosphorus compounds *(5)–(7)* with –M substituents it is reflected in the pK values of the acids *(5a)–(7a)*, in the infrared spectra by the frequency [and for *(6e)* also by the intensity] of the stretching vibrations of the –M substituents, and in the NMR spectra of *(6f)* and *(7f)* by the position of the formyl proton signal[5].

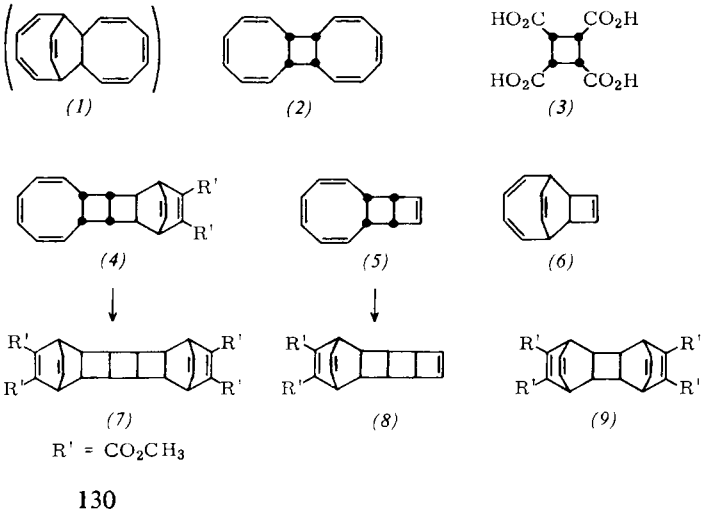
## Structure of the Cyclooctatetraene Dimer of Melting Point 53 °C

By Priv.-Doz. Dr. G. Schröder and cand. chem. W. Martin

Institut für Organische Chemie
der Technischen Hochschule Karlsruhe (Germany)

When cyclooctatetraene is heated at 100 °C two dimers $C_{16}H_{16}$ are formed, with melting points 53 and 76 °, respectively [1, 2]. After 68 h the yield of each isomer is about 40 % calculated on the cyclooctatetraene that has reacted (*ca.* 25 %). The structure *(1)* proposed by *Jones* for the dimer, m.p. 53 °C, is incorrect and must be replaced by *(2)*.

The dimer $C_{16}H_{16}$, m.p. 53 °C, absorbs 6 moles of hydrogen on catalytic hydrogenation. On ozonolysis in 90 % acetic acid and subsequent further oxidation with perhydrol, the dimer, m.p. 53 °C, affords the known [3] all-*cis*-cyclobutane-1,2,3,4-tetracarboxylic acid *(3)* [45 % yield, m.p. 215 °C (decomp.)]. The oxidative degradation proves the presence of an all-*cis*-cyclobutane ring as in *(2)*.



*(1)* *(2)* *(3)* *(4)* *(5)* *(6)* *(7)* *(8)* *(9)*

R' = $CO_2CH_3$

The dimer, m.p. 53 °C, reacts with one molecule of dimethyl acetylenedicarboxylate in boiling benzene to give a product $C_{22}H_{22}O_4$ (70 % yield), m.p. 140 °C [4]. The ultraviolet and NMR spectra of this compound are in agreement with the structure *(4)* [5]. When heated at about 150 °C this product decomposes [6] into dimethyl phthalate and a liquid hydrocarbon $C_{12}H_{12}$ (A), 70 % yield, m.p. 8–11 °, to which we allocate structure *(5)*, and which on catalytic hydrogenation absorbs 4 moles of hydrogen to form a hydrocarbon $C_{12}H_{20}$. The ultraviolet spectrum of compound A shows a maximum at 258 mμ (ε = 1300) in hexane; the NMR spectrum consists of a pseudo-singlet at τ = 3.66, a sharp singlet at τ = 4.39, and two multiplets centered at τ = 6.54 and τ = 6.73 with relative intensities 2:6:2:2. Degradation of compound $C_{12}H_{12}$ (A) with ozone and subsequent oxidation with perhydrol lead again to the acid *(3)* (34 %).

When the compound $C_{12}H_{12}$ (A) is warmed at *ca.* 120 °C (24 h) there are formed about equal amounts of benzene and an isomeric hydrocarbon $C_{12}H_{12}$ (B), for which we propose structure *(6)*. This compound absorbs 4 moles of hydrogen on catalytic hydrogenation and gives a product $C_{12}H_{20}$, m.p. 35–36 °C. The ultraviolet spectrum of $C_{12}H_{12}$ (B) in hexane shows maxima at 280 mμ (ε = 2700), 268.5 mμ (5000), and 258.5 mμ (4600). The NMR spectrum contains a multiplet centered at τ = 4.4, a singlet at τ = 6.80, and a pseudo-triplet at τ = 7.38 (8:2:2).

Compound *(4)* reacts with acetylenedicarboxylic ester at 80 °C, giving a diadduct $C_{28}H_{28}O_8$, m.p. 162–163 °C (46 % yield). This compound decomposes into dimethyl phthalate and cyclooctatetraene when heated at *ca.* 150 °C, and its ultraviolet and NMR spectra agree with structure *(7)* [7].

An adduct $C_{18}H_{18}O_4$ (17 %), m.p. 112–114 °C, is formed from compound *(5)* and acetylenedicarboxylic ester at *ca.* 70 °C. It decomposes into dimethyl phthalate and cyclooctatetraene when heated at 140–160 °C. Its ultraviolet and NMR spectra indicate structure *(8)* [7]. From compounds *(2)*, *(4)*, *(5)*, *(7)*, and *(8)*, each with an excess of dimethyl acetylenedicarboxylate at 100–120 °C, the same end product, $C_{24}H_{24}O_8$, m.p. 196–198 °C, is formed. When heated at 230 °C this compound decomposes into dimethyl phthalate and an unidentified gas. Ultraviolet and NMR spectra are in agreement with structure *(9)* for compound $C_{24}H_{24}O_8$ [*].

[4] *B. Flügel*, Diploma Thesis, Technische Hochschule Karlsruhe, 1964.

[5] In this case the Diels-Alder reaction is preceded by valence isomerisation of the cyclooctatriene. Cyclooctatriene itself behaves analogously: *A. C. Cope*, *A. C. Haven*, *F. C. Ramp*, and *E. R. Trumbull*, J. Amer. chem. Soc. *74*, 4867 (1952).

[6] The decomposition follows the Alder-Rickert scheme.

[7] According to the Alder-Rickert scheme tricyclo[4.2.0.0$^{2,5}$]-octa-3,7-diene should be formed alongside dimethyl phthalate on pyrolysis of compounds *(7)* and *(8)*. This tricyclic compound is thermolabile and readily undergoes valence isomerism to yield cyclooctatetraene [3c].

[*] Note added in proof: The photolysis of *(2)* in ether gives in relatively good yield a deep-red, crystalline substance $C_{16}H_{16}$, m.p. 88-90 °C, the NMR spectrum of which comprises one sharp singlet centered at τ = 3.19.

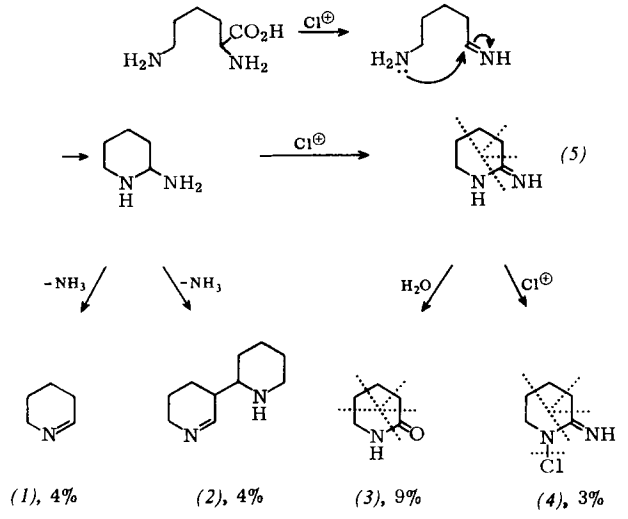
## Cyclic Oxidation Products of Lysine

By Prof. Dr. B. Franck and Dipl.-Chem. D. Randau

Organisch-Chemisches Institut
der Universität Kiel (Germany)

More than 150 alkaloids contain piperidine and quinolizidine groups that are formed in the plant by oxidative transformation of lysine[1]. We have now found that lysine can be converted also by oxidation with NaOCl into cyclic and, in some cases, alkaloid-like[2] products *(1)–(4)*.

Lysine was oxidized with 2 moles of alkaline NaOCl for 3 h at 20 °C. From a chloroform extract of the oxidation solution, piperideine *(1)* and tetrahydroanabasine *(2)* were isolated as picrates of their dihydroquinazolinium derivative with *o*-aminobenzaldehyde[4] (m.p. 172 °C and 181 °C, respectively). 2-Piperidone *(3)* (hydrochloride: m.p. 170 °C) was separated by sublimation, and *N*-chloro-2-iminopiperidine *(4)* by preparative layer chromatography. The yields under the formulae refer to the total amount of lysine, 35 % of which remained unchanged in the reaction mixture. The products *(1)–(3)* were identified by comparison with authentic specimens. In view of its benzidine reaction[5] and infrared spectrum (684 $cm^{-1}$) the previously unknown, non-basic product *(4)* contains an NCl group; its structure follows from elemental analysis, NMR spectrum, and the fragmentation in the mass spectrometer similar to that of *(3)* and *(5)*. Catalytic hydrogenation gave the known[6] hydrochloride (m.p. 157 °C) of compound *(5)*.



It may be assumed that the cyclic oxidation products arise from lysine by attack of one, two, or three $Cl^{\oplus}$ ions.

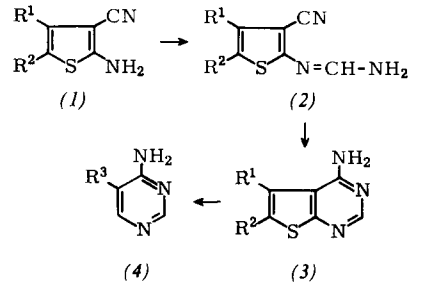
## A New Synthesis of 5-Substituted Pyrimidines

By Prof. Dr. E. C. Taylor and Dr. J. G. Berger

Department of Chemistry, Princeton University, Princeton, New Jersey (U.S.A.)

Treatment of 2-amino-3-cyanothiophenes *(1)*[1] with excess ethyl orthoformate at reflux for 3–4 h, removal of excess reagent, and treatment of the residual ethoxymethylene compounds with excess anhydrous ethanolic ammonia gives in *ca.* 90 % yield the formamidines *(2)*, which precipitate from solution. These compounds can be cyclized to thieno[2,3-*d*]-pyrimidines *(3)* by brief heating in dimethylformamide solution at 80–100 °C with a trace of sodium methoxide. Compounds *(3)* are isolated by evaporation of the solvent and addition of water. Desulfurization of the thieno[2,3-*d*]pyrimidines *(3)* with a four- to tenfold excess of W-7 Raney nickel in refluxing ethanol or dimethylformamide at 80–120 °C leads to novel 5-substituted 4-aminopyrimidines *(4)*, which are isolated by evaporation of the solvent.



| | $R^1 + R^2$ | M.p. [°C] | Yield [%] [a] |
|---|---|---|---|
| *(3a)* | $-(CH_2)_4-$ | 148–149 | 77 |
| *(3b)* | $R^1=R^2=CH_3$ | 270–272 | 85 |
| *(3c)* | 3,4-Dihydronaphtho [1,2] | 257–258.5 | 74 |
| *(3d)* | Naphtho [1,2] | 312–313 | 81 |
| *(3e)* | 4-Aminopyrimido [5,6] | 324–325 (decomp.) | 33 |

| | $R^3$ | M.p. [°C] | Yield [%] [b] |
|---|---|---|---|
| *(4a)* | Cyclohexenyl | 156–158.5 | 40 |
| *(4b)* | Isopropyl | 140–141.5 | 51 |
| *(4d)* | 2-Naphthyl | 185.5–182.5 | 15 |
| *(4e)* | 4-Amino-5-pyrimidinyl | 356 (decomp.) | 17 |

[a] Based on *(1)*.
[b] Based on *(2)*.

The condensed pyrimidine derivative *(3c)* derived from 2-tetralone was aromatized to *(3d)* by diacetylation with acetic anhydride/pyridine, bromination with *N*-bromosuccinimide in $CCl_4$, and subsequent concomitant dehydrobromination and hydrolysis of the diacetyl grouping by refluxing with alcoholic sodium hydroxide.

Desulfurization of *(3b)* in ethanol gave a mixture of the 5-isopropyl and the 5-isopropenyl derivatives (65:35), which was converted by hydrogenation over W-2 Raney nickel to homogeneous *(4b)*.

4-Amino-5-(4-amino-5-pyrimidinyl)pyrimidine *(4e)* was prepared from 2,5-diamino-3,4-dicyanothiophene[2] by twofold cyclization to *(3e)* followed by desulfurization with W-7 Raney nickel in dimethylformamide.

## Synthesis and Reactions of Tris(dimethylamino)methane

By Prof. Dr. H. Bredereck, Dr. F. Effenberger, and Dipl.-Chem. Th. Brendle

Institut für Organische Chemie der Technischen Hochschule Stuttgart (Germany)

We have prepared the first member of the tris(dialkylamino)-methane series, namely tris(dimethylamino)methane *(1)*, in good yield, by treating tetramethylformamidinium salts[1] with alkali-metal dimethylamides.

$$[(CH_3)_2N\text{-}CH{=}N(CH_3)_2]^{\oplus}\ X^{\ominus} + M\text{-}N(CH_3)_2 \rightarrow$$

$$(CH_3)_2N\text{-}HC\begin{matrix}N(CH_3)_2\\N(CH_3)_2\end{matrix} + MX$$

*(1)*

X = Cl, $ClO_4$ M = Li, Na, K

The triamine *(1)* reacts smoothly with CH-acidic compounds to give dimethylaminomethylene compounds *(2)*[2]:

$$(1) + H_2C\begin{matrix}X\\Y\end{matrix} \rightarrow (CH_3)_2N\text{-}CH{=}C\begin{matrix}X\\Y\end{matrix} + 2\ (CH_3)_2NH$$

*(2)*

| X | CN | $COOCH_3$ | $C_6H_5CO$ |
|---|---|---|---|
| Y | CN | CN | H |

and with amines to give amidines *(3)*[3]:

$$(1) + RNH_2 \rightarrow (CH_3)_2N\text{-}CH{=}NR + 2\ (CH_3)_2NH$$

*(3)*

R = *p*-$NO_2$-$C_6H_4$, $NH_2CO$, *p*-$CH_3$-$C_6H_4$-$SO_3$

*Examples*:

Tris(dimethylamino)methane: Tetramethylformamidinium chloride (68 g) was added at −20 °C to a slurry of lithium dimethylamide (prepared according to [4] and [5] from 15.2 g of lithium, 137 g of n-butyl bromide, and 180 g of dimethylamine) in 600 ml of anhydrous ether. The mixture was stirred for 15 h at room temperature while nitrogen was led through the apparatus. The ether was distilled off and then the tris-(dimethylamino)methane in a vacuum (water-pump). Crude yield: 51.0 g, b.p. 40–43 °/12 mm. After redistillation through a Vigreux column: yield of pure product, 46.0 g (63 %), b.p. 42–43 °C/12 mm.

Methyl 2-cyano-3-dimethylaminoacrylate: A solution of 3.63 g of tris(dimethylamino)methane in 50 ml of anhydrous ether was dropped into a solution of 2.48 g methyl cyanoacetate in 50 ml of anhydrous ether at room temperature with stirring, moisture being excluded. The mixture was refluxed for 15 min and the solid filtered off. Crude yield: 3.8 g, m.p. 97–100 °C; after recrystallization from 30 ml of acetone/light petroleum (1:1), yield of pure product: 3.2 g (83 %), m.p. 101–102 °C.

*N,N*-Dimethyl-*N'*-*p*-nitrophenylformamidine: This was prepared from 3.45 g of *p*-nitroaniline in 50 ml of anhydrous ether and 3.63 g of tris(dimethylamino)methane in 50 ml of anhydrous ether as described above, but after the heating the ether was distilled off in a rotating evaporator and the yellowish-green crystals were recrystallized from 40 ml of anhydrous ethanol. Yield: 4.2 g (87 %), m.p. 82–83 °C.

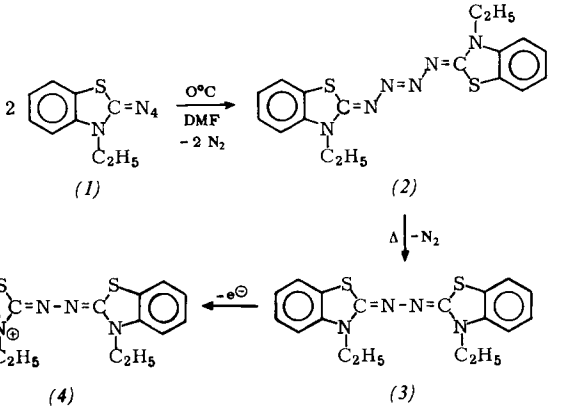
## "Thermolysis" of 3-Ethyl-2-tetrazobenzothiazoline

By Priv.-Doz. Dr. H. Balli

Physikalisch-Chemisches Institut der Universität Marburg (Germany)

When 3-ethyl-2-tetrazobenzothiazoline *(1)*[1] is kept in dimethylformamide at 0 °C for 1 hr, *trans*(N),*trans*,*trans*(N)-1,4-bis(3-ethylbenzothiazolinylidene)tetrazene *(2)*[*] is formed in 35 % yield as a yellow compound, m.p. 297 °C (decomp.), that is very difficultly soluble in most organic solvents and fluoresces green only in the solid state.



*(1)* *(2)* *(3)* *(4)*

The constitution of the product *(2)* is proved by elemental and X-ray structure[2] analysis. Ultraviolet spectrum (in dimethylformamide, 275–500 mμ): $\lambda_{max}$ = 396 mμ (ε = 52500) [shoulders at 380 and 415 mμ], 304 mμ (4500). Formation of the tetrazene *(2)* from the tetrazo compound *(1)* corresponds formally to the formation of azines from diazoalkenes[3]. At the melting point *(2)* decomposes into nitrogen and bis(3-ethylbenzothiazolinylidene)hydrazine *(3)*[4], which can be oxidized by lead tetraacetate in dimethylformamide to the radical ion *(4)*[4].

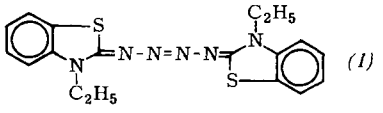
## Crystal Structure of 1,4-Bis-(3-ethyl-1,2-dihydrobenzothiazol-2-ylidene)tetrazene

By Dr. R. Allmann

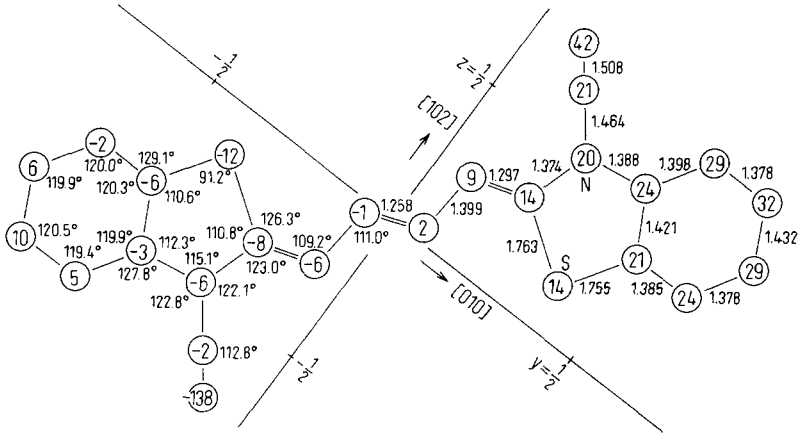
Mineralogisches Institut
der Universität Marburg (Germany)

X-Ray structure analysis of 1,4-bis(3-ethyl-1,2-dihydrobenzothiazol-2-ylidene)tetrazene *(1)* [1] has shown that the tetrazene chain is present in the *trans*(N)-*trans-trans*(N)-form



*(1)*

(see figure). The substance crystallizes in space group $P\bar{1}$ with one molecule per unit cell, whence it follows that in the crystalline form the molecule has a center of symmetry. Except for the terminal methyl groups the molecule is almost planar, *i.e.*, the surroundings of the ring nitrogen are also planar. This atom is thus in the $sp^2$ state. The C–N single bonds of the ring are much shorter than usual; the N–N bonds are similarly shortened, whereas the C=N and N=N double bonds of the tetrazene chain are slightly longer than usual. The plane N–C–C of the 3-ethyl group is almost perpendicular (82°) to the plane of the rest of the molecule.



Projection of a tetrazene molecule on the plane ($\bar{2}01$). In the right-hand half of the figure, bond distances are given in Å and x-coordinates in a/100. In the left-hand half, angles are given, together with deviations from the best plane 7.02x–1.62y–1.84z = 0 in 1/100 Å.

Lattice constants are $a_0 = 7.307$ Å, $b_0 = 9.145$ Å, $c_0 = 7.252$Å, $\alpha = 94.95°$, $\beta = 111.06°$, $\gamma = 84.89°$; density measured 1.40, calculated 1.41 g cm$^{-3}$. 1888 X-ray intensities were estimated from Weissenberg photographs. In the Patterson synthesis calculated therefrom essentially only the S–S, S–N, and S–C Patterson peaks appeared, so that the coordinates of the S, N, and C atoms could be obtained at once. Subsequent Fourier synthesis showed also weak electron maxima for all the H atoms (not illustrated in the figure). After 5 cycles of refinement with 22 atoms and isotropic individual temperature factors the R index fell from 32 % to 12 %. The standard deviations of the bond lengths and angles given in the figure are less than 0.01 Å and 1°, respectively.

## Relation between Coulomb Potentials and Positions of Protons in Crystalline Hydroxo Compounds

By Priv.-Doz. H. G. von Schnering

Anorganisch-Chemisches Institut
der Universität Münster (Germany)

*Dedicated to Professor Wilhelm Klemm on the occasion of his 70th birthday*

Knowledge of the positions of the protons was needed for a study of the structure of complex hydroxides [1]. Direct determination of these positions cannot be carried out quickly or simply for crystalline compounds by neutron diffraction or nuclear resonance. We have now found that information on the proton positions in such compounds can be obtained by simple potential calculations [2].

Hypothesis: In crystalline hydroxo compounds, the lattice constituents, considered as point charges, produce minima of electrostatic potential at the proton sites. The potential minima and thus the positions of the protons should become apparent on calculation of the potential profile in the neighborhood of the atoms carrying the protons.

Restriction: It suffices always to calculate the potential profile for a spherical surface surrounding the proton carrier at a distance of $r_0$, where $r_0$ is taken as the probable separation d(O–H) [3]. The difficult calculation of the equilibrium distance d(O–H) is avoided in favor of determination of the bond vector $(\overrightarrow{O-H})$. The position of the proton is then determined approximately from $r_0$ and $(\overrightarrow{O-H})$.

The method of calculation was checked on compounds whose proton positions are known. There is surprisingly good agreement between experiment and the position of the potential minima at a distance $r_0$ from the proton carriers (cf. Table).

Calculations were then carried out for azurite $Cu_3(OH)_2(CO_3)_2$ [8] and for $\alpha$-$KNH_2$ [9]. According to measurements with polarized infrared radiation [10] the bond vector $(\overrightarrow{O-H})$ for azurite lies in the plane (010) and is

| Compound | $(xyz)_H$ exp. | $(xyz)_H$ calc. | |
|---|---|---|---|
| LiOH | z = 0.42 [4] | z = 0.42 | caused by |
| $Ca(OH)_2$ | z = 0.425 [5] | z = 0.42 | symmetry |
| AlO(OH) (Diaspore) | 0.909 [6]<br>0.412<br>0.750 | **0.91**<br>0.42<br>0.75 | Potential at $O_1$ less favorable |
| $KH_2PO_4$ (ferroel. form) | 0.1880 [7]<br>−0.0375<br>0.1355 | 0.20<br>−0.02<br>0.14 | |

inclined towards [100] at 138 ± 5°. The calculation shows a very small deviation from the plane (010) (about 5° in the direction [010]) and an inclination towards [100] of 140 ± 5°. With $r_0$ = 0.98 Å, $(xyz)_H$ = 0.75, 0.18, 0.61. Results for α-$KNH_2$ agree with the assumptions of *Juza* and collaborators [9].

It thus appears that a direct relation exists for crystalline hydroxo compounds between the course of the electrostatic equipotential lines near the proton-carrying particles and the positions of the protons, by means of which the latter can be estimated. Moreover the occurrence of bent hydrogen bonds can be traced to the interaction of the protons with their lattice neighbors, and the angle O–H···O can be calculated quite accurately.

## Potassium, Rubidium, and Cesium Thiomanganates(II)

By Dr. W. Bronger

Anorganisch-Chemisches Institut
der Universität Münster (Germany)

*Dedicated to Professor Wilhelm Klemm on the occasion of his 70th birthday*

When a mixture of manganese powder, sulfur, and potassium, rubidium, or cesium carbonate is heated at 750 to 850 °C in an atmosphere of nitrogen and the melt is then cooled and treated with water, the three ternary compounds $K_2Mn_3S_4$ [1], $Rb_2Mn_3S_4$, and $Cs_2Mn_3S_4$ can be isolated as garnet-red, platelike crystals. The preparation of analytically pure alkali thioamanganates, free from MnS, depends on temperature control during the experiment.

Evaluation of rotating-crystal and integrated Weissenberg diagrams for [010] and [001], as well as of Guinier photographs, showed an orthorhombic unit cell (space group: $C_{2v}^{21}$–Iba2) for $Cs_2Mn_3S_4$. Patterson, Fourier, and difference syntheses along [010] led to coordinates of the Mn, Cs, and S atoms with an R value of 0.16 for all the observed reflections. A statistical distribution of four Mn atoms at point positions 4a and 4b was obtained from the intensity distribution of the weak reflections (h 1 *l*) and (h 3 *l*). There was less satisfactory agreement between $F_0$ and $F_c$ values on inclusion of eight further Mn atoms at point positions 8c in a statistical distribution. Values of the parameters are:

4 Mn statisitically dstributed over 4a and 4b with z always 0.000.
8 Mn at 8c with x = 0.000, y = 0.250, z = 0.000;
8 Cs at 8c with x = 0.249, y = 0.125, z = 0.249;
8 S at 8c with x = 0.746, y = 0.126, z = 0.099;
8 S at 8c with x = 0.253, y = 0.124, z = 0.901.

Examination of Debye-Scherrer and Guinier powder photographs, and intensity calculations with the parameters found for $Cs_2Mn_3S_4$ led to a type of structure for $K_2Mn_3S_4$ and $Rb_2Mn_3S_4$ similar to that for the cesium compound.

| | Lattice parameters [Å] | Density | Z |
|---|---|---|---|
| $Cs_2Mn_3S_4$ | a = 5.92<br>b = 11.47<br>c = 14.16 | pyk. 3.83<br>X-ray 3.86 | 4 |
| $Rb_2Mn_3S_4$ | a = 5.86<br>b = 11.21<br>c = 13.68 | pyk. 3.37<br>X-ray 3.42 | 4 |
| $K_2Mn_3S_4$ | a = 5.83<br>b = 11.11<br>c = 13.49 | pyk. 2.85<br>X-ray 2.83 | 4 |

The alkali thiomanganates(II) have a layer structure. A series of manganese and cesium layers, each separated by a sulfur layer, is perpendicular to the plate axis c. The arrangement of the manganese layers is always the same, but the cesium layers are packed into gaps, *i.e.*, every third layer – or every fifth if the surrounding sulfur layers are counted – is identical with the first. In this structure the relatively short Mn–Mn distance is noteworthy; it is made possible because the sulfur tetrahedra surrounding the Mn atoms are joined along edges.

Magnetic measurements on $K_2Mn_3S_4$, $Rb_2Mn_3S_4$, and $Cs_2Mn_3S_4$ between 90 and 700 °K show paramagnetism that is substantially temperature-independent, indicating relatively strong Mn–Mn interactions within the Mn layers.

## Tri(cyclopentadienyl)americium(III)

By Prof. Dr. F. Baumgärtner, Prof. Dr. E. O. Fischer, Dr. B. Kanellakopulos, and Dipl.-Chem. P. Laubereau

Kernforschungszentrum Karlsruhe,
Anorganisch-Chemisches Laboratorium der
Technischen Hochschule München, and
Lehrstuhl für Radiochemie
der Universität Heidelberg (Germany)

*Dedicated to Professor Wilhelm Klemm on the occasion of his 70th birthday*

We have prepared the first organometallic derivative of americium by treatment of $AmCl_3$ with molten $Be(C_5H_5)_2$ at 65 °C:

$$2\ AmCl_3 + 3\ Be(C_5H_5)_2 \rightarrow 2\ Am(C_5H_5)_3 + 3\ BeCl_2\ [*]$$

0.6 g of $^{241}AmO_2$ was converted, in 4 batches, into rose-colored $AmCl_3$ by passage of a $Cl_2/CCl_4$/argon stream over it at 650 °C for several hours. The chloride melted at 750 to 760 °C and traces began to sublime in the argon stream from 1000 °C. Quantitative sublimation, as for $PuCl_3$ [1] and $NpCl_4$ [2], could not be effected.

The yield of $Am(C_5H_5)_3$ from freshly prepared, powdered $AmCl_3$ amounted to 50 % (calculated on $AmCl_3$) after 12 h; it was materially less if a fused $AmCl_3$ cake or an older $AmCl_3$ powder was used.

$Am(C_5H_5)_3$ can be separated in an analytically pure state by fractional sublimation at $10^{-5}$ mm and 160–205 °C as a flesh-colored compound which glows in the dark with a pale light. It does not melt below 330 °C when heated in argon. At higher temperatures it darkens. It decomposes only slowly in air.

The compound is not pyrophoric, unlike $Pu(C_5H_5)_3$ [1], but discolors very quickly during C–H analysis in pure oxygen, with formation of a black decomposition product. For quantitative recovery of the americium as $AmO_2$, very careful ignition is necessary to avoid loss by volatilization. Solutions in benzene or tetrahydrofuran are very sensitive to moisture and oxygen.

The compound is decomposed by water or dilute acids, with gas evolution and deposition of white flocks, to give a rose-colored Am(III) solution.

Infrared spectra, taken for polycrystalline samples in Nujol or poly(tetrafluoroethylene), show the presence of symmetrical five-membered rings (intense, characteristic bands at 768/788 $cm^{-1}$ ($\gamma_{CH}$), 843 $cm^{-1}$ and 1010 $cm^{-1}$ ($\delta_{CH}$)]. The high specific radioactivity of the preparation requires measurement of the spectra by a special compensation technique; in poly(tetrafluoroethylene) only bands at *ca.* 3040 $cm^{-1}$ ($\nu_{CH}$) and *ca.* 1480 $cm^{-1}$ ($\omega_{CC}$) have so far been found.

It is concluded from the results that $Am(C_5H_5)_3$ and $Pu(C_5H_5)_3$ have analogous structures. The higher sublimation temperature, the greater thermal stability, the behavior in solution, and the absorption at 768/788 $cm^{-1}$ [*i.e.*, at lower wave numbers than for $Pu(C_5H_5)_3$] indicate that $Am(C_5H_5)_3$ resembles the cyclopentadienyl complexes of lanthanides [3] more closely than does $Pu(C_5H_5)_3$ [1].

# CONFERENCE REPORTS

## 7th Conference on Carbon

The 7th Conference on Carbon, which was organized by the American Carbon Committee and held at the Case Institute of Technology in Cleveland, Ohio, from June 21st to 25th, 1965, was concerned with the chemistry, physics, and technology of elementary carbon. 200 papers were presented to some 350 participants, about one fifth of whom came from abroad.

The parameters of the energy bands of graphite were accurately determined by *G. F. Dresselhaus* and *J. G. Mavroides* (Lexington, Mass., U.S.A.), by measurement of magneto-reflection and of the de Haas – van Alphen effect [1]. The authors referred to the important part played by spin-orbit interaction close to the Fermi level, which give rise to a band gap of 0.01 eV near point K.

*S. Sato, T. Oku,* and *T. Honda* (Tokyo) prepared thermocouples for very high temperatures (> 2000 °C) from polycrystalline graphite and vitreous carbon, a particularly impermeable and disordered microcrystalline from that does not graphitize even at 3000 °C.

*G. Montet* (Argonne, Ill., U.S.A.) irradiated single crystals of graphite with fast electrons and used an etching technique to determine the number of vacancies produced. An electron beam energy of at least 150 keV is required in order to knock carbon atoms out of the layer lattice. The displacement energy transferred to the C atoms [*] was found to be about 30 eV. *C. A. Coulson* (Oxford, England) found that in the neighborhood of C atoms situated between the layers, the C atoms in the layer can be displaced to a maximum extent of about 0.6 Å. The energy per interstitial atom was calculated to be 2.32 eV, while the migration energy is 0.14 eV.

Mass-spectrometric measurements by *P. D. Zavitsanos* (Philadelphia, Penn., U.S.A.) showed that carbon vapor in equilibrium with polycrystalline graphite contains $C_3$ and $C_1$ molecules as well as a relatively small number of $C_2$ molecules. Pyrolytically produced graphite evaporates predominantly in the direction of the carbon layers, and gives relatively large quantities of $C_2$ and $C_1$ together with relatively small quantities of $C_3$. When the vapor is produced by fast heating with a laser beam (no establishment of equilibrium), it contains no $C_3$. The vaporization coefficients [2] of $C_1$, $C_2$, and $C_3$ are 0.23, 0.34 to 0.46, and 0.023 to 0.046, respectively. The activity coefficient of boron dissolved in the graphite lattice was found to be about 0.3.

The electron spin resonance spectra of carbonization products that have been heated above 500 °C are affected by oxygen. *S. Mrozowski* (Buffalo, N.Y., U.S.A.) found that the resonance line is not broadened by $O_2$ if the carbonization products have been vapor-coated with alkali metals (Li toCs).

In connection with the determination of the crystallite dimensions, *F. A. Heckman* and *J. S. Clarke* (Cambridge, Mass., U.S.A.) and *W. Fritz* (Karlsruhe, Germany) referred to the importance of taking into account the broadening of the X-ray reflections in the X-ray diffractometer curves caused by the low absorption of carbon. – *C. Schiller, J. Mering,* and *M. Oberlin* (Paris, France) use the broadening of the X-ray reflections to determine the range of variation $\delta$ of the lattice dimensions in carbons and graphites. Only in graphitizable carbon is there any clear relationship between the values of $\delta$ in the a-direction and in the c-direction. As $\delta_c$ decreases, the diamagnetic susceptibility increases until it reaches a limiting value at very low values of $\delta_c$. In perfectly crystalline graphite, $\delta_c = 0$. In the course of the graphitization, the mean square $\overline{\delta_c^2}$ first passes through a minimum, then a maximum, and finally becomes zero. The coefficient of thermal expansion changes in the opposite direction to $\overline{\delta_c^2}$.

According to *A. Pacault* and *A. Marchand* (Bordeaux, France), the graphitization of cokes, pyrolytic carbon, and acetylene black takes place in several overlapping steps. The graphitization of acetylene black is so slow that it is possible to follow the kinetics of the individual steps; the paramagnetism, diamagnetism, and the Hall effect were measured. The first step leads to the formation of many localized unpaired electrons (free radicals), which rapidly become free electrons. In the second step, "aromatic" layers grow into crystallites with relatively large distances between the layers, little interaction between the layers, and strong diamagnetism. Unpaired electrons are trapped at lattice defects. The last

[1] For a description of the band model and its parameters for graphite, see *J. W. McClure,* Physic. Rev. *108*, 612 (1957).

[*] The displacement energy is the energy that must be transferred to a lattice atom by an incident particle in order that the former may be removed from its position in the lattice.

[2] In dynamic vapor-pressure measurements, the vaporization coefficient of a solid is a measure of the relative rate of vaporization or of the proportion of the surface that can contribute to the vaporization. See, *e.g., H. Cordes* and *H. Cammenga,* Z. physik. Chem. N.F. *45*, 186 (1965).

stage is the formation of a three-dimensional ordered graphite structure, with a slight decrease in the diamagnetic susceptibility; the valence band and the conductivity band overlap. Substantial changes take place in the first few minutes, or even seconds, of graphitization. – *D. B. Fischbach* (Pasadena, Calif., U.S.A.) used X-ray methods to study the kinetics of the graphitization of pyrolytic carbon at 2400 to 3000 °C. In this temperature range, many first-order reactions follow one another. In the first step the carbon layers become oriented parallel to one another; this is accompanied by a rapid decrease in the distance between the layers, but with no change in diameter. In the second step the layers grow rapidly in the layer direction, the distance between layers simultaneously decreasing, while the texture becomes more pronounced. The activation energy for these two processes is approximately 270 kcal/mole. An activation energy of 260 kcal/mole has also been found for the graphitization of petroleum cokes and coked coal tar pitch. *E. S. Bale* (London, England) and *A. Pacault* and *A. Marchand* (Bordeaux, France) found that the graphitization of cokes and carbon blacks is generally very fast and crystallite growth is usually complete after only 5 minutes.

*J. J. Kipling* and *P. V. Shooter* (Hull, England), using a polarizing microscope, observed optical anisotropy in graphitizable carbons prepared at about 700 °C, whereas non-graphitizable carbons are isotropic. Flow lines in the graphitizable carbons suggested that the first step, which takes place at about 425 to 550 °C, involves melting and parallel orientation of aromatic components.

According to *H. Honda* (Tokyo), many carbons, including some that normally do not graphitize at 3000 °C, or which do so only partially (*e.g.* carbon black) form well-crystallized graphite when electric arcs pass through the compressed sample. Examination with the aid of an electron microscope reveals the presence of flakes, which are very similar in appearance to those of a natural graphite with a small particle size. The lower the temperature at which the pretreatment of the carbon was carried out, the higher is the degree of graphitization (determined from the size of the crystallites and the distance between the layers).

*W. T. Eeles, M. S. Stagg,* and *J. A. Turnbull* (Berkeley, England) prepared single crystals of graphite containing about 1 % of boron by cooling a melt of boron and reactor graphite or by doping graphite crystals that had been irradiated with neutrons. The lattice constants of these crystals are initially greater than those of pure graphite. The a- and c-axes contract on annealing. At 1400 °C the c-axis becomes smaller than in pure graphite; at 2000 °C it begins to expand once more, to reach the ideal value at about 2500 °C. Examination with an electron microscope after heating at 1800 °C clearly shows the presence of loops exhibiting vacancy contrast.

Interesting growth spirals from 5 to 40 μ in diameter were observed by *E. Fitzer* and *H. Schlesinger* (Karlsruhe, Germany) in pyrographite deposited from methane at 1400 to 1700 °C.

Graphite is oxidized by $CO_2$ at 300 to 350 °C if atomic oxygen is released from the $CO_2$ by the action of ultraviolet light or β-radiation of more than 3 eV energy. In the course of this reaction, *I. M. Dawson* and *F. S. Feates* (Harwell, England) observed the formation of solid products, which were deposited from the gas phase, particularly at lattice defects, and which could be distinguished with the electron microscope. The oxidation of graphite by photolytically decomposed $CO_2$ is completely inhibited by free radicals, *e.g.* methylene from diazomethane. *P. G. Palmer* (Richland, Wash., U.S.A.) reported that the air oxidation of graphite is strongly retarded by small quantities of $CF_2Cl_2$ or $CF_3Cl$. The formation of etch pits in the basal surfaces was greatly reduced, whereas the specific surface area increased more rapidly than during oxidation in pure air.

*F. M. Lang* (Saclay, France) found that when graphite is oxidized in perfectly dry $O_2$, hexagonal etch pits are formed in the basal faces, whereas in the presence of small quantities of water, the boundaries of the pits become irregular. Penetrating into the graphite particles pores are formed, which have a larger radius when moist oxygen is used than with dry oxygen. Some of the water vapor is chemisorbed, *i.e.* bound in the form of functional groups.

When carbon blacks are oxidized with oxygen, ozone, or nitric acid, the external diameter of the particles decreases only slightly. In confirmation of an earlier report by *U. Hofmann*, it was found by *J.-B. Donnet* (Mulhouse, France) and *A. I. Medalia* (Cambridge, Mass., USA) that some of the particles are not oxidized, while others are hollowed out from the inside. According to *J.-B. Donnet*, the crystallites in the resistant outer shell have a shorter interlayer distance and a higher density than those in the center of the particles.

*J. M. Thomas* and *C. Roscoe* (Bangor, North Wales) produced oxidation etch pits on single crystals of graphite contaminated with boron. Examination under the microscope revealed dislocations, which are not parallel to the basal planes but are due to structural faults in the hexagonal honeycomb of the carbon layers. *J. M. Thomas*, together with *P. L. Walker* (University Park, Penn., U.S.A.) filmed the oxidation behavior of single crystals of graphite with the aid of a hot-stage microscope. The formation and growth of the etch pits could be clearly observed. The oxidation is fastest in the $<10\bar{1}0>$ direction, so that a boundary is formed parallel to $<11\bar{2}0>$. The oxidation is strongly accelerated by catalysts, such as small particles of Ag, Mo, Mn, Fe, Co, Mo, or Ti. The etch channels previously observed by *G. Hennig* are formed, their direction being fixed by the crystallographic a-axes; the etch pits start at defects. The "unwinding" of a screw dislocation could be clearly observed.

On the basis of kinetic measurements on the reaction of graphite with $CO_2$ between 900 and 1100 °C, *P. L. Walker* (University Park, Penn., U.S.A.) concluded that an unstable surface oxide is formed as an intermediate. This first-order reaction is inhibited by CO, and particularly strongly by $H_2$ or $CH_4$. The rate of reaction is reduced by more than one order of magnitude by $H_2$ at a pressure of $5\times10^{-4}$ mm Hg, hydrogen being simultaneously bound to the surface. Oxidation with labelled oxygen ($^{18}O_2$) at low pressures showed that both CO and $CO_2$ are formed as direct products. The two oxygen atoms of the $CO_2$ do not generally come from the same $O_2$ molecule. An equilibrium exists between gaseous $CO_2$ and chemisorbed $CO_2$. Some of the surface oxide formed on the oxidation of active charcoal yields $CO_2$ on thermal decomposition. According to *B. R. Puri* (Chandigarh, India), this "surface complex" (probably carboxyl groups) is responsible for the ion-exchange properties, adsorption of water or alcohols, wettability, *etc.* of charcoal. Thermal decomposition gives rise to unsaturated sites which are capable of binding one molecule of $Br_2$ or $O_2$ for every two molecules of $CO_2$ lost. After the oxidation of carbon black with $HNO_3$ or ozone, *A. Charlier* and *P. Taglang* (Mulhouse, France) observed an additional sharp peak in the relatively broad electron spin resonance signal of carbon black; this peak is associated with the presence of chemically bound oxygen, but is not affected by chemical reactions on the surface. *H. P. Boehm* and *R. Sappok* (Heidelberg, Germany) studied surface oxides on diamonds [3].

*P. L. Walker* (University Park, Penn., U.S.A.) replaced the hydrogen bound to anthracite by treatment with chlorine at 200 to 900 °C, the reaction being accompanied by evolution of HCl. The electrical conductivity increases more rapidly in this case than on heating in an inert gas. *D. Rivin* and *J. Aron* (Cambridge, Mass. U.S.A.) replaced part of the hydrogen at the edges of the carbon layers in carbon black by halogen at temperatures as low as 0 to 100 °C. The first step in this reaction was assumed to be the transfer of an electron from the carbon layer to physically adsorbed halogen molecules. Some of the bound halogen could be replaced by other functional groups, *e.g.* by treatment with alcohols, amines, water, or alkali metal hydroxides.

[3] Cf. Angew. Chem. *77*, 722 (1965); Angew. Chem. internat. Edit. *4*, 698 (1965).

*V. R. Deitz* (Washington, D.C., U.S.A.) studied the physical adsorption of $CO_2$ on a wide range of forms of carbon (*e.g.* natural graphite, pyrographite, graphitized carbon black, activated charcoal) at 0 °C, and found that the $CO_2$ was strongly absorbed on the edges of the carbon layer even at low pressures, while at higher pressures this is accompanied by relatively loose adsorption on the basal surfaces.

From density measurements with helium, *J. J. Kipling* (Hull, England) found that carbon samples prepared below 700 °C generally have a lower density at 300 °C than at 20 °C, while non-porous graphites prepared at 2700 to 3000 °C give identical values. On the other hand, many carbon samples prepared at an intermediate temperature were found by the helium displacement method to have higher densities at 300 °C than at 0 °C. This is attributed to the presence of very narrow pores, which permit the entry of the gas molecules only when the thermal vibration of the carbon atoms is sufficient. *T. G. Lamond, J. E. Metcalfe*, and *P. L. Walker* (University Park, Penn., U.S.A.) found that carbon samples obtained by the thermal decomposition of Saran [*] or polyvinylidene chloride at 1000 to 1500 °C act as molecular sieves. The adsorption behavior towards molecules with different shapes (isobutane, neopentane, benzene, and cyclohexane) indicates the presence of slot-shaped pores between 4.5 and 5.7 Å wide, which connect cavities having a diameter of at least 12 Å.

By the cleavage of large graphite crystals parallel to the basal planes, *G. Hennig* (Argonne, Ill., U.S.A.) obtained extremely thin single crystals from which it was possible to prepare intercalation compounds. The infrared spectra of these compounds could be measured directly between 0.2 and 25 μ. All intercalation compounds have a transmission band with a relatively low absorption coefficient and a half-width of about 0.2 μ. The wave number of this transparency maximum is proportional to the square root of the number of charge carriers in the carbon layer. Intercalation compounds of K, Rb, Cs, $AlCl_3$, and $FeCl_3$, and graphite hydrogen sulfate, were studied.

*W. Ostertag* and *W. E. Craven* (Wright-Patterson Air Force Base, Ohio, U.S.A.) prepared new intercalation compounds of graphite with Tb, Er, and Yb, containing one atom of a rare earth metal, two to three molecules of $NH_3$, and about 0.5 atom of I for every 18 to 24 carbon atoms.

*D. E. Nixon, G. S. Parry*, and *A. R. Ubbelohde* (London, England) determined the crystal structures of single crystals of graphite nitrates containing anion layers and acid layers in every space (1st stage), every second space (2nd stage), every third space (3rd stage), *etc.* between carbon layers. The layer sequence in graphite is ABABAB..., *i.e.* successive layers are mutually displaced by $^1/_3$ or $-^1/_3$ of the a-axis. In the first stage of graphite nitrate, the arrangement of the carbon layers is A/A/A/A..., *i.e.* the centers of the hexagons in one layer are directly above those in the next, as had been found earlier by *W. Rüdorff*. The arrangements in the higher stages are A/AB/BC/CA/A... (2nd stage), A/ABA/ACA/A... (3rd stage), and A/ABAB/BCBC/CACA/A... (4th stage). The oxidation proceeds through all the stages in turn. In the transition from the fourth stage to the third stage, for example additional layers of anions or acid are intercalated; at the same time, some of the spaces between layers must be emptied again, and when this happens, the former layer sequence is restored. Changes in the relative positions of two carbon layers occur only when an anion layer is inserted or removed. The structures of the graphite nitrates are evidently determined not by kinetic effects, but by the energies of the electron bands.

*J. G. Hooley, W. P. Garbey*, and *J. Valentin* (Vancouver, Canada) observed that the intercalation of $Br_2$ in pyrographite discs begins at the frontal surfaces and proceeds in stages towards the middle. The bromine diffuses only parallel to the basal planes, and cannot penetrate the frontal surfaces of sheets of well-graphitized pyrographite. Swelling in the middle layer of the sheet is probably hindered at first by the fact that, as the bromine penetrates, the distance between the layers increases from the edge inwards, and bending of the layers is possible only near the frontal surfaces. The replacement of carbon by boron in graphite leads to a considerable lowering of the Fermi level. *R. Tremion, J. Maire, F. Tombrel*, and *J. Mering* (Paris, France) accordingly observed marked hindrance of the intercalation of bromine in pyrographite doped with boron.

*F. J. Salzano* and *S. Aronson* (Brookhaven, N.Y., U.S.A.) have studied the kinetics of the thermal decomposition of the intercalation compound $C_8Cs$, and found a distinct discontinuity at the composition $C_{10}Cs$. The heat of formation of $C_8Cs$ is 33.8 kcal/mole. Between $C_{72}Cs \rightarrow C_{60}Cs$ and $C_{24}Cs \rightarrow C_{10}Cs$, $\Delta H$ steadily decreases from one stage to the next; in the stage $C_{10}Cs \rightarrow C_8Cs$, on the other hand, $\Delta H$ shows a pronounced increase. The entropy of formation for the first stage of cesium graphite ($C_8Cs$) is 40 cal/°K, while the values for all the other stages are between 16 and 19 cal/°K. An energy of 1.4 kcal/g-atom of carbon is required in order to separate the graphite layers.

When petroleum coke is heated rapidly during graphitization, the presence of sulfur leads to "puffing" and to destruction of the molding. *H. F. Volk* and *M. Janes* (Parma, Ohio, U.S.A.) found an analogy between the behavior of petroleum coke containing sulfur and that of petroleum coke containing small quantities of $Br_2$ between the layers (residue compounds). Destruction of the molding is avoided by the addition of Fe or Ca. At 1200 to 1500 °C, a compound containing carbon is formed, in which Fe or Ca and S are present in equal atomic proportions. The corresponding Br compound contains two Br atoms instead of one S atom. Excess Fe or Ca can be readily leached out, whereas the ternary compounds $FeSC_x$ and $CaSC_x$ are completely insoluble. The Hall coefficient indicates that the Fe in these compounds is not ionic. The quantity of Fe or Ca required in order to prevent puffing depends not only on the sulfur content, but also on the crystallite structure of the coke.

# Physical Chemistry of Protactinium

A colloqium at which 39 papers were read concerning the present state of the chemistry of protactinium was organized by the Centre National de la Recherche Scientifique in the Institut du Radium at Orsay near Paris for July 2nd–8th, 1965.

The preparation of metallic protactinium on the milligram scale by reduction of $PaF_4$ by metallic barium or calcium was described by *J. A. C. Marples* (Harwell, U.K.) and *B. B. Cunningham* (Berkeley, U.S.A.). The tetragonal body-centered structure ($a = 3{\cdot}925$ Å and $c = 3{\cdot}238$ Å at 25 °C, $Z = 2$, $\rho = 15.37$ g·cm$^{-3}$) found by *Zachariasen* [1] was confirmed, but two further modifications appear to exist at higher temperatures. The melting point of metallic protactinium was determined as 1570 °C; the molar magnetic susceptibility at 25 °C is $270 \times 10^{-6}$ CGS units and is substantially independent of temperature, as is that of tantalum.

[1] *P. A. Sellers, S. M. Fried, R. E. Elson*, and *W. H. Zachariasen*, J. Amer. chem. Soc. 76, 5935 (1954).

According to *L. E. J. Roberts* (Harwell) there exist in the system Pa–O, besides $PaO_{2.00}$ (fluorite structure, a = 5·509 Å) and $Pa_2O_5$ (3 modifications: at 700–900 °C tetragonal, a = 5·429 Å, c = 5·503 Å; at 1050 °C hexagonal, a = 3·817 Å; c = 13·32 Å; and above 1240 °C rhombohedral, a = 5·424 Å, a = 89·76 °), four further phases, namely: $PaO_{2.17}$–$PaO_{2.20}$ (cubic face-centered, a = 5·473 Å), $PaO_{2.33}$ (tetragonal, a = 5·425 Å, c = 5·568 Å), $PaO_{2.40}$–$PaO_{2.42}$ (tetragonal, a = 5·480 Å and c = 5·416 Å), and $PaO_{2.42}$–$PaO_{2.44}$ (rhombohedral, a = 5·449 Å, α = 89·65 °). $PaO_{2+x}$ thus shows great structural similarity to $UO_{2+x}$. $PaO_2$ forms a continuous series of mixed crystals with $ThO_2$. The mixed crystals are oxidized without alteration of structure to a fluorite phase $Pa_2O_5$–$ThO_2$, in which the additional oxygen ions are accomodated at intermediate lattice positions. Protactinium peroxide, $Pa_2O_9 \cdot 3H_2O$, is formed as an amorphous, easily decomposable precipitate, according to *T. Stchouzkoy* (Paris), when $H_2O_2$ is added to a protactinium(V) solution; above 200 °C it can be degraded to a hydrate of protactinium pentoxide, $Pa_2O_5 \cdot H_2O$.

As *C. Keller* (Karlsruhe), Germany was able to show, $PaO_2$ and $Pa_2O_5$ behave in their solid-state reactions as typical actinide oxides. Compounds such as $PaGeO_4$, $PaSiO_4$, $Pa_{0.25}TaO_3$, and $PaNb_3O_{10}$ correspond largely to the analogous oxides of quadrivalent thorium, uranium, and transuranium elements. $Pa_2O_5$ reacts with sesquioxides of actinides and lanthanides, giving double oxides $(M_{0.5}, Pa_{0.5})O_2$ with fluorite structure and statistical distribution of the heavy-metal atoms. These double oxides, like the actinide oxides themselves, take up any excess of $M_2O_3$ or $Pa_2O_5$ into solid solution. In the system alkali oxide/$PaO_5$, *C. Keller* and *A. J. Smith* (Sheffield, U.K.) obtained compounds of the type $MPaO_3$ (M = Li–Cs), $M_3PaO_4$ (M = Li or Na), and $Li_7PaO_6$; fluorite phases of unknown extent, with Pa:Na(Li) = 2:1 to 4:1, occur in the $Pa_2O_5$-rich region. A crystallochemical relation of protactinium(V) to the elements niobium and tantalum is recognizable only among the ternary oxides such as $Ba(Ba_{0.5}, Pa_{0.5})O_{2.75}$ (a = 8·932 Å) and $Ba(M^{III}_{0.5}, Pa_{0.5})O_3$ (a = 8·885 Å for M = La).

Several authors reported on protactinium fluorides. *L. Stein* (Argonne, U.S.A.) obtained $Pa_4F_{17}$, isostructural with $U_2O_9$, besides the known fluorides $PaF_4$, $PaF_5$, $PaF_5 \cdot 2H_2O$, and $Pa_2OF_8$, by reaction of $Pa_2O_5$ with a $HF/H_2$ stream at 500 °C; it is cubic face-centered, with a = 8·507 Å. Interest attaches to the preparation of $PaF_2SO_4 \cdot 2H_2O$ and particularly the analogous uranium compound from aqueous solution, since the ion $UF_2^{2+}$ appears to be a uranium(IV) analogue of the stable uranyl ion $UO_2^{2+}$. From solutions of protactinium(V) in hydrofluoric acid, *L. B. Asprey* (Los Alamos, U.S.A.), *O. L. Keller* (Oak Ridge, U.S.A.), *A. G. Maddock* (Cambridge, U.K.), and *C. Ferreira de Miranda* (Paris) prepared double fluorides of the type $M^IPaF_6$ ($NH_4$, K, Rb), $M^I_2PaF_7$ ($NH_4$, K, Rb), and $M_3PaF_8$ (Li, Na), in which the anions $PaF_6^-$, $PaF_7^{2-}$, and $PaF_8^{3-}$ were detected by electrochemical and spectroscopic methods even in aqueous solution and their stability constants were determined. NMR investigations showed that the mean residence time of a $F^-$ ion in the Pa-F complexes in hydrofluoric acid solution lies between $1{\cdot}6 \times 10^{-5}$ sec ($PaF_6^-$) and $3{\cdot}6 \times 10^{-4}$ sec ($PaF_7^{2-}$). The fluoro-complexes of protactinium(V) are adsorbed by anion-exchangers with high distribution coefficients, a fact that can be used for many analytical separations. Double fluorides of the type $(NH_4)_4PaF_8$ and $7MF \cdot 6PaF_4$ (tetragonal for M = Li, rhombohedral for M = Na, K, Rb), derived from protactinium(IV) by reaction in the solid state were described. These are isotypic with the corresponding compounds of thorium and uranium(IV). According to *J. Flegenheimer* (Buenos Aires) $PaCl_5$ is obtained by chlorination of $Pa_2O_5$ with $Cl_2/CCl_4$ at 300–400 °C. The ready volatility of $PaCl_5$ can, according to *J. Merinis* (Paris) be utilized for separation of protactinium – even in tracer amounts – from thorium, *e.g.* for the preparation of pure $^{233}Pa$ from irradiated $ThCl_4$, by which method high yields can be achieved. By reduction of $PaCl_5$ with hydrogen at 400 °C one obtains pure $PaCl_4$. $PaCl_5$ dissolves readily in organic solvents; with thionyl chloride it forms a double chloride $SO(PaCl_6)_2$ and on addition of CsCl, $[(CH_3)_4N]Cl$, or $[(C_6H_5)_4As]Cl$ to a solution of $PaCl_5$ in $SOCl_2$ the corresponding sparingly soluble double chlorides, *e.g.* $CsPaCl_6$, are precipitated [*D. Brown* and *K. W. Bagnall* (Harwell)]. With phosphine oxides, *e.g.* $(C_6H_5)_3PO$, $PaCl_5$ forms addition compounds of the type $PaCl_5 \cdot (C_6H_5)_3PO$. The hexabromoprotactinates(V) can be obtained, like the analogous double chlorides, only from non-aqueous solutions, since extensive hydrolysis of the $Pa^{5+}$ ion occurs immediately even in concentrated acids. In contrast to the bromo-complexes, but in analogy to uranium, octachloroprotactinates(V) such as $[(CH_3)_4N]PaCl_8$ can also be obtained in pure form. The oxide bromides $PaO_2Br$ and $PaOBr_3$ were prepared by reaction of $Pa_2O_5$ with bromine at elevated temperatures. According to *P. J. Jones* (Harwell) the action of $N_2O_5$ on Pa hydroxide, $PaCl_5$, or $SO(PaCl_6)_2$ affords hydrogen hexanitratoprotactinate(V), $HPa(NO_3)_6$, salts of which can be prepared by interaction of $N_2O_5$ and the corresponding double halides, *e.g.*:

$$CsPaCl_6 + N_2O_5 \rightarrow CsPa(NO_3)_6.$$

The analogous reaction with niobium or tantalum leads only to oxide nitrates, *e.g.* $CsNbO(NO_3)_4$.

In contrast to the unambiguous results of the investigations into the solid-state chemistry and the chemistry of its non-aqueous solutions, the chemistry of protactinium in aqueous solution is often difficult to interpret. The formation of oxo and hydroxy species of protactinium cannot be suppressed even in concentrated acids, except in hydrofluoric acid. The results may however be due more to condensation of protactinium species than to hydrolysis of a species with one protactinium atom:

$$\text{Pa–OH} + X^- \rightleftharpoons \text{Pa–X} + OH^-$$

$$\downarrow$$

$$(\gtrless\text{Pa–O–Pa}\lessgtr)_n \text{ irreversibly with } n \approx 4\text{–}5$$

Up to the present no $PaO_2^+$ ion analogous to $UO_2^+$ or $NpO_2^+$ has been found. Thus the behavior of protactinium(V) in aqueous solution is rather unclear, like that of niobium(V) or tantalum(V).

The results of investigations of sulfuric acid solutions are the easiest to interpret, because of the formation of strong Pa(V)–$SO_4^{2-}$ complexes; but according to *D. O. Campbell* (Oak Ridge, U.S.A.), the distribution coefficient for extraction of protactinium(V) by 0.03 M trilaurylamine (in diethylbenzene) decreases greatly if the protactinium concentration is greater than 4 μg/ml. This indicates condensation reactions of protactinium(V) species. With protactinium concentrations of 0.01 mg/ml distribution equilibrium is not attained even after very long extraction times; the reproducibility of the results is poor. By evaporating a solution of protactinium(V) containing $H_2SO_4$–HF with sulfuric acid, *K. W. Bagnall* (Harwell) obtained hydrogen oxotrisulfatoprotactinate(V) $H_3PaO(SO_4)_3$ (hexagonal, a = 9·743 Å, c = 5·506 Å), which above 300 °C is transformed into $HPaO(SO_4)_2$. Analogous seleno acids were also obtained. From extraction experiments with thionyltrifluoroacetone (TTA) *R. Guillaumont* (Paris) concluded that the ion $Pa(OH)_3^{2+}$ [or $PAO(OH)^{2+}$] occurs in acid solutions of protactinium(V) and that this is hydrolysed at low acid concentrations to $Pa(OH)_4^+$ [or $PaO(OH)_2^+$] (hydrolysis constant $K_1 = 0.09$ at 25 °C). A synergistic effect was observed on extraction of protactinium(V) with TTA + tributyl phosphate (TBP) and was ascribed to extraction of a mixed species $Pa(OH)_3(TTA)_2 \cdot 2 \updownarrow$ TBP. Extraction of protactinium(V) with 8-quinolinol (*C. Keller*, Karlsruhe) or acetylacetone (*J. Rydberg*, Göteborg, Sweden) is, however, hardly to be explained by postulating species $Pa(OH)_3^{2+}$ and $Pa(OH)_4^+$. Protactinium is partly extracted even from 8 M $H^+$ solutions, specifically and with high distribution coefficents, by secondary or tertiary amines (*R. Muxart* and *P. Guillot*, Paris), by phenylarsonic acid (*B. Mjassoedov*, Moscow), or by derivatives of hydroxylamine such as *N*-benzoylphenylhydroxylamine or *N*-nitrosonaphthylhydroxylamine (*A. V. La-*

*pickij*, Moscow); these reagents can be used for analytical separations. From systematic study of the extraction of protactinium(V) with dialkylphosphinic acids, *e.g.* di-n-octylphosphinic acid (HY) [*], *G. W. Mason* (Argonne) postulates extraction of the species:

$(Cl)(O)(HY_2)PaY_2Pa(HY_2)(O)(Cl)$

Experiments with the extraction of protactinium(IV) by a benzene solution of TTA lead to the conclusion that protactinium(IV) behaves like other quadrivalent actinides in aqueous solution. Hydrolysis of the $Pa^{4+}$ occurs stepwise over $Pa(OH)^{3+}$ (hydrolysis constant $K_{0,1} = 0.725$) and $Pa(OH)_2^{2+}$ ($K_{0,2} = 0.302$) to $Pa(OH)_3^{+}$ ($K_{0,3} = 0.017$) before $Pa(OH)_4$ is precipitated (*R. Guillaumont*, Paris). $Pa^{4+}$ shows a stronger tendency than $Pa(OH)_3^{2+}$ to complex-formation.

*H. W. Kirby* (Miamisburg, Ohio, U.S.A.) reported on the hydrolysis of protactinium(V). By utilizing the approximately 100-times greater stability of the niobium oxalate complex than of the analogous protactinium(V) complex a highly specific precipitation of protactinium(V) can be achieved from Nb–Pa solutions (enrichment factor for Nb up to 10). With pure $^{231}Pa$ solutions, hydrolytic precipitation from 1 N to 6 N HCl or 1 N $HNO_3$ can be used for separation from the decay products $^{227}Ac$, $^{227}Th$, and $^{223}Ra$. Specific adsorption of traces of protactinium on glass or silica gel is possible from solutions in 1–6 M HCl or 1–10 M $HNO_3$, and desorption occurs with over 90% yield by use of complexing agents (oxalic or tartaric acid).

*W. H. Burgus* (Idaho Falls, U.S.A.) described a process for separating 1 g of $^{233}Pa$ (20000 C) from 200 g of irradiated metallic thorium. The enrichment steps for $^{233}Pa$ comprised three $MnO_2$ precipitations, and the final purification a protactinium iodate precipitation. The heat evolution of the dried product (50 watts/g) sufficed for partial decomposition of the iodate. The neutron-capture cross-section for $^{233}Pa_2O_5$ was measured, the value found being only about half that previously assumed. [VB 950/257 IE]

# Symposium on Molecular Relaxation Processes

The Symposium on Molecular Relaxation Prozesses, organized by the Chemical Society and held in Aberystwyth, Wales, on July 7th–9th, 1965 was attended by some 180 scientists. In the 38 lectures delivered, the speakers discussed problems of molecular relaxation arising in electric polarization, nuclear magnetic resonance, electron spin resonance, excitation of molecular vibrational states, and ultrasonic propagation. These lectures and the subsequent discussions are to be published soon in book form.

From the lectures:

## Dielectric Relaxation

*C. P. Smyth* (Princeton, U.S.A.) pointed out that dielectric relaxation times supply valuable information on molecular and intramolecular motion, enabling inferences to be drawn concerning molecular structure, the shape and size of particles, the intermolecular forces responsible for internal friction, and even concerning the structure of liquids. When the molecular dimensions of a solvent and solute are about the same, the simple Debye model treating a molecular dipole as a spherical rotator in a viscous medium leads to appreciably longer relaxation times than the observed values. In such cases, Stokes' law is clearly not applicable. Good agreement with observed values is obtained only when the volume of a solute molecule is about three or more times larger than that of a solvent molecule.

The particularly interesting appearance of two relaxation processes has been ascertained on numerous systems, such as solutions of substituted benzenes containing the $CH_2Cl$, $CH_2CN$, $CH_3O$, $CH_3CO$, or OH group. The longer relaxation time is ascribed to rotation of the whole molecule, and the second, generally shorter relaxation time (of the order of $10^{-12}$ sec) to free rotation of the substituent. In some cases, however, the short relaxation time is absent, indicating a suppression of the free rotation by steric hindrance. The extraordinarily short intramolecular relaxation time of various arylamines is probably due to inversion such as that known to take place in the ammonia molecule.

Measurements carried out on ten straight-chain alcohols at 16 wavelengths between 0.22 cm and 300 m revealed three different relaxation times in each case. The longest of these is explained by the rupture of hydrogen bonds in molecular aggregates, resulting in molecular rotation. The other two relaxation times are again attributed to the rotation of a monomeric molecule and of an OH group, respectively. Relaxation observed in water-dioxane mixtures is also to be attributed to the rupture (and re-formation) of hydrogen bonds and to the rotation of the water molecules as a whole. Dielectric dispersion measurements carried out on binary mixtures of some polar liquids indicate the presence of relaxation processes of molecules, but not of larger aggregates. *G. Williams* (Teddington, England) discussed the complex dielectric constants of polar compounds (*e.g.* polymethyl acrylate and polyethyl methacrylate) as a function of the frequency, temperature, and pressure, and pointed out that the effect of pressure had previously been neglected in most cases. Increasing pressure at constant temperature leads to restriction of molecular motion, as shown by an increase in the relaxation time. Quantitatively, however, this effect varies greatly, depending on the relaxation mechanism. The effect of pressure (up to 3000 atm) on the dielectric relaxation of polar linear polymers (*e.g.* polymethyl acrylate) was mainly disussed. These molecules usually exhibit two relaxation processes -- a medium-frequency $\alpha$-dispersion due to the motion of the whole chain, and a high-frequency $\beta$-dispersion due to rotation of small sub-units of the molecule. It is interesting that the broad relaxation band observed for polyethyl methacrylate at 1 atm is split into two relaxation bands ($\alpha$ and $\beta$) when the pressure is increased to about $10^3$ atm, because one of the two mechanisms is much more greatly affected than the other by the change in the pressure.

*D. W. Davidson* (Ottawa, Canada) summarized the results of recent investigations on the dielectric relaxation of six ice structures (I–VI) formed at high pressures. The static dielectric constant and the relaxation frequency increase with increasing density. In the case of structures III, V, and VI, the relaxation frequency is about 10 kc/s, which is much higher than that of common ice (structure I), 150 c/s. The rotation in structure II is independent of the temperature. These results support the general Bjerrum model of relaxation based on defect diffusion in the ice crystal.

*J. D. Hoffman* (Washington, D.C., U.S.A.) developed a theory for the interpretation of the relaxation spectra of systems in which polar molecules form a molecular lattice, as in the case of long-chain ketones in urea addition compounds. This theory treats the polar molecule as a rigid

rotator and represents the crystal field, where the rotation takes place, by a system of potential barriers. The orientation of the dipole then corresponds to a site displacement process, and the elementary process is represented by a transition between two adjacent sites (lowest-energy orientations), taking place over the intermediate potential barrier. The periodic change in the occupancy of the individual sites is expressed by a set of n linear differential equations, where n is the number of sites. We thus obtain (n−1) non-vanishing relaxation times for the description of the dielectric relaxation of the system. The theory has already been confirmed experimentally on long-chain ketones and secondary bromides in urea addition complexes.

*M. Davies* (Aberystwyth, Wales, Great Britain) discussed some dielectric studies on molecular motion in solids, selecting systems whose dielectric properties indicate that the transition from the liquid to the solid state is not accompanied by the disappearance of dipole orientation. The degree of rotation varies greatly in systems of this group, as shown by variation of the relaxation time from about $5\times10^{-12}$ sec [for $(CH_2)_2O$ in ice and for $SO_2$ in hydroquinone] to over 1 sec (for zeolites, according to their water content).

*E. H. Grant, M. W. Aaron,* and *S. E. Young* (London, England) investigated the dielectric properties of some amino acids, peptides, and proteins in solution, the wavelength region used being of the order of 10 cm. The observed dipole moments of glycine, and α- and β-alanine obtained by using *Kirkwood*'s method of calculation are in good agreement with the values expected on the basis of structural data. The results show that peptides are not fully extended in solution. The activation energies for the relaxation process of the dissolved substances are about 3 to 4 kcal/mole, indicating deformation or rupture of a hydrogen bond. Measurements on ovalbumin and bovine serum albumin carried out in the region 15 to 160 cm revealed an additional, weak dispersion between the β-dispersion (due to orientation of the protein molecules) and the γ-dispersion (due to relaxation of the water dipole). This effect is attributed to the relaxation of bound water molecules. The enthalpy of the relaxation process is given approximately as 13 kcal/mole, the weight fraction of bound water being 0.30 for ovalbumin and 0.35 for bovine serum albumin.

*G. Schwarz* (Göttingen, Germany) pointed out that – under the usual conditions of measurement – molecular dielectric relaxation can also result from chemical relaxation, *i.e.* the process of readjustment of an equilibrium which has been disturbed, provided that the dielectric polarization of the system is altered by the chemical reaction (*e.g.* by changing the dipole moment of the partners), and provided that the relaxation of the dipole orientation is slower than the chemical relaxation. While the second condition is usually not fulfilled in the reactions of simple molecules, the prospects are more promising in macromolecular systems. The change in the configuration of polypeptides in solution (helix-coil transformation) is thus expected to result in a measurable dielectric relaxation effect. – Results of preliminary measurements on poly(benzyl-L-glutamate) in dichloroethylene/dichloroacetic acid mixtures support the theoretical predictions.

## Relaxation of Nuclear Magnetic Resonance and Electron Spin Resonance

*J. S. Waugh* (Cambridge, U.S.A.) emphasized the versatility of nuclear magnetic resonance in its applications to the study of molecular phenomena ranging from fast chemical reactions to lattice vibrations. More specifically, the statistical treatment of molecular motion in gases and liquids was discussed.

*J. G. Powles* (Canterbury, England) dealt with the correlation time $\tau_c$ [*] obtained from NMR measurements of molecular orientation in molecular liquids along the liquid-vapor coexistence line. The correlation frequencies $\nu_C$ [$= 1/2\,\pi\tau_c$)] between the glass transition temperature and the critical temperature have been collated for a great number of liquids. For practically all substances, $\nu_C$ at high temperatures (*i.e.* in the vicinity of the critical temperature) reaches approximately the same upper limiting value of somewhat over $10^{12}$ c/s. In the case of certain substances however, the value of $\nu_C$ is significantly lower. At low temperatures, the values of $\nu_C$ may become very small. Comparison between $\tau_C$ and the dielectric relaxation times $\tau_D$ shows the frequent failure of the relationship $\tau_D/\tau_C = 3$, which has been derived by assuming a continuous rotational diffusion. According to a recent theory of *Ivanov*, $\tau_D/\tau_C$ assumes a smaller value whenever the change in the molecular orientation is not continuous but stepwise.

[*] The correlation time is the time needed for orientated molecules to re-establish statistical distribution.

*H. S. Resing* (Washington, D.C., U.S.A.) showed that a wide spectrum of correlation times causes an apparent phase shift in the spin-spin relaxation time. A sensitive test of this theory is provided by measurements of the spin-spin relaxation time for liquid water adsorbed in the pores of a charcoal adsorbent. This effect allows an estimation of the range of the activation energies for surface diffusion, and therefore provides a new technique for studying surface heterogeneities.

*K. Bergman* and *K. Nawotki* (Ludwigshafen, Germany) discussed a new method of determining molecular motion in high polymers. The method consists in representing the observed NMR lines as a superimposed pattern of known unit spectra and calculating the statistical weights of the components. This method offers certain advantages over the usual second moment technique. Measurements on amorphous, solid high polymers, such as polymethyl methacrylate, show that rotation of the methyl groups in the chain increases as the temperature increases from −180 to −100 °C, and that rotation of the methyl groups in the side chain begins at about −100 °C.

*A. Carrington* (Cambridge, England) spoke on the effect of molecular relaxation on electron spin resonance, as shown in electronic transition, rupture and re-formation of hydrogen bonds, proton transition equilibria, the equilibrium of ligand exchange in metal chelates, and processes occurring in crystals.

## Ultrasonic Relaxation

*T. A. Litovitz* (Washington, D.C., U.S.A.) surveyed molecular relaxation processes causing the absorption and dispersion of ultrasound in liquids, mentioning structural relaxation, transitions between vibrational and translational energy, and rotational isomerism. *Litovitz* discussed structural relaxation, *i.e.* the temporary establishment of the equilibrium structure in water and fused salts. It is of great interest that the relation associated with the lattice structure generally exhibits a scatter of relaxation times. This is apparently connected with the fact that the shear viscosity does not obey the Arrhenius law. He also discussed the relationship between structural relaxation and the relaxation processes of NMR and of dielectric polarization. According to his theory concerning the appearance of relaxation spectra, a wide scatter of relaxation times is expected if the dielectric relaxation time $\tau_D$ is of the same order of magnitude as the structural relaxation time $\tau_S$, while on the other hand a single relaxation time arises when $\tau_D$ is large compared to $\tau_S$.

*G. Atkinson* (College Park, Maryland, U.S.A.) reported on measurements of ultrasonic absorption for the determination of fast reactions in solutions, such as the dissociation of manganese sulfate in aqueous organic solvents. The results indicate a preferential solvation of the ions by water molecules, which must be removed in two steps in the recombination of the ions. Furthermore, the water molecules and the organic solvent are believed to form a complex which is stabilized by hydrogen bonding and is associated with desolvation. At about 30 to 40 Mc/s, an ultrasonic absorption

band is observed which is so sharp that it cannot be attributed to a relaxation effect; its nature has not yet been elucidated.

*E. W. Jones* and *W. J. Orville-Thomas* (Aberystwyth, Wales, Great Britain) have carried out measurements of ultrasonic absorption to determine the difference between enthalpies ($\Delta H \sim 0.9$ to 2.1 kcal/mole) of rotational isomers in the liquid state. These values differ appreciably from those obtained from infrared measurements ($\Delta H \sim 0$ to 0.83 kcal/mole). The data on sound absorption apparently lead to incorrect values of $\Delta H$. It can be shown that, in the case of rotation around a C—C bond, the basic assumptions used for calculating the enthalpies are incorrect. On the other hand, the values obtained for the activation energies are acceptable.

### Relaxation of Excited Molecular Vibrational States

*R. C. Millikan* (Schenectady, N.Y., U.S.A.) surveyed the processes of energy transfer in the gas phase. In favorable cases, the vibrational relaxation times can be found with an accuracy of ± 20 %. *Millikan* also discussed the effect of rotation on the vibrational relaxation, the exchange of vibrational energy on collision, and the energy transfer between molecular vibrational states and excited electronic states of atoms and free electrons.

*H. J. Bauer* and *H. Roesler* (Stuttgart, Germany) dealt with the relaxation of the vibrational degrees of freedom in binary mixtures of diatomic gases. An exchange reaction between the excited and the non-excited molecules of different components of mixtures ensures a coupling between the relaxation processes of the two components. The two relaxation times for the sound absorption of the entire system depend in a complicated manner on the composition. The reciprocal relaxation times give a conic curve when plotted against the mole fraction. They were determined experimentally by measuring the sound absorption in $O_2/N_2$ and in $O_2/CO$ mixtures. With the aid of these values, the transition probability for the return to the ground state at 300 and 365 °K was found, *e.g.* for $O_2/O_2$ collision at 300 °K, to be $8.3\times10^{-9}$.

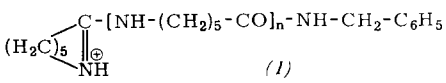
## Oligoamides and their Role in Lactam Polymerization

*M. Rothe*, Mainz (Germany) [1]

Higher linear oligomers or pleionomers of ε-aminocaproic acid containing up to 14 monomer units per chain and their derivatives with protected amino and carboxyl functions were synthesized *via* the carbobenzoxyoligoamide benzyl esters using the phosphite method conventionally [2] or occasionally on a polymeric support [3]. Cyclic oligomers containing up to 8 monomer units per ring were obtained by cyclizing the chain compound by the phosphite method [2]. Separation of the linear oligomers with up to 7 monomer units was achieved by thin-layer electrophoresis and the separation of cyclic oligomers containing up to 8 monomer residues by thin-layer chromatography with n-butanol/acetic acid/ammonia (1:4)/water (6:1:1:2) or with ethyl acetate/acetone/water (10:10:2).

In the absence of water, oligomers with *N*-terminal amidinium groups *(1)* do not initiate cationic lactam polymerization



*(1)*

even on heating them with the monomer at 250 °C for several hours. Hence the formation of terminal amidinium groups during lactam polymerization [4] does not contribute to normal chain propagation [5], but causes chain termination. Higher lactams, *e.g.* caprylolactam or laurolactam do not form amidine rings in appreciable amounts, since these would have to have 9 or 13 ring members.

## The Influence of Neutral Salts on the Hydrogen Ion Activity

*K. Schwabe*, Dresden (Germany)

It was shown by comparison of potentiometric, polarographic, and spectrophotometric measurements of pH in dilute solutions of strong acids and bases that the addition of large amounts of neutral salts produces a genuine, occasionally large change in the pH. The conventional pH value was determined using glass and hydrogen electrodes. Simultaneous measurements of the pwH and ptH values [1] revealed that shifts sometimes as large as 2 pH units were caused by a change in the activity coefficient of the hydrogen ion at constant hydrogen ion concentration. In salts with a common anion, the pH shift to lower values increases as the radius of the cation decreases; with very large cations, *e.g.* quaternary ammonium ions, an increase in pH may be observed. With a common cation, the shift to higher pH values becomes greater, the smaller the radius of the anion. Salts with large, non-hydrated ions *e.g.* $NH_4CNS$, cause only small changes in pH, even at very high concentrations (> 20 moles/kg). The decrease in the pH of acids usually is proportional to the molality m of the salt. The same applies for some cations, *e.g.* $Li^{\oplus}$, for the reduction in the pH of alkali metal hydroxide solutions; in other cases, *e.g.* with sodium salts, the pH of sodium hydroxide solution passes through a minimum as the amount of salt added increases.

The results can be interpreted by assuming that the change in the activity coefficients of $H^{\oplus}$ (or $OH^{\ominus}$) is caused by the electrostatic interaction of the charge of the $H^{\oplus}$ (or $OH^{\ominus}$) ions, which is "smeared out" uniformly over the whole solvent on account of the rapid exchange with water molecules, and the cations and anions of the salt. With the additional assumption that this interaction increases with the number of water molecules held in the hydration sphere of the salt ions, an equation can be set up for the excess Gibbs free energy of the $H^{\oplus}$ ions which fits at least the experimental values for the decreases in the pH of acids $\Delta pH/\Delta m_{salt}$.

The binding of water molecules by hydration of the salt and the resultant increase in the $H^{\oplus}$ concentration in the "quasi-eutectic" system and the observed decrease in the product $m_{H^{\oplus}} \cdot m_{OH^{\ominus}}$ at high salt concentrations may also contribute to the change in pH. It was shown that the kinetics of decomposition of acetoacetic ester and of the anodic dissolution of Fe and Co depend on the $H^{\oplus}$ activity, but that cathodic discharge of $H^{\oplus}$ depends upon the $H^{\oplus}$ concentration.

[Lecture at Saarbrücken (Germany), July 16th, 1965]

[VB 953/254 IE]

German version: Angew. Chem. *78*, 151 (1966)

---

[1] $pwH = -\log m_{H^+} \cdot f_{H^+} \cdot f_{Cl^-}$, $ptH = -\log m_{H^+} \cdot f_{\pm}$.

## Formation of Coordination Complexes in Anhydrous Acetonitrile

*V. Gutmann*, Vienna (Austria)

Chloride or azide ions were added gradually to solutions of anhydrous perchlorates, tetrafluoroborates, hexafluoroantimonates, and hexachloroantimonates of $Ti^{3\oplus}$, $V^{3\oplus}$, $VO^{2\oplus}$, $Cr^{3\oplus}$, $Mn^{2\oplus}$, and $Fe^{3\oplus}$ in anhydrous acetonitrile. The formation of coordination complexes was followed by spectrophotometric, potentiometric (silver/silver azide electrode), and conductometric methods. With the azides, the following complex species were identified:

$Ti(N_3)_3$, $[Ti(N_3)_4]^{\ominus}$, and $[Ti(N_3)_6]^{3\ominus}$

$V(N_3)_3$ and $[V(N_3)_6]^{3\ominus}$

$VO(N_3)_2$ and $[VO(N_3)_5]^{3\ominus}$

$[Cr(N_3)_6]^{3\ominus}$

$Mn(N_3)_2$ and $[Mn(N_3)_4]^{2\ominus}$

$Fe(N_3)_3$ and $[Fe(N_3)_6]^{3\ominus}$

With chloride ions, on the other hand, the tetrachloro complexes were the highest formed:

$TiCl_3$ and $[TiCl_4]^{\ominus}$

$VCl_3$ and $[VCl_4]^{\ominus}$

$[CrCl_2]^{\oplus}$, $CrCl_3$, and $[CrCl_4]^{\ominus}$

The formation of complexes of $SbCl_5$, $SnCl_4$, $TiCl_4$, $BCl_3$, $AlCl_3$, $GaCl_3$, $InCl_3$, $BBr_3$, $AlBr_3$, $GaBr_3$, and $BF_3$ with *trans*-azobenzene, *p*-dimethylaminoazobenzene, and *p*-methoxyazobenzene was examined spectrophotometrically in anhydrous acetonitrile. The equilibrium constants were determined and the validity of the Hammett equation established. A few of the complexes could be isolated. The results of infrared spectrographic studies made it possible to fix the position of the –N=N- vibration in azobenzene derivatives.

## Structural Investigations on New Mercury Compounds

*K. Brodersen*, Erlangen (Germany)

Addition of methylamine to ethereal or benzene solutions of mercury(II) chloride or bromide leads to precipitation of the compounds $HgX_2 \cdot 2\ NH_2CH_3$ and $HgX_2 \cdot NH_2CH_3$ (X = Cl or Br). The former are converted into stable, pure compounds $HgX_2 \cdot NH_2CH_3$ on treatment with the pure solvent or with a solution of the mercury(II) salt. The 1:2 adducts also lose amine on thermal degradation, whereas the monoadducts sublime unchanged. The compound $HgCl_2 \cdot NH_2CH_3$ contains four molecules per unit cell, and the following lattice constants were found for single crystals: a = 15.05 Å; b = 5.81 Å; c = 5.72 Å; $\beta = 97°$.

Dimethylamine gives 1:2 adducts from benzene solution, but only the 1:1 adducts from ether. Under the same conditions trimethylamine gives only the adducts 3 $HgX_2 \cdot 2\ N(CH_3)_3$, which can occlude $HgX_2$. Daylight or ultraviolet irradiation decomposes these adducts with production of mercury(I) compounds.

Primary aliphatic amines (ethyl-, n-propyl, n-butyl-, and n-pentyl-amine) give the substitution products $Hg_3(RN)_2X_2$ alongside the 1:1 and 1:2 adducts, the relative amounts depending on the solvent used.

# SELECTED ABSTRACTS

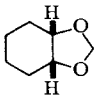
**The chemisorption of nitrogen on various surfaces of tungsten single crystals** at room temperature and below was investigated by *T. A. Delcher* and *G. Ehrlich* by measurement of the contact potentials against platinum (platinum does not adsorb nitrogen at room temperature). The work function for electron emission from tungsten is reduced by chemisorption of nitrogen on the (100) surface by 0.4 eV, for the nitrogen is present in the atomic state. The work function is increased by 0.15 eV on the (111) surface; here some of the nitrogen is adsorbed as atoms, some as molecules. At low pressures (ca. $10^{-7}$ mm) and room temperature the (110) surface does not adsorb nitrogen; adsorption occurs only at lower temperatures (ca. 130 °K) or at relatively high pressures ($10^{-3}$ mm). Here too the adsorbed nitrogen is atomic but is attached differently from that on the (100) surface; the work function is lower than that of the pure surface. / J. chem. Physics *42*, 2686 (1965) / –Hz. [Rd 364/573 IE]

**Benzene is synthesized from acetylene in Avocado pears.** *E. F. Jansen* and *J. M. Wallace* kept the unripe fruit for 4 h in an atmosphere of [$^{14}$C]acetylene. Four-fifths of the absorbed radiocarbon recurred in the respired carbon dioxide, the remainder was incorporated into several compounds in the fruit. Of these, 25% were non-volatile and 30% was benzene with a specific activity of 0.5% of that of the acetylene. Another radioactive product identified was toluene. The benzene was identified by converting it into β-benzoylpropionic acid, benzoic acid, and *p*-phenyl phenacylbenzoate, the toluene analogously. / J. biol. Chemistry *240*, 1042 (1965) / –Hö. [Rd 374/583 IE]

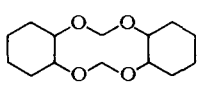
**The oxidation of tungsten** at 1400 to 3150 °K has been followed mass-spectrometrically by *P. O. Schissel* and *O. C. Trulson*. The principal oxidation products are $W_3O_9$, $W_2O_6$, $WO_3$, and $WO_2$, the ratio depending on the oxygen pressure and on the temperature of the metal surface. The observations can be explained by a reaction scheme involving two oxygen species bound firmly to the surface. / J. chem. Physics *43*, 737 (1965) / –Hz. [Rd 397/606 IE]

**The reactivity and function of the thiol groups of alcohol dehydrogenase** from horse-liver have been studied by *T. L. Li* and *B. L. Vallee*. The alcohol dehydrogenase (ADH) can be inhibited by iodoacetate, two of the 24 thiol groups being carboxymethylated. The other 22 groups react much less readily; after denaturation, however, the reactivities of all the thiol groups are the same. DPNH protects the ADH against inhibition and carboxymethylation. The inhibited and dicarboxymethylated ADH still interacts with DPNH and alcohol, as can be seen from the rotatory dispersion and the spectrum. Thus the two most reactive thiol groups are not required for the binding of the coenzyme and the substrate. However, the dissociation constant (at pH 7.5) of the complex of carboxymethylated ADH with DPNH is increased to $4 \times 10^{-5}$ (native enzyme with DPNH: $4 \times 10^{-7}$). The exchange of enzyme-bound $^{65}Zn^{2+}$ with $Zn^{2+}$ is faster, the "half-life" under the conditions used being 20 hours for the native enzyme and 14 hours for the carboxymethylated enzyme. / Biochemistry *4*, 1195 (1965) / –Hö. [Rd 402/611 IE]

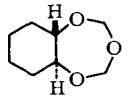
**The reaction of *cis*- and *trans*-1,2-cyclohexanediols with dihalogenomethanes** has been studied by *J. S. Brimacombe, A. B. Foster, B. D. Jones*, and *J. J. Willard*. At room temperature, the *cis*-compound reacts with dibromo- or dichloromethane and a suspension of NaH in dimethylformamide to give *cis*-cyclohexa-1,3-dioxolane *(1)* as major product together with about 2% 1,3,6,8-biscyclohexa[*d,i*]tetraoxacyclodecane *(2a)*, m.p. 142–143 °C. This new ring system occurs



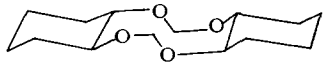
*(1)*



*(2a)*



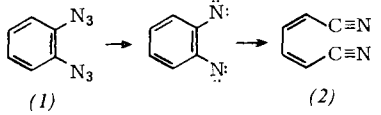
*(3)*



*(2b)*

in the *cis,syn,cis*- or *cis,anti,cis*-forms. Similarly, the *trans*-diol gives mainly *trans*-cyclohexa-1,3-dioxolane, b.p. 50 to 51 °C/15 mm, plus a little *trans*-cyclohexa-1,3,5-trioxepane *(3)* and a tetraoxacyclodecane *(2b)*, m.p. 166–167.5 °C, which has probably the stable *trans,syn,trans*-configuration. / Chem. Commun. *1965*, 174 / –Ma. [Rd 345/554 IE]

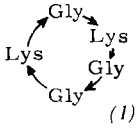
**The thermolysis of derivatives of *o*-azidoaniline** has been studied by *J. H. Hall* and *D. R. Kamm*. *o*-Azidoaniline readily condenses with aromatic aldehydes containing strongly electron-attracting groups in the *o*- or *p*-positions to form Schiff bases. Thermolysis of the latter affords high yields of 2-substituted benzimidazoles. When *o*-azidoaniline is diazotized and coupled with phenol, *p*-cresol, α-naphthol, or β-naphthol it gives rise to *o*-azidoazo compounds, while with *N,N*-dimethylaniline and *N*-methylaniline it gives the *o*-azidoazo and *o*-azidoazoamino derivatives which on heating decompose to 2-substituted benzotriazoles. Diazotization of



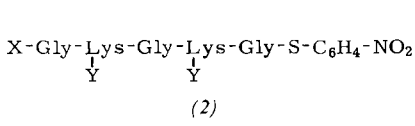
*(1)* *(2)*

*o*-azidoaniline and subsequent treatment with $NaN_3$ gives *o*-diazidobenzene *(1)*, which on refluxing in decalin undergoes cleavage of the benzene ring to yield 79% 1,4-dicyano-1,3-butadiene. / Abstracts 149th Meeting Amer. Chem. Soc. *1965*, 55P / –Ma. [Rd 335/544 IE]

**The cyclic pentapeptide *(1)* is not hydrolysed by trypsin.** *G. W. Kenner* and *A. H. Laird* have found that *(1)* is completely resistant to trypsin for a period of 24 hours, whereas the open-chain peptide Gly–Lys–Gly–Lys–Gly is completely broken down within 3 hours. *(1)* was prepared from the *p*-nitrophenyl thiol-ester of the pentapeptide *(2)*, which had previously been provided with protective groups, (X = t-butoxycarbonyl, Y = benzyloxycarbonyl). The protected peptide *(2)* was cyclized with the ion-exchanger Amberlite



*(1)*



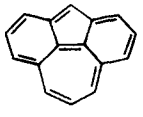
*(2)*

IRA 410 (OH form) in dimethylformamide (yield 52%). No other cyclic peptides were formed. The protective groups were removed with HBr in glacial acetic acid, and the cyclic product was separated from open-chain material by chromatography on Amberlite IRA 410. / Chem. Commun. (London) *1965*, 305 / –Hö. [Rd 399/608 IE]

**The transport of acetyl-CoA from the mitochondria** (site of formation from pyruvate) into the cytoplasm space (site of fatty-acid synthesis) has been studied by *J. Bartley, S. Abraham*, and *I. L. Chaikoff*. Four possibilities are discussed: 1. diffusion as acetyl-CoA; 2. hydrolysis and diffusion of the acetate, followed by regeneration of acetyl-CoA; 3. conversion into acetylcarnitine and transport of the latter; 4. incorporation into citrate and transport of the citrate or of one of its reaction products, followed by liberation of acetyl-CoA. When methyl-tritiated acetyl-CoA is used, tritium should be lost only in case 4. The starting materials used were [1-$^3$H, 1-$^{14}$C]-glucose, [6-$^3$H, 6-$^{14}$C]-glucose, 1-[3-$^3$H, 3-$^{14}$C]-lactate, and [2-$^3$H, 2-$^{14}$C]-acetate. The ratio $^3H/^{14}C$ was then compared with that in the terminal methyl groups of the fatty acids synthesized from the four substrates. Assuming the ratio in the starting material to be equal to 1, the ratios in the fatty acids were 0.54, 0.54, 0.61, and 0.90. Thus the conversion of acetate into acetyl-CoA involves very little tritium exchange. The results obtained with glucose and lactate, on the other hand, can only be explained by possibility 4 above. / Biochem. biophysic. Res. Commun. *19*, 770 (1965) / –Hö. [Rd 401/610 IE]

**There is only a single cysteine residue in the active center of streptococcal proteins** and its precursor cymogen according to observations of *W. H. Stein, S. Moore, et al.* Nevertheless, no mercapto group can be detected in cymogen. A volatile, hitherto unidentified thiol is split off on reaction with sodium borohydride or cysteine. The SH group in reduced cymogen and in the proteinase can be blocked with [$^{14}$C]iodoacetic acid; the enzymatic activity of the proteinase is lost during this process. Hydrolysis of the labelled enzyme with trypsin yields a single radioactive polypeptide containing 27 amino acids whose sequence was established. The cysteine is next to a histidine. / J. biol. Chemistry *240*, 1143, 1150 (1965) / –Hö. [Rd 375/584 IE]

**Cyclohepta[*def*]fluorene** *(1)*, according to MO calculations by *P. Baumgartner, E. Weltin, G. Wagnière*, and *E. Heilbronner*, must have an unusually low lying triplet state, which is either lower than, or at most 0.25 eV higher than, the



*(1)*

lowest singlet state. The molecule should therefore exist as a biradical in a triplet ground state, or else the triplet form should exist in measurable concentration in equilibrium with the singlet state. Preparation of compound *(1)* is being attempted. / Helv. chim. Acta *48*, 751 (1965) / –Hz. [Rd 398/607 IE]

**Reversible denaturation of a univalent antibody fragment** was observed by *P. L. Whitney* and *C. Tanford*. The antibody fragment against the haptene group dinitrophenyl from rabbit contains two polypeptide chains A and B and both inter- and intramolecular disulfide bridges. Reduction with 2-mercaptoethanol in 6 M guanidine hydrochloride denatures the antibody with complete loss of activity. Dialysis and reoxidation restores up to 80% of the activity according to assays by titration with dinitrophenyllysine followed by fluorescence spectroscopy. Thus the specificity in antibodies too appears to be determined solely by the amino acid sequence. The identity of the renatured and the native antibody was demonstrated by the similarity in reaction of the two with an antibody obtained by immunizing goats with the natural antibody fragment (now used as antigen). / Proc. nat. Acad. Sci. U.S.A. *53*, 524 (1965) / –Hö. [Rd 373/582 IE]

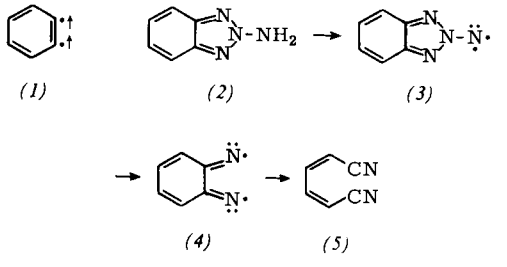
**Indole compounds were isolated from bovine pineal glands** by *W. M. McIsaac, G. Farrell, R. G. Taborsky*, and *A. N. Taylor*. Compounds identified were 5-methoxytryptophol (tryptophol = 3-indolylethanol), *N*-acetyl-5-methoxytryptamine (melatonin), 5-hydroxytryptophol, 5-methoxy-3-indolylacetic acid, and 5-hydroxy-3-indolylacetic acid. Comparisons were made with the melting points (sometimes of picrates), electrophoretic mobilities, color reactions, and $R_f$ values in 5 solvent systems of authentic samples. These serotonin derivatives are of physiological importance, *e.g.* *N*-acetyl-5-methoxytryptamine affects thyroid functions, the onset of estrus, and the ovary weight, while 5-methoxytryptophol inhibits the onset of estrus and suppresses ovary growth. / Science (Washington) *148*, 102 (1965) / –De.

[Rd 377/586 IE]

**A serotonin synergist was found in the blood of schizophrenics** by *D. W. Woolley* and *B. W. Gommi*. In combination with this substance, small amounts of serotonin which are otherwise insufficient to cause contraction of isolated rat uterus effect a strong muscular contraction. The synergist is possibly a ganglioside and cannot produce a muscular contraction alone. It augments the tissue sensitivity to acetylcholine and bradykinine. The substance cannot be dialysed, is thermostable, and dissolves in chloroform/methanol; it does not occur in the blood of normal persons. It seems possible that there is a causal connection between this substance and schizophrenia. / Science (Washington) *148*, 670 (1965) / –De.

[Rd 378/587 IE]

**The oxidation of 1- and 2-aminobenzotriazoles** with lead tetraacetate in benzene was studied by *C. D. Campbell* and *C. W. Rees*. Dehydrobenzene is produced rapidly and quantitatively from 1-aminobenzotriazole, which in the absence of a trapping agent yields nitrogen and 83% biphenylene plus about 0.5% triphenylene as by-product. Analogously, 1-amino-5-methylbenzotriazole yields 67% 2,6-dimethylbi-



*(1)* *(2)* *(3)* *(4)* *(5)*

phenylene. This tendency to dimerize is not so marked in dehydrobenzene that has been prepared in other ways. It is possible that the dehydrobenzene made from 1-aminobenzotriazole occurs more in a triplet state *(1)* than in a singlet state. Oxidation of 2-aminobenzotriazole *(2)* causes evolution of nitrogen and formation of *cis,cis*-muconitrile *(5)*, m.p. 127 °C, in 64% yield. The latter is probably formed *via* the nitrenes *(3)* and *(4)*. / Chem. Commun. *1965*, 192 / –Ma.

[Rd 356/565 IE]

**A new synthesis of ketones** involves treatment of acid chlorides or anhydrides with hexaalkyldisilanes *(2)*. *E. Frainnet, R. Calas, P. Gerval*, and *J. Bonastre* found that acyl chlorides *(1)* react rapidly with *(2)* in the presence of equimolar amounts of $AlCl_3$ to give ketones *(3)*, in yields of 60–85%.

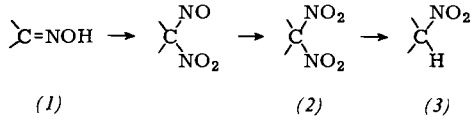
$$RCOCl + R'_3Si{-}SiR'_3 \rightarrow R{-}CO{-}R' + R'_3Si{-}SiR'_2Cl$$

*(1)* *(2)* *(3)*

$R = C_2H_5$, $C_3H_7$, or $C_6H_5$; $R' = CH_3$ or $C_2H_5$

If dimethyltetraethyldisilane is used, a mixture of methyl and ethyl ketones is formed. Acid anhydrides react analogously./ Bull. Soc. chim. France *1965*, 1259 / –Ma. [Rd 352/561 IE]

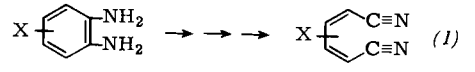
**A new preparation of nitrosteroids** is described by *J. R. Bull, E. R. H. Jones*, and *G. D. Meakins*. Nitration of steroid oximes *(1)* with fuming nitric acid and subsequent oxidation of the pseudo-nitrols with $H_2O_2/HNO_3$ gives the *gem*-dinitro compounds *(2)*, which are converted by careful hydrogenation into the mononitro compounds *(3)*. The α-nitro group is removed selectively from 4,4-, 6,6-, and 17,17-dinitro steroids. The 3,3-dinitro compound yields a mixture of α- and



*(1)* *(2)* *(3)*

β-mononitrosteroid. Reduction of the 7,7-dinitro derivative gave the 7α-mononitro compound. The equatorial conformer is the more stable epimer in mononitro compounds. The relative stabilities of the equatorial and axial conformers depend on the position substituted. / J. chem. Soc. (London) *1965*, 2601 / –Ma. [Rd 354/563 IE]

**The formation of *cis,cis*-1,4-dicyano-1,3-butadienes** *(1)* was observed by *K. Nakagawa* and *H. Onoue* on oxidation of *o*-phenylenediamines with nickel peroxide in benzene or ether at room temperature. The *cis,cis*-configuration was concluded from the melting points and infrared, ultraviolet, and NMR spectra. The dienophilic character of *cis,cis*-1,4-dicyano-1,3-butadiene is demonstrated by its formation of a Diels-Alder adduct with cyclopentadiene. For example, *o*-phenylenediamine → 14.2% 1,4-dicyano-1,3-butadiene *(1)*, X = H, m.p. 128–129 °C; *(1)*, X = 3-methyl, m.p. 70.5–71 °C, 8.2%; *(1)*,

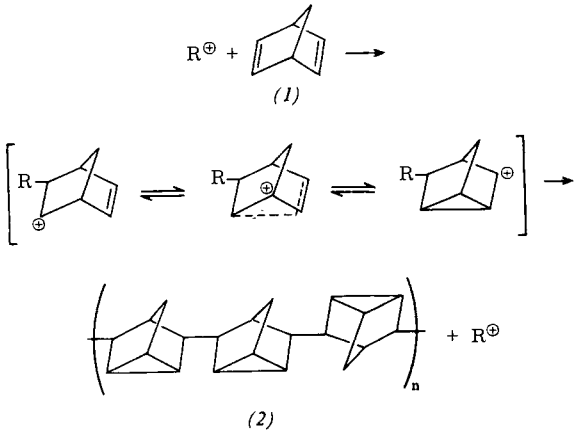


*(1)*

X = 4-methoxy, m.p. 116–117 °C, 11.6%; and 1,2-diaminonaphthalene → 25.8% 1-cyano-2-(β-cyanovinyl)benzene, m.p. 70–70.5 °C. / Tetrahedron Letters *1965*, 1433 / –Ma.

[Rd 355/564 IE]

**Cationic transannular polymerization of norbornadiene** is described by *J. P. Kennedy* and *J. A. Hinlicky*. Norbornadiene, *i.e.* bicyclo[2.2.1]hepta-2,5-diene *(1)*, can be polymerized in chloroethane at –123 °C with $AlCl_3$ as initiator. The amorphous polymer obtained in 17.2% yield after 37 min has a molecular weight of 5500 and is completely soluble in benzene, ether, and carbon tetrachloride. The yield of poly-



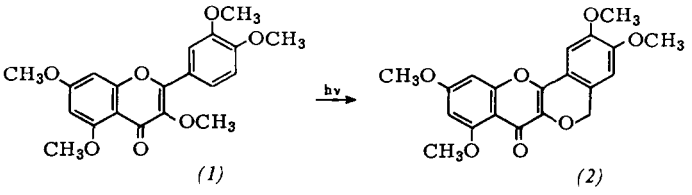
*(1)* *(2)*

mer increases at higher temperatures (–78, 0, or +40 °C) but the products are then partially cross-linked. It is assumed that the norbornadiene behaves like butadiene under these conditions. The structures of the polymers were shown by infrared and NMR spectroscopy to involve 2,6-disubstituted nortricyclene units *(2)*. / Polymer *6*, 133 (1965) / –Hl.

[Rd 379/388 IE]

**The photochemical decarboxylation of acyl hypoiodites** was found by *D. H. R. Barton, H. P. Faro, E. P. Serebryakov*, and *N. F. Wooley* to be useful for preparing iodides. A solution of the acid plus lead tetraacetate in an inert solvent, *e.g.* carbon tetrachloride or benzene, is boiled and irradiated, and iodine is added until its color persits. The reaction probably proceeds via an acyl hypoiodite, which on photolysis liberates acyloxy radicals. On decarboxylation, these leave carbon radicals which add iodine (Method a). The formation of acyl hypoiodites can also be effected by an exchange reaction with t-butyl hypoiodite (Method b). For example, n-hexanoic acid gives 100% iodide (a), 12-acetoxystearic acid, 82% (a), 12-oxostearic acid, 87% (a), cyclohexanecarboxylic acid, 91% (a), 70% (b), and apocamphanecarboxylic acid, 62% (b). / J. chem. Soc. (London) *1965*, 2438 / –Ma. [Rd 351/560 IE]

**A photo-oxidative cyclization of quercetin pentamethyl ether** *(1)* was observed by *A. C. Waiss* and *J. Corse*. Irradiation of an oxygen-free solution of *(1)* in methanol under nitrogen with light of 350 mμ wavelength for 40 h produced a 31% yield of a yellow compound, m.p. 209–210 °C, whose NMR spectrum and chemical properties indicate it to be 2,3,8,10-tetramethoxy-7-oxo[2]benzopyrano[4,3-*b*] [1]benzopyran *(2)*.



*(1)* *(2)*

This reaction is the first example of a photo-oxidative cyclization of an alkoxyl group with an aromatic ring. A similar type of cyclization may be involved in the formation of some unusual flavonoid compounds. / J. Amer. chem. Soc. *87*, 2068 (1965) / –Ma. [Rd 353/562 IE]

# BOOK REVIEWS

**Handbuch der Spurenanalyse.** (Handbook of Trace Element Analysis). By *O. G. Koch* and *Gertrud Koch-Dedic*. Bestimmung von Spurenelementen unter Anwendung extraktiver, photochemischer, spektrochemischer, mikrobiologischer und anderer Verfahren (Determination of trace elements using extractive, photometric, spectrochemical, microbiological, and other methods). Springer-Verlag, Berlin-Göttingen-Heidelberg-New York 1964. 1st edit., XVI + 1232 pp., 273 figs., linen DM 226.– (about $ 56.90).

This manual deals in its general section with units, detection and estimation methods, and methods of separating and enriching trace elements, with experimental techniques, and the sensitivity and accuracy of these processes. The specialized section contains chapters on sample preparation, extraction techniques, scope of application of extracting agents, and then an alphabetically arranged description of the assays of the elements Ag, Al, As, Au, B, Be, Bi, Ca, Cd, Co, Cr, Cu, Fe, Ga, Ge, Hf, Hg, In, Ir, Mg, Mn, Mo, Nb, Ni, Os, P, Pb, Pd, Pt, Re, Rh, Ru, Sb, Sc, Se, rare earths (seltene Erden), Si, Sn, Ta, Tc, Te, Th, Ti, Tl, U, transuranics, V, W, Y, Zn, and Zr. Further sections are to be found on the determination of the element groups in water, biological materials, metals and alloys, soils, and rock samples, and on microbiological methods for assaying Cu, Fe, Mg Mn, Mo, Zn, K, and P. Detailed practical procedures are given mainly for separations and photometric determinations, less often for spectrographic and polarographic estimations and microbiological assays. The author index contains about 4800 names covering around 3800 publications; there is a 23-page subject index.

The book is intended for the use of the practical worker. It is the first anthology of the methods of trace analysis arranged according to elements and groups of materials. The text is easy to read, and the numerous survey tables contain an abundance of experimental material. Scrutiny of selected German publications revealed that the literature has been well covered. The numerous practical methods described often make recourse to the original publications unnecessary. The quality of the print and binding – and unfortunately the high price – are in keeping with the high standards of the publishers.

Without wishing to decry the magnificent achievement of the authors, who both work in the laboratories of a large foundry works, a few minor wishes for future editions might be voiced. The alkali metals and the halogens should also be included and – in contrast to the monograph by *Sandell* – greater attention should be paid to non-photometric methods.

It is a little disturbing that the literature references are given at the end of each of the many individual sections and then in the sequence in which they appear in the text. A list at the end of the book arranged alphabetically according to author names would save one the tedious task of searching at the ends of the chapters, would eliminate repetitions, and would facilitate further searches in the literature by giving leading authors' names.

The make-up of the book calls for an indication of the future development of trace analysis. Trace analysis means the detection of less than 0.01 % of a substance in a large excess of foreign matter – the matrix – which determines the method of analysis applicable. High sensitivities and selectivities usually can be achieved only by making preliminary chemical separations; this often calls for initial samples of 10–1000 g. It must be emphasized that any chemical separation is always undesirable because of the danger of introducing impurities, the dificulties sometimes involved, and the amount of time required. However, only a few physical methods can forego prior chemical separations; for example, apart from spectrography and X-ray fluorescence analysis, both of which are not extremely sensitive, there are differential cathode-ray and pulse polarography, modifications of double-focussing mass spectrometry, and gamma-ray spectrometry. Analyses in the nanogram and picogram range are beyond the potentialities of normal methods and can be achieved only by activation analysis, mass spectrometry, and occasionally electron microscopy, but then sometimes only after previous chemical separations.

It is clear that this handbook of chemical trace analysis naturally cannot follow these developments. As a supplement, it would be desirable to have a corresponding handbook of instrumental trace analysis, which could of course be written only by a group of specialists. The present volume is an indispensible aid to the analyst. As the sole comprehensive treatise of its kind, it should be present in every general chemical library. *B. Sansoni* [NB 388/264 IE]

**Les nucleases. Application à l'étude des acides nucleiques** (Nucleases. Their Application to the Study of Nucleic Acids). By *M. P. de Garilhe*. Chimie des substances naturelles (Chemistry of natural products). Edited by *E. Lederer*. Edition Hermann, Paris 1964. 1st edit., 284 pp., 22 figs., 26 tables, linen NF 36.– (about $ 7.50).

Here introductory chapters deal with the (French) nomenclature, properties, syntheses, and isolation of nucleic acids.

Numerous methods of isolation are carefully described. The beginner is also introduced to all the relevant analytical methods.

Thus there remain only about 100 pages for the discussion of nucleases. For the more important of the 50 nuclease preparations mentioned, details are given of their preparation and properties. Among the endonucleases, the enzymes from *Staphylococcus pyogenes* and *Azotobacter agilis* which attack DNA and RNA to yield nucleoside-3′-phosphates or oligonucleotides with 5′-phosphate receive such attention. Ribonuclease from beef pancreas hydrolyses specifically at positions adjacent to pyrimidines and affords 3′-phosphates; the crystallization and amino-acid sequence of this enzyme are described, and data on its mode of action are given. The T1-RNase which splits the chains next to guanosine to give 3′-guanylic acid derivatives is discussed very briefly. DNase I from beef pancreas and DNase II from calf thymus yield 5′- and 3′-phosphates respectively. The most important exonucleases which attack DNA and RNA lead to either 3′- or 5′-nucleoside monophosphates. An exo-DNase from *Escherichia coli* splits off 5 nucleotides. Most monoesterases produce an alcohol or phenol plus orthophosphate. There are some specific 5-nucleotidases, whereas an alkali phosphatase from *E. coli* hydrolyses even polyphosphates. A table is given at the end of the book in which the ion requirements, pH optima, substrate specificity, *etc.* of the enzymes discussed are given together with references. A bibliography with 665 titles, table of contents and author and subject indices close the book, which is intended as an introduction to practical experimentation in this field, but which offers indications of new methods for the expert as well.

*J. H. Matthaei* [NB 357/215 IE]

**Molecular Orbitals in Chemistry, Physics, and Biology. A Tribute to R. S. Mulliken.** Edited by *P.-O. Löwdin* and *B. Pullman*. Academic Press, New York-London 1964. 1st edit., VIII + 578 pp., numerous illustrs. and tables, clothbound $ 22.–.

"In addition to the Schrödinger equation, there is a second fundamental law in quantum chemistry which states:

M. O. = Molecular orbital = Mulliken orbital."

With these words the editors describe the extraordinary contribution that *R. S. Mulliken* has made to the development of theoretical chemistry. This volume has appeared in his honour on the occasion of his retirement and contains 33 contributions on the subject of quantum theory and molecular structure research which impressively document the influence of the ideas and work of *R. S. Mulliken* on this subject. The articles range from biographical notes (by *C. A. Coulson* and *J. C. Slater*) to short communications; they deal with the development of the SCF theory and calculations on small molecules (*R. G. Parr*; *P.-O. Löwdin*; *G. Berthier*; *M. Simonetta*, and *E. Gianinetti*; *W. A. Bingel*; *L. Pauling*; *K. Reudenberg*; *B. G. Anex* and *H. Shull*; *E. Scrocco* and *J. Tomasi*; *S. J. Strickler* and *K. S. Pitzer*; and *T. L. Gilbert*), with the theory and analysis of molecular spectra (*F. A. Matsen* and *J. C. Browne*; *A. C. Hurley*; *S. J. Strickler* and *M. Kasha*; *G. Amat* and *H. H. Nielsen*; *G. J. Hoijtink*; and *M. Kotani*), with π-electron theory (*R. McWeeny*; *E. Heilbronner*; *I. Fischer-Hjalmars*; *W. T. Simpson*; *A. L. H. Chung*, *M. J. S. Dewar* and *N. L. Sabelli*; *T. Nakamura*, *S. Kwun* and *H. Eyring*; *R. Pauncz*; and *T. Nakajima*), with chemical reactivity (*O. Chalvet*, *R. Daudel* and *F. Peradejordi*; *R. D. Brown*; and *K. Fukui*), with group theory (*H. C. Longuet-Higgins*; and *J. Serre*), and with the applications of the MO theory to biological problems (*A. Pullman* and *B. Pullman*).

The book gives a very good survey of the current status of knowledge in the field of theoretical chemistry. Since most of the contributions contain not only new results but also summaries of the field they deal with, the book will be of value not only to the specialist but also to those with only a secondary interest in the theoretical side of molecular structure research. Of major interest for chemists are the justification and generalization of the Hückel theory on the basis of the SCF theory by *McWeeny*, the derivation of the rules of resonance theory for excited states from the Hückel theory by *E. Heilbronner*, the detailed discussion by *I. Fischer-Hjalmars* of the semiempirical determination of parameters in the Pariser-Parr-Pople theory, and the review by *R. D. Brown* on MO calculations and electrophilic substitution. However, it may be a despondent experience for many to read here the "Elementary Introduction to the SCF Theory" given by *M. Simonetta* and *E. Gianinetti*, which is explicitly for the use of chemists, for it shows that much more importance is attached to the mathematical and theoretical training of chemists abroad than in Germany.

*M. Klessinger* [NB 374/232 IE]

**Analytical Methods for Pesticides, Plant Growth Regulators, and Food Additives** (in 4 volumes). Edited by *G. Zweig*. Academic Press. New York-London 1964. 1st edit., Vol. II: Insecticides. XVII + 619 pp., numerous figs. and tables, linen $ 23.00; Vol. III: Fungicides, Nematicides and Soil Fumigants, Rodenticides, and Food and Feed Additives. XII + 237 pp., numerous figs. and tables, linen $ 12.00; Vol. IV: Herbicides. XIII + 269 pp., numerous figs. and tables, linen $ 12.00.

Volumes II, III, and IV of this series have appeared in a most welcome rapid sequence soon after Vol. I [1] and deal with 47 insecticides, including acaricides (Vol. II), 14 fungicides, 5 nematicides and soil fumigants, 2 rodenticides, 3 food or feedstuff additives (Vol. III), and 27 herbicides (Vol. IV), *i.e.* 98 exit ingredients in all.

In the individual chapters, brief details are given on the composition, designations, history, properties, synthesis, toxicology, and applications of each preparation discussed, followed by a critical review supported by literature references of the methods known for quantitative estimation of its components and of residues which remain in harvested products of foodstuffs. One or more recommended analytical methods are then given for most of the preparations with detailed practical instructions.

These foolproof analytical procedures, worked out by acknowledged experts, make the volumes – which are also of tasteful outward appearance – a reliable laboratory aid for the analyst. It is to be hoped that the editor will soon complete his valuable work with supplementary volumes and then keep it up to date. The widespread development of chemical crop protection and the increasing demand for routine control of foodstuffs for toxic residues necessitate the development of fast and reliable methods of analysis of every poison used in agriculture. In addition, there is often a need to check analytical results by other methods. In the present volumes, methods are given neither for the most recent products (perhaps because suitable analytical procedures have not yet been worked out well enough) nor for some well-established biocides; *e.g.* the important insecticide Lindane should have been included in Vol. II. In view of the widespread distribution that the work will probably attain, it seems advisable to designate the active ingredients of pesticides in future by the "common names" proposed by the technical committee TC 81 of the International Standardization Organization (ISO) instead of trade names of the formulations in which they are contained, for these are often not generally known, *e.g.* Dylox® for trichlorophon.

*H. Maier-Bode* [NB 392/250 IE]

[1] Cf. Angew. Chem. 77, 358 (1965); Angew. Chem. internat. Edit. 4, 377 (1965).

**Mammalian Protein Metabolism.** Edited by *H. N. Munro* and *J. B. Allison*. Vol. 1. Academic Press, New York-London 1964. 1st edit., XV + 566 pp., numerous figs. and tables, linen $ 18.50.

It is the intention of the editors to present in this two-volume work all aspects of protein metabolism in higher animals and humans. This first volume is devoted to physiological-

chemical and biochemical aspects. The second volume is to contain the contributions from nutritionalists and clinicians. After a short historical introduction (*H. N. Munro*), protein digestion and the absorption of nitrogenous compounds (*C. Gitler* and *A. T. Phillipson*) are discussed. Next come articles on the free amino acids and peptides in tissues (*H. N. Christensen*), on amino acid metabolism (*H. A. Krebs*) and plasma protein metabolism (*A. S. McFarlane*), on the mechanism of protein synthesis (*A. Korner*), and on turnover studies in the whole animal (*A. Neuberger* and *F. F. Richards*). The last three chapters deal with the relationships between hormones and protein metabolism (*J. H. Leatham*), the regulation of protein metabolism (*H. N. Munro*)) and nitrogen elimination from the body (*J. B. Allison* and *J. W. C. Bird*).

The editors stress the didactic aims of the book: scientists with some knowledge of physiological chemistry who want to initiate studies in this field can read the book from cover to cover. However, most readers will probably be satisfied to read only one or a few chapters in order to obtain insight into special problems. Extensive indexing makes the book useful as a work of reference, although it must be realized that, as is usual for works of this nature, the latest literature is seldom included. For example, in the chapter on protein synthesis, most 1962 publications, a few 1963 publications, but no 1964 publications have been included. Older literature, particularly the classical work in this field, has been well reviewed, so that the book can assume and hold a justified position in chemical libraries alongside books of a more chemical and biochemical nature such as "The Proteins" and "Advances in Protein Chemistry".

*H. G. Zachau* [NB 372/230 IE]

**Structure Elucidation of Natural Products by Mass Spectrometry.** Vol. II: Steroids, Terpenoids, Sugars, and Miscellaneous Classes. By *H. Budzikiewicz, C. Djerassi*, and *D. H. Williams*. Holden-Day Series in Physical Techniques in Chemistry. Holden-Day Inc., San Francisco-London-Amsterdam 1964. 1st edit., X + 306 pp., numerous figs. and tables, linen $ 10.50.

This book is an exhaustive review covering even the latest literature reports of the results of mass spectrometric investigations of steroids, steroid alkaloids, terpenes, amino acid derivatives, carbohydrates, long-chain aliphatic compounds, microbiological metabolites, and oxygen heterocycles. This is particularly welcome because numerous publications have recently appeared in these fields and it is therefore becoming more and more difficult to get a clear overall picture of the spectral data published. The book is therefore a valuable help for natural-products chemists who want to obtain information on the possibilities of applying mass spectrometric methods to their special problems.

As in earlier books by the same authors, the mechanistic interpretation of the pertinent fragmentation reactions is placed in the forefront Since such interpretations are extremely difficult, particularly in the analysis of the spectra of complex steroids and terpenes, many of the conclusions are highly speculative. Such speculations are not always justified, as witnessed by the discussion of the mechanism of formation of the ion of mass number 149 on p. 96: in effect it is concluded that the fragment either must add on a hydrogen atom in some inexplicable manner (when, however, it would attain the mass number 150) or must contain a carbon atom with an electron sextet (an impossibility).

Since the book is intended for the use of students as well, it would have been better to lay less emphasis on mechanistic considerations which cannot be proved, and to concentrate more on the facts, even though not every fragmentation step can be explained. However, the book is indispensable to the expert in the interpretation of the spectra of natural products, alone on account of its ordered presentation and comprehensive evaluation of the literature.

*G. Spiteller* [NB 367/225 IE]

**Applications of NMR Spectroscopy in Organic Chemistry.** Illustrations from the Steroid Field. By *N. S. Bhacca* and *D. H. Williams*. Holden-Day, Inc., San Francisco-London-Amsterdam 1964. 1st edit., X + 198 pp., 74 figs., 24 tables, linen $ 7.95.

The aim of this book is to furnish "an up-to-date account of the basic knowledge required to obtain structural information from an NMR spectrum". The practical examples used to achieve this aim are nearly all taken from the steroid field, hence it might have been better to point out this restriction even more precisely in the title, for not all the important applications of nuclear magnetic resonance in organic chemistry can be illustrated with these compounds. Thus there are no data given of effects of intramolecular mobility or intermolecular exchange reactions on the NMR spectra. Moreover, not all of the coupling types frequently encountered in practice are discussed, because $A_2B_2$ and $A_2X_2$ systems, for example, occur only rarely in steroids.

On the other hand, many aspects of proton magnetic resonance can in fact be demonstrated particularly well with the rigid steroid skeleton. The absorptions of the individual CH proton types are discussed in detail (72 pp.), even slight differences in the chemical shifts due to steric effects being considered in order to solve structural problems. The factors affecting vicinal and geminal coupling constants are described very clearly on 13 pages; the same applies for long-range coupling (26 pp.). It is a great credit to the authors that in the section on configuration and conformation (23 pp.), they demonstrate in detail why analysis of ABX spectra whose AB portion is concealed often gives rise to erroneous results; some methods are given which can nevertheless be applied successfully here.

The book is illustrated with numerous very clear structural formulae and spectra. Two hundred references, some of them from 1964, make the book a good work of reference. It is absolutely up to date – not only on account of the discussion of double resonance and of 100 Mc spectra, but especially because it has appeared only three to four months after completion of the manuscript! The book is not intended as an introduction to proton magnetic resonance. It can, however, be recommended to every chemist who wants to devote himself to the measurement and interpretation of spectra to the full extent at present possible with the available equipment and knowledge, whether he is interested in steroids or not.

*A. Mannschreck* [NB 398/256 IE]

**Molecular Complexes in Organic Chemistry.** By *L. J. Andrews* and *R. M. Keefer*. Holden-Day, Inc., San Francisco-London-Amsterdam 1964. 1st edit., VIII + 196 pp., numerous illustrs. and tables, linen $ 8.75.

The size of this book and the organization of the material are sufficient to indicate that the authors have not intended to produce a comprehensive and detailed presentation of this field. Their aim has apparently been to give some insight into the most important results of research on molecular compounds of the type of electron donor/electron acceptor complexes and thus to provide a book, particularly for the use of students, supplying an introduction to this interesting, many-sided field of physical and organic chemistry. The six chapters of the book deal with the following topics:

I. General considerations of donors, acceptors, inclusion compounds, and the formation of complexes. II. The spectra of molecular complexes. III. The geometry of molecular complexes, particularly crystal structures. IV. The stability of molecular complexes in solution. V. Electrical and magnetic phenomena such as dipole moments, conductivity, and paramagnetism. VI. The function of complexes in organic chemistry.

Despite the brevity of the presentation, which disregards any theoretical derivations, the book gives a very good introduction to the problems of this line of research and clearly brings

to the view of the reader just how many physico-chemical aspects are encountered in organic chemistry here. The book can therefore be recommended to all students to aquaint themselves with this field of research.

*H.-H. Perkampus* [NB 386/244 IE]

**Encyclopedia of Polymer Science and Technology. Plastics, Resins, Rubbers, Fibers.** Edited by *H. F. Mark*, *N. G. Gaylord*, and *N. M. Bikales*. Vol. 1: A to Amino Acids. Interscience Publishers, a Division of John Wiley & Sons, New York-London-Sydney 1964. 1st edit., XVIII + 893 pp., numerous illustrs. and tables, price of single volume £ 18.15.0 (about $ 51.50), subscription price £ 15.0.0 (about $ 41.50).

In view of the rapid development of polymer science and plastics production within the past decades and of the accompanying divergence of individual aspects of the subject, a complete survey of the field is highly welcome. The present series will comprise about twelve volumes appearing at a rate of at least two per year. About one thousand individual contributions written by acknowledged authorities are planned.

The editors' aims are clear from the following comments. The production and the physical, chemical, and toxic properties of all monomers will described together with their polymerization behavior. The production, properties, processing, and fields of application of polymers will be discussed. Finished articles, *e.g.* rubber goods, and economic questions will also be dealt with. Wherever appropriate, theoretical considerations are also to be interspersed.

This first volume contains 31 contributions. Each contribution contains a detailed bibliography (including patents); particularly many references are given under the keywords Abrasion Resistance (187 citations, not including general references), Acids and Derivatives, Aliphatic (198), Acrylic Ester Polymers (447), Acrylonitrile Polymers (333), Adhesion and Bonding (156), Amines (176). The literature is covered to 1962 (inclusive), in some places to 1964. Several tables and figures contain previously unpublished results, mostly made available by chemical companies.

A table ($5^1/_2$ pp.) gives a detailed list of the symbols and abbreviations used in the work. However, the list is not consistent. For example, the symbols for kinetic and thermodynamic quantities are missing and there is no mention that x can mean "conversion" as well as "degree of polymerization" (DP) or that the DP can also be denoted by n or y or that c indicates the concentration. The average degree of polymerization is denoted by DP, but the number and weight averages of the DP are designated $x_n$ and $x_w$.

Some space could have been saved here and there, *e.g.* by reduction of the size of some figures or by omission of simple formulas in tables; moreover, in the reviewer's opinion, descriptions of methods for producing saturated compounds of low molecular weight (*e.g.* alcohols, acids, and esters) or for preparing alkali metals need not have been included in this encyclopedia.

Since the r-values of copolymerization depend on the temperature and on the reaction medium, indications of these should have been given in all the tables or in the text, but these are often omitted. On p. 512, the boiling point given for methanol is 0.3 °C too high.

Temperatures are sometimes given in Centigrade and sometimes in Fahrenheit degrees, so that conversions have to be made for comparison. To simplify this matter, a centigrade-Fahrenheit conversion table should be included as a loose insert in a future volume. Conversion tables for area, volume, and mechanical units might also be added.

A few proposals might be made of features for inclusion in the last volume in order to simplify use of the book.

1. In the contributions on individual polymers and monomers, the same concepts and properties are often given in more than one place. Comparison of the data for various products is made difficult by the fact that one does not know where to look for numerical data. It is therefore suggested that the last volume contain an index of key words including such headings as r-values for copolymerization, conversion temperatures, Θ-temperatures, solubilities, solubility parameters, types of polymerization, graft and block polymers (subheadings: production, properties), transfer constants, statistics, methods for characterizing polymers (subheadings: structure, molecular-weight distribution), *etc.* 2. Many substances (monomers, polymers, auxiliaries, *etc.*) are mentioned in many contributions, but then mostly in different connections. Consequently, many searches for specific information of certain substances will remain futile. Hence, in order to find data on substances throughout the whole work, a substance index would be very useful. 3. A list of important technical terms in several languages would be most helpful. Some readers will frequently encounter translation difficulties, especially in the field of rheology, or relative to mechanical properties and plastics processing. Numerous clear structural formulas are given (in Equation 24 on p. 60 and at the foot of p. 735 there are errors in the equations which do not however change the sense); the reproduction of the figures is good.

After perusal of the first volume, the reviewer feels that he can recommend the work to those engaged in the field of polymers.

*O. Fuchs* [NB 390/248 IE]

**Phospholipids. Chemistry, Metabolism and Function.** By *G. B. Ansell* and *H. M. Hawthorne*. B. B. A. Library. Vol. 3. Elsevier Publishing Co., Amsterdam-London-New York 1964. 1st edit., XIII + 439 pp., 56 figs., 39 tables, linen DM 61.50 (about $ 15.50).

In 14 chapters the authors give a really comprehensive survey of the current status of our knowledge in the field of phosphatides. It was only the development of new synthetic and analytical methods within about the past 15 years that made it possible to achieve a more intimate knowledge of this class of compounds, whose importance still cannot be fully appreciated at present. This realization is expressed primarily in the chapter on the theory of the functions of phosphatides, which is relatively short, probably for this reason. However, the authors give a detailed discussion of the structures of phosphatides and of analytical and preparative methods for their identification and isolation. Finally, after all the known facts about the biosynthesis and degradation of phosphatides are presented, a description of the phospholipids from individual organs and tissues or subcellular components is given. It is a moot point whether the father brief treatment given to the interesting and characteristic fatty acids, especially those of glycerophosphatides, is justified or not. Here the authors were undoubtedly led by the consideration that much has already been written on this topic elsewhere.

Since both authors work on the experimental biochemistry of phosphatides in animal organisms, they have restricted their presentation to this field and have not included vegetable lipids. This necessarily reduces the readership of the book. However, since any such book was not hitherto available, this new publication is particularly welcome and will therefore be gratefully greeted by many biochemists, clinicians, and other scientists.

*Hildegard Debuch* [NB 369/227 IE]

**The Biosynthesis of Steroids, Terpenes, and Acetogenins.** By *J. H. Richards* and *J. B. Hendrickson*. Frontiers in Chemistry. Edited by *R. Breslow* and *M. Karplus*. W. A. Benjamin Inc., New York-Amsterdam 1964. 1st edit., X + 416 pp., a few figures and tables, linen $ 20.35.

In this book, possible and established routes for the biosynthesis of two classes of natural products are described. The first class comprises the acetogenins, which can, in principle at least, be formed by head-to-tail condensation of acetate units, with or without subsequent rearrangement or

substitution; this category includes fatty acids, flavonoids, quinones, coumarins, xanthones, depsides, macrolides, *etc.* The second class comprises the terpenes, which are acetate derivatives arising *via* isopentenyl pyrophosphate.

There are twelve chapters dealing with the principles of biogenetic theory, the construction of the acetate hypothesis, a statistical survey of important natural products, the experimental verification of the acetate theory, the isoprene unit, mono-, di-, sesqui-, and triterpenes, higher terpenoids. the biosynthesis of cholesterol, and further transformations of cholesterol. An impressive number of compounds are treated (about 1000 acetogenins are listed in one appendix) and many references are given; the list of references is not always complete but mostly covers the literature up to 1963.

The best features of the book are the large amount of material it contains and the purely chemical approach adopted in considering many of the biosynthetic steps postulated; its weaknesses become apparent when the discussion turns to enzymological data or hypotheses. Probably any enzymologist consulted would have recommended deletion of the whole second chapter, for here much is encountered to which objection must be taken. One can read there, for example, that many natural products have no or only secondary importance in metabolism and it is therefore reasonable to assume that for economic reasons the cell uses as few reactions as possible for their production. It is not always indicated clearly enough in the text and in formula schemes what is speculation, hypothesis, or fact, *e.g.* in the scheme for the synthesis of fatty acids on p. 130, which has since been revised. This weakness applies especially to the writing of biochemical reactions; when the stoichiometry of a reaction is known, it is desirable to include all the participating species in writing the reaction, *e.g.* on p. 178:

$$CO_2 + (CH_3)_2C{=}CH{-}COSCoA \rightarrow$$

$$HOOC{-}CH_2{-}C(CH_3){=}CH{-}COSCoA$$

By elimination of a few errors (*e.g.* that the enzymes of the fatty acid cycle do not react with *S*-acylcysteamines on p.128) or inaccuracies (*e.g.* in the scheme for the biosynthesis of shikimic acid and its derivatives on pp. 20–21, steric formulae are only occasionally used, and the formation of *p*-hydroxybenzoic acid without 5-phosphoshikimic acid as an intermediate is highly improbable), the extraordinary value of this book as a work of reference for the expert in this field will be increased further. The quality of the volume is de luxe and printing errors are few.

# Allyl-Transition Metal Systems

BY PROF. DR. G. WILKE, DR. B. BOGDANOVIĆ, DR. P. HARDT, DR. P. HEIMBACH, DR. W. KEIM, DR. M. KRÖNER, DR. W. OBERKIRCH, DR. K. TANAKA, DIPL.-CHEM. E. STEINRÜCKE, DR. D. WALTER, AND DIPL.-CHEM. H. ZIMMERMANN

MAX-PLANCK-INSTITUT FÜR KOHLENFORSCHUNG, MÜLHEIM/RUHR (GERMANY)

*Dedicated to Prof. K. Freudenberg on the occasion of his 80th birthday*

*As a continuation of a report published in 1963, recent results in the field of allyl-transition metal complexes are described*[*]. *Syntheses and reactions of these compounds, as well as the bonding between metal and allyl group, are discussed. Allyl-transition metal complexes form the basis of extremely selective catalysts for homogeneous reactions of 1,3-diolefins and of olefins; the metal atoms in these "matrix" catalysts are either "bare"* [**] *or are bound to only a few ligands.*

Introduction
1. Synthesis of Pure Allyl Compounds of Transition Metals
2. Properties and Reactions of the New Compounds
3. Structure and Bonding
4. Particular Allyl Compounds of Nickel
5. Allyl-Nickel Halides
6. Catalytic Processes Induced by Allylmetal Complexes
7. Comparison of Cyclopentadienylmetal and Allylmetal Systems

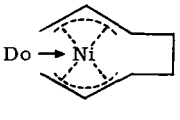
## Introduction

In 1963 we gave an outlook [1] on allyl-transition metal complexes, which we believed would offer new and interesting possibilities for preparative chemistry, and especially for homogeneous catalysis. This belief has been fully justified, though many difficulties have had to be overcome on the preparative side.

Our interest was first drawn to allyl-transition metal systems when a study of the cyclotrimerization of butadiene to cyclododeca-1,5,9-triene led us to the intermediate *(1)* which is crystalline below 0 °C [2].

The ends of the $C_{12}$ chain in this compound are bonded to the central metal atom *via* $\pi$-allyl groups. We subsequently found a similar system [1] in the (also crystalline) intermediate *(2)* in the cyclodimerization of butadiene to cycloocta-1,5-diene (Do denotes donor).

*(1)*



*(2)*

These results led to the recognition of two basic facts:

1. Allyl-metal systems evidently play an essential part in the reactions of butadiene (and probably of 1,3-diolefins in general) on transition metal catalysts.

2. A "bare" transition metal atom, either as such or combined with a ligand system, forms the matrix for

[*] The term "allyl compounds" in the present paper refers not only to compounds containing the simple allyl group ($CH_2$=CH–$CH_2$–), but also to those that contain substituted allyl groups or allyl groups forming part of a ring system.

[**] The description "bare" is applied to complexed metal atoms from which the ligands can be quantitatively displaced by the substances taking part in catalytic reactions.

[1] *G. Wilke et al.*, Angew. Chem. *75*, 10 (1963); Angew. Chem. internat. Edit. *2*, 105 (1963).

[2] *G. Wilke, M. Kröner*, and *B. Bogdanović*, Angew. Chem. *73*, 755 (1961).

[3] *G. Wilke* and *B. Bogdanović*, Angew. Chem. *73*, 756 (1961).

extremely stereospecific and selective homogeneous catalytic processes.

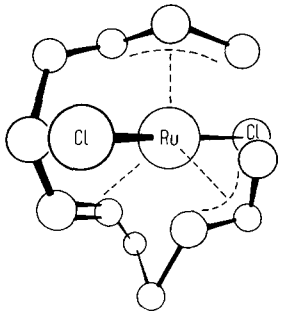
These two principles could at first not be deduced from the results obtained with catalysts containing nickel. However, the investigations of the latter led to a general method for the synthesis of allyl-metal compounds [1,3], so that we were then able to carry out similar experiments with catalysts based on other metals.

Our assumption that *(1)* contains two allyl systems bonded to one metal atom was supported by the synthesis of bis-(π-allyl)nickel *(3)* [3], the properties of which are analogous to those of *(1)*.

$$NiBr_2 + 2\ CH_2{=}CH{-}CH_2{-}MgBr \longrightarrow \text{Ni} + 2\ MgBr_2$$

*(3)*

Meanwhile, *Shaw et al.* [4] treated butadiene with ruthenium(IV) chloride at 100 °C, and obtained a crystalline complex $C_{12}H_{18}RuCl_2$ *(4)*, on which X-ray studies were carried out by *Truter* [4].



*(4)*

As in our nickel complex *(1)*, the $C_{12}$ chain is joined to the metal atom by two terminal π-allyl groups and a double bond.

## 1. Synthesis of Pure Allyl Compounds of Transition Metals [5][*]

The method first used for nickel was subsequently improved somewhat for more critical cases, and can now be used in the following form for the preparation of pure allylic compounds of a wide range of transition metals.

A Grignard compound is prepared from the desired allyl halide (preferably the chloride) at the lowest possible temperature (−15 to +20 °C) It is advisable in some cases to distil off the solvent (usually ether) and any dimers that may have been formed, and to use a suspension or solution of the residue in *e.g.* ether for the actual reaction. The Grignard compound, which is generally used in excess, is treated with halides of transition metals at temperatures of −78 to +20 °C, depending on the stability of the product expected. The reaction generally gives rise to colored solutions.

The isolation of bis-(π-allyl)nickel [3] from the reaction mixture is a special case, since this compound is so volatile that the best method is distillation or sublimation. In nearly all other instances, as much of the solvent as possible is distilled off at low temperatures (−78 °C in some cases), and the residue is extracted with a hydrocarbon such as pentane or toluene. Only the pure allylmetal compounds dissolve; metal salts and excess of Grignard compound are insoluble. The color of the solutions and their freedom from halide can generally be taken as a good indication of a successful synthesis. The compounds are separated from the filtered solutions by crystallization at low temperatures. All operations must naturally be carried out in the strict absence of air and moisture.

Table 1. Pure allyl compounds of transition metals.

| | | | | | | | |
|---|---|---|---|---|---|---|---|
| $(MgA_2)$ [a] [6] colorless | | | | | | | |
| | $(TiA?)$ [7] brown (−80 °C) [b] | $VA_3$ [7] brown (−30 °C, deflagrates) | $CrA_3$ [8] red m.p. 70–80 °C (20 °C) | $FeA_3$ [10] golden orange (−40 °C) | $CoA_3$ [11] golden red (−40 °C) | $NiA_2$ [3, 12] yellow m.p. 1 °C (20 °C) | $ZnA_2$ [6, 14] colorless m.p. 84 °C |
| | | | $(CrA_2)_2$ [9] red-brown (70–80 °C) | | | | |
| | $ZrA_4$ [7] red (0 °C) | $(NbA_4)$ [7] green (0 °C) | $MoA_4$ [8] green (125–130 °C, spontan.) | | | $PdA_2$ [13] light yellow m.p. 30 °C (20 °C) | |
| | | | $(MoA_2)_2$ [8] deep green (110–115 °C, spontan.) | | | | |
| | | $(TaA_4)$ [7] green (0 °C) | $WA_4$ [8] light brown (95 °C) | | | $PtA_2$ [13] colorless m.p. 44 °C (20 °C) | |
| | $ThA_4$ [7] light yellow (0 °C) | | | | | | |

[a] A = $CH_2{\cdots}CH{\cdots}CH_2$. The compounds in parentheses have not yet been definitely characterized. All the other compounds exist in the crystalline form.

[b] The compounds decompose at the temperatures indicated, though sometimes very slowly. Diallylmagnesium [6] and diallylzinc [6, 14] were synthesized for comparison.

The above method was used for the synthesis of the allylmetal compounds listed in Table 1.

[5] π-Allyl compounds of Group IIIb–VIIIb metals: German Published Patent Application 1190939 (April 18th, 1962), Studiengesellschaft Kohle.

[*] "Pure" allylmetal compounds in this context are those in which no ligands other than allyl groups are bonded to the metal.

During these syntheses it was found, at least as an approximation, that in a given group of the periodic system the stabilities of the allylmetal compounds increase with the atomic number of the transition metal. This is particularly noticeable in the sequences Ni < Pd < Pt, Cr < Mo < W, and Ti ≪ Zr < Th. Surprisingly, however, the yields decrease within each triad in the order of increasing stability. Another rule appears to be that the allylmetal compounds of elements with even numbers of electrons are much easier to prepare and to handle than those of elements with odd numbers of electrons. Another observation is that within the above three groups, the color intensity of a compound decreases as the atomic number of the metal increases. Some of our attempts to synthesize compounds of this type have so far been unsuccessful, *e.g.* in the case of manganese and to some extent that of titanium.

The situation with manganese is still obscure. The difficulties in the preparation of allyltitanium compounds may be due to the high reactivity of intermediates such as allyltitanium halides. Even in the case of titanium, however, we were able to prepare halide-free orange-yellow solutions (in pentane), containing extremely reactive titanium compounds, by the above general method of synthesis (at −78 °C). The low-temperature infrared spectra of these solutions seem to indicate that at least some of the allyl groups are σ-bonded. Similar remarks apply to the allyl compounds of niobium and tantalum; although green solutions (in pentane) have been obtained, the compounds present have not yet been identified.

Though a number of gaps still remain, one can regard as confirmed our guess expressed in 1963, *i.e.* that the allyl group can combine with most transition metals to form complexes in which the transition metal need not be bonded to other groups such as anions (particularly halide ions) or to donor molecules such as carbon monoxide.

## 2. Properties and Reactions of the New Compounds

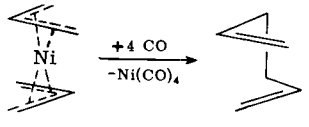
The allyl compounds of the transition metals are true organometallic compounds in which pure hydrocarbon residues are attached to the metal atoms through C atoms. However, they appear to be compounds of a special kind, since with few exceptions transition metals do not form stable metal-carbon bonds unless these bonds are stabilized by other ligands attached to the metal.

The most typical property common to all allyl-transition metal compounds, which they share with the organometallic compounds of the elements of the main groups, is their reactivity towards oxygen, which is so great that most of the compounds ignite in air. However, the position with regard to protolysis is different. Thus most allyl-transition metal compounds behave towards H-acids in the same way as the organometallic compounds of the main group elements, *i.e.* in the presence of water, alcohol, or even organic acids, at least some of the allyl groups are split off as propylene. The allyl compounds of nickel, palladium, and platinum, on the other hand, are characterized by excellent stability under these conditions; solutions of these complexes in ether are essentially stable towards water or alcohol.

All the allyl-transition metal compounds prepared so far are at least slightly volatile, and in many cases readily volatile, in a high vacuum. The mass spectra of some of the compounds can therefore be recorded. Those molecular weights that have been determined cryoscopically in benzene show that the compounds are monomeric, with the exception of diallylchromium[9] and diallylmolybdenum[8], both of which are dimeric, evidently because of metal-metal bonding.

Thus the allyl-transition metal compounds are best compared to the organoboron or organoaluminum compounds, but not to the strongly associated organometallic derivatives of the elements of groups 1 and 2. The allylmetal compounds apparently do not form electron-deficient bonds such as are typical of trialkylaluminum compounds. However, exchange experiments (see Section 6c) indicate that allyl groups attached to one metal atom can interact with another metal atom in solution, this interaction presenting a certain analogy with the alkyl exchange in trialkylaluminum compounds. The relationships between the allyl-transition metal compounds and the cyclopentadienyl-transition metal compounds will be discussed in Section 7.

Carbon monoxide was excluded as far as possible from our experiments, particularly those involving catalytic processes, since this compound often exerts an inhibiting action; on the other hand, it was frequently used to displace ligands from metal atoms. The reaction of carbon monoxide with some allylmetal compounds is particularly informative in this respect. Bis-(π-allyl)nickel *(3)* takes up one equivalent of CO at −78 °C and atmospheric pressure. The quantity of CO consumed increases above −40 °C to a total of four equivalents at +20 °C[3]. The two allyl groups combine to form hexa-1,5-diene (diallyl) with concurrent formation of $Ni(CO)_4$.



*(3)*

The product of the reaction between triallylcobalt *(5)*[11] and CO at −35 °C, on the other hand, is π-allylcobalt tricarbonyl *(6)*, which was first shown to be a π-allyl compound by *Heck* and *Breslow*[5] on the basis of its $^1$H-NMR spectrum.

$$(C_3H_5)_3Co \xrightarrow{+3\ CO} C_6H_{10} + \text{}$$

*(5)* *(6)*

The processes occurring in the cases of nickel and cobalt are comparable in that two allyl groups are detached from the metal; in the cobalt compound, however, one

allyl group remains attached to the metal. Possibly the third allyl group cannot be removed by simple displacement, since it has no partner with which to form hexa-1,5-diene, and since the CO ligands evidently give rise to further stabilization. This third allyl group could then only come off as a free radical.

A process of this type seems to take place with triallyliron *(7)* [10]. The reaction with CO in pentane does not begin below +15 °C, a temperature at which *(7)* already decomposes. It is possible, however, to isolate a complex that appears to be π-allyl-σ-1-propenyliron tricarbonyl *(8)*; thus one allyl group has been removed, another has isomerized, and three molecules of CO have been bound.

$$(C_3H_5)_3Fe \xrightarrow{+3\ CO} \underset{\displaystyle Fe(CO)_3}{\overset{\displaystyle CH{=}CH{-}CH_3}{\text{⟨allyl⟩}}} + \cdot C_3H_5$$

*(7)* *(8)*

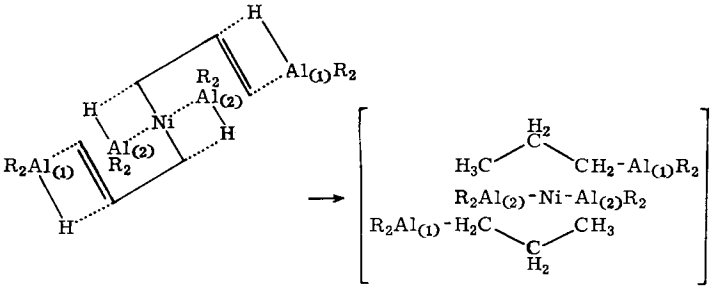
Triallylchromium *(8)* in solution takes up CO at atmospheric pressure even at −60 °C, but the reaction does not proceed completely to the $Cr(CO)_6$ stage, since the product also appears to contain a diallylchromium monocarbonyl, although this has not been definitely identified. Under pressure, on the other hand, only $Cr(CO)_6$ is formed.

$$(C_3H_5)_3Cr + 6\ CO \rightarrow Cr(CO)_6 + {}^3/_2\ C_6H_{10}$$

*(9)*

The allyl groups usually can also be removed by hydrogenation. This reaction proceeds particularly readily with the allyl compounds of nickel, palladium, and platinum, which react when simply shaken with hydrogen at normal pressure; the compounds of the group 6 elements, on the other hand, require the addition of a catalyst or the use of elevated pressures for hydrogenation. The products are the free metals and propane.

In this connection we may mention a reaction that has so far been studied in two cases, and which leads to a remarkable result for which no satisfactory explanation has yet been found. If diethylaluminum hydride is allowed to act on bis-(π-allyl)nickel or triallylchromium, the Al-H bond adds to the allylmetal system in such a way that subsequent deuterolysis yields 1-deuteriopropane as the principal reaction product of the allyl group.



$$\xrightarrow{4\ D_2O} 4\ R_2AlOD + 2\ CH_3{-}CH_2{-}CH_2D + D_2 + Ni$$

The addition of $R_2Al_{(1)}$-H (see formula) is the usual reaction of $R_2Al$–H with terminal CC double bonds. $R_2Al_{(2)}$–H, on the other hand, must formally react with the Ni-C bond in such a way as to form a $CH_3$ group and an Al-Ni bond. This interpretation is supported by the fact that the deuterolysis gas contains $D_2$. On the basis of our experiences with similar reactions, it seems necessary in all cases to consider intermediate bonding between aluminum and the transition metal, as indicated above [*].

An important part in catalytic reactions is played by another reaction of pure allyl-transition metal compounds. These compounds react even at low temperatures with anhydrous hydrogen halides in ether to form well-defined allylmetal halides, with loss of some of the allyl groups. The compounds listed in Table 2 (some of which had already been obtained by other methods) have been synthesized in almost quantitative yields by this method.

Table 2. Allyl-transition metal halides

| Complex | Preparation [a] | Color | Ref |
|---|---|---|---|
| π-Allylnickel chloride | A | brown | [32c] |
| π-Allylnickel bromide [b] | A, B | red | [32a] |
| π-Allylnickel iodide | A, B | deep red | [32b] |
| π-Methallylnickel chloride [c] | A | red-brown | [32c] |
| π-Crotylnickel chloride [d] | A | red-brown | [32c] |
| π-Cinnamylnickel chloride | B | red | |
| Benzyl-π-allylnickel chloride | B | red | |
| Triphenyl-π-cyclopropenylnickel bromide | B | red | [34] |
| 1,3-Dimethyl-π-cyclobutenylnickel bromide | B | red | |
| π-Cyclopentenylnickel chloride | B | red | |
| π-Cyclohexenylnickel chloride | B | red | |
| π-Cycloheptenylnickel bromide | B | red | |
| π-Cyclooctenylnickel chloride | A, B | red | |
| Bis-(π-allyl)chromium chloride | A | red-brown | |
| Bis-(π-allyl)cobalt chloride | A | dark-red | |
| π-Allylpalladium chloride | A | yellow | [17,b,d] |
| π-Allylplatinum chloride | A | quince yellow | |
| Tris-(π-allyl)zirconium chloride | A | red-brown | |

[a] Method A: prepared from allyl-transition metal compounds with anhydrous hydrogen halides in *e.g.* ether (see Section 2).
Method B: prepared from bis(cycloocta-1,5-diene)nickel and allyl halides in *e.g.* ether (see Section 5).
[b] This compound was also obtained from allyl bromide and cyclooctatetraenenickel(0).
[c] Methallyl = $CH_2{=}C(CH_3){-}CH_2{-}$
[d] Crotyl = $CH_3{-}CH{=}CH{-}CH_2{-}$

Partial elimination of allyl groups and formation of defined allylmetal derivatives generally occurs [16] with H-acids, *e.g.* phenol, hydrogen cyanide, and acetylacetone.

### 3. Structure and Bonding

Allylmetal compounds in which other ligands in addition to allyl groups are bonded to the transition metal were known in the pure form as early as 1958 [17]. How-

[*] *G. Wilke, G. House,* and *T. Arakawa,* Angew. Chem., in press.

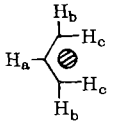
[15] *R. F. Heck* and *D. S. Breslow,* J. Amer. chem. Soc. *82,* 750 (1960).
[16] Organometallic compounds: German Published Patent Application 1 197453 (Aug. 10th, 1963), Studiengesellschaft Kohle.

ever, it was not until 1960 that *Heck* and *Breslow*[15] showed that the allyl group in allylcobalt tricarbonyl is bonded as a symmetrized system to the metal atom. The final proof was supplied by the $^1$H-NMR spectrum. According to *McClellan et al.*[18] and *Nordlander* and *Roberts*[19], it is possible to distinguish three types of allylmetal compounds on the basis of their $^1$H-NMR spectra. Both π- and σ-allylmetal compounds have so far been reported for transition metals, whereas the "dynamic" type is observed for main-group elements, such as magnesium.

The simplest $^1$H-NMR spectrum is given by the allyl system of the allylmagnesium halides *(10)*[19]. This spectrum contains a quintet and a doublet in the ratio 1:4, *i.e.* the protons of the $CH_2$ groups are indistinguishable. This result is formally explained as resulting from a rapid interchange between the following forms:

$$XMg-CH_2-CH=CH_2 \rightleftarrows CH_2=CH-CH_2-MgX$$

When the allyl group is bonded as a symmetrized system to a transition metal[15], the $^1$H-NMR spectrum contains three signals with intensity ratio 1:2:2; one of these signals, corresponding to $H_a$ in formula *(11)*, is split into at least seven components. It is accompanied



*(11)*

by two doublets due to $H_b$ and $H_c$. Thus the protons of the $CH_2$ groups can be distinguished in pairs, the $H_b$ protons (which are *syn* with respect to $H_a$) being less shielded than the $H_c$ protons (which occupy the *anti* position), which are more strongly influenced by the transition metal.

Finally, the NMR spectra of σ-allylmetal compounds, *e.g.* σ-allylmanganese pentacarbonyl[20], contain four signals, and their infrared spectra contain the C=C stretching band at 1620 $cm^{-1}$ characteristic of an unperturbed vinyl group. π-allyl and dynamic allyl systems cannot be distinguished simply by their infrared spectra, even though the C=C stretching bands of π-allyl systems generally occur at longer wavelengths (*ca.* 1500 $cm^{-1}$) than those of dynamic allyl systems. The position of the band in dynamic systems depends on the electropositivity of the metal attached to the allyl group, its wavelength increasing with the ease with which the metal can give up an electron to the allyl group [$C_3H_5Na$: 1535 $cm^{-1}$, $(C_3H_5)_2Mg$: 1575 $cm^{-1}$, $(C_3H_5)_2Zn$: 1605 $cm^{-1}$].

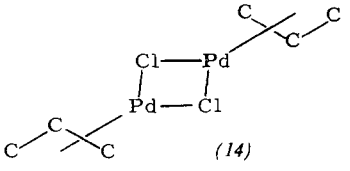
Transitions[18,20] between the types σ-allyl- ⇌ π-allylmetal compounds [*e.g.* between *(12)* and *(13)*] and π-allyl- → dynamic allylmetal compounds[21] have been

$$CH_2=CH-CH_2-Mn(CO)_5 \rightleftharpoons \text{(13)} Mn(CO)_4 + CO$$

*(12)*

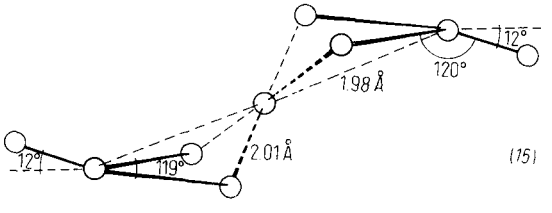
reported. The latter transition was only recently observed with the addition products of triphenylphosphine to π-methallylpalladium chloride[22] and to π-allylnickel bromide[23]. For zinc we also found a transition from the dynamic to the σ-allyl system (see page 156).

The clearest evidence for the symmetrical bonding of the allyl groups to the metal is provided by X-ray structure analysis. The dimer of π-allylpalladium chloride is a typical example[24]. The formula *(14)* shows the positions of all the atoms except hydrogen. The C atoms of each allyl group lie in a plane perpendicular to that containing the Pd and Cl atoms.



*(14)*

The results of our studies on pure allylmetal compounds have been corroborated by X-ray analysis[25] of bis-(π-methallyl)nickel *(15)*[13]. This compound, which is prepared by the general method described above, crystallizes very readily (m.p. 31 °C) and is much more stable than bis-(π-allyl)nickel. It has a sandwich structure in



*(15)*

which the methyl groups are *trans* to each other. Three C atoms in each methallyl group are situated at about the same distance from the central nickel atom. It should be noted that the methyl groups are inclined towards the metal at an angle of about 12 ° to the planes of the allyl groups. The latter are symmetrized, so that each formally occupies two coordination positions of the nickel atom, which is presumably $dsp^2$-hybridized.

X-ray structure analyses of the compounds $M(C_3H_5)_4$ (M = Zr, Th, Mo, W) are in progress. In these complexes, the metal

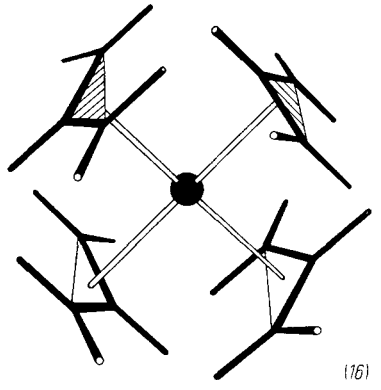
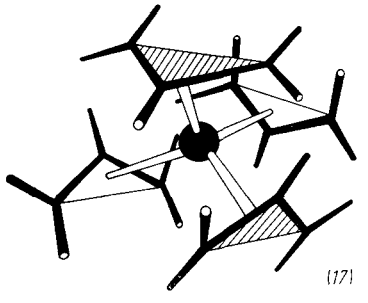
atom has a coordination number of 8 if each of the allyl groups occupies two coordination positions. Since $Zr(C_3H_5)_4$[7] and $Th(C_3H_5)_4$[7] in particular have typical π-allyl $^1$H-NMR spectra, it can be assumed that they have a very regular structure, since all four allyl groups could not otherwise give the same spectrum.

Two particular arrangements of the four allyl groups about the central atom would ensure that all the groups were perfectly equivalent. In the first of these, the centroids of the allyl groups occupy the corners of a square with the metal atom at the center, and the eight coordination positions lie at the corners of a square prism: *(16)*. In the second case the basic framework is tetrahedral, and the eight coordination positions are situated at the eight corners of a solid bounded by two rectangles and four trapezia, *i.e.* a tetrahedron truncated at two non-intersecting edges: *(17)*. The tetraallyl systems cannot be represented by the usual arrangements found with eight-fold coordination ($d^5p^3$ – square antiprism: $d^4sp^3$ – dodecahedron), since the separation in each pair of coordination positions, determined by the structure of the allyl group, is disproportionately small.



(16)



(17)

It can be seen from the model that the distance between allyl groups, and particularly between $CH_2$ groups, is greater in the arrangement *(17)*, so that this structure should be the more likely. Complications seem to arise in the analogous complexes of molybdenum[8] and tungsten[8], where $^1$H-NMR spectra indicate that either two of the allyl groups are bonded differently to the other two, or that the two terminal C atoms of each allyl group do not interact with the metal in the same way.

The $^1$H-NMR spectra of only a few allylmetal compounds can be discussed here (detailed discussion will be reserved for another publication). It should first be pointed out that the $^1$H-NMR spectra of some complexes could not be recorded, either because the substances decompose too readily or are not sufficiently soluble at low temperatures (V, Co), or because of interference due to paramagnetism (Cr, Fe, Nb, Ta).

$Zr(C_3H_5)_4$ and $Th(C_3H_5)_4$, both of which crystallize very well, were found to be particularly interesting. Both of these compounds have temperature-dependent $^1$H-NMR spectra. The classic π-allyl spectrum given by *e.g.* $Th(C_3H_5)_4$ in $C_6D_6$ at 10 °C ($H_a$: $\tau = 3.97$; $H_b$: $\tau = 6.46$; $H_c$: $\tau = 7.61$ with tetramethylsilane as internal standard) slowly changes with rising temperature, and ultimately (at 80 °C) exhibits the characteristics of a dynamic allylmetal system ($H_a$: $\tau = 3.95$; $H_{bc}$: $\tau = 7.09$). Similar results were obtained with $Zr(C_3H_5)_4$, for which the transition temperatures, however, are about 80 to 100 °C lower. This was the first demonstration of a thermal transition from a π-allyl to a dynamic allyl system. A particularly remarkable feature of this transition is that the infrared spectra of the two compounds show no comparable effect of temperature on the position of the typical C=C stretching band.

For comparison purposes, we also prepared $(C_3H_5)_2Mg$[6] and $(C_3H_5)_2Zn$[6] and recorded their infrared and $^1$H-NMR spectra. At 20 °C, both of these compounds give the typical $^1$H-NMR spectrum of a dynamic allyl system, and the C=C stretching bands in the IR spectra are situated at 1575 $cm^{-1}$ and 1605 $cm^{-1}$. *Thiele* and *Zdunnack*[14] independently described the preparation and properties of diallylzinc. The reported $^1$H-NMR spectrum agrees well with that obtained in our own work at 20 °C in tetrahydrofuran. We observed another peculiarity at −100 °C, namely the conversion of the dynamic system into a σ-allyl system[*]. All the transitions π-allyl → dynamic allyl → σ-allyl have thus been observed for allylnickel halides.

A final explanation for the transition from the π-allyl to the dynamic allyl system cannot yet be given. The hypothesis agreeing best with all results is that in the initially symmetrized allyl groups, the CC bonds, which are already weakened by the interaction with the transition metal (C=C stretching band at *ca.* 1500 $cm^{-1}$) become further loosened at higher temperatures. The $CH_2$ groups can thus be relatively easily rotated around the CC-axis. The frequency of this rotation should be roughly 150–200 $sec^{-1}$ at the coalescence temperature; *i.e.* above this temperature the signals of the *syn* and the *anti* protons coalesce as a result of rapid exchange of their positions.

The activation energy of the π-allyl → dynamic allyl transition was estimated very roughly by *Gutowsky*'s method[26] from the $^1$H-NMR spectra of $Zr(C_3H_5)_4$ and $Th(C_3H_5)_4$ at various temperatures. The values obtained are about 10 and 15 kcal/mole, respectively.

It is particularly noteworthy that the above temperature-dependent transition occurs for $Zr(C_3H_5)_4$ and $Th(C_3H_5)_4$. If it is assumed that four allyl anions are bonded to the central metal in these two compounds, the metal cations can have no filled d-orbitals available for normal back-donation to the ligand. Formally, therefore, the bonding of the allyl groups to the metal must depend entirely on the donor function of the allyl anion, any additional charge transfer from the metal to the ligand as described in the *Chatt-Duncanson* picture[27] of olefinmetal complexes being at most of minor importance. The easy transition from the π-allyl to the dynamic

[*] It is not impossible that THF acts as a ligand on the Zn at low temperatures.

[26] *H. S. Gutowsky* and *A. Saika*, J. chem. Physics *21*, 1688 (1953).

[27] *J. Chatt* and *L. A. Duncanson*, J. chem. Soc. (London) *1953* 2939.

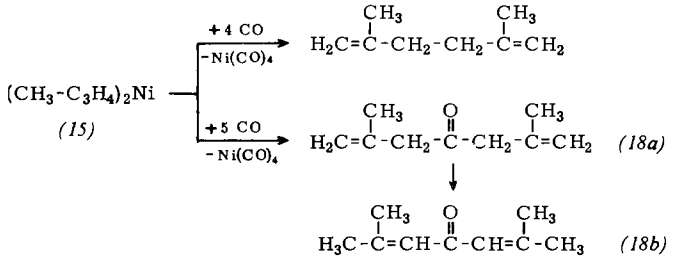
allyl system could therefore be due to the absence of sufficiently strong back-donation.

According to this rather primitive picture, the allyl compounds of zirconium and thorium occupy a position between the π-allyl compounds of metals with pronounced acceptor and donor properties, such as nickel, and those of the main-group elements, which form only dynamic allyl systems. Zinc, which has a filled d-shell, also forms the dynamic type.

## 4. Particular Allyl Compounds of Nickel

### a) Bis-(π-methallyl)nickel and Bis-(π-crotyl)nickel [13]

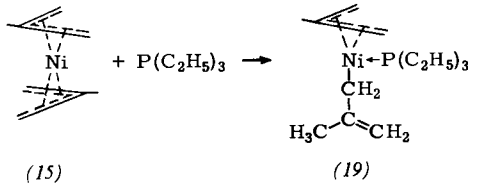
The most convenient complexes to work with are those of nickel. Variations of the allyl system were therefore studied with nickel as the central atom. That bis-(π-methallyl)nickel is more stable than bis-(π-allyl)nickel is shown by the fact that butadiene does not react directly with the methallyl complex at 20 °C, as it does with π-$(C_3H_5)_2Ni$. Cyclododeca-1,5,9-triene is formed only at elevated temperature. Displacement experiments with CO showed that a very unstable 1:1 adduct is first formed at −80 °C; this takes up further CO at higher temperatures, and is finally converted into $Ni(CO)_4$, with displacement of 2,5-dimethylhexa-1,5-diene. A minor side reaction is the insertion of CO, leading first to the formation of the ketone *(18a)*, which isomerizes to phorone *(18b)*.



*(18a)*

*(18b)*

A 1:1 adduct of bis-(-methallyl)nickel with triethylphosphine has been isolated in the crystalline form. This complex formation should lead to an increase in the number of outer electrons on the nickel from 16 to 18, and so stabilize the complex. This is not so, however, since firstly the triethylphosphine can be easily removed at $10^{-4}$ mm Hg, and secondly the infrared spectrum of the adduct shows that complex formation apparently occurs at the expense of one π-allyl group, which appears to be σ-bonded as in *(19)* (band at 1605 $cm^{-1}$).



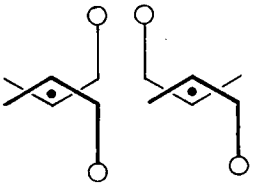
*(15)* *(19)*

It must therefore be concluded that the sandwich arrangement is a particularly preferred system, even when the nickel atom formally has at its disposal only 16 outer electrons.

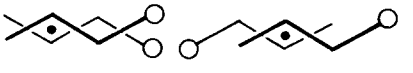
Bis-(π-crotyl)nickel, which also has been obtained in the crystalline form, should exhibit stereoisomerism, since the crotyl group can be bonded to the metal in either the *syn* or the *anti* form [*], as had already been observed for π-crotylcobalt tricarbonyl *[(20), (21)]* [28].

*(20)*, anti *(21)*, syn

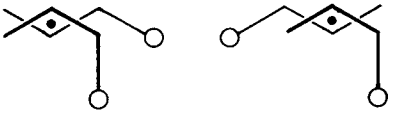
Bis-(π-crotyl)nickel probably also has a sandwich structure. If we look along an axis perpendicular to the planes of the allyl groups and passing through the central atom, the structures of the isomers will be as shown in *(22)* to *(24)* (the circles denote methyl groups).



*(22)*, anti-anti



*(23)*, syn-syn



*(24)*, syn-anti

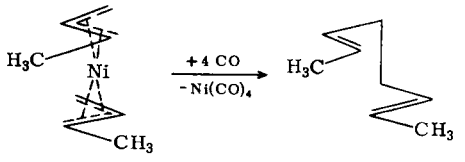
Assuming that the crotyl groups cannot rotate freely around this axis and that the mutual arrangement of the crotyl groups corresponds to the *trans* arrangement in bis-(π-methallyl)-nickel *(15)*, six isomers are possible (not counting optical isomers). Six isomers are also expected for free rotation around the axis. The number of isomers increases to twelve if two positions differing by an angle of 180 °C (*cis* and *trans*) are possible.

Dissimilar bonding of the C atoms in the allyl systems to the nickel atom must also be considered.

In view of these relatively complex structural relationships, the results obtained in the reaction of bis-(π-crotyl)nickel with CO appear even more surprising. When the reaction is carried out with the crystalline product or in solution at −40 °C and normal pressure, the products are $Ni(CO)_4$ and a mixture of *trans,trans*-octa-2,6-diene *(23a)* (98 %) and 3-methylhepta-1,5-diene *(23b)* (2 %) in a total yield of 96 to 98 %. The displacement reaction is stereospecific under these conditions, and proceeds as if the bis-(π-crotyl)nickel consisted only of the *syn,syn* forms.

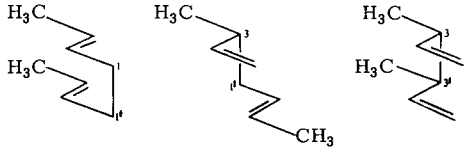
[*] Here the terms *syn* and *anti* refer to the position of the central H atom of the allyl group with respect to the methyl group.

[28] *J. A. Bertrand, H. B. Jonassen*, and *D. W. Moore*, Inorg. Chem. *2*, 601 (1963).



(23) (23a)

Thus the linkage occurs almost exclusively through the unsubstituted ends of the allyl systems. At higher temperatures, this reaction leads to the formation of three dienes in a total yield of 88 %, consisting of 58 % of octa-2,6-diene *(23a)*, 38 % of 3-methylhepta-1,5-diene *(23b)*, and 4 % of 3,4-dimethylhexa-1,5-diene *(23c)*, *i.e.* all three possible products are formed. No ketone was found among the products.



(23a) (23b) (23c)

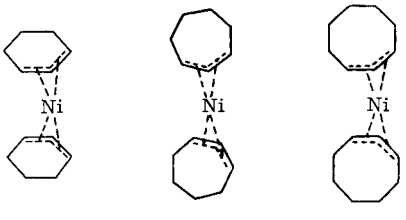
The reasons for the highly specific course taken by the bond formation at low temperatures presumably are as follows:

1. A definite spatial arrangement of the crotyl groups in the starting material.

2. The activation energies for the formation of the 1-1′, 3-1′, and 3-3′ linkages are not equal, but increase in this order.

b) Cyclic Bis-(π-allyl)nickel Compounds [13]

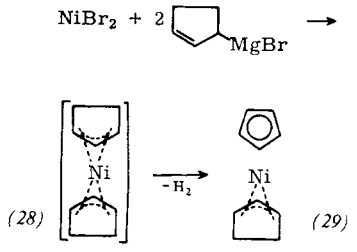
In order to find whether cyclic allyl systems can be bonded to nickel, we synthesized the compounds *(25)* to *(27)*, which exist in the *anti,anti* form.



(25) (26) (27)

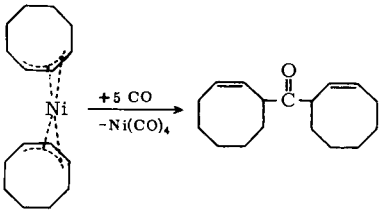
Though all three compounds were ultimately obtained in the crystalline form, considerable difficulty was encountered in the synthesis of those containing 6- and 7-membered rings. Bis-(π-cyclohexenyl)nickel *(25)* decomposes already between −40 °C and −30 °C, whereas bis-(π-cycloheptenyl)nickel *(26)* is stable for short periods at room temperature. Bis-(π-cyclooctenyl)nickel *(27)* is very stable, and nickel separates from crystals kept in a sealed tube only after a number of days.

Examination of Dreiding models shows that all three compounds should be stable if it were simply a question of finding a strain-free arrangement of three adjacent C atoms as $sp^2$ hybrids. The same applies to *(28)*, but instead of this compound, we obtained cyclopentadienyl-π-cyclopentenylnickel *(29)*, first prepared by *E. O. Fischer* and *H. Werner* [29], which is very stable, probably because of the electron-attracting action of the cyclopentadienyl group. A similar stabilizing effect is shown by halogen atoms (see Section 5).



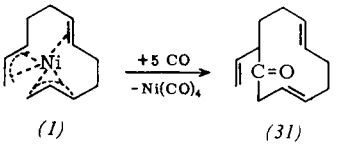
(28) (29)

Bis-(π-allyl)nickel and bis-(π-crotyl)nickel undergo exclusively displacement with CO. With bis-(π-methallyl)-nickel, insertion of CO to form a ketone was observed as a side reaction (see Section 4a), and this insertion becomes the principal reaction (92 % yield) in the case of bis-(π-cyclooctenyl)nickel, the product being the ketone *(30)*.



(27) (30)

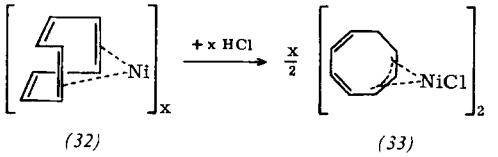
The insertion observed in the case of *(1)*, with formation of *(31)* [1, 12] also belongs to this group of reactions.



(1) (31)

It is not yet known what factors determine whether the reaction of a given system will lead to displacement or insertion, but steric effects could be of some importance, *i.e.* insertion may always occur when linkage to form a diallyl system is sterically opposed.

A special type of cyclic allylnickel compound was obtained by another method. Cyclooctatetraenenickel *(32)* [30] reacts with HCl gas at −80 °C in toluene to form red crystals of π-cyclooctatrienylnickel chloride *(33)*.

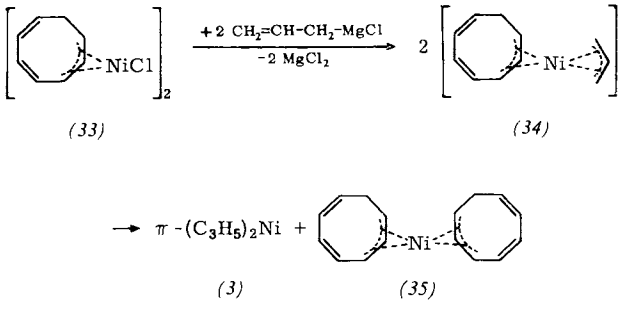


(32) (33)

[29] *E. O. Fischer* and *H. Werner*, Chem. Ber. *92*, 1423 (1959); Tetrahedron Letters *1961*, 17.

[30] *G. Wilke* and *M. Kröner*, unpublished work.

In the course of attempts to obtain π-cyclooctatrienyl-π-allynickel *(34)* by the reaction of *(33)* with allyl Grignard compounds, we obtained a product that decomposed immediately into volatile bis-(π-allyl)nickel and the red crystalline bis-(π-cyclooctatrienyl)nickel *(35)*.

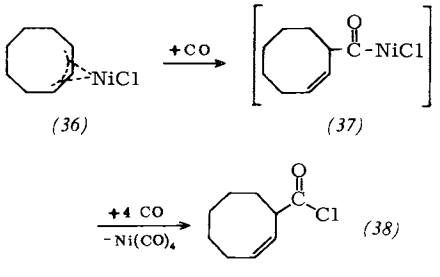


## 5. Allylnickel Halides [31]

In connection with the formation of cyclopentadienyl-π-cyclopentenylnickel *(29)* it has already been pointed out that strongly electron-attracting ligands, such as halogen atoms, can often stabilize an allyl system bonded to the same nickel atom. We have frequently observed that the bis-(π-allyl)nickel complexes have poor or no stability, whereas the corresponding allylnickel halides can be prepared without difficulty.

We shall first describe a simple, general method for the synthesis of allylnickel halides. *E. O. Fischer* and *G. Bürger* [32] were the first to show that $Ni(CO)_4$ reacts with allyl halides, *e.g.* with allyl bromide to form π-allylnickel bromide. The yields leave much to be desired (10 %), evidently because the displaced CO reacts with the π-allylnickel halide by insertion, at least to a great extent [33].

Insertion of this type has been observed particularly with π-cyclooctenylnickel chloride *(36)*, which initially forms an insertion product *(37)*. The nickel reacts with excess of CO to form $Ni(CO)_4$, or else separates as the metal, and the acid chloride *(38)* is formed at the same time.



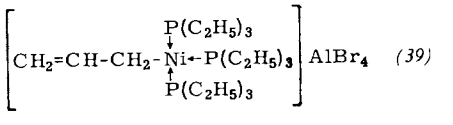
For this reason, $Ni(CO_4)$ is not the ideal starting material for the synthesis of π-allylnickel halides. On the other hand, bis-(cycloocta-1,5-diene)nickel, which can readily be prepared in good yields and in a very pure state, reacts with allyl halides in ether to give almost quantitatively any desired allylnickel halide [31] (COD = cycloocta-1,5-diene).

Equally good results are obtained with cyclododeca-1,5,9-trienenickel, but this complex of nickel(0) is much more difficult to handle. Owing to its greater reactivity, the reaction can be carried out at very low temperatures.

Bis(cyclo-octa-1,5-diene)nickel was used to synthesize a number of π-allylnickel halides (see Table 2). All these complexes are very stable, including those of which the allyllic components do not form stable diallylnickel compounds. The complexes containing 3-, 4-, and 6-membered rings are particularly worthy of mention. Bis-(π-allyl)nickel compounds with cyclopropenyl or cyclobutenyl systems have not so far been obtained, and all attempts to prepare them have yielded elementary nickel and the dimeric hydrocarbons.

The π-allylnickel halides can be used as components for the preparation of highly active catalysts (see Section 6). According to *E. O. Fischer* and *G. Bürger* [32], these compounds ($C_3H_5NiX$ with X = Cl, Br, or I) are dimeric; they behave in the same way as π-allylpalladium chloride. The $^1$H-NMR spectra agree with the π-allyl structure. With phosphines various adducts are formed, in which the perturbation of the allyl group is strong, weak, or absent, depending on the nature and number of phosphine molecules introduced. A general characteristic of these additions is the conversion of the original, readily ether-soluble complexes into sparingly soluble products, and the breaking of the halogen μ-bridges so that the adducts are monomeric in solution. It can be seen from the $^1$H-NMR spectra that the ligands exert an important and interesting effect on the allyl groups. Increasing donation of electrons to the nickel atom causes the π-allyl group to change into a dynamic allyl system, and in the extreme case into a σ-allyl system.

These transitions were observed in the following cases [23]: Whereas the $^1$H-NMR spectrum of a 1:1 adduct of π-allylnickel bromide and triphenylphosphine clearly shows the characteristics of a π-allyl group, the 1:2 adduct $C_3H_5NiBr \cdot 2P(C_2H_5)_3$ gives the spectrum of a dynamic allyl system. Finally, in the 1:3 adduct $C_3H_5NiBr \cdot 3P(C_2H_5)_3$, the symmetrical allyl system "opens up" (σ-allyl system). However, this case[*(39)*] is observed only when the halogen of the allylnickel bromide becomes part of a complex anion.



These transitions depend, not on the quantity, but rather on the basicity of the phosphine used. Although with an excess of triphenylphosphine a 1:2 adduct is formed, its $^1$H-NMR spectrum shows that it contains a π-allyl system. A 1:2 adduct containing a dynamic allyl system is formed only by the more strongly basic triethylphosphine, *i.e.* the electron configuration of the nickel atom becomes similar to that of the zinc atom, which has a completely filled d-shell.

The π-allylnickel halides become catalytically active only when the halogen atoms form part of a complex anion. This situation can generally be brought about with Lewis acids, and particularly aluminum halides. In polar solvents, complexes such as $C_3H_5NiAlCl_4$ are formed, in which the allyl group is bound as a π-allyl system. These complexes also react with phosphines to form 1:1 adducts in which the phos-

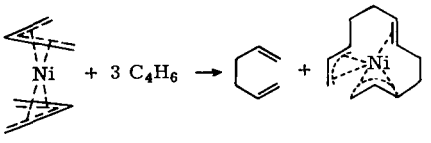
phine molecules clearly interact with the nickel atom. If amines are used instead of phosphines, the complexes dissociate immediately, since aluminum halide-amine complexes are formed preferentially. This behavior illustrates the difference in donor properties of phosphines and amines: whereas phosphines exhibit both donor and acceptor properties, amines are exclusively donors.

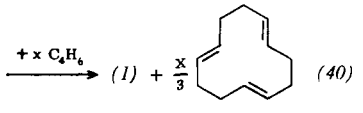
## 6. Catalytic Processes Induced by Allylmetal Complexes [35]

### a) Oligomerization of Butadiene with Bis-(π-allyl)palladium

The synthesis of bis-(π-allyl)nickel *(3)* described in the Introduction was originally intended only to show that two allyl groups can be bonded to a nickel atom, as had been postulated for the intermediate *(1)* in the cyclotrimerization of butadiene. It was subsequently found that bis-(π-allyl)nickel can function as an active catalyst system, *i.e.* as a source of "bare" nickel. Butadiene displaces the allyl groups, which combine to form hexa-1,5-diene, while the butadiene itself forms cyclododecatriene *(40)*.



*(3)* *(1)*

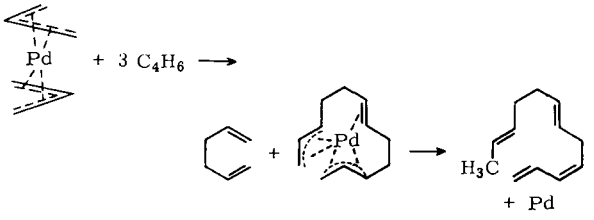


*(40)*

This experiment was repeated later with bis-(π-allyl)-palladium, whose infrared and $^1$H-NMR spectra do not appear at first glance to differ from those of bis-(π-allyl)-nickel. The compounds differ, however, in color, stability, yield, and (understandably, in view of the difference in molecular weight) volatility. Apart from the inner shells, the electronic configurations should be the same, but the crystallographic ionic radii of the metals ($Ni^{2+}$ 0.69 Å; $Pd^{2+}$ 0.80 Å) differ considerably, as do their first ionization energies (Ni 7.61 eV; Pd 8.3 eV).

The catalytic activity of bis-(π-allyl)palladium is comparable to that of the nickel compound at 40 °C, but in this case butadiene does not react to form cyclododecatriene. In a reaction carried out at 40 °C for three days, 30 % of the product consisted of n-dodecatetraenes, which gave only n-dodecane on catalytic hydrogenation. The only other products, apart from traces of vinylcyclohexane, were higher oligomers. At higher temperatures, elementary palladium separated out after a short time.

It can be concluded from the products that the reaction steps involved in the case of bis-(π-allyl)palladium are probably the same as in that of bis-(π-allyl)nickel, *i.e.* butadiene first displaces the allyl groups and is itself trimerized on the palladium. It is possible that an intermediate complex similar to that occurring with the nickel compound is formed, but the chain ends evidently cannot link up in this case to form cyclododecatriene. The subsequent steps are either a hydrogen shift to form dodecatetraene which can react further (to some extent at least, since it is a substituted butadiene) or reaction with further butadiene to form higher oligomers.

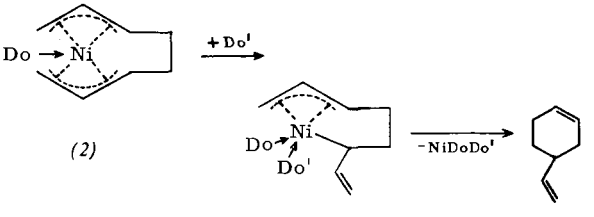


This reaction sequence is supported by the fact that practically the only products are n-dodecatetraenes and higher oligomers. The position of the double bonds in the initially formed dodecatetraene, and hence the position to which the H atom has migrated, cannot be established with certainty, since traces of palladium that separate during the reaction induce migration of double bonds.

It may be very tentatively concluded from this result that the chain ends of the intermediate complex are prevented from comming together because of the greater atomic volume of palladium. The intervention of steric factors is also suggested by the low stability of the "bare" palladium in excess of butadiene, *i.e.* the $C_{12}$ chain does not appear to be such a good ligand system for palladium as for nickel. It must be borne in mind that two separate allyl groups apparently form a more stable complex with palladium than with nickel. Bis-(π-allyl)-platinum, which is still more stable, does not react with butadiene; at higher temperatures, platinum is simply deposited.

By analogy with the dimerization of butadiene on donor-nickel catalysts, experiments were also carried out with bis-(π-allyl)palladium in the presence of donors. As in the case of nickel, it was expected that the donors would activate the catalyst and change the course of the reaction. No appreciable improvement in activity was observed, but the course of the reaction could be fundamentally altered. The greatest effect was obtained with phosphorus trichloride as the donor, added to a solution of bis-(π-allyl)palladium in a molar ratio of 1:1. With this catalyst at 90 °C vinylcyclohexene was practically the only product; control experiments showed the reaction to be catalytic and not thermal.

This result provides a link with the behavior of nickel. We were able to show that donor→nickel catalysts always give vinylcyclohexene when the intermediate *(2)* is

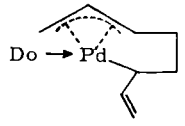


*(2)*

long-lived and when the nickel atom is insufficiently shielded by the donor against attack by other donors, *i.e.* butadiene. Similar intermediate complexes presumably are formed with the palladium compound. However, it must also be borne in mind that the transition

[35] Oligomerization and polymerization of olefins: Belg. Pat. 651 596 (Aug. 7th, 1964), Studiengesellschaft Kohle.

from the π-allyl to the σ-allyl system under the influence of the donor may be easier with palladium than with nickel. In contrast to bis-(π-allyl)nickel it is possible, even with triphenylphosphine, to prepare 1:1 adducts of bis-(π-allyl)palladium in which one of the allyl groups is σ-bonded. The vinylcyclohexene could therefore be derived from the intermediate *(41)*.



*(41)*

The results described give a good indication of the similarities of the bis-(π-allyl) derivatives of nickel and palladium, as well as of the considerable differences between them, which are presumably due in part to steric reasons, but also to a large extent to the difference between the electron shells of the two elements and their interactions with the nuclei.

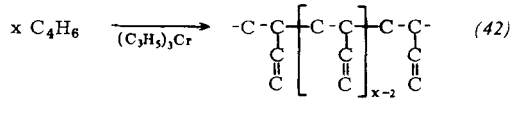
Catalytic reactions proceeding *via* a rapid succession of intermediates separated by low energy barriers appear to be particularly sensitive to influences of the type described, especially since the formation of products such as cyclododecatriene from three molecules of butadiene require that the catalyst atom should exert highly directional forces.

The suitability of "bare" nickel as a matrix for the catalytic formation of cyclododecatriene is shown particularly clearly by the results of X-ray analyses of all-*trans*-cyclododeca-1,5,9-triene and of all-*trans*-cyclododeca-1,5,9-trienenickel(0). The structures, which were determined independently by *Dietrich*[36] (nickel complex) and *Allegra*[37] (hydrocarbon), are practically identical except for the presence of the nickel atom, *i.e.* the nickel atom fits into the center of the ring without altering the cyclododecatriene structure. This is in agreement with the fact that the two compounds appear to form a continuous range of solid solutions, from which the more volatile cyclododecatriene can be sublimed.

### b) Polymerizations with Allylchromium Complexes

Titanium and chromium should form matrices similar to that formed by "bare" nickel for the cyclotrimerization of butadiene, since both elements give catalysts that convert butadiene into cyclododecatriene. However, these matrices must differ sterically, since titanium catalysts give almost exclusively *trans,trans,cis*-cyclododeca-1,5,9-triene, whereas chromium catalysts give mixtures of *all-trans* and *trans,trans,cis*-cyclododecatriene(60:40).

Butadiene cannot be cyclotrimerized with triallylchromium itself. Although this readily soluble complex reacts instantaneously with butadiene, the product is

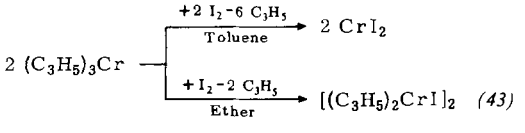


*(42)*

1,2-polybutadiene *(42)*, *i.e.* the reaction is a highly stereoselective polymerization.

Triallylchromium is not a true Ziegler catalyst, since it contains neither halide ions nor organometallic compounds of elements of groups 1 to 3 of the periodic system. Thus the conversion of butadiene into 1,2-polybutadiene by catalysts[38] obtained from chromium acetylacetonate and triethylaluminum is probably due to the much simpler triallylchromium system or the products formed by its reaction with butadiene.

However, the real object of our experiments, *i.e.* the preparation of a cyclotrimerization catalyst, had not been achieved. We had previously isolated the component of a chromyl chloride triethylaluminum catalyst responsible for the formation of cyclododecatriene from butadiene after reaction with 2-butyne in the form of the bis(hexamethylbenzene)chromium cation[39]. The chromium in this complex is formally univalent, and is bonded to a halide ion. In subsequent experiments we replaced one of the three allyl groups in triallylchromium by a halogen atom to obtain a diallylchromium halide as a source of a cyclotrimerization catalyst. Triallylchromium reacts with solutions of elementary iodine at temperatures as low as about 0 °C. The nature of the product depends on the solvent. In non-polar solvents, such as toluene, the only product is $CrI_2$, even when triallylchromium is used in excess. In ether, on the other hand, the reaction proceeds very rapidly with formation of crystalline diallylchromium iodide *(43)*. The diallylchromium halides can also be obtained from triallylchromium and anhydrous hydrogen halides, as was pointed out in Section 2.



*(43)*

Diallylchromium iodide and butadiene in benzene give cyclododecatriene in a yield of about 40 %. The yield can be increased to about 70 % by the use of methylene chloride as solvent or by addition of aluminum halides or alkylaluminum halides. The success of the synthesis appears to depend on disscociation of the dimeric diallylchromium halides.

This is in agreement with the fact that the chloride, which appears to be more strongly associated, gives polymers together with only traces of cyclododecatriene, whereas the iodide, which dissociates more readily, gives considerable quantities of cyclododecatriene. Polar solvents such as methylene chloride or chlorobenzene favor dissociation, and hence also the formation of cyclododecatriene. Aluminum halides or alkylaluminum halides also cause dissociation by formation of the complex $(C_3H_5)_2CrAlX_4$.

Much better catalysts than diallylchromium halides are now available, but this system is making an important contribution to our knowledge of the processes that take place on these catalysts. The cyclotrimerization of butadiene on *(43a)* can be interpreted in the same manner as the cyclotrimerization on "bare" nickel.

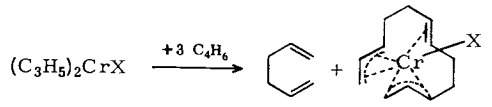
[36] *H. Dietrich* and *H. Schmidt*, Naturwissenschaften *52*, 301 (1965).

[37] *G. Allegra* and *J. W. Bassi*, Atti Accad. naz. Lincei, Rend., Cl. Sci. fisiche, mat. natur. *33*, 72 (1962).

[38] Diolefin polymers: Belg. Pat. 549554 (Juli 14th, 1956), Soc. Montecatini, inventors: *G. Natta* and *L. Porri*.

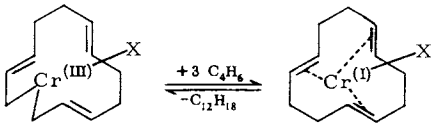
[39] *G. Wilke* and *M. Kröner*, Angew. Chem. *71*, 574 (1959); *M. Kröner*, Dissertation, Technische Hochschule Aachen 1961.

The intermediate *(44)* has not yet been isolated. In the classic formulation, the catalysis would, as in the case of



*(43a)* *(44)*

nickel ($Ni^0 \rightleftarrows Ni^{II}$) be accompanied by a continuous change in the oxidation state of the chromium ($Cr^I \rightleftarrows Cr^{III}$). Thus the matrix provided by the "bare" nickel atom for butadiene is again present in the $Cr^IX$ system.



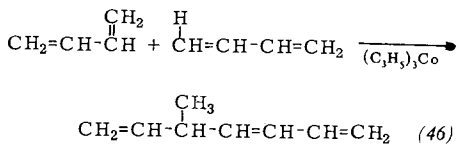
*(45)* *(44a)*

Allylmetal catalysts, like Ziegler catalysts, can induce either polymerizations or oligomerizations, as shown by the above example. Solutions of triallylchromium in *e.g.* hexane polymerize ethylene at 20 °C and *e.g.* 1 to 15 atm, the product being a high-molecular weight polyethylene with nearly the same infrared spectrum as that of Ziegler polyethylene. However, the products have very low solubilities, and therefore probably are cross-linked. The remarkable feature of this result is the fact that ethylene is polymerized under extremely mild conditions by pure soluble triallylchromium in the absence of halide ions or organometallic compounds of elements from groups 1 to 3.

This can be explained in two ways. Either triallylchromium is another new catalyst system for the polymerization of ethylene, or not all views on the mechanism of the Ziegler polymerization of ethylene (which involve the participation of halide ions and the co-operation of the transition metal component with the organometallic component) can be correct.

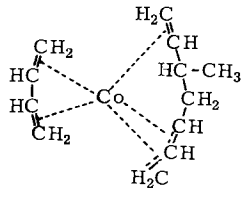
### c) Polymerizations with Allylcobalt Complexes

Two types of reactions are observed with allyl compounds of cobalt, with which butadiene may be either selectively dimerized or stereospecifically polymerized [11]. Triallylcobalt can be prepared at low temperatures in the form of golden-red crystals and is readily soluble in hydrocarbons, but starts to decompose at −40 °C. In the presence of butadiene, it is converted into a much more stable complex, so that solutions containing excess of butadiene can be safely heated to about 10 to 20 °C. Under these conditions, however, the butadiene dimerizes to give in more than 90 % yield 5-methylhepta-1,3,6-triene *(46)*, which we had already prepared for the first time with the aid of other catalysts [40].



*(46)*

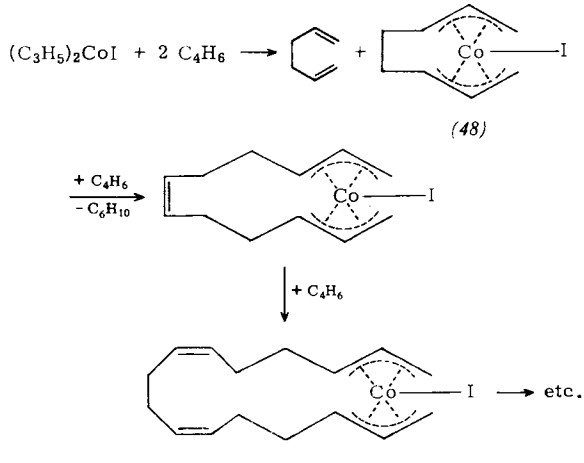
The dimerization proceeds with migration of a hydrogen atom. In the course of investigations on the polymerization of butadiene, *G. Natta, U. Giannini, P. Pino*, and *A. Cassata* [41] isolated the cobalt complex *(47)*. Possibly the same product is formed as an intermediate in the dimerization of butadiene with triallylcobalt.



*(47)*

The second type of reaction on allylcobalt compounds was observed during attempts to replace an allyl group in triallylcobalt by halogen (cf. the experiments with triallylchromium). This replacement can be carried out either with elementary iodine or with hydrogen halides. The same pattern was observed as in the chromium system, *i.e.* the activity of the diallylcobalt halide depends on the halide, the presence or absence of aluminum halide, and the solvent. It appears, therefore, that effects similar to those discussed in connection with chromium are also involved in the case of cobalt. However, the product obtained from butadiene is different; it consists of 1,4-*cis*-polybutadiene together with a little 1,2-polybutadiene; 1,4-*trans*-polybutadiene is absent. The polymerization can also be induced by pure bis(allyl)cobalt iodide. Addition of *e.g.* aluminum bromide leads to a considerable increase in activity and to the formation of essentially pure 1,4-*cis*-polybutadiene. Thus the situation is the opposite of that obtaining for chromium; the pure allyl compound causes dimerization, while the diallylcobalt halides induce polymerization.

The following 1,4-*cis*-polymerization sequence *via* a $C_8$-diallyl system *(48)* has not yet been proved, but it agrees with all the results on the cyclo-oligomerization of butadiene.

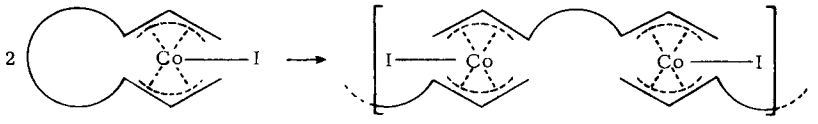


*(48)*

[40] Di- or trimerization of 1,3-diolefins: Austrian Pat. 219580 (Dec. 5th, 1960), Studiengesellschaft Kohle.

[41] *G. Natta, U. Giannini, P. Pino*, and *A. Cassata*, Chim. e Ind. (Milano) *47*, 524 (1965).

It is also quite possible that allyl groups, *i.e.* chain ends, are transferred from one cobalt atom to another so that the ends of a chain may be attached to two different cobalt atoms.



*(49)*

We have studied a number of allyl transfers of this kind[6,13,42]. For example, bis-(π-allyl)nickel exchanges its ligands for those of bis-(π-methallyl)nickel when the two compounds are present in the same solution. Subsequent displacement of the ligands with CO gives 2-methylhexa-1,5-diene as well as hexa-1,5-diene and 2,5-dimethylhexa-1,5-diene. The transfer of allyl groups from one metal to another, *e.g.* from nickel to palladium, has also been observed.

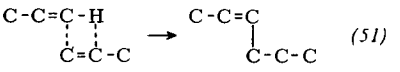
### d) Polymerizations with Activated Allylnickel Halide Systems

The observation that π-allylnickel halides (cf. Section 5) can act as very active catalysts prompted us to carry out a comprehensive study of these complexes[43]. We first observed catalytic activity[30] when ethylene or propylene was brought into contact with cyclooctatrienylnickel chloride under pressure (about 50 atm) at about 70 °C. The reaction proceeded relatively slowly, and the product consisted mainly of dimers, *i.e.* 2-butene or mixtures of hexenes, methylpentenes, and dimethylbutenes. When the activating influence of aluminum halides, first observed with allylchromium halides, was applied to π-allylnickel halides, very active catalysts were obtained with which ethylene, and even propylene, could be dimerized very rapidly between −30 and −40 °C under reduced pressure. The best results were again obtained in polar solvents such as methylene chloride or chlorobenzene. The yields of dimers were 80 to 85 % for a very low catalyst consumption, and 15 to 20 % of the monomer that had reacted was found as higher oligomers (mainly trimers in the case of propylene).

The catalysts are generally prepared by the following method: dicyclooctadienenickel is allowed to react with *e.g.* allyl bromide to form π-allylnickel bromide, which can be isolated in the crystalline form. This is dissolved in *e.g.* chlorobenzene, and an alkylaluminum dihalide, or most simply an aluminum trihalide, is added to the solution in a molar ratio of 1:1 or 1:2. Propylene is passed into the strongly cooled solution, which is deep red in most cases. 80 % of the resulting dimers consists of 2-methylpentenes and 20 % is n-hexenes *(51)*. Modified catalysts give another mixture containing up to 70% of 2,3-dimethylbutenes, together with 2-methylpentenes and traces of n-hexenes.

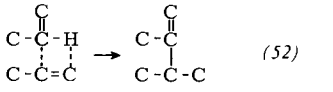
The dimerization can be directed by the addition of phosphines. Thus a catalyst containing triphenylphosphine in a molar ratio Ni:P:Al = 1:1:2 leads to the same products as the catalyst without phosphine, but with a smaller content of higher oligomers. Catalysts containing strongly basic phosphines such as triisopropylphosphine lead to a mixture of 2,3-dimethylbutenes *(52)* and 2-methylpentenes *(50)*. The formation of these two products can be explained as follows: In the first case [*(50)*, *(51)*], a C–H bond of the terminal $CH_2$ group of one propylene molecule is activated and adds to the C=C bond of the second. In the second case [*(50)*, *(52)*], the C–H bond on

*(50)*

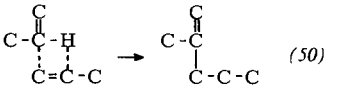


*(51)*

the central C atom of one propylene molecule appears to be activated and to add to the C=C bond of the second.



*(52)*



*(50)*

Model experiments have shown that the dimers initially formed according to the formulae isomerize to varying extents under the influence of the catalysts, the isomerization being confined to the migration of double bonds. These catalytic reactions undoubtedly proceed *via* intermediate complexes in which the monomeric olefins are attached to free coordination positions on the nickel atoms. This is shown by the fact that blockage of these free coordination positions by addition of other donors causes immediate interruption of the catalysis at low temperatures. Thus the simplest of these catalysts (π-allylnickel bromide with $AlBr_3$) can be instantaneously blocked in this way by cycloocta-1,5-diene. The product isolated after the reaction of π-allylnickel tetrabromoaluminate with cyclo-octa-1,5-diene is the complex[23] $\pi\text{-}C_3H_5\cdot Ni\cdot C_8H_{12}\cdot AlBr_4$, which is not catalytically active. In the case of a catalyst system containing Ni:P:Al = 1:1:2, blockage can be effected with a further equivalent of phosphine.

Our experience indicates that this directing influence on the dimerization depends only on the nature (*i.e.* the basicity) of the phosphine. The structure of the dimers formed is not affected by modification of the allyl group or of the Lewis acids used for complex formation with the halide ion.

This method permits the first technically simple preparation of 2,3-dimethylbutenes from the cheap raw material propylene. It provides a technically convenient route to 2,3-dimethylbuta-1,3-diene, which was important some 50 years

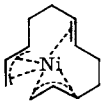
[42] *H. Zimmermann*, Diploma Thesis, Technische Hochschule Aachen 1965.

[43] *G. Wilke* and *B. Bogdanović*, unpublished work; see also [35].

ago, but has since then disappeared from the market because of the excessive cost of production.

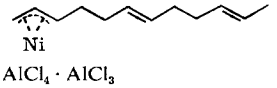
In the pilot plant at our Institute, we have carried out the continuous dimerization of propylene with the new catalysts on a scale of up to 1 ton/24 h. The catalyst used in this work was obtained by a somewhat different method [cf. the cyclotrimerization of butadiene on nickel(0)]: $NiCl_2$ is reduced with $Al(C_2H_5)_3$ in the presence of butadiene; this leads to the formation of the intermediate *(1)* of the cyclotrimerization. The excess of butadiene is removed, and the bis-($\pi$-allyl) system is cleaved with HCl, the diethylaluminum chloride being simultaneously converted into aluminum trichloride. The

$$NiCl_2 + 3\ C_4H_6 + 2\ Al(C_2H_5)_3 \xrightarrow{-2\cdot C_2H_5}$$



$$+\ 2\ (C_2H_5)_2AlCl \xrightarrow{+5\ HCl}$$

*(1)*



$$+\ 4\ C_2H_6$$

$AlCl_4 \cdot AlCl_3$

desired phosphine is added, and the resulting catalyst solution is pumped, together with liquid propylene, into a reactor, from the head of which the product is taken off.

Up to 30000 molecules of propylene (depending on its purity) could be dimerized per nickel atom. An idea of the results obtained in the laboratory and in the pilot plant can be gained from Table 3. Note particularly the considerable reaction rate.

Table 3. Dimerization of propylene with a catalyst based on $C_{12}H_{19}NiAl_2Cl_7$ and a phosphine.

| Pressure [atm] | Temp. [°C] | Throughput [kg $C_3H_6$/g Ni/hour] | Product $C_6$ [%] | Product $>C_6$ [%] |
|---|---|---|---|---|
| 1 | −15 to −20 | 6.25 | 95.5 | 5.4 |
| 4.5–5 | +35 to +40 | 13 | 89.0 | 11.0 |

As a final example of catalytic processes, we mention the polymerization of butadiene with $\pi$-allylnickel halides, which must also be activated with Lewis acids. Butadiene is polymerized very rapidly by $\pi$-allylnickel tetrabromoaluminate, and the product consists mainly of 1,4-*trans*-polybutadiene, together with some 1,2-polybutadiene. The polymerization can be directed. A combination of the catalyst with tricyclohexylphosphine converts butadiene mainly into 1,4-*cis*-polybutadiene. The course of the reaction also depends on the solvent.

## 7. Comparison of Cyclopentadienylmetal and Allylmetal Systems

Allyl-transition metal systems have sometimes been compared with cyclopentadienyl-transition metal systems. Qualitatively there are undoubtedly distinct similarities, but many of the results described above indicate considerable quantitative differences between the two systems. Cyclopentadienylmetal systems are generally characterized by significant stabilities, and hence by low catalytic activities; this is true even if one ignores the extreme case of ferrocene. Allylmetal systems, on the other hand, are not very stable; this property, although a disadvantage from the point of view of synthesis, is of the utmost importance to the high catalytic activity of these complexes. The properties of allylmetal compounds evidently lie between those of stable cyclopentadienylmetal compounds and those of alkyl compounds of transition metals, most of which, if they exist at all, are extremely unstable. The higher stability of the allyl-transition metal compounds may be due to the type of bonding, which is characteristic of the cyclopentadienylmetal compounds; in catalytic processes, however, the transition to the $\sigma$-bonded allyl system, *i.e.* formally to the alkyl-transition metal system, is often important. This intermediate position of the allylmetal compounds is evidently due *inter alia* to two factors: 1. The delocalization energy of the allyl anion according to the HMO theory[44] (0.828$\beta$) is considerably lower than that of the cyclopentadienyl anion (2.472$\beta$), so that the transition to the $\sigma$-bonded system requires much less energy. This takes into account only the ligands, any interactions between these and the metal being disregarded. 2. It was shown for two examples that the catalytic reactions of 1,3-diolefins appear to be associated with a constant change of the oxidation state of the catalyst metal ($Ni^0 \rightleftarrows Ni^{II}$ and $Cr^I \rightleftarrows Cr^{III}$).

However, "redox processes" of this type can take place only if the electron affinities of the metal and the ligand are of roughly the same order of magnitude, so that electrons can easily pass back and forth between the two. This condition seems to be satisfied by the allyl group, but not by the cyclopentadienyl group (high electron affinity). In this connection, the reader is referred to calculations[44] based on the HMO theory, in which the mutual repulsion of the electrons is ignored, and which show that no resonance energy is gained by the transition from the allyl radical to the allyl anion, since the extra electron occupies a non-bonding orbital. In the corresponding transition of the cyclopentadienyl system, on the other hand, the extra electron is accomodated in a bonding orbital, so leading to a gain in resonance energy. Thus the cyclopentadienyl radical has very pronounced electron acceptor properties in relation to metals, whereas the allyl radical does not.

*We are very grateful to Prof. K. Ziegler for the generous support provided for this work, and to Dr. E. G. Hoffmann, Dr. D. Henneberg, and Dr. G. Schomburg, as well as to their co-workers, for the recording and discussion of numerous infrared and proton resonance spectra, mass spectra, and gas chromatograms.*

# The Biosynthesis of Cyclitols

BY DR. H. KINDL, R. SCHOLDA, AND PROF. DR. O. HOFFMANN-OSTENHOF

ORGANISCH-CHEMISCHES INSTITUT DER UNIVERSITÄT WIEN (AUSTRIA)

*Dedicated to Professor Karl Freudenberg on the occasion of his 80th birthday*

*Information has recently been obtained, mainly with the aid of radioactive compounds, about the biosynthesis of various cyclitols. It was found that the most widely occurring cyclitol, meso-inositol, is biosynthesized by a pathway probably common to all organisms, in which the cyclohexane ring is formed by ring closure between the two terminal carbon atoms of* D-*glucose. Cell-free extracts or enzyme systems that catalyse the conversion of* D-*glucose into meso-inositol can be prepared from various biological materials. The biosynthesis of the other hexahydroxycyclohexanes (inositols) involves meso-inositol as an intermediate. A few steps in the conversion of meso-inositol into other inositols have been studied.*

## A. Introduction

The term "cyclitol" was coined by *Micheel*[1], and denotes carbocyclic polyalcohols in which the hydroxy groups are attached to ring carbon atoms. All naturally occurring cyclitols known at present are derivatives of cyclohexane, the most important being the hexahydroxycyclohexanes or inositols.

In 1850, *Scherer*[2] isolated what he believed to be a sugar from muscle extract, and he named this substance muscle sugar or inositol. It was mainly due to the work of *Maquenne*[3] that this compound came to be recognised as hexahydroxycyclohexane. It was given the name *meso*-inositol[4], and its configuration was established almost simultaneously by two groups of workers in 1942[7,8].

The first of the inositols to be discovered, *i.e. meso*-inositol *(1)*[9], is also the one that is most widely distributed in nature; it probably occurs in all organisms, either in the free form or attached to another residue. *Eastcott*[10] showed that *meso*-inositol is an essential constituent of the growth-promoting mixture for yeast known as "bios". It has been suggested that *meso*-inositol may act as a vitamin for mice and other mammals[11], and it is required in the nutrient medium for various strains of cell cultures of human origin[12]. The principal function of *meso*-inositol is probably to act as a building block for the phosphoinositides, the metabolic role of which has not yet been fully elucidated. These phospholipids were recently found to be involved in the adenosine triphosphate-dependent contraction of

[4] Of the nine stereoisomeric hexahydroxycyclohexanes, seven are optically inactive and could therefore be denoted by the prefix *meso*. Although many workers in this field welcomed the suggestion that the substance formerly known as *meso*-inositol should now be called *myo*-inositol [5], this name and the systematic cyclitol nomenclature proposed by the same authors has been generally adopted. The nomenclature of the cyclitols is at present being reviewed by a sub-group of the International Nomenclature Commission for Biochemical Compounds. In the present paper we have used the nomenclature employed in the excellent monography by *Posternak* [6].

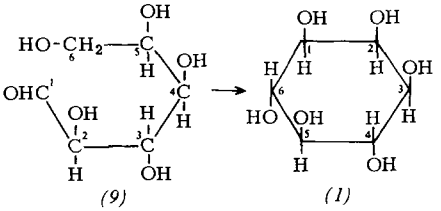
the mitochondria[13]. In general, it must be assumed that cells and organisms requiring *meso*-inositol as a growth promoter or as a vitamin are themselves incapable of producing enough of this substance for the formation of the phosphoinositides.

In higher plants and *e.g.* in bird erythrocytes, *meso*-inositol also occurs as phytic acid (the hexaphosphate of *meso*-inositol) or as salts of this acid. Monomethyl and dimethyl ethers of *meso*-inositol are found in some higher plants and occasionally in the animal kingdom[14].

In contrast to the wide distribution of *meso*-inositol and many of its derivatives, the occurrence of the optically active inositols [D-inositol *(2)* and L-inositol *(3)*] and their methyl ethers [D-pinitol, L-quebrachitol, and L-pinitol] is confined to a few plant families. Scyllitol *(4)* has also been detected both in plants and in animals. Of the cyclitols that are not isomeric with *meso*-inositol and are not derived from an isomer, algae and mussels contain two *C*-methylinositols, mytilitol, and laminitol, while higher plants contain two pentahydroxycyclohexanes, L-viburnitol *(5)*, and D-quercitol *(6)*, and two tetrahydroxycyclohexenes, leucanthemitol *(7)* and conduritol *(8)*.

## B. Biosynthesis of meso-Inositol

*Maquenne* believed that there was a biogenetic relationship between *meso*-inositol and the simple monosaccharides. He pictured the formation of *meso*-inositol as resulting from a kind of aldol condensation between the two ends of a monosaccharide[15]. Since *meso*-inositol has the same configuration as D-glucose *(9)* for four successive carbon atoms, it could be formed by internal aldol condensation of this sugar[16]. As will be shown below, this picture actually appears to fit the facts.



*(9)* *(1)*

The principal techniques used in the study of the biosynthesis of *meso*-inositol are single and multiple labelling with isotopes, the mutant-block method, and kinetic investigations. Radioactive labelling has been used in nearly all the work carried out so far in this field, both with whole organisms and with cell homogenates or enzyme preparations.

According to *Fernandez et al.*[17], D-glucose and its phosphates can be converted into *meso*-inositol by apricot leaves under the influence of ultraviolet radiation. The same authors[18] described an enzyme, "cyclase", which was isolated from the same material and which was reported to bring about the synthesis of *meso*-inositol from D-glucose and from D-glucose phosphates. However, it must be regarded as unlikely that the low conversions involved (less than 1 % for whole plant tissues and even lower for enzyme preparations) should be detectable by a simple colorimetric method, *i.e.* without the use of paper chromatography and without radioactive labelling.

### I. Preliminary Tests Using $^{14}CO_2$ and [$^{14}$C]-D-Glucose

The formation of *meso*-inositol from $^{14}CO_2$ by photosynthesis was first studied in gramineae[19] and leguminosae[20]; 0.07 % of the total radioactivity was incorporated in these experiments. In later work on *Petroselinum*[21], *Pisum sativum*[22] and *Chrysanthemum leucanthemum*[23], much higher activity yields were obtained, the value in the last case being up to 3.5 %. Experiments of this kind give no information about the route followed in the synthesis; they do, however, show the principal sites of biosynthesis, and they also facilitate the choice of plants.

The postulated vitamin function of *meso*-inositol for many animals raises the question of whether the formation of *meso*-inositol in animal tissue is due to biosynthesis in the tissue itself, or is caused by microorganisms. *Halliday* and *Anderson*[24] injected a solution of labelled D-glucose into the leg muscle of rats, and were subsequently able to isolate *meso*-inositol from the whole bodies of the rats with a radiochemical yield of 0.07 %. A similar experiment in which a solution of [u-$^{14}$C]-D-glucose was introduced into the chorion of hens' eggs, which had been pre-incubated for 7 days, led in 64 hours to a 0.01 % incorporation into *meso*-inositol[25]. Human cell cultures (HeLa and KB) that require *meso*-inositol as a growth promoter can synthesize *meso*-inositol from [u-$^{14}$C]-D-glucose. The same is true of mouse fibroblasts, which do not require *meso*-inositol as a growth promoter[26]. In experiments with rats that had been reared germ-free, *meso*-inositol was biosynthesized from labelled D-glucose[27]; 0.03 to 0.08 % of the activity of the D-glucose was built into *meso*-inositol within 3 to 6 hours. This proves that it is the animal tissue, and not the intestinal microflora, that is responsible for the biosynthesis of the *meso*-inositol. In male rats most of the cyclitol is synthesized in the testicle, according to *Eisenberg* and *Bolden*[28].

## II. Incorporation of the Carbon Atoms of D-Glucose into meso-Inositol

In addition to the direct cyclization of D-glucose, there are other biosynthetic routes to be considered, the most important being the formation of *meso*-inositol from two or more smaller fragments. Since evidence for such a mechanism was obtained by *Charalampous* [29] is his work on the biosynthesis of *meso*-inositol in the yeast *Candida utilis*, attempts have been made to distinguish between biosynthesis from smaller components and direct cyclization of D-glucose. These attempts were based on the assumption that in direct cyclization all the carbon atoms of the sugar should be incorporated into *meso*-inositol to the same extent, whereas differences in the extent of incorporation should point to synthesis from fragments.

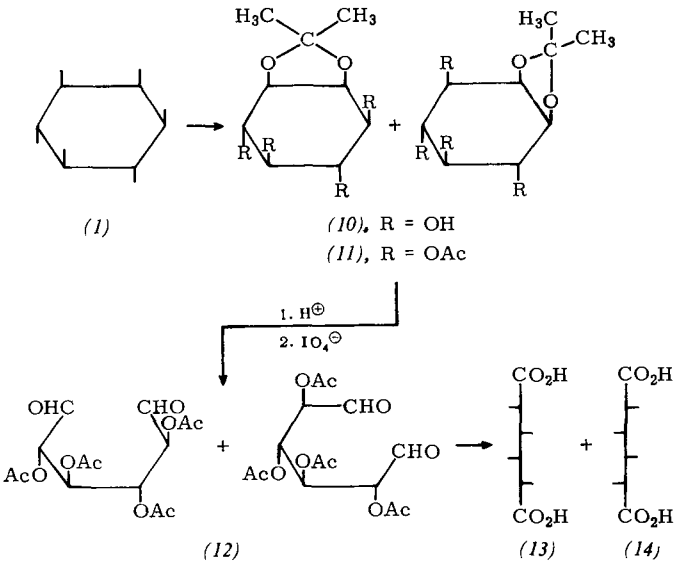
Experiments of this nature with [1-$^{14}$C]-D-glucose, [2-$^{14}$C]-D-glucose, and [6-$^{14}$C]-D-glucose on various subjects gave different results. While *Posternak et al.* [30] and *Imai* [31] observed approximately equal incorporation of the carbon atoms 1, 2, and 6 in rats, *Hauser* and *Finelli* [32] reported that in sections of rat kidney tissue, conversion into *meso*-inositol was 1.8 to 2.4 times as great for [1-$^{14}$C]-D-glucose and [2-$^{14}$C]-D-glucose as for [6-$^{14}$C]-D-glucose. *Charalampous* also found a difference in the case of *Candida utilis* [29]. However, it is doubtful whether the last result can be taken as evidence for the fragmentation of D-glucose before incorporation into *meso*-inositol; it must not be forgotten that both the starting material and the product are subject to metabolism in the whole organism, and even in the section.

## III. Incorporation of Selectively Labelled Precursors and Subsequent Degradation of the meso-Inositol

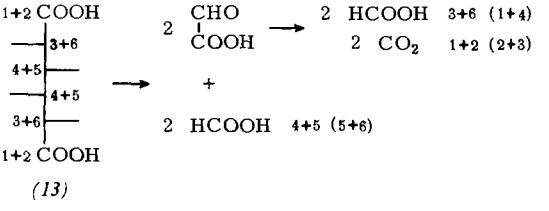
To learn more about the conversion of D-glucose into *meso*-inositol, it was necessary to carry out incorporation tests with selectively labelled D-glucose. The *meso*-inositol formed was then broken down in such a way that the radioactivity of the individual atoms could be determined. Several degradation methods were developed, and in view of their importance in the solution of the problem, we shall now consider these methods critically.

### 1. *Charalampous*' Degradation Method [29]

The *meso*-inositol is degraded to DL-idaric acid *(13)* + *(14)* by a method described by *Dangschat* [8] (Scheme 1a). Further degradation is carried out by a modification of the *Fleury-Lange* method [33] (Scheme 1b): the mixture of stereoisomers is resolved by fractional crystallization of the dibrucine salts, and each of the two sugar acids is oxidized with periodic acid to formic acid and glyoxalic acid. In Scheme 1b, the figures beside the D-idaric acid *(13)* and its oxidation products indicate the original positions of the carbon atoms in the *meso*-inositol; the corresponding figures for L-idaric acid *(14)* are given in brackets.



Scheme 1a. Degradation of *meso*-inositol to DL-idaric acid *(13)* + *(14)*.



Scheme 1b. Periodate oxidation of D- and L-idaric acids.

### 2. *Loewus* and *Kelly*'s Degradation Method [34]

Another selective degradation, using biochemical reactions, was developed by *Loewus* and *Kelly* in the study of the biosynthesis of *meso*-inositol in *Petroselinum*. [1-$^{14}$C]-D-Glucose was injected into leaves, from which *meso*-inositol was isolated two days later; the product contained 0.2% of the total radioactivity.

The labelled *meso*-inositol obtained in this way was allowed to infuse into unripe strawberries, where it was incorporated into the pectin *(16)*, which is formed there in large quantities. An enzyme of microbial origin was then used to degrade the pectin to D-galacturonic acid *(17)*, which was purified by ion-exchange chromatography (gradient elution) [35]. The D-galacturonic acid was reduced with sodium borohydride to L-galactonic acid *(18)*, which was oxidized with permanganate [36].

[29] *F. C. Charalampous* and *P. Abrams*, J. biol. Chemistry *225*, 575 (1957); *F. C. Charalampous*, J. biol. Chemistry *225*, 585, 595 (1957).

[30] *T. Posternak*, *W. H. Schopfer*, and *B. Boetsch*, Arch. Sci. (Genève) *12*, 467 (1959).

[31] *Y. Imai*, J. Biochemistry (Tokyo) *53*, 50 (1963).

[32] *G. Hauser* and *V. Finelli*, J. biol. Chemistry *238*, 3224 (1963).

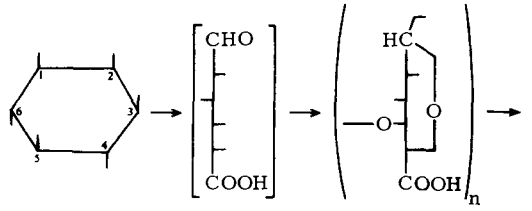
[33] *P. Fleury* and *J. Lange*, J. Pharmac. Chim. *17*, 313 (1933).

[34] *F. A. Loewus* and *S. Kelly*, Biochem. biophys. Res. Commun. *7*, 204 (1962).

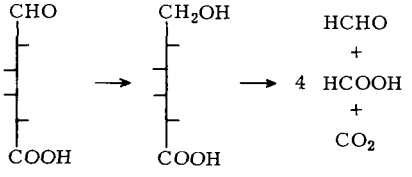
[35] *F. A. Loewus* and *S. Kelly*, Arch. Biochem. Biophys. *102*, 96 (1963).

[36] *C. G. Seegmiller*, *B. Axelrod*, and *R. M. McCready*, J. biol. Chemistry *217*, 765 (1955).

The enzymatic hydrolysis of pectin formed from [2-$^{14}$C]-*meso*-inositol gave [5-$^{14}$C]-galacturonic acid [37]; furthermore, enzymes that degrade *meso*-inositol to D-glucuronic acid occur at least in animal tissue [38] and in one micro-organism [39]. It is very probable, therefore,



*(1)* *(15)* *(16)*



*(17)* *(18)*

that the route from *meso*-inositol to pectin in strawberries involves conversion of the former into D-glucuronic acid *(15)* followed by epimerization to D-galacturonic acid. This establishes the position at which the ring opens; biosynthesis from [1-$^{14}$C]-D-glucose by the route postulated by *Maquenne* and *Fischer* should lead to [6-$^{14}$C]-*meso*-inositol, the degradation of which should proceed *via* [1-$^{14}$C]-D-glucuronic acid to yield [6-$^{14}$C]-L-galactonic acid. After periodate oxidation of the L-galactonic acid, in fact, 81% of the activity was found in the formaldehyde and 11% in the $CO_2$. This randomization of activity must be at least partly due to the biological degradation *via* pectin.

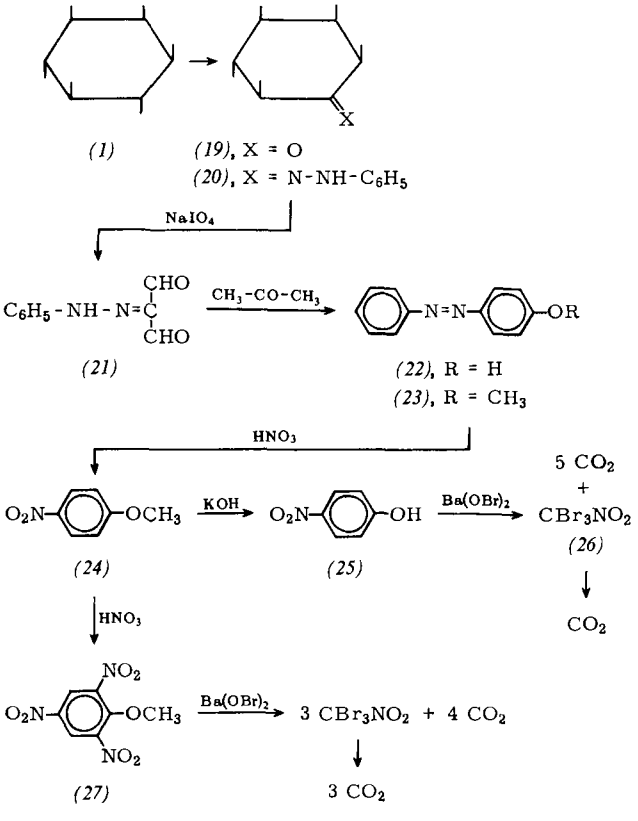
The same degradation route was used to elucidate the biosynthesis of *meso*-inositol in cell-free extracts of animal origin. *Eisenberg* and *Bolden* [40] were able to obtain homogenates from rat testicles that convert D-glucose into *meso*-inositol. These homogenates were incubated for 2 hours with labelled D-glucose. The *meso*-inositol formed was isolated and purified *via* the hexa-acetate. The L-galactonic acid *(18)* obtained by *Loewus-Kelly* degradation was converted into the amide, which gave only 3 moles of formic acid on oxidation with periodate. C-2 of the *meso*-inositol could also be determined indirectly in this way.

When [1-$^{14}$C]-D-glucose was used, 80% of the activity was found in C-6; when [2-$^{14}$C]-D-glucose was introduced, 88% of the activity was found in C-3, C-4, and C-5, and 95% in C-2, C-3, C-4, and C-5, while with [6-$^{14}$C]-D-glucose, 96% of the activity was discovered on C-1. It can be concluded from these results that the *meso*-inositol must be synthesized from D-glucose without fragmentation of the latter, as proposed by *Maquenne* and *Fischer*.

### 3. *Kindl* and *Hoffmann-Ostenhof*'s Degradation Method [42]

Another selective degradation method was developed in our own laboratory for the study of the biosynthesis of *meso*-inositol in mustard plants *(Sinapis alba)*. This method is based on chemical reactions only, and should therefore be free from any inaccuracies due to metabolic processes.

The starting substance in this method is a cyclose (inosose); since all cyclitols can be readily converted into cycloses, the method is generally applicable. In biological or catalytic oxidation ($Pt/O_2$), axial OH groups are preferentially converted into keto groups; nitric acid, on the other hand, converts *meso*-inositol into a racemic mixture of *meso*-inosose-4 and *meso*-inosose-6. The phenylhydrazone *(20)* of the cyclose [*e.g.* (±)-*epi-meso*-inosose *(19)*] is prepared and then oxidized to mesoxaldialdehyde phenylhydrazone *(21)*. To separate the central carbon atom of this $C_3$ fragment from the other two carbon atoms, *(21)* is condensed with acetone



*(1)* *(19)*, X = O; *(20)*, X = N-NH-$C_6H_5$

*(21)* *(22)*, R = H; *(23)*, R = $CH_3$

*(24)* *(25)* *(26)* *(27)*

to obtain *p*-hydroxyazobenzene *(22)*, and this is methylated and then oxidized to *p*-methoxynitrobenzene *(24)*. The *p*-hydroxynitrobenzene *(25)* obtained by demethylation of *(24)* is degraded to tribromonitromethane *(26)*, which contains the central carbon atom of the $C_3$ fragment. Its radioactivity can be measured after oxid-

[41] *F. Eisenberg, Jr.*, *A. H. Bolden*, and *F. A. Loewus*, Biochem. biophys. Res. Commun. *14*, 419 (1964).

[42] *H. Kindl* and *O. Hoffmann-Ostenhof*, Biochem. Z. *339*, 374 (1964); Abstr.6th intern.Congr.Biochem.NewYork 1964, p. 515.

ation to barium carbonate. If, on the other hand, the radioactivity is expected in the two outer carbon atoms of the $C_3$ fragment, the *p*-hydroxynitrobenzene *(24)* may be degraded *via* 2,4,6-trinitroanisole *(27)*.

Using this method, it was possible to show that in *Sinapis alba* [1-$^{14}$C]-D-glucose gives a *meso*-inositol (0.2% incorporation) in which the radioactivity is located on C-6 (or C-4) [42]. [2-$^{14}$C]-D-Glucose is converted into [5-$^{14}$C]-*meso*-inositol in the same plant [43].

Although *Loewus* and *Kelly*'s findings for *Petroselinum* [34] and our own findings for *Sinapis alba* [42,43] were obtained by different methods, both sets of results indicate that in higher plants, *meso*-inositol is formed by ring closure between C-1 and C-6 of D-glucose, as suggested by *Maquenne* and *Fischer*.

We have recently been able to show that [u-$^{14}$C]-*scyllo*-*meso*-inosose ([u-$^{14}$C]-*meso*-inosose-2) is incorporated into *meso*-inositol to the extent of 25% in the leaves of *Sinapis alba* and to the extent of 40% in the leaves of *Chrysanthemum leucanthemum* [44]. This suggests (but does not prove) that this cyclose may be a precursor in the synthesis of *meso*-inositol in higher plants. A cell-free extract that converts D-glucose into *meso*-inositol has been prepared from mustard plants [45].

Since the experiments on rat-testicle extracts [41], on *Petroselinum* [34], and on *Sinapis alba* [42,43] showed that in both animal tissues and higher plants, *meso*-inositol is formed from D-glucose by linkage of the terminal carbon atoms of the sugar, it was of interest to consider whether this process takes a completely different course in the yeast *Candida utilis*, as had been postulated by *Charalampous* [29].

*Chen* and *Charalampous* [46] recently obtained an enzyme preparation from *Candida utilis* that converts D-glucose and D-glucose 6-phosphate into *meso*-inositol. When the substrate is D-glucose, this reaction occurs only if adenosine triphosphate (ATP), nicotinamide adenine nucleotide (NAD), and $Mg^{2+}$ are present as cofactors; only NAD and $Mg^{2+}$ are required for the conversion of D-glucose 6-phosphate into *meso*-inositol.

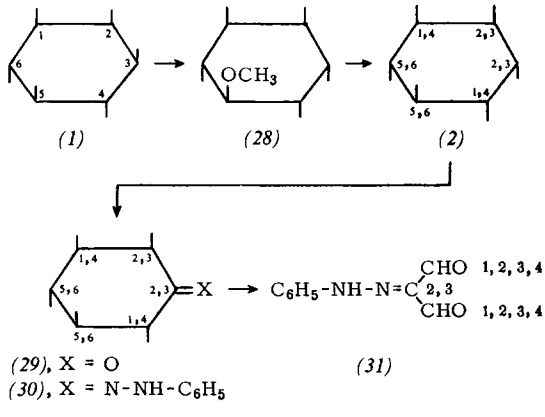
We were able to confirm these results, and we then used this enzyme preparation (with small modifications in its production) for the elucidation of the synthesis of *meso*-inositol. Using our degradation method we were able to show that the enzyme preparation converts [2-$^{14}$C]-D-glucose into [5-$^{14}$C]-*meso*-inositol [47]. Further investigations [48] using differently labelled D-glucose preparations and [1-$^{14}$C]-D-glucose 6-phosphate showed that with D-glucose 6-phosphate, the yield of *meso*-inositol was from 3 to 5 times as great as with D-glucose; moreover, the radioactivity was much less randomized in *meso*-inositol from D-glucose 6-phosphate than in that from D-glucose. This agrees with the results obtained by *Chen* and *Charalampous* [46], and indicates that D-glucose 6-phosphate or a substance formed from it is closer to *meso*-inositol in the biosynthetic pathway than D-glucose itself.

The *meso*-inositol obtained from [1-$^{14}$C]-D-glucose 6-phosphate was degraded *via* mesoxaldialdehyde phenylhydrazone *(21)* and *p*-hydroxynitrobenzene *(25)* (Table 1); 96% of the activity could be traced in this way

Table 1. Distribution of radioactivity in the degradation products of *meso*-inositol synthesized from [1-$^{14}$C]-D-glucose 6-phosphate (A) or [6-$^{14}$C]-D-glucose (B) with enzyme preparations from *Candida utilis* [48]; cf. Scheme 3.

| Compound | Relative specific activity [*(22)* = 1.00] | |
|---|---|---|
| | A | B |
| (±)-*epi*-*meso*-Inosose *(19)* | 2.17 | — |
| *scyllo*-*meso*-Inosose | — | 1.06 |
| (±)-*epi*-*meso*-Inosose phenylhydrazone *(20)* | 2.10 | — |
| *scyllo*-*meso*-Inosose phenylhydrazone | — | 1.03 |
| Mesoxaldialdehyde phenylhydrazone *(21)* | 1.06 | 0.97 |
| *p*-Hydroxyazobenzene *(22)* | 1.00 | 1.00 |
| *p*-Methoxyazobenzene *(23)* | 1.06 | 0.98 |
| *p*-Methoxynitrobenzene *(24)* | 1.06 | 0.96 |
| *p*-Hydroxynitrobenzene *(25)* | 1.14 | — |
| 2,4,6-Trinitroanisol *(27)* | — | 1.01 |
| $BaCO_3$ from C-1 of *(25)* | 1.06 | — |
| $BaCO_3$ from C-2 and C-6 of *(25)* | 0.02 | — |
| $BaCO_3$ from C-4 of *(27)* | — | 0.08 |
| $BaCO_3$ from C-3 and C-5 of *(27)* | — | 0.98 |

to C-6 or C-4 of the *meso*-inositol. To distinguish between these positions, another variant of the degradation method was used. The *meso*-inositol obtained from sugar phosphate labelled on C-1 was infused into the leaves of *Trifolium incarnatum*, which converts *meso*-inositol into D-pinitol *(28)* (4-*O*-methyl-D-inositol) [49]. The D-pinitol was isolated and demethylated to D-inositol *(2)*, and this was then oxidized to *meso*-inosose-3 *(29)*. On periodate oxidation, the phenylhydrazone *(3)* of this inosose yields the fragment mesoxaldialdehyde phenylhydrazone *(31)*, which represents C-1, C-2, C-3, and C-4 of the original *meso*-inositol.



*(1)* *(28)* *(2)*

*(29)*, X = O
*(30)*, X = N-NH-$C_6H_5$

*(31)*

In the degradation of the *meso*-inositol obtained from [1-$^{14}$C]-D-glucose 6-phosphate, this fragment *(31)* was inactive. This, together with the findings reported above proves that C-1 of the D-glucose 6-phosphate becomes C-6 of the *meso*-inositol.

The *meso*-inositol obtained from [6-$^{14}$C]-D-glucose was degraded *via meso*-inosose-2, mesoxaldialdehyde phenyl-

hydrazone *(21)*, and 2,4,6-trinitroanisole *(27)*. The radioactivity was located on C-1 (or C-3) (Table 1).

Thus it has been shown that C-1 of the D-glucose becomes C-6 of the *meso*-inositol, C-2 of the D-glucose becomes C-5 of the *meso*-inositol, and C-6 of the D-glucose becomes C-1 (or C-3) of the *meso*-inositol. There can therefore be little doubt that the biosynthesis of *meso*-inositol in *Candida utilis* also proceeds by direct ring closure between the ends of the sugar molecule. This seems to prove that this pathway is the general route for the biosynthesis of *meso*-inositol. Moreover, *Chen* and *Charalampous* [50] recently deduced the same reaction mechanism from new experiments with their enzyme preparation from *Candida utilis*, and consequently withdrew their earlier conclusions [29].

### IV. The Mechanism of Ring-Closure

Since NAD takes part in the reaction, a redox step should be involved. On grounds of analogy, the ring closure could proceed by an aldol or an acyloin condensation.

Experiments with the enzyme preparation from *Candida utilis* in $^3H_2O$ appear to rule out the possibility of an acyloin condensation. Incorporation experiments with [6-$^3H_2$,6-$^{14}$C]-D-glucose, both in whole plants and with the enzyme extract from *C.utilis*, led to a change in the $^3H/^{14}C$ ratio, which points to an aldol condensation [50a].

*Chen* and *Charalampous* [50b] recently reported the accumulation of *meso*-inositol 1-phosphate from systems of low $Mg^{2+}$ content with the enzyme preparation from *C.utilis*; this phosphate is thought to be an intermediate in the synthesis of *meso*-inositol.

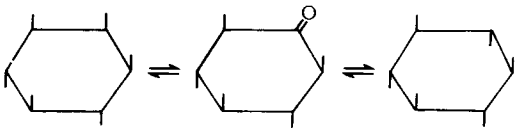
Thus the most likely route for the conversion of D-glucose into *meso*-inositol is as follows (intermediates that have not yet been isolated are printed in brackets):

D-glucose → D-glucose 6-phosphate → [5-keto-D-glucose 6-phosphate] → [1-phospho-*meso*-inosose-2] → *meso*-inositol 1-phosphate → *meso*-inositol.

## C. Biosynthesis of the other Hexahydroxycyclohexanes and their Methyl Ethers

### I. Scyllitol

Since the ingestion of large quantities of *meso*-inositol in the food leads to marked scyllitoluria in human beings, *Helleu* [51] suggested that *meso*-inositol may be converted into scyllitol *(4)* in the body. This was confirmed for rats by experiments with labelled precursors [52]; an equilibrium between the two cylitols evidently exists in the organism, with *meso*-inosose-2 *(31)* as an intermediate. Labelled *meso*-inositol is converted into scyllitol *(4)* in the rat, and labelled scyllitol is converted into *meso*-inositol. When labelled *meso*-inosose-2 *(31)* was introduced, the activity was transferred in varying proportions to both the *meso*-inositol and the scyllitol; the radiochemical yields for *meso*-inositol varied between 2.9 and 12.3 %, while that for scyllitol varied between 0.9 and 46.1 %.



*(1)* *(31)* *(4)*

Similar relationships seem to exist in plants containing scyllitol. When radioactive *meso*-inositol was infused into the leaves of *Calycanthus occidentalis*, the extent to which it was incorporated into scyllitol was almost two orders of magnitude greater than the extent of incorporation of labelled D-glucose [53]; approximately 8 % of *meso*-inosose-2 *(31)* was converted into *meso*-inositol, and 30 % into scyllitol. However, these processes appear to depend on the season; thus incorporation into scyllitol is observed only in spring, while in autumn only the *meso*-inositol becomes radioactive.

### II. D-Inositol and D-Pinitol

We have recently studied the biosynthesis of D-inositol *(2)* and of D-pinitol *(28)* in *Trifolium incarnatum*. This plant was known to contain D-pinitol [54], and small quantities of *meso*-inositol, D-inositol, and sequoyitol (5-*O*-methyl-*meso*-inositol) had also been detected by paper chromatography [49,55]. Labelled D-glucose, D-galactose, and *meso*-inositol were introduced into the plant to find whether it possesses special biosynthetic pathways for D-inositol and D-pinitol, or whether both are formed from *meso*-inositol [55,56]. *Meso*-inositol was incorporated into D-pinitol to a greater extent than was the monosaccharide, *i.e.* *meso*-inositol or a substance formed from it is a direct precursor of the D-pinitol.

The individual steps of the route leading from *meso*-inositol to D-pinitol have also been elucidated [57,58].

[54] *V. Plouvier*, C. R. hebd. Séances Acad. Sci. Paris *230*, 125 (1950).

[55] *R. Scholda*, *G. Billek*, and *O. Hoffmann-Ostenhof*, Hoppe-Seylers Z. physiol. Chem. *335*, 180 (1964).

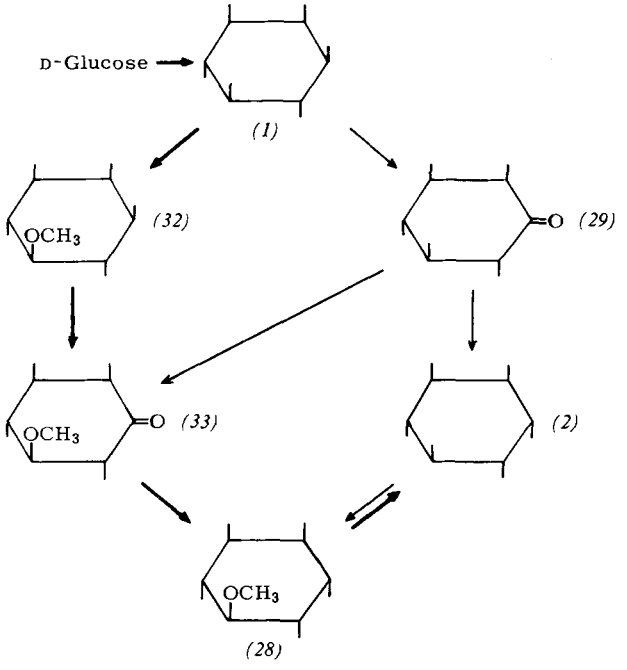
[56] *R. Scholda*, *G. Billek*, and *O. Hoffmann-Ostenhof*, Hoppe-Seylers Z. physiol. Chem. *337*, 277 (1964).

[57] *R. Scholda*, *G. Billek*, and *O. Hoffmann-Ostenhof*, Mh. Chem. *94*, 1311 (1964).

[58] The labelled D-pinitol and sequoyitol preparations used in these investigations were obtained by photosynthesis with $^{14}CO_2$ in the same plant; labelled D-inositol was prepared by demethylation of D-pinitol. The biosynthesized radioactive sequoyitol could be converted in good yield into 5-*O*-methyl-*meso*-inosose-3 by catalytic oxidation with air [59].

[59] *K. Heyns* and *H. Paulsen*, Chem. Ber. *86*, 833 (1953); *L. Anderson* and *G. Post*, Abstr. 124th Meeting Amer. chem. Soc. 1958, p. 12D.

Labelled *meso*-inositol is partly incorporated into D-inositol and sequoyitol. Either of these two cyclitols could thus be an intermediate in the conversion of *meso*-inositol into D-pinitol, but each would rule the other out.



Scheme 2. Possible routes for the synthesis of cyclitols in *Trifolium incarnatum*.

It was therefore necessary to decide whether the methyl group enters the molecule before, during, or after the epimerization, *i.e.* whether the substrate for the methylation is *meso*-inositol, *meso*-inosose-3 *(29)*, or D-inositol *(2)*.

Table 2. Incorporation of labelled compounds into D-inositol and D-pinitol in the leaves of *Trifolium incarnatum* [55—57].

| Precursor | Incorporation [%] into | |
|---|---|---|
| | D-pinitol | D-inositol |
| D-Glucose | 0.72 | — |
| D-Galactose | 0.52 | — |
| *meso*-Inositol | 14.2 | 2.1 |
| D-Inositol | 0.1 | (80.7) |
| Sequoyitol | 72.8 | — |
| 5-*O*-Methyl-*meso*-inosose-3 | 31.2 | 6.9 |
| *meso*-Inosose-3 | 1.75 | 50.2 |
| D-Pinitol | (25.8) | 5.9 |

It can be seen from Table 2 and Scheme 2 that labelled D-inositol is not incorporated into D-pinitol. On the other hand, both sequoyitol *(32)* and 5-*O*-methyl-*meso*-inosose-3 *(33)* are converted into D-pinitol in excellent yields. Moreover, when labelled D-pinitol is introduced into the plant, it undergoes partial demethylation to form D-inositol. This establishes the biogenetic relationships of the cyclitols in *Trifolium incarnatum* as those indicated by the heavy arrows in Scheme 2.

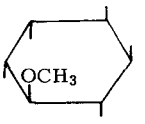
The enzyme system that catalyses the epimerization of sequoyitol to D-pinitol[60] seems to consist of two specific oxidoreductases, the actions of which can be represented by the equations:

sequoyitol + NAD ⇌ 5-*O*-methyl-*meso*-inosose-3 + NADH+H$^+$

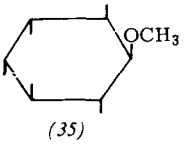
5-O-methyl-*meso*-inosose-3 + NADPH + H$^+$ ⇌ D-pinitol + NADP

### III. L-Inositol, L-Pinitol, and L-Quebrachitol

Experiments on the biosynthesis of L-inositol *(3)* and its methyl ethers have been carried out on two types of *Artemisia*. The common mugwort *(Artemisia vulgaris)* contains L-quebrachitol *(35)*[61]; L-inositol and traces of L-pinitol have also been detected by paper chromatography[62]. In tarragon *(A.dracunculus)*, on the other hand, the most abundant of the cyclitols is L-pinitol *(34)*[61], while L-inositol, L-quebrachitol, and sequoyitol



*(34)*



*(35)*

are also present in varying amounts[62]. When labelled *meso*-inositol is infused into the leaves of both plants, the quantities of radioactive cyclitols found are much larger than after the introduction of labelled D-glucose (Table 3). This suggests that *meso*-inositol or a substance derived from it is an intermediate in the synthesis of L-inositol and its methyl ether. As in the work on the

Table 3. Incorporation of labelled compounds into the cyclitols of *Artemisia vulgaris* and *Artemisia dracunculus* after infusion into the leaves of these plants [62, 63].

| Precursor | Incorporation into | [%] |
|---|---|---|
| *Artemisia vulgaris* | | |
| D-Glucose | *meso*-Inositol | 0.027 |
| | L-Inositol | 0.018 |
| | L-Quebrachitol | 0.27 |
| *meso*-Inositol | L-Inositol | 0.82 |
| | L-Quebrachitol | 13.6 |
| L-Inositol | L-Quebrachitol | 12.4 |
| *Artemisia dracunculus* | | |
| D-Glucose | *meso*-Inositol | 0.02 |
| | L-Inositol | 0.035 |
| | Sequoyitol | 0.02 |
| | L-Pinitol | 0.17 |
| *meso*-Inositol | L-Inositol | 1.31 |
| | Sequoyitol | 1.60 |
| | L-Pinitol | 1.62 |
| Sequoyitol | L-Pinitol | 0.05 |
| L-Inositol | L-Pinitol | 8.04 |

biosynthesis of D-pinitol, the route from *meso*-inositol to the two L-inositol methyl ethers was studied with the aid of labelled forms of the likely intermediates[63]. In contrast to the formation of D-pinitol in *Trifolium*, the epimerization precedes the methylation in the formation

[60] *G. J. Kremlicka*, and *O. Hoffmann-Ostenhof*, Hoppe-Seylers Z. physiol. Chem., in press.

[61] *V. Plouvier*, Ann. pharmac. franc. *7*, 192 (1949); C. R. hebd. Seances Acad. Sci. Paris *243*, 1913 (1956).

[62] *R. Scholda*, *G. Billek*, and *O. Hoffmann-Ostenhof*, Mh. Chem. *95*, 541 (1964).

[63] *R. Scholda*, *G. Billek*, and *O. Hoffmann-Ostenhof*, Mh. Chem. *95*, 1305 (1964).

of L-inositol methyl ethers; in both types of *Artemisia*, labelled L-inositol *(3)* is incorporated into the corresponding methyl ether in a high radiochemical yield (Table 3).

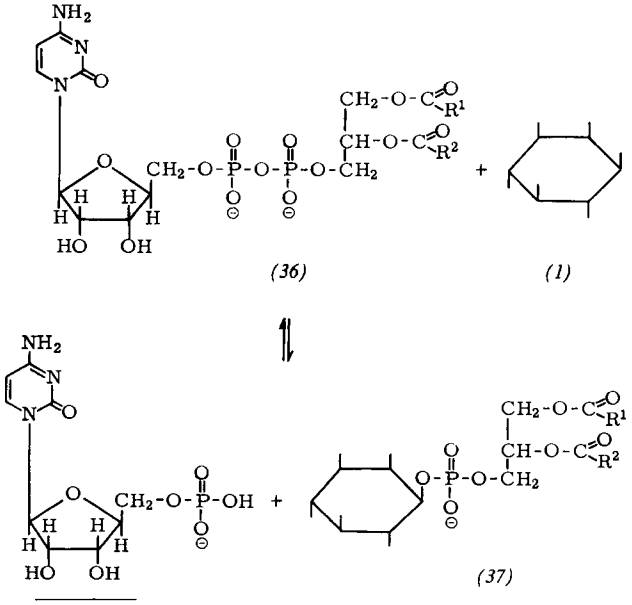
As for the biosynthesis of D-pinitol in *Trifolium*, these results indicate that both types of *Artemisia* contain an epimerase system consisting of two dehydrogenases, and that this enzyme system attacks the *meso*-inositol directly and converts it *via* *meso*-inosose-1 into L-inositol, which is then methylated, as also appears to be proved by the fact that sequoyitol is not incorporated into L-pinitol in *A. dracunculus*.

Thus it seems that the naturally occurring isomers of *meso*-inositol and their methyl ethers are not biosynthesized by independent routes. The first step in every case appears to be the cyclization of D-glucose; only after *meso*-inositol or a very close precursor of the latter has been formed, further rearrangement to give the isomers of *meso*-inositol takes place. No evidence has ever been found to suggest the formation of such a substance directly from D-glucose or from any other monosaccharide, although ring closures of this nature would be feasible.

## D. Phosphorylated Derivatives of meso-Inositol

### I. Phosphoinositides[64]

The route by which *meso*-inositol is incorporated into the phosphoinositides has now been largely established. It is known that this process does not involve *meso*-inositol phosphates as intermediates, although such substances can be detected in the organism[65]. In the synthesis of phosphoinositides, a cytidine diphosphate diglyceride [CDP diglyceride *(36)*] is first formed from phosphatidic acid and cytidine triphosphate (CTP);

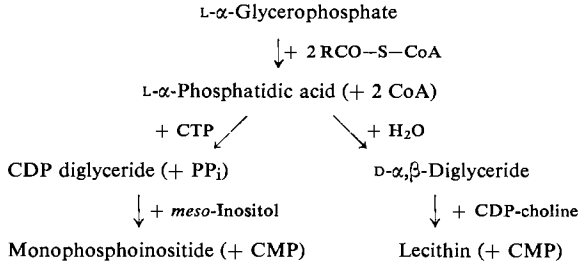


*(36)* *(1)*

*(37)*

this then reacts with free *meso*-inositol to form the monophosphoinositide *(37)* with loss of cytidine monophosphate (CMP). The enzymes responsible for this series of reactions are known[66].

Thus the synthesis of the phosphoinositides is different from that of phospholipids containing nitrogen. In the formation of lecithins and cephalins, the nitrogen bases choline and ethanolamine (the position of which in the phospholipid molecule is formally analogous to that of *meso*-inositol) are first phosphorylated, and the products then react with CTP to form CDP-choline and CDP-ethanolamine, respectively. α,β-Diglyceride, which is formed by hydrolysis of phosphatidic acid, reacts with both compounds to form lecithin and cephalin, with loss of CDP. The enzymes responsible for these reactions are also known[67]. The syntheses of phosphoinositides and lecithins are compared in Scheme 3.



Scheme 3. Biosyntheses of phosphoinositides and of lecithin.

The higher phosphoinositides (diphospho- and triphosphoinositides) are probably formed by stepwise phosphorylation of monophosphoinositide, the phosphate donor being ATP[68–70].

### II. Phytic Acid

Phytic acid, the hexaphosphate of *meso*-inositol, occurs mainly as its calcium and magnesium salts in higher plants, but is also present in the erythrocytes of birds and reptiles. This substance, which supposedly acts as a phosphate reserve, has been known for some time, but very little is known about its biosynthesis. According to *Ahuja*[21] and our own work[71], *meso*-inositol is incorporated into phytic acid in higher plants, but it seems that *meso*-inositol is not a direct precursor of phytic acid: [$^3$H]-*meso*-inositol is not incorporated into phytic acid as an intact unit[71].

The incorporation of radioactive phosphate into phytic acid in birds' erythrocytes proceeds very slowly in the organism[72,73]. No attempt seems to have been made so far to find whether free *meso*-inositol is a direct precursor of phytic acid in this case. Whereas the erythrocytes of mammals always con-

tain relatively large quantities of 2,3-diphosphoglyceric acid, this substance appears to be replaced by phytic acid in the red blood cells of birds.

### E. Other Naturally Occurring Cyclitols

Nothing is known as yet about the biosynthesis of the *C*-methylinositols mytilitol (1-*C*-methylscyllitol) and laminitol (6-*C*-methyl-*meso*-inositol), which occur in algae and in mussels.

Moreover, no detailed studies have been carried out on the pentahydroxycyclohexanes L-viburnitol *(5)* and D-quercitol *(6)* or on the tetrahydroxycyclohexenes leucanthemitol *(7)* and conduritol *(8)*. On phylogenetic grounds, *Plouvier*[74] postulated that in *Anthemideae*, in which L-inositol and its methyl ethers occur together with L-viburnitol and leucanthemitol, L-inositol is a precursor of the other substances. However, preliminary work in our laboratory[75] seems not to substantiate this, but indicates instead that the pentahydroxycyclohexanes are biosynthesized by a special route, which differs from that of *meso*-inositol (and hence also from that of L-inositol) at least in the last step. Labelled *meso*-inositol infused into plants containing L-viburnitol, D-quercitol, or leucanthemitol was not incorporated into these substances, although *meso*-inositol can be epimerized directly to L-inositol.

*The work carried out in our laboratory was generously supported by contributions from the Ludwig-Boltzmann Gesellschaft, Vienna, and from Sektion IV (Verstaatlichte Betriebe) des Bundeskanzleramts der Republik Österreich, for which we would like to express our gratitude.*

# The Synthesis of Oligo- and Polynucleotides

BY PROF. DR. F. CRAMER

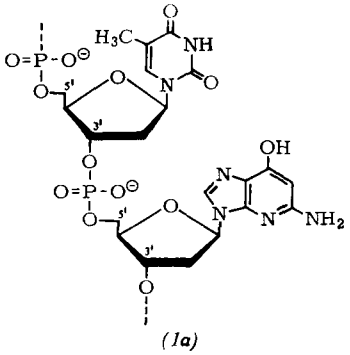
MAX-PLANCK-INSTITUT FÜR EXPERIMENTELLE MEDIZIN, CHEMISCHE ABTEILUNG, GÖTTINGEN (GERMANY)

*Dedicated to Professor K. Freudenberg, one of the pioneers of the biopolymers*[1], *on his 80th birthday.*

*Problems and results of the synthesis of oligonucleotides are reviewed. The central role of the nucleic acids in biochemistry is a challenge to synthesize nucleic acids of known base sequence and chain length. Oligomers with various sequences of up to 12 members and homo-oligomers with a maximum chain length of 30 nucleotides can be obtained by chemical synthesis. The enzymatic synthesis of ribonucleic acids can be directed in such a way that polynucleotides with definite sequences are produced.*

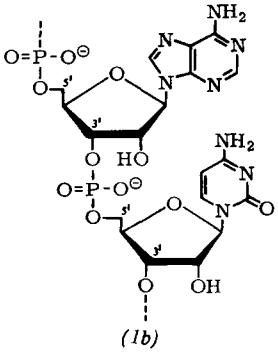
## 1. Structure and Nomenclature

Nucleic acids are mixed polyesters; two basic units are represented by the formulae *(1a)* and *(1b)*.



*(1a)*

Deoxyribonucleic acid (DNA)
Symbol: d-...pTpG...



*(1b)*

Ribonucleic acid (RNA)
Symbol: ...pApC...

The main chemical characteristic of the nucleic acids is the phosphoric ester bond (internucleotide bond), which is responsible for the sensitivity of these substances to hydrolysis. The glycosidic bond between the ribose and the nucleo-bases is acid-labile, particularly so in purine nucleosides. In synthetic work, the amino groups of cytosine and adenine, and sometimes that of guanine, must be taken into account as functional groups. Because of the hydroxy group in the 2′-position of the ribose, ribonucleic acids are particularly alkali-labile.

Abbreviated symbols are used for polynucleotides[2]. Here "p" on the left-hand side of the letter denoting the nucleoside indicates a phosphate residue in the 5′-position of the ribose,

[1] *K. Freudenberg*: Tannin, Cellulose, Lignin. Springer-Verlag Berlin 1933. – Über die blutgruppenspezifische Substanz A. Sitzungsber. Heidelberger Akad. Wiss., math.-naturw. Kl. *1940*, 9. Abhandlung. – Die Stärke *15*, 199 (1963). – High-molecular natural substances, J. Polymer Sci. *16*, 155 (1955).

[2] Terminology and Abbreviations, Tentative Rules: J. biol. Chemistry *237*, 1381 (1962).

and a "p" on the right-hand side of this letter a phosphate residue in the 3′-position. The nucleosides are represented by the following abbreviations: A = adenosine, C = cytidine, G = guanosine, T = thymidine, and U = uridine. In the case of a deoxynucleoside, a "d" is placed before the abbreviation. RNA denotes ribonucleic acid and DNA deoxyribonucleic acid.

## 2. The Problem

The role of DNA as a carrier of genetic information is well known. Only five years ago it was possible to read the following statement about the function of RNA in a review on polynucleotide syntheses [3]: "the role of RNA is still more obscure. It is known only that RNA is responsible for the synthesis of proteins by directing the synthetic process. Here, too, definite sequences of nucleotides seem to determine the synthesis of definite proteins". Meanwhile, the advance of molecular biology [4] has elucidated the functional relationships between the various types of nucleic acids and between these and the biosynthesis of the proteins (Scheme 1).

| | Function | Structural example | Localization |
|---|---|---|---|

Scheme 1. Functions of DNA and RNA in the biosynthesis of proteins.

The chemical synthesis of oligo- and polynucleotides is important, since the replication and translation processes in the biosynthesis of proteins can be studied particularly well with synthetic polymers [5]. Definite oligonucleotides are also necessary for studies on base pairing and on the stability of double helices [6]. To decipher the genetic code, the trinucleotides acting as code words must be synthesized or isolated from natural material [7,8]. Determination of the direction of reading of the genetic alphabet requires polynucleotides with definite terminal triplets [7,9]. The mode of action and the specificity of enzymes which split nucleic acids can be studied on dinucleoside phosphates [10]. Oligonucleotides could be used as models for studying mutations on transforming DNA. The secondary structure of polynucleotide strands must be elucidated on relatively simple compounds. Determination of the structure and analysis of the nucleic acid sequence could be aided by the synthesis of fragments.

A chemical synthesis of transforming DNA, *i.e.* that containing genetic information, with at leats $10^5$ chain members exceeds human capabilities even with substantial automation of all steps. Even the synthesis of messenger-RNA with at least 500 nucleotides or that of transfer-RNA with approximately 80 chain members appears to be impossible.

## 3. Chemical Syntheses

### 3.1. Phosphorylation Reactions

The classical condensing agent in the synthesis of oligonucleotides is dicyclohexylcarbodiimide (DCC) [11,12]. In addition, numerous other reagents for the preparation of nucleotide esters or oligonucleotides have been tested and have been found to be suitable in special cases; thus, for example, acid chlorides [13,14], trichloro-

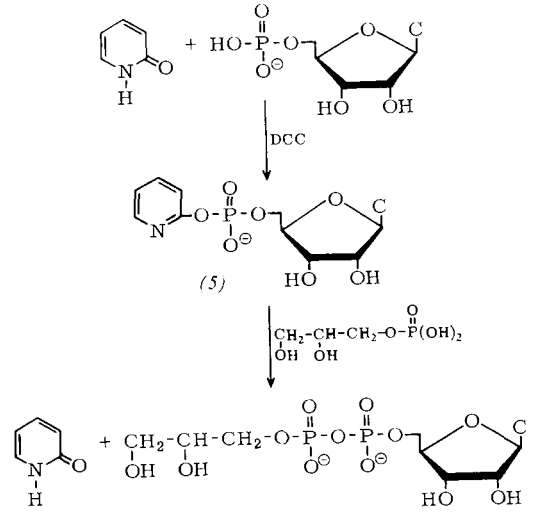
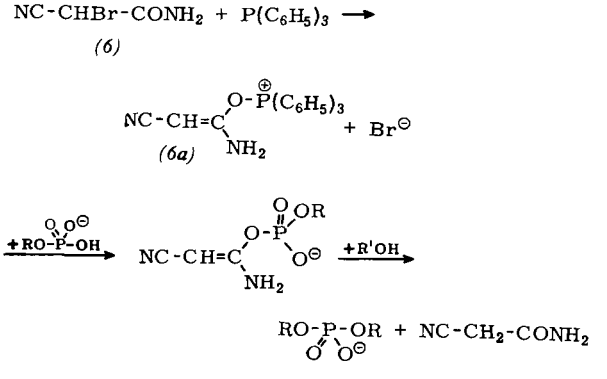
acetonitrile[15,16], Woodward's reagent[17], picryl chloride *(2)*[18], and nucleotide imidazolides *(3)* have been tested for the synthesis of oligonucleotides[19]. Dimethylformamide chloride *(4)* is an esterifying reagent for nucleotides[14,20,21].

New phosphorylation reagents are α-hydroxypyridyl phosphates[22]. α-Hydroxypyridyl esters *(5)* of nucleotides transfer the nucleotide residue to other nucleophiles, *e.g.* to phosphates, so that pyrophosphate



coenzymes are formed. No synthesis of oligonucleotides has yet been carried out with these compounds. A vigorous phosphorylating reagent is a mixture of α-bromocyanoacetamide *(6)* and triphenylphosphine[23]. In a reaction with this mixture, the first step is similar to a Perkow reaction; an intermediate *(6a)* arises which corresponds to the enol phosphate of malonic ester[24],



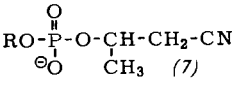
which has earlier been used for the synthesis of oligonucleotides.

The phosphorylating activities of cyclohexyl isonitrile, ethoxyacetylene, bromocyanogen, dichloromalonodinitrile, perfluorooctanecarbonitrile, benzonitrile, benzyl cyanide, and malodinitrile have been investigated[25], but none of these reagents proved to be appreciably superior to those used hitherto. The ynamines 1-dimethylamino-2-phenylacetylene and 1-dimethylamino-3,3-dimethylbut-1-yne, as well as 4-nitrophenyl cyanate, *N*-ethylbenzoiso-oxazolium fluoroborate[25a] as well as *N*(1),*N*(4)-diethyltetrazolium and *N*(1)-ethyl-*N*(4)-methoxyphenyltetrazolium *p*-toluenesulfonates also failed to give satisfactory yields of dinucleoside phosphates[25b].

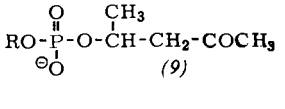
## 3.2. Protecting Groups

### 3.2.1. Protecting Groups for Phosphoric Acids

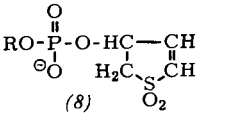
During the linkage of two nucleotides, the phosphoric acid residue of one nucleotide must be protected if the condensation is to proceed in the desired sequence. In general, it is sufficient to prepare the monoester; phosphoric diesters are no longer activated by most condensing agents. Benzyl phosphates[26] can be split by hydrogenation, but a pyrimidine ring may also be hydrogenated under the conditions used. A β-cyanoethyl group[27] can be split off with alkali (β-elimination). Of the alkali-labile esters *(7)–(10)*, R = nucleoside, the esters *(9)* and *(10)* are particularly suitable as protecting groups for phosphoric acid residues in nucleotides[28].



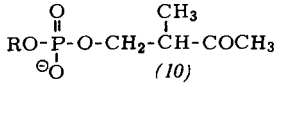
*(7)*



*(9)*



*(8)*



*(10)*

Benzhydryl esters of nucleotides are obtained[29] when nucleotides are treated with diphenyldiazomethane. They can be split with dilute acid. t-Butyl esters are also acid-labile[30]. β,β,β-Trichloroethyl esters of deoxyribonucleotides *(11)* can be split reductively by means of Zn/Cu in acetic acid or in dimethylformamide without

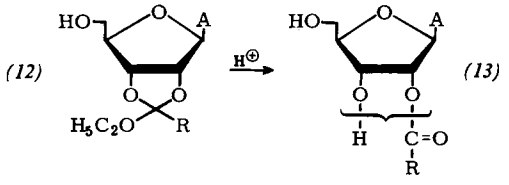
loss of *O*-acetyl or *O*-benzoyl groups [31]. The ethylthio group may be split off oxidatively [32].

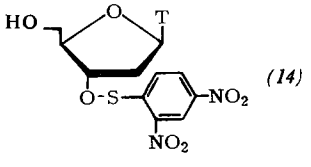
### 3.2.2. Protecting Groups for Hydroxy and Amino Groups

Acetyl and benzoyl derivatives of nucleosides and deoxyribonucleotides can be prepared by the methods customary in carbohydrate chemistry. In the acylation of 3′-ribonucleotides, the formation of cyclophosphates must be avoided [33]. Trityl derivatives or the more easily cleaved methoxytrityl derivates are used for the specific protection of the primary OH group in position 5′ [36]: the 2′-OH group can be masked with dihydropyran [34,36] or with ethyl vinyl ether [35]. The 2′- and 3′-positions of ribose can be protected reversibly by the formation of benzylidene derivatives (*p*-methoxybenzylidene [36] or *p*-dimethylaminobenzylidene groups [37]), which can be easily split off with acids. The 2′,3′-*O*



ethoxymethylene derivatives *(12)*, which can be converted into the 2′- and 3′-*O*-acyl derivatives *(13)* by treatment with acetic acid, serve the same purpose [38–40].

A dinitrophenylsulfenyldeoxyribonucleoside *(14)* has been used in the synthesis of a dinucleotide on a polymeric carrier. Such compounds can be split by thiophenol or Raney nickel [41,42]. Formylnucleosides [30, 43,44] have been synthesized, but have not been used for the synthesis of oligonucleotides.



## 3.3. Synthesis of Oligodeoxyribonucleotides

### 3.3.1. Homopolymers

Homo-oligomers can be prepared by the condensation of thymidylic acid with dicyclohexylcarbodiimide [45], picryl chloride [18], or other reagents. In the resulting mixture of oligomers, the content of the longer chains decreases obeying Poisson's distribution (Fig. 1). The

compounds are separated on columns of DEAE-cellulose [45] (Fig. 2) or on thin-layer plates of polymin-cellulose [48] (Fig. 3). The longest oligomer prepared so far is a polythymidylic acid with 30 chain members [50], which was obtained by condensation with picryl chloride.

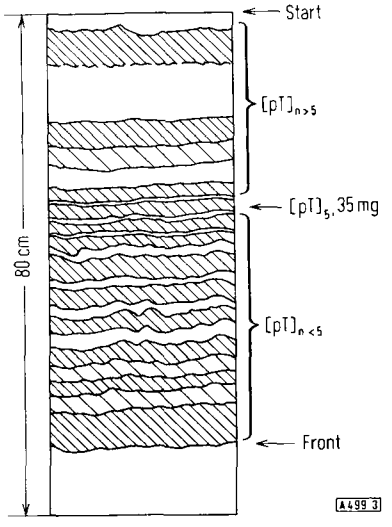

Fig. 3. Thin-layer chromatography of oligothymidylic acids of different chain lengths on polymin-cellulose [48]. The individual bands were eluted and worked up by the $Zn(OH)_2$ method [49].
Solvents: 0.25 M NaCl (2 h), 0.50 M NaCl (2 h), 0.75 M NaCl (2 h), 1.00 M NaCl (2 h), 1.50 M NaCl (2 h).

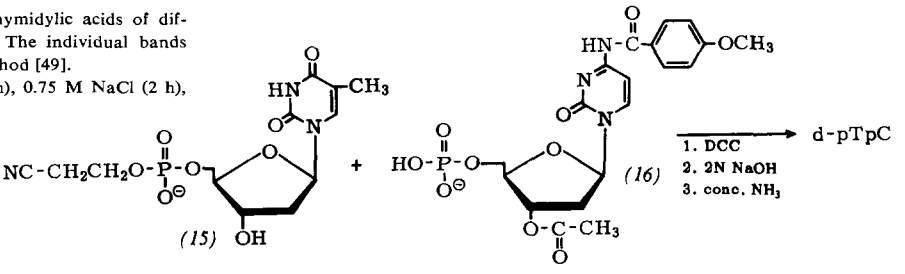
Poly-d-A [51], poly-d-C [52], poly-d-G [53], and poly-T have been synthesized by this process, sometimes in low yields. The oligonucleotides contained in the fractions can be isolated by precipitation with $Zn(OH)_2$ [49]. Graft polymerization can be achieved according to the following scheme [46]:

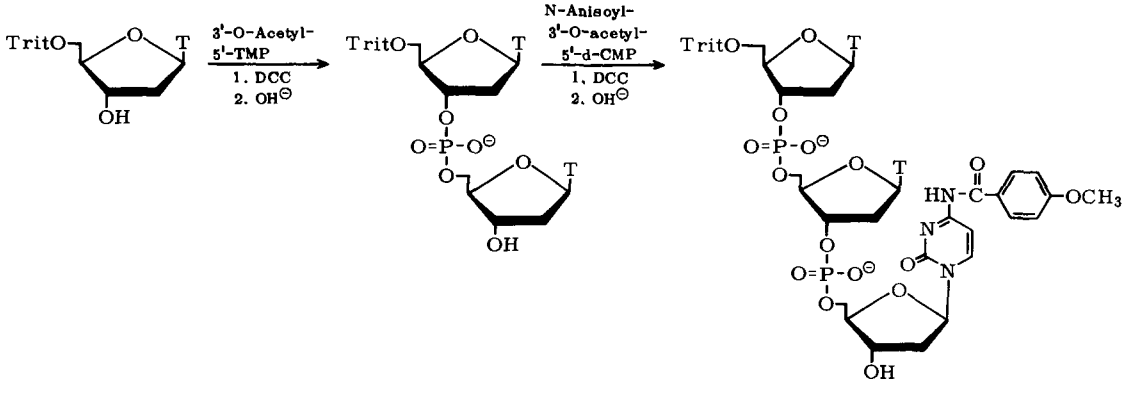
$$n\ pT \xrightarrow[\text{picryl chloride}]{} (pT)_n \xrightarrow[\text{picryl chloride}]{\text{m d-pA}} \text{d-}(pT)_n(A)_m$$

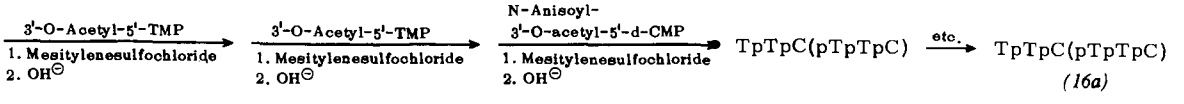
### 3.3.2. Stepwise Synthesis of Oligodeoxyribonucleotides

The condensation of the β-cyanoethyl ester *(15)* of a 5′-nucleotide with a 3′-*O*-acetylnucleotide *(16)* gives a dinucleotide from which the protecting groups can be removed with alkali. The following substances have been prepared in this way:

d-pTpT, d-pGpC, d-pCpG [54], d-pTpA [55], d-pTpG, d-pTpG, d-pTpC, d-pApG, d-pCpA [56], d-pCpT [57], and d-ApTp [55]. For the stepwise synthesis of trinucleoside diphosphates and higher homologues, the 5′-OH group at the beginning of the growing chain must bear a protecting group, *e.g.* the acid-labile trityl group,







which remains in position during all stages of the condensation and is removed only at the end. In this way it has been possible to obtain the dodecanucleotide d-TpTpC(pTpTpC)$_3$ *(16a)* [58], and to synthesize homo-

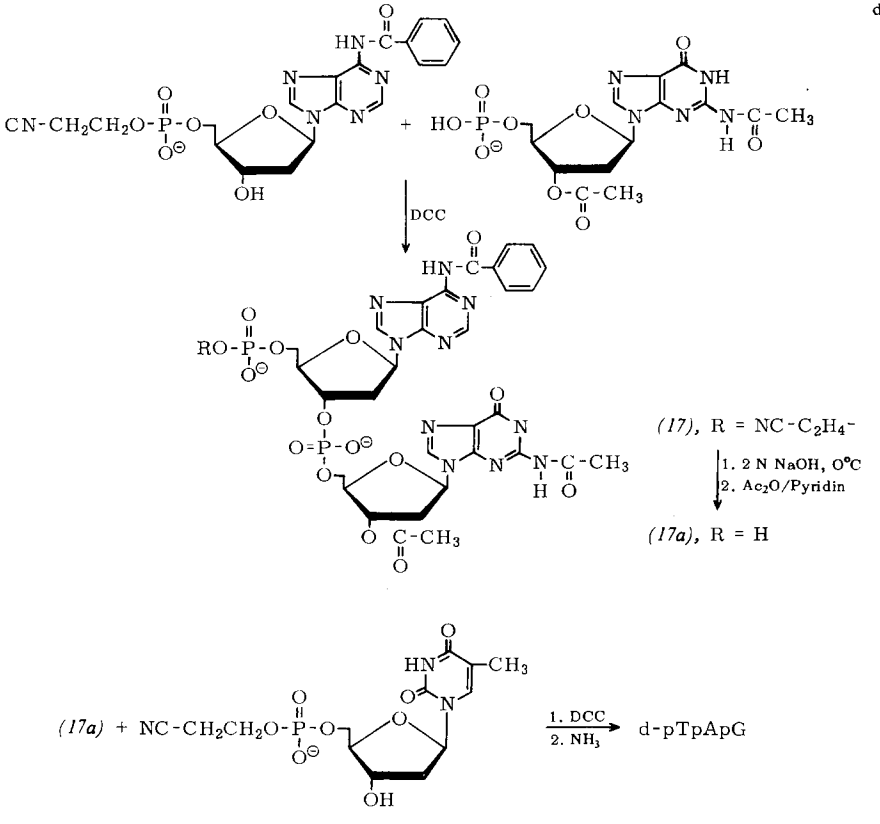
[57] *H. Schaller* and *H. G. Khorana*, J. Amer. chem. Soc. *85*, 3828 (1963).

logous oligothymidylic acids [59] and, analogously, the oligonucleotides d-TpTpI(pTpTpI)$_3$ [60], d-CpApApCpApA [61], d-GpApApGpApA [61], and d-TpApTpTpT [55].

The problem of the stepwise synthesis of oligonucleotides with a terminal 5′- or 3′-phosphate group, *i.e.* of compounds of the type pXpYpZ or XpYpZp, has been solved less satisfactorily. For this one needs either two protective groups $S^1$ and $S^2$ in the dinucleotide ($S^1$–pXpY–O–$S^2$) which can be eliminated under different conditions or the trinucleoside diphosphate XpYpZ must be re-phosphorylated in the last step of the synthesis. Another possibility [62] consists in first removing all the protecting groups with alkali at the stage of the dinucleotide *(17)*, then acetylating the product, and finally condensing it to the trinucleotide.



### 3.3.3. Block Polymerization

By block polymerization will be understood the condensation of oligonucleotides to higher units. Up to the present time, only dinucleotides have been linked by block polymerization (Table 1) [55]:

$$n\ pXpY \rightarrow (pXpY)_n$$

Important biochemical information has been obtained with these products. For example, (d-pTpA)$_4$ [55] can be used as a template for the Kornberg enzyme [63]. The oligomers act as templates for DNA-polymerase and RNA-polymerase and are used by RNA-polymerase to produce the complementary RNA sequence without errors [64]. In a cell-free system, the messenger-RNA so produced catalyses the synthesis of a polypeptide with an alternating amino acid sequence.

Table 1. Oligonucleotides obtained by the polymerization of dinucleotides [55, 56].

| Dinucleotide | Block polymer | n |
|---|---|---|
| d-pTpA | (d-pTpA)$_n$ | 2–7 |
| d-pTpG | (d-pTpG)$_n$ | 2–6 |
| d-pTpC | (d-pTpC)$_n$ | 2–8 |
| d-pApG | (d-pApG)$_n$ | 2–6 |
| d-pCpA | (d-pCpA)$_n$ | 2–6 |

## 3.4. Synthesis of Oligoribonucleotides

### 3.4.1. Homopolymers

Because of the 2′-OH groups of the ribose residues, the synthesis of oligoribonucleotides is substantially more complicated than corresponding syntheses in the deoxyribose series; the 2′-hydroxy group gives rise to isomerizations and renders the end product alkali-labile. If the exclusive presence of 3′→5′ bonds in the polymer is not required, it is relatively simple to obtain oligomers of the type *(18)* from 2′,3′-*O*-cyclophosphates with diphenyl phosphorochloridate or other vigorously acting acid chlorides as condensing agents [65,66].

These oligomers, which may be valuable for physicochemical studies but which do not behave as natural

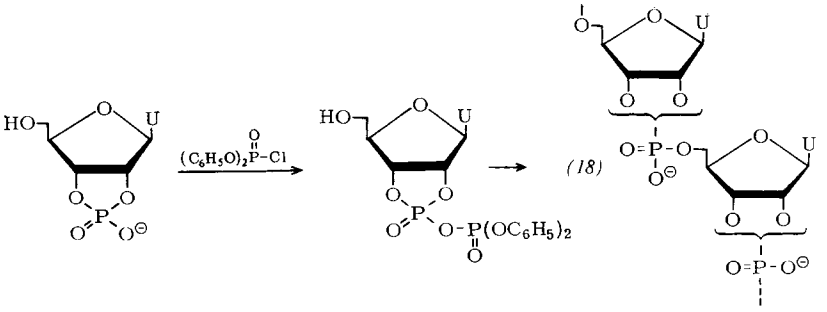
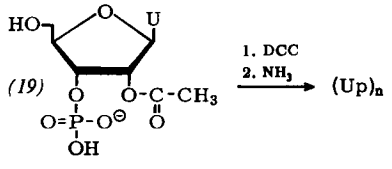
[66] *A. M. Michelson*: The Chemistry of Nucleosides and Nucleotides. Academic Press, London, New York 1963, pp. 418–441.



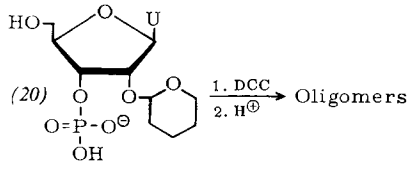
material with respect to most enzymes, have chain lengths of up to 20 units. Addition of chain-terminating 2′,3′-*O*-diacetylnucleosides [66] or 2′,3′-*O*-benzylidene-nucleosides [67] yields oligomers of the type XpXp···XpY with fairly uniform chain lengths.

With polyphosphoric ester as the condensing agent, 3′- or 5′-nucleotides give high-molecular compounds [69] which do not possess the biological properties of polynucleotides; they are obviously cross-linked and partially substituted, and are not degraded by ribonuclease [50, 70].

If isomerizations are to be avoided, the 2′-position must be protected. In this way, 2′-*O*-acetyl-3′-uridylic acid *(19)* can be polymerized up to the decanucleotide, although not in very satisfactory yields [68], and 2′-*O*-tetrahydropyranyl-3′-uridylic acid *(20)* has been con-



densed to oligomers from which, however, the tetrahydropyranyl group can be removed only with difficulty and not without isomerization [36]. Guanosine derivatives protected in the 2′-position have also been prepared [71, 72].

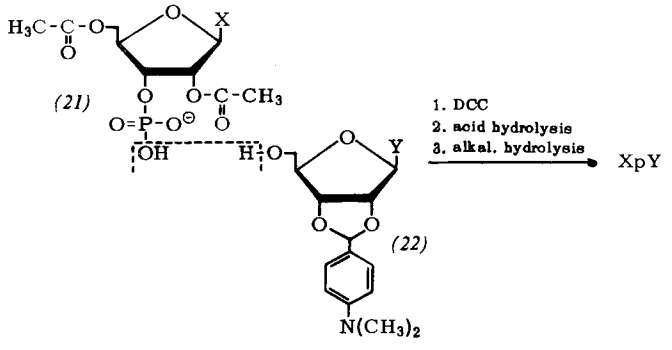


### 3.4.2. Stepwise Synthesis of Oligoribonucleotides

#### 3.4.2.1. *Dinucleoside Phosphates and Analogous Compounds*

Dinucleoside phosphates (XpY) have been synthesized by various methods:

2′,5′-Di-*O*-acetyl-3′-nucleotides *(21)* [73] can be condensed with *p*-methoxybenzylidene- or *p*-dimethylaminobenzylidenenucleosides *(22)* [36, 73a]. At the present time this is probably the most useful procedure for the preparation of dinucleoside phosphates. However, it is impossible to extend the chain further at the 5′-hydroxy group liberated by alkaline hydrolysis, since the acetyl



group in the 2′-position of the nucleotide is also removed. This disadvantage is not associated with the following two procedures:

A 5′-*O*-methoxytrityl-2′-*O*-acetyl-3′-nucleotide *(23)* is esterified with a 2′,3′-di-*O*-benzoylnucleoside *(24)* [74]. The methoxytrityl group can be removed from the dinucleoside phosphate *(25)* with acid without the acetyl or benzoyl groups being split off. Further condensation with a 2′,5′-di-*O*-acetyl-3′-nucleotide *(26)* then gives the trinucleoside diphosphate XpYpZ. In this way, the 64 possible nucleotide triplets have been synthesized [80] and used for the complete deciphering of the genetic code [81]. The tetranucleoside triphosphate UpApUpU has been obtained by the same method [82].

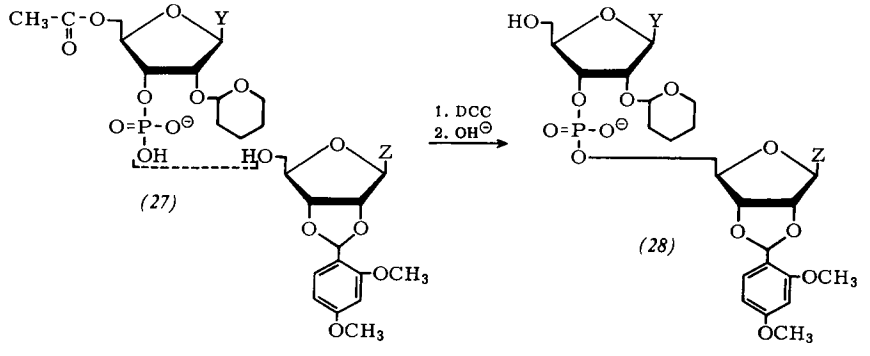
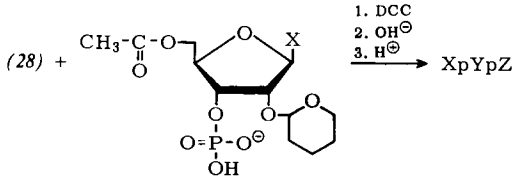
(25) + (26) → XpYpZ

Another method, which again allows subsequent extension of the chain, starts from a 5′-*O*-acetyl-2′-*O*-tetrahydropyranyl-3′-nucleotide *(27)* [83]. After the first condensation, the 5′-*O*-acetyl group can be split off by alkaline hydrolysis. The chain *(28)* may be extended by



(27) → (28)



(28) → XpYpZ

one nucleoside by means of another condensation [84]; UpUpU and CpUpU have been obtained in this way. However, in the case of higher oligonucleotides it is difficult to remove the tetrahydropyranyl groups completely. Nevertheless, it has been possible to obtain a hexanucleoside pentaphosphate, UpUpUpUpUpU, although only in low yield [85].

Table 2 lists the dinucleoside phosphates obtained by various methods.

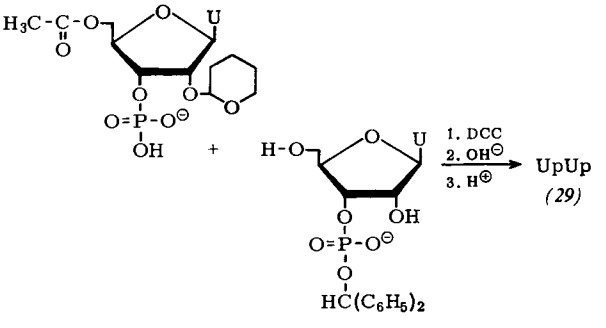
### 3.4.2.2. *Diribonucleotides*

In many cases, the enzymatic or alkaline hydrolysis of the ribonucleic acids leads to oligonucleotides with terminal 3′-phosphate groups. Various routes to their synthesis have been attempted. The first diribonucleotide *(29)* was obtained by the benzhydryl ester method [86]. UpAp, ApAp [86, 87], CpAp, and CpUp [78] have been synthesized in basically the same way. Dinucleotides possessing a 2′,3′-*O*-cyclophosphate grouping (that can be opened by ribonuclease) in the terminal



[86] *F. Cramer* and *K.-H. Scheit*, Angew. Chem. *74*, 717 (1962); Angew. Chem. internat. Edit. *1*, 510 (1962).

[87] *F. Cramer, K.-H. Scheit*, and *H. J. Rhaese*, Liebigs Ann. Chem., in the press.

position and an internucleotide bond (which is stable to ribonuclease), *i.e.* dinucleotides of the type XpPyp [*], are obtained by condensation of the 2',3'-*O*-cyclophosphates with protected 3'-nucleotides [89]. The β-cyanoethyl group has also been used for the protection of the terminal phosphate residue [88], but there is a danger of isomerization when it is split off under alkaline conditions. CpUp, ApUp, IpUp [89], UpUp, UpCp, and CpUp [88] have been prepared by this method.

The synthesis of diribonucleotides with 5'-terminal phosphate groups requires the phosphorylation of a protected dinucleside phosphate [76]. Here, many preparative problems remain to be solved.

## 4. Enzymatic Syntheses

Enzymatic syntheses of nucleic acids are treated here only to the extent that they lead to the synthesis of polymers of a definite sequence. It is impossible to go into all details with respect to biochemistry and molecular biology.

### 4.1. Synthesis of DNA

#### 4.1.1. DNA-Polymerase (Kornberg Enzyme; E.C. 2.7.7.7.)

An enzyme has been isolated from *E. coli* [90–92] which catalyses the synthesis of high-molecular polydeoxyribonucleotides when all four 5'-triphosphates – namely d-ATP, d-GTP, d-CTP, and d-TTP – and a DNA template are present.

The native DNA double strand is a poor primer for the polymerization by the purified enzyme (which is substantially free from DNases). Much more suitable is DNA slightly digested by pancreatic DNase and subsequently denatured by brief heating to 77 °C. From this and other findings, it has been concluded that the natural function of the DNA-polymerase is that of a repairing enzyme. *In vitro*, up to 20 °C, the Kornberg enzyme in fact repairs only gaps in the double strand of DNA [92a], the intact strand serving as a template. At higher temperature, however, excessive polymerization extending beyond repair begins, leading to branchings on the DNA. Under these conditions, the net amount of DNA synthesized may reach twenty times the amount of the template. All results, particularly the molar ratio of the bases in the DNA template and in the newly synthesized DNA [93], point to the fact that base-paired double strands are always produced in this polymerization.

No synthesis of DNA takes place in the absence of a DNA template. If, however, the polymerase from *E. coli* is incubated without a DNA template but with d-ATP and d-TTP in the presence of $Mg^{2+}$ ions, the formation of a high-molecular compound is observed after a lag phase of 2–6 hours (depending on the concentrations of enzyme and substrate). Chemical analysis (base ratio and determination of the nearest neighbors) [92,94] and physicochemical investigations [95] have shown that the product consists of complementary double strands in which d-Ap and d-Tp units alternate [poly-d-(AT)]. On the other hand, incubation with d-GTP and d-CTP does not give an alternating poly-d-(GC) double strand but a double-stranded polymer consisting of complementary homopolymeric d-G and d-C strands [92,96].

The enzyme has also been used to copy short-chain synthetic oligodeoxyribonucleotides, *i.e.* to obtain long-chain complementary polynucleotides. Even a heptanucleotide d-$(pA)_7$, in the presence of a template $(pT)_{11}$, acts as a primer for the enzymatic formation of high-molecular poly-d-A. It seems therefore that the template can be shifted with respect to the growing nucleotide chain (slipping mechanism) [63]. In a few cases, it has been possible with the aid of chemically synthesized oligodeoxyribonucleotides to prepare polydeoxyribonucleotides with strictly alternating base sequences (Table 3) [97].

Table 3. Polydeoxyribonucleotides obtained enzymatically from chemically synthesized oligodeoxyribonucleotides.

| Template and primer | Substrate | Product |
|---|---|---|
| $(pT)_{11}$:d-$(pA)_7$ | d-ATP | Poly-d-A (50–100 nucleotides) |
| $(pT)_{11}$:d-$(pA)_7$ | d-ATP<br>d-TTP | d-$(pA)_n$:d-$(pT)_n$<br>M.W. $6 \times 10^6$ |
| d-$(pTpC)_5$:d-$(pApG)_5$ | d-ATP<br>d-TTP<br>d-CTP<br>d-GTP | d-$(pTpC)_n$:d-$(pApG)_n$<br>M.W. $> 10^6$, $S_{20,w} - 16$ |

#### 4.1.2. "End-Addition Enzyme"

In addition to a DNA-dependent (template-dependent) DNA polymerase, a second DNA-polymerizing enzyme, the "end-addition enzyme", has been detected in purified extracts of calf thymus. It has been separated from the DNA-dependent DNA polymerase on a hydroxylapatite column [98,99]. The "end-addition enzyme" extends

oligodeoxyribonucleotides by the repeated addition of deoxyribonucleotide units to long homologous chains:

$$pTpTpT + n\ d\text{-}ATP \xrightarrow{\text{end-addition enzyme}} d\text{-}pTpTpTpApApApA.....$$

The rate of this polymerization decreases in the sequence d-ATP > d-ITP > d-CTP ≫ d-TTP and d-GTP. d-CTP is incorporated only in the presence of $Co^{2+}$ ions [100]. The oligonucleotides acting as primers must have a minimum length of three nucleotides; at the same concentration of enzyme, the length of the newly formed chain depends on the substrate/primer ratio.

### 4.2. Synthesis of RNA

#### 4.2.1. DNA-Dependent RNA Polymerase (E.C. 2.7.7.6)

A DNA-dependent RNA polymerase is present in bacteria and other tissues [101–105]. It requires a DNA template and all four ribonucleoside 5′-triphosphates. The polyribonucleotides synthesized are single-stranded and of high molecular weight. Their composition is determined by the composition of the DNA template. *In vitro*, the enzyme copies DNA single and double strands. If single strands are copied, the base composition of the product is complementary to that of the template. If synthetic polydeoxyribonucleotides with a known base sequence, *e.g. (30)* or *(31)*, are used as templates, complementary polyribonucleotides also having definite base sequences are obtained [64]. Which strand of the DNA is used as a template depends on the nature of the nucleoside triphosphate offered. The ribonucleic acids produced have contributed to the deciphering of the genetic code.

"Translation" into the complementary polyribonucleotides can also be effected with RNA polymerase starting from templates consisting of trideoxyribonucleotides [5, 106]. A template of only 9 nucleotides (3 triplets) is sufficient to synthesize a complementary polyribonucleotide with more than 150 nucleotide units. Here again a slipping of the oligomeric template during the synthesis has been postulated.

The chemical synthesis of polydeoxyribonucleotides is substantially simpler than that of polyribonucleotides. Using the described enzyme, it is possible to utilize the information contained in chemically synthesized polydeoxyribonucleotides for the enzymatic synthesis of polyribonucleotides and thus to circumvent the difficulties associated with the chemistry of the ribopolymers.

#### 4.2.2. Polynucleotide Phosphorylase (E.C. 2.7.7.8)

##### 4.2.2.1. *Homopolynucleotides*

Polynucleotide phosphorylase polymerizes nucleoside diphosphates to polynucleotides in which the bases are distributed at random:

$$n\ XDP \rightleftharpoons (XMP)_n + n\ P_i$$

The enzyme requires no template [107]. It has been isolated from *Azotobacter vinelandii* [108, 109] and from *Micrococcus lysodeicticus* [110]. The enzyme from *Micrococcus lysodeicticus* possesses somewhat different properties, and is easier to purify. Even after 500-fold concentration, the enzyme from *Azotobacter vinelandii* contains ca. 3% of a firmly bound oligonucleotide, which may have the function of a prosthetic group [111]. Both enzymes are specific for ribonucleoside 5′-diphosphates; even chemically modified 5′-diphosphates can be used as substrates [112]. If several nucleoside 5′-diphosphates are present, they are incorporated into the polymer at random, with the exception of GDP [113] which is incorporated preferentially [114].

Highly purified enzyme preparations require a primer which must be at least a dinucleoside phosphate; less highly purified preparations and crude extracts contain sufficient oligonucleotides to act as primers [115, 116]. A net synthesis of polynucleotides is possible with crude extracts from *Azotobacter vinelandii* if the process is carried out in 1–2 M

urea [117, 118] (the optimum concentration of urea is different for the individual homopolynucleotides [119]). The reason for this is that the crude extract contains ureases, which raise the concentration of ammonium ions by decomposition of the urea to such an extent that the phosphate produced ($P_i$) is precipitated with the magnesium ions present. In this way the equilibrium

$$n\ XDP \rightleftharpoons (XMP)_n + n\ P_i$$

is displaced to the side of the polymer [121, 122]. The optimum conditions for the synthesis of polynucleotides with crude extracts from *Azotobacter vinelandii* are: addition of $NH_4^+$ ions in the form of ammonium hydrogen carbonate and a pH of 9.15, together with an increase in the concentration of magnesium ions so that the phosphate can be precipitated quantitatively as ammonium magnesium phosphate. Under these conditions, the yield of polynucleotide is almost quantitative (Fig. 4) [120].

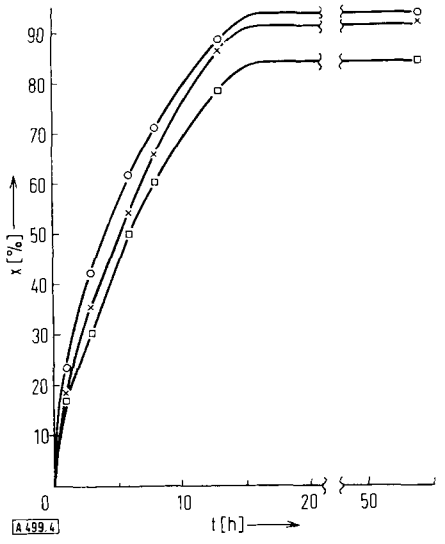

Fig. 4. Course of the synthesis of polynucleotides with a crude extract from *Azotobacter vinelandii* in the presence of equimolar (referred to the nucleoside diphosphate added) amounts of $Mg^{2+}$ and a 208-fold molar excess of ammonium hydrogen carbonate [120].
o—o Poly-C; ×—× Poly-A; □—□ Poly-U.
Ordinate: yield of polymer [%].
Abscissa: time [hours].

### 4.2.2.2. *Polynucleotides with Definite Terminal Triplets and Oligoribonucleotides*

The fact that polynucleotide phosphorylase is not specific with respect to nucleo-bases can be utilized to obtain polymers with definite triplets at the 3'-end [7]. For this purpose, a nucleotide is incorporated randomly into the polymer, and the latter is subsequently split specifically at the site of this nucleotide. For example:

UDP + GDP (30:1)
↓ Polynucleotide phosphorylase
....pUpUpUpGpUpU....pUpUpGpU....
↓ $T_1$ ribonuclease
....pUpUpUpGp + UpU....pUpUpGp + U....
↓ Phosphatase
....pUpUpG

As a check, the terminal guanosine in the example shown here was split off by the periodate method and determined [123]. Polymers synthesized in this way are shown in Table 4. One of these polymers, namely ...ApApC, has been used to determine the direction of reading of the messenger-RNA [9]. In the case of G-containing polymers, in particular, the base ratio in the product does not completely correspond to that in the substrate mixture (Table 4), *i.e.* part of the chains have "wrong" ends, which must be be ascribed to the presence of endonucleases which split the polynucleotide in the homologous part of the chain.

Table 4. Polynucleotides with definite triplets at the 3'-end [124].

| Polynucleotide | Substrate ratio | Base ratio in the polymer | Average chain length [nucleotides] | Chains with pXpXpX ends [%] |
|---|---|---|---|---|
| Up...UpUpG | 30:1 | 20:1 | 17 | 12 |
| Cp...CpCpG | 30:1 | 27:1 | 24 | 13 |
| Ap...ApApG | 30:1 | 19:1 | 14 | 33 |
| Ap...ApApC | 30:1 | 28:1 | 26 | 9 |
| Ap...ApApU | 30:1 | 37:1 | 31 | 17 |
| Ip...IpIpC | 30:1 | 26:1 | 23 | 12 |
| Ip...IpIpU | 30:1 | 36:1 | 29 | 15 |

Purified polynucleotide phosphorylase [125] requires a primer [126, 127] and extends a nucleoside diphosphate to a homopolymer with a definite triplet at the 5'-end [128], *e.g.*:

$$GpU + ppU \xrightarrow{37\,^\circ C,\ 48\ h} GpUpUpUpUpUp...U$$

Polynucleotide phosphorylase from *M. lysodeicticus* [127] (protein content 1.45 mg/l, $\varepsilon_{280}:\varepsilon_{260} = 1.76$) is used. The charges (1 ml of solution) contain

24 μmole of nucleoside diphosphate,
0.5 μmole of primer (dinucleoside phosphate),
150 μmole of Tris buffer (pH 8.1),
0.8 μmole of EDTA,
6 μmole of $MgCl_2$, and
0.11mg of polynucleotide phosphorylase.

The following polymers have been obtained under these conditions [124]:

ApG + ADP → ApGpApApAp... A
UPG + UDP → UpGpUpUpUp... U
GpA + ADP → GpApApApAp... A
GpA + UDP → GpApUpUpUp... U
ApU + ADP → ApUpApApAp... A
ApU + UDP → ApUpUpUpUp... U
ApA + UDP → ApApUpUpUp... U
UpC + APD → UpCpApApAp... A
GpC + ADP → GpCpApApAp... A
GpC + UDP → GpCpUpUpUp... U
UpG + ADP → UpGpApApAp... A
CpU + ADP → CpUpApApAp... A
GpU + ADP → GpUpApApAp... A
GpU + UDP → GpUpUpUpUp... U

[125] *M. F. Singer*, *L. A. Heppel*, and *R. J. Hilmoe*, J. biol. Chemistry *235*, 738 (1960).

[126] *M. F. Singer*, *R. J. Hilmoe*, and *L. A. Heppel*, J. biol. Chemistry *235*, 751 (1960).

[127] *M. F. Singer* and *B. M. O'Brien*, J. biol. Chemistry *238*, 328 (1963).

[128] *H. Küntzel*, Göttingen, unpublished work.

The chains are 50 to 100 nucleotides long, depending on the amount of primer and the experimental conditions.

Polynucleotide phosphorylase can also be used for the synthesis of short chains. With the primer-dependent enzyme from *M. lysodeicticus*, a dinucleoside phosphate is extended by only a few units if the reaction takes place in 0.4 M NaCl [129] and is allowed to proceed until the few long chains formed initially have been converted by phosphorolysis into a large number of short chains [129]:

ApU + ADP (1:4)
↓ Polynucleotide phosphorylase, 2 h
ApUpApA...A (high molecular weight)
↓ +ApU (unused primer) Polynucleotide phosphorylase, 24 h

ApU (small amount) + ApUpa (main product) + ApUpApA + ApUpApApA + a small amount of polynucleotides of higher molecular weight.

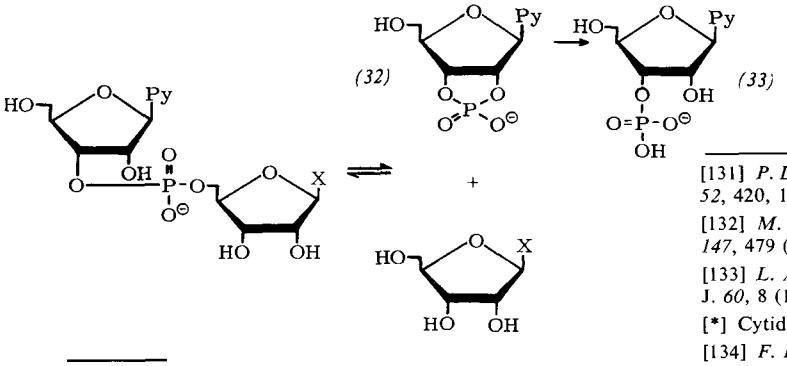
When a highly purified polynucleotide phosphorylase is used and the ratio of primer to nucleoside diphosphate equals 1:1 or 2:1, trinucleoside diphosphates are obtained in yields of 5 to 15% [130].

The trinucleoside diphosphates XpYpZ can be separated chromatographically from more highly polymerized material and unused primer. Fourteen trinucleoside diphosphates have been synthesized in this way, and have contributed to the deciphering of the genetic code [131, 132]. The method is suitable in principle for the synthesis of all 64 nucleotide triplets.

#### 4.2.2.3. *Reversible Action of Ribonucleases*

Pancreatic ribonuclease splits the internucleotide bonds of ribonucleic acids close to the sites of the pyrimidine bases. The 2',3'-*O*-cyclophosphates *(32)* arising as intermediates are hydrolysed by the enzyme to the pyrimidine nucleoside 3'-phosphates *(33)*. The first step of the hydrolysis is reversible [133], if the concentration of the cyclophosphate is greater than 0.1 M. The 2',3'-*O*-cyclophosphate then gives methyl esters of nucleoside 3'-phosphates with methanol, and dinucleosides are produced with nucleosides. The following products were found in the reaction of the 2',3'-*O*-cyclophosphate of cytidylic acid with cytidine [133]:

| | Cp | CpC | CpC>p [*] | CpCpC |
|---|---|---|---|---|
| % | 3.5 | 4.5 | 9 | 1 |



[129] *R.E.Thach* and *P.Doty*, Science (Washington) *184*, 632 (1965).

[130] *P. Leder, M. F. Singer*, and *R. L. C. Brimacombe*, Biochemistry *4*, 1561 (1965).

Uridine 2',3'-*O*-cyclophosphate reacts similarly [134] (Table 5).

Table 5. Synthesis of UpU from uridine 2',3'-*O*-cyclophosphate [134]: a solution of 65 mg of the cyclophosphate, 300 mg of uridine, and 1.4 mg of ribonuclease in 20 ml of water was kept at pH 7.0 and 4 °C. Figures in % of the cyclophosphate used.

| Time [h] | Up [%] | UpU [%] | U>p [a] [%] |
|---|---|---|---|
| 1.75 | 36 | 26 | 38 |
| 2.5 | 45 | 29 | 26 |
| 3.5 | 48 | 28 | 24 |
| 6.0 | 54 | 26 | 20 |
| 25 | 78 | 10 | 12 |
| 54 | 83 | 7 | — |

[a] Uridine 2',3'-*O*-cyclophosphate

Mixed oligomers such as CpU and CpCpU (0.8% yield) can also be prepared [134].

Still more pronounced is the reversible action of $T_1$ ribonuclease [135]. Guanosine 2',3'-*O*-cyclophosphate is partially polymerized in concentrated solution to oligoguanylic acids. In the presence of an excess of nucleotide with a free 5'-hydroxy group, dinucleoside phosphates of the type GpX are produced, and with dinucleoside phosphates one obtains trinucleoside diphosphates of the type GpXpY [79]. In addition, small amounts of higher oligonucleotides ...GpGpXpY are formed. The further growth of the chain can be prevented if the 5'-position of the guanosine 2',3'-*O*-cyclophosphate is blocked by acetylation [136]. GpU and GpC have been obtained in 16 and 15% yields, respectively, in this way.

*Own investigations that have been cited in this review are the result of a fruitful collaboration with my colleagues whom I should like to thank above all. Thanks are also due to Dr. Reinhard, Dr. Eckstein, and Dr. Lezius for their assistance in preparing the manuscript. The investigations were supported financially by an initial grant from the Rockefeller Foundation (1958), by several grants of the Deutsche Forschungsgemeinschaft, the Bundesministerium für Wissenschaftliche Forschung, and the Fonds der Chemischen Industrie.*

# The Passivity of Metals

BY PROF. DR. K. SCHWABE

INSTITUT FUR ELEKTROCHEMIE UND PHYSIKALISCHE CHEMIE
DER TECHNISCHEN UNIVERSITÄT DRESDEN (GERMANY)

*After a survey of the various factors, depending both on the metal and on the attacking substance, that can influence the anodic dissolution of metals, the nature of the passive layer is discussed on the basis of electrochemical and optical studies. Passivation is characterized by a rapid decrease in the anodic current density as the Galvani tension is increased; this is due to the presence of a monomolecular layer, which prevents the metal ions from passing across the phase boundary. The growth of this layer is strongly influenced by transport processes, particularly within the layer itself. The kinetics of the passivation and activation processes can be explained by the simultaneous occurrence of competing reactions which depend on the potential; exchange adsorption appears to play some part in the passive behavior of metals towards various acids.*

## Introduction

Titanium, zirconium, niobium, and tanatalum, as well as their alloys, have an even greater affinity (*i.e.* a very large decrease in free energy $\Delta G$; Table 1) for oxygen, water, and acids than the more common metals iron, aluminum, chromium, nickel, and copper. Nevertheless Ti, Zr, Nb, and Ta react with oxygen, water, acids, or other chemicals very slowly or not at all, *i.e.* they are passive; this is the only reason that the growing use of these metals in chemical engineering and in reactor engineering is possible.

It is generally known that reactions between substances having a high affinity for one another ($\Delta G \ll 0$) may proceed very slowly because of high reaction barriers, *i.e.* high activation energies (*e.g.* the reaction of $H_2$ with $O_2$ or of Fe with S at room temperature). The resistance of (base) metals towards components of the atmosphere or towards other substances for which they have a high affinity is known in general as passivity. This very general definition, which also applies to electrochemical reactions of the metals, makes no stipulation as to the reasons for this inhibition, which differ widely in nature, and which are not yet fully understood.

Table 1. Values of $\Delta G_{298}$ for the reaction $x\,M + y/2\,O_2 \rightarrow M_xO_y$.

| $M/M_xO_y$ | $\Delta G_{298}$ (kcal/mole) | $M/M_xO_y$ | $\Delta G_{298}$ (kcal/mole) |

[1] *Ch. Schönbein* and *M. Faraday*, Philos. Mag. (3) *9*, 53, 57, 100 (1836).

*Schönbein* and *Faraday*[1], who coined the term "passivity", regarded the phenomenon as being due to the presence of an oxide layer. This theory has been shown to be correct in principle. The corrosion of metals in the presence of water (which is nearly always present, if only as an adsorbed layer) is regarded as an electrochemical reaction comprising the anode process (a) and the cathode process (b).

$$M(s) + x\,H_2O \rightleftarrows M^{n+}(x\,H_2O) + n\,e^- \quad (a)$$

$$n\,H_2O + n\,e^- \rightleftarrows n/2\,H_2 + n\,OH^- \quad (b)$$

$$M(s) + (x+n)\,H_2O \rightleftarrows M^{n+}(x\,H_2O) + n\,OH^- + n/2\,H_2 \quad (c)$$

In acidic solutions, other anions may naturally be present instead of $OH^-$. According to these equations, the rate of reaction of the metal depends partly on the rate of reduction of water, or more generally on the rate of the cathode process, but since this process cannot generally be regarded as characteristic of the reactivity of the metal, the phenomenon of passivation is usually studied by examination of the anode process. The decrease in the free energy as a result of this process is known as the "electrochemical affinity", and it can be made as large as desired by increasing the anodic polarization of the metal (*i.e.* by withdrawing electrons); the rate of the anode reaction (a), as measured by the current density, can then be found.

The general definition of passivity still remains valid when this approach is used, and can be expressed in the form proposed by *Lange* and *Göhr*[2]: Passivity is the state of a metal surface in which the rate of corrosion is very low, in spite of an appreciable positive chemical affinity. Where the reaction of a metal is inhibited only because the cathode process is retarded by a high hydrogen overvoltage (*e.g.* zinc in acids), the metal should not be referred to as passive.

It is difficult to define the passivity of a metal on the basis of a measuring technique, and particularly on the basis of the current density-potential curves, which are

[2] *E. Lange*: Thermodynamische Elektrochemie. Hüthig Verlag, Heidelberg 1962, p. 360–371.

generally used for the characterization of passivity [3]. Since the reasons for inhibition can vary widely even in the case of the anode process, it is practically impossible to limit the concept of passivity on this basis, as was emphasized earlier by *Franck* [3].

If we wish to assess the reactivity, and hence the passivity, of a metal towards water and aqueous solutions, the above definition requires that the free energy of the reaction or the position of the equilibrium should be known. Since Equation (c) can be written in the form (d), the position of the equilibrium depends also on the

$$M(s) + n\,H^+ + (n\,A^-) \rightleftarrows M^{n+} + n/2\,H_2 + (n\,A^-) \qquad (d)$$

hydrogen ion concentration (or activity). The electrochemical equilibria relevant to the reactivity of metals have been compiled [4] as a function of pH and in potential-pH diagrams. Comparison of the affinity $A = -\Delta G$ with the rate of reaction (which is usually found from the current density) gives a measure of the passivity, but yields no information about its cause.

Since the surfaces of all metals (including the noble ones [5a,5b]) react very rapidly with oxygen to form an oxide or at least a chemisorbed film of oxygen, the old oxide layer theory of *Faraday* may be a valid explanation for the passivity of metals if the oxide layer prevents the attacking substance from reaching the metal surface and is not broken down by aqueous solutions.

However, not only do the metals behave differently in the same medium, but their reactivities depend very strongly on the attacking substance (*e.g.* chloride ions).

If the oxide layer acted simply as a layer separating the reactants, the passivity provided by this protective layer should be the same in all aqueous media. In reality, however, a given metal often behaves differently in different solutions, even when the oxide layer is destroyed by the solution. To obtain a better understanding of the differences in passivity, therefore, it is necessary to study the kinetics of the formation and breakdown of passive layers, as well as the kinetics in general of the electrode processes (a) and (b) involved in the dissolution of metals. The process (a), which is typical of all metals, can be used for the assessment of the specific passivity and is studied by means of galvanostatic and potentiostatic current-potential curves.

The advantage of potentiostatic measurements [6a–7] is that the whole of the potential range in question can be swept continuously without danger of a sudden, very marked change in the metal/reference electrode Galvani tension, such as occurs in galvanostatic measurements when a certain current is reached.

## I. Factors Affecting the Anodic Dissolution of Metals

### 1. The Crystallinity of the Surface

As in any heterogeneous reaction, the rate of an electrochemical reaction at the metal/solution (or moisture/film) interface is proportional not only to the concentrations, but also to the area of the interface. If the rate of the reaction is to be expressed, as usual, by the current density (mA/cm²), it must be possible to find the area of the interface at any moment. Increasing anodic polarization of a metal originally not possessing a passive layer generally gives a "stationary" current density-potential curve of the type shown in Fig. 1. The current density gradient in the active region and the current density itself after the fall in the passive region depend not only on the nature of the metal, its purity, and the structure of its surface, but also to a large extent on the composition of the electrolyte.

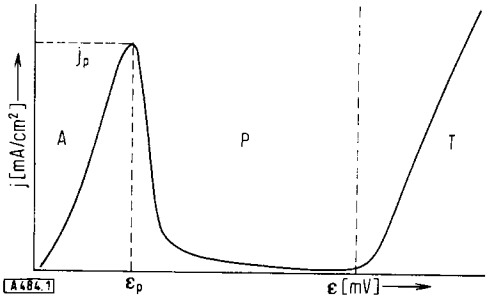

Fig. 1. Typical potentiostatic current density-potential curve for passivation. j = current density = current/geometrical surface area; $\varepsilon$ = Galvani tension between the anode and the reference electrode; A = active region; P = passive region; T = transpassive region; $j_p$ = passivation current density; $\varepsilon_p$ = passivation potential.

Curves of this type, which are used for the examination of the electrode kinetics [8], are not strictly stationary, since the current is never quite constant. It is usual, therefore, to fix a time after which the current is read (5, 30, 60 min or more). The curves obtained in this way sometimes differ considerably [9]. A common practice is therefore to sweep the entire potential range continuously and at a constant speed, and to register the current-potential curve with a pen-type recorder [6b, 10]. This "potentiodynamic" or "potentiokinetic" method is very convenient and time-saving for comparative studies, but the curves still depend on the rate at which the potential is increased.

The current density-potential curves are subject to an error due to the fact that the true surface area is natur-

ally greater than the geometrical area. The rugosity factor, which is generally assumed to be between 1.5 and 4, would not affect the shape of the curve if it remained constant. In reality, however, the nature of the attack on the metal surface, and hence also the rugosity factor, may vary appreciably with the potential, as can be seen, for example, in Fig. 2. Whereas the surface of

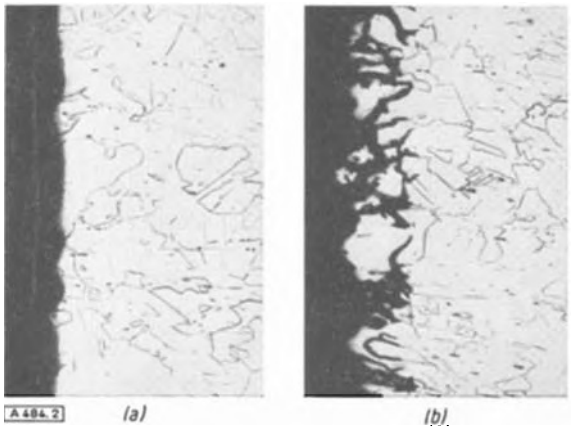

Fig. 2. Attack on nickel after anodic polarization in 5 N $H_2SO_4$ at 25 °C (a) at $E_H$ = 300 mV and (b) at $E_H$ = 1450 mV (against the standard hydrogen electrode). Section perpendicular to the attacked surface. Magnification 150 ×.

nickel is uniformly dissolved at +300 mV, pronounced grain boundary corrosion is found at +1450 mV under the same conditions and when the same quantity of nickel has passed into solution [11]. Uniform surface attack begins again at still higher potentials. Stable surface oxide films would scarcely be able to withstand this concentration of acid (5 N). In any case it is clear that in view of this considerable dependence of the rugosity factor on the potential, any conclusions regarding the kinetics of the electrode process can be only qualitative. The grain boundaries and sub-grain boundaries of the metal (which is generally polycrystalline) are naturally very important.

Structure defects (sub-microscopic fissures) can affect anodic attack on polycrystalline materials. A polished nickel surface (cross section of a rod) with no microscopically visible defects exhibited a granular surface with holes after anodic polarization in 0.7 N sulfuric acid at 60 °C, although the solution was free from halide ions. A 5.5 mm layer was then cut off, and the electrode was anodically polarized under the same conditions; the holes reappeared in the same positions. The rod evidently contained defects running in an axial direction. Since the diameter of a hole is some 50 times as great as that of a crystallite, this attack could hardly be due to impurities concentrated at the boundaries, as has been suggested.

On the other hand, structural defects of this type may be the cause of remarkable "memory effects" in relation to passivity, if electrolyte enters these cracks. For example, a nickel electrode that had been anodically polarized in hydrochloric acid was thoroughly cleaned and its surface ground; when this electrode was subsequently polarized in sulfuric acid, it had a much higher passivation current density $j_p$ (cf. Fig. 1) than an electrode of the same material that had not been in contact with hydrochloric acid. This has been assumed [12] to result from the penetration of electrolyte anions into normal metal structures; however, this explanation is unacceptable, since it has been shown that for "smooth" surfaces of polycrystalline metals, the intensity ratio of $\beta$ to $\gamma$ radiation from $^{82}Br^-$ ions absorbed from the solution does not change [13]. If the $^{82}Br^-$ ions had penetrated into the grain boundaries, the absorption of the $\beta$ radiation by the metal should have led to a marked decrease in this ratio. Autoradiographic studies [14] have shown, however, that anions are preferentially adsorbed at the grain boundaries of the metal surface (60 to 70% of the total adsorption). Since (as we shall see later) the breakdown of the passive layer begins with the adsorption of anions, the grain boundaries play an important part in the transition from the passive to the active state.

Even single crystals of metal can differ enormously in their anodic behavior, owing to differences in the behavior of the lattice planes, defects and dislocations, or traces of impurities. The adsorption of anions depends on the surface energy of the metal atoms in the various lattice planes, and is much less pronounced for the (111) plane of nickel than for the (110) and (100) planes, as has been shown with the aid of $^{14}CN^-$ and $H^{35}S^-$ ions [15]. In autoradiographs of a polycrystalline iron surface on which $^{35}S$ vapor was adsorbed, *Lacombe* [16] obtained differences in blackening that corresponded to the etch micrograph (Fig. 3).

*Piontelli* [17] showed, for nickel and lead, that during anodic (and cathodic) polarization, the difference in the surface energies of the various lattice planes gives rise

to different overvoltages and to different patterns of attack and deposition. The reactivity of an atom on the surface of the metal in this case must obviously be assessed in the same way as in the case of the catalytic activity of a contact; consequently, differences in behavior must be expected even in the same lattice plane, as a result of defects, dislocations, *etc.* [18].

### 2. Influence of the Solvent

The effect of the solution on the kinetics of the anode process depends on the activities of the hydrogen ions, the metal ions, and the anions at the interface. These activities are not the same as those found in the bulk of the solution, and they vary with time and with potential. Moreover the activities (particularly that of the hydrogen ions) are strongly dependent on the presence of other ions, especially metal ions [19]. Thus the current, $i_a$, measured potentiostatically against a reference electrode at a constant Galvani tension and at a constant concentration of the various reactants depends on a number of factors:

$$i_a = \Phi(f_i, \varepsilon, a^{o}_{H^+}, a^{o}_{M^{n+}}, a^{o}_{A^-}, t) \qquad (e)$$

$f_i$ = effective surface area of the electrode; $\varepsilon$ = Galvani tension between the working electrode and the reference electrode; $a_0$, a = activities of the ions at the interface and in the bulk of the solution; t = time; and

$$f = \varphi_1(t, \varepsilon); \; \varepsilon = \varphi_2(a_{H^+}, a_{M^{n+}}, a_{A^-}, t)$$

$$a_{M^{n+}} = \varphi_3(t); \; a_{H^+} = \varphi_4(t, a_{M^{n+}})$$

$$a^{o}_i \neq a_i$$

Thus conflicting views are held [20] regarding even the kinetics of the anodic dissolution of iron. Owing to the strong interionic interactions, the activity coefficients of the ions are very different from unity, and must therefore be taken into account. This was demonstrated in the anodic dissolution of iron in $HClO_4$, where the hydrogen ion activity at a constant $HClO_4$ concentration was changed by a factor of more than 100 by the addition of large quantities of $NaClO_4$ [21]. The anode current density was found to depend on the hydrogen ion concentration in accordance with

$$j_{Fe} = K_+ a^{z}_{H^+} \exp K' \qquad (f)$$

where $K_+$ and $K'$ are proportionality factors ($K'$ contains characteristic electrode-kinetic factors such as the transition factor and transition valence). The order of the reaction with respect to the hydrogen ion activity is $z \approx -2$ at constant $H^+$ concentration.

The rapid build-up of high metal salt concentrations in the diffusion layer as a result of the anodic dissolution leads to large changes in the hydrogen ion activity [19]. A number of variants of the pulse technique are used to avoid changes at the site of the surface reaction due to diffusion and transport, since these changes are generally the slowest of all the processes, and would therefore be rate-determining. For example, the Galvani tension may be measured during the passage of a short pulse of current, or the decay of polarization may be measured after the current has been switched off; alternating current methods, *e.g.* with square pulses, are used in many cases, the inhibiting processes being studied by means of impedance measurements [22]. However, the formation and breakdown of passive layers are often controlled by slower changes taking place on the surface of the electrode. The situation is further complicated by the fact that we must now consider two interfaces (metal/passive layer and passive layer/solution: "multiple electrodes") and transport processes through these layers.

For these reasons it is not possible to give a qualitative and quantitative interpretation for, or even to predict, the passivity of metals under any given conditions. Nevertheless, important information about the nature of the passive layer and about its formation and breakdown has been obtained by the study of simple systems.

## II. Nature and Properties of Passive Layers. Chemisorbed Film or Oxide Phase?

Only a few years ago it was generally thought that in order to prevent dissolution of the metal, the passive layer must be an independent phase, generally an oxide phase [6, 23]. It was usually assumed in accordance with *Müller*'s covering theory [24] that during the anodic dissolution of the metal, a porous salt layer is deposited on the anode when the concentration of the salt in the diffusion layer rises above the saturation limit. The current density (and hence the polarization) at the parts of the anode that are not covered is then so high that a new process, *e.g.* that represented by Equation (g),

$$M + OH_2 \rightarrow MO + 2\,H^+ + 2\,e^- \qquad (g)$$

begins. This new process leads to the formation of the actual non-porous passive layer, the oxide phase itself.

[24] *W. J. Müller*: Die Bedeckungstheorie der Passivität der Metalle und ihre experimentelle Begründung. Verlag Chemie, Berlin 1933.

*Bonhoeffer* [25] improved this theory by careful experimental and theoretical studies on iron. It was also shown in the course of this work [26], however, that the quantity of electricity required for the cathodic reduction of the passive layer formed on iron in $HNO_3$ corresponds to a monomolecular layer. In the case of metals exhibiting so-called chemical passivity (Fe, Co, Ni, Cr) it was unanimously accepted that the passive layer was an oxide. The chemically passive metals are characterized by a steep increase in current in the transpassive region (cf. Fig. 1), accompanied by evolution of $O_2$ or formation of a higher valence state of the metal. In so-called mechanical passivity (Al, Ta, Ti, Zr), the passive range is very much wider; the current generally rises very gradually, the rise often starting only at a potential of about 20 V or more, and the passive layer being broken down in places by spark discharge [27]. This type of passivity can be obtained with all metals that do not form higher valence states, if the metals are anodically polarized in saturated solutions of their salts [28]. Salt barrier layers are formed in many cases [29], and the structures of these layers have a marked influence on the beginning of the current increase. In any case, the salt barrier layers give rise to appreciable inhibition only if they are formed directly from the metal, and not *via* the solution [28].

The study of the passive oxide layers on Fe, Ni, and Cr is difficult, since these layers are very thin and can change during the isolation process. Many attempts have been made to study these layers by optical and electron-optical methods [30]. However, these studies are all open to the objection that the layers observed may not have been the same as the layers responsible for passivation, particularly when they were not studied in the passive state, *i.e.* in the solution itself, but (as in most cases) were isolated by dissolution of the metal. Even optical measurements carried out during the passivation process are not very informative, as has been shown by *Kruger* [30], who observed the presence of oxide layers even before the passive state had been reached. Polarization measurements on light reflected from the passive layer on iron [31] indicated that the layer is between 10 and 80 Å thick. Roughly the same result was obtained by the optical measurement of the layer thicknesses on nickel, chromium, and chromium-nickel stainless steels [31, 32]. Electron-diffraction studies by *Pfisterer*, *Politycky*, and *Fuchs* [33] on passive layers produced on nickel by treatment with chromosulfuric acid indicated an average thickness of 12 Å.

The thickness of the passive layer cannot be reliably determined by cathodic reduction. In the first place, it is not certain that the electricity required in order to reach the active state is used only for the reduction of the passive layer [34] (some may be used, *e.g.*, to reverse the charge of the double layer); secondly, the active state may be reached after the passive layer has been removed from only part of the surface; and finally, it is necessary to make more or less arbitrary assumptions regarding the rugosity factor. Further, local currents may also contribute to the reduction of the oxide layer [35]. The layer thicknesses found by cathodic reduction are approximately the same as, or in some cases smaller than, those found by optical methods [26, 36].

About the same thicknesses are found from the quantity of electricity required for passivation by anodic polarization. *Arnold* and *Vetter* [37] found that the quantity of electricity required to break down a passive layer on nickel is 4 millicoulomb/cm², corresponding roughly to a monomolecular "oxide layer". If, on the other hand, the nickel is polarized to the range in which evolution of oxygen begins, 28 millicoulomb/cm² is required according to *Okamoto* and *Sato* [38], corresponding to an oxide layer about 40 Å thick and having a rugosity factor of 3 [37]. *Franck* and *Weil* [39] had already shown, from the spontaneous widening of the activation range in passive iron wires, that the thickness of the passive layer depends on the potential. Using anodic coulometry *Nagayama* and *Cohen* [40] recently found layer thicknesses of 10 to 30 Å on iron in alkaline borate solutions.

Another method of determining the thickness of a passive layer during its formation is based on the measurement of the change in capacitance of the double layer [41] during anodic polarization. An oxide phase with a thickness that differs appreciably from that of the adsorption layer should, if it is firmly attached to the metal, show its presence by a reduction in capacitance. *Hackerman* and *Popat* [42] have shown, however, that the anodic capacitance-potential curves for Ni, Fe, and Cr/Ni steels are the same as that for Pt, which certainly

does not form an oxide phase under these conditions. Aluminum, on the other hand, behaves as would be expected if an oxide layer were formed [43] (see Fig. 4).

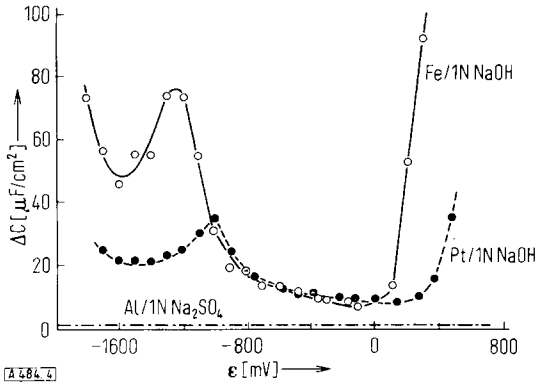

Fig. 4. Capacitance-potential curves of the anodic double layer on Fe, Pt, and Al at 25 °C. $\Delta C$ = differential double layer capacitance; $\varepsilon$ = Galvani tension, measured against a saturated $Hg/Hg_2SO_4,Na_2SO_4$ electrode.

The steep increases in capacitance at the cathodic and at the anodic ends of the curve can be attributed to the liberation of $H_2$ and $O_2$, respectively (high pseudo-capacitance due to the transition current).

The differences from the trough-shaped capacitance curves observed in neutral solutions [43a, 43b], *i.e.* the presence of the maximum at about −1200 mV, is probably due to the absorption of $OH^-$ ions. A similar maximum was observed by *Hackerman* [43c].

It follows that the passive layer on iron, nickel, and chromium (if an oxide layer is in fact formed) cannot consist of more than a few layers of molecules. The energy relationships in extremely thin layers are by no means comparable to those in the bulk materials [44]. If, therefore, the inflection in the potential curve, and particularly the Flade potential [28] of iron, is used as an argument for the existence of oxide phases because they point to equilibria between the metal and the oxide, it must be borne in mind that the free energies calculated from these inflections will not be the same as those corresponding to an equilibrium reaction such as that represented by Equation (h). Moreover, the activities at the surface of the metal are unknown, and the electrode processes are not generally reversible. In fact, the

$$M + n\,H_2O \rightleftharpoons MO_n + 2\,n\,H^+ + 2\,n\,e^- \qquad (h)$$

inflection of the Galvani tension of iron found by *Flade* [45] (from potential-time curves) when the external current was switched off after passivation of the iron in, *e.g.*, sulfuric acid is nowhere near the equilibrium Galvani tension $E_H$ [*] of any of the iron oxides.

$$Fe/FeO: E_H = -0.060\ V;$$
$$Fe/Fe_3O_4: E_H = -0.082\ V;$$
$$Fe/Fe_2O_3: E_H = -0.040\ V \text{ at pH } 0$$

The Galvani tension $E_{H_F}$ of iron against the standard hydrogen electrode during the transition from the passive to the active state (Flade potential) varies with the pH as expected in a reversible reaction of this type:

$$E_{H_F} = (0.580 - 0.058)pH \qquad (i)$$

It is therefore necessary to make further assumptions, the most important of which is that the passive layer consists of two oxides, the iron being in equilibrium with a layer of $Fe_3O_4$, which in turn is in equilibrium with an overlying $\gamma$-$Fe_2O_3$ layer [46]. The Galvani tension calculated from the corresponding $\Delta G$ values is much closer to the experimental Flade potential (+0.580 V at pH 0), but it is difficult to imagine two oxide phases in a layer between 10 and 30 Å thick, particularly since the equilibria must have been reached in fractions of a second during the passivation. Assumptions involving iron oxides with particularly high energies and containing excess oxygen have also failed to yield a satisfactory explanation for the activation or passivation potentials [47].

Different oxide phases have also been postulated for nickel, on the basis of the passivation and activation Galvani tensions, but no such pronounced inflections are found as in the case of iron. On the other hand, up to five activation Galvani tensions have been found for very pure nickel in sulfuric acid when the current was switched off [48]. The Galvani tension corresponding to the Flade potential of iron is more negative in the case of nickel, and changes linearly with pH. *Okamoto* and *Sato* [49] found for the passivation of nickel:

$$E_{H_F} = (0.48 - 0.060)pH \qquad (k)$$

Since the activation and passivation Galvani tensions of nickel again do not agree with values calculated from equilibria between the metal and a single oxide, *Okamoto* and *Sato* [50] recently postulated that the passive layer consists of several oxides, *i.e.* NiO and $Ni_3O_4$, and possibly also $Ni_2O_3$. However, multiphase passive layers are even less likely in this case, owing to the thinness of the layers.

For chromium, which goes into solution as $CrO_4^{2-}$ in the transpassive state, *Lange* and *Weidinger*[51] also assumed that the passive layer consists of two oxides or hydroxides [$Cr(OH)_2/Cr(OH_3)$], the chromate formed in the transpassive range being derived from the $Cr(OH)_3$, in accordance with Equation (l). Once again this theory is opposed by the extreme thinness of the

$$Cr(OH)_3 \rightarrow CrO_3 + 3\,H^+ + 3\,e^- \qquad (l)$$

layer, as well as by deviations from the equilibrium Galvani tensions.

However, if oxide phases of this nature are morphologically and thermodynamically improbable in the stationary passive state, which is the only state in which the thickness of the layers can be measured directly, there is even less justification for regarding them as the primary causes of passivation, *i.e.* of the negative current-potential characteristic, since even fewer layers of molecules would have to be sufficient in that case. This brings us to the view favored by *Uhlig*[52], *Kolotyrkin*[53], *Schwabe*[54a,54b], and other autors, *i.e.*, that the primary cause of passivation is chemisorbed layers of oxygen, or more generally, monomolecular surface layers that inhibit the phase transition.

According to *Uhlig*, when an anodic potential is applied to iron, a layer of chemisorbed atomic oxygen is formed and this is followed by a layer of chemisorbed molecular oxygen, as indicated in Equation (m).

$$Fe + 3\,H_2O \rightleftarrows Fe(O{-}O_2)_{ads} + 6\,H^+ + 6\,e^- \qquad (m)$$

From the heat of chemisorption of the oxygen/iron system, *Uhlig*[55] calculated the standard contact potential and found $E_H = +0.56$ V; this value agrees fairly closely with that found by experiment (0.58 V). Equation (m) also predicts the experimentally observed dependence on pH. The fact that the Flade potential varies with the metal surface and with the electrolyte (particularly in the case of nickel) can be explained by the difference in the heats of adsorption. *Uhlig*'s calculated values for the "thicknesses" of the chemisorbed films can also be reconciled with the experimental values if it is borne in mind that an oxide phase may be formed over this chemisorbed layer in the stationary state. $Fe^{3+}$ ions may be formed in the passive state in accordance with Equation (n), and these would be converted by hydrolysis into iron oxide. The experimental

$$Fe_2(O{-}O_2)_{ads} + 6\,H^+ \rightarrow 2\,Fe^{3+} + 3\,H_2O \qquad (n)$$

potentials obtained for nickel can also be essentially explained by a chemisorbed layer of oxygen, although they cannot be readily reconciled with the calculated values in this case[56].

*Kolotyrkin*[53] carried out impendance and double-layer capacitance measurements on chromium, nickel, and stainless steel, partly based on investigations by *Kabanow*[57,58], and found that the dissolution of these metals was inhibited by activated adsorption of oxygen from the water; he pointed out the analogy with the inhibition of the oxidation of $H_2$ on Pt electrodes coated with oxygen. *Trümpler*[59] has also recently postulated chemisorbed oxygen as the primary cause of passivation, on the basis of impendance measurements carried out mainly on anodically polarized nickel.

An argument advanced against the chemisorption theory is that a monomolecular chemisorbed layer could not form a continuous covering, and so could not cause passivation, since this would be counteracted by the dissolution of the oxide film in the steady state. A perfectly non-porous covering layer could exist only while the thickness of the layer was increasing[6]. However, if the chemisorbed layer of oxygen is formed from the water in accordance with Equation (o), then since the

$$M + OH_2 \rightleftarrows MO_{ads} + 2\,H^+ + 2\,e^- \qquad (o)$$

surface of the metal in an aqueous solution is completely covered with adsorbed water dipoles, this reaction should give a non-porous passive layer at least above a certain anode potential, provided that the dissolution process is not promoted by the displacement of the water or the oxygen by other strongly adsorbed molecules or ions. In the case of the base metals moreover, the reaction (p) must also be expected to occur. Even films of iron formed by evaporation in a high vacuum react in-

$$M + OH_2 \rightleftarrows MO + H_2 \qquad (p)$$

stantaneously with water vapor in accordance with Equation (p) to form $H_2$, which can be detected mass-spectrometrically[56].

Studies on the protection of iron surfaces by dibenzyl sulfoxide show that a monomolecular adsorbed layer is sufficient to inhibit completely the dissolution of the metal[60][*].

[*] It has been observed repeatedly that monomolecular layers of inhibitors can effect almost complete inhibition of corrosion [see, *e.g.*, *G. Karagounis* and *H. Reis*, Z. Electrochem. Ber. Bunsenges. physik. Chem. *62*, 865 (1958)]. What is possible in inhibition (*i.e.* prevention of the reaction of a metal in an aggresive medium by the addition of a foreign substance to the medium) is even more likely to occur in passivation (*i.e.* prevention of reaction in an aggresive medium by the metal itself).

It has been shown [54,54a,61], for nickel and chromium in sulfuric acid, that the Galvani tensions of the passivity range can be maintained and inhibited dissolution can be observed if, during the anodic polarization, the electrodes are ground with a corundum disk so that more metal is removed mechanically in a given time than is carried into solution by the current. However, the current-voltage curve is still found to be typical of those observed during passivation. Although the current is much higher in the passive range than for an unground electrode, it is still at least two orders of magnitude smaller than it should be at the same potential on the basis of the trend of the curve in the active range (see Fig. 5). It follows that neither a porous salt layer nor an

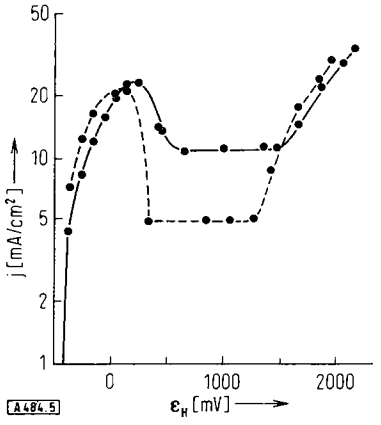

Fig. 5. Potentiostatic current density-potential curves for a ground Cr electrode in 1 N $H_2SO_4$ [61]. Quantity of Cr reacting at the anode *ca.* $2.7 \times 10^{-6}$ g cm$^{-2}$ sec$^{-1}$; $\varepsilon_H$ = potential, measured against a standard hydrogen electrode.
• - - - • Rate of abrasion = $2.2 \times 10^{-5}$ g cm$^{-2}$ sec$^{-1}$.
• ·-·-· • Rate of abrasion = $4.4 \times 10^{-5}$ g cm$^{-2}$ sec$^{-1}$.

oxide phase is a necessary condition for passivation, since if the anodic polarization is adequate and if water is preferentially adsorbed, any metal atom that is exposed mechanically is immediately re-covered by oxygen. The high current densities that are required for passivation when the electrode is ground in acids could not be achieved in the case of iron [62]. In alkaline solution, however, the electrode could not be activated by grinding, owing to the preferential adsorption of $OH^-$.

If we accept that passivation, at least in the cases of iron, nickel, and chromium, is primarily due to chemisorbed layers, oxide phases may still be gradually formed in the steady passive state, since a corrosion current flows even in the passive state, owing to the passage of metal ions through the chemisorbed layer. However, these layers are not the cause of the marked inhibition of the dissolution of the metal, although they hinder the access of the ions required for the dissolution. Consequently, the mechanism of conduction in these layers (in the cases of Ni, Fe, and Cr) is also of minor importance; the main factor is the junction between the metal and the oxide phase, which can be regarded as a chemisorbed layer. Chemisorbed layers on the surface of an ideal single crystal are probably non-porous, but penetration of the metal ions will be easier at edges, grain boundaries, and other points of high energy. An effect of this nature due to lattice defects was used by *Pryor* [63] to explain the Flade potential in a passivating $\gamma$-$Fe_2O_3$, and a similar effect would explain the marked dependence of the passivity on the pretreatment of the metal surface.

The growth of a passive layer is greatly influenced by its conduction mechanism [64,68]. If the oxide is an electronic semiconductor, the migration of the metal ions through oxide layers of appreciable thickness will require a higher anode potential than the process (q). Oxy-

$$2\,H_2O \rightarrow O_2 + 4\,H^+ + 4\,e^- \qquad (q)$$

gen will therefore be liberated, unless further oxidation of the metal ions in the passive layer, and hence breakdown (r) down to the chemisorbed film, is possible.

$$2\,MO + OH_2 \rightarrow M_2O_3 + 2\,H^+ + 2\,e^- \qquad (r)$$

If the Galvani tension is suitable, the reactions (q) and (r) can occur simultaneously. Further, the higher oxide may have an additional inhibiting action if it grows directly on the metal (secondary passivation) [65]. In the cases of Fe, Ni, Cr, and Co, it appears that the electronic conductivity of the passive layer formed during the steady passive state normally predominates over the passage of ions to such an extent that a further increase in voltage leads to an increase in the current and to reactions (q) and (r) (cf. Fig. 1). In the case of Al, Ta, Ti, and Zr [66], on the other hand, the electronic conductivities of the oxides are so low that, at the high field strengths that prevail [67], metal ions are transported through the passive layer to the solution side, where their hydrolysis leads to the growth of the layer. Consequently, the current does not increase to the breakdown point as the voltage is increased (cf. Fig. 9).

The first step in the passivation of very base metals is based mainly on reaction (p). If the passive state is maintained for long periods, oxide phases, sometimes containing different oxidation states, are observed. Thus in

the case of titanium, *Tomashov*[69] observed TiO, $Ti_3O_5$, $Ti_2O_3$, and $TiO_2$, several oxidation states being present at the same time in some cases. The occurrence of high field strengths in very thin passive layers with low ionic conductivities during anodic polarization explains *Güntherschulze* and *Betz*'s observation[66] that the thickness of such layers on aluminum and on tantalum increases exponentially with the applied potential. Even where the surface layer is electronically conducting, a high field strength (diffusion potential) can lead to an exponential relationship between the rate of growth of the layer and the voltage [see Equation (s)], as has been shown for iron by *Vetter*[70] and *Weil*[71]; this is due to the much higher mobility of the electrons in relation to the defects.

$$dx/dt \propto \exp(K\Delta U/x) \qquad (s)$$

(x = thickness of layer; $\Delta U$ = voltage; K = constant).

Oxide layers on aluminum and on tantalum exhibit a rectifying effect towards anode currents. *Van Geel*[72] has described the $Al_2O_3$ layer as a semiconductor diode consisting of an n- and a p-conducting layer. *Sasaki*[73] explains the behavior of the rectifying layer on tantalum by assuming that the layer consists of a very thin n-conducting layer containing an excess of metal on the metal side, an ionically conducting layer in the middle, and a p-conducting layer containing an excess of oxygen in contact with the electrolyte. This explains not only the rectifying effect, but also the dependence of the capacitance on the potential. However, owing to the change in the situation with different electrolytes, as well as for other reasons, doubt has been expressed regarding the interpretation of the rectification as a semiconductor effect[74–76]. It must be remembered in practice that the secondary passive layers, which are polycrystalline oxides or salts exhibiting pores and cracks, always contain water or electrolyte solution in their capillary system.

Thus with the aid of a microthermobalance, *Okamoto*[77] found that even the passive layers on stainless steels contain from 30 to 50 % of water. Where the layers contain such large quantities of electrolyte, an appreciable proportion of the current will be transported by the ions. At the field strengths encountered in ionically conducting salt or oxide layers ($10^6$ to $10^7$ V/cm), on the other hand, it is necessary to take into account the appreciable increase in the resistance of the layer as a result of the electroosmotic expulsion of water from its capillary system. This process, which *Müller*[78] regards as the cause of the rectifying effect of aluminum oxide layers, has also been observed in investigations on zinc in saturated $ZnSO_4$ solution and on aluminum in ammonium borate solution, using electrolytes containing $^3H_2O$[79]. The passive layers were formed in water containing $^3H_2O$, the anode current was switched off when the steady state was reached, and the electrode was allowed to stand for a short time, washed with dioxane, and transferred to an electrolyte containing no $^3H_2O$. When the isotope-exchange equilibrium was reached, a field was applied with the passivated electrode as the anode; the $^3H_2O$ content of the solution increased rapidly. It can be seen from Fig. 6 that this increase is proportional to the applied

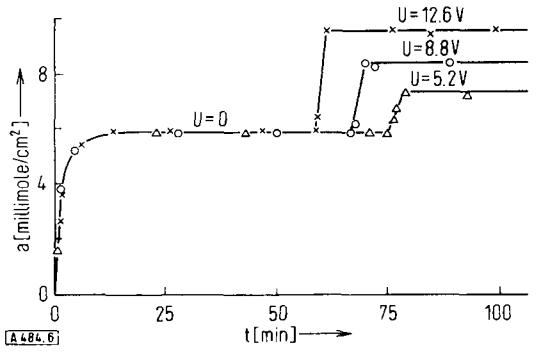

Fig. 6. Anodic loss of water from the passive layer on zinc in saturated $ZnSO_4$ solution, as a function of time and of the applied potential. a = surface concentration of water given off from the oxide layer.

potential. Passive layers on aluminum in borate solution also give up water. The fact that even anhydrous sulfuric acid labelled with $^{35}S$ is electroosmotically expelled[79] invalidates *Güntherschulze*'s objection[80] that electroosmotic dehydration cannot be considered as a cause of the rectifying effect in aluminum, because aluminum exhibits this effect even in practically anhydrous $H_2SO_4$. The elimination of charge carriers from the phase boundary by electroosmotic dehydration is similar to the "cut-off" state in a semiconductor diode (Fig. 7). The anions are carried away from the interface with the water, while the cations are removed by transport, the electrons being removed on the metal side. In any case, water

plays an important part, not only in the formation of the primary passive layer, but also in the transport of current in the secondary layer.

The passivity of a metal is strongly dependent on the nature of the aqueous electrolyte, and particularly on the pH value and on the anions present. However, investigations on this aspect of passivity have so far failed to provide an explanation. The specific effect of the electrolyte can be best understood on the basis of the mechanism of formation and breakdown of the passive layer.

## III. Kinetics of the Passivation and Activation Processes

If we regard passivation as being due primarily to the coating of the metal with an initially monomolecular film of a compound formed from the metal and bound to it two-dimensionally, while phases growing over this film[81] can provide powderful additional inhibition of the dissolution of the metal, but are not essential to passivation, the question arises of why the protective action varies from one metal and from one corrosive medium to another.

Following the fundamental work carried out by *Mott* and *Cabrera*[82], the kinetic inhibition observed during the oxidation of metals with dry oxygen has been the subject of a number of studies and theoretical interpretations[56,83]. Difficulties are encountered in the quantitative interpretation of the different rates of oxidation, since metals with very high affinities for oxygen (Al, Ta, W) frequently have much lower oxidation rates than metals (*e.g.* Cu) with lower affinities[84]. The principal factor involved here is the transport of the reactants through the boundary layer.

The kinetics of the anodic formation of oxide phases, and in particular of rectifying layers, have been studied by *Vermilyea*[85], *Young*[86], and *Dewald*[87]. However, these studies have explained neither the difference in the stabilities of these layers towards the same attacking agent, nor the differences in the action of different media on the same passive layer.

*Schwabe* has considered these questions in connection with the passivation of iron, nickel and chromium, and regards chemisorption as the primary and essential cause of passivation. The specific effect of the attacking agent (the anion in the case of acids) must become operative during the passivation, and not simply during the attack on the passive layer. In the case of a nickel anode, for example, passivation does not occur in HCl even at very high current densities; in $H_2SO_4$ or $HClO_4$ at the same concentration, however, passivation occurs at relatively low current densities, the current density falling off rapidly with increasing potential (Fig. 8).

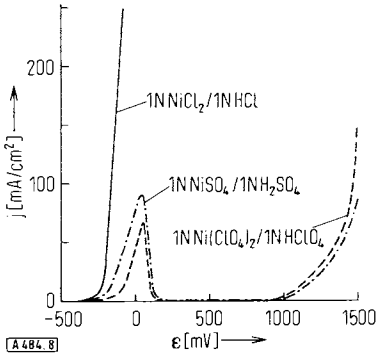

Fig. 8. Effect of the anion on the current density-potential curves for polished nickel electrodes in acidic solutions of nickel salts. ε is measured *versus* a saturated calomel electrode.

$Cl^-$, $Br^-$, and $I^-$ ions have been repeatedly observed [88–89b] to have a particularly corrosive action on the metals of the iron group, even in alkaline electrolytes, in which these metals are very stable in the absence of halide ions. This attack generally leads to pitting, even in the case of Cr/Ni steels. We shall confine ourselves here to a few possible explanations for the activating effect of halide ions on Fe, Ni, and Co, although the effects of these ions on metals such as titanium and zirconium have also been studied recently. The last two metals are particularly affected by fluoride ions, which have hardly any activating effect on the metals of the iron group[90]. This alone indicates the extreme complexity of the situation in relation to the attacking medium, and in particular the anion (Fig. 9). In the case of the iron metals, the chemisorption theory of the passive layer has been found to be capable of explaining the effect of the anion if the activation can be assumed to be due to the displacement of chemisorbed oxygen.

During active dissolution, not only must water molecules be available for the hydration of the metal atom, but anions must also be available to maintain electro-

neutrality. In any case, the water dipoles adsorbed in the double layer cannot remove metal atoms from the lattice as cations unless anions are also available in the solution to compensate the charge [91]; the water molecules, on the other hand, can give up oxygen to form the passive layer (see page 191).

However, anions are also specifically adsorbed on the metal surface, with partial dehydration and incorporation into the inner Helmholtz double layer [92]. It is fairly safe to assume that this adsorption favors the anodic transition-reaction with active dissolution of the metal. Thus if we start with a metal surface free from oxygen, the anion that is most strongly adsorbed on the metal will be the first to contribute to the uninhibited anodic dissolution. Of the anions of the strong acids HCl, $H_2SO_4$, and $HClO_4$, the $Cl^-$ ion is the most rapidly and the most strongly adsorbed, as has been shown with the aid of radioactively labelled anions [93]. The general case involves the displacement of adsorbed water dipoles or of chemisorbed oxygen by the anions in question. This can be seen from the fact that the saturation state on Pt and on Ni, which always corresponds to only 30 to 40% of a monolayer (provided that there is no chemical reaction, *e.g.* with $HS^-$), is reached only after several hours. Table 2 shows the quantities of anions adsorbed on Pt from aqueous solution in 1000 min

Table 2. Adsorption of various anions on Pt sheets from $2 \times 10^{-3}$M $Na^+$ solutions. Exposure time $10^3$ min.

| Ion | $10^{-10}$ g ions/cm² of true surface |
|---|---|
| $HS^-$ | 17.0 |
| $I^-$ | 9.1 |
| $CN^-$ | 8.6 |
| $HPO_4^{2-}$ | 6.3 |
| $Cl^-$ | 2.1 |
| $SO_4^{2-}$ | 1.3 |
| $ClO_4^-$ | 0.8 |

[91] *Ya. M. Kolotyrkhin*, Usp. Khim. *31*, 322 (1961); J. electrochem. Soc. *108*, 209 (1961) has also stressed the fact that the anions must be involved in the dissolution of the metal.

[92] *D. C. Grahame*, Chem. Reviews *41*, 441 (1947); J. Amer. chem. Soc. *74*, 1207 (1952).

under the same conditions. Further, it can be shown with the aid of radioactively labelled ions that after the metal has been precoated with ions of one type, these can be displaced by more strongly adsorbed ions. This effect is evident in Fig. 10.

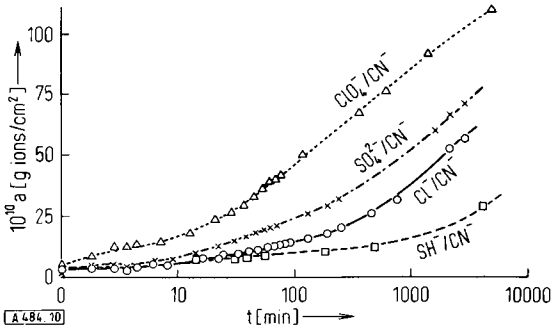

Fig. 10. Adsorption of $CN^-$ ions to pre-adsorbed films on platinum.

This strong adsorption is obviously not enough in itself to bring about anodic dissolution, since the still more strongly adsorbed $CN^-$ even inhibits the anodic dissolution of iron in neutral and alkaline solutions [94]. It may be that the anions are not so strongly chemisorbed, with the displacement of water, that they prevent hydration. It should also be borne in mind that the adsorption depends on the potential of the metal [95]; the anions can be completely desorbed by the use of a sufficiently negative Galvani tension. *Kolotyrkin* [96] postulated that the adsorption can lead to anodic dissolution only above a critical Galvani tension; below this critical potential adsorbed ions can even inhibit corrosion, a phenomenon that is attributed in some cases to the hindrance of the cathode process (increase in the $H_2$ overvoltage [97]). The adsorption of the anions will increase with increasing anodic polarization, but the passivating reaction (o) may at the same time become more pronounced, with the result that the anions may again be displaced.

Fig. 11 shows the increase in the adsorption of $I^-$ on a nickel plate in the active range, and the rapid decrease

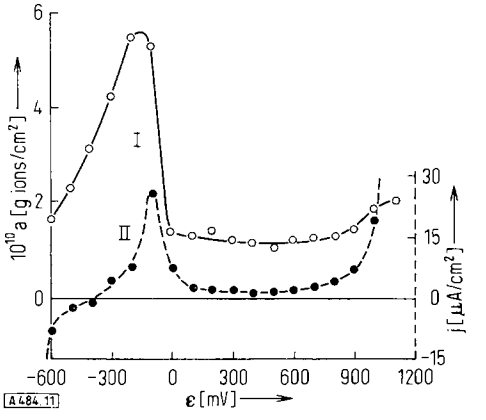

Fig. 11. Curve I: Dependence of the adsorption of $^{131}I$ on Ni plates, at pH 4.3 in 0.1 M $Na_2SO_4$ solution, on the Galvani tension. in adsorption on passivation [98]. In any case, during the anodic dissolution of an oxide-free metal, the slower the anodic dissolution, the more pronounced will be the passivating reaction in comparison with the anodic transition reaction with the chemisorbed anions. Thus anodic polarization gives rise to two competing anode processes, one being the active dissolution of the metal with hydration and with the aid of the anions, and the other being the formation of an adsorbed film of oxygen from the water. If this passivating reaction predominates, the metal becomes completely covered by the passive layer, and the characteristic rapid decrease in current is observed. The contribution of reaction (o) to the anode process increases with the inhibition of active dissolution (in the absence of the passive layer). A measure of this is the exchange current density of the process (t), *i.e.* the lower the current density, the greater

$$M + n\,H_2O \rightleftharpoons M^{y+} + n\,H_2O + y\,e^- \qquad (t)$$

is the contribution of reaction (o). The exchange current densities reported for Fe, Ni, and Cr are 6 to 10 orders of magnitude smaller than that reported for silver [99]. Thus there is no passivation of a polished Ag anode in $HClO_4$ even at current densities of more than 1 A/cm² [60]. However, the passivating reaction also competes with the displacement of adsorbed oxygen by activating anions, in accordance with Equation (u) (in

$$[^{\ominus\ominus}M^{(++)}\ {}^{\ominus\ominus}M^{(++)}] - O_{ads} + 2\,A^- + H_2O \rightarrow [^{\ominus\ominus}M^{(++)}] + M^{2+} + 2\,A^- + 2\,OH^- \qquad (u)$$

which brackets denote the metallic phase). This process leads to the removal of the chemisorbed oxygen layer and the reactivation of the metal. Finally, another process that competes with reaction (o) is the chemical dissolution of the metal by acids:

$$[^{\ominus\ominus}M^{(++)}] - O_{ads} + 2\,H \rightarrow H_2O + M^{2+} \qquad (v)$$

Thus the passivation, which inhibits both itself and the active dissolution, is stopped by reactions (u) and (v) [54b, 100]. If the metal is originally covered with oxygen, the active dissolution must be preceded by the displacement of the oxygen by activated anions. In any case, even if the active dissolution can follow the anodic polarization, it is also inhibited by the formation of a blocking layer of salt or oxide directly from the metal when the concentration rises above the saturation point [28]. In this case we generally find an anodic rectifying effect (*e.g.* Zn in saturated $ZnSO_4$ solution). The high polarization caused by salt layers can lead in some cases to the formation of compounds of higher valence.

Thus the competition of various activating and passivating reactions gives rise to a large number of possibilities for the formation or breakdown of passive layers [*]:

The metal will in general be covered with oxide; this oxide layer must be removed by reactions (u) or (v), or both, before active dissolution according to Equation (t) can occur. The re-passivation reactions (o) and (p), however, compete with (u) and (v). If the former are faster than the latter, no activation can take place. It should further be noted that reaction (o) depends on potential and is accelerated by increasing anodic polarization. The same applies to the active anodic dissolution according to Equation (t). When the latter, and particularly the passage of metal ions across the phase boundary, is not inhibited, reaction (o) will not take place after removal of the passivating oxide layer, and eventually solid salt will be deposited on the metal surface. Since it is an ionic conductor, this salt acts as an electrical barrier layer, and a marked current decrease results (*e.g.* zinc in zinc sulfate [103]). A substantial current increase with increasing potential occurs only when the layer has undergone dielectric breakdown or a transition in which, *e.g.*, ions of higher charge are formed. The latter occurs with lead in sulfuric acid, where $PbSO_4$ is converted into electronically conducting $PbO_2$. With iron in $FeCl_2$ solution, the blocking layer of $FeCl_2$ initially formed is removed [100a] at higher Galvani tensions by the reaction

$$[Fe^{(++)} - Cl_2^{(--)}] + Cl^- \xrightarrow{H_2O} Fe^{3+} + 3\,Cl^- + e^- \qquad (w)$$

If the active anodic dissolution is strongly inhibited (overvoltage), however, the reaction (o) can cause re-passivation and a decrease in current long before saturation is reached on increase of Galvani tension; Equation (v) shows that the passivating potential will depend on pH. If the passive layer is a good electronic semiconductor, reaction (q) will initiate another current increase above the oxygen potential; such an increase can also be caused by formation of higher oxidation states in the passivating oxide (*e.g.* in Cr). Ionically conducting oxide layers which are not oxidizable, however, block the current until dielectric breakdown occurs.

In case the passivating reactions (o) and (p) are much faster than the activating ones (u) and (v), activation is not possible; the base metals (Ti, Al, *etc.*) remain passive in neutral or weakly acidic solution on anodic polarization, since they react faster according to Equa-

[101] *K. Schwabe* and *R. Radeglia*, Werkstoffe u. Korrosion *13*, 281 (1962).

[102] Chemisorbed oxygen layers may also be particularly stable because of the feasibility of localized bonding to the metal and transverse bonding of the oxygen atoms to one another; cf. *K. Schwabe* and *Ch. Weissmantel*, Mber. dtsch. Akad. Wiss. Berlin *5*, 23 (1963).

[103] For investigations on zinc in saturated zinc sulfate solutions, cf. *K. Schwabe* and *F. Lohmann*, Z. physik. Chem. *215*, 158 (1960/61).

tion (p) than they pass into solution. (The simplifying assumption is made that all parts of the metal surface react in the same way or have the same coverage).

According to *Kolotyrkin*[96], the increased adsorption can lead to a further increase in the activating action of the anions with increasing anodic polarization. According to *Müller*[54b, 100], the area not covered by the oxide film, *i.e.* the active area, decreases exponentially with increasing polarization. The Flade potential can therefore be interpreted as the value of the Galvani tension above which the passivating reaction (o) is faster than the active dissolution. The negative current-voltage characteristic is due to the fact that as the voltage is increased, the covering of the metal surface as a result of reaction (o) inhibits both the active dissolution and reaction (o) itself.

The quantitative treatment of this competition between electrode processes is extremely difficult, since the free (active) and covered (passive) fractions of the surface are themselves functions of time, current, and potential, and since the attack on the surface of the electrode may not be uniform. However, the behavior of nickel and iron in alkaline solutions containing halogen ions (in spite of the pitting that occurs in these cases) has been quantitatively explained on the basis of competing electrode reactions[89b, 101]. The difficulties connected with the conditions at the metal/corrosive medium interface cannot be overcome by impulse methods in the study of the passivation and reactivation processes, since these processes proceed slowly. Thus even for the most widely studied metals, *i.e.* iron, nickel, and aluminum, a quantiative kinetic treatment has not yet been achieved.

The situation is further complicated, however, by the fact that the primary monomolecular passive layer is not ideal; its structure is abnormal or it is less stable at various parts of the surface, owing to grain boundaries, dislocations, and impurities. More metal atoms will react with the water or the anions in these regions, with the result that the passive layers become thicker and the course of the attack may be largely determined by the transport processes in these layers. In the primary layer, the transport of the metal atoms in the metal lattice and the bond energy in the chemisorbed layer will be the main factors controlling further passage through the layer (except at faults in the layer)[102]. In the base metals (Al, Ti, Zr, *etc.*), each fault will lead to further oxide formation in accordance with Equation (p). The passive layer will therefore become steadily thicker, but the rate of growth will decrease owing to the increasing diffusion path. This may ultimately lead to a steady state in which the thickening of the layer with increasing potential compensates for the increased rate of transport, so that the current is found to be independent of the voltage[103]. Studies on alloys are therefore much more difficult to interpret[104].

# The Significance of Enterobacterial Mutants for the Chemical Investigation of their Cell-Wall Polysaccharides

BY DR. O. LÜDERITZ AND PROF. DR. O. WESTPHAL

MAX-PLANCK-INSTITUT FÜR IMMUNBIOLOGIE, FREIBURG (GERMANY)

*Dedicated to Professor Karl Freudenberg on the occasion of his 80th birthday*

*The outer cell surface of Enterobacteriaceae, i.e. the cell wall, consists of a rigid structure (murein) on which additional proteins, lipids, and polysaccharides are deposited. In the bacterial wild types (S forms) the polysaccharide is species-specific and carries the serologically determinant groups of the respective O antigen. These specific polysaccharides often consist of a large number of monosaccharides; up to eight different monosaccharides may be involved. Bound to lipid A, the cell-wall lipopolysaccharides represent the endotoxins of the bacteria. During the past few years the structures of the enterobacterial cell-wall polysaccharides have been elucidated by chemical, immunochemical, biochemical, and genetic investigations, particularly in the Salmonella. Here the polysaccharides consist of a basal polysaccharide common to all species, to which (in the S form) are bound longer species-specific side chains, consisting of repeating oligosaccharide units. Spontaneous S → R mutation leads to R forms which are deficient mutants of the wild types in regard to the biosynthesis of the complete cell-wall polysaccharide. In contrast to the multiplicity of the serological specificities of the somatic antigens of the S forms, only a few serological types were found among the R forms (R I, R II, etc.). These R polysaccharides correspond to intermediates in the biosynthesis of the wild-type polysaccharides. The S → R mutation leads to the loss (or block) of an enzyme (transferase, synthetase) participating in the synthesis of the S polysaccharides. Recently many deficient mutants have been isolated and analysed, and in this way numerous stages in the biosynthesis of the cell-wall polysaccharides, for example, of Salmonella minnesota, have been made accessible to direct analysis. According to these investigations, the cell-wall polysaccharides of Salmonella consist of a basic polyheptose phosphate core which is bound to lipid A via ketodeoxyoctonic acid. To the basic core are linked pentasaccharide units of*

*N-acetylglucosaminyl→glucosyl→galactosyl→glucosyl→galactosyl*

*(R II structure). All other R forms are structurally deficient mutants of R II. In the complete polysaccharides of Salmonella S forms (wild types), the repeating oligosaccharide units of the specific side chain are bound to the terminal N-acetylglucosamine of the R II structure.*

## Introduction

Enterobacteriaceae form a large group of microorganisms which is subdivided into several genera comprising *Salmonella*, *Shigella*, *Coli* bacteria, and others[1]. On the basis of serological reactions, these genera consist of several species or serotypes. The genus *Salmonella*, for example, comprises more than 700 species which are classified serologically in the Kauffmann-White scheme[2,3]. They include pathogenic and hence clinically important organisms, *e.g.* typhoid and paratyphoid bacteria, but also many non-pathogenic representatives. Similarly, several hundred *Coli* species have been discovered and new ones are constantly being isolated and characterized serologically.

Much work has been carried out on the morphological cell structure of Enterobacteriaceae[4]. Particular interest has been devoted to the cell wall which forms the outer structured surface of the cell[5]. It is superposed on the cytoplasmic membrane which encloses the cytoplasm and consists principally of two main parts, a rigid structure and filling material. The rigid structure, which imparts stability to the bacterial cell, has been investigated by *Weidel*[6] and his group and others. Each cell forms a giant bag-shaped molecule or sacculus, the murein, which consists of chains of alternating *N*-acetylglucosamine and *N*-acetylmuraminic acid units

with peptide cross-linkages [7,8]. In these muramyl peptides, which have a similar composition in all bacteria investigated so far, D-amino acids (D-alanine, D-glutamic acid) are regularly encountered in addition to L-amino acids (L-alanine, L-lysine, *etc*). The chemical elucidation of the rigid structure has provided an interpretation of the effect of enzymes such as lysozyme and of antibiotics such as cycloserine and penicillin on bacteria.

Characteristic higher-molecular cell-wall building units are superimposed on the rigid structure [4]: protein, lipid, and polysaccharide (Fig. 1).

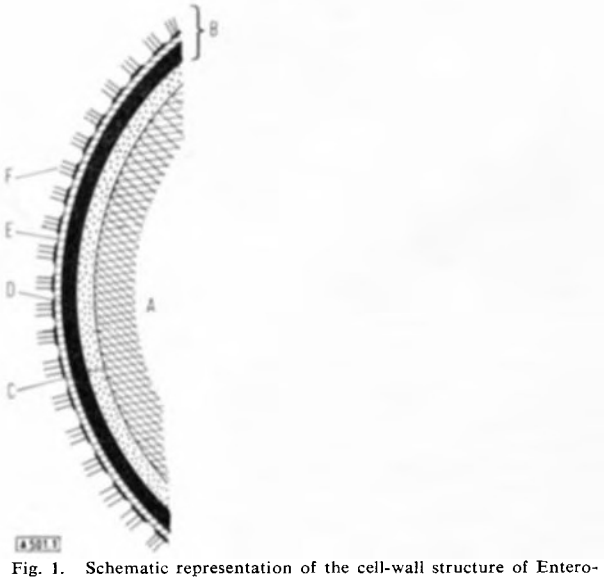

Fig. 1. Schematic representation of the cell-wall structure of Enterobacteriaceae.
A: Cytoplasm. B: Cell wall. C: Cytoplasmic membrane. D: Rigid structure (muramyl peptide). E: Protein, lipid. F: Polysaccharide.

Of these building units, proteins and lipids seem to have a similar composition in many, if not all, species, and the same holds for the rigid structure of the cell wall [9,10]. In contrast, Enterobacteriaceae exhibit an extraordinary multiplicity in regard to the polysaccharide, which is largely responsible for the serological species- or group specificity. When rabbits are immunized with killed bacteria, they form antisera which cause agglutination of the bacteria and of serologically cross-reacting types. Of the somatic antigens on the surface of the bacteria, which are responsible for this agglutination, the polysaccharide antigen (or O antigen in wild types) plays an important part, *i.e.* specific determinant structures of the cell-wall polysaccharides react with corresponding antibodies. These determinant oligosaccharidic structures (see *e.g.* [11]) form the basis for the understanding of the serological diagnosis of enterobacterial serotypes, *e.g.* as established in the Kauffmann-White scheme of the *Salmonella* [3]. The immunochemical elucidation of the determinant regions in these polysaccharide antigens was made possible only by the use of monospecific antisera (factor sera), the preparation of which has been described by *Kauffmann* [3].

In the cell wall, the polysaccharide antigens are firmly bound to a lipid component, the so-called lipid A [12], and to protein. Depending on the extraction method used [9–11,13], these antigens can be transferred into aqueous solution in more or less complex form. It has been found that particularly the lipopolysaccharides (lipid A-polysaccharides) of Enterobacteriaceae act not only as O antigens but also as endotoxins, *i.e.* substances of extreme biological activity (pyrogens *etc.* [14]). In this way, the non-specific endotoxic and the specific antigenic properties of these bacteria reside in the same complex molecule, the lipopolysaccharide. While the lipid A component is essential for the endotoxic activity, the polysaccharide component is responsible for the antigenic (serological) specificity (see [15,16]). The bacterial lipopolysaccharides can be extracted directly from the bacteria with phenol/water [17], and are then obtained together with nucleic acid, from which they must be subsequently separated. Otherwise, purified cell walls can be initially prepared [18] and subsequently extracted with phenol/water.

## The Specific Polysaccharides of the Enterobacterial Wild Types (S Forms)

The general principle of the structure of the enterobacterial cell-wall polysaccharides has been largely elucidated. The results show that the polysaccharides of the wild-types (smooth or S forms) consist of a polyheptose phosphate core (a), to which side chains are bound. These, in turn, consist of a substantially ubiquitous inner oligosaccharide chain (b), to which longer chains (c) are bound consisting of periodically repeating species-specific oligosaccharide units. The repeating units themselves can be straight chains or may carry short side chains of several monosaccharides. *Staub et al.* [11,19–23] at the Pasteur Institute in Paris have

pioneered the investigation of the chemistry and immunochemistry of these side chains. The sugars involved in the repeating units, the type of their glycosidic linkage, and the bond between the units determine the specificity of the polysaccharide and hence the serotype.

Because of this structure, the enterobacterial S forms contain comb-shaped polysaccharide molecules (see Fig. 1), which consist of a basic heptose phosphate chain and an inner ubiquitous side chain, to which the specific repeating units are linked (Fig. 2).

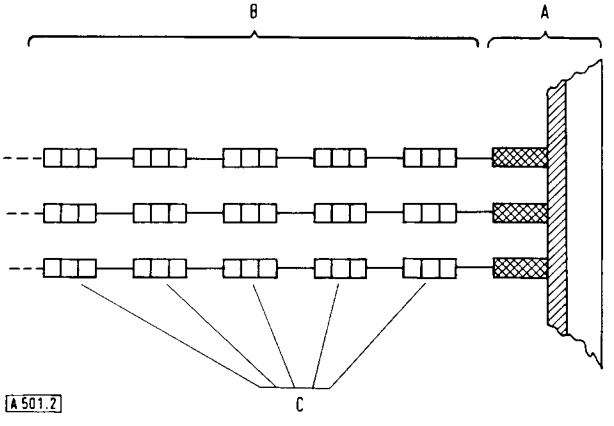

Fig. 2. Schematic representation of the specific and non-specific regions in the polysaccharide of *Salmonella* O antigens.

A: Basal structure. B: O-specific side chain. C: Repeating units.

*Osborn*[18] and *Heath*[24] have demonstrated that the heptose phosphate core in the lipopolysaccharides is bound to lipid A *via* ketodeoxyoctonic acid (KDO). This latter compound was discovered by *Heath* and *Galambor*[25] who also elucidated its structure. Lipid A is a derivative of poly-*N*-β-hydroxymyristinoyl-D-glucosamine phosphate esterified with long-chain fatty acids[15,26,27]. The analysis of enterobacterial lipopolysaccharides therefore always reveals D-glucosamine and KDO, and it is necessary to determine whether, and in which position, glucosamine occurs in the polysaccharide as well as in the lipid A.

For several years we have concerned ourselves with chemical and immunochemical analyses of the O-specific polysaccharides from enterobacterial S forms. Together with *Kauffmann* (Copenhagen), who worked out the serological classification of the *Salmonella* over a period of several decades (Kauffmann-White scheme), we have isolated the lipopolysaccharides from the S forms of over a hundred *Salmonella* species and indified the sugars contained in their polysaccharide components[28,29]. Figure 3 shows the results and is intended merely to convey an indication of the multiplicity of the sugar combinations (chemotypes)[28]. Some polysaccharides contain as many as eight different monosaccharides.

Fig. 3. Sugar constituents of *Salmonella* lipopolysaccharides (classification into chemotypes) [28,29].

Empty circles: Specific sugars. Hatched circles: Basal sugars.

It is noteworthy that all investigated *Salmonella* lipopolysaccharides contain KDO, heptose, galactose, glucose, and glucosamine, which we have termed "basal sugars" (hatched circles in Fig. 3). In addition to these basal sugars different combinations of the specific sugars, *e.g.* galactosamine, mannose, fucose, or rhamnose and the 3,6-dideoxyhexoses[30] (paratose, abequose, tyvelose, or colitose), may be present. The combination of the basal sugars without specific sugars corresponds to chemotype I. In *Salmonella* O antigens, the 17 different sugar combinations (chemotypes I–XVI and XXV) compiled in Figure 3 have so far been found. Approximately 25 different chemotypes are obtained when the specific polysaccharides from the S forms of *E. coli* analysed to date are added[31,32]. The variety of heteropolysaccharides is even greater when one considers that, for the same qualitative composition,

the sugars in dieffrent O antigens can occur in different sequences and also with different linkages between them.

The multiplicity of the serological specificities of *Salmonella* O antigens, expressed by the Kauffmann-White scheme, is matched by a corresponding multiplicity of the structures of the polysaccharide side chains (Figures 4 and 5). The oligosaccharides listed in Fig. 4 were elucidated by analysis of partial hydrolysates from the side chains of the polysaccharides of several *Salmonella* species. Their constitutions were determined by *Staub et al.* [19–23, 33] for *Salmonella* groups B, D, and $E_4$, and by *Robbins*, *Uchida*, and *Luria* [34] for groups $E_1$, $E_2$, and $E_3$. The side chains of all these polysaccharides contain the same sugar sequence, *i.e.* galactose→mannose→rhamnose (Gal→Man→Rha), while the linkages may be different and short side chains may be present or absent.

Fig. 4. Structurally related O-specific oligosaccharides (repeating units) in lipopolysaccharides of various *Salmonella* species of serogroups B, D, and E [11, 33, 34, 36, 80].

Any alteration in the structure of these repeating units is expressed by a new partial serological specificity, on the basis of which the bacterial genus can be characterized and which corresponds to an individual antigen formula which had its place in the Kauffmann-White scheme long before these structures were recognized.

Several of the side-chain structures shown in Fig. 4 are interconvertible by lysogenic conversion and are therefore often closely related genetically, although they may belong to different, sometimes serologically little related, serogroups. For example, infection of *Salmonella uganda* (O antigen factors 3, 10) with the lysogenic phage $\varepsilon_{15}$ converts the former into *Salmonella newington* [3, 15]. In turn, this strain is converted into *S. illinois* (O factors 3, 15) after infection with phage $\varepsilon_{34}$. The structural changes in the corresponding polysaccharides, which were elucidated by *Robbins et al.* [34], can be seen in Figure 4. A further example of lysogenic conversion was investigated by *Le Minor* and *Staub* [33, 35]. *Salmonella* of groups A, B, and D were transformed into new serological types after infection with phage $\varphi_{27}$, *i.e.*

Group A: 2,12 $\xrightarrow{\varphi 27}$ 2, 12, 27A, 27

Group B: 4,12 $\xrightarrow{\varphi 27}$ 4, 12, 27B, 27

Group C: 9,12 $\xrightarrow{\varphi 27}$ 9, 12, 27D, 27

In all three antigens the glycosidic linkage between galactose and mannose is altered throughout the entire chain:

α-galactose(1→4)mannose→α-galactose(1→6)mannose. This change gives rise to new specificities. *Staub* and her group have also elucidated the chemical changes leading to the appearance of specificity 1 after infection with phage P22 [36].

The biological information contained in the phage nucleic acid provides a genetic link between several of the *Salmonella* serotypes shown in Figure 4. They may form a family of species which has emerged during the evolution of the *Salmonella* from an original form containing (Gal → Man → Rha) chains.

Figure 5 shows that the specific chains of polysaccharides of other *Salmonella* groups (*e.g.* G, N, and U) may consist of other sugars, for example, galactosamine, glucosamine, galactose, glucose, and fucose. The constitution of the corresponding lipopolysaccharides has been investigated by *A. R. Simmons* in our laboratory [37]. Their sugar compositions resemble those of the human blood-group substances. *Springer et al.* [38] have shown that *S. milwaukee* has a strong blood-group B specificity. The last formula in Figure 5 indicates that this cross-reaction is presumably due to the α-galactosyl-(1→3)galactose grouping, which, according to *Morgan* [39], is also involved in the structure of the blood-group B substance.

Figures 4 and 5 show oligosaccharide units isolated from partial hydrolysates of the lipopolysaccharides.

[39] *V. P. Rege, T. J. Painter, W. M. Watkins*, and *W. T. J. Morgan*, Nature (London) *200*, 532 (1963).

It is still unknown in which sequence the oligosaccharides of Figure 5 are linked within the chain, which sugar starts the chain, and how long the chain is.

The oligosaccharides shown in Figure 4 are linked in the manner indicated. Glucose and the 3,6-dideoxyhexoses form short side chains. The first sugar in the O-specific chain is galactose. The isolated units Gal→Man→Rha are therefore different from the biological units (Man→Rha→Gal)[40].

It should be interesting to obtain information about the structure of the repeating oligosaccharide units of as many O antigens of *Salmonella* S forms and other genera as possible. During comparative analyses of numerous *E. coli* species, *Jann et al.*[31,32] have found that 14 non-cross-reacting *Coli* strains form O antigens of chemotype I (only basal sugars), while 17 strains form O antigens of chemotype VII (basal sugars plus L-rhamnose). All these strains, with chemotypically the same polysaccharide antigen, must therefore have structurally different side chains.

## The S→R Mutation

It has been known for a long time that the wild types of Enterobacteriaceae can undergo spontaneous mutation. The mutated strains are easily recognized because, in general, they form rough shallow colonies (R forms) on agar, while the parent strains grow in smooth, shiny colonies (S forms)[3]. With this morphological change is connected a loss of certain biological properties. R mutants have lost the serological O specificity of the original strain and generally do not agglutinate in the related O antiserum. The R forms frequently exhibit spontaneous agglutination in liquid nutrient media. In comparison with the wild types (S forms), R mutants are less pathogenic; rapid phagocytosis and intracellular destruction occurs in higher organisms. R mutants also synthesize a cell-wall lipopolysaccharide which can be extracted with phenol/water[41,42] and which, in the animal, is generally as effective an endotoxin as the lipopolysaccharide from the related S forms.

Because of the loss of the serological O specificity during S→R mutation, it was to be expected that R lipopolysaccharides differ in constitution from the corresponding O-specific S lipopolysaccharides. Starting from about 25 different *Salmonella* S forms with O antigens of nearly all chemotypes (cf. Fig. 3) *Kauffmann* has isolated R mutants from which we extracted the corresponding lipopolysaccharides[42]. The results of the sugar analyses of these R lipopolysaccharides can be seen in Figure 3. In contrast to the multiplicity of the sugar combinations (chemotypes) in the lipopolysaccharides of the S forms, the lipopolysaccharides of the R mutants contain only the basal sugars (shaded in Fig. 3), irrespective of which chemotype the S form belonged to. The specific sugars of the wild-type lipopolysaccharides have disappeared in the corresponding R lipopolysaccharides. After S→R mutation the multiplicity in the constitution of the O antigens is replaced by a very uniform picture; the investigated R antigens all belong to chemotype I (basal sugars only)[42].

Two facts appear to be significant: (1) the *Salmonella* O antigens always contain the same five basal sugars in addition to the specific sugars, and (2) the same five sugars make up the lipopolysaccharides of the investigated R mutants. This led us to the hypothesis[42,43], which was independently developed by *Nikaido*[44], that the polysaccharides of the R forms are preformed as the nucleus in the polysaccharides of the S forms (see Fig. 2).

According to this scheme, O antigens consist of a basal polysaccharide with the five basal sugars and the O-specific side chains. These side chains form the bulk of the molecule; the basal polysaccharide appears to be the common underlying structure of all O antigens. When the biosynthesis of the O-specific side chains in an enterobacterial wild type has been interrupted by an enzyme block produced as a result of a mutation, only the synthesis of the basal part occurs. Accordingly, this part represents the R-specific polysaccharide of the R mutants. In addition, it is plausible that R form polysaccharides contain no sugars which are not also present in the S form.

This postulate of an ubiquitous basal polysaccharide and of specific side chains has admittedly not yet been finally proved as a general principle, but it is now largely accepted for the *Salmonella*. This hypothesis (Fig. 2) is supported by the findings presented in the following sections.

## RI- and RII-Specific Polysaccharides

As shown above, the lipopolysaccharides from R forms of *Salmonella* are chemically very uniform. All investigated R lipopolysaccharides consist of the five basal sugars KDO, glucosamine, heptose, galactose, and glucose. This chemical uniformity is matched by a great serological uniformity. The R lipopolysaccharides,which have lost the O-specificity of the related wild types, exhibit strong mutual serological cross-reactions[3,45]. In hemagglutination inhibition experiments[45], it was found that R lipopolysaccharides can be be classified into two serological groups on the basis of their serological reactivity with two R antisera (Table 1).

To carry out passive hemagglutination[46,47], lipopolysaccharides pretreated by heating or with weak alkali are fixed on the surface of erythrocytes. When the blood corpuscles sensitized in this way are incubated with antisera prepared by immunization of rabbits against the appropriate bacterium, the erythrocytes undergo agglutination. This reaction is in-

hibited when serologically identical or cross-reacting lipopolysaccharides are added to the agglutinating system. These then react with the antiserum, so that hemagglutination fails to take place. This inhibition reaction is highly specific and can be performed with microgram quantities of antigen.

Kauffmann-White scheme by numerous antigen factors (specificities of S forms) and their combinations, is therefore reduced to a few R specificities.

We had initially assumed that the S→R mutation would, for unknown reasons, lead to RI mutants in some species and to RII mutants in others, *i.e.* that the result of mutation is determined by properties of the wild type. However, *Kauffmann* then isolated a second *S. minnesota* R mutant which differs serologically from the RI type; the analysis of its lipopolysaccharide showed that it belongs to the RII group. At the same time, *Stocker* [48,50] isolated RI and RII mutants of *S. typhimurium*, and we now assume that each *Salmonella* species can undergo mutation to RI as well as to RII.

In recombination experiments with colicinogenic strains, *Subbaiah* and *Stocker* [48] found that for *S. typhimurium* the mutation to RI mutants occurs at the gene locus rou A, while during mutation to RII mutants gene locus rou B is involved. Further experiments showed that locus rou A is responsible for the biosynthesis of the basal polysaccharide and locus rou B for the biosynthesis of the O-specific side chains [49].

An attempt to elucidate the chemical structure and the biosynthesis of RI and RII-specific (lipo)polysaccharides, their mutual relationship, and that to the (lipo)polysaccharide of the S form has meanwhile been undertaken by several groups of workers. We have been concerned primarily with the comparative analysis of

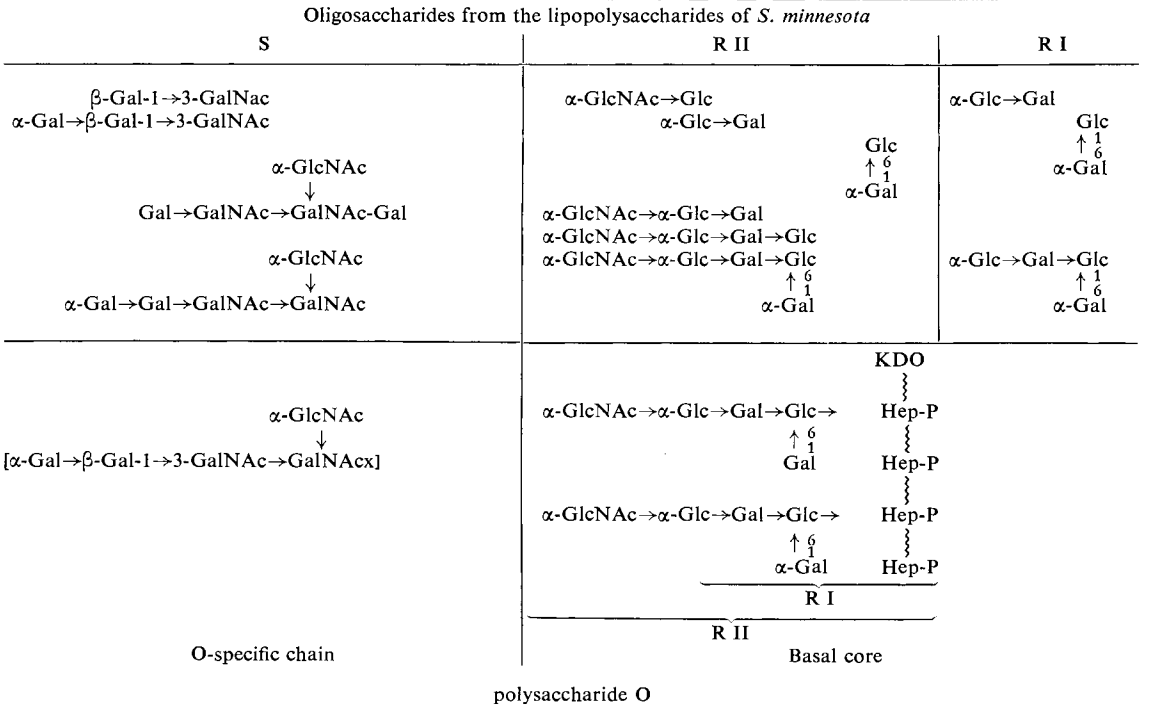

Fig. 6. Possible structures of the oligosaccharides of *S. minnesota* S, RI, and RII lipopolysaccharides (top) and a hypothetical formula of the O-specific polysaccharide (bottom) [51, 53].

The first group of R lipopolysaccharides inhibits the antiserum obtained with an R mutant of *Salmonella minnesota* (system I), and the second group inhibits a *Salmonella inverness* R antiserum (system II). Because of their serological specificities, the R lipopolysaccharides can be assigned to the serological groups RI or RII.

In the *Salmonella* R mutants, the great serological diversity of the S forms, which is expressed in the

[48] *T. V. Subbaiah* and *B. A. D. Stocker*, Nature (London) *201*, 1298 (1964).

[49] *P. H. Mäkelä*, J. gen. Microbiol. *41*, 57 (1965).

[50] *I. Beckmann*, *T. V. Subbaiah*, and *B. A. D. Stocker*, Nature (London) *201*, 1299 (1964).

[51] *I. W. Sutherland*, *O. Lüderitz*, and *O. Westphal*, Biochem. J. *96*, 439 (1965).

the S form of *S. minnesota* and the mutants *S. minnesota* RI and RII. *Salmonella minnesota* belongs to the O serogroup L. In addition to the main antigen 21, it contains the weakly established factor 26[3], which was introduced, because of a cross-reaction with species of group $E_1$ *(e.g. S. london)* with the factors 3, 10. The formulae are therefore: *S. minnesota* 21, 26 and *S. london* 3, 10, 26. Factor 26 was not included in the Kauffmann-White scheme. In addition to the basal sugars, the *S. minnesota* lipopolysaccharide contains galactosamine as the specific sugar[28].

To elucidate the chemical structure of the O antigen and the R antigens of *S. minnesota*, partial hydrolyses were carried out. The oligosaccharides thus obtained from the RI, RII, and S lipopolysaccharides are listed in Figure 6[51].

### The RII Polysaccharide

Of the listed RII oligosaccharides, five fragments can be recombined to form a pentasaccharide. This pentasaccharide has the structure of an *N*-acetylglucosaminyl→glucosyl→galactosyl→glucose with an α(1→6)-linked galactosyl residue in the side chain and glucose as the reducing end-group. The provisional formula for the RII polysaccharide (Fig. 6, bottom) contains this pentasaccharide linked to heptose. The formula is based partly on investigations on other mutants by *Nikaido*[52], who isolated a glucose-heptose oligosaccharide. *Kuriki* and *Kurahashi*[52a] recently isolated oligosaccharides from a UDP-glucose deficient mutant, which consist of 10 heptose units and one (reduced) KDO unit. This proves that part of the heptose units is linked glycosidically (probably 1→2).

### The RI Polysaccharide

A similar set of oligosaccharides, but without the terminal *N*-acetylglucosamine, was obtained by partial hydrolysis of the *S. minnesota* RI lipopolysaccharide (Fig. 6). This leads to the formula of the RI polysaccharide which is shown at the bottom of Figure 6 as part of the RII formula.

Thus the RI polysaccharide of *S. minnesota* differs from the RII polysaccharide merely by the absence of the terminal non-reducing glucosamine unit, or, alternatively, the RII polysaccharide is obtained from the RI polysaccharide when the glucosamine unit is added onto the non-reducing terminal glucose residue (Fig. 6). The RI polysaccharide therefore behaves as a precursor of the RII polysaccharide.

We have also investigated the lipopolysaccharides of the RII mutants of *S. typhimurium*, *S. inverness*, and *S. poona*. Their partial hydrolysates contained the same oligosaccharides as the *S. minnesota* RII lipopolysaccharide. It follows that RII lipopolysaccharides of different origin are not only serologically identical but also have the same chemical composition.

### The O-Specific Polysaccharide of the Wild Type

*Schulte-Holthausen*[33] in our laboratory isolated 15 basic or neutral oligosaccharides from the lipopolysaccharide of the S form of *S. minnesota*. So far, only the four compounds shown on the left-hand side of Figure 6 have been purified sufficiently for analyses to be carried out (sugar determinations before and after borohydride reduction, Morgan-Elson reaction, attempts to split the molecule with glycosidases). The formulae shown have not yet been finally confirmed. α-Linked *N*-acetylglucosamine very likely acts as a specificity-determining immunodominant sugar[11] in antigen factor 21[54], while α-linked galactose may be important for the specificity of antigen factor 26[34]. The formula reconstructed in the lower left-hand part of Figure 6 from the structures of the oligosaccharide fragments is a provisional one. However, it can be assumed that these or similar oligosaccharides form the repeating units of the long chains of the O antigen of *S. minnesota*.

If the RI structure is a precursor of the RII structure, and if the RII structure is the same in all *Salmonella*, it may be assumed that the RII lipopolysaccharide represents the ubiquitous basal structure to which the specific side chains with their repeating oligosaccharide units are bound, and which carry the O-antigenic specificity of the S forms. It should then be possible to obtain at least small amounts of oligosaccharidic RI and RII fragments by partial hydrolysis of wild-type O-antigenic lipopolysaccharides. *Schulte-Holthausen*[53] was indeed able to isolate three glucose-containing oligosaccharides from partial hydrolysates of the lipopolysaccharide of *S. minnesota* O antigen (together with O-specific galactosamine-containing oligosaccharides), and these proved to be identical with the glucosamine-containing di-, tri-, and tetrasaccharides from the RII lipopolysaccharide shown in Figure 6. Analogously, *Simmons* was able to isolate R-specific oligosaccharides from three further *Salmonella* O antigens[37].

In a further series of experiments, we subjected different lipopolysaccharides of *Salmonella* S forms to mild acid hydrolysis and tested the partial hydrolysates for their activity as inhibitors towards RI and RII antisera in hemagglutination tests[55]. It was found that even the lipopolysaccharides of higher chemotypes give rise to RI-specific structures during hydrolysis. No RII structures could be detected in this way, presumably because the RII structure is more sensitive to acid.

It is noteworthy that, during partial hydrolysis of a serologically cross-reacting *E. coli* strain (comparison of *S. adelaide* with *E. coli* 0111, whose O antigens are of the identical chemo-

type, *i.e.* basal sugars plus colitose[56]), RI or RII structures could at no time be detected serologically[55]. Whether the constitution of the *Coli* polysaccharide differs fundamentally from that of the *Salmonella* polysaccharide can be established only by a study of further *Coli* strains. However, there are *Coli* O antigens which contain no galactose[31,32], and also some *Shigella* strains without glucose[57], which in *Salmonella* are basal sugars participating in the RI and RII structures (Figs. 2 and 6).

The above results support the postulate that in *Salmonella* the RII (and RI) polysaccharide is a fundamental structure and an inner part of the O-antigenic lipopolysaccharide of the wild type (S form).

## Biochemical Investigations of R Mutants

On the basis of the investigations on deficient mutants of *Salmonella*, which have been carried out particularly by *Nikaido et al.*[44,58] in Boston, it was postulated that, during S→R mutation, enzyme defects arise in the resulting RII- and RI-specific *Salmonella* strains. A first insight into the mechanism of the S→RII and S→RI mutations in *S. minnesota* was obtained when we tested three strains, *viz.* S, RII, and RI, in regard to their content of enzymes necessary for the biosynthesis of the O antigen of the S form.

From results deduced so far, the biosynthesis of the O-specific polysaccharides proceeds in two stages. In the first stage, the activated monosaccharides are synthesized in the form of their nucleoside diphosphate derivatives. The enzymes involved are termed synthetases. In the second stage, the sugar residues are transferred to the growing polysaccharide by specific transferases[59-61].

In addition to the basal sugars, the *S. minnesota* O antigen contains galactosamine, and this sugar is the only one which is absent from the lipopolysaccharide of the R mutants.

In the bacteria, galactosamine is formed from glucosamine under the action of a 4-epimerase, which converts UDP-*N*-acetylglucosamine into UDP-*N*-acetylgalactosamine. We have determined this enzyme in the S form and in both R types (RI and RII) of *S. minnesota*[54] (Fig. 7). For this purpose, [$^{14}$C]-UDP-*N*-acetylglucosamine was prepared and incubated with cell-free extracts from S and R cells. After hydrolysis, the three *N*-acetylhexosamines were separated chromatographically on borate-treated paper, and the distribution of the radioactivity was determined. It was found that incubation of radioactive UDP-*N*-acetylglucsoamine with S and RI extracts leads to the formation of galactosamine, whereas in the case of an RII extract no galactosamine is formed. The RII species is therefore a mutant, from which the UDP-acetylglucosamine 4-epimerase is missing, and we assume that the inability to synthesize UDP-*N*-acetylgalactosamine is the cause for the block in the biosynthesis of the cell-wall polysaccharide, so that it stops at the stage of the RII structure.

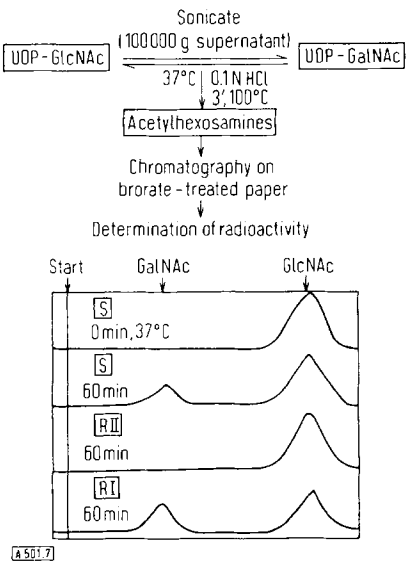

Fig. 7. Detection of UDP-*N*-acetylglucosamine 4-epimerase in S, RI, and RII forms of *S. minnesota* [54].

Other RII mutants which are likewise characterized by a defect in the synthesis of a specific sugar (which is a constituent of the side chain of the O antigen) can be isolated from *S. typhimurium* cultures. Examples are a mutant which is unable to form TDP-rhamnose[58], and another mutant which forms no GDP-mannose[61,62]. In contrast, the RI mutant of *S. minnesota* contains UDP-acetylglucosamine epimerase, and is therefore capable of forming galactosamine. However, the galactosamine is not incorporated into the cell-wall lipopolysaccharide, because a block in the biosynthesis (RI appears as the precursor of RII) prevents complete synthesis of the substrate for galactosamine incorporation.

### The O-Specific Polysaccharide Hapten in RI Mutants

A further important discovery was that of an O-specific polysaccharide in RI mutants by *I. Beckmann*[50] in our laboratory.

To obtain the lipopolysaccharides the cells are generally extracted with phenol/water[17] (Figure 8), and the crude aqueous extract is subsequently centrifuged at 100000 g. The lipopolysaccharide is obtained as a sediment, while the supernatant contains chiefly nucleic acid. During fractionation of the supernatant from an extract of *S. typhimurium* RI, *Beckmann*[50] found a polysaccharide containing the sugars mannose, rhamnose, and abequose, characteristic for the related O-antigenic wild-type lipopolysaccharide (see Figure 3, chemotype XIV), but no heptose, and which precipitates specifically with *S. typhimurium* O antiserum. While the RI bacterium serologically exhibits only RI specificity it forms in addition a relatively low-molecular polysaccharide with the O specificity of the wild type.

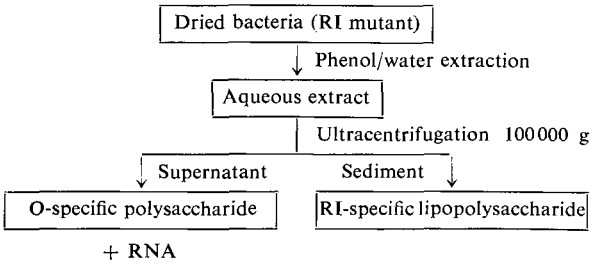

Fig. 8. Scheme illustrating the phenol/water extraction of RI mutants [17,50].

After phenol/water extraction of *S. minnesota* RI cells appreciable quantities of non-dialysable galactosamine were found in the supernatant obtained on ultracentrifugation. This sugar is completely absent from the lipopolysaccharide of the RI mutant and is characteristic for the side chain of the lipopolysaccharide of the O-antigenic wild type. It was shown [54] that in *S. minnesota* RI cells galactosamine is the constituent of a polysaccharide with the O specificity of the *S. minnesota* wild type which is precipitated by *S. minnesota* O-antiserum.

In RI mutants of *Salmonella* of different serological groups (B and L), R lipopolysaccharides are found in the cell wall, while the polysaccharide specific for the wild type is found in the cell interior. This polysaccharide, which presumably represents the isolated side chain of the O antigen, is not antigenic for rabbits, *i.e.* it is a hapten. In contrast, no O-specific polysaccharide hapten has ever been found in RII cells.

The conclusion is that RI mutants have a defect in the biosynthesis of the complete RII structure. The latter appears to be the substrate for the incorporation of the O-specific side chains, *i.e.* the repeating O-specific oligosaccharide units. RII mutants, on the other hand, have a block in the biosynthesis of one of the sugars in the side chain (or in its transfer). Thus RI mutants retain the ability to form the specific side chain, but the necessary substrate, *i.e.* the complete RII structure (Figure 6) with terminal *N*-acetylglucosamine, is missing, so that the side chain cannot be incorporated in the cell-wall lipopolysaccharide, whose biosynthesis stops after the RI structure has been formed.

## Further R Forms

If the concepts concerning the S→R mutation in Enterobacteriaceae are correct, then the existence of mutants other than RII and RI must be anticipated. These would differ from the ones described by an even less complete R antigen (R lipopolysaccharide), *i.e.* by a block at an even earlier stage of the polysaccharide biosynthesis. The complete bacterial cell-wall lipopolysaccharide is built up in a sequence of many steps, in which numerous synthetases and transferases participate. The formation of each of these enzymes is controlled genetically and each enzyme can in principle be affected by a mutation. It should therefore be possible to detect each stage of the (lipo)polysaccharide biosynthesis by isolation of a mutant which has an enzyme defect at precisely this stage. Deficient mutants of *S. typhimurium* of this type have indeed been described some years ago, particularly by Japanese workers.

*Nikaido* [44,63,64] was the first to describe a mutant (M mutant) lacking UDP-galactose 4-epimerase, *i.e.* which cannot form galactose on a glucose nutrient because the reaction

$$\text{UDP-Glu} \overset{\text{4-epimerase}}{\rightleftharpoons} \text{UDP-Gal}$$

is blocked [44,63,64]. *Nikaido*'s work was based on investigations of *Kalckar et al.* [65,66]. In this M mutant, the biosynthesis of the cell-wall lipopolysaccharide ceases where (in the wild type) the first incorporation of galactose takes place. The lipopolysaccharide of the M mutant contains only (lipid)glucosamine, KDO, heptose, and glucose. Subsequently, *Fukasawa et al.* [67] described a mutant in which the conversion of glucose 1-phosphate into UDP-glucose is blocked by the absence of the enzyme UDP-glucose pyrophosphorylase. This mutant forms only the polyheptose phosphate core with KDO and lipid A, and even the incorporation of glucose is blocked because the cell is unable to synthesize activated glucose.

Mutants without UDP-galactose 4-epimerase (M mutants) or without UDP-glucose pyrophosphorylase were later isolated from cultures of other *Salmonella* (and *E. coli*) species, so that it can be assumed that, like the RII and RI mutants, they can arise from any *Salmonella* species.

In collaboration with *J. Schlosshardt* [68], we have attempted in recent years to isolate and analyse a great number of R mutants from *S. minnesota*, in order to obtain as many intermediate stages of the biosynthesis of the O antigen (wild-type lipopolysaccharide) as possible. *S. ruiru* (antigen factor 21) was included in the investigation; it belongs to the same chemotype and serotype as *S. minnesota*.

To isolate the mutants, a synthetic medium of pH 8.2, which contained citrate and ammonia, was inoculated with *S. minnesota* or *S. ruiru* and incubated at 37 °C. After various periods of time, samples were transferred to agar and rough colonies were selected for further single-cell culturing. After five days, almost all colonies were rough. During the bacteriological investigations, the principal difficulty was to isolate new mutants with as yet unknown properties. *Schlosshardt* has used the sensitivity of the R strains to phages in order to differentiate between the various R mutants. She attempted to isolate as many R strains of different phage-sensitivity as possible, in the hope that some of the phages would require structurally different R lipopolysaccharides on the cell surface as the receptor and in this way would permit the differentiation of R classes.

Approximately 30 mutated strains were isolated [68], all of which possessed the flagella antigens (H antigens) and

the fermentation properties of the parent strain. The lipopolysaccharides were extracted with phenol/water and their sugars were identified and determined quantitatively. The mutants were then classified into different chemotypes on the basis of the composition of their lipopolysaccharide sugars (Figure 9).

Injection of the heat-killed bacteria into rabbits led to the formation of antisera. Hemagglutination inhibition tests (cf. Figure 6) were again employed to detect serological cross-reactions of the R lipopolysaccharides. The results are shown in the right-hand part of Figure 9.

Fig. 9. Chemical and serological classification of R-mutants of *S minnesota* and *S. ruiru* [68].

Strain numbers followed by a dot are genetically related to *S. ruiru*; the others were isolated from *S. minnesota*.

+ : present but not determined quantitatively.
n.d. : not determined.

[*] Glucosamine was determined after separation of lipid A from the polysaccharide.
Hemagglutinating system: Alkali-treated lipopolysaccharide fixed on erythrocytes) and homologous serum.
Circles denote inhibition of the hemagglutinating system by the lipopolysaccharide isolated from the strain shown on the left. Example: *S. minnesota* R3 lipopolysaccharide (group Rd, line 2) inhibits the hemagglutinating system with *S. minnesota* R3 (homologous system, indicated by a cross), *S. minnesota* R4, and *S. ruiru* R3.

It is seen that mutants of numerous chemotypes were found (Ra–Re) [11]. In Figure 9, the lipopolysaccharides of these mutants become progressively poorer in sugars from top to bottom. In each succeeding group (chemotype) a further sugar is missing. At the bottom of Figure 9, the R antigens of chemotype Re contain no hexoses and no heptose, and the only identifiable building units are lipid A and ketodeoxyoctonic acid (KDO), which together comprise at least 80 to 90% of the substance.

It is further seen from Figure 9 that the chemically classified mutants also form serological groups, and groups of different phage sensitivity [68]. This parallelism of chemical composition, serological specificity, and phage sensitivity may indicate that the lipopolysaccharides of these mutants can function as determinant groups during antibody formation and as phage receptors, although they are partly rather incomplete. With these R mutants a large number of steps in the biosynthesis of the *S. minnesota* O antigen has been verified.

This is illustrated by Figure 10, showing lipopolysaccharide structures which – provided our concept is correct – are all traversed in the course of O antigen biosynthesis. Details of these structures, which represent the innermost part of the core polysaccharide, will have to be determined. We trust that the newly discovered R strains and their R lipopolysaccharides will facilitate the structural analysis.

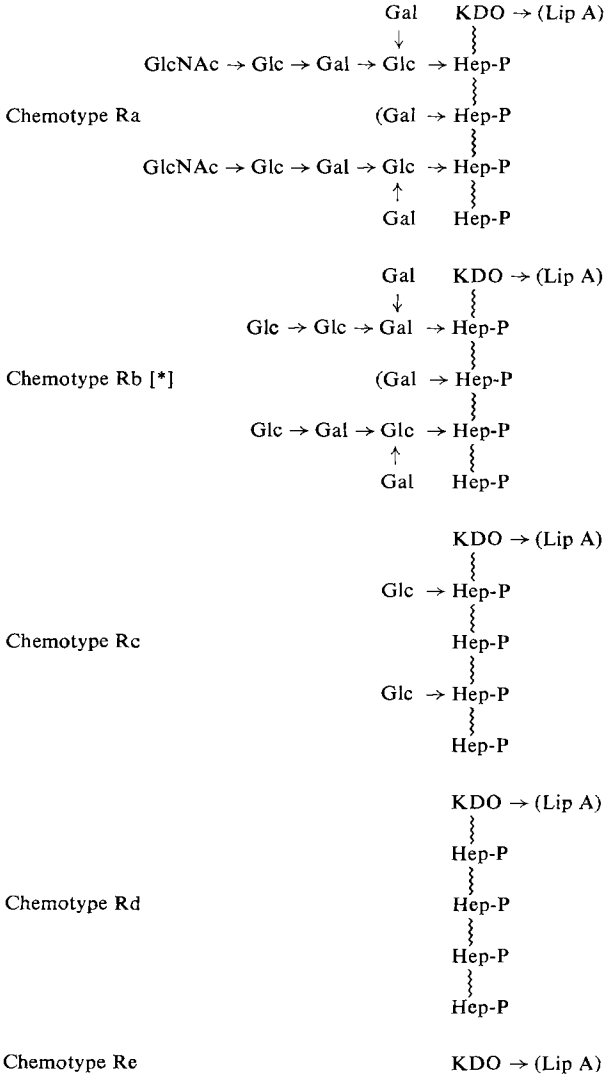

Fig. 10. Possible structures of polysaccharides isolated from R mutants (intermediates in the biosynthesis of O-specific polysaccharides).

[*] This structure follows from the analysis of the RI polysaccharide of *S. minnesota*. Structures intermediate between the Rb and Rc structures shown are probable. All belong to chemotype Rb (*i.e.* they consist of lipid A, glucosamine, KDO, heptose, galactose, and glucose); see *e.g. I. W. Sutherland et al.* [51].

The heptose-containing (but hexose-free) and the heptose-free lipopolysaccharides are of particular interest. It is possible that heptose is a serologically determinant sugar in Ra mutants. We do not know which groups are the carriers of serological specificity in the heptose-free mutants, and the same is true of the phage receptors. Furthermore, heptose-free mutants will be particularly suitable for investigations on the anabolism and the activation of heptose, about which little is known. The heptose in the basal chain of *Salmonella* lipopolysaccharides has been identified as L-glycero-D-manno-heptose[69, 70].

### The Chemical Nature of the Endotoxins

The mutants described are of considerable interest in the study of the biological effects of bacterial lipopolysaccharides (endotoxins) and especially in the search for active structures. In the lipopolysaccharides of Enterobacteriaceae, the polysaccharide part is responsible for the serological specificity. In addition, it may serve as a water-soluble carrier and consequently be of indirect significance for non-specific, endotoxic effects. However, we assume that lipid A, present in all lipopolysaccharides, is the factor determining endotoxic properties. *Nakano*[71] showed recently that lipopolysaccharides from M mutants (cf. Figure 10), containing only lipid A, KDO, heptose, and glucose, exhibit the same toxicity as the lipopolysaccharides of the related wild type with the complete O-specific polysaccharide. Lipid A can be obtained only by acid hydrolysis from the lipopolysaccharides, and a greater or smaller loss in activity is inevitable. Hydrolysis under very mild conditions, on the other hand, provides no guarantee

Arrows denote the time of application.

[69] *G. Bagadian, W. Dröge, K. Kotelko, O. Lüderitz*, and *O. Westphal*, Biochem. Z. 1966, in the press.

[70] *M. J. Osborn, S. M. Rosen, L. Rothfield*, and *B. L. Horecker*, Proc. nat. Acad. Sci. USA *48*, 1831 (1962).

[71] *M. Nakano*, Nature (London) 1118 (1962).

that all residual polysaccharide components have been split from the lipid. Extracts from Re mutants (Figure 10) which contain only lipid A and KDO – with a lipid A content of more than 70% – and are free from heptose and hexoses, seem suitable for a renewed study of the significance of the lipid A and of the polysaccharide components in bringing about endotoxic effects.

In collaboration with *E. Eichenberger* of the Wander laboratories in Berne, Switzerland, we have tested the pyrogenic activity of two extreme lipopolysaccharides: the polysaccharide of the S form and of the Re mutant of *S. minnesota*. Figure 11 shows that both preparations exert approximately equal pyrogenicity in rabbits after intravenous injection.

Table 2 shows the results of toxicity determinations after intraperitoneal application to mice. The $LD_{50}$ value for the lipopolysaccharide of the S form of *S. minnesota* is about 250 μg per mouse. The lipid A-KDO complex from the R mutant has a weaker effect (about one-quarter of that of the wild-type lipopolysaccharide), but here also the "polysaccharide-free" lipid A is endotoxically active, and allowance must be made for the fact that the preparation has only moderate solubility in water. Similar results were obtained by *Tripodi* and *Nowotny*[79] with our R lipopolysaccharides.

Table 2. Lethal toxicity of *S. minnesota* S and R lipopolysaccharide in mice [68]. The numbers in the table denote the proportion of deaths.

| Lipopolysaccharides from | Quantity injected per mouse 125 μg | 250 μg | 500 μg | 1000 μg | 2000 μg |
|---|---|---|---|---|---|
| *S. minnesota* S | 0/16 | 11/20 | 19/26 | 16/16 | |
| *S. ruiru* S | 1/10 | 7/10 | 7/10 | 7/10 | |
| *S. minnesota* RII | | | 7/10 | 7/10 | 10/10 |
| *S. minnesota* RI | | | 8/10 | 10/10 | 10/10 |
| *S. minnesota* R3 | | | 1/10 | 3/10 | 10/10 |
| *S. minnesota* R4 | | | 2/10 | 8/10 | 8/10 |
| *S. minnesota* R595 | 0/6 | | 2/26 | 9/26 | 11/20 |
| *S. minnesota* R613 | | | 0/10 | 2/10 | 9/10 |

These experiments demonstrate that the polysaccharide component of bacterial lipopolysaccharides has little or no effect on the endotoxic action produced in the animal, except possibly as a solubilizing agent. Instead, lipid A appears to be the factor decisive for at least some endotoxic effects.

## Intermediate Forms

### Semi-R Mutants

If the hypothesis that in the lipopolysaccharides of *Salmonella* S forms the repeating oligosaccharide units of the specific side chains are bound to the terminal *N*-acetylglucosamine of the RII structure (basal polysaccharide) (Figures 6 and 12) is correct, then the type of linkage of the first specific oligosaccharide unit is different from that of all the following ones. The repeating units of many *Salmonella* lipopolysaccharides are (mannose→rhamnose→galactose→) oligosaccharides (Figures 4 and 12), with the galactose of the first unit (denoted by Gal I in Figure 12) bound to the *N*-acetylglucosamine of the RII structure, while the galactose of

the second unit (Gal II), like all further galactose groups, is bound to the mannose of the preceding unit. Therefore, the Gal I transferase, which leads to the incorporation of the galactose in the first unit, differs from Gal II transferase, which participates in the incorporation of the galactose residues in all further units. The existence of *Salmonella* mutants in which the Gal II transferase is blocked is therefore indicated.

Such mutants have indeed been isolated recently from *S. typhimurium* cultures by *Naide*, *Nikaido*, *Mäkelä*, *Wilkinson*, and *Stocker*[72]. They were designated as semi-rough or SR mutants. The colonies of the SR strain of *S. typhimurium* are morphologically intermediate between rough and smooth. The cells are agglutinated by O antisera but not as strongly as the wild type; however, O phages do not cause lysis. In contrast to the wild form, the lipopolysaccharide contains small quantities of mannose, rhamnose, and abequose. A characteristic result is also found on partial hydrolysis, during which, in contrast to the wild type, the SR lipopolysaccharide forms only a single disaccharide with reducing rhamnose, namely mannosyl-rhamnose[40].

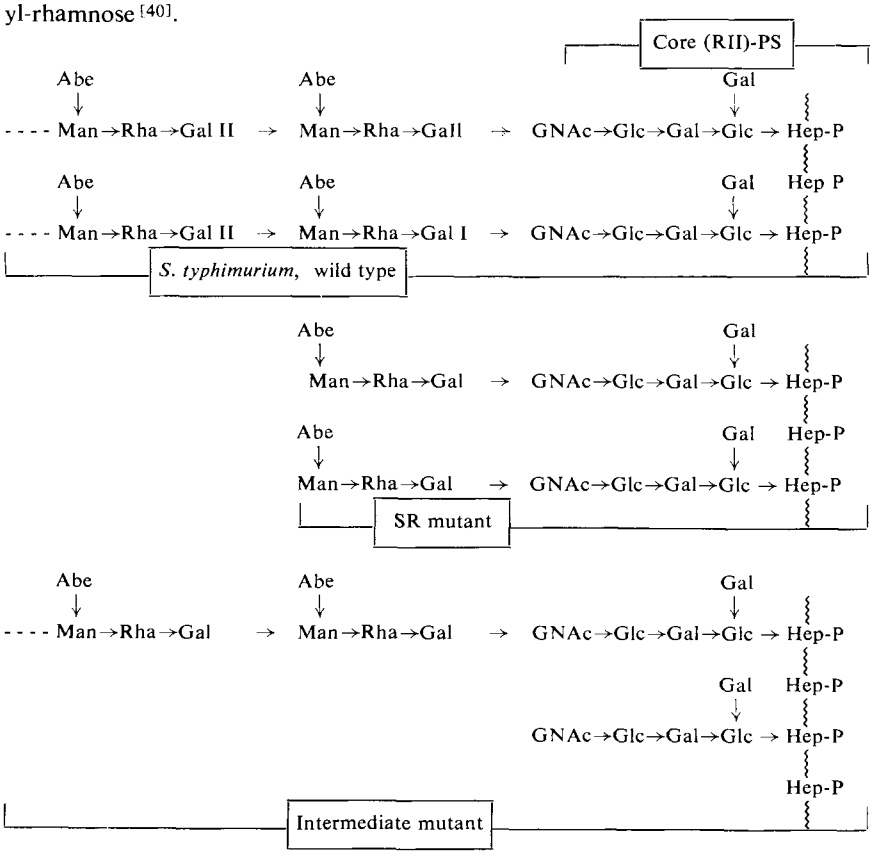

Fig. 12. Proposed structures of the polysaccharides from *S. typhimurium* wild type, SR mutant, and intermediate mutants [72].

### Other Intermediate Mutants

The same authors have discovered a different class of mutants of *S. typhimurium*[42,72], the lipopolysaccharides of which have the same composition as those of the SR-mutants, *i.e.* they contain little mannose, rhamnose, and abequose. In contrast to the SR mutants, these mutants are lysed by O phages and agglutinated by O and R antisera, while partial hydrolysis of the lipopolysaccharides leads to the same oligosaccharide (with reducing rhamnose) as is obtained from the wild-type lipopolysaccharide. These properties suggest the formula shown in the lower part of Figure 12 for this antigen: few, but complete, O-specific chains are bound to the RII core. The enzyme defect which leads to such mutants has not yet been identified.

### T Forms

We have been engaged for some time in a study of a third class of intermediate *Salmonella* mutants, which were discovered by *Kauffmann*[3,73] about 10 years ago and termed "transient" or T forms. Like the R forms they have lost the O specificity of the wild type and do not contain the specific sugars of the side chain, but, like the wild type, they grow in smooth colonies (S form). Serologically, they are characterized by T specificity, *i.e.* they react specifically with T antisera. These T mutants deserve particular interest; we have found[29, 68,74] that their lipopolysaccharides contain a sugar which is not present in the polysaccharide of either the wild type (S form) or the R forms. While all *Salmonella* mutants investigated so far have been shown to be deficient mutants, and their lipopolysaccharides contain fewer sugar units than the lipopolysaccharide of the wild type, it has been demonstrated that T forms contain large quantities of ribose in their lipopolysaccharide. Table 3 shows the analyses of different T lipopolysac-

[72] *Y. Naide*, *H. Nikaido*, *P. H. Mäkelä*, *R. G. Wilkinson*, and *B. A. Stocker*, Proc. nat Acad. Sci. USA *53*, 147 (1965).

[74] *R. W. Wheat*, *O. Lüderitz*, *E. Ruschmann*, and *O. Westphal*, unpublished work.

charides. All contain the basic sugars; in addition, there is 14–22% of ribose, and the same quantity of galactose [74]. Ribose is not present as a nucleoside (no absorption at 260 mμ). Ribose and galactose do not form a separate polysaccharide but appear to be incorporated into the T polysaccharide. This was indicated by specific precipitation [74]. When T lipopolysaccharide is precipitated by specific T antiserum, the ribose is obtained quantitatively in the precipitate. After treatment with alkali, the same antiserum precipitates a polysaccharide without ribose. We are at present engaged in carrying out partial hydrolysis with the aim of isolating and analysing the oligosaccharides and, above all, of studying the relationship of T antigens to S and R antigens. T forms mutate relatively easily into R forms. In addition to T forms, there are also *Salmonella* serogroups (M, 52, 56; see Figure 3) which form O-antigenic lipopolysaccharides and contain ribose as the building unit of the specific side chain [28,29].

Table 3. Composition of lipopolysaccharides isolated from various *Salmonella* T1 mutants [74].

| | KDO % | Hep % | Glc % | GlcN % | Gal % | Rib % |
|---|---|---|---|---|---|---|
| *S. typhimurium* T 1 | 4.0 | 7.1 | 4.8 | 5.9 | 20.8 | 14.9 |

| | 4.2 | 7.5 | 4.6 | 6.2 | 18.0 | 17.1 |

## Concluding Remarks

The analysis of lipopolysaccharides from enterobacterial wild forms (S forms) and their numerous deficient mutants (SR and R forms) has made it possible to determine the structure of the complex heteropolysaccharide components. Detailed results have so far been obtained for *Salmonella*. Since the analysed deficient mutants form intermediates occurring in the biosynthesis of the complete wild-type polysaccharide, it is possible to reconstruct the steps of this synthesis. In agreement with structural analyses, *Horecker, Osborn, et al.* [61,75,76], *Nikaido et al.* [40,52,77], and also *Heath et al.* (in *E. coli* [24]) were able to study in detail many stages of the polysaccharide biosynthesis in isolated systems, using radioactively labelled nucleoside diphosphate hexoses.

In lipopolysaccharides of M mutants, containing a polyheptose phosphate core plus glucose, the incorporation of galactose could be verified experimentally [6,24,44]. Starting from mutants which contain no UDP-glucose pyrophosphorylase (and have only a polyheptose phosphate chain), successful incorporation of glucose, *i.e.* biosynthesis of the M polysaccharide, was achieved. Ultimately, all stages in the biosynthesis of the oligosaccharide chain of the RII structure (cf. Figure 6) could be verified by stepwise incorporation of glucose, galactose, again glucose, and *N*-acetylglucosamine [24,61]. Cell-wall preparations containing RII lipopolysaccharides were found to act as the substrate for the transfer of the specific sugars of the side-chains [76,78], again in agreement with the chemical and immunochemical analyses of the polysaccharides. Here, it was found that the rate of incorporation of each sugar is increased when all sugars participating in the repeating oligosaccharide unit are added in the form of their nucleoside diphosphate derivatives. It is now assumed that in the biosynthesis of the specific side chains, the repeating oligosaccharide units, or at least their main chains (*e.g.* Man→Rha→Gal in *Salmonella* of groups A, B, D, and E; Figure 4) are preformed as lipid-bound oligosaccharides and are then transferred as a whole to the growing chain [76,78].

In this way the two parts of the *Salmonella* polysaccharides, *i.e.* the core polysaccharide up to the RII structure and the specific side chains (Figure 2), are matched by two biosynthetic reaction sequences: the ubiquitous basal polysaccharide is built up as far as the RII structure by transfer of monosaccharides, while the specific side chains present in wild types (S forms) are attached by the transfer of activated species-specific oligosaccharides. Three classes of cell-wall lipids can be distinguished on the basis of their biological activity and chemical constitution. Lipid A, bound to the O-specific polysaccharide, is a part of the O antigen and is responsible for its endotoxic effects. A phosphatidylethanolamine isolated by *Rothfield* and *Horecker* [81] from the cell wall of *Salmonella* acts as a cofactor in the biosynthesis of the basal structure of the O antigens. A further lipid, whose chemical composition is as yet unknown, has recently been recognized as an activator of the oligosaccharide 1-phosphate which is used by the cell to synthesize the specific chains of the O antigens [76,78].

It is reasonable that, in the R mutants, many different genotypes can lead to the same phenotype. For example, defects in the enzymes necessary for the formation and transfer of a specific sugar of the repeating oligosaccharide unit of a specific side chain will generally lead to phenotypic R forms with RII polysaccharide. The same is true of other mutants.

Recent chemical, immunochemical, biochemical, and genetic investigations, are in accord with the present postulates about the structure and biosynthesis of enterobacterial cell-wall polysaccharides. It will be of great interest to analyse many more Enterobacteriaceae from as many genera as possible, in order to obtain a comprehensive picture of the extraordinary multiplicity of the polysaccharides of the bacterial cell surfaces and of their effects on the biological behavior of the cell.

# Diels-Alder-Reactions
# Part I: New Preparative Aspects[*]

BY PRIV.-DOZ. DR. J. SAUER

INSTITUT FÜR ORGANISCHE CHEMIE DER UNIVERSITÄT MÜNCHEN (GERMANY)

*Cycloadditions of conjugated dienes, named after their discoverers, have claimed preparative and mechanistic interest for nearly 40 years. The almost inexhaustible variability of the components of these one-stage reactions offers entry to important classes of compounds. The systematization of the preparative uses of these reactions which is offered in this paper relates predominantly to recent results. The mechanistic aspects of the Diels-Alder reactions will be discussed later in the second part of this contribution.*

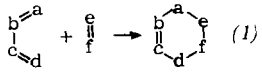
## A. Definition and History

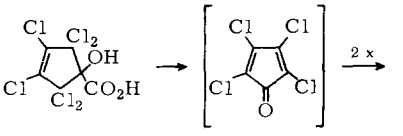
The combination of conjugated dienes with olefins is only a special case of the more general reaction of cycloaddition[1]; in the formation of the six-membered ring *(1)*, two new σ-bonds are formed at the expense of two π-bonds.

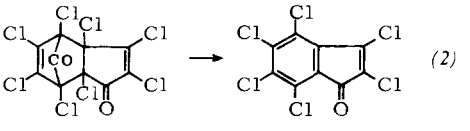


*(1)*

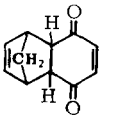
Other examples of cycloadditions are epoxidations and carbene additions, dimerizations of olefins to cyclobutane derivatives, and 1,3-dipolar addition reactions[1,2].

Individual examples of diene additions according to the Diels-Alder scheme are found in the literature as early as the turn of the century. Although *Zincke*[3] correctly explained the dimerization to perchloroindenone *(2)* of the tetrachlorocyclopentadienone occurring as an intermediate in the pyrolysis of 1-hydroxyperchlorocyclopent-3-enecarboxylic acid, an elucidation of the structure of the 1:1 adduct *(3)* of *p*-benzoquinone and cyclopentadiene was first given by *Diels* and *Alder*[4]; structures proposed earlier by *Staudinger* (with a cyclobutane ring) and *Albrecht* proved to require revision.



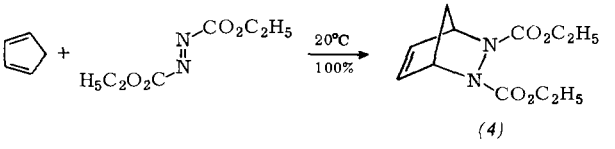


*(2)*



*(3)*

The structure of the 1:1 addition compound *(4)* from cyclopentadiene and diethyl azodicarboxylate[5] first indicated that these addition reactions of dienes were cases



*(4)*

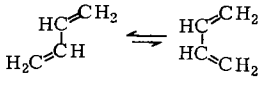
of a more general reaction principle. The classical paper of *Diels* and *Alder* [4a] provided the mental breakthrough and introduced the fruitful preparative and mechanistic investigations of these authors.

Complete treatment of the extensive experimental material is possible only within the scope of a monograph. In this survey, the reviews that appeared before 1955 [6–13b] and a recent article [1] will be supplemented by newer examples from the literature.

## B. The Diene Components

### 1. Acyclic Dienes

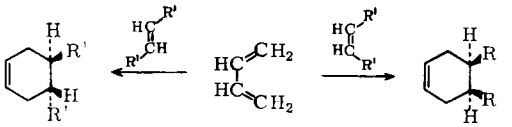
Owing to the possibility of rotation about the single bond between the two conjugated double bonds, open-chain dienes can occur in two conformations. With butadiene and its simple alkyl derivatives, the *transoid* form *(5)* frequently predominates in the conformer equilibrium [14]. However, only the *cisoid* conformer *(6)* is capable of taking part in the Diels-Alder reaction.



transoid *(5)* cisoid *(6)*

Substituents in butadiene influence the rate of cycloaddition to form six-membered rings, both through their electronic nature and by displacing the conformational equilibrium.

By combining butadiene with dimethyl maleate or fumarate in toluene at 155 °C the *cis*- *(7)* and the *trans*-form *(8)*, respectively, of the cyclohexene-4,5-dicarboxylic ester are readily accessible *via* a stereospecific *cis*-addition [15].

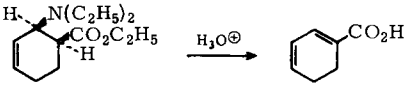


*(8)* 84% R' = $CO_2CH_3$ *(7)* 68%

1-Substituted butadienes can be used [16] almost without exception provided the substituent R is in the *trans*-arrangement *(9)*, while the *cis*-form *(10)* generally undergoes a Diels-Alder reaction only with poor yield.

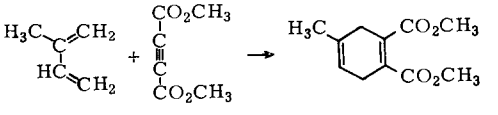
*(9)* *(10)*

The extremely acid-sensitive 1-diethylaminobutadiene *(9)*, R = $N(C_2H_5)_2$, adds to ethyl acrylate in benzene at 20 °C to form the 1:1 *cis*-adduct *(11)*, which changes readily into 2,3-dihydrobenzoic acid [17]. In the analogous reactions of 1,4-bis(dialkylamino)butadiene the two-fold elimination of amine from the Diels-Alder adduct yields the aromatic system [18].



*(11)* 94%

1,4-Dihydroaromatic compounds, *e.g. (12)*, are obtained in excellent yields when butadienes react with dienophiles containing triple bonds [19] (at about 150 °C in toluene in the example illustrated).



*(12)* 87%

1-Hydroxybuta-1,3-dienes can be regarded as tautomers of the α,β-unsaturated aldehydes and ketones. As an example, we select a reaction of 2-methylpent-2-enal (2-ethyl-1-methylacrolein) [7]; here the primary adduct *(13)* can be isolated [20].

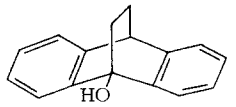
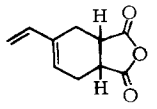
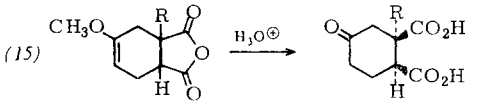
The mechanistic relationship of this sequence of reactions to the Diels-Alder scheme has not, however, been shown. Recently, anthrone has been made to react with ethylene in the presence of bases according to the same scheme to give *(14)* in 60 % yield [21].



*(14)*



*(16)*



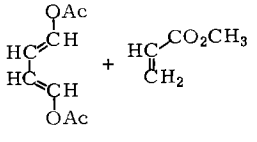
*(15)*

*a* R = H, 93%
*b* R = $CH_3$, 94%

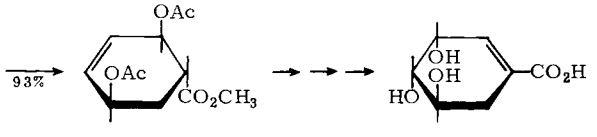
R = H, 96%

The adducts *(15)* of 2-alkoxybutadienes with maleic anhydride and its derivatives, which are obtained in high yields, can, as enol ethers, easily be hydrolysed to cyclohexanone derivatives [22]. In the case of 2-methylene-1,4-pentadiene (2-vinylbutadiene), the reaction with maleic anhydride does not stop at the stage of the 1:1 adduct *(16)*; the new diene system adds on a second molecule of the dienophile to give the 1:2 adduct [23].

Disubstituted dienes have been used very frequently; 2,3-diphenylbutadiene, for example, gives *o*-terphenyl derivatives [24]. The reaction of *trans,trans*-1,4-diacetoxybutadiene *(18)* with methyl acrylate forms the first step of a total synthesis of shikimic acid *(17)* [25]; a second

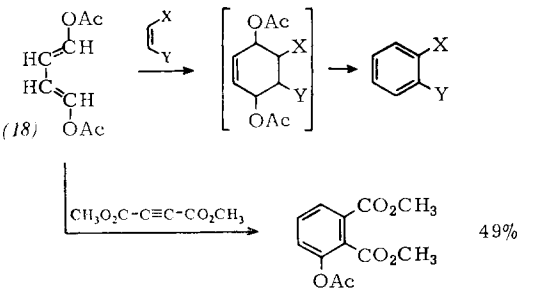


*(18)*



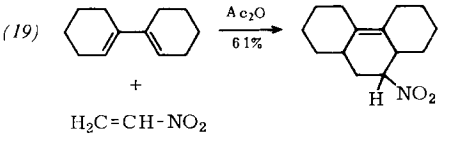
*(17)*

route to this compound begins with the Diels-Alder reaction between butadiene and propiolic acid (yield 85 %) [26]. Diacetoxybutadiene *(18)* has very recently been recognized as a suitable diene component for the synthesis of benzene derivatives without isolation of intermediate products [27].



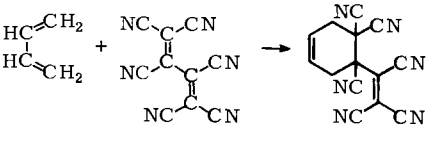
49%

Tetraalkylbutadienes are eminently suitable for diene additions provided they do not exhibit the structural element *(10)* of *cis*-1-substituted butadienes; 1,1'-bicyclopentenyl and 1,1'-bicyclohexenyl *(19)* [28] lead to polycyclic compounds [29], as illustrated here for nitroethylene as the dienophile.



*(19)*

Hexacyanobutadiene *(20)* [30] acts not as a diene but as a dienophile with respect to butadiene, *i.e.* it behaves as a derivative of the very reactive tetracyanoethylene (see Section C 1).



*(20)*

## 2. Acyclic Dienes with Heteroatoms

Whereas one or both carbon atoms in the dienophile component can be replaced by heteroatoms (see Sections C. 4 and C. 5), there are fewer analogous examples in the case of the dienes [31]. Replacement of carbon atom 1 in 1,3-dienes by oxygen yields α,β-unsaturated aldehydes and ketones which combine preferentially with electron-rich double bonds, enol ethers, olefins [32], enamines [33], *N*-vinylcarbamic esters, and *N*-vinylureas [34] to form 1:1-adducts; these addition compounds arise formally from a Diels-Alder reaction. Hydrolysis of the enamine adducts *(21)* and the enol ether adducts yield 1,5-dicarbonyl compounds, which are valuable starting compounds for syntheses of alkaloids [35]. With acrolein *(22)* as the diene component,

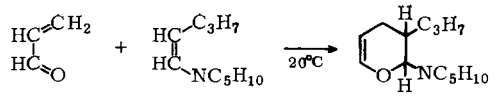
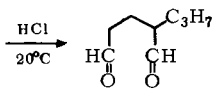
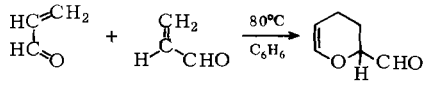
[35] *K. Alder, H. Betzing, R. Kuth,* and *H. A. Dortmann,* Liebigs Ann. Chem. *620,* 73 (1959).



(22) (21) 79%

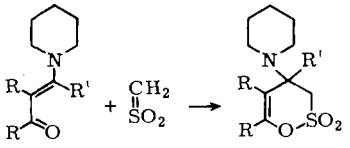


the use for less reactive dienophiles is limited by the competing dimerization of the unsaturated aldehyde, which formally is also a Diels-Alder reaction [36].



(22) (22) 40-45%

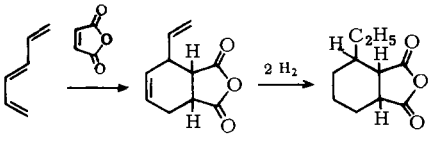
The reaction of compound *(23)*, prepared *in situ* from methanesulfonyl chloride and triethylamine, with vinylogous amides can also be regarded as a Diels-Alder reaction [37].



(23) R = $CH_3$, R' = H, 80%

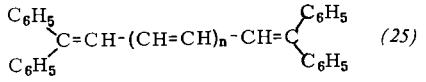
### 3. Polyenes

The mode of reaction of conjugated polyenes in diene addition can be understood by regarding them as substituted butadienes. The case of 2-vinylbutadiene has already been mentioned in Section B. 1. *trans*-Hexa-1,3,5-triene reacts as 1-vinylbutadiene; the hydrogenation product *(24)* of the Diels-Alder adduct with maleic anhydride can also be obtained from *trans*-hexa-1,3-diene [38].



*(24)*

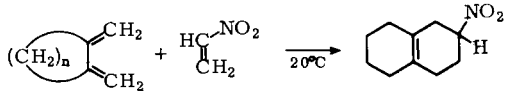
*cis*-Hexa-1,3,5-triene, as a *cis*-1-substituted butadiene *(10)*, R = $CH{=}CH_2$, does not react with dienophiles, so that it can be separated from the *trans* isomer by the Diels-Alder reaction [39]. Of the *trans*-ω,ω,ω'ω'-tetraphenylpolyenes *(25)*, only the representatives with n > 1 are capable of adding dienes; with large values of n, *Alder* and *Schumacher* observed a relationship between the chain length and the position of addition of the dienophile [40].



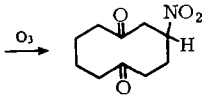
*(25)*

### 4. 1,2-Dimethylenecycloalkanes

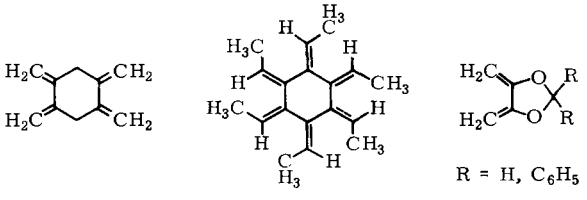
1,2-Dimethylenecycloalkanes *(26)*, in which the *cisoid* conformation *(6)* necessary for reaction is fixed by the linkage of the 2,3-positions of the diene through a ring, are characterized by high reactivity [41]. This, and the ready accessibility of this class of compounds by the pyrolysis of esters or the Hofman elimination of suitable bifunctional quaternary ammonium salts [42], make the 1,2-dimethylenecycloalkanes *(26)* the favorite dienes for the synthesis of polycyclic compounds, *e.g. (27)*; the reaction of 1,2-dimethylenecyclohexane [*(26)*, n = 4] may serve as an example [43].



*(26)* *(27)* 85%



With *(28)*, the Diels-Alder addition goes as far as the 1:2-adduct [44]; with *(29)* only two of the three diene systems are



*(28)* *(29)* *(30)*

R = H, $C_6H_5$

used for the addition of the dienophile [45]. The dioxolane derivatives *(30)* react only with the "record" dienophile tetracyanoethylene [46].

The four-membered cyclic diene *(26)*, n = 2, adds to one equivalent of maleic anhydride at 20–80 °C; for the formation of the 1:2-adduct an opening of the four-mem-

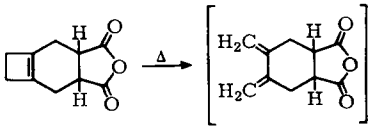
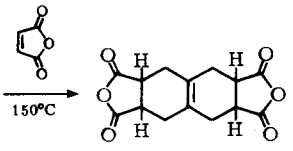
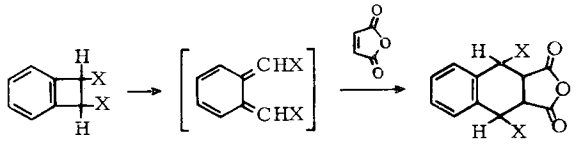
bered ring of the 1:1-addition compound *(31)* has been discussed [47]. In the reactions of benzocyclobutene derivatives *(32)* with dienophiles (see Table 1), a primary



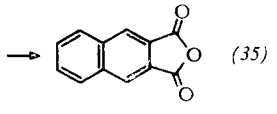
*(31)*



ring opening to the 1,2-dimethylene derivative *(33)*, which here has an *o*-quinonoid structure, is also assumed [48,49]. The diiodo compound *(32)* (X = I) reacts similarly with *N*-phenylmaleimide [49] to give 35 % of the naphthalenedicarboxylic derivative.



*(32)* *(33)* *(34)*



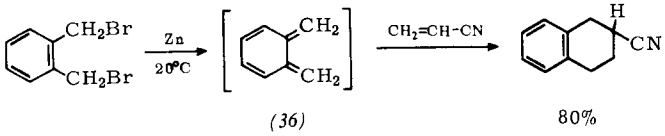
*(35)*

Table 1. Reaction of benzocyclobutene derivatives *(32)* with maleic anhydride.

| *(32)*, X | Temp. [°C] | Yield of *(34)* [%] | Yield of *(35)* [%] |
|---|---|---|---|
| $C_6H_5$ | 25 | 100 | |
| Br | 100 | | 32 |
| H | 200 | 98 | |

*Huisgen* and *Seidl* [50] have recently shown that a valence-tautomeric equilibrium *(32)* ⇌ *(33)*, in which the four-membered ring opens stereospecifically, precedes the Diels-Alder reactions of *cis*- and *trans*-2,3-diphenylbenzocyclobutenes [*(32)*, X = $C_6H_5$].

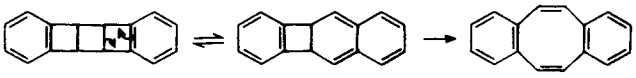
"*o*-Quinonoid" 1,2-dimethylenecycloalkenes have been postulated as intermediates in other reaction sequences. Thus the highly reactive 5,6-dimethylenecyclohexa-1,3-diene (*o*-quinodimethane) *(36)*, which cannot be isolated, can be trapped in solution with maleic anhydride, *N*-phenylmaleimide, or acrylonitrile [51,52]. The "*in situ*" occurrence of 2,3-dihydronaphthalene and 2,2-dimethyl-2*H*-indene has been shown similarly



*(36)* 80%

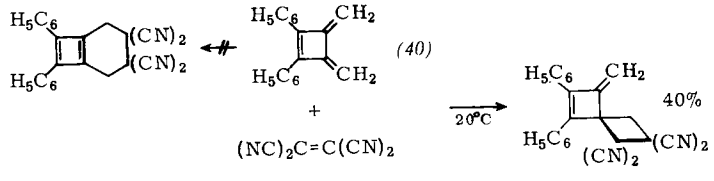
by means of trapping reactions [53,51]. Both compounds, like *(36)*, were obtained by dehalogenation of dibromo compounds.

An intermediate *(39)* with the dihydronaphthalene unit occurs also in the two-stage valence isomerization of the benzocyclobutadiene dimer *(37)* to dibenzocyclooctatetraene *(38)*. Compound *(39)* can be detected by a Diels-Alder reaction with *N*-phenylmaleimide [54].



*(37)* *(39)* *(38)*

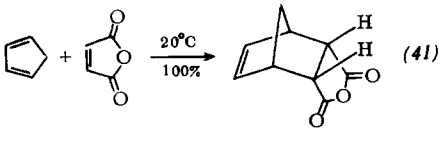
The expectation that the Diels-Alder reaction of *(40)* with tetracyanoethylene would lead to a derivative of cyclobutadiene proved incorrect; instead an adduct with spiro structure [55] is formed.



*(40)* 40%

## 5. Alicyclic Dienes

The Diels-Alder reactions of alicyclic dienes claim both historic and preparative interest. *Diels* and *Alder* recognized the general validity of the reaction scheme with cyclopentadiene [4]. For example, with maleic anhydride, the 1:1-adduct *(41)* arises stereospecifically in quantitative yield.



*(41)*

The preferred *endo*-orientation in the addition is observed with many reactions of cyclic dienes, and is a characteristic of this type of reaction [56]. Thus *endo*-di-

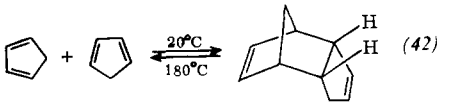
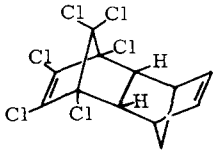
cyclopentadiene *(42)* is formed in high purity from the monomer; in this reaction, cyclopentadiene acts both as a diene and as a dienophile. This phenomenon, already



*(42)*

observed with acrolein, will be encountered again with cyclopentadienones (see Section B.6), *o*-quinones (see Section B.7), and thiophene 1,1-dioxide (see Section B.9). Compound *(42)* serves as a source of cyclopentadiene, which can be obtained from it at 180 °C in a retro-Diels-Alder reaction.

The combination of cyclopentadiene with alkenes and alkynes leads in single-stage syntheses and in high yields to derivatives of the angularly strained bicyclo[2.2.1]hept-2-ene and bicyclo[2.2.1]hepta-2,5-diene. Substituted cyclopentadienes yield camphor derivatives in a few reaction steps[8]. Bicyclo-



*(43)*

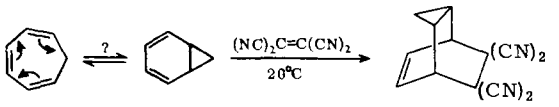
*(43a)*

heptadiene itself is made industrially from cyclopentadiene and acetylene in 60 to 65 % yield[57]; with hexachlorocyclopentadiene[58] it gives quantitatively compound *(43)*, which has become known as an insecticide under the name Aldrin; many other insecticides and heat-resistant polymers are derived from the Diels-Alder adducts of hexachlorocyclopentadiene.

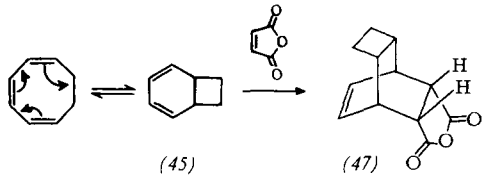
Like cyclopentadiene itself, hexafluorocyclopentadiene *(43a)*, which has been synthesized only very recently, tends to undergo dimerization[58a], while hexachlorocyclopentadiene is stable as a monomer. The reactions of *(43a)* with dienophiles such as ethylene, maleic anhydride, or bicyclo[2.2.1]hepta-2,5-diene take place smoothly; on the other hand, no reaction is obtained with tetrafluoroethylene or tetracyanoethylene. With respect to dienes (*e.g.* cyclopentadiene or anthracene), *(43a)* behaves sometimes as a diene and sometimes as a dienophile.

The reactivity decreases on passing to higher monocyclic conjugated dienes; cyclooctadiene has almost no ability for addition[9]; dienes with 14- and 15-membered rings again react with dienophiles, although under relatively severe conditions.

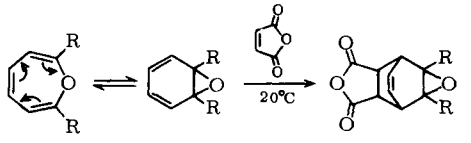
The Diels-Alder adducts of cycloheptatriene and cyclooctatriene are derived from the valence-bond tautomers *(44)* and *(45)*, respectively[59–62]. Whereas the tautomeric equilibrium between the monocyclic and the bicyclic compound can be detected in the eight-membered cyclic triene[62] (15 % of the bicyclic tautomer is present in the equilibrium mixture at 100 °C), the existence of such an equilibrium for the seven-membered cyclic triene is still uncertain; it seems likely, however, from the recent investigations of *Vogel et al.*[63] on oxepin [*(48)*, R = H] and its dimethyl derivative [*(48)*, R = $CH_3$].



*(44)* *(46)* 77%



*(45)* *(47)*



*(48)* *(49)* *(50)* R = $CH_3$: 100%

The Diels-Alder adducts are again derived from the bicyclic compound *(49)*; spectroscopic investigations have shown a valence-tautomeric equilibrium *(48)* ⇌ *(49)* (in each case R = H), which is established very rapidly. However, spectroscopic detection fails with bicyclo-[4.2.0]octa-2,5,7-triene, a valence-bond isomer of cyclooctatetraene. Nevertheless, *Huisgen* and *Mietzsch* demonstrated a small equilibrium concentration (*ca.* 0.01 %) by kinetic studies[64]. At 165–170 °C, a product analogous to *(47)* but poorer by 2 H is formed in 87 % yield with maleic anhydride.

Heating of cyclooctatetraene gives several dimers[65]. *G. Schröder* recently revised the structure proposed for one of them, and assigned to it the constitution *(51)*[66]; he used this compound for his elegant synthesis of bullvalene *(52)*[67]. The typical Diels-Alder additions of the

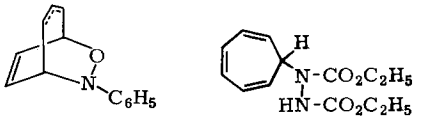
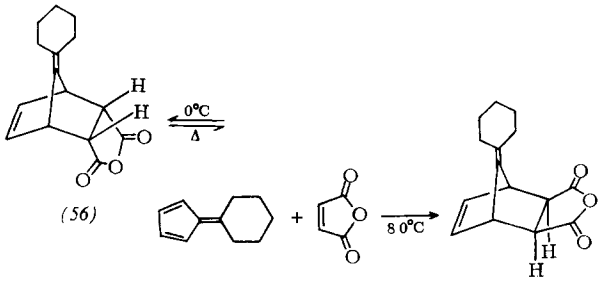
cyclohexadiene system in *(51)* with dienophiles have facilitated the elucidation of the structure of the dimer *(51)*.

It may be recalled that cycloheptatriene reacts with nitrosobenzene [68] or azodicarboxylic ester [69] to give 1:1-adducts *(53)* and *(54)* respectively, which are not derived from the valence tautomer *(44)*. Compound *(54)* opens up a productive route to tropylium salts [69].



*(53)* *(54)*

Fulvenes can be regarded as derivatives of the alicyclic cyclopentadiene; dienophiles add onto the *cisoid* diene system of the ring [70,71]. The splitting into the starting materials, which takes place with the Diels-Alder adducts of the fulvenes even under mild conditions, makes it difficult in many cases to elucidate the configuration of the products; a critical study by *Woodward* and *Baer* has clarified the situation with the pentamethylenefulvene *(55)* maleic anhydride system [72]. The reaction leading to the *endo*-adduct *(56)* at low temperatures is reversible; this enables the formation of the thermodynamically more stable *exo*-adduct *(57)* at 80°C.

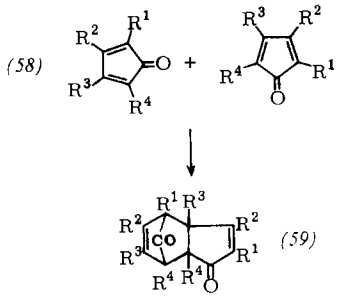


*(56)* *(55)* *(57)*

The position of the adduct ⇌ components equilibrium and the rate of the Diels-Alder addition have been measured in the diarylfulvene-tetracyanoethylene and diarylfulvene-acetylenedicarboxylic ester systems [73].

## 6. Cyclopentadienones

The diene activity of cyclopentadiene is retained in cyclopentadienone and its derivatives *(58)*. Depending on the substituents (see Table 2), cyclopentadienones exist as monomers *(58)* or dimers *(59)* [74]. Like cyclopentadiene, cyclopentadienones may act as diene and dienophile components.

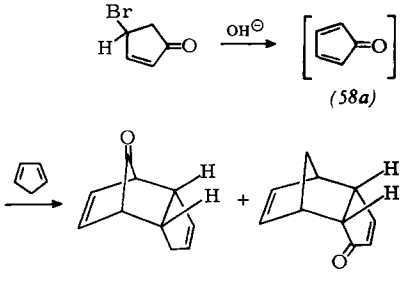


*(58)* *(59)*

Table 2. Reaction 2 *(58)* ⇌ *(59)* as a function of the substituents.

| *(58)*, $R^1$ | $R^2$ | $R^3$ | $R^4$ | Forms present |
|---|---|---|---|---|
| H | H | H | H | *(59)* |
| Cl | Cl | Cl | Cl | |
| H | $C_6H_5$ | $C_6H_5$ | H | 2 *(58)* ⇌ *(59)* |
| $CH_3$ | $C_6H_5$ | $C_6H_5$ | $CH_3$ | |
| $C_2H_5$ | $C_6H_5$ | $C_6H_5$ | $C_2H_5$ | *(58)* |
| $C_6H_5$ | $C_6H_5$ | $C_6H_5$ | $C_6H_5$ | |

The tendency towards dimerization is particularly pronounced with the unsubstituted compound *(58a)*. All attempts to prepare this compound – *e.g.* by a retro-Diels-Alder reaction – gave only the dimer [75]. However, the brief occurrence of cyclopentadienone *(58a)* – *i.e.* a finite lifetime for this compound – is suggested by a trapping experiment [76,77]; *(58a)* again exhibits diene and dienophile properties, in this case in the reaction with cyclopentadiene. The *N,N*-dimethylhydrazone of



*(58a)*

*(58a)*, on the other hand, exists in the monomeric form [78]. The tendency of *(58a)* to dimerize can be deduced from its electron distribution [79]. Tetrachlorocyclopentadienone could be trapped as a monomer with cyclopentadiene and norbornadiene [79a].

All cyclopentadienone derivatives existing in the monomeric form and the dimers which dissociate can take part

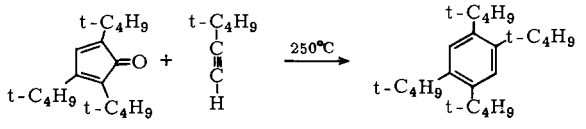
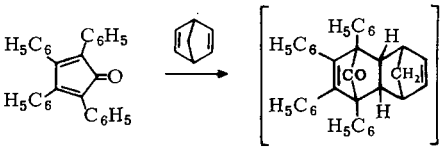
in Diels-Alder reactions as diene components. With double-bond dienophiles as co-reactants, the 1:1-adducts occurring as primary products can as a rule be isolated; when the temperature is raised, the CO bridges break [74]. The primary adducts with alkynes can be isolated only in exceptional cases; the tendency towards aromatization possibly brings about the spontaneous elimination of CO [74,80]. Even the highly strained 1,2,4,5-tetra-t-butylbenzene can be obtained in good yield in this way from *(60)* [81].

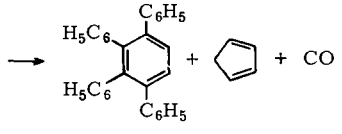


*(60)*

An interesting complication occurs in the reaction of tetraphenylcyclopentadienone with bicyclo[2.2.1]heptadiene (in $CHCl_3$ under reflux) [82]. The angulary strained 1:1-adduct *(61)* undergoes a retro-Diels-Alder reaction under astonishingly mild conditions; here the tendency towards aromatization is an additional driving force.

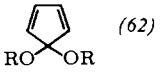


*(61)*



92% 32%

It is not only cyclopentadienone *(58a)* that is characterized by an extraordinary tendency to undergo dimerization, but also the ketals *(62)* derived from it. Earlier attempts to obtain the monomers *(62d)* gave only the dimers [82a].



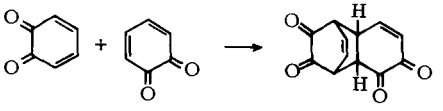
*(62)*

*a* R = $CH_3$ *c* R–R = $-(CH_2)_3-$
*b* R = $C_2H_5$ *d* R–R = $-(CH_2)_2-$

*Eaton* and *Hudson* [82b] recently showed that the ketals *(62a)–(62d)* have finite lifetimes. Trapping experiments with some dienophiles gave the expected Diels-Alder adducts in good yields. The rate of dimerization of compounds *(62)* depends on the group R; *(62d)* dimerizes about 1100 times faster than *(62a)*, and *(62b)* almost 500 times faster than cyclopentadiene.

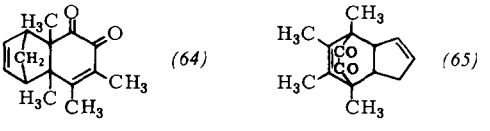
### 7. *o*-Quinones and *o*-Quinonoid Systems

The dimerization observed with many *o*-quinones shows that these compounds are in principle capable of reacting as dienes and dienophiles, *e.g.* to give *(63)* [83,84]; however, as a rule, their capacity for acting as dienes predominates [85]. Thus the structure *(64)* of the 1:1-adduct



*(63)* 30-50%

from cyclopentadiene and tetramethyl-*o*-benzoquinone [86] proved to require revision: cyclopentadiene takes part in the reaction as the dienophile and *(65)* is formed [87].



*(64)* *(65)*

*o*-Quinones contain two diene systems – the carbocyclic system of the six-membered ring and that of the 1,2-diketo grouping with two heteroatoms. *Horner* and *Merz* [88] observed an interesting competition of these two

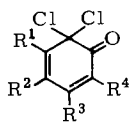
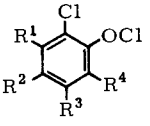
diene systems in tetrachloro-*o*-benzoquinone *(66)*. Addition to the cyclohexadiene system or to the heterodiene system takes place depending on the nature of the dienophile (styrene, 1,1-diphenylethylene); with cyclopentadiene as the dienophile (all reactions at 80 °C in benzene) both reactions occur to comparable extents. Tetrachloro-*o*-benzoquinone is, however, inert to typical dienophiles such as acrylonitrile and maleic anhydride.

On the basis of the addition reactions with cyclopentadiene and maleic anhydride as dienophiles, it has been found that the chlorination products of phenol and some methylphenols possess the *o*-quinonoid structure *(67)* and not the hypohalite structure *(68)* ($R^1$–$R^4$ = Cl or $CH_3$) [89].

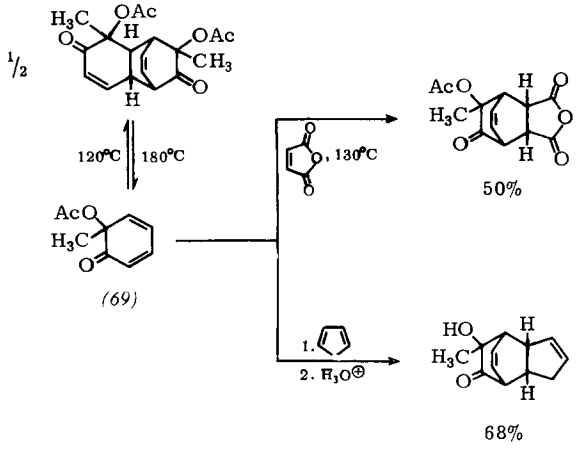


*(67)*



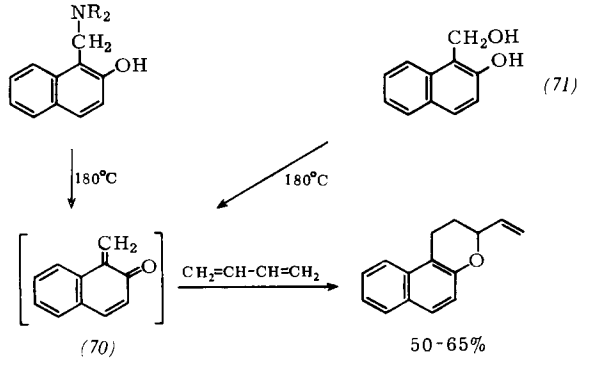
*(68)*

The tendency of the *o*-quinones to dimerize is retained even in 6,6-disubstituted cyclohexadienones [90,91], as can be seen from the example of methyl-*o*-quinol acetate *(69)* [92].



*(69)*

It is also reasonable to assume an *o*-quinonoid intermediate *(70)* for reactions of certain Mannich bases



*(71)*

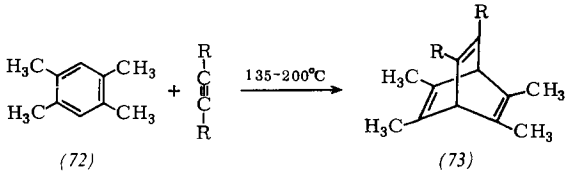
*(70)*

with dienophiles [93]. The reaction again takes place preferentially with electron-rich dienophiles such as butadiene, styrene (55 %), isobutylene (45 %), and 1,1-diphenylethylene (87 %). The intermediate *(70)* is also accessible *in situ* by intramolecular elimination of water from *(71)*.

Analogous reactions are possible in the benzene series with *o*-dialkyl(aryl)aminomethylphenols or *o*-hydroxymethylphenol as sources of dienes, although the yields are only moderate [93].

### 8. Aromatic Compounds

In the adducts from aromatic compounds and dienophiles, the low-energy state of cyclic conjugation is completely destroyed. Since the loss of aromatic resonance may already be quite considerable in the transition state of cycloaddition, high activation energies, *i.e.* low reactivities, are to be expected for the Diels-Alder additions of this class of compounds. In agreement with theoretical considerations [94], the diene properties increase in the sequence benzene < naphthalene < anthracene. As expected, benzene itself takes part in Diels-Alder reactions only very sluggishly, and no 1:1-adducts have yet been isolated; the formation of 1,2-bis(trifluoromethyl)benzene in the reaction of benzene with hexafluorobut-2-yne can, however, be rationalized as a normal diene addition with subsequent elimination of acetylene [95]. With durene *(72)* as the diene component, the 1:1-adduct *(73)* is obtained; this is a derivative of the interesting bicyclic compound barrelene [95,96].



*(72)* *(73)*

R = $CF_3$: 41%
R = CN: ≈ 4%

The reactions of naphthalene with dienophiles, *e.g.* maleic anhydride, still require drastic reaction conditions (100 °C) [97,98]; with maleic anhydride a total yield of 5 % of the adducts *(74)* and *(75)*, approximately in a 1:1 ratio, is obtained. 1,2,3,4-Tetramethylnaphthalene

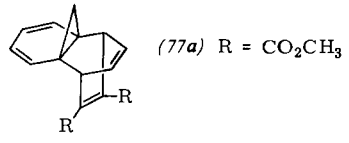
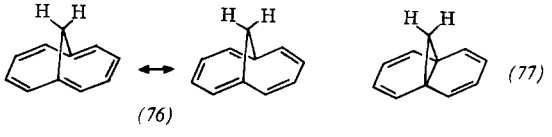
reacts substantially faster than naphthalene. Surprisingly an excess of the dienophile is said to slow down the reaction with naphthalene[98]. In contrast to other examples[99a], the reaction is not accelerated by the action of light[99b].

Similarly to naphthalene, the 1,6-methanocyclodecapentaene *(76)* recently synthesized by *Vogel* and *Roth*[100] has a cyclic conjugated 10 $\pi$-electron system with aromatic character. Diene addition with maleic anhydride sets in only at about 150 °C and stops at the 1:1-adduct; here the reaction involves the valence tautomer *(77)* (two cyclohexadiene systems). The 1:1-addition compound *(77a)* from *(76)* and dimethyl acetylenedicarboxylate readily undergo thermolysis to give dimethyl phthalate and benzocyclopropene (see Section D).

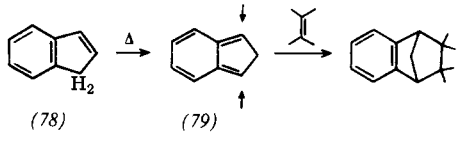


*(77a)* R = $CO_2CH_3$



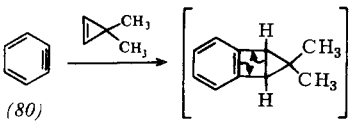
*(76)* *(77)*

On the basis of the structure of the resulting 1:1-adducts, *Alder*, *Pascher*, and *Vagt*[101] postulated for the addition reactions of indene *(78)* a preliminary transition into 2*H*-indene *(79)*, which adds dienophiles in the positions

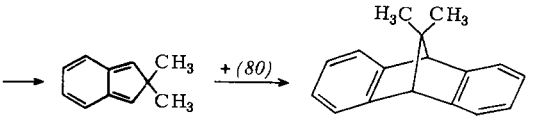


*(78)* *(79)*

indicated. The fact that such an isomerization with a hydrogen shift is possible in the temperature range of diene additions (200 °C) has recently been shown by *Roth* in an elegant NMR study on deuterated indene[102]. *Berson* and *Aspelin*[102a] have come to the same conclusion concerning the reaction mechanism. The formation of *(82)* in small amount in the reaction of benzyne *(80)* with 1,1-dimethylcyclopropene can also be explained readily by a 2*H*-indene intermediate *(81)*[103].

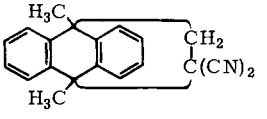


*(80)*

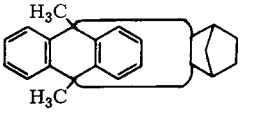


*(81)* *(82)*

As with other additions (*e.g.* halogenations to 9,10-dihalogeno-9,10-dihydroanthracenes), with anthracene and its derivatives the dienophile usually adds in positions 9 and 10. With 1,1-dicyanoethylene, 9,10-dimethylanthracene yields 95 % of *(83)* even at room temperature, while reaction with the angularly strained norbornene to yield 88 % of *(84)* requires heating to 140 °C[104].

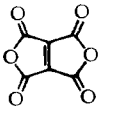


*(83)*



*(84)*

The addition in dioxane of the compound $C_6O_6$ *(85)*, a bis-anhydride of ethylenetetracarboxylic acid, to 9,10-dialkoxyanthracenes in the 9,10-positions is reversible at 20 °C; at 100 °C the dienophile adds irreversibly in the 1,4-positions of the anthracene system[105]. This reaction resembles that of 9,10-diphenylanthracene with maleic anhydride; here a Diels-Alder addition takes place only in the melt, again in the 1,4-position[106].



*(85)*

In this case of the naphthacene derivative *(86)*, as with 9,10-diphenylanthracene, steric factors are probably responsible for the fact that the dienophiles add to the "external" diene systems in the positions indicated[107].

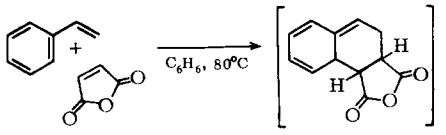
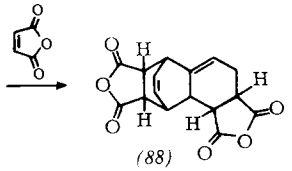
[107] *J. Rigaudy* and *N. K. Cuong*, C. R. hebd. Séances Acad. Sci. *254*, 4184 (1962). Other anthracene derivatives preferring 1,4-addition are described by *J. Rigaudy* and *N. K. Cuong*, *ibid. 260*, 1705 (1965); *J. Rigaudy* and *K. V. Thang*, *ibid. 260*, 2527 (1965).

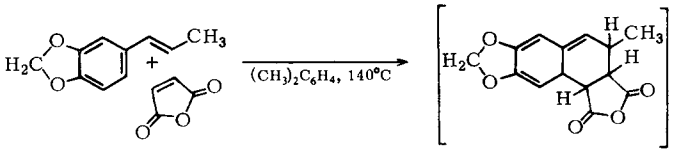
The red-orange naphthothiadiazole *(87)* is less reactive than anthracene, but, like the latter, adds *e.g.* maleic anhydride to the central ring [108].

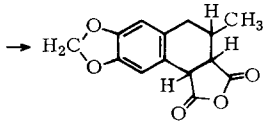
The reactions of styrene and its derivatives, in which only one double bond of the diene system belongs to the aromatic ring, sometimes give yields too low for preparative purposes because of the tendency of styrene to undergo polymerization or copolymerization. As a rule, the 1:1-adduct first produced is not isolated; this can either add a second molecule of the dienophile [*e.g.* to give *(88)*] or can undergo aromatization with a hydrogen shift [*e.g.* to *(89)*] [109,110].





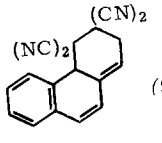
*(88)*



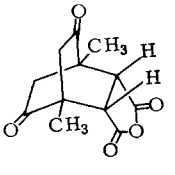


*(89)* 40-50%

In contrast, 2-vinylnaphthalene and tetracyanoethylene give 95 % of the 1:1-adduct *(90)* at room temperature [111]



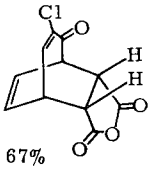
*(90)*



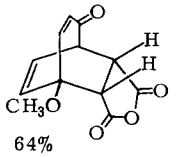
*(91)*

Phenols react with dienophiles only under drastic conditions [112–114]; the adducts are derived from the tautomeric keto forms of the phenols, as in the case of 2,5-dimethylhydroquinone and maleic anhydride: at 200 °C, 21 % of *(91)* is obtained and not the primary adduct [112].

Of the pseudoaromatic compounds azulene and tropolone, only some derivatives of the latter are suitable for the Diels-Alder reaction [115]. 2-Chlorotropolone [116] and γ-tropolone methyl ether [117] react with maleic anhydride to give respectively *(92)* and *(93)*.



*(92)* 67%

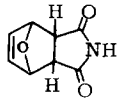


*(93)* 64%

## 9. Heterocyclic Compounds

Since the discovery of the Diels-Alder reaction, the heterocycles furan, pyrrole, and thiophen have been thoroughly investigated with respect to their suitability as diene components; their reactivity decreases in the above sequence.

Furan adds maleic acid derivatives even at room temperature [118,119]; oxabicycloheptene derivatives are readily accessible in this way [*e.g. (94)* by reaction with maleimide in ether at 20 °C]. The tendency of the adducts to redissociate is as pronounced as with the fulvene adducts (cf. Section B.5). Like the alkyl derivatives, the derivatives of cyanofuran [120] and chlorofuran [121], are capable of undergoing cycloaddition.



*(94)*

Some intramolecular diene additions of furan derivatives take place particularly readily; thus the non-activated olefinic part of *(95)* adds to the furan nucleus even at room temperature; dissociation takes place on

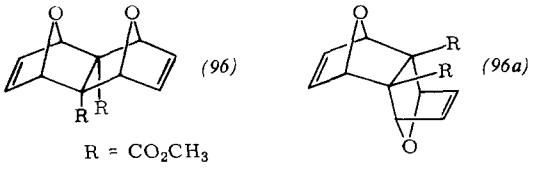
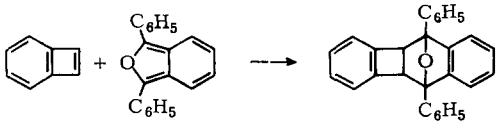
vacuum distillation[122]. Furan itself combines with acetylenedicarboxylic ester to give a 2:1-adduct *(96)* [123].



*(96)* *(96a)*

R = $CO_2CH_3$

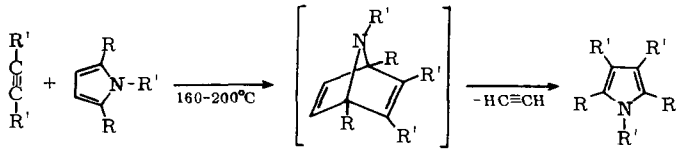
Diphenylisobenzofuran *(97)*, which itself is easy to obtain by a sequence including a Diels-Alder reaction[124], is a valuable diene component; the benzocyclobutadiene *(98)* appearing as an intermediate has recently been



*(98)* *(97)* *(99)*

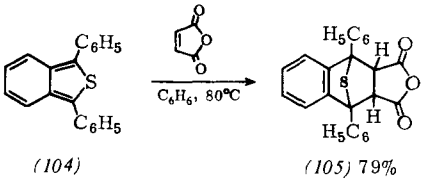
trapped in the form of its diene adduct *(99)* with the aid of this substance[125–127]. The addition of *(98)* to furan itself is possible, but gives a yield of only 5 %[128].

Pyrrole and its derivatives have for many years had the reputation of being unsuitable for Diels-Alder additions; the electrophilic substitution readily occurring in the α-position of the base substance gave rise to side reactions: with maleic anhydride α-pyrrylsuccinic acid was obtained after hydrolysis. Some examples appearing in the last few years show that pyrrole derivatives also possess, in principle, the capacity for taking part in Diels-Alder reactions: *N*-benzylpyrrole[129,130], *N*-methoxycarbonylpyrrole[131], *N*-triphenylmethylpyrrole, and *N*-1-naphthylpyrrole[132] can be converted into Diels-Alder adducts, particularly with acetylenedicarboxylic ester. In the reaction of *N*-methoxycarbonylpyrrole [*(100)*, R = H], the primary adduct *(101)* cannot be isolated because it eliminates acetylene at the high temperature.

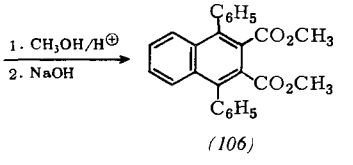


*(100)* *(101)* *(102)* R = H: 43%
*(103)* R = $CH_3$: 51%
R' = $CO_2CH_3$

It has so far been impossible to cause thiophene to react with dienophiles; in fact, with hexachlorocyclopentadiene the heterocycle acts as a dienophile with the formation of a bis-adduct[133]. 2- and 3-vinylthiophenes, in which only one double bond belongs to the diene system of the heterocycle, react in a manner similar to that of styrene[134]. Of a number of benzo[*c*]thiophenes[135], the diphenyl derivative *(104)* may be selected as an example[136].



*(104)* *(105)* 79%



*(106)*

Thiophene 1,1-dioxide *(108)* can be prepared "*in situ*" in several stages from the butadiene-sulfur dioxide adduct *(107)*; all attempts to isolate or trap *(108)* have so far failed[137], since dimerization outweighs all competing reactions. In the case of the stable 3,4-dichloro derivative *(109)*, on the other hand, additions are successful, *(109)* taking part in the reaction sometimes as a diene and sometimes as a dienophile. For example, the adducts *(109a)* and *(109b)* are formed in exothermic reactions in 61 and 16 % yields, respectively, based on *(109)*. Dimerization occurs only at a relatively high temperature[138].

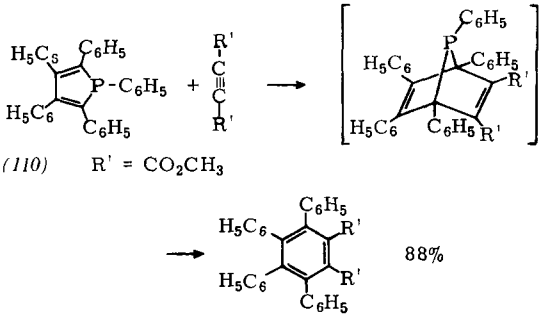
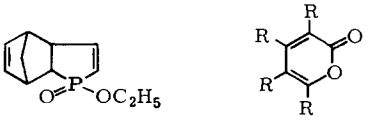
(109) (109a) (109b)

The reaction of arylphospholes with acetylenedicarboxylic ester can be formulated by means of a diene synthesis as the initial reaction step [139]; for example, the pentaphenyl derivative *(110)* forms tetraphenylphthalic ester in 88 % yield; the fate of the P-containing fragment has not been elucidated [140].



*(110)* R' = $CO_2CH_3$

1-Ethoxyphosphole 1-oxide, like thiophene 1,1-dioxide *(108)* and cyclopentadienone *(58a)*, has a pronounced tendency to dimerize and can be trapped in the form of its 1:1-adduct *(111)* only with a 50- to 100-fold excess of cyclopentadiene [141].



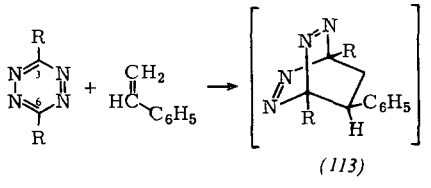
*(111)* *(112)*

Of the five-membered heterocycles with several heteroatoms, only oxazoles [142–145] can be used successfully in Diels-Alder additions, while pyrazoles, thiazoles, imidazoles, and isoxazoles fail [146]. Pyridine derivatives can be obtained in good yields by hydrolytic treatment of the adducts of the oxazoles with dienophiles.

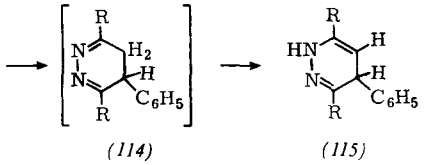
Of the six-membered heterocycles, the α-pyrones *(112)* deserve to be mentioned; they react with olefins to give 1:1-adducts, while the Diels-Alder adducts from *(112)* and acetylenes spontaneously lose $CO_2$ and undergo aromatization [147].

The diene activity is retained in perchloro-α-pyrone [148]. Like anthracene, acridinium bromide adds dienophiles to the central ring [149]. The fact that the addition compounds from 2,3-dimethylquinoxaline and alkenes are not true Diels-Alder adducts has been shown only recently [150].

The reactions of symmetrical tetrazines with simple olefins, discovered by *Carboni* and *Lindsey* [151], deserve interest; *Avram, Dinulescu, Marica*, and *Nenitzescu* [152] have studied some conversions of the very reactive 1,2,4,5-tetrazine-3,6-dicarboxylate. Nitrogen is evolved in an exothermic reaction under surprisingly mild conditions, sometimes at room temperature. 1,4-Dihydropyridazines, whose structures have been established by NMR spectroscopy [153, 154], are produced in high yields. The reaction sequence formulated with a primary dienophile addition in the 3,6-positions of the tetrazines to give



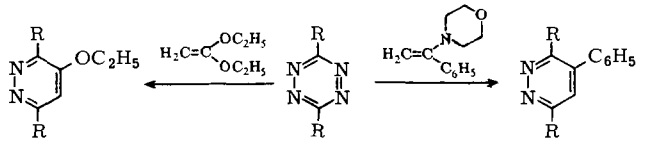
*(113)*



*(114)* *(115)*

R = $CH_3$, $C_6H_5$, $CHF\text{-}CH_3$, $CO_2CH_3$

*(113)* was elucidated on the basis of mechanistic investigations [155]. When enamines, enol ethers, or esters and ketene acetal are used, substituted pyridazines such as *(116)* and *(117)* are obtained directly by single-stage syntheses in excellent yields [154].



*(116)* *(117)*

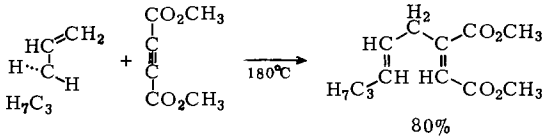
Some particularly reactive dienophiles also take part in reactions with simple olefins and non-conjugated dienes, giving 1:1-adducts. The mechanistic relation to Diels-Alder diene additions [1] justifies a brief discussion.

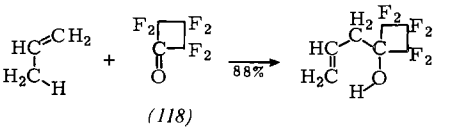
The reaction of 1-hexene with dimethyl acetylenedicarboxylate [156], as an example, includes all the characteristics of this type of reaction which *Alder*, in analogy with "diene synthesis" has called the "ene synthesis", or "indirect substitution addition" [8]: the product of allyl substitution always arises with double displacement in a stereospecific *cis*-addition. The experimental results, together with an elegant study of the asymmetric induction



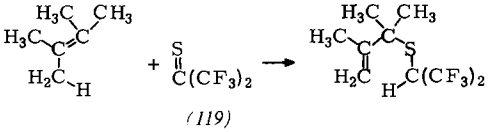
in "ene syntheses" [157], suggest a multi-center mechanism.

"Indirect substitution addition" also takes place with azodicarboxylic ester, as *Huisgen* and *Pohl* [158] have shown with 1,3-diarylpropenes and 1,2- and 1,4-dihydronaphthalenes as the olefinic components; radical and ionic modes of reaction were excluded. The reaction of the azo ester with simple olefins (1-hexene, 1-pentene, cyclopentene, and cyclohexene) also is an "ene synthesis" [159].

The C=O and C=S functions in chloral [160], carbonyl cyanide [161], pyruvic acid [162], perfluorocyclobutanone *(118)* [163], and hexafluorothioacetone *(119)* [164] can



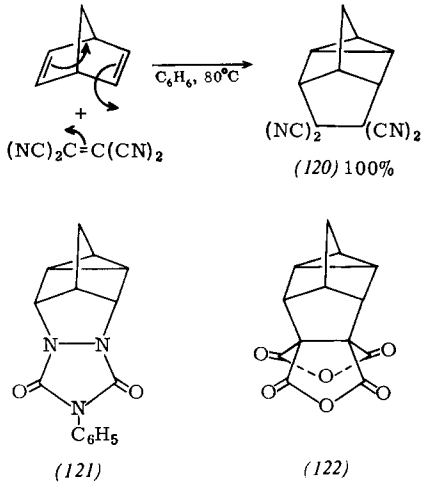
*(118)*



*(119)*

also take part in ene syntheses; however, ketones and thioketones sometimes undergo a change in orientation.

The definition of Diels-Alder additions given in Section A (two π-bonds changing into two σ-bonds) does not apply to the reactions of dienophiles with homodienes, in which the two double bonds are separated by a tetrahedral center. In the homo-Diels-Alder additions of bicycloheptadiene, three new σ-bonds are formed at the expense of three π-bonds in a 1,5-addition. The addition of maleic anhydride, the first example of this type of reaction, takes place in low yield [165]. A substantially higher yield is given by reaction with the "record dienophiles" tetracyanoethylene [166], 4-phenyl-1,2,4-triazoline-3,5-dione [167], and the bis-anhydride *(85)* [105], the products being respectively *(120)*, *(121)*, and *(122)*. Acrylonitrile [168], azodicarboxylic ester [169], dicyanoacetylene [96], and some other highly reactive cyanoethylenes [169a] react similarly.



The combination of barrelene (bicyclo[2.2.2]octa-2,5,7-triene), which has one more double bond, with alkynes also leads to the formation of homo-Diels-Alder adducts [170].

The 1,7-addition of tetracyanoethylene to 1,3,5,7-tetramethylenecyclooctane *(124)* in tetrahydrofuran takes place in accordance with the same structural principle: 3 π-bonds → 3 σ-bonds [171].

## C. The Dienophilic Components

The enormous preparative importance of Diels-Alder additions is based on the great variability of both the reactants; the discussion above has given a small insight into the variability of the dienes. A short systematization of the dienophiles will now follow. Without going into mechanistic details at this point, it may be mentioned that the reactivity of the dienophiles is a function of the diene component: with electron-rich dienes (*e.g.* cyclopentadiene or 9,10-dimethylanthracene), electron-attracting groups X on the double bond accelerate the reaction [104]; with electron-deficient dienes (*e.g.* hexachlorocyclopentadiene and 1,2,4,5-tetrazines), electron-donating substituents in the dienophile have a promoting effect [154, 155, 172].

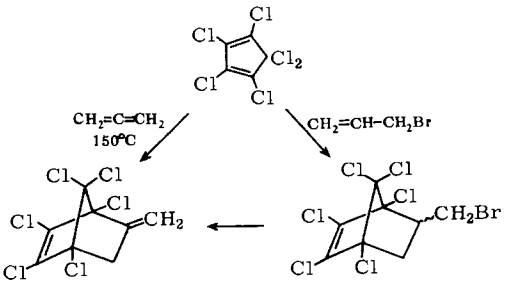
### 1. Acyclic Alkenes and Alkynes

The low reactivity of ethylene and of allylic compounds with respect to electron-rich dienes limits the use of these dienophiles; the necessity of working in autoclaves at high temperatures is also troublesome in the laboratory. Of the monosubstituted ethylenes, acrolein, methyl acrylate and acrylonitrile, styrene derivatives, and nitroolefins [173] enjoy greater favor. 1,1-Disubstituted olefins (*e.g.* dimethyl methylenemalonate and 1,1-dicyanoethylene) are more reactive than their 1,2-disubstituted isomers (dimethyl fumarate and fumaronitrile) [104]. Tri- and tetrasubstituted olefins with several activating substituents increase the preparative possibilities to a considerable extent. The interesting reactions of tri- and tetracyanoethylene, in particular, may be recalled at this point [174, 175].

Acetylene itself reacts with electron-rich dienes only under severe conditions; working with relatively large amounts of acetylene under pressure in the laboratory is not without danger. The reaction of dienes with vinyl bromide and the subsequent elimination of HBr from the Diels-Alder adduct, however, leads to the same product as the direct addition of acetylene. Among the dienophiles derived from mono- and disubstituted alkynes propiolic acid, phenylpropiolic acid, and acetylenedicarboxylic ester may be mentioned in particular. Dicyanoacetylene and hexafluorobut-2-yne have been discussed above in Sections B. 10 and B. 8 [95, 96].

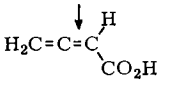
### 2. Allenes

Allene itself exhibits sufficient activity only with respect to electron-deficient dienes – e. g. hexachlorocyclopentadiene [176]. Reference may be made to the addition of allyl bromide with subsequent elimination of HBr, which was used in the example below for establishing the structure of the allene adduct *(125)* [177].

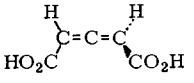


*(125)*

Cyclopentadiene combines with allenecarboxylic acid *(126)* to give a 1:1-adduct in 84 % yield; in this process the dienophile reacts as a derivative of acrylic acid at the double bond indicated [178].



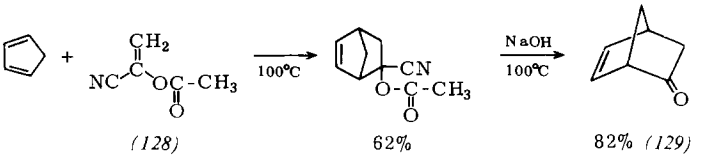
*(126)*



*(127)*

The absolute configuration of allenedicarboxylic acid *(127)* was determined by *Agosta* [179]; a diene addition to cyclopentadiene formed the introductory step of the sequence of reactions.

Extensive investigations by *Staudinger* [180] have shown that for ketenes the four-center cycloaddition to form cyclobutane derivatives is preferred to the formation of a six-membered ring. *Bartlett et al.* pointed out an artifice for the preparation of the Diels-Alder adducts of ketene itself [181]. The diene is treated with 1-cyanovinyl acetate *(128)* to give an adduct which on alkaline hydrolysis yields the desired ketone *(129)*.



*(128)* 62% 82% *(129)*

### 3. Cyclic Dienophiles

Among the cross-conjugated dienophiles, the greatest importance is attached to the derivatives of *p*-benzoquinone [13]. Quinones substituted with electron-attracting groups prove to be particularly reactive with respect

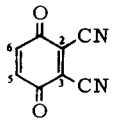
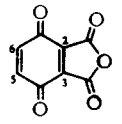
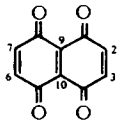
to electron-rich dienes. The dicyanoquinone *(129)* reacts more slowly than tetracyanoethylene, whereas quinonedicarboxylic anhydride *(130)* does so considerably faster [182].



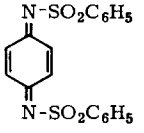
*(129)*



*(130)*



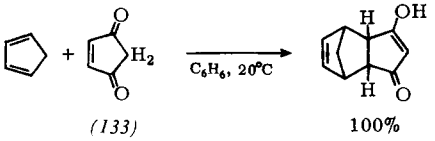
*(131)*



*(132)*

In *(129)*, *(130)*, and 1,4,5,8-naphthodiquinone *(131)* [182], as expected, cyclopentadiene, 2,3-dimethylbutadiene [182], and 1,2-dimethylenecyclobutadiene [183] add to the more highly activated double bond [in the 2,3-position in *(129)* and *(130)* and the 9,10-position in *(131)*] to form the monoadduct. An interesting difference is found with butadiene: *(129)* forms two monoadducts by the reaction of the 5,6- and the 2,3-positions (yields 16 and 62 %, respectively) [184], whereas *(131)* gives a 2:1-adduct (addition in the 2,3- and 6,7-positions) and a 1:1-adduct (reaction of the 9,10-double bond) with comparable yields [182]. On the other hand, *(130)* adds butadiene in the 2,3-position with a yield of about 75 % [182]. There is still no satisfactory explanation for this phenomenon. The dienophilic activity of *p*-benzoquinones is even retained in *N,N'*-disulfonylquinonedi-imines [*e.g. (132)*] [185].

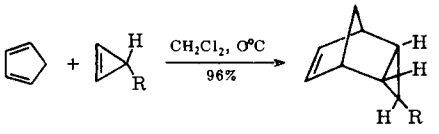
Through its diene additions, cyclopent-1-ene-3,5-dione *(133)*, which exists completely in the diketo form, makes enolized 1,3-dioxocyclopentanes readily accessible [186].



*(133)* 100%

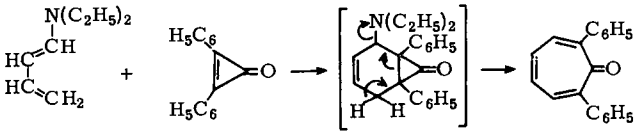
A fairly large number of cyclic olefins and acetylenes with pronounced angular strain have found application as dienophiles in the last few years. Already in the transition state, adduct formation is associated with a reduction in angular deformation; this acts as a driving force in the Diels-Alder addition.

Cyclopropene [*(134)*, R = H] combines with cyclopentadiene even at 0 °C rapidly and stereospecifically to give the *endo* adduct [*(135)*, R = H] [187]. Methylcyclopropene reacts similarly to give *(135)* [R = $CH_3$] [188], but dimethylcyclopropene, probably for steric reasons, does notre act [188]. Triphenylcyclopropene and tetraphenylcyclopentadienone give heptaphenylcycloheptatriene by the elimination of CO from the primary 1:1-adduct [189].



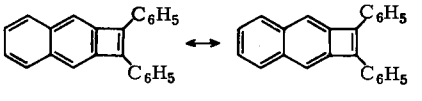
*(134)* *(135)*

Diphenylcyclopropenone and 1-diethylaminobutadiene in boiling benzene give 2,7-diphenylcyclohepta-2,4,6-trienone *(136)* in a single-stage reaction with a yield of almost 70 % [189a]; the adduct *(136a)* probably occurring as an intermediate undergoes elimination and valence-isomerization to *(136)*.



*(136a)* *(136)*

In cyclobutene derivatives, as well, the angular strain has a reaction-promoting effect; 3,3,4,4-tetrafluorocyclobutene reacts with dienes under remarkably mild conditions [190], as do unsaturated four-membered cyclic sulfones [190a]. Trapping reactions with the benzocyclobutadiene probably appearing "*in situ*" (cf. Section B. 9) take place at room temperature. The isolable cyclobutadiene derivative *(137)* also proves to be a very reactive dienophile [191]. The corresponding monobromonaphthocyclobutadiene and the dibromo compound are too short-lived, and could only be detected by trapping [191a].



*(137)*

The sp-hybridization determines the linear structure of acetylene and permits the strain-free incorporation of a triple bond only in rings with nine or more members. The increase in the angular deformation with decreasing ring size in the sequence cyclooctyne → cyclopentyne is shown in an increasing tendency to undergo additions; cyclooctyne exhibits pronounced dienophilic properties. Lower cycloalkynes have not been isolated, but their existence has been proved by trapping reactions [192]; for

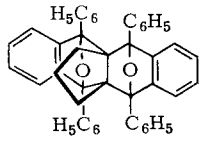
example, cyclopentyne gives the bis-adduct *(138)* with diphenylisobenzofuran.

*(138)*

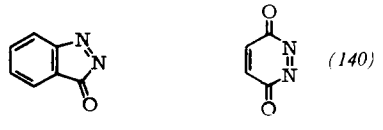


Arynes, *e.g.* dehydrobenzene *(80)* (see also Section B. 8), represent cyclic acetylenes in one resonance form. In brilliant investigations, *Wittig* and his school [193] have demonstrated the Diels-Alder additions of the "dehydroaromatic" intermediates. Cyclopentadiene [193], cyclohexadiene [194], and even benzene and naphthalene [195] add to the highly reactive species $C_6H_4$ *(80)*. The dienophilic activity is also retained in the "dehydroaromatics" of the pyridine series and in quinoline derivatives [196].

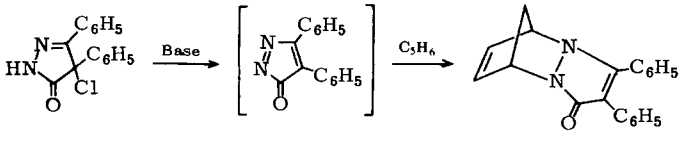
## 4. Cyclic Azo Compounds

Some cyclic azo compounds, which have been synthesized only recently, possess high dienophilic activity; however, only some of them are stable. Thus indazol-3-one *(139)* [197], 2,3-diaza-*p*-benzoquinone *(140)* [198], and 2,3-diaza-1,4-naphthoquinone have been detected by their reactions with dienes at low temperatures; in all cases the azo compounds were prepared by oxidation of the corresponding cyclic hydrazo compounds. The dienes add to the –N=N– bond system of *(139)* and *(140)*. In the dehalogenation of the

*(139)* *(140)*



pyrazolinone *(141)*, it is reasonable to postulate an intermediate with a cyclic azo grouping [199].



*(141)* 70-90%

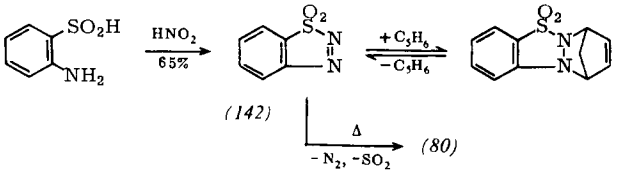
[196] *T. Kauffmann* and *F. P. Boettcher*, Chem. Ber. *95*, 949, 1528 (1962); *R. J. Martens* and *H. J. den Hertog*, Tetrahedron Letters *1962*, 643.

[197] *E. F. Ullman* and *E. A. Bartkus*, Chem. and Ind. *1962*, 93.

[198] *T. J. Kealy*, J. Amer. chem. Soc. *84*, 966 (1962); *R. A. Clement*, J. org. Chemistry *25*, 1724 (1960); *27*, 1115 (1962).

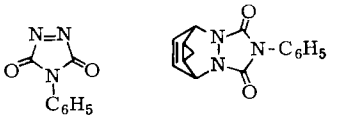
[199] *L. A. Carpino*, *P. H. Terry*, and *S. D. Thatte*, Tetrahedron Letters *1964*, 3329.

The cyclic compounds *(142)* [200] and *(143)* [167], on the other hand, can be isolated. Compound *(142)* adds to cyclopentadiene reversibly; slightly above room temperature *(142)* offers a high-yield route to dehydrobenzene *(80)*.

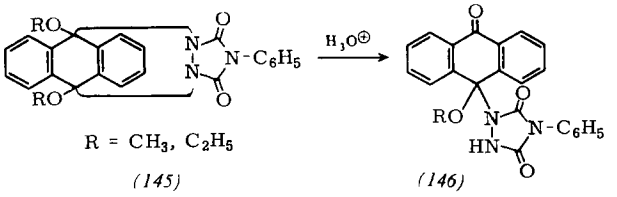


*(142)* *(80)*

4-Phenyl-1,2,4-triazoline-3,5-dione *(143)* was found in kinetic experiments to be a dienophile with extremely good addition properties, many times better than tetracyanoethylene [182]; it combines with cycloheptatriene even at –50 °C to give *(144)* [167]. The Diels-Alder adducts with 9,10-dialkoxyanthracenes undergo an acid-catalysed rearrangement at room temperature to give *(146)* [182].



*(143)* *(144)*



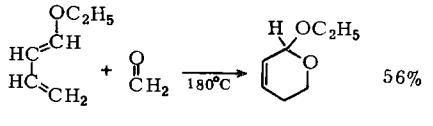
R = $CH_3$, $C_2H_5$

*(145)* *(146)*

## 5. Other Dienophiles with Heteroatoms

The replacement of carbon in the diene chain by heteroatoms is possible only in individual cases, as shown by the examples of the α,β-unsaturated aldehydes and ketones and the 1,2,4,5-tetrazines (cf. Sections B. 2 and B. 9). In contrast, in the dienophiles one or both C atoms of the dienophilic multiple bond can frequently be replaced by heteroatoms without loss of activity. This has already been illustrated by the cyclic azo compounds described in Section C. 4.

Carbonyl functions in aldehydes and ketones add to dienes particularly well if the C=O double bond is deprived of electrons by means of suitable substituents. Formaldehyde reacts slowly [201]; the reactivity increases on passing to chloral [202] and mesoxalic ester or



56%

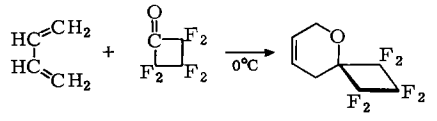
mesoxalonitrile [203], and reaches a maximum with perfluorinated cyclobutanone *(118)* [204, 104]; other fluoroketones *(147)* also react readily [205]. Glyoxylic ester and



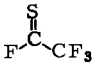
*(118)* 100% *(148)*

*(147)* R = $CF_3$, $CF_2Cl$, $C_2F_5$

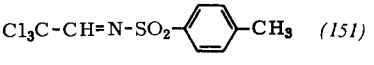
its semiacetals also react with dienes to give partially hydrogenated pyrans [206].

While the C=S bond system has proved to be a highly dipolarophilic grouping [2], only a few examples of a dienophilic activity are known; the dienophilic systems *(119)*, *(149)*, and *(150)* again bear electron-attracting groups [164].

*(149)*



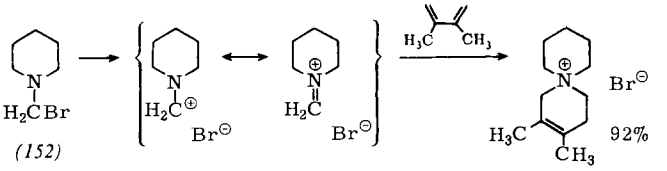
*(150)*



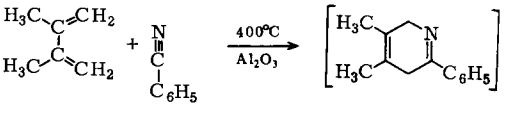
*(151)*

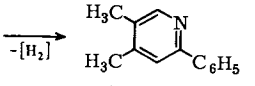
More recent investigations [164, 206a] have shown that simple thioketones – for example, thiofluorenone – react with dienes to give Diels-Alder adducts even at room temperature. Obviously the dienophilic nature of compounds with the C=S double bond has been overlooked, not least because of their unpleasant odor. Here is presumably a wide field of preparative application.

Among Schiff bases [207], immonium salts [208], and nitriles [209] (the latter react only at high temperatures) C=N or C≡N heterodienophiles are occasionally found. *(151)* generally combines with dienes to give Diels-Alder adducts in high yields (> 90 %) [207]. The immonium salts that may be formed as intermediates from α-halogenoamines such as *(152)* make spirocyclic ammonium compounds accessible [208]. Simple nitriles, such as benzonitrile, acetonitrile, and dicyanogen, add to dienes only at about 400 °C; the products of a subsequent dehydrogenation, *e.g. (153)*, are immediately formed [209]. α-Ketonitriles and cyanopyridines react at temperatures as low as about 250 °C [210].



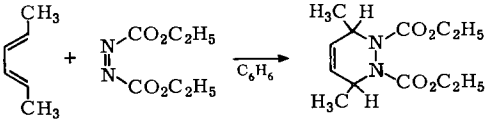
*(152)*



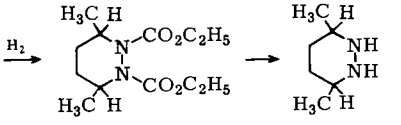


*(153)* 53%

Some of the longest-known addition reactions are those of azodicarboxylic ester [5]. Tetrahydropyridazines such as *(154)* can be isolated, usually in excellent



*(154)* 86%



yields [211, 212], and they can be converted into cyclic hydrazine derivatives. The Diels-Alder adducts, *e.g. (4)*, lead in many cases to new azo compounds, such as *(155)* which, in turn, are capable of undergoing interesting reactions and make new compounds accessible [213, 214].

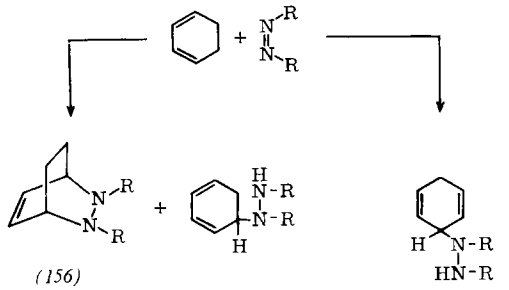
The possibility, mentioned in Section B. 10, of a radical allyl substitution [215] or a multi-center reaction with a shift of the double bond in the reaction of azodicarboxylic ester with olefins also exists in principle with dienes, and sometimes makes it difficult to establish the constitution of the Diels-Alder 1:1-adducts. Apparently slight changes in the reaction conditions lead to the formation of different products [216]. Thus azodicarboxylic ester and cyclohexa-1,3-diene at 20 °C in cyclohexane give the compounds *(156)* and *(157)* in an exothermic reaction (total yield 89 %). Without a solvent, between 20 and 80 °C, only *(158)* is formed.



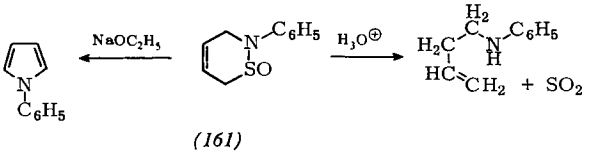
*(156)* *(157)* *(158)*

R = $CO_2C_2H_5$

Possibly the influence of light, recently discovered by *Askani* [216a], offers an explanation of the apparent discrepancy: on irradiation with a high-pressure mercury lamp, cyclohexadiene and azodicarboxylic ester form only the adduct *(156)* in 87 % yield.

Finally, there is also a possibility of replacing the two C atoms of the double bond in the dienophile by two different heteroatoms: nitroso compounds *(159)* and *N*-sulfinyl compounds *(160)*, on addition to dienes, form six-membered heterocycles [31,217]. The adducts of the nitrosoaromatic compounds can easily be converted by hydrogenolysis into *cis*-1,4-aminoalcohols [218], and the diene adducts of *N*-sulfinyl compounds such as *(161)* give rise to a wealth of new reactions [217], two of which are illustrated here.

R–N=O *(159)* R–N=S=O *(160)*



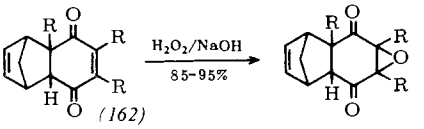
*(161)*

The 1:1-addition compounds from dienes and molecular oxygen, which frequently are formed on irradiation [219], can be regarded formally in some cases as Diels-Alder adducts. These reactions will not be discusssed in this review.

### D. Retro-Diels-Alder Reactions

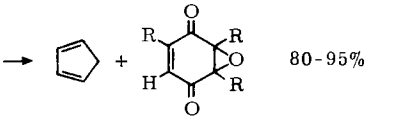
The diene additions are reversible, often under surprisingly mild conditions; for the fulvenes and furans (Sections B. 5 and B. 9) we have already demonstrated this capacity for undergoing the retro-Diels-Alder reaction. Many adducts can be modified chemically and yet still undergo cleavage in a retro-Diels-Alder reaction. In this way a modified diene and/or dienophile are obtained. The fact that the retro-Diels-Alder reactions frequently claim preparative interest may be illustrated by the following example.

The alkali-lability of the simple *p*-benzoquinones interferes with their epoxidation with alkaline $H_2O_2$. On the other hand, the benzoquinone adducts *(162)* with cyclopentadiene can be easily epoxidized; pyrolysis at 420 °C/10 mm smoothly yields the desired quinone epoxides [220].



*(162)*

R = H, $CH_3$



As further examples may be mentioned: the preparation of 6,6-disubstituted cyclohexadienones from dimeric fulvene epoxides [91], the preparations of *o*-quinodimethane [48,49], and of acetylenedicarbonyl dichloride from the anthracene adduct of the free acid [221], and the conversion of 1-vinylcyclohexene into vinylcyclohexane *via* the anthracene adduct [222]. The determination of the position of groups in the cycloheptatriene ring has been carried out through the addition of acetylenedicarboxylic ester and pyrolysis of the adduct to substituted phthalic esters [223]. The transient existence of isobenzo-

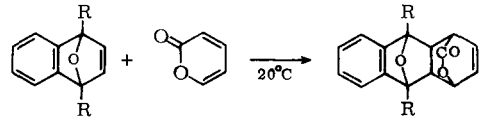
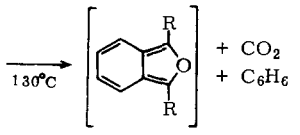
furan [*(163)*, R = H] and its dimethyl derivative was also shown for the first time by the retro-Diels-Alder reaction with trapping experiments [224].

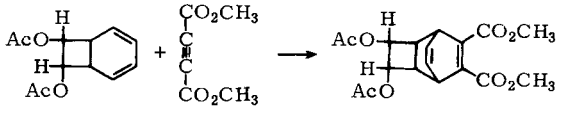


R = H, $CH_3$ 95%

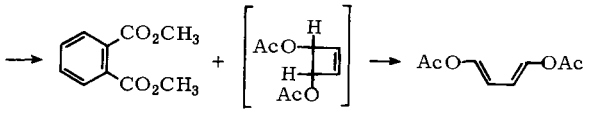


*(163)* R = H: > 92%

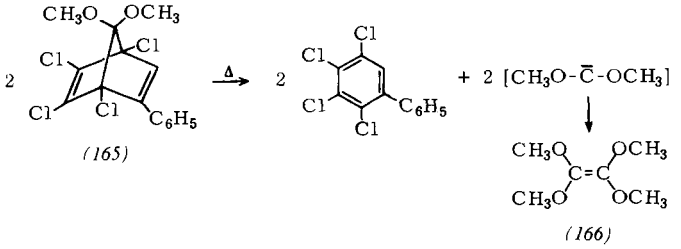
It is not always the bonds formed in the addition that are split on pyrolysis, as can be seen from an example due to *Criegee* [225]. The adduct *(164)* decomposes at about 200 °C/18 mm into dimethyl phthalate and diacetoxybutadiene. Tetramethoxyethylene *(166)* was first obtained by *Hoffmann* and *Häuser* [226] by a retro-diene



*(164)*

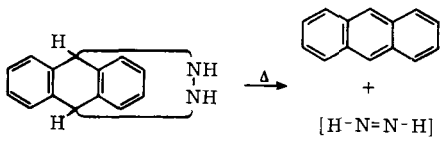


synthesis from the easily accessible adduct *(165)* of 5,5-dimethoxytetrachlorocyclopentadiene and phenylacetylene.



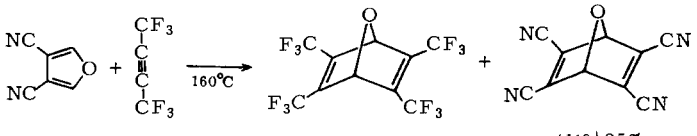
*(165)* *(166)*

The adducts of tri- and tetracyanoethylene, dicyano-*p*-benzoquinone, and dicyanomaleimide with 9,10-dialkoxyanthracenes decompose into the components in solution, even at room temperature, sometimes immeasurably fast [227]; the preparation of the compound $C_6O_6$ *(85)* in solution (Section B. 8) in a similar manner may be recalled. In warm ethanol, the hydrolysis product *(167)* of the adduct from azodicarboxylic ester and anthracene gives the diimide, which is capable of stereospecific *cis*-addition [228].



*(167)*

Compounds *(168)* and *(169)*, which were isolated as the only products, probably arise from many addition and splitting steps: the reversibility of the addition step possibly ensures the establishment of thermodynamic equilibrium [229].



*(168)* 30% *(169)* 35%

A particularly fine example of a retro-Diels-Alder reaction has recently been contributed by *Vogel et al.* [230]. The adduct *(77a)* (see Section B. 8) decomposes at 100 °C/1 mm to give a 45 % yield of benzocyclopropene, which is very interesting in relation to bond theory, and phthalic ester.

## E. Future Prospects

Any short account of the Diels-Alder reaction must necessarily be incomplete. However, the discussion of the modes of reaction of diene and dienophile, possible here only in a sketchy fashion, shows that the preparative possibilities of diene additions are still not exhausted. It has not been possible to discuss Diels-Alder reactions initiated by irradiation.

In addition to preparative investigations, since the discovery of this cycloaddition to form six-membered rings attempts have been made to clarify the reaction mechanism. An account of systematic mechanistic studies with the inclusion of stereochemical and kinetic results and of orientation and catalysis phenomena will be given in the second part of this paper.

# The Quaternary Structure of Proteins

BY PRIV.-DOZ. DR. H. SUND [1a] AND DR. K. WEBER [1b]

CHEMISCHES LABORATORIUM DER UNIVERSITÄT FREIBURG (GERMANY)

*Many protein molecules, particularly those with high molecular weights, consist not of a single polypeptide chain, but form a complex made up from several polypeptide chains. This structure, which can be reversibly broken down, is known as the quaternary structure. A number of metabolic phenomena can be explained on a molecular basis by invoking the quaternary structure.*

## I. Introduction [2]

Important advances have been made in recent years in the elucidation of the structure of proteins. One of these advances is the realization that protein molecules very often do not consist of a single polypeptide chain. Although these proteins behave under physiological conditions as monodisperse substances with a defined molecular weight, they actually are complexes of several polypeptide chains not joined to one another by peptide linkages [3]. In an extension of the *Linderstrøm-Lang* terminology [4], *Bernal* (1958) introduced the term "quaternary structure" for this phenomenon [5].

### The Linderstrøm-Lang Terminology [4]

For the description of particular aspects of the structure of a protein molecule *Linderstrøm-Lang* introduced the terms primary, secondary, and tertiary structure (cf. Fig. 1a–1c). The primary structure of a polypeptide chain is given by the number and sequence of the amino-acid residues that are joined together by peptide linkages. Secondary structures (helical and pleated sheet structures) may result from hydrogen bonding between the CO and NH groups of the peptide linkages. Tertiary structure is the spatial arrangement due to interactions between the side-chains of the amino-acid residues. Finally, a protein molecule has a quaternary structure if it consists of a defined number of polypeptide chains (Fig. 1d) [6].

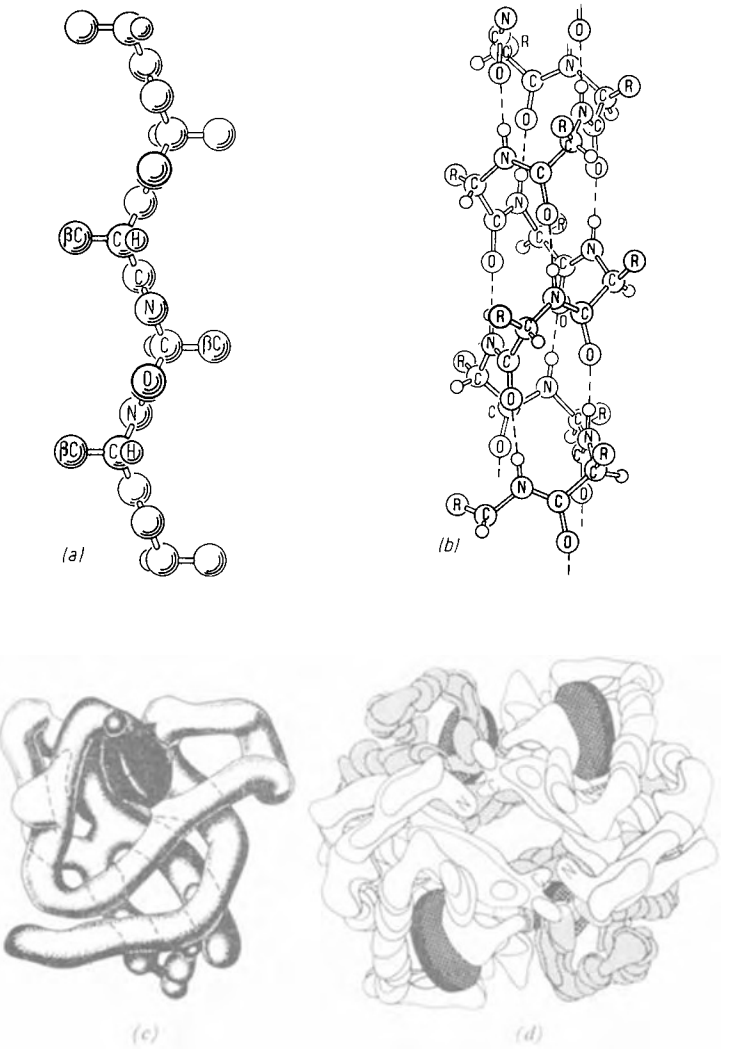

Fig. 1. The principles of protein structure (after *Bernal* [5]).
a) Primary structure (polypeptide chain after [9]).
b) Secondary structure (example: α-helix after *Pauling* and *Corey* [9]).
c) Tertiary structure (example: myoglobin after *Kendrew* [10]).
d) Quaternary structure (example: hemoglobin after *Perutz* [11]). White: polypeptide α-chains, grey: polypeptide β-chains, black disks: heme groups, C and N: C- and N-terminal groups of the two α-chains.

[1a] Based on lectures held during 1964 *(H. S.)*.

[1b] Present address: Biological Laboratories, Harvard University, Cambridge, Massachusetts (USA).

[2] For the historical development of views on the structure, size, and homogeneity of proteins, see *J. T. Edsall*, Arch. Biochem. Biophysics Suppl. *1*, 12 (1962).

[3] Under given conditions the protein molecules, sub-units, and polypeptide chains [cf. Equations (1a)–(1c)] have a characteristic particle weight, which can be measured by physicochemical methods. This weight will be referred to as the molecular weight of the particle.

[5] *J. D. Bernal*, Discuss. Faraday Soc. *25*, 7 (1958).

[6] Secondary, tertiary, and quaternary structures are aspects of the conformation of the protein molecule. *Wetlaufer* [7] has suggested that the spatial arrangement of the polypeptide chains and the side-chains of the amino-acid residues should be termed "chain conformation". However, this suggestion has not been adopted. A further proposal concerning the quaternary structure has been made [8].

### Polypeptide Chains and Sub-Units [3]

A protein molecule consisting of more than two polypeptide chains can dissociate stepwise into these components. A dissociation product that still contains at least two polypeptide chains will be referred to as a sub-unit. The polypeptide chains themselves, on the other hand, consist entirely of amino-acid units joined to one another by peptide linkages. Thus a protein molecule consisting of several polypeptide chains can dissociate in three ways:

(1a) protein molecule $\rightleftharpoons$ *a* polypeptide chains

(1b) protein molecule $\rightleftharpoons$ *a* sub-units $\rightleftharpoons$ *xa* polypeptide chains

(1c) protein molecule $\rightleftharpoons$ *a* sub-units + *b* polypeptide chains

$\Updownarrow$

*xa* polypeptide chains

The polypeptide chains of a protein molecule may all be identical (homogeneous type of quaternary structure) or they may be different (heterogeneous type).

## II. Stabilization of the Protein Structure

### 1. Bond Types

The native conformation of a protein molecule is stabilized by covalent and by non-covalent bonds. These bonds reduce the flexibility of the polypeptide chains, and ensure that they are arranged in an ordered, compact form, instead of as a random coil [12].

Among the covalent bonds, the only type that appears to be of general occurrence is the disulfide bond. This may link different parts of the same polypeptide chain, as in ribonuclease [13,14], or it may join different polypeptide chains, as in insulin [15] and γ-globulin (cf. Section IV.3). No conclusive evidence has yet been found for covalent peptide linkages between different polypeptide chains or between different parts of the same chain (*e.g.* between the ε-amino group of lysine and the γ-carboxyl group of glutamic acid). Ester and phosphate links and linkages *via* carbohydrates or other components are probably peculiar only to a small number of proteins.

Non-covalent bonds include the hydrogen bond, the hydrophobic bond, and the ionic bond [16] (Fig. 2). Recent investigations have shown that the bond energy of a hydrogen bond between a carbonyl oxygen and an amide nitrogen in aqueous solution is at most 1.5 kcal/mole [17,18], *i.e.* much lower than the value of 8 kcal/mole that has previously been accepted [19]. However, the bond energy may be appreciably higher in a non-polar (hydrophobic) medium [16]. Hydrogen bonding may occur not only between peptide groups, but also between suitable donors and acceptors in the amino-acid side-chains (*e.g.* between the OH group of a tyrosine residue and a carboxylate group).

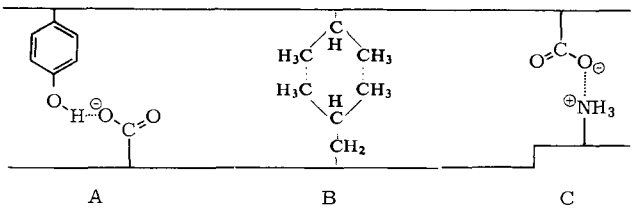

Fig. 2. Examples of non-covalent bonds between amino-acid side-chains, which stabilize the conformation of a protein molecule (cf. also [16a]). A. Hydrogen bond; B. hydrophobic bond; C. ionic bond.

Nowadays it is often considered that the greatest contribution to stabilization of the protein structure is made by hydrophobic bonds. In most proteins, some 40 % of the amino-acid residues have non-polar side-chains. According to *Kauzmann* [12], those protein conformations which bring many of these non-polar groups into contact with one another and thus "remove" them from the aqueous phase are more stable than others. This leads to the formation of "hydrophobic micelles" in the protein molecule. According to *Némethy* and *Scheraga* [16], the hydrophobic bond is not simply a result of van der Waals forces between the non-polar groups, but is due largely to the physical properties of liquid water and its tendency to form hydrogen-bonded clusters (cf. also [16a]).

Coulomb forces between ionic groups in the protein molecule may also have a stabilizing effect, and like hydrogen bonds, these ionic bonds should be stronger in non-polar than in polar media.

The native conformation may in addition be stabilized by metal ions and prosthetic groups, as well as by co-enzyme-substrate interaction.

### 2. Denaturation

A change in the native structure of a protein molecule is referred to as denaturation. This process is generally accompanied by a change in the optical properties and loss of biological activity. Moreover, the unusual reactivity exhibited by functional groups in the native protein molecule is often lost on denaturation. Globular protein molecules are transformed into a less compact structure, and if the changes are sufficiently extensive, the new arrangement may even approximate to the random-coil model. The solubility of the protein often is also affected by denaturation.

Denaturation can be brought about by modification of the solvent (addition of organic solvents, salts, urea, or guanidine hydrochloride) or by a change in pH, by the

addition of detergents, heavy metal ions, or complexing agents, or by a temperature change. Other methods involve the chemical modification of the protein by oxidative or reductive cleavage of disulfide groups, oxidation of thiol groups to sulfonic acid groups, or substitution of functional groups.

Most of the early attempts to convert denatured proteins back into the biologically active forms were unsuccessful. Since there were very few cases of successful renaturation [20], denaturation [*] was generally regarded as irreversible, and the denatured form was assumed to be particularly stable in comparison with the native structure. However, this view has now been abandoned, mainly as a result of many successful reactivations and on the basis of present knowledge of the biosynthesis of proteins. Today, the native conformation of a protein is often regarded simply as a function of the amino-acid sequence of the polypeptide chain *and* the surrounding medium (cf. also Section V).

A considerable conformational entropy has to be overcome during renaturation, and this leads to an increase in free energy of the native conformation. If the native conformation is nevertheless favored relative to the random coil, the formation of hydrogen bonds, hydrophobic bonds, and ionic bonds must make a substantial negative contribution to the free energy in order to make the renaturation possible. The overall change in free energy during the formation of the native compact structure from the random coil should then be small and negative. This is confirmed by the few thermodynamic results available [20]. With regard to attempts to estimate the contribution made by non-covalent bonds to the stabilization of the native structure, the reader is referred to the original publications [16, 21, 22].

## III. Detection of the Quaternary Structure

The quaternary structure can be studied by the following methods [23]:

1. With X-ray analysis, even at relatively low resolutions, the individual sub-units or polypeptide chains can be distinguished, and their arrangement in space recognized.

2. The arrangement of the sub-units can be observed directly by means of the electron microscope, particularly when the technique of negative staining is used.

3. The "classical" technique in protein chemistry is end-group analysis, in which the N-terminal or C-terminal amino-acid of each polypeptide chain is determined with specific reagents or by enzymatic hydrolysis.

4. In "fingerprint analysis", the protein is broken down with trypsin, and the resulting mixture of peptides is separated by chromatography and electrophoresis. The equivalent weight of the polypeptide chain can be found from the lysine and arginine content of the protein and from the number of peptides obtained. The enzymatic degradation may be replaced by reaction of the protein with BrCN; in this case, cleavage of the polypeptide chains occurs at methionine residues [24].

5. A protein molecule consisting of several polypeptide chains often dissociates into sub-units or polypeptide chains on denaturation. The problem of finding the number of sub-units and polypeptide chains then reduces to a molecular-weight determination. Investigations of this nature are usually carried out with the aid of the ultracentrifuge [25, 25a]. If the polypeptide chains are not identical, they can be separated in the denatured state by electrophoresis, counter-current distribution, or chromatography.

6. If, as is the case with bacteria, it is possible to obtain an isotopically labelled protein molecule, the hybridization technique may be used: if denaturation results in reversible dissociation of the protein molecule into its sub-units, it is possible to prepare hybrids of "heavy" molecules and "light" molecules; these hybrids can then be separated by centrifugation in a density gradient. The number of sub-units formed on denaturation can be found directly from the differences in the densities of the heavy, the hybrid, and the light molecules.

7. If an enzyme contains several active centers, the determination of the number of sites at which the substrate becomes attached contributes to the study of the quaternary structure.

## IV. The Quaternary Structures of Various Proteins

A number of proteins whose quaternary structures have been studied are listed in Tables 1 and 2 (for others, see [25–30]). Some of these are discussed in the following Sections.

### 1. Respiratory Proteins (Erythrocruorins, Hemocyanins, Hemoglobins)

The respiratory proteins (erythrocruorins and hemocyanins) of invertebrates give pH-dependent association-dissociation equilibria in solution [25, 54, 54a, 56]. The molecular weight in the associated state can be as high as several million, whereas molecular weights of 40000 to 400000 are obtained for the fragments formed on dissociation. The larger dissociation products are prob-

Table 1. Quaternary structures of some proteins (for dehydrogenases see Table 2).

| Protein | M. W. | Polypeptide chain | | | Notes | Ref. |
|---|---|---|---|---|---|---|
| | | M. W. | Number | Method [a] | | |
| Beef thrombin | 33700–40000 | ≈ 8000 | 4–5 | D/M | Reversible formation of larger associates. | [31] |
| Hemoglobins from various species | 65000 | 15000–16000 | 4 | C, D/M, EA, F, X, S | See Section IV, 1 | |
| Alkaline phosphatase from *E. coli* | 80000 | 40000 | 2 | D/M, F | Dissociation into polypeptide chains (probably identical) is reversible, with reactivation. | [32] |
| Enolase from rabbit skeletal muscle | 82000 | 40000 | 2 | D/M, EA | Dissociation into polypeptide chains is reversible, with reactivation. | [33] |
| Procarboxypeptidase A-S6 from beef pancreas | 87000 | 34500 and 2 x ≈25000 | 3 | D/M, EA | The polypeptide chain having M.W. 34500 and one of the two having M.W. about 25000 are the inactive forms of carboxypeptidase A and of an endopeptidase. The function of the third polypeptide chain is unknown. | [34] |
| Hexokinase from yeast | 96000 | 24000 | 4 | D/M, EA,F | Dissociation into polypeptide chains (probably identical) is reversible, with reactivation. The molecule can dissociate into two enzymatically active sub-units. | [35] |
| Hemerythrin from *Golfingia gouldii* | 107000 | 13500 | 8 | C, D/M | Dissociation into the polypeptide chains is reversible, with recovery of the ability to bind $O_2$. | [36] |
| Tryptophane synthetase from *E. coli*, B protein | 117000 | 60000 | 2 | C, EA | The sedimentation coefficient of 1.2 S indicates the presence of more than two polypeptide chains. The A protein consists of only one polypeptide chain (M.W. 29500). The A and B proteins form a functional unit. | [37] |
| Aldolase from rabbit skeletal muscle | 142000 | 23500 | 6 | D/M | See Section IV, 4. | |
| γ-Globulins from various species | 150000 | 25000 and 50000 | 2 each | D/M | See Section IV, 3. | |
| Thetin homocysteine methylpherase from horse liver | 180000 | 50000 | 3–4 | D/M | Enzyme aggregates, probably with formation of disulfide bridges. Depolymerized by compounds that cleave disulfides. Specific activity independent of particle size. | [38] |
| Fumarase from pig heart muscle | 194000 | 48500 | 4 | D/M, EA, F | Dissociation into polypeptide chains (probably identical) is reversible, with reactivation. | [39] |
| Catalase from beef liver | 240000-248000 | 65000 | 4 | C, D/M, EM, F | Fingerprint analysis indicates four identical polypeptide chains. The dissociation product (M.W. 65000) may consist of several dissimilar polypeptide chains. At pH 3, catalase dissociates into two sub-units having M.W. 120000. | [40] |
| Edestin from hemp seed | 300000-360000 | 23000 and 27000 | 6–7 each | D/M, EA, F | The two dissimilar polypeptide chains (in one sub-unit) may be joined together by disulfide bridges. | [42] |
| Fibrinogen from beef serum | 340000-390000 | 51000-65000 | 6 | D/M, EA | Six polypeptide chains, probably as three sets of two identical chains. | [44] |
| Lipovitellin from egg yolk | 400000 | 200000 | 2 | D/M | Lipid content 20%. Dissociation is reversible. The molecular weight of the polypeptide chain appears to be less than 100000 (end-group analysis). | [45] |
| Apoferritin from horse spleen | 480000 | 24000 | 20 | D/M, EA, EM, F, X | See Section IV, 2. Dimerization was observed [45a]. | |
| Glycogen phosphorylase from rabbit skeletal muscle | 495000 | 135000 | 4 | C, D/M | See Section IV, 6. | |
| Urease from jack-bean meal | 483000 | 83000 | 6 | D/M | Larger associates were observed. | [46] |
| β-Galactosidase from *E. coli* | 518000 | 35000-40000 | 12–16 | D/M | See Section IV, 7. | |
| DNA-dependent RNA-polymerase from *E. coli* | 600000-900000 | 100000-150000 | 6 | EM | | [47] |
| Bromegrass mosaic virus | 4600000 | 20000 | ≈ 180 | F | RNA content 21.4%. Treatment with 1 M $CaCl_2$ yields sub-units with M.W. 40000. | [48] |

| Protein | M.W. | Polypeptide chain | | | Notes | Ref. |
|---|---|---|---|---|---|---|
| | | M.W. | Number | Method [a] | | |
| Turnip yellow mosaic virus | 5000000 | 21300 | ≈ 150 | D/M, EA, EM, F, X | RNA content 37%. Polypeptide chains are probably identical. | [49] |
| Poliomyelitis virus (Sabin type II) | 5500000 | 27000 | ≈ 130 | D/M | RNA content 36%. | [50] |
| Alfalfa mosaic virus | 7400000 | ≈36000 | ≈ 160 | D/M | RNA content 21%. | [51] |
| Potato X virus | 35000000 | 52000 | ≈ 650 | D/M | RNA content 5%. End-group analysis indicates that the polypeptide chains are identical. | [52] |
| Tobacco mosaic virus | 39400000 | 17530 | 2130 | D/M, EA, F, X, S | RNA content 5%. Dissociation into identical polypeptide chains and RNA is reversible. Sub-units of different sizes occur as dissociation products. | [53] |

The structures of the respiratory proteins of mammals, *i.e.* hemoglobin and myoglobin, are the best known of all protein structures. Not only has the amino-acid sequence been completely elucidated [57–59], but the spatial structure has also been analysed by X-ray methods [10, 11, 60] (cf. Fig. 1).

The adult human hemoglobin (HB–A, molecular weight 64458) consists of two pairs of identical polypeptide chains, *i.e.* four chains in all [57–60]. The two types of chain are denoted by $\alpha$ and $\beta$, so that HB–A has the formula $\alpha_2\beta_2$. In addition to HB–A, a second hemoglobin (HB–$A_2$:$\alpha_2\delta_2$) is present at a low concentration, while fetal blood contains HB–F ($\alpha_2\gamma_2$). The $\alpha$ chains of these types are all identical; the $\gamma$ and $\delta$ chains differ from the $\beta$ chain, but all four polypeptide chains exhibit numerous coincidences, and they all have the same or similar chain lengths [61].

Each polypeptide chain carries a heme group, which is the point of attachment of oxygen. The binding of oxygen affects the interaction between the polypeptide chains [11, 63], which can be seen from the fact that attachment of the first molecule of oxygen facilitates the uptake of the other three (see Section V.4) [63a].

## 2. Apoferritin from Horse Spleen

Ferritin is an iron-storage protein, and consists of two components: an iron(III) hydroxide-phosphate complex forms the nucleus, and this is surrounded by a protein shell, the apoferritin, which can be isolated and crystallized.

X-ray analysis gives a molecular weight of 480000 for the compact molecule [64]. The native apoferritin molecule has a very stable structure, although the polypeptide chains are only linked by non-covalent bonds. The protein ($s^0_{20,w}$ = 17.6 S) dissociates in the presence of dodecyl sulfate (DS). At a weight ratio of protein: DS = 2:1, the protein dissociates completely into components the sedimentation coefficient of which is 2.5 S. These components are protein-DS complexes (33% DS) with a molecular weight between 38000 and 41000, the protein component having a molecular weight between 25000 and 27000; thus the reaction with DS causes apoferritin to dissociate into about 20 identical polypeptide chains [65]. Reaction with succinic anhydride yields the same protein components (molecular weight 25000) [66].

Fingerprint analysis indicates about 20 peptides (apart from a few trace peptides), only one of which contains tryptophan. This corresponds to 20 identical polypeptide chains having a molecular weight of 24000 each [67]. There are no free N-terminal groups, but 20 acetyl groups can be detected per molecule of apoferritin. Carboxypeptidase B splits off about 20 C-terminal arginyl residues per molecule of apoferritin [66].

According to the results of X-ray analysis, the molecule forms a spherical shell with an outside radius of 61 Å and a ratio of inside radius: outside radius of 0.6 [64, 67a]. The shell has the form of a pentagonal dodecahedron with the 20 polypeptide chains (which, according to electron-microscope studies [68], are roughly spherical) situated at its twenty vertices [64] (Fig. 4).

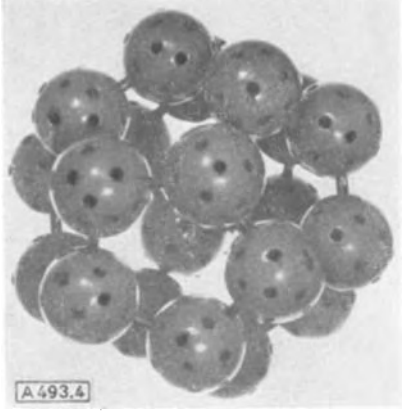

Fig. 4. Model of the quaternary structure of apoferritin, as suggested by *Harrison* [64]: 20 polypeptide chains at the corners of a pentagonal dodecahedron. (Each sphere represents a polypeptide chain; in the real molecule, the chains are in contact with one another and are not perfectly spherical).

## 3. $\gamma$-Globulins

The $\gamma$-globulins, the carriers of the antibody activity, have sedimentation coefficients of about 7 S and molecular weights of about 150000 [69, 70]. The molecules can be described as elongated prisms with an elliptical cross section [71] (see Fig. 5). Investigations on $\gamma$-globulins from various sources [69, 70, 72–75] indicate that they

Perutz*, Nature (London) *199*, 633 (1963); *M. F. Perutz* and *L. Mazzarella*, Nature (London) *199*, 639 (1963); *R. Benesch* and *R. E. Benesch*, Nature (London) *202*, 773 (1964).

[63a] Recent results [*R. E. Benesch, R. Benesch*, and *G. Macduff*, Proc. nat. Acad. Sci. U.S.A. *54*, 535 (1965)] suggest that the oxygenation of hemoglobin involves a reaction in which an oxygenated $\alpha\beta$ sub-unit ($\alpha^0\beta^0$) exchanges with deoxygenated $\alpha_2\beta_2$ to form a mixed molecule with high oxygen affinity:

$$\begin{matrix}\alpha\beta\\ \beta\alpha\end{matrix} + \alpha^0\beta^0 \rightleftharpoons \begin{matrix}\alpha^0\beta^0\\ \beta\alpha\end{matrix} + \alpha\beta$$

have the formula $H_2L_2$, *i.e.* they consist of two heavy chains (H, molecular weight about 50000) and two light chains (L, molecular weight about 25000). The two H chains are linked by a disulfide bridge [76], and each of the H chains is attached to an L chain by a disulfide bridge [73, 77, 78]. After reduction of these bridges, H and L chains can be separated by chromatography. Further disulfide bridges are present within the individual chains. In acidic solutions, reduction of the particularly reactive disulfide bridge between the two H chains yields the sub-unit HL [75].

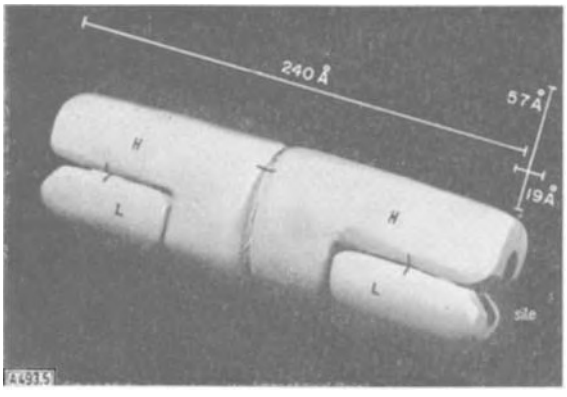

Fig. 5. Model of the 7-S antibody molecule after *Edelman* and *Gally* [74]. H: heavy polypeptide chain; L: light polypeptide chain; Site: one of the two antigen-binding sites. The lines on the model represent the disulfide bridges between the polypeptide chains. The molecular dimensions correspond to the results of low-angle X-ray diffraction measurements [71].

The antibody molecule has two sites at which antigens can become attached [79]; electron-microscope studies [80] indicate that these are situated at the ends of the cylindrical molecule ("site" in Fig. 5). The dissociation into the HL sub-units can be reversed, with recovery of immunological activity [81], although the disulfide bridge seems not to be re-formed. H and L chains obtained by mild reduction and chromatographic separation also re-associate to form the molecule $H_2L_2$, the chains again being held together only by non-covalent bonds [82], and the biological activity being restored. If the polypeptide chains in the renatured molecule are in fact held togehter by non-covalent bonds alone [81, 82], the antibody activity cannot be associated with the presence of disulfide bridges between the chains. Hybrid γ-globulin molecules [84] can be obtained *in vitro* by dissociation and association [81–83].

## 4. Aldolase from Rabbit Skeletal Muscle [85]

Aldolase catalyses the conversion of fructose 1,6-diphosphate into dihydroxyacetone phosphate and glyceraldehyde 3-phosphate. The enzyme molecule is almost spherical, and has a relatively high helical content; its molecular weight is 142000 [88]. Below pH 3, the sedimentation coefficient decreases from 7.9 S (native) to 2.0 S; the aldolase molecule dissociates into three sub-units of equal size, with extensive unfolding and loss of helical structure [88, 89]. This dissociation also takes place in the presence of dodecyl sulfate [88], urea [88], or guanidine hydrochloride [90], as well as on reaction with succinic anhydride [90].

Aldolase that has been treated with acid or urea regains up to 100% of its original activity on dialysis or on rapid dilution with buffer [88, 89, 91]. The hydrodynamic, optical, immunological, and chemical properties of the renatured molecule are identical with those of the native molecule. The association probably proceeds in two steps. Three sub-units combine relatively rapidly to form a complex which is still largely unfolded; the transformation of this into the native compact molecule is accompanied by the return of the enzymatic activity [89]. Kinetic analysis of the re-activation indicates that the first step is not rate-determining [88, 89].

When the pH is increased to 12.6, the aldolase dissociates into six fragments of equal size; these are probably the polypeptide chains. Re-activation after this dissociation has so far not been observed [92]. Equation (2) shows the dissociation scheme of aldolase (A) [92].

$$\underset{(142000)}{\text{Native A}} \rightleftharpoons \underset{(142000)}{\text{unfolded A}} \rightleftharpoons \underset{(3\times 47000)}{\text{sub-units}} \overset{?}{\rightleftharpoons} \underset{(6\times 23500)}{\text{polypeptide chains}}$$

Recent analysis of the N-terminal groups indicates 4 moles of proline per mole of aldolase. This value is regarded as a minimum, and supports the belief that the molecule contains more than three polypeptide chains [90, 92a]. Carboxypeptidase splits off three C-terminal tyrosine residues [93]. The

[84] Regarding the identity of the polypeptide chains and the problem of explaining the specificity of the antibodies obtained by combination of various types of H and L polypeptide chains, see [74].

[85] It was observed as early as the 1930's that aldolase is composed of sub-units [86, 87]. *Gralén* [87] obtained a value of 72000 for the molecular weight in urea, and assumed that the molecule had dissociated into two sub-units (instead of three, see text). *Gralén* also observed the marked decrease in the sedimentation coefficient in alkaline solutions. As far as we know aldolase (formerly known as myogen) is the first enzyme for which the quaternary structure was established.

[92] *L. F. Hass* and *M. S. Lewis*, Biochemistry *2*, 1368 (1963).

[92a] According to a recent investigation of the C-terminal and N-terminal groups [*J. A. Winstead* and *F. Wold*, J. biol. Chemistry *239*, 4212 (1964)], the aldolase molecule consists of only three polypeptide chains having a molecular weight of 47000, two of which may be identical. The components with a molecular weight of 23500 [92] could result from the cleavage of an alkali-labile bond within a polypeptide chain.

[93] *A. Kowalsky* and *P. D. Boyer*, J. biol. Chemistry *235*, 604 (1960).

question of whether all the polypeptide chains are identical is of special interest since aldolase consists of six polypeptide chains, but contains only one active center [91,94].

## 5. Lactic Dehydrogenase and the Isoenzyme Problem

Lactic dehydrogenases (LDH) are found in all animal tissues. They catalyse the reversible pyridine nucleotide-dependent oxidation of lactic acid to pyruvic acid. The enzymes have molecular weights of about 130000 [95–98]. It was observed in 1952 that ox heart LDH consists of two enzymatically active components [95]. *Wieland* and *Pfleiderer* subsequently showed [99] that various tissues can contain up to five LDH's, and that it is very rare for one to occur alone. These LDH's can be separated by electrophoresis, and they are found to differ in their amino-acid composition, their sensitivity to heat, and their enzymatic and immunological properties [99–108,110d].

*Appella* and *Markert* showed that in the presence of 5 M guanidine hydrochloride, LDH dissociates into four sub-units, each of which has a molecular weight of 34000 [96]. Every species possesses two LDH's which consist of four identical sub-units [96,100,103,105,106,109]. One of these LDH's occurs mainly in the muscle (M type), the other mainly in the heart (H type); the sub-units are accordingly denoted by M and H, so that the formulae of these LDH's are $M_4$ and $H_4$. Combination of M and H sub-units gives (*in vivo* and *in vitro*) a maximum of five LDH isoenzymes: $H_4$, $H_3M$, $H_2M_2$,$HM_3$, and $M_4$. This is confirmed by the fingerprint analysis [102,109,110,110a].

The dissociation into sub-units can be largely reversed, with re-activation of the enzyme [110c]. Moreover, hybridization between lactic dehydrogenases from various sources, *e.g.* between $H_4$-LDH from cattle and $H_4$-LDH from hens or $M_4$-LDH from frogs, can be carried out *in vitro*. On the other hand, hybridization between frog $H_4$-LDH and frog $M_4$-LDH has not been possible. No information is available which would indicate that the sub-units by themselves are enzymatically active. The interactions between the four sub-units seem to be essential for enzymatic activity.

The enzymatic and immunological properties of the hybrid LDH molecules $H_3M$, $H_2M_2$, and $HM_3$ are roughly equivalent to an additive combination of the contributions from the H and M sub-units [102–104,109,110d]. For example, substrate inhibition is strong in the case of $H_4$-LDH and weak in the case of $M_4$-LDH; for the hybrid types it lies somewhere between these extremes [101–103,107]. In agreement therewith, the H type favors aerobic oxidation of pyruvic acid and occurs mainly in "aerobic" tissue (heart muscle). The M type, on the other hand, favors the anaerobic pyridine nucleotide-dependent formation of lactic acid, and occurs mainly in "anaerobic" tissue (skeletal muscle) [102,103,107,112].

The LDH isoenzyme pattern changes during ontogeny [102,103,112–114]. In the embryonic state, H or M type LDH is present exclusively or mainly depending on the species ("embryonic LDH"). With increasing cell differentiation an isoenzyme pattern is formed which corresponds to the alterations in metabolism of the differentiated cell (Fig. 6). It is assumed that the synthesis of H and M sub-units is controlled by different genes [102].

## 6. Glycogen Phosphorylase from Rabbit Skeletal Muscle

Glycogen phosphorylase occurs in two forms, a and b, which can be interconverted by the action of enzymes: thus in the presence of a phosphorylase b-kinase, the b enzyme takes up four moles of phosphate from ATP to form the a enzyme, which is reconverted into the b enzyme by a phosphorylase a-phosphatase [115].

Sedimentation and diffusion measurements indicate the molecular weight of the a enzyme to be 495000 and that

[110] It is not yet known whether this also applies to rat liver LDH. This enzyme has a molecular weight of 126000, and contains only two coenzyme-binding sites [111]. Results obtained with the other dehydrogenases (Section IV,10) suggest that this LDH consists of only two polypeptide chains having a molecular weight of 63000 each.

[110a] Studies of the hydrodynamic properties after denaturation [27,97] and of the N-terminal groups, as well as fingerprint analysis [110b] suggest that LDH consists of a total of eight polypeptide chains, each sub-unit containing two.

of the b enzyme 242000. The conversion of the b enzyme into the a enzyme thus involves dimerization as well as phosphorylation [116].

When treated with *p*-chloromercuribenzoate, both enzymes dissociate into sub-units having a molecular weight of about 135000. The a enzyme contains four of these sub-units, and the b enzyme two [117, 118]. In agreement with this structure, one molecule of the a enzyme binds four molecules of AMP and contains four molecules of pyridoxal 5'-phosphate, whereas the b enzyme binds two molecules of AMP and contains two molecules of pyridoxal 5'-phosphate [115, 119–121]. In the formation of the a enzyme from b enzyme, the four additional phosphate groups (*i.e.* one per sub-unit) are bound by esterification of seryl groups [115]. The pyridoxal phosphate, which probably is covalently bound to lysyl groups, is probably responsible for the conformation of the protein molecule, but is not involved in the enzyme reaction itself [122]. Its removal from the molecule leads to reversible inactivation, accompanied by a change in the conformation of the protein: the a enzyme is largely dissociated into sub-units. The cleavage by *p*-chloromercuribenzoate is also reversible, and the original associated state, together with the enzyme activity, can be restored by treatment with cysteine [117].

At high salt concentrations, phosphorylase a dissociates reversibly to form "half-molecules", which have the same molecular weight as the b enzyme [123, 123a]. Since phosphorylase b is built up from two sub-units, it is understandable that three isoenzymes have been found [124]. The relatively high molecular weight of the sub-units (135000) suggests that they may contain more than one polypeptide chain.

## 7. β-Galactosidase from E. coli

β-Galactosidase from *E. coli* catalyses the hydrolysis of lactose to galactose and glucose. The molecular weight of the protein is about 520000, and its sedimentation coefficient is about 16 S [125–128]. The hydrodynamic data indicate that the molecule can be described as an oblate ellipsoid of revolution [125] with an axial ratio of about 3, assuming 30% hydration. The length and height of the molecule are about 150 and 50 Å respectively [127]. The molecular weight remains unchanged even at extremely high dilutions [129], and is very probably also characteristic of the enzymatically active protein *in vivo* [130, 131].

Urea or guanidine hydrochloride cause reversbile [128] dissociation of the β-galactosidase molecule into four sub-units, which appear from sedimentation and diffusion measurements to be equal in size [132] (molecular weight about 130000). It is therefore possible to obtain hybrids of "light" enzyme ($^{12}C$, $^{14}N$) and "heavy" enzyme ($^{13}C$, $^{15}N$), and to compare the densities. The results again show that the β-galactosidase molecule consists of four sub-units of equal size [128]. Electron-microscope studies [133, 134] indicate that the four sub-units are arranged at the corners of a square (Fig. 7). The dimensions of the molecule are about 120 Å and 70 Å [133]. These values and the molecular weight (500000) calculated from them [133, 134] agree closely with the values obtained from hydrodynamic data.

On oxidation with performic acid, the molecular weight decreases to about 35000 [132, 135]. The β-galactosidase

molecule also dissociates into the polypeptide chains (molecular weight about 35000) in a mixture of formic and acetic acids [136], showing that each sub-unit of β-galactosidase consists of three or four polypeptide chains, which are not joined by disulfide bridges. This dissociation, too, is at least partly reversible.

Fingerprint analysis gave values of about 40000 [137] and 60000 [137, 138] for the "molecular weight" of the polypeptide chain. If the higher value is correct, it must be assumed, from the discrepancy between this and the much lower value obtained by hydrodynamic methods, that not all polypeptide chains making up the sub-unit are identical [136, 138a].

The β-galactosidase molecule contains four active centers [139], which can be assigned to the four sub-units. However, the number of polypeptide chains is greater than the number of active centers [140].

Enzymatically inactive β-galactosidase proteins have been isolated from some *E. coli* mutants [142]. The molecular weights of these proteins are generally lower than that of the enzymatically active β-galactosidase. Mutation thus appears to have deprived the protein of the ability to associate "correctly". It was possible in some cases to obtain enzymatically active β-galactosidase by complementation between two different inactive samples [142, 143]; the active enzyme ("complementation enzyme") obtained in this way, like the normal enzyme, has a sedimentation coefficient of 16 S.

### 8. Glutamic Dehydrogenase from Beef Liver

Glutamic dehydrogenase catalyses the reversible oxidative deamination of glutamic acid to α-ketoglutaric acid. The spontaneous reversible dissociation of the protein on dilution explains its anomalous sedimentation behavior [144]. The long, associated particle, which has a molecular weight of $2\times10^6$ [29, 145], exists in an association-dissociation equilibrium with its sub-units, the molecular weights of which are $10^6$, $5\times10^5$, and $2.5\times10^5$, and all of which are enzymatically active [29, 146]. Nucleotides, phenanthroline, inorganic ions, steroids, thyroxine, sulfonylurea derivatives, or even the coenzyme can displace the equilibrium in either direction, and act as inhibitors or activators of the enzyme reaction [29, 147–150]. The dissociation leads to an increase in the binding capacity for the coenzyme [151, 153, 155].

In the liver glutamate dehydrogenase occurs almost entirely within the mitochondria. Here the enzyme concentration is very high (between 2 and 9 mg/ml), *i.e.* in a range in which the association-dissociation equilibrium and the influence on it of nucleotides, coenzymes, and the other compounds mentioned are significant [29, 153].

Glutamic dehydrogenase has no absolute substrate specificity for glutamic acid, but can react (although much more slowly) with other amino acids. The oxidation of alanine has been particularly closely studied in connection with quaternary structure [150]: All compounds or experimental conditions that favor spontaneous dissociation of the enzyme into sub-units activate the oxidation of alanine and inhibit the oxidation of glutamic acid. On the other hand, all compounds that favor spontaneous association activate the oxidation of glutamic acid and inhibit that of alanine. Contrary to earlier views [147, 150], the relationship between the effects on quaternary structure and enzyme activity is due to the fact that the compounds react with the functional groups of the enzyme molecule and/or alter the conformation of the latter. This reaction affects both the association-dissociation equilibrium and the enzymatic catalysis, although there is no direct connection between particle size and enzyme activity: both phenomena simply result from the same cause [29, 152–154].

[139] *M. Cohn*, Bacteriol. Rev. *21*, 140 (1957).

[140] The size of the structural gene (= z-gene) of the *E. coli* chromosome responsible for the synthesis of β-galactosidase corresponds to a "polypeptide chain equivalent" of 135000 [141]. Since the polypeptide chains of the β-galactosidase molecule are not more than one-third of this size, the z-gene cannot be the polypeptide chain equivalent. It must therefore be assumed that the z-gene is a genetically functional unit, which also corresponds to a certain unit in the protein molecule. This could be the identical sub-units having a molecular weight of about 130000. The z-gene would then consist of several gene segments corresponding to the polypeptide chains, which consequently should not be identical [127, 138a].

If a protein dissociates spontaneously into its sub-units, or if the dissociation is brought about by conditions under which there is little change in conformation, it is possible to obtain information about the geometrical arrangement of the sub-units by means of viscosity measurements. A decrease in the intrinsic viscosity indicates a decrease in geometrical anisotropy and *vice versa*. This method is successful only for non-globular proteins, since the change in viscosity on dissociation of globular proteins is too small [153].

The sub-unit of glutamic dehydrogenase has a lower intrinsic viscosity than the original molecule, and is only about half as long as the latter [29, 145, 153]. If we regard the glutamic dehydrogenase molecule as an ellipsoid of revolution, this means that the dissociation involves a transverse cleavage. In the associated state, therefore, the sub-units must be held together over relatively small areas, and hence by relatively few bonds. Perhaps this can explain the spontaneous dissociation (cf. Fig. 8).

In the presence of urea or long-chain alkyl sulfates, or at extreme pH values, the sub-unit having a molecular weight of 250000 dissociates into polypeptide chains, with loss of the native conformation and enzymatic activity. The polypeptide chains obtained in this way have a molecular weight of about 50000, and end group analysis indicates that they are all identical [29, 149, 156]. It has recently been shown that this dissociation is also largely reversible, again with re-activation [157] (cf. Fig. 8).

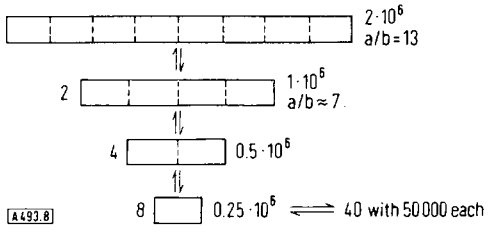

Fig. 8. Diagrammatic representation of the association-dissociation equilibrium of glutamic dehydrogenase from beef liver (after *Sund*[29]). a/b = axial ratio.

## 9. Multienzyme Complexes

Multienzyme complexes, in which the individual enzymes are held together by non-covalent bonds, catalyse successive steps of a reaction sequence. In the course of this process, the substrate and the intermediate products never leave the enzyme complex, but are "passed on" from one reaction site to the next. The occurrence of such complexes *in vivo* is probably relatively frequent. Whether they can be isolated depends on their stability and on the isolation conditions. The most extensively studied of these complexes are the fatty acid synthetase complex from yeast and the pyruvic dehydrogenase complex from *E. coli*.

According to *Lynen et al.* [158, 159], the fatty acid synthetase catalyses the synthesis of fatty acids in seven steps from acetyl-CoA and malonyl-CoA. This multienzyme complex has a molecular weight of $2.3\times10^6$, and consists of seven different sub-units (molecular weight 110000), each of which occurs three times. Electron-microscope studies show that the fatty acid synthetase complex is a hollow oval particle surrounded by an equatorial ring (Fig. 9). The longitudinal diameter of the particles is about 250 Å, and the transverse diameter about 210 Å [160].

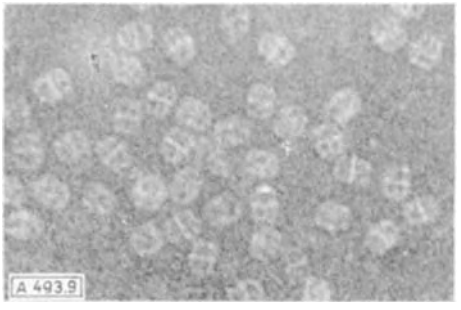

Fig. 9. Fatty acid synthetase from yeast (after *Hagen* and *Hofschneider* [160]). Magnification 200000.

The pyruvic dehydrogenase complex from *E. coli* catalyses the decarboxylation of pyruvic acid to acetyl-CoA, which involves at least three steps. According to *Reed et al.* [161, 162], this multienzyme complex (molecular weight $4.8\times10^6$) can be broken down into three enzymatically active components: pyruvate decarboxylase (molecular weight 183000), lipoic reductase-transacetylase (molecular weight $1.6\times10^6$) and dihydrolipoic dehydrogenase (molecular weight 112000). Lipoic reductase-transacetylase consists of 64 polypeptide chains (molecular weight about 27000), and is present only once in the multienzyme complex. Decarboxylase and dihydrolipoic dehydrogenase, on the other hand, are presen sixteen times and eight times, respectively. Dihydrolipoic dehydrogenase contains two polypeptide chains. The quaternary structure of the decarboxylase has not yet been investigated. Electron-microscope studies indicate that the pyruvic dehydrogenase complex has the form of a decahedron with a diameter of 300 to 400 Å and a height of 200 to 250 Å. The centrally located lipoic reductase-transacetylase is surrounded by the decarboxylase and the dihydrolipoic dehydrogenase both of which are arranged in the form of superimposed octagonal rings [161].

## 10. Other Pyridine Nucleotide-Dependent Dehydrogenases

The molecular weights, coenzyme binding, and quaternary structures of the dehydrogenases studied so far are listed in Table 2. It can be seen from this table that the

Table 2. Molecular weight, quaternary structure, and coenzyme binding of pyridine nucleotide-dependent dehydrogenases.

| Dehydrogenase (= DH) | M.W. | Polypeptide chain | | Equivalent weight per binding site | n [b] | Ref. |
|---|---|---|---|---|---|---|
| | | M.W. | Method [a] | | | |
| Vitamin K reductase from beef liver | 52000 | ? | | 56000 | ?; 1 | [163] |
| Isocitric DH from pig heart | 61000–64000 | ? | | ≈30000 | ?; 2 | [164] |
| L-Glycerol 1-phosphate DH from rabbit skeletal muscle | 78000 | 40000 | D/M | 39000 | 2; 2 | [165–167] |
| Malic DH from pig heart | 70000–85000 | 51000 | EA | 35000–42000 [c] | ≈2; 2 | [166, 168, 169] |
| Alcohol DH from horse liver | 84000 | 42000 | S [d] | 42000 | 2; 2 | [172–174] |
| Dihydrolipoic DH from pig heart | 102000 | 50000 [e] | D/M, EA, F | 50000 | 2; 2 | [175] |
| Dihydrolipoic DH from *E. coli* or *Spinacia oleracea* | 102000–112000 | ? | | 56000 | ?; 2 | [176] |
| Glutathione reductase from yeast | 118000 | ? | | 56500 | ?; 2 | [177] |
| 3-Phosphoglyceraldehyde DH from pig or rabbit skeletal muscle | 137000–145000 | 36000–40000 [d,f] | D/M, F, EA, S | 35000–46000 | 4; 4 | [27, 166, 167, 178–181a] |
| 3-Phosphoglyceraldehyde DH from yeast | 122000–140000 | 38000–44000 [d,f] | D/M, F, EA, S | 37000–40000 | 4; 4 | [167, 180–185] |
| Lactic DH from chicken, beef, or pig heart [g] | 118000–140000 | 34000–37000 | D/M, F, S | 36000–39000 | 4; 4 | [27, 95–98, 102, 109, 110d, 166, 186–189a] |
| Lactic DH from rat liver | 126000 | ? | | 64000 | ?; 2 | [111, 188] |
| Alcohol DH from yeast | 150000 | 36000–37000 [d,h] | D/M, F, S | 30000–42000 | 4; 4 | [29, 166, 173, 174, 188, 190] |
| Glutamic DH from *Neurospora crassa* | 267000 | 28000 [h] | F | ? | 8–10; ? | [191, 192] |
| Glutamic DH from beef liver [i] | 2000000 | 50000 | D/M, EA, EM | 31000–49000 | 40; 40–60 | [29, 145, 149, 153, 155–157, 166, 193] |

[a] For abbreviations, see Table 1.
[b] n = M.W. of the DH per M.W. of the polypeptide chain or M.W. of the DH per equivalent weight.
[c] The equivalent weights of the enzymes from horse heart [169], rat liver [170], and beef heart [171] are between 34000 and 50000.
[d] The partial elucidation of the amino-acid sequence suggests that the polypeptide chains are identical.
[e] End-group and fingerprint analyses indicate that the two polypeptide chains, which may be linked by disulfide bridges, are identical.
[f] End-group analysis indicates that the polypeptide chains are identical.
[g] Cf. Section IV, 5.
[h] Fingerprint analysis indicates that the polypeptide chains are identical.
[i] Cf. Section IV, 8.

molecular weights of the polypeptide chains always are approximately the same as the equivalent weights of the coenzyme binding sites. Most of the dehydrogenases consist of polypeptide chains with molecular weights of 30000 to 50000. This is probably also true for dehydrogenases that have not yet been studied [153, 166, 193a].

In general, one "active center" is assigned to each coenzyme binding site. This raises the question of the smallest enzymatically active unit. It seems reasonable to assume that each polypeptide chain should be enzymatically active, provided that the single polypeptide chain possesses the same conformation as in the associated molecule. But this is obviously not the case. In the native state one can observe only the associated molecule; so far it was not possible to obtain single polypeptide chains in enzymatically active form. Therefore one can assume that only in the associated state is the number of non-covalent bonds high enough to stabilize that specific three-dimensional structure of the polypeptide chain which is essential for the catalytic activity. In principle there exists also the possibility that several polypeptide chains participate in one active center. In this case only the associated molecule can manifest enzymatic activity. It may be assumed, at least in some cases, that the active centers influence each other by allosteric transition (cf. Section V, 4).

## V. Discussion

### 1. Universal Occurrence

The molecular weights of proteins vary within wide limits, ranging from a few thousand to several million. Proteins with molecular weights higher than $10^5$ are complexes of several polypeptide chains, the molecular weights of the individual chains generally not exceeding 50000. In some cases (*e.g.* hemocyanine, lipovitellin), it appears that the dissociation products obtained so far are not the polypeptide chains (cf. Section IV and Table 1). For other proteins, such as phosphorylase, RNA-polymerase, or myosin (cf. Table 1 and Section IV, 6 as well as [194]), the methods for the study of quaternary structure have not yet been exhausted. Particularly one has to consider methods which can detect very stable non-covalent bonds or non-peptide covalent bonds. In collagen, for example, the sub-units consist of several polypeptide chains held togehter by carbohydrate components [194a]. As shown by the examples of serum albumin [195] and yeast enolase [196], some polypeptide chains have molecular weights as high as about 70000, but such cases are rare.

Quaternary structure is a general structural feature of proteins, since it can be detected in many protein types: in enzymes and respiratory proteins of low and of high molecular weight, in seed globulins, serum proteins, and structural proteins such as collagen [43, 194a, 197], or in the flagella of bacteria (*e.g.* flagellin from *Salmonella typhimurium* or *Bacillus pumilus* [198]), as well as in viruses, multienzyme complexes, and ribosomes (cf. Tables 1 and 2, Section IV,9, and [199]).

In most cases, and particularly in globular proteins, the polypeptide chains are held together exclusively by non-covalent bonds; linkage of the chains by disulfide bridges is less common [200]. The effects of denaturing agents indicate that the stability of the quaternary structure varies widely from one protein to another. Thus a denaturing agent may cause dissociation into the polypeptide chains in some proteins, while in others the dissociation may proceed only to the sub-unit stage, or may not occur at all.

As indicated by Equations (1a) to (1c) (cf. Introduction) protein molecules dissociate, either directly or in steps,

[194a] Collagen (molecular weight about 300000) consists of three sub-units, in general of two $\alpha_1$ sub-units and one $\alpha_2$ sub-unit. Each sub-unit contains at least four polypeptide chains which are joined by carbohydrate components through ester or ester-like bonds. The carbohydrate component was called collagenalose [43, 194b].

[200] Chymotrypsinogen is converted into chymotrypsin by specific hydrolysis of peptide linkages. This "activation" involves the conversion of the single polypeptide chain of chymotrypsinogen into the three polypeptide chains of chymotrypsin. These three polypeptide chains are linked by disulfide bridges [201]. It has also been suggested that insulin (two polypeptide chains) may be formed in a similar manner from a single-chain precursor [202]. Recently, however, evidence was obtained [*R. E. Humbel*, Proc. nat. Acad. Sci. U.S.A. *53*, 853 (1965)] that the two polypeptide chains of insulin are synthesized separately.

[202] *W. J. Dreyer* quoted in *M. Vaughan* and *D. Steinberg*, Advances Protein Chem. *14*, 115 (1959).

into polypeptide chains. The dissociation scheme represented by Equation (1c) is much less common than the other two schemes. First results indicate that the dissociation of the heterogeneous type of quaternary structure into the sub-units [Equation (1b)] proceeds symmetrically, *i.e.* the sub-units formed are identical.

In some enzymes, the number of polypeptide chains is equal to the number of active centers (cf. Section IV,10). In other cases (*e.g.* aldolase or β-galactosidase) the number of polypeptide chains is greater than the number of active centers (cf. Sections IV,4 and 7). It might be thought that the polypeptide chains are not all identical in these cases. However, there are also proteins, such as hemoglobin, or the isoenzymes of lactic dehydrogenase (cf. Section IV,1 and 5), in which the number of polypeptide chains is equal to the number of active centers, although not all the polypeptide chains are identical.

## 2. Spontaneous Formation of the Native Conformation

X-ray analysis shows that every protein molecule in the native state has a defined structure [203]. The question arises of whether this structure is determined by the amino-acid sequence or by special mechanisms. After the molecule has been dissociated into the polypeptide chains, generally with complete loss of the folded structure, it is often possible to restore both the native conformation and the original biological activity (cf. Section IV). The "correct" disulfide bridges between different parts of a "reduced" polypeptide chain can also be spontaneously re-formed in the presence of oxygen. However, recently discovered enzyme systems [204] catalyse the re-formation of the "correct" disulfide bridges in reduced ribonuclease. It is therefore possible that when disulfide bridges are involved, the formation of the native conformation *in vivo* is accelerated by an enzyme system.

Renaturation [20] and the estimated stabilization of the conformation by non-covalent bonds [21, 22] support the hypothesis [205–207] that the conformation of a protein molecule is simply a function of the sequence of amino acids in the polypeptide chains, *i.e.* the "structural information" is contained in the primary structure. However, it is not yet possible to predict the overall structure of a protein molecule from the amino-acid sequence.

## 3. Svedberg's Law of Multiples

Any discussion of quaternary structure must mention the pioneering work carried out by *Svedberg* in the 1920's [25, 208]. He was the first to show that proteins are macromolecules with a definite size. He also showed that the molecules of some proteins consist of smaller sub-units. From comparative investigations he concluded that the molecular weights of globular proteins are multiples of a "unit molecular weight" of 17500 ("*Svedberg*'s sub-unit"). His assumption that proteins with high molecular weights are not single polypeptide chains was found to be correct. We now know, however, that the molecular weights of the polypeptide chains vary over a wide range, and that there is no unit molecular weight.

## 4. Feedback and Allostery

The synthesis of the end product of a metabolic pathway may be controlled by inhibition of the first enzyme in the synthesis chain by the product itself when it reaches a certain concentration. In this case the substrate of the first enzyme is not structurally related to the end product. This control principle is known as end-product or feedback inhibition. To explain this phenomenon, *Monod, Changeux*, and *Jacob* introduced the concept of "allostery" [209]: An allosteric effector (*e.g.* a metabolite) becomes attached, not to the active center, but to the allosteric site of the enzyme. This is then thought to cause a change in conformation (allosteric transition), which affects the binding of the substrate to the active center, and hence also the rate of the enzymatic reaction. This change in conformation may even lead to dissociation or association. These ideas are not confined to enzymes, but can be extended to other proteins (*e.g.* hemoglobin).

The inhibition of aspartate transcarbamylase (reaction: carbamyl phosphate + aspartate → carbamyl aspartate) by the end product of the synthesis chain, *i.e.* cytidine triphosphate, is observed only with the associated enzyme molecule (molecular weight $3.1 \times 10^5$) [41]. On dissociation, it is possible to detect two different sub-units: the "regulatory" sub-unit and the "catalytic" one. The regulatory sub-unit (molecular weight about 30000) combines with the inhibitor, *i.e.* the cytidine triphosphate, and is enzymatically inactive. The "catalytic" sub-unit (molecular weight about 96000) is enzymatically active, does not combine with the inhibitor, and is therefore not inhibited by the latter. Since interaction between the sub-units is possible only in the associated enzyme molecule, the catalytic sub-unit, unlike the associated molecule, exhibits normal Michaelis kinetics even in the presence of the inhibitor. Homoserine dehydrogenase provides an example of the modification of quaternary structure by an end-product inhibitor [210].

If a protein contains several active centers and several polypeptide chains, the principle of allostery suggests that the active centers of regulatory proteins should influence one another by changes in conformation. Thus the attachment of one oxygen molecule to hemoglobin, which consists of four polypeptide chains, facilitates the attachment of the other three [11, 63a]. X-ray analysis shows that the attachment of oxygen is accompanied by a change in conformation. The

distances between the iron ions in the two β chains of hemoglobin in the presence and absence oxygen differ by about 7 Å [111]. The oxygen dissociation curve of "monomeric" myoglobin is therefore fundamentally different from that of the "tetrameric" hemoglobin [209].

## 5. Quaternary Structure and the Biosynthesis of Proteins

According to current views [211–213] the biosynthesis of proteins is controlled by a section of the DNA, namely the structural gene. The information contained here is transported by a "mobile template" (messenger RNA) to the ribosomes, where the biosynthesis of the protein takes place. In the ribosomes the amino-acid residues attached to transfer RNA are arranged in the correct order from the information of the messenger RNA.

A point mutation in the structural gene can lead to the replacement of an amino-acid unit by another in the polypeptide chain. This is shown particularly impressively in the case of the hemoglobins. A change of only one amino-acid unit (replacement of glutamic acid by valine) gives sickle-cell hemoglobin, the modified physicochemical properties of which lead to a hemoglobinopathy [58]. Mutation can also result in a change in quaternary structure, as in β-galactosidase (cf. Section IV,7).

In some cases, active enzymes with the native quaternary structure (complementation enzymes) can be obtained *in vivo* and *in vitro* by hybridization of different inactive enzyme proteins resulting from point mutations (*e.g.* β-galactosidase [142, 143] and glutamic dehydrogenase [192]. It is very likely that the genetic phenomenon of interallelic complementation can be explained on the basis of quaternary structure, and that it does not occur in enzymes consisting of a single chain [214].

The quaternary structure and its changes are biologically important, *e.g.* in the control of enzyme activities. Metabolic products can control their own biosynthesis by allosteric transition. Where isoenzymes exist, they can be adapted to the metabolism by modification of their composition (cf. Section IV,5 and 6). A high biological activity can be achieved with no increase in osmotic pressure by the fitting together of sub-units [214a].

The fact that the native conformation of a protein molecule forms spontaneously from the polypeptide chains is in agreement with current views on the biosynthesis of proteins [215]. It also explains the universal importance of quaternary structure: this principle permits the synthesis of macromolecular protein molecules from a relatively small amount of genetic information if only the complexes formed by association are biologically active. This economy principle is particularly obvious for molecules with high molecular weights consisting of identical polypeptide chains, *e.g.* virus-sheath proteins (the sheath protein of tobacco mosaic virus has a molecular weight of $37\times10^6$, and consists of 2130 identical polypeptide chains) and structural proteins. Apoferritin (cf. Section IV,2) and glutamic dehydrogenase from *Neurospora crassa* [192] also consist of identical polypeptide chains. A simple calculation shows that with the aid of a triplet code, *ca.* 600 pairs of bases in DNA store the information for the biosynthesis of the apoferritin polypeptide chain, which consists of about 200 amino acids (molecular weight 24000). If, on the other hand, the apoferritin molecule would consist of a single polypeptide chain, then 20 times this number of base pairs would be required. The same is true of the messenger RNA. The economy principle also applies to proteins that, while not consisting of identical polypeptide chains, do contain identical sub-units.

[215] The size of the gene as a "functional" unit can be estimated by various genetic methods. The values for the molecular weight of the polypeptide chain equivalent range from about 10000 to more than 100000 [216]. Since a gene may be the functional unit for several polypeptide chains at the DNA level, the polypeptide chain equivalent (particularly for high values) often corresponds to several polypeptide chains (cf. [140]). This agrees with the discussion in Section V,1.

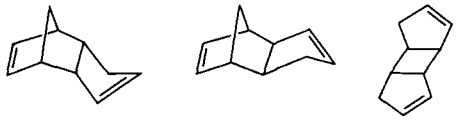
## Low-Temperature Photolysis of Cyclopentadiene [1]

By Dr. E. H. Gold and Prof. Dr. D. Ginsburg
Department of Chemistry,
Israel Institute of Technology, Haifa (Israel)

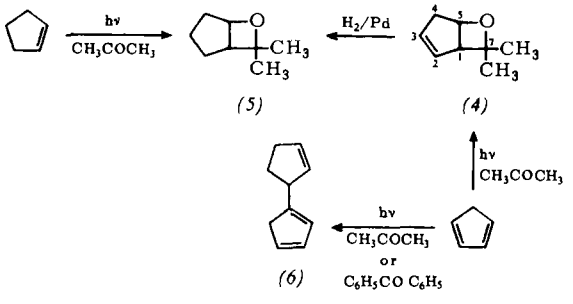
*Dedicated to Professor K. Freudenberg on his 80th birthday*

The photolysis of cyclopentadiene at *ca.* −10 °C in the presence of ketonic sensitizers is reported [2] to afford the products *(1)*–*(3)* in equal proportions. We found that photolysis at −78 °C with either acetone or benzophenone as sensitizer [3] yields in addition to *(1)*–*(3)*, the compounds *(4)* and *(6)*, and various polymers of cyclopentadiene.



*(1)* *(2)* *(3)*

Irradiation [3b] of 30 g of a mixture consisting of cyclopentadiene plus 10 % by weight of acetone under *Hammond*'s conditions [2a] (*ca.* −10 °C, 2 h) yields the compounds *(1)*–*(4)* and *(6)* in a weight ratio of [*(1)* + *(2)* + *(3)*]:*(4)*:*(6)* = 11:11:1, whereas at *ca.* −78 °C [3] the ratio is 3:14:1. On irradiation of a 1:1 mixture of cyclopentadiene and acetone at *ca.* −78 °C, the product ratio is 2.4:8.5:1.



A temperature effect is also observed on photolysis [3a] of cyclopentene/acetone (1:1 w/w): at −78 °C the oxetane *(5)* is formed in 28 % yield [4], whereas the yield is only 16 % at room temperature [3a, 5].

When 35 g of cyclopentadiene is irradiated [3b] with 5 g of benzophenone for 2.5 h at *ca.* −78 °C, no oxetane *(4)* is formed, and the product ratio is [*(1)* + *(2)* + *(3)*]:*(6)* = 2:1 (*ca.* 13 % overall reaction). This ratio increases upon further irradiation with concurrent polymer formation. That these polymers are formed from *(6)* is also shown by the fact that the ratio of olefinic to aliphatic hydrogens (NMR) is 1:2 for both types of compounds. At *ca.* −10 °C, the product ratio [*(1)* + *(2)* + *(3)*]:*(6)* = 11.5:1 in good agreement with the results of *Hammond*, who obtained 130 g of the mixture *(1)*–*(3)* from 140 g of cyclopentadiene.

Neither acetone nor benzophenone undergo pinacol formation under these conditions.

The structures of the products *(4)*–*(6)* follow from their ultraviolet, infrared, and NMR spectra:

*(4)*: b.p. 38 °C/17 mm; IR: 955 $cm^{-1}$; NMR: τ = 4.06 (m, H–2), 4.30 (m, H–3), 4.99 (m, H–5), 6.81 (m, H–1), 7.63 (m, H–4), 8.53 (s, $CH_3$), 8.94 (s, $CH_3$), relative areas: 1.0:1.0:1.0:1.0:2.1:3.0:2.9. – The fact that the chemical shift of the signal of H–5 in oxetane *(5)* is the same as in *(4)* whereas the signal of H–1 in oxetane *(5)* is shifted upfield relative to *(4)* is in accord with the double bond in *(4)* being between C–2 and C–3. This is the structure to be expected according to the Büchi mechanism [6].

*(5)*: IR: 961 $cm^{-1}$; NMR: τ = 5.05 (q, H–5.H–1, H–2), 7.42 (q, H–3), *ca.* 8.2 (m, H–4), 8.61 (s, $CH_3$), 8.93 (s, $CH_3$), relative areas: 0.96:0.96:12.1.

*(6)*: UV: $\lambda_{max}$ = 248 mμ (ε = 2730) in ethanol; NMR: τ = 3.63–4.37 (m, olefinic H,) 6.3 (m, allylic tert. H), 7.18 (m, cyclopentadienyl H), 7.5–8.6 (m, aliphatic H), relative areas: 4.8:0.95:2.2:4.0. Hydrogenation of *(6)* over Pt (3 moles of $H_2$) affords only bicyclopentyl. With tetracyanoethylene, *(6)* forms only one adduct (yield 70–80 %), the NMR spectrum of which shows four olefinic and two tertiary allylic hydrogen atoms.

## Bis(2,5-di-t-butylphenyl)methyl, a Non-associating Diarylmethyl

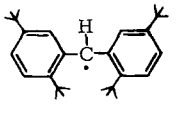
By Prof. Dr. W. Theilacker and Dipl.-Chem. F. Koch

Institut für Organische Chemie
der Technischen Hochschule Hannover (Germany)

*Dedicated to Professor K. Freudenberg on his 80th birthday*

Whereas, unlike hexaphenylethane, 1,1,2,2-tetraphenylethane does not dissociate in solution into free radicals, such dissociation does occur at elevated temperature for 1,1,2,2-tetraphenylethanes that carry methyl groups at all *ortho*-positions [1], and at room temperature 1,1,2,2-tetra-(*o*-t-butylphenyl)ethane dissociates into radicals to about the same extent as hexaphenylethane [2]. Considerable dissociation is shown also by 1,1,2,2-tetrakis(2,6-diethylphenyl)ethane [3], and 1,1,2,2-tetrakis(2,6-diisopropylphenyl)ethane appears to be fully dissociated into radicals [3], which however are stable only at low temperature.

We have now found that, in distinction to 1,1,2,2-tetra-(*o*-t-butylphenyl)ethane, 1,1,2,2-tetrakis(2,5-di-t-butylphenyl)ethane as a 6 % solution in benzene is completely dissociated at room temperature into the deep yellow bis(2,5-di-t-butylphenyl)methyl *(1)*. Whereas 27 h after preparation from the diarylmethyl chloride and thallium amalgam only about 70 %



*(1)*
⟩ = tert. Butyl

of radicals is found with the magnetic balance (35 % after 150 h), this can be traced to disproportionation: if one extrapolates to half the time of preparation, 100 % of radicals is found. That complete dissociation occurs is confirmed by the fact that increase in temperature causes no increase but rather an accelerated decrease in radical content.

It is surprising that a t-butyl group in position 5 reinforces the effect of a 2-t-butyl group to such an extent that no radical association then takes places. It seems, therefore, that the steric effect plays a notable role in the dissociation of tetraarylethanes, as it does in that of hexaarylethanes.

The ESR spectrum of the radical *(1)* shows a splitting due to the proton on the central carbon atom into two line groups with a separation of 15.2 gauss.

## Ammonothermal Synthesis of Magnesium and Beryllium Amides

By Prof. Dr. R. Juza and Dipl.-Chem. H. Jacobs

Institut für Anorganische Chemie
der Universität Kiel (Germany)

*Dedicated to Professor Karl Freudenberg on the occasion of his 80th birthday*

The preparation of metal amides from a metal and liquid ammonia at room temperature or gaseous ammonia at 1 atm and higher temperatures has its limitations. The reaction is successful with barium, strontium, and calcium, but with magnesium no amide is obtained at higher temperatures, and on using liquid ammonia at room temperature we obtained only small quantities of amorphous (to X-rays) magnesium amide after 1.5 years[1]. For preparative purposes we are therefore now using liquid ammonia up to its critical point (132.5 °C, 111.5 atm), and ammonia pressures up to 4000 atm in the supercritical region. We have developed autoclaves made from "Vacumelt ATS 115" in which the closures also can be heated. The reagents are placed in small silver tubes. The pressure in the autoclave is calculated from the specific volume of ammonia.

$Mg(NH_2)_2$ was obtained quantitatively at 250 °C and 2500 atm in 40 hours as a finely crystalline material. On addition of $NaN_3$ (which forms $NaNH_2$) at 300 to 350 °C we obtained products suitable for X-ray single-crystal investigations. $Be(NH_2)_2$, which is not formed from $BeI_2$[2] or from $Be(CH_3)_2$[3] and ammonia at room temperature, was obtained in well-crystallized form from the metal at 360 °C and 2500 atm in five days.

We have also obtained imides and nitrides by this method. For instance, reaction of beryllium with ammonia at 400 °C and 200 atm for about a week gives pure cubic $Be_3N_2$, whereas with an ammonia stream at 1000 °C this preparation succeeds only on repeated heating and pulverization.

The study of metal amides is often complicated by the difficulty that the materials are formed only in amorphous or poorly crystalline form. Such difficulties can often be overcome by use of the procedure described above, which is patterned on hydrothermal synthesis. For instance, amorphous $Zn(NH_2)_2$, obtained from $Zn(C_2H_5)_2$ and ammonia, can be recrystallized without difficulty.

## Cyclopentadienylbis(trifluorophosphine)cobalt [1]

By Doz. Dr. Th. Kruck, Prof. W. Hieber, and Dipl.-Chem. W. Lang

Anorganisch-Chemisches Laboratorium
der Technischen Hochschule München (Germany)

*Dedicated to Professor Karl Freudenberg on the occasion of his 80th birthday*

Cyclopentadienylbis(trifluorophosphine)cobalt *(1)* is formed in 20–30 % yield on treatment of dicyclopentadienylcobalt with $PF_3$ at 300 atm and 170 °C:

$$(C_5H_5)_2Co + 2\ PF_3 \rightarrow C_5H_5Co(PF_3)_2 + \bullet C_5H_5$$
*(1)*

As a consequence of the similarity in complex-chemical behavior between trifluorophosphine and carbon monoxide[2], cyclopentadienyl-trifluorophosphine-metal complexes, of which *(1)* is the first representative, resemble their CO analogues $[C_5H_5Co(CO)_2$[3] in this case] closely in their chemical and physical properties. Compound *(1)* is a deep red, oily liquid, m.p. −8 °C, b.p. 51 °/13 mm, readily soluble in organic solvents. Its stability to atmospheric oxygen is poor, as is to be expected for a trifluorophosphine complex with a central metal in the (formal) oxidation stage +1. However, it is stable in a sealed tube up to 195 °C.

Nuclear magnetic resonance and infrared spectra confirm a structure containing a π-bonded, pentagonal, symmetrical cyclopentadienyl ligand. The $^1$H-NMR signal of the aromatic ring occurs at $-5.02\times10^{-6}$ (measured for the pure liquid *versus* tetramethylsilane), which is in the range expected for such a structure; there is no splitting due to coupling of the nuclear spins of the protons with those of the P and F nuclei. In the infrared spectrum bands appear at 1112 $cm^{-1}$ (C–H deformation) and 325 $cm^{-1}$ (metal-ring vibration) with medium intensity, characteristic of the π-bonded cyclopentadienyl ring. The P–F stretching frequencies are at 905 (vs), 856 (vs), and 842 (vs) $cm^{-1}$[4]. They are thus only slightly shifted from the positions for trifluorophosphine and it can be concluded that there is considerable π-bond contribution to the metal-phosphorus linkage.

## Adsorption of Methylene Blue on Clays

By Prof. Dr. U. Hofmann, Dipl.-Chem. H. Kottenhahn, and Dr. S. Morcos

Anorganisch-Chemisches Institut
der Universität Heidelberg (Germany)

*Dedicated to Professor Karl Freudenberg on the occasion of his 80th birthday*

Some time ago we found[1] that adsorption of Methylene Blue on charcoal offers a good possibility of determining the surface area.

Methylene Blue is a quaternary ammonium chloride, $C_{16}H_{18}N_3SCl$, so it was expected[2] that it would undergo cation exchange on clay earths; the Table shows that this indeed occurs. The amount of Methylene Blue taken up is

always approximately equivalent to the amount of exchangeable cation, and it is substantially independent of the surface area. Moreover, the nature of the cation is without influence.

The solution separated from the clay after treatment with Methylene Blue contains 90–100 % of the chloride ion of the dye and about 95 % of the exchangeable cation originally bound to the clay. The amount of Methylene Blue entering the exchange is substantially independent of the concentration of Methylene Blue in the equilibrium solution.

| Clay (and Source) | Surface area by BET ($m^2/g$) [a] | Exchangeable cations (meq./100 g) | Methylene Blue taken up (meq./100g) | Cations |
|---|---|---|---|---|
| Kaolin OF (Schnaittenbach) | 6 | 1.9 | 1.4 | Ca, Mg |
| Kaolin (Zettlitz) | 22 | 6.3 | 6.3 | Ca, Mg |
| Colloidalkaolin (Chodau) | 23 | 9.85 | 10.15 | Ca, Mg |
| Kaolinite clay JL (Provins) | 70 | 17.9 | 17.2 | Ca, H |
| Illite (Füzerradvany) | 37 | 18.6 | 17.8 | $NH_4$ |
| Halloysite (Djebel Debar) | 66 | 9.2 | 10.8 | Ca, Mg |
| Halloysite (Morocco) | 61 | 24.4 | 21.9 | Ca, Mg |
| Montmorillonite (Wyoming) | 770 [b] | 82 | 84 | Na |
| Montmorillonite (Bavaria) | 770 [b] | 93 | 96 | Ca, Mg |
| Montmorillonite (Switzerland) | 770 [b] | 106 | 111 | Ca, Mg |

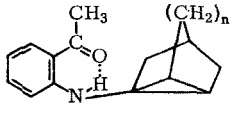
## Synthesis of Nortricyclenes from Bicyclic Ketones in a One-Stage Reaction

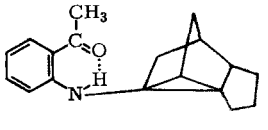
By Prof. Dr. G. Kempter[1], Prof. Dr. M. Mühlstädt, and Dipl.-Chem. D. Heilmann

Institut für Organische Chemie
der Universität Leipzig (Germany)

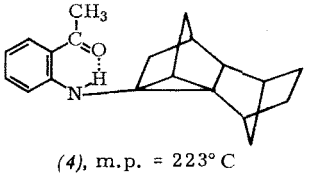
We have found that compounds containing the skeleton of nortricyclene (tricyclo[2.2.1.$0^{2,6}$]heptane) are formed in a one-stage reaction if norcamphor, bicyclo[2.2.2]octan-2-one, 5,6-*exo*-trimethylenenorcamphor, or *exo,endo*-1,4;5,8-dimethano-2-decalone is allowed to react with *o*-aminoacetophenone hydrochloride. The products are compounds *(1)* to *(4)*; product *(2)* contains the ring skeleton of homotricyclene (tricyclo[2.2.2.$0^{2,6}$]octane).



*(1)*, n = 1, m.p. = 155.5° C, yield 37%
*(2)*, n = 2, m.p. = 172.5° C, yield 14.5%

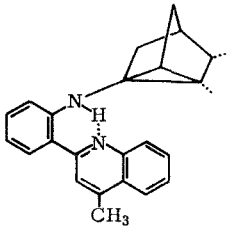


*(3)*, m.p. = 192.5-194°C
yield 26.3%



*(4)*, m.p. = 223° C
yield 30.6%

Compounds *(1)* and *(3)* react with a further quantity of *o*-amino ketone hydrochloride to give *N*-nortricyclyl-substituted *o*-flavanilines of type *(5a,b)*, which also appear as by-products in the preparation of compounds *(1)* and *(3)*.

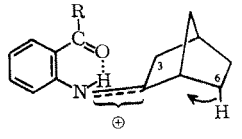


*(5a)*, m.p. = 214.5-216° C
*(5b)*, m.p. = 232.5-234.5° C

30 mmoles of bicyclo-ketone and 20 mmoles of *o*-aminoacetophenone hydrochloride are allowed to react at 155 to 170 °C by the hydrochloride method[2]. When the product is rubbed with ethanol/ligroin the products *(1)*–*(4)* crystallize; the by-products of type *(5)* are separated by fractional crystallization.

The structures of compounds *(1)* to *(5)* were proved by elemental analysis, NMR spectra [no olefinic proton, ratio of aromatic: aliphatic protons in the tricyclic system = 4:9 for *(1)* and 4:11 for *(2)*], ultraviolet and infrared spectra, and mass-spectrometric determination of the molecular weight.

We assume that reaction is initiated by nucleophilic attack by the amino ketone on the carbonyl group of the bicyclic ketone, followed by removal of the OH group produced, which is protonated under the reaction conditions. The mesomeric cation *(6)*[3] may be an intermediate.



*(6)*

A derivative containing the tetracyclic skeleton present in *(3)* has already been synthesised by *Schleyer*[4], although only in 1.5 % yield. The pentacyclic skeleton present in *(4)* was not, to our knowledge, previously known.

## Ecdysterone, a New Metamorphosis Hormone of Insects

By Dr. H. Hoffmeister

Physiologisch-Chemisches Institut der Universität Marburg and I. Medizinische Universitätsklinik, Hamburg (Germany)

The first insect hormone, ecdysone, was isolated in 1954[1]. It is a moulting hormone of silk-worms (*Bombyx mori*) but is active in all the arthropods investigated.

From whole-body extracts of *Bombyx mori* we have now obtained a further substance, which we term ecdysterone, that has moulting activity. Starting material was an aqueous extract[2] that still showed hormone activity in the Calliphora test[3] after separation of the ecdysone. It was extracted exhaustively with ethyl acetate. The residue remaining after evaporation of the ester was fractionated on an alumina column with gradient-elution by methanol and benzene. The pure hormone was then obtained from the hormone-containing fractions by repeated thin-layer chromatography on silica gel. Ecdysterone is three to five times as active as ecdysone in the Calliphora test. It is soluble in water and crystallizes in large anhydrous plates, m.p.226 °C, from ethyl acetate/methanol.

The mass spectrum gives $C_{27}H_{44}O_6$ as the molecular formula of ecdysterone. The substance contains an α,β-unsaturated keto group (UV: $\lambda_{max}$ = 240 mμ, ε = 13600). Its infrared spectrum is very similar to that of ecdysone but there are differences in the fine structure; the carbonyl band lies at 1645 $cm^{-1}$, the ethylenic band at 1612 $cm^{-1}$ (in KBr). The NMR spectrum contains a signal at 8.66 τ for the terminal $-(CH_3)_2C-OH$ group of the steroid side chain; the steroid methyl groups at C-10 and C-13 also appear in the spectrum.

Ecdysterone is probably a $C_{27}$-steroid with a cholesterol side chain. On thin-layer chromatography (silica gel) it appears to be more polar than ecdysone; when sprayed with vanillin/sulfuric acid it develops an intense turquoise color.

## New Metal-Azide Complexes [1]

By Priv.-Doz. Dr. W. Beck, Dr. E. Schuierer, and Dipl.-Chem. K. Feldl

Anorganisch-Chemisches Laboratorium
der Technischen Hochschule München (Germany)

In continuation of previous investigations[2] we have prepared the following azide complexes of platinum(II), platinum(IV), and gold(III) by treating the corresponding chloro complexes with sodium azide in aqueous solution and precipitation of the azidometallate anions with tetraphenylarsonium chloride:

Orange-red tetraphenylarsonium tetraazidoplatinate(II), $[C_6H_5)_4As]_2[Pt(N_3)_4]\cdot H_2O$, decomp. at 185 °C, from a solution of $K_2[PtCl_4]$ and $NaN_3$ (molar ratio 1:100) at 80 °C.

Orange-yellow tetraphenylarsonium hexaazidoplatinate(IV), $[(C_6H_5)_4As]_2[Pt(N_3)_6]$, decomp. at 205 °C, from hydrogen hexachloroplatinate(IV) and $NaN_3$.

Brownish-red tetraphenylarsonium tetraazidoaurate(I), $(C_6H_5)_4As[Au(N_3)_4]$, decomp. at 145 °C, from $K[AuCl_4]$ and $NaN_3$ (molar ratio 1:40).

These compounds can be recrystallized from acetone/water or methylene chloride/ligroin. As expected, the azidometallate anions $[Pt(N_3)_4]^{2-}$, $[Pt(N_3)_6]^{2-}$, and $[Au(N_3)_4]^-$ are diamagnetic (measurements in acetone or nitrobenzene)[3]. An aqueous solution of $[Pt(N_3)_4]^{2-}$ reacts in the same way as azidopalladate(II)[2] with triphenylphosphine, giving colorless diazidobis(triphenylphosphine)platinum(II), $[(C_6H_5)_3P]_2Pt(N_3)_2$, decomp. at 225 °C.

After treatment of cadmium(II) sulfate with $NaN_3$ (molar ratio 1:15), the salt $(C_6H_5)_4P[Cd_2(N_3)_5]\cdot H_2O$, decomp. at 265–266 °C, can be precipitated by addition of tetraphenylphosphonium chloride.

The crystalline complex salts with bulky cations are thermally very stable and are insensitive to touch; however, they deflagrate in a flame.

In the infrared spectra of the azido complexes of platinum and gold the symmetric and asymmetric $N_3$ stretching vibrations appear at 1270 and 2030 $cm^{-1}$, but additional $\nu_{as}N_3$ bands at larger wave numbers, probably attributable to azido bridges[4], are observed for the cadmium compound and for the salt $[C_6H_5)_4As]_2[Pd(N_3)_6]$[2].

Benzylmercuric azide, $C_6H_5CH_2HgN_3$ [from $C_6H_5CH_2HgCl$ and $NaN_3$ in anhydrous methanol; decomp. at 120 °C] and diphenylthallium(III) azide, $(C_6H_5)_2TlN_3$ [from $(C_6H_5)_2TlF$ and $NaN_3$ in water; decomp. at 321 °C] are very similar to the corresponding fulminates in solubility and thermal stability[5].

## A New Synthesis of L-Felenine

By Prof. Dr. A. Schöberl, Dipl.-Chem. J. Borchers, Dr. H. Gräfje, and Dr. Ch.-V. Grewe-Pape

Chemisches Institut
der Tierärztlichen Hochschule Hannover (Germany)

We have found that L-felenine [*S*-(3-hydroxy-1,1-dimethylpropyl)cysteine *(3)*], which previously was difficultly accessible[1], can be prepared in yields of up to 80% by heating 3-methyl-1,3-butanediol *(1)* and L-cysteine *(2)* (molar ratio 2:1) in methanol/2 N HCl at 80 to 100 °C for 0.5 to 1 h with exclusion of oxygen.

$$\underset{(1)}{HO-(CH_2)_2-C(CH_3)_2-OH} + \underset{(2)}{HS-CH_2-CH(NH_2)-COOH} \rightarrow \underset{(3)}{HO-(CH_2)_2-C(CH_3)_2-S-CH_2-CH(NH_2)-COOH}$$

Oxidation of unchanged cysteine by passage of air is followed by chromatography on Dowex W50, $H^+$ form, with 2 N $NH_3$. The eluted L-felenine is purified by precipitation from aqueous solution with acetone: $R_f$ = 0.52 in butanol/glacial acetic acid/water (2:1:1), m.p. 185° (decomp.), $[\alpha]_D^{22}$ = −12.5° (c = 2 in $H_2O$), + 9.0° (c = 2 in 1 N HCl).

L,L-2,10-Diamino-5,5-dimethyl-4,8-dithiaundecanedioic acid *(4)* is obtained as by-product in the condensation. Its formation is favored by longer reaction times: heating for 4 days in the stated conditions leads to a 50% yield [recrystallization from methanol/$H_2O$; $R_f$ = 0.30 in butanol/glacial acetic acid/water (2:1:1); $[\alpha]_D^{20}$ = +18.8° (c = 2 in 1 N HCl); m.p. *ca.* 240 °C (decomp.)]. Separation from felenine and purification of the bissulfide *(4)* are achieved by chromatography[2] on Dowex W50, $H^+$ form, with citrate buffer (pH = 3.4). When L-felenine is treated with 6 N HCl at 70 or 80 °C for 4 h the bissulfide *(4)* is formed as decomposition product[3].

$$\underset{(4)}{HOOC-CH(NH_2)-CH_2-S-CH_2-CH_2-C(CH_3)_2-S-CH_2-CH(NH_2)-COOH}$$

L-Cysteine condenses smoothly with t-butyl alcohol under similar conditions (heating in 5 N HCl for 10 h on the water bath under $N_2$), giving *S*-t-butyl-L-cysteine (yield about 70 %). Recrystallization from butanol/$H_2O$ gives shiny needles; $R_f$ = 0.73 in butanol/glacial acetic acid/water (2:1:1); $[\alpha]_D^{20}$ = +9.9° (c = 1 in 1 N HCl); m.p. = 244 °C (decomp.).

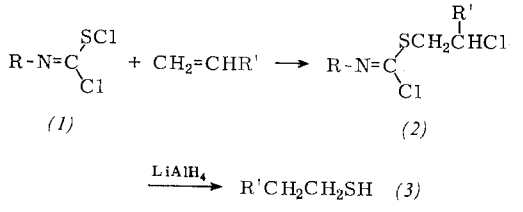
## N-Aryl- and N-Alkyl-S-(2-chloroalkyl)isothiocarbamoyl Chlorides [*]

By Dr. G. Ottmann and H. Hooks, Jr.

Olin Mathieson Chemical Corporation
Chemicals Division, New Haven, Conn. (U.S.A.)

We reported recently[1,2] on the synthesis of *N*-aryl- and *N*-alkyl-*S*-chloroisothiocarbamoyl chlorides *(1)* by careful chlorination of the corresponding isothiocyanates. *S*-Chloroisothiocarbamoyl chlorides *(1)* react predominantly as sulfenyl chlorides but some of their properties also resemble those of imidoyl chlorides. As derivatives of sulfenyl chlorides, they react with olefinic double bonds[3] to form *N*-aryl- and *N*-alkyl-*S*-(2-chloroalkyl)isothiocarbamoyl chlorides *(2)* (cf. Table), compounds which have not been described previously.



*(1)* *(2)*

*(3)*

The exothermic reaction is performed either by adding the *S*-chloroisothiocarbamoyl chloride slowly and with stirring to the olefin at 0–20 °C under complete exclusion of moisture, or in case of ethylene by passing the gaseous hydrocarbon into a solution of *(1)*. Excessive olefin or an inert solvent ($CCl_4$, ether) are employed as reaction media. Evaporation of the solvent *in vacuo* renders compounds *(2)* in satisfactory purity. Analytically pure products are obtained by recrystallizing the solid representatives from pentane at low temperature (*e.g.* 50 °C) or by extracting the liquid representatives with pentane at room temperature. Reactions of *(1)* with vinyl alkyl ethers lead to highly reactive *S*-(2-chloro-2-alkoxyalkyl)isothiocarbamoyl chlorides *(2)*, R′ = $OC_nH_{2n+1}$, which are only stable at low temperatures or in solution.

The structure *(2)* was secured by $LiAlH_4$-reduction to the corresponding n-alkylthiols *(3)*, by elemental analysis, and by infrared, NMR, and mass spectroscopy.

*S*-(2-Chloroalkyl)isothiocarbamoyl chlorides *(2)* behave like imidoyl chlorides and are readily converted by nucleophiles to a variety of open-chain or cyclic compounds depending on the nature of R′. Hydrolysis[4] of compounds *(2)*, R′ = H, alkyl, chloroalkyl, or cycloalkyl, leads to *N*-alkyl- and *N*-aryl-*S*-(2-chloroalkyl)thiocarbamates *(4)* (cf. Table). If R′ is a more strongly electron-attracting moiety such as a phenyl group, hydrolysis affords the corresponding compounds *(4)*, albeit in reduced yields since 4-aryl-1,3-thiazolidin-2-ones *(5)* are predominantly formed, *e.g.* 3,4-diphenyl-1,3-thiazolidin-2-one *(5)*, R = R′ = $C_6H_5$, m.p. 159–160 °C, besides a minor amount of the thiocarbamate *(4)*.

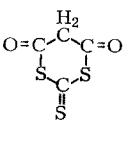
## Reactions of Trithiocarbonic Acid with Malonyl Chloride [1]

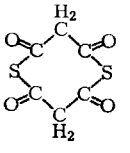
By Dr. B. Krebs and Priv.-Doz. Dr. G. Gattow

Anorganisch-Chemisches Institut
der Universität Göttingen (Germany)

Whereas the wine-red 4,5-dioxo-2-thioxo-1,3-dithiolane[3] is formed by reaction of trithiocarbonic acid $SC(SH)_2$[2] with oxalyl chloride, use of malonyl chloride leads to the dimeric thiomalonic anhydride [2,4,6,8-tetraoxo-1,5-dithiocane]*(2)*[4] by way of the unstable red 4,6-dioxo-2-thioxo-1,3-dithiane *(1)*.



*(1)*



*(2)*

A solution of 7.1 g of freshly distilled malonyl chloride in 50 ml of $CHCl_3$ is dropped slowly into a solution of 5.5 g of $SC(SH)_2$ in 50 ml of $CHCl_3$ at 0 ° with exclusion of moisture; much HCl is evolved. Colorless crystals of product *(2)* separate in several hours or days from the solution, which is initially red owing to the presence of the intermediate *(1)*; the crystals are filtered off and washed with $CHCl_3$.

The compound *(2)*, m.p. 124 ± 1 °C, $d_4^{25}$ = 1.710 ± 0.005 g/cm³, is not soluble without decomposition in any of the usual solvents. It is not decomposed by cold water or alcohols, but hydrolysis occurs in hot water or in acids or aqueous

alkali hydroxides. Heating of compound *(2)* in a high vacuum affords $C_3O_2$, COS, and thioacetic acid, but heating in the presence of $P_2O_5$ affords $C_3O_2$, $H_2S$, $C_3S_2$, COS, and ketenethiocarboxylic acid *(3)* (colorless crystals; m.p. 60 °C) (cf. [5]).

O=C=CH–COSH *(3)*

Infrared spectrum of *(2)* (in Nujol and hexachlorobutadiene): 2980(m), 2910(m), 1720(vs), 1685(vs), 1395(s), 1388(s), 1298(s), 1210(m), 1055(s), 980(s), 970(s), 910(m), 800(s), 750(w), 640(s), 558(m), 463(w) $cm^{-1}$ [6].

X-Ray investigations showed that compound *(2)* forms tetragonal crystals with Z = 4 in space group $D_{2d}^4$–$P\bar{4}2_1c$ (No. 114): a = 11.88 ± 0.02, c = 5.61$_1$ ± 0.01 Å; X-ray density 1.714 g/cm³. From consideration of the structure it follows that the eight-membered ring of compound *(2)* is symmetrically puckered (symmetry $C_{2v}$).

If the red solution of compound *(1)* in $CHCl_3$ is cooled immediately after the reaction to −30 °C and the solvent is distilled off in a vacuum, compound *(1)* remains behind as an oil. When warmed it decomposes to a yellow oil, which gives off large amounts of $CS_2$ in a vacuum at 25 °C. This oil is a polymer of composition *(4)*; its distillation at 0.5 mm (b.p. 150–200 °C) affords polymers *(4)* with x = 4–6, having –SH (and –Cl) end groups. The distillation residue contains polymers of higher molecular weight (x > 6) as decomposition products.

[–S–CO–$CH_2$–CO–]x *(4)*

Infrared spectrum of *(4)* with x = 4–6: 3380(w), 2970(m), 2900(m), 2580(m), 1720–1708–1690–1675(vs), 1550(w), 1402(m), 1375(m), 1300(s), 1196(m), 1085(s), 1056(s), 1035(s), 950(w), 885(m), 790(w), 642(s), 552(w), 465(w) $cm^{-1}$ [6].

## Rotational Isomerism in Vinylcyclopropanes

By Dr. H. Günther and Dipl.-Chem. D. Wendisch

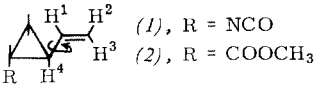
Institut für Organische Chemie
der Universität Köln (Germany)

The angular dependence of vicinal H,H-coupling constants has been employed for the conformational analysis of ethanes, propenes, and butadienes [1]. We have used this method to study the rotational isomerism of the vinyl group in *trans*-2-vinylcyclopropyl isocyanate *(1)* [2] and methyl *trans*-2-vinylcyclopropylcarboxylate *(2)* [2] (see Table).

With respect to the orientation of the vinyl group relative to the three-membered ring, results obtained for bicyclopropyl [3] indicate that in *(1)* and *(2)* there is an equilibrium between an s-*trans* form (A, Θ ≈ 180°) [4] and two *gauche* forms (B, Θ ≈ 40°; B′, Θ ≈ 320°) of equal energy ($p_B = p_{B'}$). Because interconversion between rotamers A, B, and B′ is rapid in the temperature range studied, only a mean value is observed for the coupling constant $J_{14}$:

$$J_{14} = p_A J_{14}^{trans} + 2p_B J_{14}^{gauche} \quad (a)$$

where $J_{14}^{trans} \gg J_{14}^{gauche}$. If all rotamers are of equal energy [$p_A = p_B = p_{B'} = 1/3$; $J_{14} = 1/3\ J_{14}^{trans} + 2/3\ J_{14}^{gauche}$ (b)], a value of *ca.* 6 cps is found for $J_{14}$ [5]. The observed coupling constants therefore indicate a domination of the s-*trans* form in *(1)* and *(2)*, that increases from + 37 °C to −40 °C. The changes $\Delta\nu_i$ of the chemical shifts with decreasing temperature are consistent with this interpretation and may have their origin in the diamagnetic anisotropy of the cyclopropane ring.



*(1)*, R = NCO
*(2)*, R = $COOCH_3$

| | Temp. [°C] | $J_{14}$ [cps] | $\Delta\nu_1$ [cps] [a] | $\Delta\nu_2$ [cps] | $\Delta\nu_3$ [cps] | $p_A$ | $p_B = p_{B'}$ |
|---|---|---|---|---|---|---|---|
| *(1)* | +37 | 7.82 | +8.29 | +0.40 | −1.97 | 0.53 | 0.23 |
| | −40 | 8.50 | | | | 0.61 | 0.20 |
| *(2)* | +37 | 8.17 | +7.71 | −0.31 | −2.23 | 0.58 | 0.21 |
| | −40 | 9.03 | | | | 0.67 | 0.16 |

[a] The $^1$H-NMR-spectra were recorded at 60 Mc/s in $CS_2$ (20 % by vol.) with a Varian A 60 spectrometer. $p_i$ are the mole fractions of rotamers (see text). Positive $\Delta\nu_i$ denotes a shift to higher field.

With a value of 12 cps for $J_{14}^{trans}$ [6], $J_{14}^{gauche}$ and the equilibrium concentrations of the rotamers may be estimated using the Equations (b) and (a), respectively. With $K = p_A/p_B$ for the equilibrium constant the enthalpy difference ΔH between the *gauche* and s-*trans* forms is obtained from the temperature dependence of K. For *(1)* and *(2)* ΔH values of *ca.* 0.6 and *ca.* 0.7 kcal/mole, respectively, were found.

## A Stable Methylenenorcaradiene

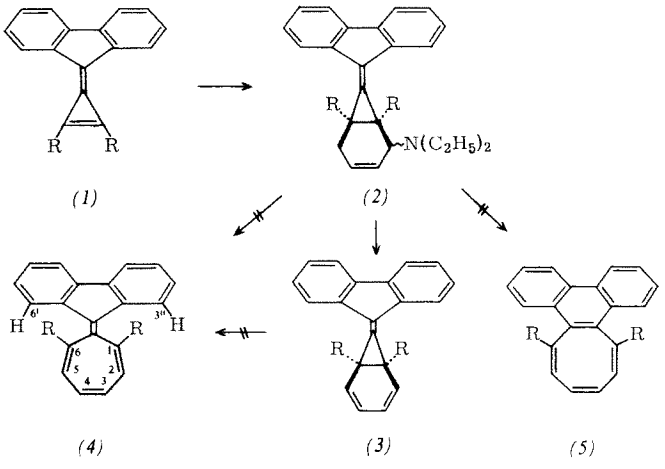
By Prof. Dr. H. Prinzbach [1], Dipl.-Chem. U. Fischer, and Dipl.-Chem. R. Cruse

Chemisches Laboratorium
der Universität Freiburg (Germany)

Calculations of the molecular geometry of dibenzosesquifulvalene *(4a)* [3] by means of a simple model [2] show that the spheres of influence of the H atoms at positions 1 and 6 interpenetrate appreciably those of the H atoms at positions 3″ and 6′ if the fluorenylidene and cycloheptatrienylidene parts of the molecule are assumed to be coplanar, but that in spite of this an approximately planar conformation is not improbable. On the other hand, 1,6-dimethyldibenzosesquifulvalene *(4b)* cannot, according to an analogous calculation, assume an even approximately planar conformation. An attempt to synthesize compound *(4b)* should therefore lead to the methylenenorcaradiene structure *(3b)*. We have confirmed this experimentally.

Treatment of dimethyldibenzocalicene *(1b)* [4] (6.85 mmoles) with *N,N*-diethylbutadienylamine (10.3 mmoles) in anhydrous benzene (60 ml) at 90 °C for 20 h and subsequent addition of 2 N HCl affords the hydrochloride of the adduct *(2b)* in 70 to 75 % yield. The free base, whose structure was

proved by elemental analysis, and infrared, ultraviolet, NMR, and mass spectroscopy[5], can be liberated from the crude hydrochloride by NaOH (yield *ca.* 60 %). When heated at 160–180 °C and 0.1 mm its trifluoroacetate liberates diethylamine; simultaneously a colorless compound (fine needles from ethanol; m.p. 208–209 °C) sublimes which elemental analysis and mass spectroscopy[5] indicate to have the composition $C_{22}H_{18}$ (M = 282); we assign to it the structure *(3b)*.



*(a)*: R = H; *(b)*: R = $CH_3$

This structure is supported by the following data: The NMR spectrum ($CDCl_3$) consists of a multiplet between 2.10 and 2.90 τ, an $A_2B_2$ group of signals around 3.64 τ, and a singlet at 7.73 τ (ratio of areas 8:4:6). The ultraviolet spectrum [in $CH_3CN$: $\lambda_{max}$ = 325 mμ (ε = 9000), 312.5 (10700), 296.5 (10400), 279 (16000), 267 (16200), 258 (33500), 249 (31500), and 230.5 (51500)] shows, *inter alia*, the maxima of the methylenefluorene chromophore. The infrared spectrum includes C=C absorption bands of medium intensity at 6.1 and 6.26 μ; the intense bands of the sesquifulvalene system at 6.3–6.4 μ are absent. The most important peaks in the mass spectrum[5] are at m/e = 282, 267, 252, 202 and 165. Contrary to *(4a)*, *(3b)* is not protonated in $CF_3CO_2H$. Ozonolysis in ethyl acetate at −15 °C and oxidative working-up give fluorenone (52 %). Hydrogenation (Pd, ethanol, 20 °C) leads to a mixture whose NMR spectrum comprises two multiplets between 2.13 and 2.95 τ and between 7.25 and 9.47 τ (ratio of areas 8:18), and whose ultraviolet spectrum is almost identical with that of fluorene.

The sesquifulvalene structure *(4b)* and the mechanistically plausible cyclooctatetraene structure *(5b)* are thus excluded.

The norcaradiene *(3b)* is stable up to at least 275 °C; its NMR spectrum is unchanged up to 200 °C. Irradiation with ultraviolet light filtered through Vycor glass does not cause isomerisation to *(4b)*; photolysis of the cyclohexadiene ring is opposed by the three-membered ring fused to it, which prevents conrotative ring opening[6]. At temperatures up to 200 °C the compound *(3b)* reacts neither with maleic anhydride nor with dimethyl acetylenedicarboxylate. Treatment with tetracyanoethylene leads to a π-complex that is stable in solution ($\lambda_{max}$ in $C_{16}H_{12}$ = 545 mμ, in $CH_2Cl_2$ 570 mμ).

Complexes *(3)* probably are intermediates in these reactions as there the nitrogen atom is favorably placed for attack on the carbonyl group. On reaction with alcohols the compounds *(1)* afford carbonates. Since, however, hydroxy group reacts appreciably more slowly, selective alkoxycarbonylation can be achieved with amino alcohols.

## Reaction of Tungsten Hexacarbonyl with Azide [1]

By Priv.-Doz. Dr. W. Beck and Dipl.-Chem. H. S. Smedal

Anorganisch-Chemisches Laboratorium
der Technischen Hochschule München (Germany)

Tungsten hexacarbonyl reacts with alkali or tetraalkylammonium halides or pseudohalides $M^IX$ (X = halogen or NCS) with elimination of one CO ligand, giving compounds of the type $M^I[W(CO)_5X]$ [2]. However, tetraethylammonium azide [3] and $W(CO)_6$ (molar ratio 1:15) in diethylene glycol dimethyl ether (diglyme) at 80 °C afford yellow, diamagnetic tetraethylammonium isocyanatopentacarbonyltungstate(0), $[N(C_2H_5)_4][W(CO)_5NCO]$. The anion $[W(CO)_5NCO]^-$ is also directly accessible from $W(CO)_6$ and potassium cyanate in diglyme at 100 °C and can be precipitated by tetraphenylarsonium chloride in ethanol/water as a lemon-yellow, crystalline salt, $[As(C_6H_5)_4][W(CO)_5NCO]$, m.p. 157 °C (decomp.), soluble in ethanol, acetone, and tetrahydrofuran. This complex corresponds in analysis and infrared spectrum to the product obtainable from $W(CO)_6$, azide, and $As(C_6H_5)_4Cl$; conductivity and molecular-weight determinations indicate the salt to be extensively dissociated ($M_{exp.}$ = 377). In accord with $C_{4v}$ symmetry, the infrared spectrum of the anion $[W(CO)_5NCO]^-$ (in acetone) contains three CO bands, at 2067(w), 1927(st), and 1868(m) $cm^{-1}$, and pseudoasymmetric and symmetric NCO stretching vibrations at 2236(m) and 1323(m) $cm^{-1}$ [4]. The positions of the $\nu_{as}NCO$ and $\nu_sNCO$ vibrations prove the anion $[W(CO)_5NCO]^-$ to be an isocyanate complex containing a W–NCO bond.

Reaction of $W(CO)_6$ with azide probably occurs by nucleophilic attack of azide on a CO ligand, loss of nitrogen, and rearrangement to the stable isocyanate, analogously to the Curtius azide degradation. Several reactions of metal carbonyls involving nucleophilic attack on carbon monoxide bound in a complex have been discovered recently [5]. The first such reaction of $W(CO)_6$ observed was that with carbanions [6].

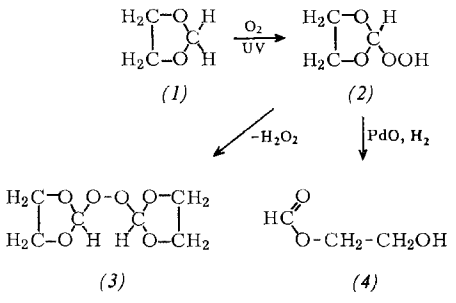
## 1,3-Dioxolan-2-yl Hydroperoxide

By Prof. Dr. A. Rieche, Dr. H.-E. Seyfarth, and
Dipl.-Chem. A. Hesse

Institut für Technische Chemie der Universität Jena (Germany)

1,3-Dioxolane (ethylene glycol formal) *(1)* is an excellent solvent but, because of its marked tendency to peroxide formation in air, it cannot always be used [1].

We have isolated 1,3-dioxolan-2-yl hydroperoxide after peroxidation of the formal *(1)*. After peroxidation to 15 % conversion (18 °C, $O_2$, UV-irradiation) enrichment was effected by distillation at 20 °C (bath temperature) and 10 mm. The colorless oily residue contained 90 % of the peroxide *(2)* (determined iodometrically), which gave hydroperoxy-OH bands at 3350 $cm^{-1}$. $H_2O_2$ and a little of the peroxide distilled at 80 °C (bath temperature) and 0.2 mm. The crystalline distillation residue was bis-(1,3-dioxolan-2-yl) peroxide *(3)* (white leaflets, m.p. 73.5–74.5 °C from alcohol, peroxide content 97.8 %, peroxide bands at 810 and 870 $cm^{-1}$).



*(1)* *(2)* *(3)* *(4)*

Hydrogenation of the hydroperoxide *(2)* (PdO in ether, 20 °C) gave 2-hydroxyethyl formate *(4)* quantitatively. After hydrolysis (1 N $H_2SO_4$, 20 °C, 2 h) of *(2)*, 98 % of $H_2O_2$ was found.

The cyclic acetals of acetaldehyde, propionaldehyde, and isobutyraldehyde behave similarly. The derived hydroperoxides were isolated in 90 to 95 % purity. Hydrogenation afforded the corresponding glycol monoesters, and peroxides of type *(3)* were either detected or isolated [2].

from acid chlorides and t-butyl hydroperoxide by the Schotten-Baumann procedure or with pyridine in pentane, ether, methylene chloride, or benzene at −20 °C. They have been characterized by their spectra and elemental analyses. They undergo thermolysis up to 50000 times faster than t-butyl peracetate or other simple peresters and thus have significance as low-temperature initiators. Product analyses, dependence of the reaction rate on solvent and concentration, activation parameters, and polymerization experiments with styrene and acrylonitrile indicate a homolytic fragmentation [1] as the rate-determining step.

Since decomposition of the compounds with oxygen-containing substituents is faster than that of those with the corresponding sulfur-containing substituents, and that of alkoxy compounds is faster than that of aryloxy compounds, it is concluded that a polar effect [1] is responsible for the thermolability of these substances. Acyloxy groups have a similar but weaker effect. The compounds should be prepared only with special precautions and in small quantities (grams), since some of them deflagrate at room temperature. Explosions have not yet occurred [2].

[1] Review and references: *Ch. Rüchardt*, Fortschr. chem. Forsch., in the press.

[2] The compounds listed in the Table under 70.5°C can be prepared and handled in 50–100 g lots if the temperature is maintained at or below 0°C by efficient cooling. Larger amounts have so far not been prepared. The more labile α-peroxyacetates should be prepared and stored only in dilute solution at −20°C except in dealing with small amounts.

# CONFERENCE REPORTS

## Eighth European Congress on Molecular Spectroscopy

The Eighth European Congress on Molecular Spectroscopy was held in Copenhagen from August 14th to 20th, 1965. Four hundred lectures were delivered to about 800 participants in up to ten simultaneous sessions.

From the lectures:

*M. Zander* (Castrop-Rauxel, Germany) discussed the continued interest in the systematic changes in absorption, fluorescence, and phosphorescence bands, brought about by systematic variation of the basic structure of a molecule. In single or multiple ortho-fusion to carbazole, for example, fusion in the 2,3-position and the 6,7-position leads to an appreciable bathochromic shift, whereas the latter is small when fusion takes place in the 3,4-position and the 5,6-position. *J. H. Eggers et al.* (Aarhus, Denmark) used the dichroism of molecules oriented in stretched films to determine the transition moment directions of individual bands.

This parameter is increasingly used in the classification of spectra and electronic excitation states. *F. Dörr* and *G. Hohlneicher* (Munich, Germany) determined the relative transition moment directions of biphenylene derivatives from the emission anisotropy, and compared the results with those of model calculations. Until recently only the energies of excited molecular states were known, and only now have attempts been made to determine other physical parameters of these states. Thus *D. E. Freeman* and *W. A. Klemperer* (Cambridge, Mass., USA) have determined the dipole moment of formaldehyde in the $^1A_2$ state (excited at 339 mμ) from the Stark shift of single rotational lines and obtained a value of 1.57 D (the dipole moment in the ground state is 2.34 D). There is a lack of detailed data on the intramolecular transitions between the energy levels, and this problem requires thorough quantitative investigations of the type carried out by *H. Labhart* (Zurich, Switzerland) to determine the probability of singlet-triplet transitions occurring when optically excited molecules return to the ground state. This new technique can also be applied to the measurement of triplet-triplet absorption spectra. *M. A. El-Sayed* (Los Angeles, USA) discussed a further means of studying the singlet-triplet transition probabilities by the perturbation of phosphorescence through incorporation of a heavy atom, or by resonance effects in the host lattice. *R. M. Hochstrasser* (University of Pennsylvania, USA) investigated the line splitting, often caused by lattice defects, in the singlet-triplet transitions taking place in crystalline derivatives of benzene and naphthalene. *H. H. Jaffé* (Cincinnati, USA) used the Pariser-Parr-Pople method to interpret the electronic spectra of *trans*-stilbene and *trans*-azobenzene.

The results of the Pariser-Parr-Pople calculations and similar approximations are known to depend on the choice of the parameters (one-electron one-center and two-center integrals and two-electron one-center integrals), and *I. Fischer-Hjalmars* (Stockholm, Sweden) attempted to deduce from theoretical considerations parameters applicable to as many compounds as possible, particularly to π-electron systems containing heteroatoms. By contrast, *M. Klessinger* (Göttingen, Germany) estimated the parameters from experimental data (transition energies, oscillator strengths, dipole moments) for simple molecules such as aniline, so as to improve the agreement between experimental values and the results of the Pariser-Parr-Pople treatment. These calculations were used to interpret the electronic spectra of merocyanines and indigoids. *F. F. Seelig* (Marburg, Germany) reported on the use of digital computers in further developments of the theory of π-electron systems on the basis of the Kuhn model of a two-dimensional electron gas. *J. Linderberg* and *Y. Öhrn* (Uppsala, Sweden) investigated a new model for the spectra of π-electron systems, particularly alternant aromatic hydrocarbons, the model being based on Green's Functions.

The model used in most theoretical treatments is still based on the assumption that the nuclear configuration does not change in the course of electronic transitions. The fact is, however, that excitation may be accompanied by a change in the nuclear configuration and even in the symmetry of the molecule. Non-vertical transitions are then determined by Franck-Condon factors. *W. L. Smith* and *P. A. Warsop* (Dundee, U. K.) calculated these factors for HCN, and compared the results with those obtained from the analysis of molecular rotations. The theoretical investigations of *L. Burnelle* (Balto, Md., USA) confirmed that, in the lowest triplet state, the $CH_2$ groups in ethylene are staggered and tilted with respect to each other.

As can be seen from the last example, the applicability of the Pariser-Parr-Pople method is not restricted to the interpretation of electronic spectra. Thus *J. Hinze* (Stuttgart, Germany) developed a theory for the excimers of alternant hydrocarbons. *H. Dreeskamp* (Stuttgart) calculated the indirect, heteronuclear spin-spin coupling, and compared his results with experimental values. *M. J. S. Dewar et al.* (University of Texas, USA) calculated the π-electron densities in monofluorinated aromatic hydrocarbons and correlated the results with the fluorine-NMR spectroscopic data. *E. A. C. Lucken*

(Geneva, Switzerland) reported on the ESR spectra of conjugated free radicals containing a bivalent sulfur atom. He found that, when the 3d orbitals of the sulfur are taken into account, the experimental data are in very poor agreement with the theoretical values.

One application of infrared spectroscopy is the determination of molecular symmetry. *F. A. Miller* and *I. Matsubara* (Pittsburgh, Pa., USA) showed definitely that the butatriene molecule, $H_2C{=}C{=}C{=}CH_2$, is planar ($D_{2h}$). In the analysis of normal coordinates and calculation of the force constants in molecules of the type $(CH_3)_3CX$ and $(CH_3)_3C{-}C{\equiv}CX$ (X = H, D, F, Cl, Br, I), *W. Zeil et al.* (Kiel, Germany) found that, owing to strong coupling, a number of vibrations can no longer be considered to be localized on one bond alone. With the improvement of experimental techniques, the long-wavelength IR region (up to 10 $cm^{-1}$) has assumed a certain interest. *W. G. Fateley* and *F. A. Miller* (Pittsburgh, Pa., USA) carried out comparative measurements with a Michelson interferometer and with a lattice-filter spectrophotometer concluding that the latter is generally a more suitable instrument. *N. T. McDevitt, F. F. Bentley*, and *A. D. Davidson* (Wright Patterson Air Force Base, Ohio, USA) showed that the far IR spectra of inorganic compounds such as simple metal oxides, sulfides, and halides are generally complex and depend on the crystal structure, the coordination number, and the lattice constant. *I. J. Wick* (Morse Laboratories, USA) has obtained some information from long-wavelength IR absorption in connection with the molecular configuration, particularly the *cis-trans* configuration of double bonds and the configuration of cyclohexane derivatives. *G. C. Hayward* and *P. J. Hendra* (London, England) showed that the spectra of charge-transfer complexes in the short-wavelength IR region are essentially superpositions of the spectra of the components, but in the long-wavelength IR region new lines may appear. This phenomenon may be due partly to the activation of forbidden transitions. The absorption lines appearing in the region of 20 to 50 $cm^{-1}$ in polar liquids such as nitriles, ketones, and nitro compounds were attributed by *G. W. Chantry* and *H. A. Gebbie* (Teddington, England) to the "lattice" of the liquid and by *E. R. Lippincott* (College Park, Maryland, USA) to the stretching vibrations of dipole complexes (dimers or clusters). The investigations may provide detailed information on the intermolecular attraction between polar molecules, and possibly also on the structure of polar liquids. The long-wavelength IR absorption of molecules linked by hydrogen bonds can contribute to the elucidation of such bonding. *K. Nakamoto* (Chicago, USA) determined the force constants and identified the bands of dimeric acetic and formic acid. *R. J. Jakobsen* and *J. W. Brasch* (Columbus, Ohio, USA) found a splitting in the OH-stretching and the OH-deformation vibrations of several hydroxy compounds, and attributed it to intermolecular association.

*H. E. Hallam* and *D. Jones* (Swansea, Wales, U. K.) used short-wavelength IR absorption to investigate the intermolecular association of alcohols and fluorinated alcohols and the formation of hydrogen bonds with various proton-acceptors in the gaseous state. *L. P. Kuhn* and *E. E. Bowman* (Aberdeen Proving Ground, Md., USA) used a similar method for determining the equilibrium constants and the frequency shifts of the hydrogen-bonded complexes of phenol with unsaturated hydrocarbons. *W. Luck* (Ludwigshafen, Germany) obtained data on the variation of the hydrogen-bond energy with the bond angle by investigating the formation of hydrogen bonds between pyrrolidone and various proton-acceptors as a function of concentration and temperature. On the basis of theoretical and experimental studies, *K. Szczepaniak* (Warsaw, Poland) concluded that charge-transfer interactions must be basically responsible for the bonding forces in hydrogen-bond complexes in which a $\pi$-electron-donor acts as a proton-acceptor, whereas in complexes in which the proton-acceptor is a non-bonding electron-donor, electrostatic attractions are also significant.

The formation of charge-transfer complexes has recently been studied on many electron donors and acceptors in solutions. This work has now been extended to gases. *M. Tamres* (Ann Arbor, Mich., USA) reported on the diethyl sulfide-iodine complex, and *J. Prochorov* and *A. Tramer* (Warsaw, Poland) on charge transfer complexes formed by carbonyl cyanid $CO(CN)_2$ with a number of electron donors. In comparison with the charge-transfer bands in the gaseous state, those in solution exhibit a relatively strong red-shift (1500 to 3000 $cm^{-1}$), as expected on the basis of the great increase in dipole moment on excitation. Besides the extinction of the fluorescence of aromatic hydrocarbons by electron donors such as anilines or amines, *A. Weller et al.* (Amsterdam) observed the appearance of a new long-wavelength fluorescence band in solvents of low polarity. This may be explained by the formation of a charge-transfer complex from an excited molecule of hydrocarbon and an electron-donor. The new emission band is due to fluorescence of the complex. The formation of charge-transfer complexes from an excited molecule and an electron-donor has also been observed in the case of the excimers of aromatic hydrocarbons such as naphthalene, and *M. D. Lumb* and *D. A. Weyl* (Manchester, England) discussed the excimer fluorescence of alkylated benzenes. Short-lived (10 to 100 $\mu$sec) ions of organic compounds have been studied by *A. Terenin et al.* (Leningrad, USSR), together with the kinetics of decomposition of these ions. These authors found that, by the use of a "superfast" spectrophotometer, the spectra (300 to 1200 m$\mu$) of ions formed by a flash can be recorded in 20 $\mu$sec on an oscillograph.

Systematic investigations carried out by *W. Brügel* (Ludwigshafen, Germany) on the NMR spectra of numerous derivatives of naphthalene and anthracene have led to a more accurate picture of the influence of substituents on the NMR parameters. *G. Karagounis* (Freiburg, Germany) studied the NMR spectra of adsorbed molecules.

Of the many possible applications of lasers in molecular spectroscopy, the excitation of Raman spectra is of particular importance and has been extensively investigated by *W. W. Ward, K. P. George*, and *R. C. Hawes* (Monrovia, Calif., USA) and by *R. C. Gove* (Norwalk, Conn., USA). *R. Deen* (Delft, The Netherlands) reported on the vibrational structure associated with the $n{\rightarrow}\pi^*$ transitions manifested in the absorption and the circular dichroism of optically active ketones. The results will be useful in interpreting many of the complicated circular dichroism and optical rotational dispersion spectra. *R. Briat, M. Billardon*, and *J. Badoz* (Paris, France) designed an instrument for recording magneto-optical rotation (Faraday effect).

Particularly many lectures dealt exclusively or predominantly with theoretical problems. Thus many groups are engaged in calculations based on simplified models. In this connection, the Hückel method is being increasingly superseded by the Pariser-Parr-Pople treatment. It appears that satisfactory approximations can now be obtained for many problems with the aid of computers, although the theoretical prerequisites (and hence the limitations of the methods) are not entirely understood. While we may either welcome or regret the increasing theoretical trend in chemistry, we certainly cannot ignore it in research and particularly in the training of students of chemistry. ## Photoalkylations

*D. Elad*, Rehovot (Israel)

The photoamidation of terminal olefins[1] (addition of formamide to the olefin induced directly by light or initiated photochemically by acetone with higher yields) has also been applied to non-terminal olefins. Here, it leads to a mixture of the two possible amides resulting from addition of the carbamoyl group, $CONH_2$, to either carbon atom of the double bond.

Cyclic olefins, such as cyclohexene and norbornene, as well as dienes, like 4-vinylcyclohexene and 1,5-cyclooctadiene,

were found to react with formamide under ultraviolet irradiation to give the higher amides. The addition of formamide to α,β-unsaturated esters was achieved through the use of benzophenone as a sensitizer and high yields of succinic amide esters have been obtained.

It is proposed that the photoaddition of formamide to olefins is a free radical chain reaction involving carbamoyl radicals $\bullet CONH_2$ and that the olefin serves as a scavenger for these radicals. The formation of the carbamoyl radicals is assumed to take place through hydrogen atom abstraction from formamide by the excited carbonyl compound.

The photoaddition of cyclic ethers to olefins can be achieved by direct irradiation or through photochemical initiation with a ketonic compound, *e.g.* acetone or acetophenone, with considerably higher yields. α-Substituted cyclic ethers are the major products of the reaction [2].

γ-Butyrolactone and 2-pyrrolidone were found to add to terminal olefins under ultraviolet irradiation to give 2-alkylated γ-butyrolactones in high yields [3], and mixtures of 3-alkylated and 5-alkylated 2-pyrrolidones [4], respectively.

*N*-Acetylglycine ethyl ester has been shown to react with olefins or toluene when irradiated in the presence of acetone, to yield the derivatives of higher amino acids and phenylalanine, respectively.

## Studies of Chemical Reactions by Pulse Radiolysis: Free Electrons and Free Radicals in Aqueous Solution

*A. Henglein*, Berlin

Reactions of OH radicals and hydrated electrons that are produced by decomposition of water can be followed by pulse radiolysis (pulses of about $10^{-6}$ sec duration), the absorption of the hydrated electrons at 7200 Å immediately after the irradiation pulse being shown oscillographically as a function of time or the absorption spectra of the reaction products being measured.

Hydrated electrons react with tetranitromethane in a bimolecular process of rate constant (at 20 °C) $6.0\times10^{10}$ l mole$^{-1}$ sec$^{-1}$, with formation of the anion of *aci*-nitroform. From simultaneous observations of the disappearance of the absorption of the hydrated electrons and of the appearance of the nitroform absorption, the extinction coefficient of electrons in water was found to be $\varepsilon_{7200\,Å} = 1.55\times10^4$ l mole$^{-1}$ sec$^{-1}$.

Nitromethane reacts with hydrated electrons, giving the anion $CH_3NO_2^-$. This is an example of the first reduction stage of an aliphatic nitro compound. The anion absorbs at 2700 Å ($\varepsilon$ = 2800 l mole$^{-1}$ cm$^{-1}$) and undergoes a further reaction which is of the second order. In acidic solution the undissociated radical acid $CH_3N^{\bullet}\!\!<^{O}_{OH}$ is formed (pK = 4.5, $\lambda_{max}$ = 2500 Å, $\varepsilon_{max} = 2.0\times10^3$ l mole$^{-1}$ cm$^{-1}$). Two examples of reactions of this radical acid or its anion are charge transfer to tetranitromethane ($k = 1.2\times10^9$ l mole$^{-1}$ sec$^{-1}$) and reaction with oxygen.

The solvated electron reacts with hydrogen sulfide in aqueous solution by a diffusion-controlled process, *i.e.*, without activation energy, although the reaction in the gas phase has an energy barrier of 1.6 eV. The rapidity of the reaction in solution is considered due to solvation effects. The heat of hydration of the electron is materially less than that of a heavy negative ion. From the kinetic results it is concluded that values below 2.0 eV are commonest in the distribution of solvation energy of the hydrated electron, which agrees with calculations from the absorption spectrum of the hydrated electron.

The reaction of catalase with the OH radical is diffusion controlled, as shown by a comparison of the measured rate constant of $8.3\times10^{10}$ l mole$^{-1}$ sec$^{-1}$ with that calculated from the Smoluchowski equation [1]. For this purpose the radius of catalase, known from diffusion measurements, and the self-diffusion coefficient of water (which was treated as equal to the diffusion coefficient of the OH radical) were used. The reaction OH + catalase is diffusion controlled although 30 % of the individual amino acids of catalase react with OH in a process that is not diffusion controlled. This result was discussed in the light of *Noyes'* theory [2] of the probability of re-encounters in diffusion-controlled reactions. It is expected that macromolecules will react with radicals of lower molecular weight by a diffusion-controlled process, even when reaction of the isolated monomer, though fast, is not wholly diffusion-controlled.

## Amidothio-, Fluoroamidothio-, and Fluorothiophosphates

*H. H. Falius*, Braunschweig (Germany)

Reaction of phosphorus sulfide trichloride with aqueous ammonia gives ammonium diamidothiophosphate $NH_4[POS(NH_2)_2]$ and diammonium amidothiophosphate $(NH_4)_2[PO_2S(NH_2)]$. These salts can be readily isolated in pure form. The anions are quite stable in neutral aqueous and alkaline solution, but in acidic solution the diamidothiophosphate is rapidly hydrolysed to the monoamidothiophosphate; an acidic solution of the latter can be kept for several days in the cold without significant hydrolysis.

These compounds react extremely rapidly with hydrofluoric acid. In an excess of 20 % HF the amido groups are replaced by fluoride. The diamidothiophosphate thus gives the difluorothiophosphate $[POSF_2]^-$ with a small amount of the monofluorothiophosphate $[PO_2SF]^{2-}$, and the monoamidothiophosphate gives monofluorothiophosphate. The difluorothiophosphate is hydrolysed in acidic, HF-free solution to the monofluorothiophosphate.

The diamiodthiophosphate reacts with $F^-$ also in neutral solution, but not as far as in acidic solution. Only one amido group is replaced in an aqueous solution of the diamidothiophosphate containing ammonium fluoride: the resulting anion is fluoroamidothiophosphate, which exchanges its second amido group in hydrofluoric acid with formation of difluorothiophosphate.

The two fluorothiophosphates are also formed on reaction of phosphorus sulfide trichloride with aqueous fluoride solutions. Products formed by reaction with ammonium fluoride and ammonia include the fluoroamidothiophosphate.

The phosphorus-sulfur bond in fluorothiophosphates is much stronger than in thiophosphates or amidothiophosphates owing to the electronegativity of the fluorine. This is shown by the resistance of the phosphorus sulfur bond to hydrolysis and by the fact that silver sulfide is formed only slowly on reaction with silver nitrate. The reason is clearly the increased strength of the $d_\pi$–$d_\pi$ bond between phosphorus and sulfur, evidence of which is being sought by spectroscopic methods.

[Lecture at Braunschweig (Germany), November 29th, 1965] [VB 967/275 IE]

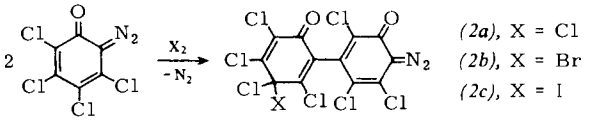
## New Results in the Preparative Chemistry of Diazocarbonyl Compounds

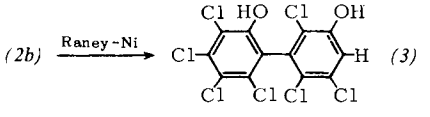
*E. Ried*, Frankfurt/Main (Germany)

Chlorine, bromine, or iodine react with tetrachloro-*o*-quinone diazide *(1)* already at room temperature, with elimination of nitrogen. Two molecules of quinone diazide dimerize by loss of one diazo group to compounds for which structure *(2)* is proposed.

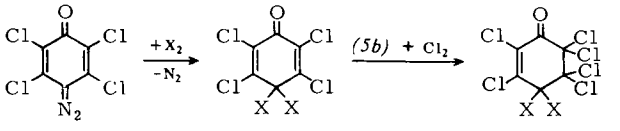


*(1)* *(2)* *(2a)*, X = Cl; *(2b)*, X = Br; *(2c)*, X = I

Raney nickel removes the halogen X again from *(2)*; simultaneously the oxo groups are converted into phenolic OH groups and the diazo group is exchanged for a H atom, giving the product *(3)*.

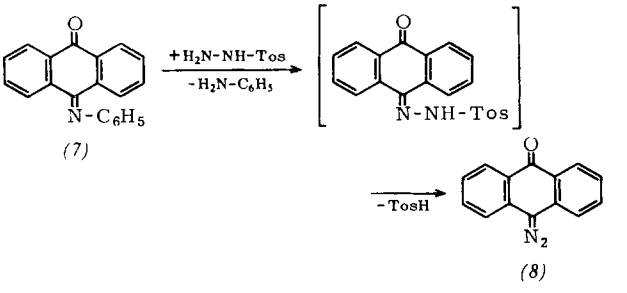


Tetrachloro-*p*-benzoquinone diazide *(4)* also loses nitrogen in presence of bromine or chlorine in ethanol. The halogen adds to the methylene-carbon [cf. *(5)*]. If an excess of halogen is used there is also addition to the C=C bond [cf. *(6)*].



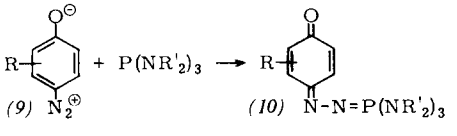
*(4)* *(5a)*, X = Cl; *(5b)*, X = Br *(6)*

Reaction of anthraquinone anil *(7)* with *p*-toluenesulfonylhydrazide leads smoothly to anthraquinone diazide *(8)*, but direct treatment of anthraquinone with the hydrazide is fruitless.



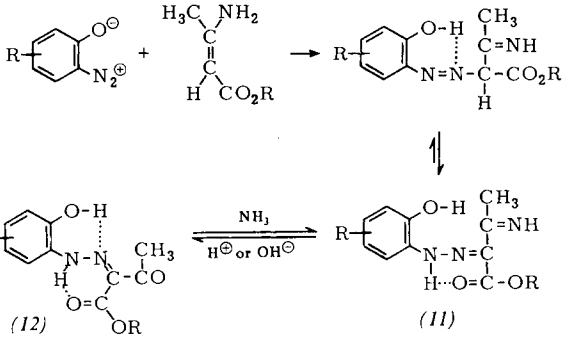
*(7)* *(8)*

*p*-Benzoquinone diazides *(9)*, analogously to *o*-quinone diazides[1], and triaminophosphines afford phosphorotriamide 4-oxocyclohexadienylidenehydrazones ("*p*-quinone triaminophosphazines") *(10)* which were previously unknown and are stable towards heat and hydrolysis.



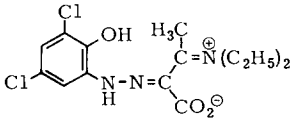
*(9)* *(10)*

In contrast to the reaction of ketenes, that of enamines with *o*-benzoquinone diazides does not lead to formation of oxadiazepines, but instead to coupling, with formation of *o*-hydroxyphenylhydrazones or *o*-hydroxyazo compounds. 3-Aminocrotonic esters or their *N*-monoalkyl derivatives give *o*-hydroxyarylhydrazones *(11)* of 3-imino-2-oxobutyric ester, which are cleaved by acid hydrolysis to *o*-hydroxyarylhydrazones of 2,3-dioxobutyric esters. In many cases the hydrolysis products can be isolated by coupling of *o*-quinone diazides with acetoacetic ester.



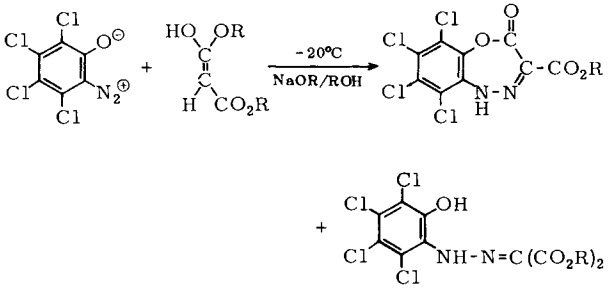
*(12)* *(11)*

*N,N*-Dialkyl derivatives of 3-aminocrotonic esters and *o*-quinone diazides couple only in sodium carbonate solution, the ester being hydrolysed to the acid and betaines [*e.g.*, *(13)*] formed.

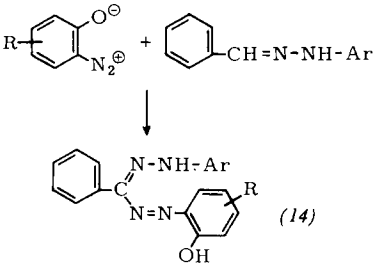


*(13)*

In certain cases sodiomalonic ester, which can be regarded as a concealed ketene derivative, adds to *o*-quinone diazides, *e.g.*:



Aldehyde arylhydrazones and *o*-quinone diazides couple to give hydroxylated formazans *(14)*, which function as indicators and give stable complexes with heavy-metal ions.



*(14)*

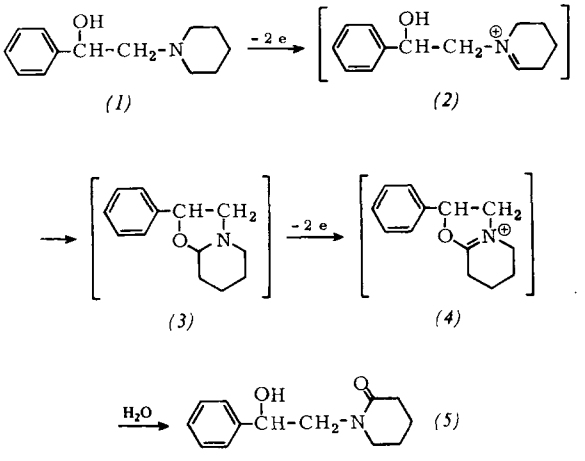
## Dehydrogenation of Amine Derivatives with Hg-EDTA

*H. Möhrle*, Tübingen (Germany)

Since the work of *Gadamer* mercury(II) acetate has been used for dehydrogenation of amines, a variant of the method, due to *Knabe*, being addition of disodium EDTA. Comparative

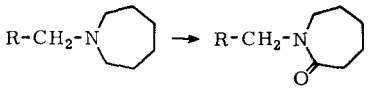
experiments have shown that Hg(II) acetate dehydrates at a higher redox potential but more slowly. When applied to amino alcohols, the two methods on occasions give different results. With Hg(II)-EDTA, lactams are formed in a reaction for which the following mechanism is assumed on the basis of model experiments. The amino alcohol, say *(1)*, is oxidized to an imonium compound *(2)*, which rearranges intramolecularly to the oxazolidine *(3)*. Further oxidation affords the hydroxy-lactam *(5)* by way of the oxazolinium cation *(4)*.



Whereas the existence of the imonium structure can be proved indirectly for open-chain amino alcohols through their hydrolysis products, this structure cannot be isolated from simple *N*-heterocyclic compounds. Nevertheless, formation of the oxazolidine from tetrahydro-2-(2-hydroxyethyl)isoquinolines involves increased ring strain, so that in these cases the hydroxy-imonium form [cf. *(2)*] can be isolated as a salt or, if worked up in an alkaline medium, as an oxazolidine.

For these relatively stable oxazolidines the rates of dehydrogenation with and without addition of disodium EDTA to the Hg(II) acetate solution have been compared as far as the hydroxy-lactam stage; here too, faster reaction was found with Hg(II)-EDTA.

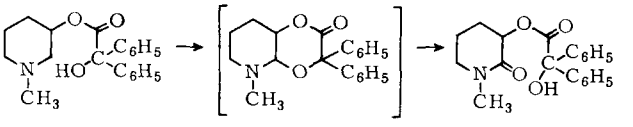
On variation of the heterocyclic component the lactams *(5')* were obtained from the amino alcohols *(1')*.



*(1')* *(5')*

R = $C_6H_5$-CH(OH), $C_6H_5$-CH(OH)-$CH_2$, $C_6H_5$-O-$CH_2$-CH(OH)

The ester *(6)* gives a lactam *(7)*, which shows that there is no necessity for the nitrogen to be the bridgehead-atom of an intermediate bicyclic compound.



*(6)* *(7)*

# SELECTED ABSTRACTS

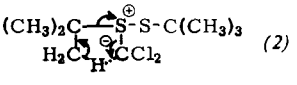
**The hydrogenation of carbodiimides to N,N'-disubstituted formamidines** with $Pd(OH)_2/BaSO_4$ and with Raney nickel has been studied by *J. C. Jochims*. On catalytic hydrogenation (room temperature, normal pressure) in ethanol, aliphatic, aromatic, and mixed carbodiimides rapidly take up 1 mole of $H_2$ to form *N,N'*-disubstituted formamidines *(1)*. The yields are generally higher than 90 %.

$$R{-}N{=}C{=}N{-}R' \rightarrow R{-}NH{-}CH{=}N{-}R'$$
*(1)*

Examples: *N,N'*-dicyclohexylformamidine, m.p. 97–99 °C, yield 99 %; *N*-isopropyl-*N'*-cyclohexylformamidine, m.p. 69–71 °C, yield 99 %; *N,N'*-bi(benzhydryl)formamidine, m.p. 90–91 °C, yield 99 %, *N,N'*-bis-(4-methoxyphenyl)-formamidine, m.p. 114–115 °C, yield 50 %. / Chem. Ber. *98*, 2128 (1965) / –Ma. [Rd 385/594 IE]

**The selective cleavage of a carbon-sulfur bond** in a disulfide has been observed for the first time by *S. Searles jr.* and *R. E. Mann*. The reaction of t-butyl disulfide with dichlorocarbene gives an 80 % yield of t-butyl dichloromethyl disulfide *(1)*, the S–S bond remaining intact.

$$(CH_3)_3C{-}S{-}S{-}C(CH_3)_3 + Cl_2C: \rightarrow (CH_3)_3C{-}S{-}S{-}CHCl_2 + (CH_3)_2C{=}CH_2$$
*(1)*



*(2)*

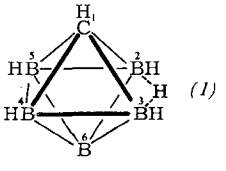
The reaction involves treatment of a boiling solution of the disulfide in glycol dimethyl ether with sodium trichloroacetate. It probably proceeds *via* the ylide *(2)*. / Tetrahedron Letters *1965*, 2899 / –Ma. [Rd 382/591 IE]

**Bis(trifluoromethylsulfonyl) peroxide and trifluoromethyl trifluoromethanesulfonate** have been prepared by *R. E. Noftle* and *G. H. Cady*. When trifluoromethanesulfonic acid is electrolysed at –23 °C, bis(trifluoromethanesulfonyl) peroxide $CF_3SO_2{-}OO{-}SO_2CF_3$ is formed at the anode. When heated to 10 °C, the peroxide decomposes to form perfluoroethane, sulfur trioxide, and the new ester trifluoromethyl trifluoromethanesulfonate $CF_3SO_3CF_3$. The ester is stable towards water; hydrolysis occurs only at 100 °C in 0.1 N sodium hydroxide solution. The decomposition products formed when the peroxide is heated can be accounted for by the following hypothetical mechanism:

$$(CF_3SO_3)_2 \rightarrow 2\ CF_3SO_3\bullet$$
$$CF_3SO_3\bullet \rightarrow CF_3\bullet + SO_3$$
$$CF_3SO_3\bullet + CF_3\bullet \rightarrow CF_3SO_3CF_3$$
$$2\ CF_3\bullet \rightarrow C_2F_6$$

/ Inorg. Chem. *4*, 1010 (1965) / –Sch. [Rd 432/641 IE]

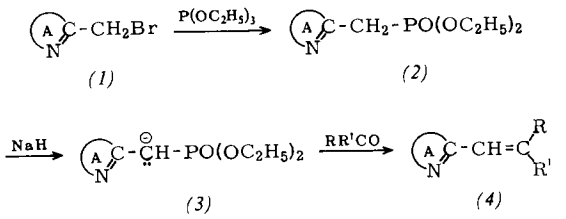
**Monocarbahexaborane(7)** *(1)*, the first carborane with only one carbon atom, was made by *T. Onak, R. Drake*, and *G. Dunks* by passing a silent electrical discharge through 1-methylpentaborane: 0.15 mole yielded 13 mg of *(1)*, which has a



*(1)*

vapor pressure of 503 mm at 26 °C. The structure *(1)* is supported by the infrared and NMR spectra, but the bridging hydrogen could also be located between B–2 and B–6. / J. Amer. chem. Soc. *87*, 2505 (1965) /–Ma. [Rd 347/556 IE]

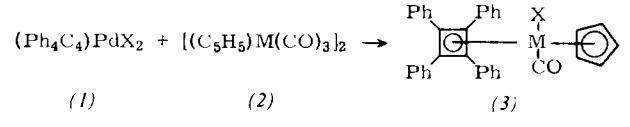
**The synthesis of basic heterocyclic alkenes** by the Horner reaction has been described by *E. B. Knott*. The reaction of the bromomethyl compounds *(1)* (A = 2-benzothiazolyl or 2-quinolyl) with $P(OC_2H_5)_3$ gives *(2)*. Treatment of *(2)* with NaOH yields the anion *(3)*, which reacts with a wide range of aldehydes and ketones to form the alkenes *(4)*.



*(1)* *(2)* *(3)* *(4)*

Example: A = 2-benzothiazolyl, R = H, R′ = $C_6H_4N(CH_3)_2$, m.p. 206 to 208 °C; A = 2-quinolyl, R = $CH_3$, R′ = $C_6H_5$, m.p. 102 to 103 °C. / J. chem. Soc. (London) *1965*, 3793 / –Kü. [Rd 416/625 IE]

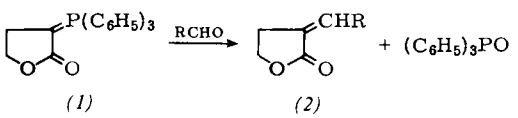
**(π-Cyclopentadienyl)(π-tetraphenylcyclobutadiene)-molyb-denum and -tungsten carbonyl halides** have been by prepared *P. M. Maitlis* and *A. Efraty*. The heterogeneous reaction of tetraphenylcyclobutadienepalladium halides *(1)* with cyclopentadienylmetal tricarbonyl *(2)* leads to the formation of (π-cyclopentadienyl) (π-tetraphenylcyclobutadiene)-metal carbonyl halides *(3)*.



*(1)* *(2)* *(3)*

[*(3a)*: M = Mo, X = Cl, decomp. p. 261 to 266 °C; *(3b)*: M = Mo, X = Br, decomp. p. 248 to 250 °C; *(3c)*: M = W, X = Br, decomp. p. 227 to 228 °C]. The molybdenum complexes *(3a)* and *(3b)* are formed in xylene in yields of approximately 18 %, whereas the tungsten complex *(3c)* is formed in benzene in a yield of about 1 %. *(3a)* and *(3b)* form red-brown crystals, which are stable in air; however, their solutions are very sensitive to heat and to air. In the NMR spectrum of *(3a)*, the areas of the phenyl-proton and the cyclopentadienyl-proton signals are in the ratio of 20:5. The infrared spectra of all the compounds are identical, indicating that the complexes all have the same structure. / J. organomet. Chemistry *4*, 172 (1965) / –Sch. [Rd 429/638 IE]

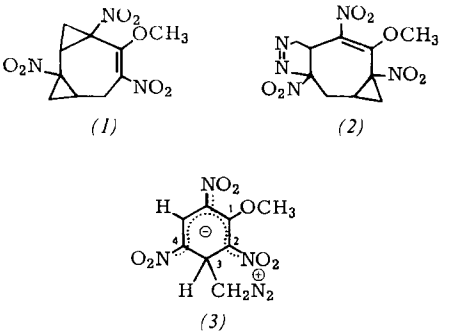
**Substituted α-benzylidene-γ-butyrolactones** *(2)* have been synthesized by *H. Zimmer* and *T. Pampalone* using a Wittig carbonyl olefination. α-Benzylidene derivatives could previously be obtained only with difficulty, if at all, by the direct reaction of butyrolactone with substituted aromatic aldehydes, but were now made in excellent yields by treating substituted aldehydes with *(1)* in refluxing tetrahydrofuran. Compounds made include *(2)* with R = 3-nitrophenyl, m.p. 147–148 °C



*(1)* *(2)*

(81 % yield); R = 4-cyanophenyl, m.p. 157–159 °C (82 %); and R = 4-acetamidophenyl, m.p. 199–200 °C (89 %). / J. heterocycl. Chemistry *2*, 95 (1965) / –Ma. [Rd 346/555 IE]

**Diazomethane adds to picric acid** to form the cycloheptene derivatives *(1)* and *(2)*, as has been reported by *Th. J. de Boer*.



*(1)* *(2)*

*(3)*

The first step is the addition of one molecule of diazomethane to form 2,4,6-trinitroanisole, and this is followed by the addition of a second molecule of diazomethane on C-3, with formation of the compound *(3)*. A three-membered ring can be formed by elimination of nitrogen accompanied by ring closure on C-2 or C-4. The compounds isomerize to form 2,4,6-trinitro-5-methoxycyclohepta-1,3,5-triene and 2,4,6-trinitro-5-methoxycyclohepta-2,4,6-triene. Further molecules of diazomethane can now add readily to the double bonds, which are strongly activated by the nitro groups. Addition of one molecule of $CH_2N_2$ to the double bond between C-3 and C-4 in the cyclohepta-1,3,5-triene derivative yields a substituted homotropilidene, *i.e.* a molecule with a fluctuating structure. *(1)* and *(2)* can be converted by oxidative degradation into nitrocyclopropanes, which are difficult to obtain by other methods. / Tetrahedron *20*, Suppl. 1, 339 (1964) / –Bu. [Rd 446/655 IE]

**Mitochondria are not the only cell organelles with an oxidizing function.** *P. Baudhuin et al.* describe a new type of microscopic particle which they have discovered in rats' liver and kidneys and in *Tetrahymena pyriformis*. The particles are characterized as containing uric acid oxidase, D-amino acid oxidase, and catalase, *i.e.* two enzymes that form hydrogen peroxide and one that decomposes hydrogen peroxide. It is thought that the particles are the site of non-phosphorylating oxidations, which lead to the formation of $H_2O_2$. / Biochem. biophys. Res. Commun. *20*, 53 (1965) / –Hö. [Rd 406/615 IE]

**Succinyl phosphate is an intermediate in the biosynthesis of succinyl-coenzyme A** from succinate, CoA, and ATP in *Escherichia coli*, which is catalysed by succinyl-CoA synthetase. *J. S. Nishimura* and *A. Meister* have shown that the reaction proceeds by the route:

$$\text{Succinate} + \text{ATP} \rightleftharpoons \text{succinyl phosphate} + \text{ADP}$$
$$\text{Succinyl phosphate} + \text{CoA} \rightarrow \text{succinyl-CoA} + \text{phosphate}$$

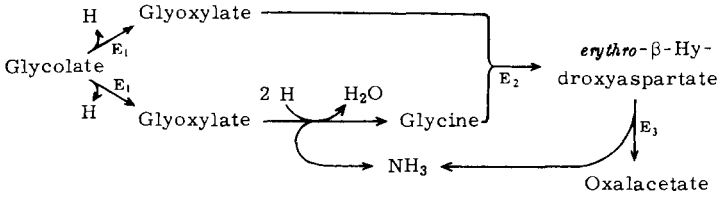
This scheme involves four reaction steps: 1. succinyl-CoA is formed from succinyl phosphate and CoA; 2. incubation of the enzyme with ADP and succinyl phosphate leads to the formation of ATP; 3. labelled succinyl phosphate (which was identified by paper chromatography) is formed from [$\gamma$-$^{32}$P]-ATP and succinate; 4. the enzyme is phosphorylated during incubation with succinyl phosphate, the phosphorylation being reduced in the presence of CoA or ADP. Thus the synthesis of succinyl-CoA differs from that of acetyl-CoA, which proceeds by the following scheme:

$$\text{Acetate} + \text{ATP} \rightleftharpoons \text{acetyl-AMP} + \text{pyrophosphate}$$
$$\text{Acetyl-AMP} + \text{CoA} \rightarrow \text{acetyl-CoA} + \text{AMP}$$

The carboxyl-activated acyl derivatives remain bound to the enzyme in both cases. / Biochemistry *4*, 1457 (1965) / –Hö. [Rd 408/617 IE]

**8,9,13-Triacetoxydocosanoic acid** is produced by yeast (NRRL YB-2501) as an extracellular lipid. *F. H. Stodola, R. F. Vesonder,* and *L. J. Wickerham* have found that 1.5 g/l of the acid are excreted into the medium (aqueous solution of glucose and salts) in seven days at 25 °C. The crude lipid was extracted with hexane and purified by chromatography on silica gel. Its composition was $C_{28}H_{50}O_8$ (oil), after hydrolysis $C_{22}H_{44}O_5$ (m.p. 157 to 158 °C). This trihydroxy acid was reduced with hydrogen iodide to docosanoic acid; reaction with periodic acid gave an aldehydo acid, which could be oxidized to suberic acid. The other fragment was the liquid 5-hydroxytetradecanal. / Biochemistry *4*, 1390 (1965) / –Hö. [Rd 407/616 IE]

**A new route for the utilization of glycolic acid** has been found by *H. L. Kornberg* and *J. G. Morris* in *Micrococcus denitrificans*. The bacteria were grown on [2-$^{14}$C]-glycolate as their only source of carbon. The first reaction product was glyoxylate, and other labelled products found included glycine, aspartate, malate, and glutamate, and after a time, phosphoglycerate. The key intermediate was *erythro*-β-hydroxyaspartate, giving the following "β-hydroxyaspartate metabolic path":



The glycolate oxidase ($E_1$) could be induced by glycolate. The enzymes $E_2$ and $E_3$, which catalyse the synthesis of β-hydroxyaspartate and its conversion into oxalacetate, could be induced by glycolate and glyoxylate. Glyoxylate carboligase and aldehydotartronic acid reductase were present only in negligible concentrations. / Biochem. J. *95*, 577 (1965) / –Hö. [Rd 409/618 IE]

**1,2-Diphenyl-1,2-diarsacyclopentane and 1,2-diphenyl-2,1-diarsacyclohexane** have been prepared by *A. Tzschach* and *G. Pacholke*. Alkali metal organoarsides *(1)* react exothermically with 1,2-dibromoethane in tetrahydrofuran or benzene:

$$C_6H_5\text{-}\underset{\text{Li}}{\text{As}}\text{-}(CH_2)_n\text{-}\underset{\text{Li}}{\text{As}}\text{-}C_6H_5 + Br\text{-}CH_2\text{-}CH_2\text{-}Br \rightarrow$$

*(1)*

$$\text{(}(CH_2)_n\text{ with }\underset{}{\text{As}}\text{-}C_6H_5\text{ and }\underset{}{\text{As}}\text{-}C_6H_5\text{)} + 2\ LiBr + H_2C{=}CH_2$$

*(2a)*: n = 3
*(2b)*: n = 4

*(2a)*, b.p. 193–195 °C/3 mm, yield 56 %
*(2b)*, b.p. 203–206 °C/4 mm, yield 68 %

The first step in the reaction may be a metal-halogen exchange to form the compound *(3)*, which is then thought to undergo an intromolecular elimination of LiBr, with formation of the cyclic biarsines *(2a)* and *(2b)*. The As–As bond in *(2a)* and *(2b)* can be broken by both nucleophilic and electrophilic reagents.

$$(2) + LiR \rightarrow \underset{(4)}{R(C_6H_5)As\text{–}(CH_2)n\text{–}As(C_6H_5)Li}$$

$R = C_6H_5, C_4H_9$

The compounds *(4a)*, n = 3, and *(4b)*, n = 4, were isolated as the dioxane adducts. / Z. anorg. allg. Chem. *336*, 270 (1956) / –Sch. [Rd 433/642 IE]

**Potassium dioxofluoroselenate(IV)** has been obtained by *R. Paetzold* and *K. Aurich* by the fusion of equimolar quantities of KF and $SeO_2$ and by reaction of $K_2SeO_3$ with $SeOF_2$.

$$KF + SeO_2 \rightarrow FSeO_2K \quad KSeO_2F$$

$$K_2SeO_3 + SeOF_2 \rightarrow 2\ SeO_2FK$$

Potassium fluoroselenate(IV) is a white crystalline substance which melts at 250 °C without decomposing, and which is very sensitive to water. Study of the hydrolysis by infrared spectroscopy showed that the products include potassium hydrogen selenite, potassium hydrogen fluoride, and selenious acid. The hydrolysis proper:

$$KSeO_2F + H_2O \rightarrow KSeO_2OH + HF$$

is followed by the reaction:

$$2\ HF + KSeO_2OH \rightarrow KHF_2 + (HO)_2SeO$$

which evidently takes place because of the high stability of $KHF_2 \cdot KSeO_2F$ reacts with methanol in the same way as with water. / Z. anorg. allg. Chem. *335*, 281 (1965) / –Sch. [Rd 434/643 IE]

**Organosilicon radicals,** according to *C. Eaborn, R. A. Jackson,* and *R. W. Walsingham*, are formed by photolysis or by pyrolysis (195 °C, 2 weeks, light excluded) of bis(trimethylsilyl)mercury in toluene. In addition to the expected Hg and hexamethyldisilane, the products include trimethylsilane, bibenzyl, benzyltrimethylsilane, and a number of polysilane derivatives. The reaction in benzene under the same conditions yields trimethylsilane and phenyltrimethylsilane. These findings can be explained by the following scheme:

$$Hg[Si(CH_3)_3]_2 \rightarrow Hg + 2\ CH_3Si^{\bullet}$$

$$2\ (CH_3)_3Si^{\bullet} \rightarrow (CH_3)_3SiSi(CH_3)_3$$

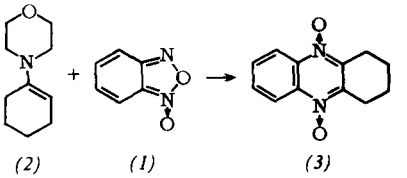
$$(CH_3)_3Si^{\bullet} + CH_3\text{–}Ph \rightarrow (CH_3)_3SiH + Ph\text{–}CH_2^{\bullet}$$

$$Ph\text{–}CH_2^{\bullet} + {}^{\bullet}Si(CH_3)_3 \rightarrow Ph\text{–}CH_2\text{–}Si(CH_3)_3$$

$$2\ Ph\text{–}CH_2^{\bullet} \rightarrow Ph\text{–}CH_2CH_2\text{–}Ph$$

/ Chem. Commun. (London) 1965, 300 / –Ma. [Rd 389/598 IE]

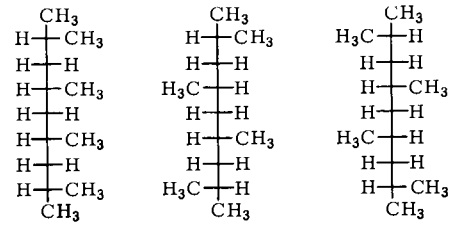
**A new synthesis of quinoxaline di-N-oxides** from enamines and benzofuran *N*-oxide *(1)* is described by *M. J. Haddadin* and *C. H. Issidorides*. When 1-morpholinocyclohex-1-ene *(2)* is added to a warm methanolic solution of *(1)*, 1,2,3,4-tetrahydrophenazine di-*N*-oxide *(3)* [m.p. 185 °C (decomp.)]



*(2)* *(1)* *(3)*

is formed in 48 % yield. Enamines of cyclopentanone, acetophenone, and cholestan-3-one react with *(1)* to form similar compounds having the melting points 182 °C (decomp.), 210 °C, and 208 °C, respectively. / Tetrahedron Letters 1965, 3253 / –Ma. [Rd 387/596 IE]

**The synthesis of meso-, racemic, and (−)-(4R:6R)-2,4,6,8-tetramethylnonane,** the simplest model compounds for isotactic and syndiotactic polypropylenes, is described by *P. Pino, S. Pucci, E. Benedetti,* and *P. Bucci.* The starting material



*(a)* *(b)*

(4S:6R) (4R:6R) (4S:6S),

*Meso*, isotactic, b.p. = 82.5 °C/20 mm Hg *(a)*

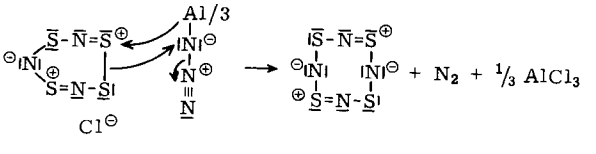
*rac.*, syndiotactic, b.p. = 85 °C/22 mm Hg *(b)*

was (+)-*(R)*-2,6,8-trimethylnonan-4-one, which was converted *via* the intermediate 2,4,6,8-tetramethylnonan-4-ol and a mixture of isomeric olefins, into 2,4,6,8-tetramethylnonane. The diastereoisomers *(a)* and *(b)* of this last compound were separated by distillation. / J. Amer. chem. Soc. *87*, 3263 (1965) / −Ma. [Rd 388/597 IE]

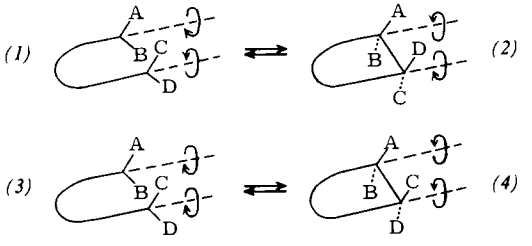
**Cycasin, a natural carcinogenic compound,** exhibits radiomimetic effects. Cycasin (methylazoxymethyl β-glucoside) is found in cycad plants (fern palms), *e.g., Cycas circinalis* L. Investigations by *H. J. Teas, H. J. Sax,* and *K. Sax* have shown that cycasin causes changes in the chromosomes in the root-tip cells *of Allium cepa* (var. Dowing Yellow Globe). Germination and growth of the onion plants in aqueous solutions containing cycasin at only 3 % of the concentration present in *Cycas circinalis* leads to chromosome changes corresponding to those caused by a γ-radiation dose of 200 Röntgen. / Science (Washington) *149*, 541 (1965) / −De. [Rd 435/644 IE]

**A synthesis of nitriles from aldehydes** is given by *K. N. Parameswaran* and *O. M. Friedman.* The aldehyde is dissolved in anhydrous benzene and dry ammonia is passed in under nitrogen. Lead tetraacetate is then added in portions over 0.5–2.5 h, and the solution is stirred for several hours. The nitrile, which is presumably formed by oxidation of the aldimine resulting from condensation of the aldehyde with the ammonia, can then be isolated. An approximately five-fold excess of oxidizing agent is used. Products obtained in this way include 3,4,5-trimethoxybenzonitrile (75.4% crude yield), *p*-nitrobenzonitrile (81 %), *trans*-cinnamonitrile (89 %), furfuronitrile (36.5 %), n-heptanenitrile (59 %), and n-butyronitrile (14 %). / Chem. and Ind. *1965*, 988 / −Ma. [Rd 357/566 IE]

**A ring expansion of the thiotrithiazyl cation** $[S_4N_3]^{\oplus}$, a planar 7-membered ring system, to give the 8-membered cage system of sulfur nitride $S_4N_4$ was achieved by *M. Becke-Goering* and *G. Magin.* When $S_4N_3^{\oplus}Cl^{\ominus}$ was added to a solution of aluminum azide in tetrahydrofuran, nitrogen was released. The reaction was completed at 40–50 °C, and when the reaction mixture was filtered and the filtrate evaporated to dryness and extracted with benzene, $S_4N_4$ was obtained in 85–90% yield. A yield of about 70% was obtained with lithium azide in acetonitrile. / Z. Naturforsch. *20b*, 493 (1965) / −Ma. [Rd 358/567 IE]



**An explanation for the stereospecificity of electrocyclic reactions** has been advanced by *R. B. Woodward* and *R. Hoffmann.* Electrocyclic reactions are isomerizations in which a σ-bond is formed between the terminal C atoms of an open-chain π-electron system, or in which the reverse process takes place. The stereochemistry of the products depends on whether the groups attached to the terminal C atoms rotate in opposite directions [disrotative, *e.g.*: *(1)* → *(2)*] or in the same direction [conrotative, *e.g.*: *(3)* → *(4)*].

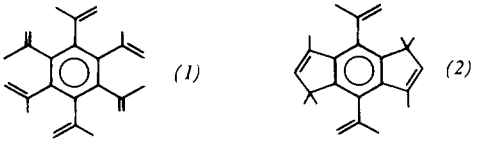


The stereochemical course of the reaction is determined by the symmetry of the highest occupied molecular orbitals of the open-chain reactant. In a 4n π-electron system, bonding between the ends of the system must be accompanied by conrotation, while in a(4n+2) π-electron system, bonding must be accompanied by disrotation. This is in fact found to be the case in all thermally induced electrocyclic reactions. In photolytic reactions, on the other hand, an electron is raised into the first excited state, so that the symmetry conditions are reversed. Thus the reactions of 4n π-electron systems is accompanied by disrotation, and those of (4n + 2) π-electron systems by conrotation.

This approach can also be used in the case of intermolecular synchronous cycloadditions (*e.g.* Diels-Alder reactions). If an open-chain system containing n π-electrons reacts with an open-chain system containing m π-electrons, so that two σ-bonds are formed in place of two π-bonds, the thermal reaction is possible if n + m = 4q + 2, while the photochemical reaction is possible if n + m = 4q (where q is a whole number).

Similar rules can also be formulated for reactions in which x σ-bonds are formed from x π-bonds. All these rules apply only to synchronous reactions. Where the course of a reaction is contrary to these rules, it must be assumed to proceed in more than one step (*e.g.* the dimerization of allenes and ketenes). / J. Amer. chem. Soc. *87*, 395, 2046 (1965) / −Bu. [Rd 447/656 IE]

**Hexaisopropenylbenzene *(1)*, an inert polyolefin,** is described by *E. M. Arnett, J. M. Bollinger,* and *J. C. Sanda.* Compound *(1)* ought to be highly reactive but is almost inert towards even very strong double-bond reagents. It was made in 4% yield from di-isopropenylacetylene and dicobalt octacarbonyl by heating the reagents in refluxing Skellysolve C and melts at 260–263 °C. It cannot be hydrogenated catalytically, does not react with tetracyanoethylene, and is only slightly substituted after prolonged standing with bromine in



carbon tetrachloride. It is however sensitive towards irradiation and strong acids. Concentrated sulfuric acid converts *(1)* into an orange carbonium ion, which yields an isomer, possibly of structure *(2)*, on treatment with base. The amazing lack of reactivity of *(1)* can be explained by the mutual shielding of the neighboring isopropenyl groups. / J. Amer. chem. Soc. *87*, 2050 (1965) / −Ma. [Rd 359/568 IE]

**Methoden der organischen Chemie** (Methods in Organic Chemistry) (Houben-Weyl). Edited by *Eugen Müller*, Vol. XII, Part 2. Organische Phosphorverbindungen (Organic Phosphorus Compounds). Compiled by *K. Sasse*. Georg Thieme Verlag, Stuttgart 1964. 4th completely revised Edition, LXXXVII + 1131 pp., 195 tables, one diagram, DM 280.–.

The user of Part 1 of "Organische Phosphorverbindungen" will have eagerly awaited the publication of the present Part 2. This part deals with compounds containing no phosphorus–carbon bonds, *i.e.* mainly with compounds that can be regarded as derivatives of phosphoric and phosphorous acids. Variation of the nature and number of organic groups, replacement of oxygen by sulfur, halogen or nitrogen, anhydride formation, *etc.*, permits the derivation of an almost countless number of types of compounds.

*Kosolapoff*'s monograph "Organophosphorus Compounds" (which now, fifteen years after its publication, is no longer adequate) has until now been the only existing review of this subject. A complete account of the field as a whole is difficult, not only because of the volume of the relevant literature, but also because of its heterogeneity. Owing to the great technical importance of these compounds (as insecticides, plasticizers, *etc.*), a very large proportion of the literature is represented by patents. Moreover, many important original papers have appeared in Russian journals, which are not always accessible. The fact that, in spite of such difficulties, a single author has managed to compile a complete and comprehensive review can be regarded as an achievement of the highest order in the field of scientific literature.

Part 2, like Part 1, is arranged according to classes of compounds. For example, the *O,O* diesters of thiophosphoric acid are discussed in the section of "Organic derivatives of phosphoric acid Derivatives of thiophosphoric acids", under "Esters and ester halides of thiophosphoric acids". The thiophosphoric acids are divided into 24 sub-groups.

The preparation and transformations of the various types of compounds are described in special sections. The preparative procedures are grouped according to starting materials, and are illustrated by representative examples. Many tables are included to show the compounds prepared by given methods. The short section on "Transformations" can be confined to little more than a brief list of properties together with a few notes, since the "transformation" is generally discussed in detail under "Preparation". The subject index contains about 10000 compounds.

To sum up, it can be said that *K. Sasse* has produced a new standard work on the organic chemistry of phosphorus. In view of the rapid progress being made in this field, however, it is impossible to predict how long it will be valid. In any case, by virtue of the numerous suggestions offered, the book will undoubtedly make a considerable contribution to further progress and hence to its own "obsolescence".

*H. Hoffmann* [NB 421/292 IE]

**Nuclear Techniques in Analytical Chemistry.** By *A. J. Moses*. International Series of Monographs on Analytical Chemistry. Edited by *R. Belcher* and *L. Gordon*. Pergamon Press, Oxford - London - Edinburgh - New York - Paris - Frankfurt 1964. 1st Edit., VII + 142 pp., numerous illustrations and tables, 1 color plate, £ 2.5.0.

There is probably no other branch of chemistry in which radiochemical methods find such varied and valuable use as in analysis.

The present book, which describes the principal analytical applications of radiochemical methods (*i.e.* the methods of activation analysis, isotope-dilution analysis, radiometeric measurements, *etc.*), is therefore very welcome. However, those who hope to satisfy completely their thirst for knowledge in this field will be disappointed in many places; thus the book repeatedly recommends special methods of measurement or special practical procedures, but when the eager reader then seeks for details, he finds that he has to turn to other publications. On the other hand, where a method is described in detail, the description is very well presented and is supplemented by practical directions.

The value to the reader would have been greater, however, had the author commented on the directions, since these alone frequently do not explain to the inexperienced worker the need for a special procedure. Nevertheless, the reader will undoubtedly be pleased by the comprehensive bibliography provided.

*F. Baumgärtner* [NB 427/297 IE]

**Radionuklid-Tabellen** (Radionuclide Tables). Compiled by *W. Seelmann-Eggebert* and *G. Pfennig*; published by the Bundesministerium für wissenschaftliche Forschung. Verlag Gersbach & Sohn. München 1964. 1st edit., 79 pp., cardboard DM 4.– ($ 1.00).

The booklet lists the radionuclides in order of increasing nuclear charge, nuclides of the same element being arranged in order of increasing mass number. Owing to this simple arrangement, it is easy to find any given radionuclide. The types of decay, abundances, half-lives, and radiation energies are given for each nuclide. The table also gives the conversion coefficients and daughter nuclides, so that all the essential data are reported. Two additional tables show the estimated yields of a number of longer-lived fission products from tomic explosions and the cumulative yields for various fission reactions. Two diagrams are included to show the time-dependence of the percentage contributions of longer-lived fission products from atomic explosions to the total β-activity.

This book is an indispensible aid to all who work with radionuclides. Its publication is therefore very welcome, and its low price places it within the reach of all.

*W. Strohmeier* [NB 412/284 IE]

**Klinische Chemie, Theorie und Praxis** (Clinical Chemistry, Theory and Practice). By *R. Richterich*. Akademische Verlagsgesellschaft, Frankfurt/M., S. Karger AG., Basel 1965. 1st Edit., XII + 416 pp., 76 illustrations, 89 tables, DM 59.50 (about $ 15.–).

This new book by *Richterich* (whose Enzyme Pathology, which was published in 1957, is still a valuable reference work) is unusual in several respects. On glancing through it, one is impressed by the excellent layout. The divisions of the individual chapters are well marked and attention is drawn to important details by the use of "boxes". The divisions (in the case of experimental procedures these are: principle, reagents, procedure, calculation, and normal values) are marked in the margin, and this arrangement quickly familiarizes the reader with the book. It would be very gratifying if this clear, concise style were to become generally used in textbooks!

It is also unusual, at least in German-language books, to find advertisements in an appendix. However, anyone who has experienced the difficulty of equipping a small clinical-chemistry laboratory with apparatus and reagents will applaud the author's and publishers' courage in introducing this novel feature. It is to be hoped that the size of this appendix will be doubled in the next edition.

The book is not a reference work and is not claimed to be exhaustive; it can probably be best described as an introduction to clinical chemistry. It is accordingly dominated by the chapters on units of measurement, introduction to statistics,

normal values, reliability of samples, the sampling of blood, *etc.* The author makes many references to his own practical experience in this field. This can be seen already from the Table of Contents, which includes a code used by the author for classification purposes and as a key for punched cards.

Having been pampered by these excellent chapters on general clinical chemistry, which serve as an introduction to the special chapters, the reader becomes aware of the following shortcomings when he turns to the special chapters themselves: The arrangement of the material becomes unclear when he tries to refer to the book for details of methods. For example, the enzyme determinations are to be found in a number of different chapters. Furthermore, the selection of methods included is very narrow, and a number of important clinical determinations, such as the determination of iron, are omitted altogether.

However, this criticism ignores the aim of the book. As the author himself stresses in the preface, the emphasis is placed on the general part, which will still be valid when all the special methods are obsolete. It is to be hoped, and indeed it can almost be predicted, that this book will enjoy a very wide circulation. *F. W. Schmidt* [NB 422/293 IE]

**Handbuch der physiologisch- und pathologisch-chemischen Analyse, für Ärzte, Biologen und Chemiker** (Handbook of Physiological and Pathological Chemical Analysis, for Physicians, Biologists, and Chemists). By *Hoppe-Seyler/Thierfelder*, edited by *K. Lang* and *E. Lehnartz*, with the collaboration of *O. Hoffmann-Ostenhof* and *G. Siebert*. Vol. 6. Enzymes, Part A. Springer-Verlag, Berlin-Göttingen-Heidelberg-New York 1964. 10th Edit., XX + 1052pp., 119 illustrations, DM 360.–(subscription price DM 288.–).

Enzymatic methods are finding increasing use in quantitative analysis, and they have become indispensable in biochemical, clinical, and forensic medical laboratories. We therefore welcome the publication of this, the last volume of "Hoppe-Seyler/Thierfelder", which was originally intended to comprise only 5 volumes. The present book is the first of three parts of Vol. 6.

The first third of this sub-volume contains the general chapters on nomenclature and methods. *Hoffmann-Ostenhof* describes the classification and nomenclature of enzymes as well as enzyme units in a short, clear summary of the "Report of the Commission on Enzymes", published in 1961. Unfortunately, the rules given here and on page 348 are only partly adopted in the book. For example, the "suggested abbreviations" on page 19 do not correspond to those recommended by the Enzyme Commission, and it is particularly confusing when NAD and $DPN^+$ or $NADPH_2$ and TPNH are used side by side. An instructive introduction to enzyme kinetics (*Lumper*) should enable even workers with little experience to carry out a detailed and correct evaluation of kinetic experiments. The manometric methods are discussed (*Süllmann*) lucidly and at some length (224 pp.); this is followed by a brief outline of the use of the pH-stat (*Cunningham*) and a detailed account of the important Warburg optical test (*Bücher, Luh, Pette*). The scope of this method is clearly shown in this discussion: almost any enzyme or any metabolite can be determined optically. A chapter on the measurement of phosphate uptake during oxidative phosphorylation (*Klingenberg*) completes this excellent general section; probably the only important omissions are fluorescence methods and automatic methods.

The description of the enzymes, which are classified according to the five principal groups given in the "Report", begins with the oxidoreductases. This volume includes the pyridine nucleotide and flavin enzymes, as well as the copper enzymes and hydroxylases. A number of chapters, *e.g.* those on steroid dehydrogenases (*Breuer*, 125 pp.), isocitric acid dehydrogenase (*Siebert*, 27 pp.), 3-phosphoglyceraldehyde dehydrogenase (*Mohn*, 58 pp.), "lesser known pyridine nucleotide enzymes" (*Mohn*, 99 pp.) (are they really lesser known? The literature reference is ambiguous) and hydroxylases (*Abraham* et al., 131 pp.) are dealt with in great detail, the practical procedures being accompanied by a wealth of literature data such as cannot be found in any other review of this nature. Thus for information on any properties of these enzymes, these chapters offer a fine source. Other enzymes are dealt with much more briefly, the discussion being confined to practical procedures, as would be expected in a book on methods; this is the case with succinate dehydrogenase (*Slater*, 5 pp.), the copper enzymes (*Schirrmacher-Göllner*, 19 pp.) (uricase also is a copper enzyme!), "malic enzymes" (*Rutter*, 10 pp.) (the name "malic enzymes" should no longer be used!), and the "yellow enzymes" (*Nygaard*, 34 pp.). It is surprising to find that the flavin enzymes are accorded only about 50 pages (nitrate reductase is discussed in a single page, while no mention is made of the other enzymes that act on other N compounds and inorganic S compounds, or of *e.g.* dehydroorotic acid dehydrogenase), whereas the pyridine nucleotide dehydrogenases are spread over about 500 pages. Disparities exist between the various chapters, which suggest that the authors were allowed to decide for themselves how much detail to include in their own contributions.

In view of the high price of this book, it is regrettable that much of the literature cited extends only to 1960 or 1961, so that by the time of publication (November 1964), some chapters were largely out of date. This is particularly true for glucose 6-phosphate dehydrogenase (the enzymes from yeast and from bovine mammary glands were crystallized in 1961) and glutamic acid dehydrogenase. It is advantageous when the dates of the latest publications considered are given, as is done on pages 423 and 917.

Apart from these criticisms, the present volume will be a valuable aid to the enzyme chemist, and will provide him with a wealth of information. In many cases, he will be able to carry out estimations and preparations without recourse to the original publications. The usefulness of this volume will be greatly increased when the index, planned for Volume C, becomes available. It is to be hoped that it will then be possible to report on the hemin enzymes. The print (on yellow paper!) and layout of the book are excellent. *H. Sund* [NB 426/296 IE]

**Advances in Drug Research**, Vol. 1. Edited by *N. J. Harper* and *Alma B. Simmonds*. Academic Press, London-New York 1964. 1st Edit. X + 209 pp., numerous tables and several illustrations, £ 2.10.0.

In the first chapter, *Doyle* and *Nayler* review the chemical structure and action of penicillins and related compounds. This review is competent and up-to-date, and even includes a discussion of the new cephalosporins. The pharmacology of therapeutically interesting compounds, on the other hand, is dealt with rather briefly.

The chapter by *L. S. Schlanker* on the physiological transport of drugs contains fundamental observations on passive transport and on the possibilities of resorption in the gastrointestinal tract in relation to the physical conditions. Short sections are also devoted to transport processes in the various organs of mammals. The review as a whole is well organized and very informative.

The chapter on antitussives by *Doyle* and *Mehta* begins with a description of the coughing reflex and methods of testing the inhibition of coughing. The many cough-inhibiting compounds are considered from the chemical point of view, but the pharmacological aspects are also taken into account. The result is a comprehensive review.

*S. C. Copp* reviews adrenergic neuron blocking agents. A brief description of the methods used for the detection of pharmacological action is followed by a discussion of the active substances discovered so far. This chapter also is written largely from the point of view of structure and action. Most of the substances discussed are related to bretylium or guanethedine. The beta-receptor blocking substances are not considered. This chapter provides a particularly good picture for the chemist. *M. Kramer* [NB 411/283 IE]

**Purines, Pyrimidines, and Nucleotides, and the Chemistry of Nucleic Acids.** A Course in Organic Chemistry. Edited by *R. Robinson*. Advanced Section Vol. XXV. By *T. L. V. Ulbricht*. The Commonwealth and International Library. Edited by *R. Maxwell*. The Macmillan Company, New York, and Pergamon Press, Oxford-London-Edinburgh-Paris-Frankfurt 1964. 1st Edit., VII + 79 pp., 1 illustration, £ 0.12.6.

It is no easy undertaking to condense the chemistry of the purines, pyrimidines, and nucleotides into a 75-page monograph in such a way as to produce a well-rounded and easily understandable review. The purpose of the present monograph is to provide an introduction to the fundamentals of the chemistry of purines and pyrimidines, since this is dealt with only very briefly in most text-books of organic chemistry, particularly those written in English. The author, himself a well-known worker in this field, manages to present an excellent survey in only 60 pages and references to original papers are given at the end of each chapter for those who wish to make a deeper study. It is questionable, however, whether the chapter on nucleic acids (10 pages) should have been included in this short monograph.

*F. Cramer* [NB 423/294 IE]

**Nucleotides and Coenzymes.** By *D. W. Hutchinson*. Methuen's Monographs on Biological Subjects. Edited by *R. Peters* and *F. G. Young*, Methuen & Co., London, J. Wiley & Sons, Inc., New York, 1964. 1st Edit., VIII + 136 pp. £ 0.18.0.

This booklet is intended as a chemical supplement to the widely-read "Biochemistry of Nucleic Acids" by *J. N. Davidson* ("The Child's Guide to the Nucleic Acids"), with particular reference to low-molecular weight compounds. The discussions cover nucleosides, nucleotides, oligonucleotides, and polynucleotides, as well as the nucleotide coenzymes, pyridoxal phosphate and thiamine pyrophosphate. A wealth of data is presented in a well-organized manner and supported by extensive bibliographies at the ends of the chapters. Biochemical aspects are taken into account but the emphasis is placed on the chemical viewpoint.

A number of inaccuracies will undoubtedly be corrected in a second edition. For example, the biosynthesis of pseudouridine can by no means be regarded as having been generally elucidated, and the model for the secondary structure of sRNA has now been revised. Formulae of the nucleosides are not given in the usual, stereochemically unambigous notation. In spite of these minor short-comings, the book undoubtedly offers a good introduction to the nucleotide field.

*H. G. Zachau* [NB 413/285 IE]

**Topics in Phosphorus Chemistry,** Vol. 1. Edited by *M. Grayson* and *E. Griffith*. Interscience Publishers, a Division of J. Wiley & Sons, New York-London-Sydney 1964. 1st Edit., VII + 262 pp., numerous illustrations and tables, £ 4.10.0.

Owing to the constant increase in the number of publications in the phosphorus field, hand-books such as "Kosolapoff" very quickly become outdated. It is therefore gratifying to find that this series, the first volume of which is now available, presents a condensed review of each of the various topics.

The first three contributions deal with the organic chemistry of phosphorus, *i.e.* the preparation of organophosphorus compounds from elementary phosphorus, nucleophilic substitutions on phosphorus halides and esters by Grignard and organolithium compounds, and the Michaelis-Arbuzov and related reactions. The next two chapters are devoted to the following inorganic topics: acids of trivalent phosphorus and their salts, and condensed phosphates containing other oxyacids. The authors of the various chapters have all published papers on the topics in question, so that the problems really have been critically evaluated by specialists. Comprehensive lists of references enable the reader to make a more profound study of the subject. However, the earliest publications should at least have been mentioned. For example, the rearrangement of anhydrous $\overset{4}{P}-\overset{4}{P}$- acid was first observed by *Nylén*, whereas the preparation of salts of this acid from red phosphorus and chlorous acid was first described by *Leininger* and *Chulski*.

This book will be of value not only to the specialist, but also to chemists working in other fields. The presentation is fluid and clear, and the book nowhere gives the impression of being a reference work. *K.-H. Worms* [NB 418/290 IE]

**Boron, Metallo-Boron Compounds, and Boranes.** Edited by *R. M. Adams*. Interscience Publishers, a Division of John Wiley & Sons, New York-London-Sydney 1964. 1st Edit., XXIII + 765 pp., several illustrations and tables, £ 10.7.0.

Knowledge of the chemistry of boron compounds has greatly increased over the last few years. This is reflected in the large number of articles that, like the present book, present a condensed report of a part of the field.

Two contributions on the discovery, occurrence, and technology of the borate minerals and on the behavior of borates in aqueous solutions (*W. A. Gale*) are followed by a longer chapter on the structures, properties, and reactions of inorganic compounds of boron and oxygen (*N. P. Niess* and *G. W. Campbell*). *A. E. Newkirk* presents a very detailed account of the preparation and properties of elementary boron. *B. Post* contributes an excellent section on the refractory binary borides and their chemical and electrical properties. This is followed by two comprehensive chapters (320 pp.) on boron-hydrogen compounds (boranates by *R. M. Adams* and *R. A. Seidle*; boranes by *R. M. Adams*).

Simple metal and onium monoboranates are described in detail, organoboranates and oligo- and polyboranates also being taken into account. The text is supplemented by several illustrations and tables relating to the physical properties of the compounds (infrared spectra, $^{11}$B-NMR spectra, mass spectra). The last chapter (*G. J. Levinkas*) deals with the toxicity of boron compounds (BO, BH, and BC compounds, among others).

The chapters are subdivided in such a way that the reader can quickly find any given topic. The book has a formula index and a subject index, but no author index. The English language literature has been taken fairly fully into account up to 1962, and in some cases even up to 1964. Misprints (*e.g.* pp. 554, 562) and incorrect references (*e.g.* p. 571) are not serious. In many instances the reviewer felt that a summing-up would have been welcome. The editor should have dealt with nomenclature in a general chapter, instead of including it in the individual discussions (pp. 54, 373, 508, 706). Once again, however, the need for standardization of the nomenclature of boron compounds becomes obvious.

This well presented, but unfortunately very expensive book is a valuable synopsis and should be included in the library of anyone working in this field. It can be recommended to anyone wishing to familiarize himself with the chemistry of boron. It is to be hoped that the series which is intended to cover the "Entire Scope of Boron Chemistry" will very soon be continued in the form of good monographic chapters of the same type. *R. Köster* [NB 415/287 IE]

**New Methods of Analytical Chemistry.** By *R. Belcher* and *C. L. Wilson*, with the collaboration of *T. S. West*. Chapman and Hall Ltd., London 1964, 2nd Edit., XV + 366 pp., numerous tables, £ 3.0.0.

The "new" methods described in the first edition (1956) have now become common knowledge or have been found to be of little value. In order to justify its title, therefore, the second

edition had to be virtually a new book. It deals wholly with new reagents and new applications in conventional analysis.

In the volumetric field, many new indicators are described, in particular selective metal indicators. Gravimetric analysis, partition methods, and spectrophotometry are also enriched by new selective reagents, most of which are organic.

The new reagents and m thods are critically compared on the basis of their analytical use and their advantages and disadvantages. Although a selection of this nature must necessa ily be subjective, so that the reader may not agree with the author as to the best method, the book nevertheless fulfils the function of bringing useful new developments to the attention of the analys. This book is even more welcome in that the many progress reports on instrumental analysis often blind us to the fact that there have been just as many important new developments in conventional analytical methods.

A systematic literature search for new methods appears to have been carried out only for the period up to 1959, but a number of publications in English, particularly in the authors' own field, published up to 1963 have also been reviewed.

*F. Umland* [NB 414/286 IE]

**The Electronic Structure of Molecules. A New Approach.** By *J. W. Linnett*. Methuen & Co. Ltd., London and J. Wiley & Sons Inc., New York, 1964. 1st Edit., VII + 167 pp., 7 tables, 25 illustrations, £ 1.5.0.

This book is evidently intended for undergraduate chemistry students, and gives a very clear and easily understandable introduction to the theory of the electronic structure of molecules. Starting with sections on electrons and atoms, and on the chemical bond, it deals with diatomic and other small molecules, organic molecules and reactions, free radicals, inorganic compounds containing elements of the higher periods, and electronically excited states.

However, the reviewer would hesitate to recommend this fine booklet to the beginner, simply because the approach is very personal and one-sided. It is based on *J. W. Linnett*'s suggestion that the Lewis octet should be regarded as a double quartet, *i.e.* the electrons with $\alpha$ spin should be reg ded as practically independent of those with $\beta$ spin. This hypothesis is presented with striking consistency and with surprisingly good results, but the connection with conventional methods of quantum chemistry (the MO and VB methods) remains unclear. However, those who are familiar with these methods will benefit greatly by perusal of this book. The only regret is that the possibility of a mathematical formulation of wave functions on the basis of the qualitative ideas discussed is only touched upon in the closing paragraphs of the last chapter. *M. Klessinger* [NB 416/288 IE]

**Electrons and Chemical Bonding.** By *H. B. Gray*. W. A. Benjamin Inc., New York-Amsterdam, 1964. 1st Edit., XIV + 223 pp., numerous illustrations and tables, paper $ 4.35, cloth $ 8.80.

The quantum-mechanical treatment of atoms and molecules has led to the development of ideas that are extremely helpful to the chemist in the discussion of the structures and reactivities of compounds, and which are indispensable for the interpretation of the results obtained by the physical methods that are becoming increasingly important in chemistry. It is also becoming increasingly important, therefore, that the chemist should familiarize himself with these ideas right at the beginning of his training.

This is the purpose of *H. B. Gray*'s book, which is based on a course of lectures for beginners. This book, with its 132 two-color illustrations and 31 tables, gives an extremely lucid introduction to the electronic theory of the chemical bond. It contains nine chapters, and covers atoms, diatomic, linear triatomic, planar trigonal, tetrahedral trigonal, pyramidal and angular triatomic molecules, organic $\pi$-electron systems, and bonds involving d-electrons. The purely qualitative discussion is based mainly on the MO theory, which is used consistently, even for molecules such as $CH_4$ and inorganic complexes. For this reason concepts such as "hybridization" and "lone pairs of electrons" are only touched upon, and it is not clear why the overlap can be used as a measure of the strength of a bond, even though it is neglected in all of the derivations. No differentiation is made between VB structures and localized molecular orbitals. A particularly good chapter, on the other hand, is that dealing with bonds involving d-electrons, which provides a good introduction to the theory of inorganic coordination compounds. The book contains very few printing errors or instances of vagueness in the text.

*M. Klessinger* [NB 417/289 IE]

**Acid-Base Equilibria.** By *E. J. King*. The International Encyclopedia of Physical Chemistry and Chemical Physics. Edited by *E. A. Guggenheim, J. E. Mayer*, and *F. C. Tompkins*. Volume 4/15. Pergamon Press, Oxford-London-Edinburgh-New York-Paris-Frankfurt 1965. 1st Edit., XI + 341 pp., £ 6.0.0.

"Acid-Base Equilibria" is published as part of the "International Encyclopedia of Physical Chemistry and Chemical Physics", which comprises about 100 volumes. However, the present volume is complete in itself, and may be used independently of the other volumes. A more fitting title might have been "The Physical Chemistry of Acid-Base Equilibria".

The volume is intended for the reader who wishes to make an extensive study of acid-base equilibria, and presupposes a certain knowledge of thermodynamics and of the theory of electrolytes. In five chapters the author gives an excellent introduction to the theoretical principles of the determination of acidity constants (arranged according to the method of determination). In the course of a comprehensive discussion of the pH concept, he rightly points out that in spite of notable advances in instrumentation, the pH value remains an essentially empirical parameter. The relationships between structure and acidity are dealt with rather briefly. The author evidently recognizes that the data available at present cannot be explained by a few neat thermodynamical equations. Subsequent chapters are concerned with the effect of pressure and temperature, the behavior of polyfunctional compounds, and equilibria in non-aqueous solvent systems. The author deliberately omits any discussion of analytical aspects or of acid-base equilibria in melts.

The author has succeeded in giving a very readable account of the physical chemistry of acid-base equilibria, taking into account data from the literature up to 1963.

# Automation of Structure Analysis

## Part II. Automation of the Evaluation[*]

BY PROF. DR. W. HOPPE
ABTEILUNG FÜR RÖNTGENSTRUKTURFORSCHUNG AM MAX-PLANCK-INSTITUT FÜR EIWEISS- UND LEDERFORSCHUNG, MÜNCHEN
AND
ABTEILUNG FÜR STRUKTURFORSCHUNG AM PHYSIKALISCH-CHEMISCHEN INSTITUT DER TECHNISCHEN HOCHSCHULE, MÜNCHEN (GERMANY)

*The extent to which it is possible to automate the determination of a structure from the data collected with automatic measuring equipment is discussed. The development of the automatic evaluation is synchronous with that of digital computer programs. – Even the simple calculation of structure factors from the intensities (i.e. the analysis of the geometrical and physical intensity factors) takes several weeks when the many thousand reflections are processed "manually", i.e. with a desk calculator. A large electronic computer, on the other hand, executes these calculations in a few seconds. Nevertheless, even the largest computers available at present are too small for many of the complex steps in the calculation and for the quantity of data involved. Evaluation methods which, owing to long computing times, can at present only be tested on relatively simple structures will become more attractive with the advent of machines with computing times in the nanosecond range.*

## Introduction

The development of methods for the evaluation of X-ray structural data can be divided into three steps:

### 1. Individual Programs for Routine Calculations

The primary aim of the crystallographer was to simplify the routine work, in order to be able to concentrate on the important steps of the evaluation. As soon as the first electronic computers made their appearance, programs were developed for the calculation of structure factors from an approximation model or for the calculation of Patterson and Fourier syntheses. It soon became clear, however, that calculation with the aid of these independently compiled programs is laborious, since the input formats are different and so involve time-consuming manual operations (re-punching, short intermediate calculations).

[*] For Part I (Automation of the Measuring Process) see Angew. Chem. 77, 484 (1965); Angew. Chem. internat. Edit. 4, 508 (1965).

### 2. Program Systems

The next step, therefore, was the establishment of program systems in which a wide variety of routine programs could be carried out and combined, the only manipulation required being the insertion of a few control cards. Table 1 shows the programs that can be dealt with at present in a program system developed at our Institute. A system of this type must obviously be flexible, in order that new programs may be introduced at any time. The sub-programs themselves can naturally be obtained from a wide range of sources.

Table 1. Computer programs used in our system.

a) Scaling, Lorentz polarization-correction in various recording methods
b) Wilson statistics
c) Correction for absorption
d) Modification of the structure factors for the Patterson synthesis
e) Patterson and Fourier syntheses
f) Drawing program for Patterson and Fourier syntheses
g) Structure factor and least squares calculations
h) Bond lengths and angles and other characteristics of the structure
i) Convolution calculations
j) Calculation of convolution molecules
k) Scanning the Patterson structure with convolution molecules

## 3. Automatic Evaluation

It will ultimately be asked whether the programs in a system can be linked by other sub-programs in such a way that the structure is worked out automatically from the results of the measurements. At present, however, there is no universal process for the determination of structures by X-ray analysis; there are simply a number of promising processes, as well as beginnings that could lead to one or more universal and direct methods for the determination of structures.

The mathematical problem of the evaluation can be defined by Eq. (1):

$$\rho_{xyz} = (1/v) \sum_{h=-\infty}^{\infty} \sum_{k=-\infty}^{\infty} \sum_{l=0}^{\infty} A_{hkl} \cos 2\pi (hx + ky + lz) + \sum_{h=-\infty}^{\infty} \sum_{k=-\infty}^{\infty} \sum_{l=0}^{\infty} B_{hkl} \sin 2\pi (hx + kxy + lz)$$

$$A_{hkl} = |F_{hkl}| \cos \Phi_{hkl}$$

$$B_{hkl} = |F_{hkl}| \sin \Phi_{hkl} \qquad (1)$$

In this equation [1], $\rho_{xyz}$ is the quantity sought, *i.e.* the electron density in the unit cell. The maxima of the electron-density function mark the positions of the atoms. For the numerical evaluation of this equation (three-dimensional Fourier synthesis), it is possible to measure the values of $|F_{hkl}|$ (absolute values of the structure factors), but not its components $A_{hkl}$ and $B_{hkl}$ (obtained by multiplication by $\cos\Phi$ or $\sin\Phi$) (the "phase problem"; $\Phi$ is the phase difference between primary and scattered waves). In principle, therefore, there are an infinite number of ways in which an electron density $\rho_{xyz}$ can be calculated from a given F distribution. However, only one of these distributions is chemically meaningful, and that is one involving almost spherically symmetrical electron-density peaks with chemically reasonable bond lengths and bond angles [2]. The crystallographer can try to narrow down the diversity of structures by considering only chemically meaningful structures, or alternatively he can measure indirectly some of the ratios A/B by comparing at least two sets of structure factors. Some of the methods of evaluation are quite involved. However, in the cases that show the greatest promise for practical applications, the fundamentals can be understood without calculation, as will be seen below.

It is remarkable that automatic structure determination became feasible only after three-dimensional methods (*i.e.* the calculation of a three-dimensional electron-density distribution, instead of projections of the electron density) had gained general acceptance. This may at first seem paradoxical, since three-dimensional work involves far more calculation than two-dimensional work. It was found, however, that the much larger volume of information available greatly simplifies many of the problems. Structures which, with two-dimensional methods, can be solved (if at all) only with skill and intuition, take an almost predetermined course when tackled with three-dimensional methods.

It is expedient to carry out the structure analysis in three steps:

A. Establishment of an approximation model

B. Development of the final model from the approximation model

C. Refinement of the structure.

The approximation model generally contains only some of the atoms present (*e.g.* only the heavy atoms in the case of the heavy-atom method), and the positions of a few of these may still be wrong. The final model gives a qualitatively correct picture of the complete structure; errors of a few tenths of an Ångstrom in the interatomic distances are permissible.

This division is also useful in the so-called direct methods. The object of these methods is the calculation of the correct A:B ratios (phases) without recourse to intuitive evaluation steps; however, at least in the present form of the methods, the results are so vague that they give at best an "approximation model", the interpretation of which may be rather difficult.

## A. Establishment of an Approximation Model

### 1. Heavy-Atom Method

The determination of structures is greatly facilitated if the unit cell contains one or a few heavy atoms, and the heavy-atom method has for many years been one of the most successful techniques available to X-ray structural analysts. It is only natural, therefore, to base our attempted automation on this method.

The positions of the heavy atoms are easy to find, even in a complex organic structure. This is a consequence of a special property of the so-called Patterson function $P_{xyz}$ [Eq. (2)].

$$P_{xyz} = \sum_{h=-\infty}^{\infty} \sum_{k=-\infty}^{\infty} \sum_{l=0}^{\infty} |F_{xyz}|^2 \cos 2\pi (hx + ky + lz) \qquad (2)$$

The formula for $P_{xyz}$ is very similar to the Fourier-synthesis formula (1) for the electron density $\rho_{xyz}$. Unlike $\rho_{xyz}$, however, $P_{xyz}$ can be calculated directly from the observed results, since Eq. (2) contains only the absolute values of the structure factors $F_{hkl}$. The maxima of the Patterson function $P_{xyz}$ characterize the lengths and directions of the interatomic vectors in the crystal [3]. Since the intensities of the maxima are proportional to the product of the numbers of electrons in the atoms joined by the interatomic vector, the heavy atom-heavy atom maxima must be particularly high. This will be illustrated for *C*-(2,2'-biphenylylene)-

[1] In practice the summation limits of h, k, and l are only of the order of 10 (instead of $\infty$). Owing to the triple summation, however, the range of $F_{h,k,l}$ is of the order of 1000.

[2] We shall not be concerned here with the problems of homometry (different chemically possible structures with the same set of absolute values of the structure factors).

[3] Cf. *W. Hoppe*, Angew. Chem. *69*, 659 (1957).

$N_\beta$-cyano-$N_\alpha$-(*p*-iodophenyl)azomethinimine, the structure of which was determined at our Institute [4, 4a]. The dimensions of the unit cell, the space group, and the density of the crystal showed that the asymmetric unit of the unit cell [5] contains only one molecule, and hence only one iodine atom. Since this iodine atom contains about eight times as many electrons as the light atoms (hydrogen is completely ignored at first, because of its low scattering power), the iodine-iodine maxima should be easily recognizable above the background of light atom-light atom maxima, being 64 times as intense as the latter. However, owing to the presence of heavy atom-light atom maxima (which are eight times as intense as the light atom-light atom maxima) and the overlapping of maxima in the background, the difference in intensity is actually rather smaller: the iodine-iodine maxima, in fact, are 2.5 times as intense as the highest background maximum of the Patterson structure (Table 2).

Table 2. Weights (relative intensities) and parameters (x, y, z) of Patterson maxima in the *C*-(2,2′-biphenylylene)-$N\beta$-cyano-$N_\alpha$-(*p*-iodophenyl)azomethinimine structure, which contains one iodine and 23 light atoms in the asymmetric unit. The maxima marked with an asterisk correspond to interatomic vectors between iodine atoms.

| x | y | z | Height of maximum |
|---|---|---|---|
| 0.500 | 0.415 | 0.000 | 40* |
| 0.286 | 0.500 | -0.935 | 35* |
| 0.219 | 0.088 | 0.919 | 20* |
| 0.010 | 0.000 | 0.725 | 9 |
| 0.000 | 0.000 | 0.267 | 9 |
| 0.037 | 0.500 | 0.900 | 8 |
| 0.017 | 0.075 | 0.800 | 8 |
| 0.030 | 0.500 | 0.667 | 8 |
| 0.000 | 0.082 | 0.183 | 8 |
| 0.487 | 0.500 | 0.192 | 8 |

As an illustration, sections through the three-dimensional Patterson structure in the region of the iodine-iodine maxima are shown in Fig. 1; the intensity of the maxima can again be clearly seen [6]. The parameters of the positions of the iodine atoms in the unit cell are given directly by the positions of these Patterson maxima. However, this "iodine crystal structure" is an approximation to the complete crystal structure, in which the light atoms have been disregarded. The fact that this approximation model giving the positions of the heavy atoms is sufficient in most cases to permit the successful execution of the second step, *i.e.* the development of the final model, is of fundamental importance (cf. the discussion of step B of the evaluation).

[4] In collaboration with *R. Huisgen*, Organisch-Chemisches Institut der Universität München.

[4a] *F. Brandl*, Dissertation, Universität München, *1965*.

[5] The asymmetric unit of a unit cell is its smallest part that cannot be further reduced by the symmetry elements of the space group. It can be shown that the determination of the positions of the heavy atoms from the heavy atom-heavy atom maxima becomes particularly easy if the asymmetric unit contains only one heavy atom. This condition is satisfied in most organic heavy-atom structures (*e.g.* in vitamin $B_{12}$).

[6] The contour maps in this figure were drawn by an automatic function plotter controlled by a digital computer using a program developed at our Institute.

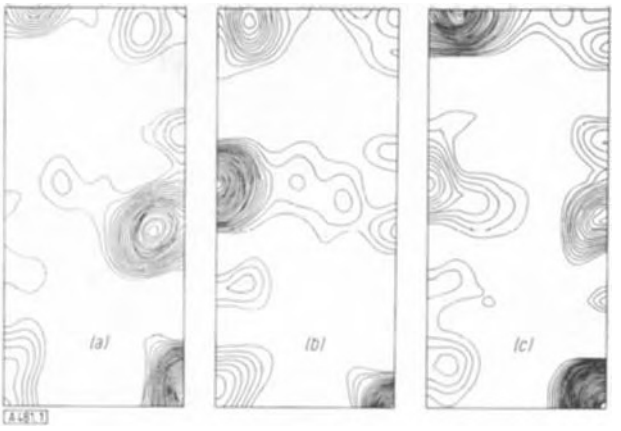

Fig. 1. Three-dimensional Patterson synthesis of *C*-(2,2′-biphenylylene)-$N\beta$-cyano-$N_\alpha$-(*p*-iodophenyl)azomethinimine (cf. Fig. 9). Sections in the neighborhood of the heavy atom-heavy atom maxima. The highest maxima correspond to iodine-iodine vectors. (a) Patterson maximum of iodine in general position (z = 55/60); (b) and (c) Harker maxima of iodine (z = 4/60 and 0).

This example indicates how the automation of step A by the heavy-atom method may by tackled. It is necessary to develop a computer program which will determine the positions of the maxima of the function $P_{xyz}$ and classify these maxima according to their intensities. In another subprogram, which takes into account the symmetry of the space group, the parameters of the positions of the intense Patterson maxima are reduced to the heavy-atom parameters. There are various ways in which this can be done, but these cannot be discussed in the present paper. Computer programs of this type are being developed in our laboratory.

We have discussed this example at some length in order to show that an approach to automatic evaluation can be achieved by simply translating the operations carried out by the crystallographer into computer language. However, since the machine does not develop "intuition", a process of this type can be successful only if no ambiguities that are difficult to resolve are encountered. The logical principle of the process described for the determination of the heavy-atom parameters clearly depends on the condition that the heavy atom-heavy atom maxima are sufficiently intense in comparison with the light atom-light atom maxima. In our next example we shall consider a case in which (for the two-dimensional calculation) this condition is not satisfied. This example will also show how it becomes possible to solve the problem when we turn from two-dimensional to three-dimensional methods.

Fig. 2a shows a Patterson projection of potassium *p*-nitrophenyl-*anti*-diazotate. Potassium contains about three times as many electrons as any of the light atoms. The potassium-potassium maxima should therefore be nine times as high as the light atom-light atom maxima, and three times as high as the light atom-potassium maxima. Although the dominance of the heavy atom-heavy atom maxima is not so pronounced as in the last example, they should be easily recognizable in the Patterson synthesis, and it should therefore be possible to determine the positions of the potassium atoms (determination of the approximation model).

However, the situation is complicated by the superposition of non-potassium-potassium maxima in this Patterson projection, so that the weight of the heavy

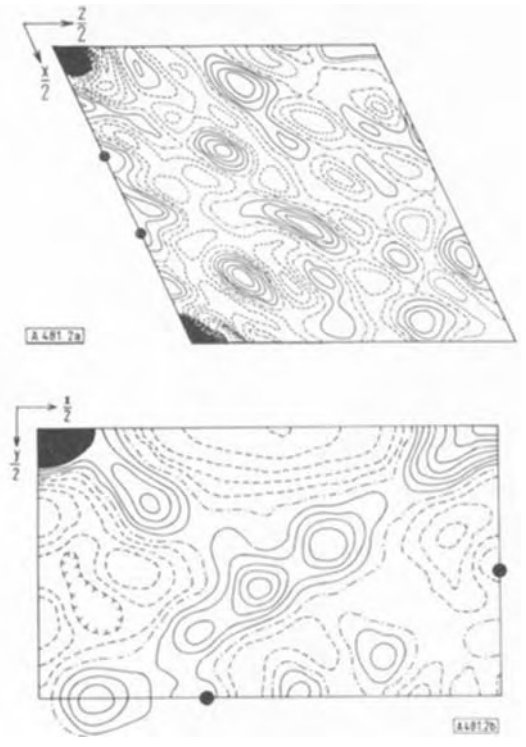

Fig. 2. Two-dimensional Patterson synthesis for potassium *p*-nitrophenyl-*anti*-diazotate (cf. Fig. 9).

(a): b-projection; (b): c-projection. The positions of the heavy atom-heavy atom maxima are indicated by dots.

atom-heavy atom maxima is only a fraction of that of the superimposed maxima. The black dots in the diagram indicate the potassium-potassium maxima. The contour lines show clearly the presence of "false" superposition maxima, which are three to four times as high. The situation is even worse in another Patterson projection of the same crystal (cf. Fig. 2b). It is clear that the heavy-atom method in projections cannot be used in this case, since neither a crystallographer nor a computer would be able to find the potassium-potassium maxima. A skilled crystallographer might be able to determine the structure by an indirect method, *e.g.* by first establishing the orientation of a benzene ring, but this would involve a great deal of effort. An entirely different situation is found when we consider the three-dimensional Patterson structure.

The left-hand column of Table 3 shows the weights of the potassium-potassium maxima, the remainder of the Table those of the highest non-heavy-atom maxima. In this case the symmetry of the crystal gives rise to so-called Harker heavy-atom maxima[7], which have double weights. These maxima are clearly also the highest maxima in the Patterson structure. However, the non-Harker heavy-atom maximum is again of the same order of magnitude as twelve other non-heavy-atom maxima, owing to certain internal symmetries of the structure in question. In other words, difficulties are encountered even in a three-dimensional evaluation if there are no Harker maxima. If (*e.g.* in the absence of Harker maxima in otherwise similar cases) there are a definite number of possibilities, an attempt can be made to resolve the ambiguity by testing the various possibilities in turn with the aid of a computer. Only the correct assumption will give a chemically meaningful structure.

Table 3. Weights of the highest maxima in a Patterson synthesis of potassium *p*-nitrophenyl-*anti*-diazotate (Harker maxima are indicated by an asterisk).

| Potassium-potassium maxima | Non-heavy-atom maxima | |
|---|---|---|
| * 5132 | 2135 | 1825 |
| * 4448 | 2117 | 1814 |
| 1959 | 2099 | 1695 |
| | 2067 | 1665 |
| | 1908 | 1626 |
| | 1889 | 1608 |

[7] Harker maxima are Patterson maxima (with double or fourfold weight) on particular planes or lines. They do not occur in all space groups.

## 2. The Convolution-Molecule Method

The convolution-molecule method[8] can to some extent be regarded as an extension of the heavy-atom method. In the latter, the approximation for an organic molecule is a heavy atom present in this molecule. In the convolution-molecule method, this function is taken over by a molecular fragment having a known steric configuration (*e.g.* an aromatic ring system). The position and orientation of this portion of the molecule in the unit cell are found from the Patterson structure. This "molecular-fragment crystal structure" (as opposed to the "heavy-atom crystal structure") then forms the basis for the next step of the structural analysis.

The convolution-molecule method makes use of certain structural properties of the Patterson function $P_{xyz}$. It can be shown that a molecular fragment having a known steric configuration gives Patterson maxima with definite structures. From the mathematical point of view, these structures are convolution products of the molecular fragments (convolution molecules). Systematic unravelling of these structures from the Patterson structure, taking into consideration the symmetry of the space group, yields the orientation and position of the molecular fragments in the unit cell. The process is similar in some respects to a jigsaw puzzle. The "picture" is the Patterson structure, and the "pieces" are the convolution molecules, of which there are two types.

The structure of the first type (convolution molecule with like indices) depends only on the molecular-fragment structure, and can therefore be calculated when this is at least approximately known. By fitting this convolution molecule into the Patterson structure, we find the orientation parameters of the molecular fragments which are required for the determination of the second type of convolution molecule (convolution molecule with mixed indices). If this convolution molecule can also be fitted correctly into the Patterson structure, we obtain the translation parameters of the molecular fragments, and since we know the orientation parameters, we can now find the complete crystal structure of the molecular fragments. This therefore concludes step A of the evaluation (cf. Fig. 3).

[8] *W. Hoppe*, Z. Elektrochem. Ber. Bunsenges. physik. Chem. *61*, 1076 (1957).

These operations can be carried out graphically in projections[9,10]. The use of three-dimensional convolution molecules, however, is very inconvenient. For this reason, the operations involved in the three-dimensional convolution-molecule method have recently been automated[11]. The rotation and displacement of the convolution molecules (which are calculated by means of Fourier series, in order to allow for the finite size of the convolution-molecule maxima) is carried out systematically by the computer. An interesting point is the criterion by which the computer judges the fit. For each orientation and for each translation the convolution molecules are subtracted at all points in the Patterson space[12] from the overall Patterson function. The sums of the negative and of the positive differences (or their squares) are then calculated separately. A large negative sum is unacceptable, since it would mean that the structure in question lacked the required Patterson maxima. On the other hand, a large positive sum is permissible, since this would simply mean that other Patterson maxima were present. This could be due to unknown molecular components, which were not taken into account in the convolution-molecule evaluation.

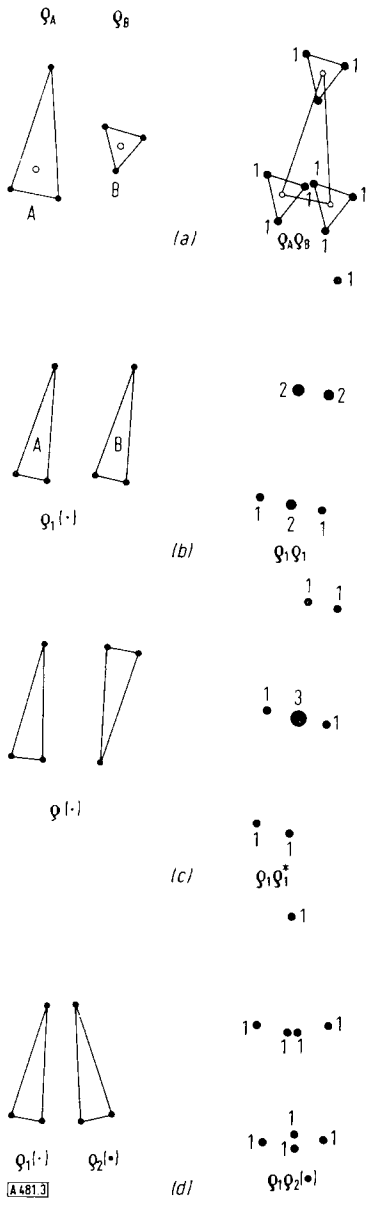

Fig. 3. The convolution method.

Convolution molecules result from the "convolution" of two molecules. The principle is shown in Fig. 3a.

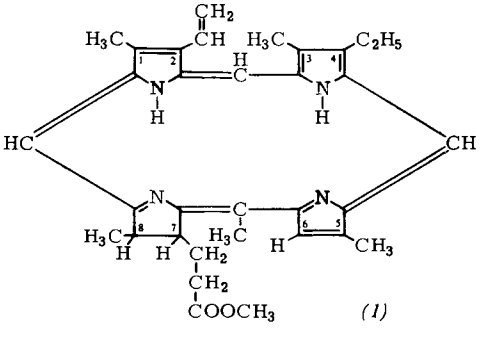
The molecule B is subjected to a parallel displacement to bring it over each of the vertices of molecule A in return, and the positions of the atoms of B are marked (black dots in the drawing). The weight of a point in the convolution molecule is the product of the weight of the vertex of A in question and the weight of the corresponding point of B. The molecules in the unit cell of a crystal are generally identical, but their positions have frequently been altered by symmetry operations.

Figs. 3b to 3d show convolution molecules of two molecules which are identical (3b), linked by a center of symmetry (3c), or linked by a mirror plane (3d). The numbers indicate the multiplicity of coincident points. In Figs. 3b and 3c, rotation of one molecule causes a similar rotation of the other, and hence leads to rotation of the convolution molecule with no change in the structure (convolution molecule with like indices). In Fig. 3d, on the other hand, rotation of the molecule leads to a change in the structure of the convolution molecule (convolution molecule with mixed indices).

As we have shown, the convolution-molecule method (particularly in the automated three-dimensional form) can deal with structures of similar complexity to those studied by the heavy-atom method. In the discussion of the method of successive Fourier synthesis we shall describe one of the structures [phyllochlorin ester *(I)*] solved by the convolution-molecule method.

This method can also be used for the constitutional analysis of organic molecules containing no heavy atoms, as has been shown[13] by the analysis of the crystal structure of ecdysone, the hormone that controls the pupation of insects. This analysis is remarkable in that the "molecular fragment" used was a sterol skeleton, the folding of which was partly incorrect. In spite of this the analysis was successful, and the complete chemical constitution, with all the oxygen functions, was found by X-ray analysis. Since the analysis was carried out on a compound containing no heavy atoms, the positions of all the atoms were found with high accuracy, and it was even possible to locate many of the hydrogen atoms.

Evidently if the "molecular fragment" used in the convolution-molecule method is a heavy atom, this method becomes the heavy-atom method. In this case the convolution molecules are very simple: they give rise to single spherically symmetrical maxima. There is no need to determine an orientation. The programs for the convolution-molecule method can therefore also be used to find the positions of heavy atoms. If, for the purposes of the analysis, the heavy atom has been introduced into the molecule by means of some large organic group (*e.g.*



*(I)*

[11] *R. Huber*, Acta crystallogr. *19*, 353 (1965).

[12] In order to reduce the computing time, however, the existing programs are confined to the maxima of the convolution-molecule functions.

[13] *R. Huber* and *W. Hoppe*, Chem. Ber. *98*, 2403 (1965).

introduction of bromine by esterification of a hydroxy group with bromobenzoic acid), it is expedient to use the convolution-molecule technique instead of the heavy-atom method. The approximation model will then contain the positions of the light atoms of the organic residue, as well as the position of the heavy atom, and the prospects for the second stage of the evaluation will be improved by the improved approximation model.

Another combination of the convolution-molecule method with the heavy-atom method may be useful when the asymmetric unit contains several heavy atoms, and when the geometrical coordination of some heavy atoms is known. In the structural analysis of 2,3,4,4-tetrachloro-1-oxo-1,4-dihydronaphthalene, the convolution-molecule evaluation is based on the known configuration of the four chlorine atoms [14].

A more complicated example is shown in Fig. 4a. In the structure analysis of the cyclopentadienyl-cyclooctatetraene-Co complex $\mu$-$C_8H_8(CoC_5H_5)_2$ [15], it was found that this compound (triclinic, space group $P\bar{1}$) crystallizes with three molecules in the asymmetric unit. The unit cell therefore contains 12 heavy atoms, so that the determination of the heavy-atom structure from the 102 heavy-atom maxima in the Patterson function presents a considerable problem. The problem was solved by regarding the two cobalt atoms as forming a diatomic molecule, in which, on chemical grounds and on the basis of a preliminary examination of the Patterson synthesis, the distance between these two atoms must be between 3.5 and 4 Å. Evaluation on this basis by the convolution-molecule method led to the correct heavy-atom structure (Fig. 5a), and hence, *via* several successive Fourier syntheses (cf. Section B.2), to the complete structure containing the 60 atoms of the asymmetric unit. The analysis showed that the cyclooctatetraene ring is in the boat form with alternating double bonds (cf. Fig. 4b).

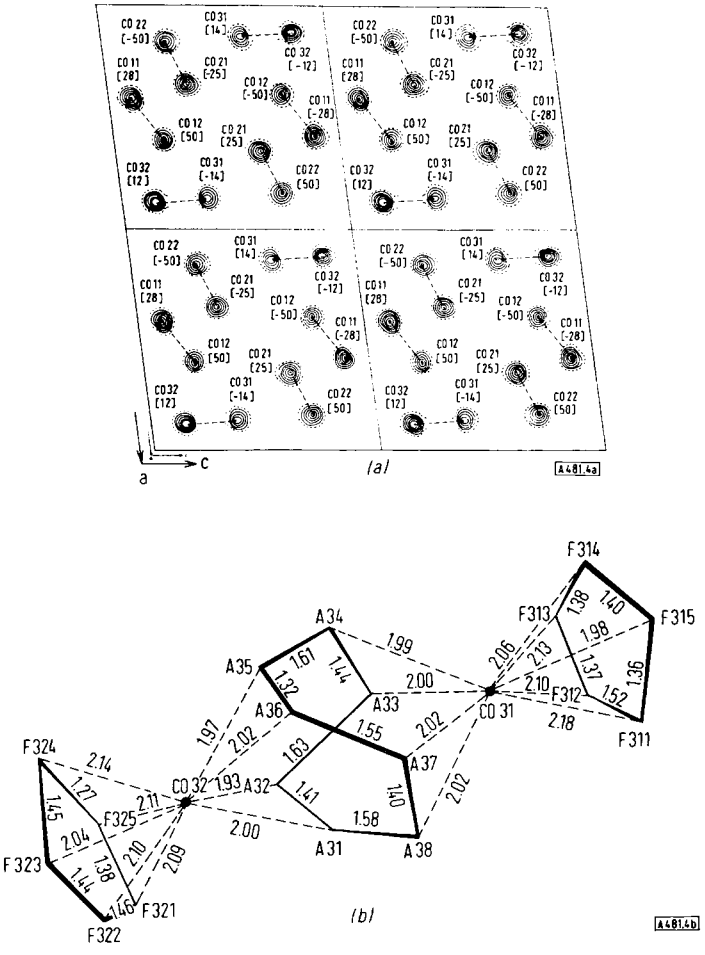

Fig. 4. The convolution-molecule method in structures with a known heavy-atom configuration. Fig. 4a shows the structure of the "$Co_2$ molecules" in $\mu$-$C_8H_8(CoC_5H_5)_2$ in the three-dimensional Fourier synthesis of the heavy atoms in a projection along the b-axis. The lines joining the ends of the "$Co_2$ molecules" are dotted.

Fig. 4b shows the molecular model of $\mu$-$C_8H_8(CoC_5H_5)_2$. State of refinement $R_1 \approx 20\,\%$; 4500 independent reflections.

### 3. The Fourier-Transform Method and the Diffuse-Scattering Method

The Fourier-transform method is related in some respects to the convolution-molecule method. If the molecular structure is known, it is possible to calculate the scattering diagram of the molecule, and then to try to match this with the intensity distribution of the X-ray reflections [16]. This leads to orientation parameters and (in a somewhat more complicated procedure) to translation parameters. Difficulties are encountered in the analysis of molecular fragments, since, in contrast to the convolution-molecule method, the influence of atoms that are neglected cannot be compensated. This method is therefore less suitable for constitutional analysis.

In a recent variant, the Fourier-transform method is used in the evaluation of thermal diffuse scattering from molecular crystals [17]. Whereas the crystal reflections form a discontinuous distribution, the diffuse scattering gives rise to a continuous blackening on the X-ray photographs (background scattering component). It has been shown that the diffuse scattering in molecular crystals is modulated approximately in accordance with a superposition of the scattering diagrams of the molecules in the unit cell. We can therefore try to match the scattering diagrams of the molecules with the distribution of the diffuse scattering instead of with the reflection distribution. Since the distribution is continuous, the information obtained is more comprehensive. It is possible, for example, to estimate the sizes and shapes of molecules before the structural analysis is commenced. No details can be given in the present paper [17]. It is naturally also possible to combine the Fourier-transform method with the convolution-molecule method.

[16] *A. Hettich*, Z. Kristallogr., Mineralog. Petrogr., Abt. A, *90*, 483 (1935); *P. P. Ewald*, *ibid. 90*, 493 (1935).

[17] Cf. *W. Hoppe* in *R. Brill*: Fortschritte der Strukturforschung mit Beugungsmethoden. Friedr. Vieweg, Braunschweig 1964, pp. 90–166.

Since the diffuse scattering provides additional experimental data, a combination of this kind can often make an analysis much easier (cf. the evaluation of the diffuse scattering in ecdysone [18]).

## 4. Image-Seeking Methods

In the convolution-molecule method, the Patterson structure is broken down into sub-structures, which depend on, but are not identical with, the molecular structure. Taking an entirely different approach, we can also regard the Patterson structure as being composed of $n$ images of the crystal structure which have been mutually displaced [19]. It would obviously be possible to recognize the crystal structure directly from the Patterson structure, if the Patterson maxima of such an image could be marked (cf. Fig. 5). This can be easily done for the Patterson structure of a crystal with a

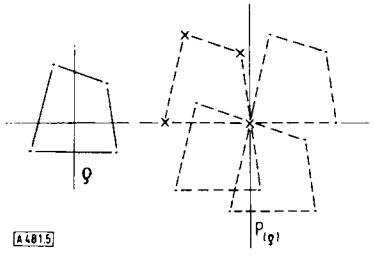

Fig. 5. Image seeking in the Patterson function.

The Patterson function P(ρ) of the structure ρ can be regarded as resulting from the superposition of identical images of the structure ρ. In the image-seeking method, all the Patterson maxima in the Patterson structure that belong to any image of the structure (marked by crosses) are sought.

center of symmetry, if two Patterson structures, which are mutually displaced by an interatomic vector that occurs only once (unique), are superimposed [20]. Patterson maxima that coincide belong to the same "image" of the crystal structure. In the case of acentric structures, however, we first obtain a double image consisting of the structure and its centrosymmetric image. Superposition of this double image on another Patterson function, followed by marking of coincident maxima again gives the structure (or its centrosymmetric image). The process described is independent of model considerations; its use obviously does not even require a knowledge of the empirical formula. This is therefore a direct method, which combines steps 1 and 2 of the evaluation, and which leads directly to the complete structure.

Unfortunately, however, this is applicable only to structures containing small numbers of atoms. If we consider an organic structure consisting of light atoms, and with about 100 atoms in the unit cell, it is necessary to unravel a Patterson structure containing about 10000 Patterson maxima. Since the Patterson maxima have a finite volume, it is hopeless to try to separate these 10000 maxima in the small volume of the unit cell.

[18] *W. Hoppe* and *R. Huber*, Chem. Ber. *98*, 2353 (1965).

[19] $n$ is the number of atoms in the unit cell.

[20] In centrosymmetric structures these are vectors between atoms which are linked by a center of symmetry.

It is not possible to find unique Patterson maxima [21] (required at the beginning of the method), nor can unique Patterson maxima be marked by coincidence as the positions of atoms in the multiple superpositions. The situation changes, however, when the structure contains one or more heavy atoms. The maxima in the Patterson structure then fall into the height classes (heavy atom-heavy atom maxima, heavy atom-light atom maxima, light atom-light atom maxima) discussed earlier. If single Patterson maxima corresponding to distance vectors between heavy atoms can be used for the interpretation of the Patterson structure, it can be shown that the crystal structure can be found from the heavy atom-light atom maxima alone [22].

Evaluation by this method has two advantages. First, it is possible to find the heavy atom-heavy atom vectors even in complex structures, owing to their great weight, and second, the number of heavy atom-light atom Patterson maxima is proportional to the number, $n$, of light atoms. Since the heavy atom-light atom maxima are higher than the light atom-light atom maxima, and since their number is of the same order as the number of light atom maxima, they should be visible separately, even in a complex structure, against a diffuse background of the very numerous light atom-light atom maxima. As we have already mentioned, separability of the Patterson maxima is essential to the success of superposition methods. Many relatively complicated heavy-atom structures have been resolved by this method.

It is admittedly desirable, even in these cases, to determine the positions of the heavy atoms before analysis in the same manner as in the heavy-atom method. Only then is it possible, for example, to decide in limiting cases which Patterson maxima correspond to heavy atom-heavy atom vectors; this is done by means of the Harker maxima (cf. Table 3). In cases of this type, however, the superposition method may be regarded simply as a special case of the heavy-atom method, in which the determination of the approximation model again consists in the determination of the heavy-atom structure.

Since the reliability of evaluation by superposition increases with the number of superpositions (as has been pointed out, at least two superpositions are required in the case of an acentric structure), the use of this method for structures consisting entirely of light atoms is more reliable when a large number of unique light atom-light atom vectors are known. If the structure of a part of the molecule is known, the positions of the light atoms can be found by the convolution-molecule method. Unique light atom-light atom vectors can then be calculated from these positions, and an attempt can be made to use these as a basis for a structural analysis by the superposition technique.

To summarize, the use of the superposition method for complex structures is likely to be successful if the re-

[21] Multiple Patterson maxima occur when a crystal structure includes several interatomic vectors of identical length and direction. Only superpositions on single Patterson maxima lead to coincidence-marking of double or single images of the structure.

[22] This condition must be satisfied for each stage of the evaluation. For example, if an acentric structure contains only two heavy atoms, there is only a single heavy atom-heavy atom vector. Only the first superposition to obtain the double image over the heavy atom-light atom maxima can then be carried out. The same ambiguity is found in the calculation of a Fourier synthesis phased with the two heavy atoms. "Phased" means that the phase shift $\Phi$ is taken into account in the structure factor.

quired unique Patterson vectors are deduced from a previous determination of an approximation model (by the heavy-atom or folded-molecule methods). The superposition method is then used to find the final model, and will therefore be discussed once more in Section B.

## 5. "Direct" Methods

The special form of the electron-density function of the crystal (positivity, separability into atomic electron-density functions) gives rise to relationships between structure factors, which lead directly to the phases of the structure. The methods are therefore automatic in themselves, since the structure can be directly calculated and interpreted by a Fourier synthesis of the phased absolute values of the structure factors. Owing to the unavoidable error in the calculation of the phases, however, this "electron-density synthesis" is often not very clear. As was pointed out in the introduction it provides at best the positions of some of the atoms ("approximation structure"). A structure determination by a direct method must therefore be followed by step B of the evaluation, although this should not really be necessary. Relatively little experience has been gained so far with direct methods. They have mostly been used in projections, and were successful with relatively simple structures. It is possible that more recent work [23–25] and programming in three dimensions will extend the scope of the method to include more complex structures.

## 6. Indirect Phase-Measurement Methods

The difficulties in the evaluation due to the fact that the phases are unknown could, of course, best be eliminated by measurement of the phases. If a direct measurement with X-rays, based on interference effects, does not seem to be possible, the phases can be determined indirectly if additional scattering centers are introduced into the unit cell. It is often not too difficult to introduce an additional scattering center. For example, it may be possible to prepare a chlorine derivative and a bromine derivative in the case of an organic compound. If the two derivatives crystallize in the same lattice (isomorphism), the scattering factor of the "additional scattering center" (in the bromine derivative) corresponds to the difference between the scattering factors of bromine and chlorine.

If the positions of these differentiating atoms in the unit cell are known, it is possible to calculate the structure factors $f_o$ of this "differentiating-atom approximation structure". The phases of the structure factors of the isomorphous crystals can then be obtained by construction, as shown in Fig. 6. The construction is based on the fact that the structure factors of the differentiating-atom approximation structure and of the two isomorphous crystals must form a vector triangle. As can be seen from Fig. 6, there are two possible solutions. This embiguity can be eliminated by preparation of a third aomorphous derivative and repetition of the same visaluation.

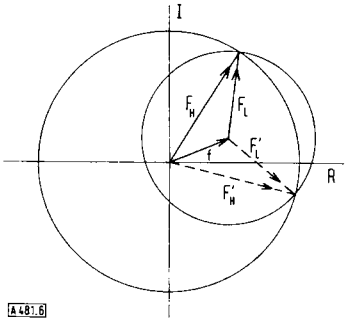

Fig. 6. Indirect phase-measurement by isomorphous replacement.
Construction of the vector characterizing the amplitude $|F_H|$ and the phase $\Phi_H$ of a structure factor $F_H$ of the isomorphous heavy-atom derivative, using the vector triangle of the structure factor of the heavy-atom approximation structure f and of the two measured absolute values $|F_L|$ and $|F_H|$ of the structure factors of the two isomorphous derivatives. The intersection of the circles drawn through the two end-points of f with radii $|F_L|$ and $|F_H|$ represents the solution.

The method of isomorphous replacement was first applied to centrosymmetric structures, in which only one isomorphous replacement is required. In the case of acentric structures, isomorphous replacement has so far been used only in the structure analysis of protein crystals. The successful analysis of these extremely large and complex structures was made possible by indirect phase-measurement by multiple isomorphous replacement.

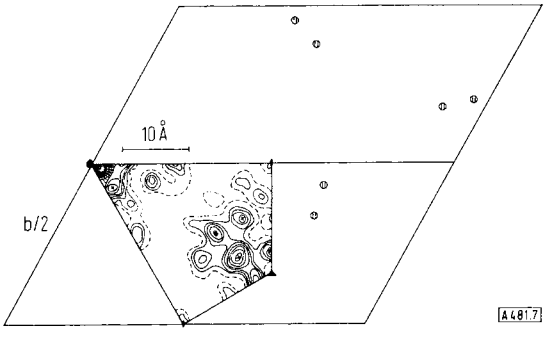

Fig. 7. Determination of the differentiating atoms in isomorphous protein derivatives. Protein [26, 27]: erythrocruorin from *Chironomus thummi*; molecular weight 16000; space group P $3_1$.

The Figure shows the "Patterson projection of the differences" in the direction of the trigonal axis, calculated from the squares of the differences between the absolute values of the structure factors $|F_S|$ of the protein-$HgCl_2$ compound (obtained by diffusion of $HgCl_2$ into the protein crystals) and the absolute values of the structure factors $|F|$ of the protein with no heavy atom. This Patterson synthesis of the differences (one asymmetric unit is shown) shows the Patterson structure of the heavy atoms in the protein (apart from a background that depends on the protein). Each protein molecule is bonded to two heavy atoms in definite positions. The Patterson point-structure of the heavy atom-heavy atom maxima is also shown (crosses) for comparison. The circles indicate the arrangement of the heavy atoms; note the threefold repetition.

[27] *R. Huber, H. Formanek*, and *O. Epp*, unpublished work.

The simple geometrical relationships of Fig. 6 can be easily programmed for each reflection, so that "automatic phase-measurement" in accordance with Fig. 6 raises no fundamental difficulties. The determination of the approximation structure of the differentiating atoms is not quite so simple; however, this evaluation can be largely automated. The real problem with the isomorphous replacement method is chemical in nature: thus it is necessary to prepare isomorphous heavy-atom derivatives in which not only the isomorphously substituted atoms are correctly located in the unit cell, but there must be no disturbance of the isomorphism owing to small displacements of the unsubstituted atoms. Fortunately, the large holes in protein structures, which are filled with solvent molecules, can accommodate quite large heavy-atom groups without disturbance of the crystal structure (cf. Fig. 7). Nevertheless, the preparation of suitable derivatives is often very difficult, even in the case of proteins.

Lack of isomorphism generally prevents the determination of phases with a resolution of better than 2 Å [28]. Although a Fourier synthesis based on these data, in principle, shows all the atoms, this synthesis cannot be interpreted directly, owing to the low resolution and the unavoidable phase error. As in the direct methods, it is necessary to include an evaluation step which, on the one hand, leads to the Fourier synthesis with all the absolute values of the structure factors that can be found by experiment [29], and on the other, eliminates the effect of the phase error (determination of the final model).

The method of anomalous scattering is related in some respects to the isomorphic replacement method. It can be shown that the scattering power of heavy atoms in a structure can be altered by variation of the wavelength of the primary beam. This change in scattering power has the same effect as the replacement of the atom by another atom. To bring about this change, it is necessary to use radiation having a wavelength close to that of an absorption edge of the heavy atom. In acentric structures the change in scattering power is accompanied by a phase change, which provides a possible method for indirect phase measurement. The measurement is made difficult by the fact that the effects are small, so that the measurements must be very accurate. The anomalous-scattering method can be automated by a system fundamentally similar to that used for the indirect phase measurement with multiple isomorphous replacement.

Since both the multiple isomorphous replacement method and the anomalous-scattering method involve measurements on heavy-atom derivatives, these may be included among the heavy-atom methods in the wider sense.

## B. Determination of the Final Model

### 1. Image-Seeking Functions

In the discussion of step A of the evaluation, we showed that the image-seeking functions permit the determination (at least in principle) of the positions of all the atoms. The method used to check for coincidence of superimposed Patterson maxima in the two mutually displaced Patterson structures is important in practice (cf. Fig. 5). The simplest method is to add the superimposed Patterson functions. Coincident Patterson maxima then appear to be intensified ("marked") in the picture obtained by superposition (additive image-seeking function).

Another method is to multiply the Patterson functions. When a Patterson maximum is situated over the background (non-coincidence), one of the factors in the multiplication is zero, and the Patterson maximum disappears in the picture obtained by superposition. In the case of coincident Patterson maxima, both factors are finite, and a maximum therefore apperas in the picture obtained by superposition. It is easy to see that, in the second of these methods, the background of non-coincident Patterson maxima is eliminated, at least in principle (product function). A third method is simply to note the lower of the two values of the superimposed Patterson functions. In this case the background is again eliminated, since non-coincident Patterson maxima lie on the background, the value for which is zero, so that the value recorded in the picture obtained by superposition is equal to zero (minimum function). All three methods can be easily programmed for electronic computers. There are therefore no obstacles to their use in routine work.

It should again be noted that in the case of complex structures, image-seeking methods are likely to be successful only if heavy atoms are present, owing to the overlapping of Patterson maxima.

### 2. Successive Fourier Syntheses

If we calculate a Fourier synthesis with the absolute values of the measured structure factors, together with the phases of an incomplete structural model (an approximation model) – *e.g.* in the case of a heavy-atom structure, the phases of a structure in which all the light atoms are neglected – the Fourier synthesis includes not only the electron-density maxima corresponding to the atoms inserted, but also maxima corresponding to some of the atoms that were neglected in the phase calculation. These atoms can then be included in the next phase calculation (improved approximation model), and a further Fourier synthesis should yield the maxima due to more new atoms. This operation is repeated until

[28] Definition of resolution: The smallest interplanar distance down to which reflections are to be measured. It can be shown that this limitation of the range of reflections measured limits the sharpness of the Fourier electron-density synthesis. In protein crystals, owing to defects in the crystal structure (small displacements of the atoms of the protein molecule) reflections can only be measured down to an interplanar distance of about 1.5 Å. An electron-density synthesis calculated with the aid of these reflection data does not lead to clear resolution of the electron-density maxima of light atoms linked by covalent bonds; it does, however, permit an unambiguous assignment of the amino-acid residues.

[29] Cf. *W. Hoppe* and *J. Gaßmann*, Ber. Bunsenges. physik. Chem. *68*, 808 (1964).

the positions of all the atoms have been found. Clearly, the better the phases of the first approximation model, the more rapidly will this procedure converge.

It is also obvious without calculation that the more atoms an approximation model contains, or – in the heavy-atom method – the higher the scattering power of the heavy atoms, the better is the model. As an illustration, Fig. 8 shows the maxima found in a Fourier

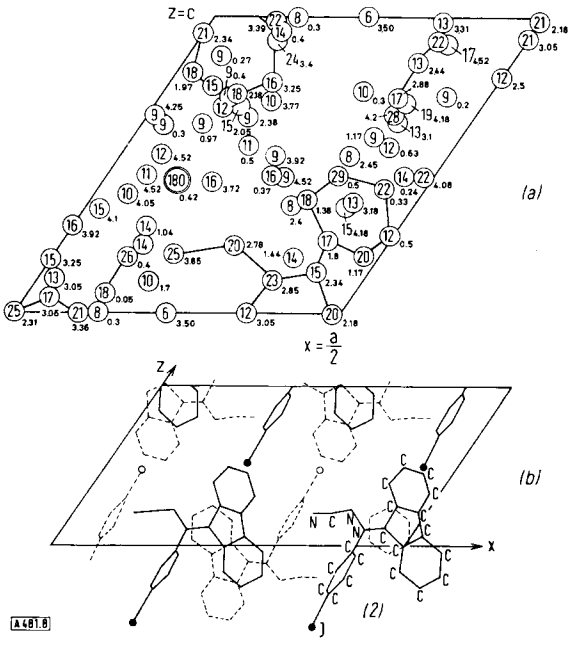

Fig. 8. *C*-(2,2'-biphenylylene)-*N*β-cyano-*N*α-(*p*-iodophenyl)azomethinimine *(2)*.

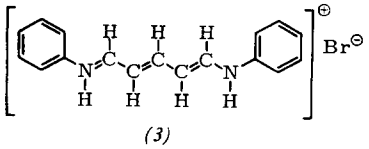
Fig. 8a shows maxima of a three-dimensional Fourier synthesis calculated with the phases of the iodine-atom approximation structure. The numbers in circles give the relative heights of the maxima; those outside the circles are the y parameters. Note the low "ghost maxima" and the deformation of the structure. Fig. 8 b shows the structure obtained when the analysis was completed.

synthesis of *C*-(2,2'-biphenylylene)-$N_\beta$-cyano-$N_\alpha$-(*p*-iodophenyl)azomethinimine phased only with the iodine atoms (cf. also Fig. 1). Since iodine has a high scattering power, this synthesis already contains the positions of all the atoms. The diagram contains a few extra "ghosts" and break-off maxima, but these can be readily distinguished on chemical grounds. Besides the maxima in Fig. 8, figures are given to indicate their heights.

For an organic structure of approximately the same size, *viz.* 5-anilinopenta-2,4-dien-1-ylideneanilinium bromide *(3)* [30], but containing the less strongly scattering bromine, the Fourier synthesis phased only with bromine did not contain the maxima for all the atoms. However, insertion of the light-atom maxima already found into the calculation of the



*(3)*

next Fourier synthesis gave the complete solution. The phase-determining power of a heavy atom depends not only on its scattering power, but also on the size of the light-atom structure. Thus the scattering power of potassium, for example, is sufficient to give the positions of all the light atoms in potassium *p*-nitrophenyl-*anti*-diazotate [31] by a single Fourier synthesis (cf. Fig. 9).

In structural analyses by the convolution-molecule method, the basis for the calculation of the first phases is the approximation structure of the known molecular

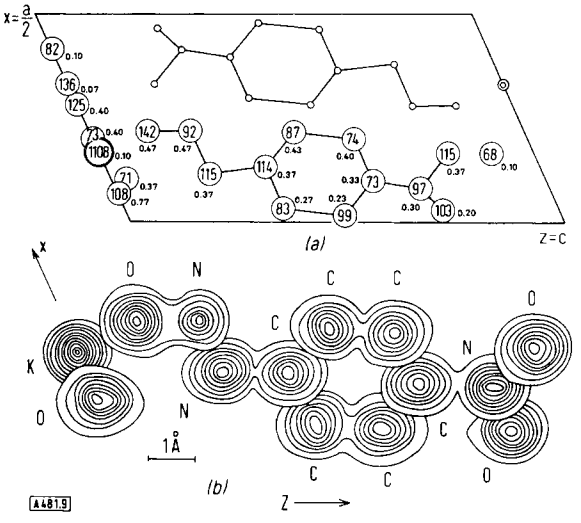


Fig. 9. Potassium *p*-nitrophenyl-*anti*-diazotate.

Fig. 9a shows maxima of a three-dimensional Fourier synthesis phased with potassium (representation as in Fig. 8). Fig. 9b shows the three-dimensional Fourier synthesis obtained when the analysis was completed. The diazotate group in *anti*-configuration is planar (cf. [32]).

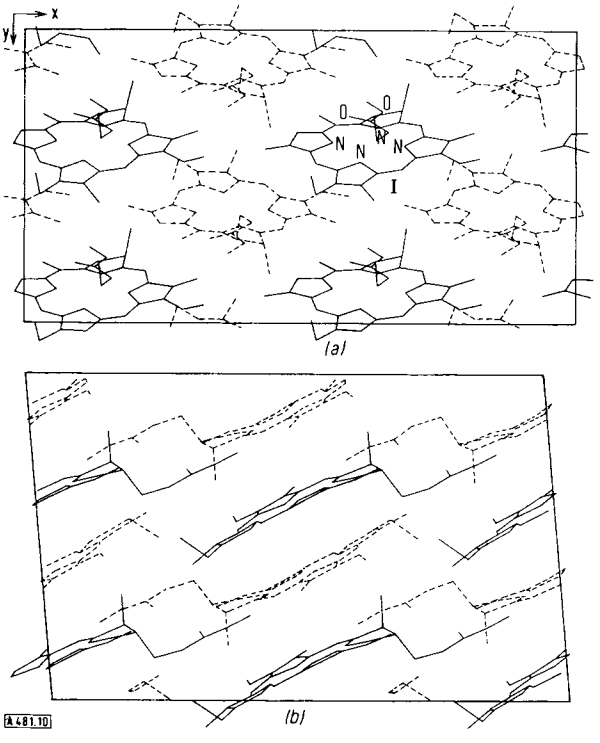

Fig. 10. Molecular model of phyllochlorine ester in c-projection (a) and in b-projection (b), derived from a three-dimensional Fourier synthesis; refined structure, $R_1$ = 15 %. Note the marked difference between the chlorine ring and the idealized planar configuration with four-fold symmetry (not shown) used in the convolution-molecule evaluation.

[30] *H.-J. Springer*, Dissertation, Technische Hochschule München, 1965.

[32] *R. Huber*, *R. Langer*, and *W. Hoppe*, Acta crystallogr. *18*, 467 (1965).

fragment. Successive Fourier analysis, apart from giving the positions of new atoms, also leads to a better picture of the molecular fragment, the stereochemistry of which is generally not accurately known. Fig. 10 illustrates this effect for the structure analysis of phyllochlorine ester [33]. The "molecular fragment" used in the convolution-molecule evaluation was a planar chlorine ring with four-fold symmetry. The chlorine ring is obviously anything but planar: apart from a slight curvature of the large ring system, the two tetrahedral carbon atoms in positions 7 and 8 are strongly displaced from the average plane.

In the determination of the structure of ecdysone *(4)* (cf. Section A.2), the coprostane skeleton used was improved so far that the position and orientation of the double bond of an α,β-unsaturated ketone could be discerned. The case of ecdysone is particularly typical, since a sterol skeleton that was wrongly convoluted at first was subsequently corrected by the convolution-model method, and since the unknown constitution of the molecule could be established (with differentiation between C atoms and O atoms) by three successive Fourier syntheses without the aid of chemical information. Fig. 11 shows the three-dimensional Fourier synthesis of ecdysone.

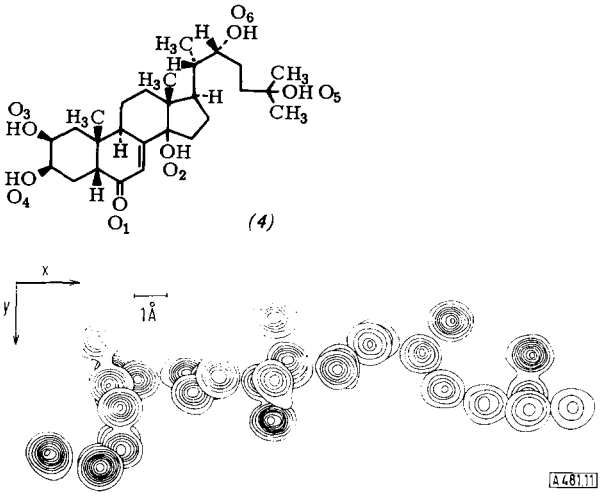

Fig. 11. Three-dimensional Fourier synthesis of the molecular model of ecdysone.

As in step A of the evaluation, the replacement of two-dimensional by three-dimensional methods greatly increases the reliability. This is due not only to the avoidance of undesirable coincident projections of atoms, but also to the large quantity of information, which leads to a partial averaging of the phase error. It must be pointed out, however, that certain positions of the heavy atoms can sometimes give rise to a false symmetry in the Fourier synthesis, which can be very difffcult to eliminate.

The automation of successive Fourier syntheses requires programs that permit the location of maxima in the electron-density functions. Programs of this type are relatively easy to develop, and have recently been introduced into our program system. In order to be complete, an iteration program must also include selection programs, the function of which is to decide which of the maxima obtained are to be interpreted as atoms. This decision can be made by neglecting maxima with intensities lower than a certain value. It has been found useful, however, to introduce an apparent occupation density of the atoms, assumed to be proportional to the height of the maximum. A variation process applied to successive calculation cycles involving least squares [34] not only leads to an improvement in the position parameters of the true atoms, but also brings the occupation densities of these atoms to unity (occupation by a single atom). The occupation densities of maxima that do not correspond to atoms, on the other hand, become zero. The new positions found in this way are used by the computer in the calculation of a new Fourier synthesis, which is interpreted in a new series of cycles. Successes achieved by this method have already been reported [35]. The interpretation of Fourier maxima by the computer may also include the use of stereochemical criteria in the selection of maxima that correspond to atoms. It is interesting to note that the trend in these programming tasks show a steady drift away from classic calculations. Programs of this type are also known as pattern-recognition programs. A non-crystallographic example of such a program is the recognition of hand-written characters. The same characters written by different persons can differ quite markedly. However, they have certain features in common, which permit the reader to read a very wide range of scripts. In this case the computer must imitate decisions that the reader generally makes subconsciuously. A distorted image of a group of atoms in a Fourier synthesis containing phase errors can also be regarded as such a "character".

### 3. Improvement of Phases by Modification of the Electron Density

Some time ago we reported methods by which the inaccurate phases derived from an approximation model could be improved without the use of model constructions in the Fourier space. We sought a function which, when operating on an approximate electron-density function, would improve the approximation to the true electron-density function [36]. The phases and absolute values of the Fourier coefficients of the improved electron-density synthesis can then be determined by a Fourier transformation. Consider a structure in which all the atoms have the same weight. A better approximation is then obtained by replacement of the absolute values of the Fourier coefficients by the measured absolute structure factors, since any deviation from the measured (and hence correct) absolute values of the structure factors indicates an error. The process is then applied to this new set of structure factors, and iteration over several cycles ultimately gives the final structure. Fig. 12 shows how such functions can be built up. In principle, the specially constructed function appraises an electron-density synthesis in the same way as a crystallographer does: new maxima with heights greater than a certain value are regarded as "probable" atoms, while maxima below this limit are regarded as "ghosts". However, the simple yes-no decision is replaced by the more cautious continuous function. Thus the modified electron-density function contains the new "probable"

[33] *W. Hoppe, G. Will, J. Gaßmann,* and *H. Weichselgartner,* unpublished work.

[34] See refinement by means of least squares.

[35] *J. D. Rollett* and *L. J. Hodgson*: Automatic Methods for Heavy Atom Phase Determination. Lecture at the Laue Symposium, Munich 1962.

[36] *W. Hoppe, R. Huber,* and *J. Gaßmann,* Acta crystallogr. *16,* A 4 (1963).

atom maxima as somewhat higher (but still too low) maxima, and the "probable" ghost maxima as somewhat lower (but still present) maxima. The relationship with the method of successive Fourier syntheses is readily apparent.

The function represented in Fig. 12 has the further advantage that it can be readily transformed into reciprocal space. It is therefore possible to modify the structure factors directly in order to improve their phases in successive cycles without intermediate calculation of electron density syntheses. Fig. 13 shows how well the method works for structures in which all the atoms are identical. Fairly small planar test structures have been chosen in order to minimize the extent of calculations required.

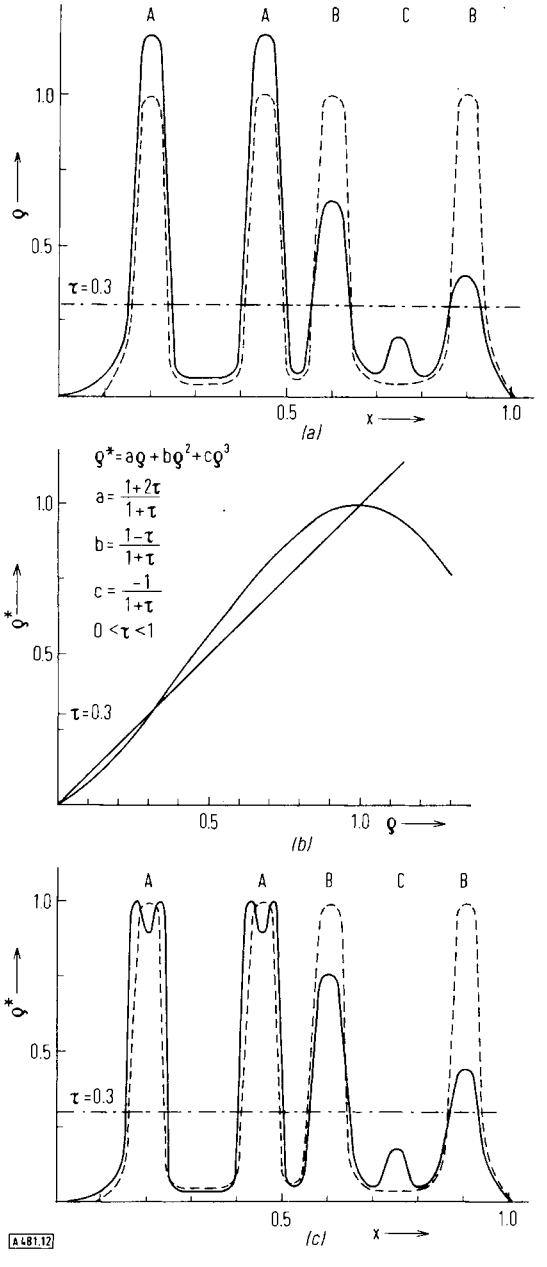

Fig. 12. Phase improvement by modification of the electron density. (a) The result of a Fourier synthesis phased with only some of the atoms present is shown in the one-dimensional example. The atoms used (A) appear to be excessively high, while the atoms (B) omitted are too low. There is also a background present (C) (the correct structure is shown). (b) A function $\varrho^*$ suitable for improvement of the structure. (c) The modified Fourier synthesis obtained on conversion of $\varrho$ into $\varrho^*$. It can be seen that the excessively high maxima (A) have been lowered, the low maxima (B) have been raised, and the background (C) has been reduced. It is to be expected that the phases of the structure in Fig. 12c will be better than those of the structure in Fig. 12a. The corresponding calculations can be carried out automatically in iterated cycles by the convolution process, without intermediate calculation of the Fourier synthesis.

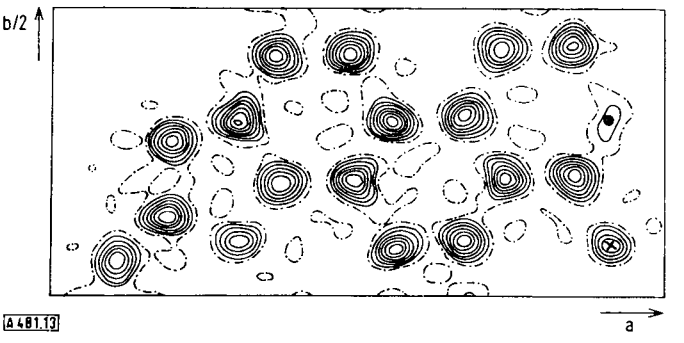

Fig. 13. Two-dimensional hypothetical test structure (a "methylated cyclopentadienophenanthrene") phased with all the atoms, but with qualitatively incorrect positioning of one of the eighteen atoms. The false maximum (cross) appears to be appreciably higher than the true one (dot). The process of Fig. 10 led to convergence in eight cycles, with complete elimination of the false maximum, and with development of the true maximum to the correct height.

The hypothetical test structure in Fig. 13 was phased with a model in which one out of the eighteen atoms given was in an entirely wrong position. As can be seen in the diagram, the maximum corresponding to the false atom is appreciably higher than the one at the position of the correct atom, which can scarcely be distinguished from the background. In considering this Fourier synthesis, the analyst would be inclined to assume that the structure is correct, and that the only errors are phase errors due to lack of accuracy of the coordinates. Only after vain attempts to refine the model would he realise that his structure must contain a qualitative error. Even in this case, however, the new phase-improvement process converges.

The programs, originally designed for two-dimensional calculations, were subsequently extended to three dimensions. It was found that even much poorer approximation models lead to convergence in three-dimensional calculations. In one case convergence was obtained with a structure phased with only four out of ten identical atoms. Moreover, the four given atoms were displaced by about 0.2 Å from their true positions. Investigations on a similar process for heavy-atom structures are in progress.

### C. Refinement of the Structure

The result of a successful Fourier synthesis is a set of atomic coordinates which still contain slight errors. Methods of refining the structure, most of which are regularly used in a semi-automatic form, were developed some time ago. We shall deal here only with those that are particularly suitable for automatic calculation, in which the experimental values are fitted by the method of least squares.

### 1. Least-Squares Refinement of Atomic Parameters

The equation for the structure factor is:

$$F_{\vec{h}} = \sum_{j=1}^{N} f_j \exp 2\pi i (\vec{h}, \vec{r_j} + \Delta \vec{r_j}) \quad (3)$$

After this equation has been linearized by the method of least squares, the $\Delta\vec{r_j}$ can be found by solution of a system of linear equations, and the difference between $(F_h)_{exp}$ and $(F_h)_{calc}$ can then be minimized.

The atomic coordinates, the scaling factor, and the thermal factors of the individual atoms may be used as parameters. Anisotropic thermal vibrations can be readily taken into account, and the method of least squares has the advantage that the residual error of the varied coordinates can be determined in a satisfactory manner. The process and the associated computing programs have for some time been an essential part of structural analysis.

### 2. Refinement of Phases

This process has only recently been described [37], and like the method of phase correction by modification of the electron density (Section B.3), has so far been successfully tested only for structures consisting of identical atoms. In structures of this kind, each structure factor

$$F_{\vec{h}} = \sum_{h'} |F_h| \, |F_{h-h'}| \exp (\Phi_{h'} + \Phi_{h-h'} + \Delta\Phi_{h'} + \Delta\Phi_{h-h'}) \quad (4)$$

can be represented as the sum of all the other structure factors, as in Eq. (4). This equation is very similar to that for the structure factor from the contributions of the individual atoms present in the structure (3), with the product $F_h \, F_{h-h'}$ of the structure factors in place of the form factors $f_j$ of the atoms.

A particularly interesting point is that – again purely formally – the coordinate-dependent exponential functions $\exp 2\pi i(hr_j + \Delta r_j)$ are replaced by ones depending on the phases of the structure factors. Owing to the formal similarity of the two equations, it is possible, in principle, to use the same mathematical process based on the method of least squares. This process, however, no longer leads to correction of the error in the atomic coordinates $\Delta r_j$, but to the correction of the phase error $\Delta\Phi$. We have successfully used the new method for a number of simple test structures. It should be noted that phase refinement also leads to the appearance of new atoms and the disappearance of wrong ones in the improved Fourier synthesis. The method gives similar results in this respect to those obtained by the method described in Section B involving modification of the electron density.

[37] *W. Hoppe*, Z. Kristallogr., Kristallgeometr., Kristallphysik, Kristallchem. *118*, 122 (1963); *W. Hoppe*, *R. Huber*, and *J. Gaßmann*, Acta crystallogr. *16*, A 4 (1963).

### 3. Other Methods of Refinement

It has been shown that the refinement methods of difference Fourier synthesis and the method of steepest descent are related to the refinement of the atomic coordinates using the method of least squares. The difference Fourier synthesis method is often used in structure analysis. In this method the differences between the calculated and experimental structure factors are used to calculate a Fourier synthesis, the course of which in the vicinity of the atom maxima gives an indication of the corrections to be applied. In principle, the method of least squares is completely analogous, but in this case the gradients of the Fourier synthesis are considered instead of the atom maxima. It cannot be said whether a gradient of this kind is subject to any disturbing effects. In the difference Fourier synthesis, however, the course of a function is considered over the entire space. It may therefore be possible to recognize any abnormalities in the course of the function. For example, if an atom is omitted in the calculation of the structure factors, the missing atom appears in the correct place in the difference Fourier synthesis. A qualitatively wrong atom gives a deep minimum at the wrong position and a Fourier maximum in the correct position. Like the phase-refinement method, therefore, difference Fourier synthesis can also lead to qualitative corrections. No attempt has yet been made to carry out an automated difference Fourier synthesis, but this is possible with the aid of principles similar to those discussed in connection with the automatic evaluation of Fourier syntheses.

## D. Closing Remarks

Crystal-structure analysis has not yet become an automatic process, and it may take some time before structures will be solved by simply running off a computer program. It is also likely that only some of the structural problems that arise will be capable of being solved automatically. However, X-ray analysis will undoubtedly become more important in chemistry, and particularly in constitutional analysis. A constitutional formula will then frequently form the starting point of an investigation instead of the end result. It will also be possible, as is the case in absorption spectroscopy, to carry out parallel studies on related compounds in a reasonable time, and so base conclusions not only on the absolute values of the bond lenghts and bond angles, but also on changes in these parameters.

## E. Appendix

Since completion of the manuscript new results have been obtained, particularly in phase correction by modification of the electron density [38]. Fig. 14 shows the Fourier synthesis of an acentric, two-dimensional test structure comprising 22 carbon and 2 phosphorus atoms calculated from the phases of the P atoms. After 30 cycles of phase correction the Fourier synthesis shown in Fig. 15 was obtained, in which the arrangement of atoms can be clearly seen (the electron densities due to the phosphorus atoms have been subtracted).

[38] *J. Gaßmann*, Dissertation, Technische Hochschule München, 1966.

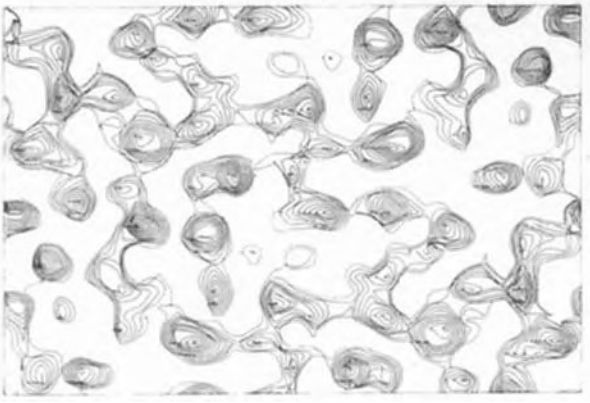

Fig. 14. Two-dimensional Fourier synthesis of a hypothetical 24-atom test structure (a naphthalene-type ring system connected by a carbon chain to a five-membered ring; short side chains) phased with two phosphorus atoms. Plane space group pg. The distorted form of the diagram makes chemical interpretation very difficult.

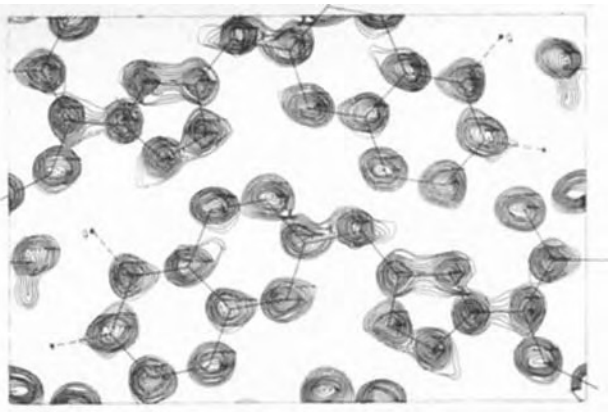

Fig. 15. Two-dimensional Fourier synthesis of the same structure as in Fig. 14 after 30 phase-correction cycles. The locations of the two phosphorus atoms used for initial phasing are marked by asterisks.

Three-dimensional phase correction was successfully tested on two real organic structures: Firstly, on phyllochlorine ester, $C_{33}N_4O_2H_{38}$, where intitial phasing was made on the basis of an idealized, plane chlorine ring model, the orientation and position of which had been determined by the convolution molecule method (cf. also Fig. 10). Secondly, on the rubidium salt of the "sulfolipid" $RbSC_9O_{10}H_{17}$ [39] (initial phasing by the heavy-atom technique with Rb and S). In both cases strong, spurious maxima were introduced into the initial Fourier syntheses on account of symmetry elements; in the course of the phase correction these maxima disappeared.

# Some Advances in the Inorganic Chemistry of Bromine [*]

BY DR. V. A. STENGER

SPECIAL SERVICES LABORATORY, THE DOW CHEMICAL COMPANY, MIDLAND, MICHIGAN (U.S.A.)

*Recent advances in the chemistry of bromine and its inorganic compounds are covered under the headings of technology, properties and reactions, liquid bromine as an inorganic solvent, analysis, and new or newly studied compounds. Much of what is new in bromine chemistry is characteristic also of what is new in inorganic chemistry as a whole. That is, more detailed information about compounds and reactions is becoming available from the application of new instrumental and theoretical techniques.*

## Technology

Bromine is obtained from ocean water and natural brines, and to a lesser extent as a by-product in the processing of sodium and potassium chlorides from salt deposits. Some attention has been given to new ways of isolating bromine, including ion exchange [1] and solvent extraction [2], but these have not come into commercial use. Practically all of the current production from ocean water is made by chlorination and volatilization, followed by the collection of bromine either in sodium carbonate or sulfurous acid solution [3, 4]. From the latter, bromine is recovered by rechlorination and distillation. It may be possible to avoid the need for chlorine in this step by a new process [5] in which a trace of butyl nitrite or an alkali metal nitrite in an acidic medium serves as a catalyst for oxidation by oxygen or air at 0 to 200 °C and pressures of 1 to 4 atmospheres.

Table 1. A typical analysis of high-purity commercial bromine.

| | |
|---|---|
| Assay as $Br_2$ | >99.98 % |
| Moisture | 0.003 % |
| Non-volatile matter | 0.0008 % |
| Chlorine plus chloride | 0.0005 % |
| Sulfate as $SO_4$ | <0.0010 % |
| Chloroform | <0.0005 % |
| Carbon tetrachloride | <0.0005 % |
| Bromoform | <0.0005 % |
| Carbonyl bromide | <0.0005 % |

The purity of commercial bromine has recently been increased markedly. A typical analysis is shown in Table 1. Whereas the various producers have their own methods for obtaining such purity, some processes have been described in the literature. Chlorine is generally removed by distillation in the presence of an excess of bromide. In a modification [6] of this step, a 5 to 30 % solution of an inorganic bromide in water is saturated with crude bromine. The undissolved liquid bromine (not over 10 % of the total) retains most of the organic matter and is removed. The dissolved bromine is distilled out, condensed, and dried, being reported then to contain less than 10 ppm of organic impurities. *Codell* and *Norwitz* [7] remove organic matter from bromine completely by passage with oxygen at 1000 °C through a furnace packed with fragmented quartz or high-silica glass (Vycor). In our experience this works well, but must be followed by a chlorine-removal step as chlorine is produced by the oxidation of chloroform or other organic chloro compounds. Drying must also be done after the oxidation. Purification by low temperature-low pressure sublimation [8] is suited only for small-scale use.

Evaluation of purity in the range shown demands improved analytical techniques. In our laboratories an infrared-spectroscopic method has been used [9]. Pure bromine is transparent throughout the usual infrared region [10]. Moisture and most of the probable organic impurities can be detected very sensitively in a half-inch cell with rock-salt windows. Figure 1 shows the infrared spectrum of typical high-purity bromine, along with the locations of bands of possible impurities.

*Chao* and *Stenger* [11] purified high-quality bromine further for use in the determination of various properties. Moisture and acidity are the critical impurities which must be removed prior to determinations of electrical conductivity. Pure, dry bromine is an extremely poor conductor and considerable difficulty surrounds the measurements. Minimum values were obtained after about ten distillations over barium oxide in a sealed apparatus. The bromine so prepared had a purity estimated as better than 99.999 mole-%, none of the impurities listed in Table 1 being detectable. The following values were obtained at 25.0 °C: Specific conductivity, $9.10 \times 10^{-12}$ ohm$^{-1}$ cm$^{-1}$; thermal conductivity, $2.93 \times 10^{-4}$ cal cm$^{-1}$ sec$^{-1}$ deg$^{-1}$; surface tension 40.9 dyne cm$^{-1}$.

Moisture is also an important factor in the corrosion of metals by bromine. When its moisture content is below about 40 ppm, bromine can be transported in nickel vessels [12]. Dry bromine also fails to react with such active metals as sodium and magnesium. *Stull et al.* [13] used a magnesium calorimeter in their work on the heat capacity of bromine, which is 0.113 cal/g at 25.0 °C.

Mass-spectrometric measurements have been made on the volatile products obtained on reaction of bromine with nickel at temperatures up to 1300 °C and at bromine pressures between $10^{-4}$ and $10^{-7}$ mm Hg. It was found [14] that bromine dissociates on the nickel surface at a temperature-dependent rate. $NiBr_2$ is formed between 300 and 900 °C with a maximum in the rate at about 600 °C. Above 900 °C, NiBr is formed at a rate increasing with nickel temperature. Both products are formed in surface reactions at rates proportional to the bromine pressure. On the basis of the volatilization rates and energy considerations, the reaction scheme shown in Table 2 was suggested. It appears that below about 880 °C (but probably above 600 °C), the nickel is covered with a monolayer of NiBr. Below 600 °C, the monolayer is more likely $NiBr_2$.

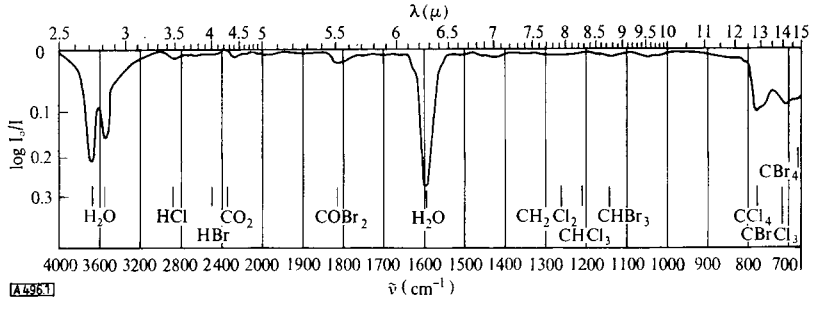

Fig. 1. Infrared spectrum of highly purified bromine.

It has long been known [15] that bromine forms lamellar compounds with graphite by penetrating between the carbon planes. Two types of such compounds are known [16].

| $Br_2$ (g) | → 2 Br | on a NiBr monolayer |
| Br | → Br (g) | |
| NiBr + Br | → $NiBr_2$ | |
| $NiBr_2$ | → $NiBr_2$ (g) | |
| NiBr | → Ni + Br (g) | |
| NiBr | → NiBr (g) | |

In those with a bromine content up to that corresponding to the composition $C_{16}Br$ (Type I), the bromine has penetrated only between some of the carbon planes and the crystallographic order is two-dimensional. On introduction of further bromine, compounds (Type II) up to composition $C_8Br$ are obtained in which there is one bromine layer for every two carbon layers; the crystallographic order is three-dimensional, and the distance between two carbon layers with an intercalated bromine layer is 3.70 Å. The crystallographic radius of a bromine atom, or the length of a carbon-bromine bond of an aromatic bromo-compound (such as might be expected from graphite and bromine) is slightly less than half as great. Only some of the bromine is ionic. The compound $C_8Br$ decomposes above 50 °C. Hysteresis is observed upon vapor-pressure change, part of the bromine being held irreversibly. For example, an intercalation compound of natural graphite at 30 °C at an atomic ratio Br/C of 0.082 has a vapor pressure of 0.49 $p_0$, where $p_0$ is the vapor pressure of pure bromine at the same temperature. After evacuation for one hour in series with a liquid nitrogen trap, 18 % of the bromine remains on the graphite.

The rate and extent of bromination [17] of natural graphite depends on the grain size. Large crystals (0.02-2 mm) form $C_8Br$ over a range of bromine partial pressures from 0.5 to 0.9 mm Hg at 20 °C. The bromine contents of small crystals (0.002-0.01 mm) increase with partial pressure. Between −12 and −20 °C, the initial activation energy was found to be 2.4 kcal/mole.

*Aronson* [18] has investigated the exchange of radioactive $^{82}Br$ with graphite-bromine compounds at 30–50 °C. The rates of exchange appear to agree with the concept that the exchange process is one of volume diffusion rather than a surface effect. The diffusion coefficients were found to increase with increasing bromine content and the reversibly absorbed bromine showed a higher rate of exchange than the "residual" bromine. The activation energy for diffusion, about 11–14 kcal/mole at 30 °C, is considerably greater than that for the initial bromination.

## Liquid Bromine as an Inorganic Solvent

Solubilities of various alkali bromides in liquid bromine were determined by *Kramer* and *Stenger* (Table 3) a number of years ago, and a process for the separation of

Table 3. Solubilities of alkali halides in liquid bromine (grams per 100 grams of solution at 25 °C).

| Alkali metal | Chloride | Bromide |
|---|---|---|
| Lithium | 0.0037 | 0.005 |
| Sodium | 0.001 | 0.010 |
| Potassium | 0.0055 | 0.0185 |
| Rubidium | 0.015 | 0.058 |
| Cesium | 0.175 | 19.3 |

cesium bromide from the other alkali bromides was based on the results [19]. During the last few years metallic cesium has been in increasing demand as the active element in ion propulsion and in thermionic converters. Purity is of great importance in these applications. The purest cesium commercially available up to the present was prepared from cesium bromide purified through the bromine extraction process. Rubidium and other alkalies are the common impurities to be removed. As can be seen from the data in Table 3, extraction of a mixture of cesium and rubidium bromides with bromine can yield after evaporation a cesium bromide product that contains only about 0.3 per cent RbBr. Subsequent crystallizations from water lower the rubidium content by about two-thirds at each step. Removal of the other alkalies is even more efficient.

*Kramer* has subsequently made approximate determinations of the solubilities of several other chlorides and bromides in liquid bromine (Table 4). No other striking solubilities such as that of cesium bromide have been encountered. It is known, of course, that several inorganic liquids, such as titanium tetrachloride, are miscible with bromine.

Table 4. Solubilities of bromides in liquid bromine (grams per 100 grams of solution at 25 °C).

| Element | Solubility of bromide |
|---|---|
| Aluminum | quite soluble (anhydrous)<br>0.002 (hydrated) |
| Iron(III) | 0.324 (anhydrous)<br>slightly soluble (hydrated) |
| Nickel(II) | 0.0003 |
| Copper(II) | 0.0001 |
| Manganese(II) | 0.0002 |
| Zinc | 0.0146 |
| Cadmium | 0.001 |
| Magnesium | 0.002 |
| Calcium | 0.003 |
| Strontium | 0.002 |
| Barium | 0.005 |

The equivalent conductance of solutions of tetrabutylammonium bromide and trimethylamine hydrochloride in bromine *increases* with increasing concentration [20]. For example, the equivalent conductance of the tetrabutyl compound at 25 °C is 1.43 $ohm^{-1}$ $cm^2$ $eq.^{-1}$ at 0.092 M and 3.04 at 0.165 M. It was postulated that this behavior is characteristic of a solution of a liquid in a supercooled fused salt. *Stenger* and *Chao* [20a] have observed the same effect with solutions of cesium bromide in bromine.

*Gorenbein* and *Kaplan*[21] have described concentration cells based on platinum electrodes in bromine containing phosphorus(V) bromide, chloride, or oxide chloride. The EMF values obtained were relatively low (about 0.03 volt). *Chao* and *Stenger* have carried out preliminary studies [20a] on batteries employing dissimilar metals in a bromine-cesium bromide electrolyte. The potential difference between magnesium and tungsten electrodes in this system is 1.9 volt. Because of rapid polarization, however, such cells have limited practical utility.

The structure of liquid bromine at 23 °C has been investigated by *Cagliotti* and *Ricci*[22], using neutron diffraction. The intensities of neutron beams scattered after impinging upon the bromine surface at various angles were measured, corrected for background, and plotted against angle. Two strong and several subsidiary maxima were observed. From a mathematical treatment of the data they conclude that the bromine molecules do not rotate freely, but that some of the structural features of crystalline bromine are preserved in the liquid.

*Waddington* and *White*[23] studied liquid hydrogen bromide as an ionizing solvent and used it as a medium for the preparation of several substituted ammonium, phosphonium, and arsonium tetrabromoborates. In general, hydrogen bromide, with a dielectric constant $\varepsilon$ of 7.0, is a poorer solvent than hydrogen chloride ($\varepsilon$ = 10.6). Upon dissolving tetramethylammonium bromide in hydrogen bromide at −83 °C, two liquid layers are formed when a concentration of 0.06 M is reached, the upper one having the greater conductivity.

## Analytical

For the detection of bromide ion in mixtures, several modifications of the Baubigny-Hahn fluorescein test[24] are known. *Haba* and *Wilson*[25] have devised a new version in which samples are treated by the Weisz ring oven technique. The disk obtained is sprayed with a 1:5 mixture of acetic acid and 30 % hydrogen peroxide, followed by 0.5 % fluorescein in ethanol. A red line of eosin in the dried sample indicates bromide. A procedure is also given by these authors for differentiating between iodide and bromide by use of a palladous nitrate reagent. *Somerville* and *Campbell*[26], working with the Hahn test in dilute solutions, recommend obtaining the proper buffer pH of 5.4 by adding an excess of pure calcium carbonate to the solution containing acetic acid. This simplifies the neutralization.

A test similar in principle but employing phenol red rather than fluorescein was developed by the author with *I. M. Kolthoff* some time ago. A spectrophotometric modification, recently revised and improved by *Goldman* and *Byles*[27], in which chloramine-T replaces the original hypochlorite, has been included with the Standard Methods of the American Public Health Association (1960).

Perhaps the most sensitive determination of bromide ion yet described[28] makes use of the fact that the oxidation of iodine to iodate by permanganate in acidic solution is catalysed by a trace of bromide. The extent of reaction unter given conditions can be followed by extracting the remaining iodine with carbon tetrachloride and comparing its color intensity with that of a control solution free from bromide. The reaction is carried out for ten minutes at 0 °C. The more bromide is present, the more iodine is converted to iodate by the permanganate and the lower is the color intensity of the extract. Sensitivity to as little as one microgram of bromide per liter of natural water is reported.

The qualitative identification of bromate was studied by *Miller*, *Philip*, and *Underwood*[29] by infrared spectrometry in potassium bromide disks. Potassium bromate shows absorption bands at 12.5 and 23.3 μ. The former band encounters interference from iodate, which has a band at 13.2 μ with a shoulder at 12.5, but the 23.3 μ band appears to be specific for bromate. *Haba* and *Wilson*[30] have also used the infrared method, but preceded it by an anion separation scheme[30a], so that only silicate, bromate, and iodate are present in the mixture to be tested. If the infrared spectrometer available does not permit measurements at 23.3 μ, interference is encountered between bromate and iodate. For such a case, a polarographic method can be recommended, as the waves of iodate and bromate are well separated in a solution buffered on the alkaline side[30b].

*Feigl* and *Pollak*[31] have reported a spot test sensitive to 0.8 μg of bromate. The bromate is reduced by sulfosalicylic acid in the presence of molybdophosphoric acid, forming molybdenum blue.

A volumetric method for the analysis of hypobromite-bromite-bromate mixtures is given by *Hashmi* and *Ayaz*[32]. The total oxidizing power is determined iodometrically in acidic solution by titration with standard thiosulfate. The sum of hypobromite and bromite is found by allowing another portion to stand for 5 minutes with an excess of standard arsenite in alkaline solution, after which the mixture is buffered with sodium bicarbonate and acetic acid and the excess of arsenite is titrated with standard iodine to a starch endpoint. To a third portion sodium bicarbonate and an excess of ammonium sulfate are added to reduce hypobromite selectively, the sum of bromite and bromate then being determined iodometrically after acidification. However, *Andersen* and *Madsen*[33] have pointed out that bromite

also reacts to some extent with ammonium sulfate. They proposed a method in which hypobromite is titrated potentiometrically with standard ferrocyanide at pH 8–9.

An apparatus has been described [34] for the analysis of corrosive halogen compounds by gas chromatography. It makes use of a nickel introduction device and a nickel column packed with Voltalef 300 LD, a fluorinated resin, impregnated with Kel-F oil, a fluorocarbon. Tested for the analysis of hydrofluoric acid and chlorine trifluoride, it should also be suitable for hydrobromic acid and the bromine fluorides.

## Bromine Compounds

A number of new or unusual inorganic compounds containing bromine have been described recently. Two which could not have been prepared at all a few years ago are technetium oxide tribromide, $TcOBr_3$ [35], and potassium bromotechnetate, $K_2TcBr_6$ [36].

The oxide tribromide, formed from technetium dioxide and bromine at 350 °C, is a brown solid that sublimes at 400 °C. Potassium hexabromotechnetate(IV) is made by evaporation of the chloro analogue or of potassium pertechnetate with hydrobromic acid. It forms large, dark red, regular octahedral crystals of the potassium chloroplatinate type. Bromides and oxide bromides of rhenium have been studied by *Colton* [37], who reported the following compounds:

$ReBr_3$: dark brown crystals (from heating $ReBr_5$); sublimes at 350 °C in vacuum.

$ReBr_4$: dark solid (?) (from $HReO_4$ + HBr); probably unstable.

$ReBr_5$: blue-green (from Re + $Br_2$ at 650 °C); melts readily; distils upon gentle heating in bromine vapor.

$ReOBr_4$: blue (from Re oxides + $Br_2$ at 150 °C); sublimes readily.

$ReO_3Br$: colorless, volatile, unstable liquid (from $ReBr_4$ + $O_2$ at 120 °C).

Potassium hexabromorhenate has also been described [36]. It is almost identical crystallographically with its technetate analogue.

Sulfur bromide pentafluoride, $SBrF_5$ [38, 39], was prepared by addition of bromine to sulfur pentafluoride at 150–200 °C. Its microwave spectrum shows that the sulfur-bromine bond (2.19 Å) is longer than the sulfur-fluorine bonds (1.597 Å).

Bromine(I) fluorosulfate, $BrOSO_2F$ [40, 41], is formed by the reaction of excess of bromine with peroxydisulfuryl fluoride. It is a red-black liquid boiling at 120.5 °C. With an excess of the peroxy compound one obtains bromine(III) fluorosulfate, $Br(OSO_2F)_3$ [40, 41], an orange, crystalline solid melting at 50 °C. Both products are strongly reactive oxidants. Addition of bromine trifluoride to the Br(III) compound, or of bromine to fluorine fluorosulfate, yields the non-stoichiometric compound $Br_2 \cdot 3SO_3F_2$ [41], a yellow, high-boiling liquid.

Phosphoryl bromide chloride fluoride, POBrClF [42], was studied as one of a series in which it was shown that substitution of bromine for a lighter halogen decreases the PO stretching frequency, the group electronegativity, and the estimated PO force constants. The changes are about 4, 10, and 7 %, respectively, on replacement of fluorine, but only about 0.8, 2, and 1 % for replacement of chlorine.

Bromochromic acid, $HCrO_3Br$ [43], was observed during the extraction of chromic acid from 5 M hydrobromic acid with t-butyl phosphate. Its formula was established from the amounts of hydrogen, chromate, and bromide ions transferred from the aqueous to the organic phase. The extraction of hydrobromic acid alone under similar conditions is negligible. The absorption spectrum in the organic phase was also shown to differ from that of solvated dichromic acid, which is obtained when hydrobromic acid in the aqueous phase is replaced by nitric, sulfuric, or perchloric acid.

Boron dibromide azide, $(BBr_2N_3)_3$ [44], is prepared by slowly bubbling nitrogen through bromine, passage of the vapors over phosphorus pentoxide for drying and then through a glass tube loosely packed with sodium azide to yield vapors of bromine azide, which in turn are passed through boron tribromide:

$$Br_2 + NaN_3 \rightarrow NaBr + BrN_3$$
$$BrN_3 + BBr_3 \rightarrow BBr_2N_3 + Br_2$$

Precautions must be taken to avoid explosions. The compound is deposited as colorless crystals when excess of boron bromide and bromine are removed by vacuum. It dissolves in benzene as the trimer, according to determinations of molecular weight. After recrystallization from carefully purified carbon tetrachloride, the product showed a melting point of 94.5 °C with very little decomposition.

Tetrafluorobromates of the higher alkali metals, as well as the corresponding products in which bromine is replaced by chlorine or iodine, result from the direct addition of fluorine to the appropriate alkali halide at 15 to 250 °C [45, 46]:

$$CsBr + 2\,F_2 \rightarrow CsBrF_4$$

At 350–400 °C the compounds dissociate into alkali fluoride and halogen trifluoride:

$$CsBrF_4 \rightarrow CsF + BrF_3$$

The compounds are white, low-melting (100–200 °C), and strong oxidants. They oxidize an excess of iodide to iodine and liberate oxygen from water. Based on violence of reaction, the order of reactivity with water in respect to the different fluorohalates is Cl > Br > I. In the case of the chloro compounds, chlorate is formed, whereas the fluorobromates are reported to yield both bromate and hypobromite. In respect to salts of the various alkali elements, the order of thermal stability is Cs > Rb > K. Potassium, silver, and barium fluorobromates had been prepared earlier [47] by the addition of excess bromine trifluoride to the corresponding chlorides.

Following the pioneer work of *Kraus* and *Moore* [48] there has been great interest in the adsorption of metal halide complex ions by anion-exchange resins of the strong base type. Differences in the acid concentrations at which various ions are adsorbed or eluted from a resin permit useful separations in some cases, and furnish information about the relative stabilities of complexes. Thus iron(III) in 6 M HCl is strongly held on a resin column, while aluminum passes through readily. The iron complex dissociates in more dilute acid, so that the iron may be eluted from the resin with 0.1 M HCl. Among the transition metals the indicated order of increasing stability of the complexes is Ni < Mn < Co < Cu < Fe(III) < Zn. This is the reverse of the order of acid concentrations required to hold the metal on a column. That is, nickel passes through even in 12 M HCl, while zinc is held tightly at any concentration above 0.005 M. The adsorbed ions are assumed to have the general formula $MX_4^{2-}$ where M denotes a divalent metal and X a halogen, or $MX_4^-$ where M is trivalent. The same order of stability applies in hydrobromic acid solutions [49], though generally the bromide complexes are bound somewhat less strongly than their chloride analogues. For example, *Horne et al.* [50], in comparing the adsorption of zinc in various concentrations of hydrochloric and hydrobromic acids, found maximum adsorption at 2.1 M in HCl as against 2.9 M in HBr. However, it should be remembered that the complex ions must compete with halide ions for positions on the resin, and that the resin holds bromide more strongly than chloride [51]. True complex dissociation constants cannot be obtained from ion-exchange data alone.

That it is primarily the halide ion concentration rather than the acidity that influences adsorbability, but that there is also a secondary cation effect, was shown by the work of *Kraus et al.* [52] and *Horne* [53]. Greater adsorption is obtained from a lithium halide solution than from the equivalent concentration of halogen hydracid. The other alkali metals appear to lose effectiveness in this respect in the order of increasing atomic number, and the same is true of the alkaline earth elements. *Lindenbaum* and *Boyd* [54] substituted a liquid anion-exchange system for the solid resin, studying the distribution of transition metal halides between solutions of trioctylammonium halides in toluene, and of HCl, HBr, or LiCl in water. The organic phase was found to extract metal halide complexes in accordance with the halide concentrations in the aqueous phase and the relative order of complex stability (above). Spectrophotometric examination of the organic phase showed the extracted species to be $MX_4^{2-}$ or $MX_4^-$. No such complex ion was found for nickel, which is not extracted.

Contrary to expectations, some of the metal halide complexes are also taken up by a cation-exchange resin [55]. Those which are [gold, gallium, iron(III)] can also be extracted from HCl solutions with ether. Indium is not significantly adsorbed either from HCl or LiCl solution. The order of adsorbability of indium halides from the corresponding acids by Dowex 50 was found to be Cl < Br < I [56]. Iron(III) in HBr or LiBr solutions is adsorbed by Dowex 50 or extracted by a cation-exchange type solution of dinonylnaphthalenesulfonic acid in toluene [57]. Spectrophotometry and analysis of the latter solution revealed that the extracted complex ion is $FeBr_4^-$, accompanied by the equivalent quantity of $H^+$ or $Li^+$. The authors concluded that in the case of cation exchange media the phenomenon is not one of ion exchange, but a salting out of ion pairs ($H^+ \cdot FeBr_4^-$) from the concentrated aqueous phase.

Many elements, including aluminum, alkaline earths, rare earths, iron(III), chromium(III), and manganese(II), are held tightly by Dowex 50 and cannot be eluted with a moderate volume (300 ml) of dilute acid. According to *Fritz et al.* [58], however, some of the heavy metals can be eluted with 0.6 M HBr because of the soluble complexes which they form. Mercury(II), cadmium, bismuth(III) and lead are eluted in that order; the separation is improved by eluting with gradually increasing concentrations of HBr. Zinc follows lead, before most other elements break through, but would probably encounter interference from copper(II) or magnesium.

Double salts of alkali metal and heavy metal halides can usually be prepared easily by dissolving stoichiometric quantities of the appropriate salts in water and allowing crystals to form by slow evaporation. They can be recrystallized from water in the same way (or, in the case of a pseudo-alkali tetraalkylammonium complex, from an alcohol). The structures of the cesium tetrahalocuprates $Cs_2CuX_4$ have been elucidated [59] with the aid

of ultraviolet, visible, and infrared spectra. The tetrachloro- and tetrabromocuprate ions are slightly distorted from a regular tetrahedral arrangement. *Sabatini* and *Saconni*[60] prepared a series of tetraalkylammonium tetrahalometallate complexes of divalent manganese, iron, cobalt, copper, zinc, and nickel, all having the general formula $(R_4N)_2MX_4$. Far infrared spectra showed the halogen atoms to have a regular tetrahedral configuration in all cases except those of the copper compounds.

All the bromine atoms in the bromoselenates of cesium and ammonium are crystallographically equivalent. Potassium bromoselenate differs from the others in this respect. It also has at least three low-temperature transition points (−33, −52, and −64 °C) as revealed by a plot of quadrupole resonance frequency against temperature[61]. The nature of the transitions has not been determined; at 25 °C the crystals are cubic[61a].

Equilibrium constants for aqueous systems of potassium bromide and zinc or cadmium bromide have been determined through shifts in the Raman spectra[62]. With zinc bromide several species are formed: $ZnBr_4^{2-}$, $ZnBr^+$, and hydrated $ZnBr_2$; with cadmium bromide only $CdBr_4^{2-}$ was found. The constant for the formation of bromocadmate is considerably larger than that for bromozincate:

$$[ZnBr_4^{2-}]/[ZnBr_2]\,[Br^-]^2 = 0.2$$

$$[CdBr_4^{2-}]/[Cd^{2+}]\,[Br^-]^4 > 1$$

The above constants help to clarify the behavior of zinc and cadmium bromides on an anion-exchange resin of the quaternary ammonium base type. Both metals are adsorbed strongly by the resin from 1 M HBr. Upon elution with water or 0.005 M HBr both come off very slowly, but cadmium much more slowly than zinc. Apparently the resin may be regarded as equivalent to an insoluble but ionizable alkali bromide, which retains the metal bromide in complex form when bromide ion is present.

A problem of long standing in inorganic chemistry involves the instability of the oxygen acids of bromine. Before 1959 bromous acid and bromite ion, $BrO_2^-$, were known only in solution. In that year *Kircher* and *Periat*[63–65] prepared crystalline barium bromite, $Ba(BrO_2)_2 \cdot H_2O$.

A suspension of 270 g of barium hydroxide in a liter of water is treated with bromine equivalent to 97 % of the theoretical requirement to form barium hypobromite. The mixture is cooled to 0 °C and kept for 70 min while the reaction

$$2\,Ba(OBr)_2 \rightarrow BaBr_2 + Ba(BrO_2)_2$$

takes place. Then 16 g of barium hydroxide is added and the suspension is cooled to −5 °C. Ammonium hydroxide is added cautiously to reduce the remaining hypobromite. An excess must be avoided. Bromate crystals are filtered out and the filtrate is partially evaporated *in vacuo* at 30 °C. Barium bromite monohydrate precipitates upon cooling to 0 °C and may be recrystallized from water.

Bromites of sodium, lithium, potassium, and calcium can be prepared by appropriate modifications of the procedure. Sodium bromite trihydrate is a yellow, crystalline compound which can be dehydrated *in vacuo*. An X-ray powder pattern showed the anhydrous sodium bromite to be a distinct species. Bromite solutions, reported to be useful in the desizing of textiles[66], are now commercially available in Europe[33].

The use of a precipitation reaction, such as that of barium bromate with the equivalent amount of sulfuric acid, for the preparation of bromic acid solutions free from impurities can now be avoided by using a cation-exchange resin[67]. A potassium bromate solution (about 0.5 M) is passed through the resin in hydrogen form; with a column of suitable length, complete removal of potassium can be achieved. The acid solution can be concentrated *in vacuo* to about 50 % $HBrO_3$.

Perbromic acid and perbromates have never been prepared in either the solid state or in solution, although perchlorates and periodates are well-known.

A solution of bromine dioxide, $BrO_2$, in trichlorofluoromethane has been prepared by *Schmeisser* and *Joerger*[68] by oxidizing a bromine solution at −50 °C with ozone. The gaseous products of reaction of potassium bromate with sulfuric acid in a shock wave[69] contain various bromine oxides. Small amounts of bromite and hypobromite are formed[70] by exposure of solid alkali bromates to γ-rays from $^{60}Co$.

## Applications of Bromine and Its Compounds

Current western world production of bromine in all forms is in excess of 250 million pounds annually. Whereas forty years ago nearly all of the bromine produced went into inorganic bromides and bromates, today only about 3 % is sold in inorganic form. By far the largest portion goes into motor fuels as ethylene bromide; here the end use may be considered as inorganic, for the bromine serves to convert lead (from the tetraalkyl-lead antiknock compound) to lead bromide. The latter is volatile at cylinder combustion temperatures and is swept out with the exhaust.

Considerable amounts of bromine are used as methyl bromide, ethylene bromide, and bromochloropropanes for insect control and soil sterilization. In this use the reactivity and the volatility of the compound are both

of importance. Methyl bromide, for example, has a boiling point of 3.7 °C and acts as a methylating agent. It penetrates stored grain or baled cotton or tobacco readily, killing insects at any stage of their life cycle. The excess of fumigant is easily dissipated by exposure to air.

Almost the only large, purely inorganic use of bromine is in the photographic industry, where alkali bromides are allowed to react with silver nitrate to produce a light-sensitive emulsion of silver bromide. The other applications of inorganic bromides and bromates are likely to be organic or biological in nature: much of the alkali bromide goes into pharmaceuticals as a mild sedative, while bromates are used as oxidants for improving the baking quality of wheat flour and for reacting with sulfur compounds in hair-wave preparations. Liquid bromine is used in organic syntheses, bleaching, and as a bactericide to purify water in swimming pools.

A few applications of bromine compounds are based on their relatively high density. Several compounds are employed as gauge fluids and some offer promise of commercial use in mineral separation by sink-float processes. In the latter application the efficiency of recovery is of great importance. Thus in the separation of potassium chloride (density 1.984) from sodium chloride (density 2.165), formulations containing bromochloromethane and dibromomethane are of interest because of their moderate boiling points. Table 5 gives the properties of some of these heavy liquids.

Table 5. Liquid bromine compounds of high density.

| Compound | Density at 25 °C | M.p. (°C) | B.p. (°C) |
|---|---|---|---|
| Bromoethylbenzene | 1.335 | −65 | 200 |
| Bromobenzene | 1.495 | −30.6 | 156.1 |
| 1-Bromo-2-chloroethane | 1.739 | −16.5 | 108.6 |
| Bromochloromethane | 1.923 | −88 | 67.8 |
| Bromodichloromethane | 1.995 | −57.1 | 90.1 |
| 1,2-Dibromoethane | 2.179 | 9.9 | 131.4 |
| Dibromomethane | 2.497 | −52.7 | 96.9 |
| Tribromomethane | 2.891 | 7.7 | 149.5 |
| 1,1,2,2-Tetrabromoethane | 2.964 | 0.1 | 151/44 mm Hg |

Some of the most useful and growing applications of bromine compounds are in the fields of fire extinguishing and prevention. Bromine vapor itself has the property of extinguishing a flame from the combustion of gas or wood when introduced even in quite small amounts into the air supply. Apparently the bromine exerts a chain-stopping effect upon the flame propagation reaction [71]. Various bromine-containing liquids have been proposed for use in fire extinguishers. Bromochloromethane is very effective on a weight basis and has a relatively low toxicity. Some effective fluorine-containing bromoethanes have still lower toxicities, but are more expensive.

In the field of fire prevention, progress is being made on the incorporation of halogen compounds into plastics to render them self-extinguishing. Some of the materials that have been found useful for formulation with vinyl polymers such as polystyrene are tetrabromobutane, 1,2-dibromotetrachloroethane, pentabromochlorocyclohexane, and tetrabromoisopropylidenebisphenol. On a weight basis, bromine derivatives are more effective than their chlorine counterparts. This is significant in decreasing the proportion of additives required, because with too great a proportion some other property of the plastic may be affected adversely. A further reduction in the quantity required has been made possible by the discovery [72] that substances capable of free-radical initiation operate synergistically with the bromine compounds, making the latter effective at considerably lower concentrations. As an example, the self-extinguishing effect of 5 % tetrabromoethane in polystyrene can be equalled by that of only 0.5 % if an equal amount of dicumyl peroxide is also present.

There is virtually no limit to the quantity of bromine available, as the oceans represent an essentially inexhaustable source. Organic chemists have been diligent in using bromine compounds in syntheses, as well as describing their properties. Inorganic chemists have prepared and characterized many compounds, but generally have not found many applications for them. Research in new uses for bromine and its compounds should be encouraged.

# Advances in Molecular Diamagnetism

BY PROF. DR. W. HABERDITZL

PHYSIKALISCH-CHEMISCHES INSTITUT DER HUMBOLDT-UNIVERSITÄT BERLIN (GERMANY)

*At the present state of instrumentation and quantum-mechanical approximations, diamagnetic measurements can supply information on chemical structure which complements the results of other approaches, such as infrared and NMR spectroscopy. General applicability and relatively low cost of equipment are among the advantages of this technique. There is growing interest in the relation to chemical shifts in NMR spectra and in the possibility offered by this technique for testing quantum-chemical approximations.*

## I. Introduction

Diamagnetism, a virtually universal phenomenon, has recently evoked increasing interest in structural chemistry. This can be attributed particularly to the development of NMR spectroscopy, to improvements in the accuracy of susceptibility measurements, and not least to new, better quantum-mechanical approximations for calculating the diamagnetism of localized and delocalized electrons in atoms, molecules, and crystals. The close correlation between diamagnetism and the chemical shift of nuclear resonance signals has greatly contributed to interest in the former. The importance of reliable diamagnetism parameters is further enhanced by the fact that these parameters are often used for testing quantum-mechanical approximations. Diamagnetism therefore plays a significant part in quantum chemistry, especially in electron correlation methods.

An attempt is made here to summarize present knowledge of intramolecular magnetic fields and the information on chemical structure obtainable therefrom. Diamagnetism of crystals is treated by a separate theory (*Landau* and *Peierls*), forming a special branch of solid-state physics, and will not be discussed here. Since the diamagnetic aspect of magnetochemistry was dominated for a long time by *Pascal*'s incremental system, the scope and the limitations of this method will first be outlined.

The atomic incremental system introduced by *Pascal*[1] and improved by *Pacault*[2] is based on resolution of the molar susceptibility $\chi_M$ into terms for the constituent atoms:

$$\chi_M = x_1 \chi_1 + x_2 \chi_2 + x_3 \chi_3 + \cdots \qquad (1)$$

where the $x_i$ and $\chi_i$ represent the numbers of atoms of kind i in the molecule and their atomic susceptibility, respectively.

*Pascal* obtained the atomic susceptibilities of hydrogen and carbon from the susceptibilities of monochlorinated hydrocarbons and of liquid chlorine. As in the case of molar refraction, it was necessary to account for deviations ("exaltations") by the introduction of structural increments $\lambda$ according to Eq. (2):

$$\chi_M = \sum_i \chi_{A_i} + \sum_i \lambda_i \qquad (2)$$

The value of this system (cf. Table 1) has been manifested in the following applications:

1. Pascal increments can be used to calculate the correction for diamagnetism in paramagnetic materials.
2. Comparison between observed and calculated susceptibilities reveals the presence of paramagnetic impurities.
3. Structural investigations based on the incremental system were of interest particularly in organic chemistry, although they did not find wide application on account of the high demands placed on experimental accuracy. With increasing precision of magnetic measurements, the number of specific molecular structural increments needed in *Pascal*'s method became so great that finally one had to be introduced for practically every type of molecule. It was discouraging that most structural terms could not be satisfactorily explained. We may mention, as an example, the positive exaltation of double bonds (see lower half of Table 1), which was believed to result from a paramagnetic component due to the equilibrium

*E. Müller*[3] showed this assumption to be incorrect by investigating the temperature-dependence of the diamagnetism of compounds containing double bonds. This problem has been solved by quantum mechanics (cf. Section II).

One of the most important advances in the theory of magnetism was *van Vleck*'s proof[4] of the inadequacy of *Langevin*'s classical theory of molecular diamagnetism, which expresses the susceptibility as the sum of a temperature-dependent "paramagnetic" term, applicable only when the molecule has a permanent magnetic moment, and a general temeprature-independent term, given by Eq. (3), for the diamagnetic susceptibility:

$$\chi_M = -\frac{e^2 \cdot N_A}{6mc^2} \sum_i \overline{r_i^2} \qquad (3)$$

| $CH_3$ | − 0.85 |
| C≡C | + 0.8 |
| C=C−C=C | +10.6 |
| N=N | + 0.8 |
| Benzene ring | −15.1 |
| Furan ring | −10.92 |
| Thiophene ring | −14.22 |

[*] All values of χ and λ are given here and in the following text in units of $-10^{-6}$ EMU per mole.

where e and m are, respectively, the charge and mass of the electron, c the speed of light, $N_A$ Avogadro's number, and $\overline{r_i^2}$ the mean square distance of the i-th electron from the nucleus.

*Van Vleck* showed on a quantum-mechanical basis that a temperature-*in*dependent "paramagnetic" term $\chi_P$ exists in addition to the temperature-independent diamagnetic term $\chi_D$. These two phenomena always occur together, and cannot be determined separately by direct susceptibility measurements.

The difficulties encountered in the application of the Pascal increment system are caused at least partly by the $\chi_P$ term, which varies appreciably with the symmetry of the electron system. This fact strongly restricts the additivity of atomic susceptibilities, as was first shown by *Guy* and *Tillieu* [5] and by *Dorfman* [6].

Further, it is now known that an atomic incremental system is not suitable for assigning the contributions to diamagnetism in a molecule. For example, in methane the k electrons of carbon contribute about 1 % of the molar susceptibility, the remaining 99 % being due to the four pairs of bonding electrons. Therefore empirical bond increments have been proposed [7,8] (see Table 2).

Table 2. Empirical bond increments according to *Pascal* [1], *Pacault* [2], and *Pascal, Gallais*, and *Labarre* [8].

| Bond | $\chi_M$ | Bond | $\chi_M$ |
|---|---|---|---|
| C–C | 3.7 | C–Cl | 20.35 |
| C–H | 3.85 | C–Br | 29.65 |
| C–O | 4.5 | C–I | 44.05 |
| O–H | 4.65 | C=C | 1.9 |
| C–S | 10.3 | C=O | 2.7 |
| S–H | 10.45 | C–C | 2.9 [8] |
| C–N | 4.85 | C–H | 4.2 [8] |
| N–H | 5.00 | | |

The quantum-mechanical theory of diamagnetism was to be of great importance for the further development of the incremental system.

## II. Theoretical Basis

### 1. Quantum-Mechanical Approximations, van Vleck Paramagnetism, and Gauge Invariance

Quantum-mechanical approximations for the calculation of molecular diamagnetism were first introduced for localized electrons by *van Vleck* [4] (perturbation method) and by *Gans* and *Mrowka* [9] (variation method), and for delocalized electrons (molecular ring currents in aromatic compounds) by *London* [10] (HMO method).

The motion of electrons with momentum $\mathbf{p}$ in an external electromagnetic field of vector potential $\mathfrak{A}$ ($\mathfrak{H}$ = curl $\mathfrak{A}$) and mean electrostatic potential energy V is described classically by the Hamiltonian (4):

$$\mathbf{H} = \sum_i \frac{1}{2m}\left(\mathbf{p}_i - \frac{e}{c}\mathfrak{A}_i\right)^2 + V \qquad (4)$$

Using $\mathbf{H}_0$ for the Hamiltonian in the absence of an external field and $\mathbf{H}_1$ for denoting the perturbed state, and assuming a constant magnetic field $\mathfrak{H}$ acting along the z-axis (x, y, and z are Cartesian coordinates), we obtain

$$\mathbf{H} = \mathbf{H}_0 - \sum_i \left[\frac{e\mathfrak{H}}{2mc}(x_i \mathbf{p}_{y_i} - y_i \mathbf{p}_{x_i}) - \frac{e^2\mathfrak{H}^2}{8mc^2}(x_i^2 + y_i^2)\right] \qquad (5)$$

Moreover, since the component of the magnetic moment in the direction of the field, $M_z$, is given by

$$M_z = -\partial \mathbf{H} / \partial \mathfrak{H} \qquad (6)$$

we obtain

$$M_z = \sum_i \left[\frac{e}{2mc}(x_i \mathbf{p}_{y_i} - y_i \mathbf{p}_{x_i}) - \frac{e^2\mathfrak{H}}{4mc^2}(x_i^2 + y_i^2)\right]. \qquad (7)$$

$M_z$ is thus the sum of two terms: one depends on $\mathfrak{H}$, the other does not vanish even when $\mathfrak{H} = 0$ (provided that the orbital angular momentum of the electron is not zero). The former represents diamagnetism, the latter paramagnetism. Since $\chi = M/\mathfrak{H}$ and $(\overline{x^2} + \overline{y^2})/\overline{r^2} = 2/3$, the second term in Eq. (7) leads to Eq. (3), due to *Langevin*. On applying quantum-mechanical methods, Eq. (5) becomes

$$\mathbf{H} = \mathbf{H}_0 - \sum_i \left[\frac{e\,h}{4\pi mc}\left(\mathbf{X}_i \frac{\partial}{\partial y_i} - \mathbf{Y}_i \frac{\partial}{\partial x_i}\right)\mathfrak{H} - \frac{e^2}{8mc^2}(\mathbf{X}_i^2 + \mathbf{Y}_i^2)\mathfrak{H}^2\right] \qquad (8)$$

It appears at first sight that, similarly to the classical expression (7), Eq. (8) gives, in the absence of an orbital magnetic moment, a relationship for $M_z$ in the

[8] *P. Pascal, F. Gallais*, and *S. F. Labarre*, C. R. hebd. Séances Acad. Sci. *252*, 2644 (1961).

[9] *R. Gans* and *B. Mrowka*, Königsberger gelehrte Ges., Nachr. *12*, 1 (1935).

[10] *F. London*, J. Physique Radium *8*, 397 (1937).

magnetic field $\mathfrak{H}$ containing only the term $\mu_i$ for the classical Langevin diamagnetism, as given by Eq. (9):

$$\mu_i = -\frac{e^2 \mathfrak{H}}{4mc^2}(x^2 + y^2) \tag{9}$$

However, the advances brought about by the quantum-mechanical theory lie in the fact that it does lead to a different result. For electron systems that are not spherically symmetrical, the perturbation method results in a temperature-*in*dependent paramagnetism, even in the absence of orbital angular momentum. This paramagnetism, of great importance in magnetochemistry, is not understandable on the classical theory. Taking into account second-order terms, we obtain for the energy $E_M$ of a system in a magnetic field:

$$\begin{aligned} E_M &= E_n^o - \mathfrak{H}(n \mid \mathbf{M}_z^o \mid n) - \mathfrak{H}^2 \sum_{n \neq m} \frac{(n \mid \mathbf{M}_z^o \mid m)^2}{E_n^o - E_m^o} \\ &+ \mathfrak{H}^2 \frac{e^2}{8mc^2} \sum (n \mid \mathbf{X}^2 + \mathbf{Y}^2 \mid n) \\ &= E_o - \frac{1}{2}\mathfrak{H}^2 \chi \end{aligned} \tag{10}$$

where m and n denote two different eigenstates, the superscript o signifies the absence of applied field, and $E_0$ is the energy in the absence of a field.

From Eq. (10) we obtain for the magnetic moment $m_z$:

$$\begin{aligned} m_z &= (n \mid \mathbf{M}_z^o \mid n) + 2\mathfrak{H} \sum_{n \neq m} \frac{(n \mid \mathbf{M}_z^o \mid m)^2}{E_m^o - E_n^o} \\ &-2\mathfrak{H} \frac{e^2}{8mc^2} \sum (n \mid \mathbf{X}^2 + \mathbf{Y}^2 \mid n) \end{aligned} \tag{11}$$

This expression is the quantum-mechanical counterpart of the classical relationship (7). The first term is the diagonal matrix element of the magnetic moment along the z-axis (*i.e.* the quantum-mechanical mean value); it corresponds to the classical orbital paramagnetism. The third term is the diagonal matrix element of the space operator $(\mathbf{X}^2 + \mathbf{Y}^2)$ [*i.e.* the quantum-mechanical average of $(x^2 + y^2)$]; it corresponds to the classical diamagnetism $\chi_d$. The second term is positive and non-classical, and represents a paramagnetic component. A more detailed treatment using Maxwell-Boltzmann statistics reveals that this paramagnetism $\chi_p$ is temperature-independent, and therefore cannot be separated from diamagnetism by carrying out measurements at various temperatures. Quantum-mechanical calculation of this term is very difficult; it requires a knowledge of the non-diagonal matrix elements in the numerator and the energies of the excited states in the denominator.

Apart from the well-known problems of electronic interaction, solution of the Schrödinger equation for molecules with the Hamiltonian operator given by Eq. (8) is associated with difficulties connected with gauging for Eq. (4) the vector potential according to Eq. (12).

$$\mathfrak{A} = -\frac{1}{2}\mathfrak{r} \times \mathfrak{H} \tag{12}$$

where $\mathfrak{H}$ is the magnetic field.

*London*[10] first attempted to eliminate these difficulties using the MO method and introducing gauge-invariant[*] atomic wave functions (see Fig. 1).

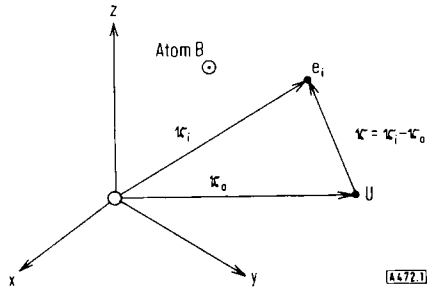

Fig. 1. Coordinates and vectors used in the construction of gauge-invariant atomic orbitals. (U is the origin of the vector potential, $\mathfrak{r}_0$ is the vector connecting the origin of the coordinate system and that of the vector potential, $\mathfrak{r}_i$ is the position vector of electron $e_i$.) If the center of atom B is taken as the new origin of the vector potential $\mathfrak{A} = -1/2\mathfrak{r} \times \mathfrak{H}$, then $\mathfrak{A} - \mathfrak{A}_0 = -1/2(\mathfrak{r}_i - \mathfrak{r}_B) \times \mathfrak{H}$ *i.e.* the new vector potential is independent of $\mathfrak{r}_0$.

The final result (sum of $\chi_d$ and $\chi_p$) of Eqs. (10) and (11) does not depend on the origin of the vector potential and is therefore gauge-invariant. However, this is not true of the absolute values of $\chi_d$ and $\chi_p$. Fig. 2 shows that, when taken separately, $\chi_d$ and $\chi_p$ vary greatly with the origin of the vector potential, $\chi_p$ reaching its minimum value when the origin is chosen as the centroid of the electronic charge distribution. Since the

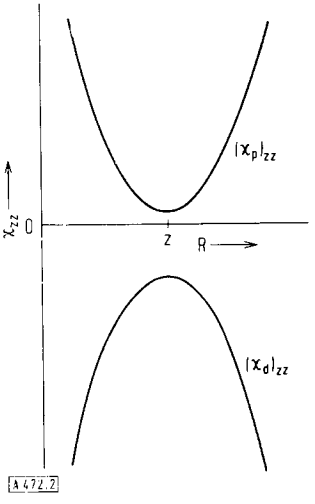

Fig. 2. The variation in the z-component of $\chi_p$ and $\chi_d$ with the distance R of the origin of the vector potential along the x-axis from the centroid, Z, of the electron charge distribution (cf. *Chan* and *Das* [119]). The abscissa and the ordinate are expressed in arbitrary units of $\chi$ and R.

series expansion of the $\chi_p$ term cannot generally be completed, the accuracy of the $\chi_p$ approximation depends considerably on the gauging and improves with increasing applicability of the condition

$$|\chi_d| \gg |\chi_p| \tag{13}$$

It must be remembered in the construction of molecular wave functions that the validity of the linear combination of atomic orbitals (LCAO) is affected by the origin of the vector

[*] A physical relationship is called gauge-invariant when it is unchanged by a gauge transformation. When the vector potential $\mathfrak{A}_i$ of the electromagnetic field is subjected to the transformation $\mathfrak{A}_i' = \mathfrak{A}_i + \frac{\partial \sigma}{\partial x_i}$ (where $\sigma$ is any function of time and space), the magnetic field, which can be represented by the rotation of the vector potential, remains unchanged. Since *Maxwell*'s equations are gauge-invariant, the origin of the vector potential can be chosen freely.

potential. For this reason, *London*[10] introduced the following atomic orbitals $\Phi_B$ which depend on the magnetic field and on the gauge:

$$\Phi_B = \Psi_B \exp\left\{-\frac{2\pi i e}{hc}\mathfrak{A}_B \cdot r\right\} \tag{14}$$

where $\mathfrak{A}_B$ is the vector potential at the center of atom B and $\Psi_B$ is the unperturbed eigenfunction belonging to atom B.

$$\Psi_i = \sum_i c_i \Phi_i \tag{15}$$

The coefficients of the linear combination (15) are determined

$$\left(\mathbf{p} + \frac{e\mathfrak{A}}{c}\right)^2 \Phi_B = \exp\left\{-\frac{2\pi i e}{hc}\mathfrak{A}_B \cdot r\right\}\left[\mathbf{p} + \frac{e}{c}(\mathfrak{A} - \mathfrak{A}_B)\right]^2 \Psi_B \tag{16}$$

as usual by a variation method. Since Eq. (16) applies, the difficulties of gauging have thus been eliminated and the Schrödinger equation has become gauge-invariant (the term in braces is a scalar, and that in the brackets a vector independent of $r_o$ as shown by Fig. 1).

One-electron variation methods have proved particularly suitable for the calculation of the diamagnetic effect of localized pairs of bonding electrons[5]. In this method, developed by *Gans* and *Mrowka*[9], the relation

$$\Psi = \Psi_o e^{\Phi} \tag{17}$$

is used for the eigenfunction $\Psi$ perturbed by the magnetic field. This relationship had previously been employed in the form

$$\Psi = \Psi_o (1 + \Phi) \tag{18}$$

by *Slater* and *Kirkwood*[11] as a first approximation. The variation involved is carried out by the Ritz method. *Tillieu*, using Eq. (10) and the field-dependent wave function

$$\Psi = \Psi_o (1 + iG_z \mathfrak{H}) \tag{19}$$

obtained the expression

$$E = E_o + \frac{e^2\mathfrak{H}^2}{8mc^2}(\Psi_o | X^2 + Y^2 | \Psi_o) - 4i\mathfrak{H}^2(\Psi_o | G_z M_z^o | \Psi_o) - \frac{h^2\mathfrak{H}^2}{4\pi^2 m}(\Psi_o | \operatorname{grad} G_z | \Psi_o) \tag{20}$$

When the bond axis A–B is normal to the z-axis, we have the simple relationship (21) for $G_z$, which is the correction function of the unperturbed wave function

$$G_z \approx ax + bxy \tag{21}$$

calculated for minimum energy. The variation method gives the following conditions of minimization:

$$\frac{\partial E}{\partial a} = 0 \text{ and } \frac{\partial E}{\partial b} = 0, \tag{22}$$

whence a = 0, and

$$b = \frac{\pi e}{hc} \cdot \frac{(\Psi_o | X^2 - Y^2 | \Psi_o)}{(\Psi_o | X^2 + Y^2 | \Psi_o)} \tag{23}$$

[11] *J. C. Slater* and *J. G. Kirkwood*, Physic. Rev. *37*, 682 (1931).

Using Eqs. (20) and (23), we obtain for the susceptibility along the three axes (the bars over $x^2$, $y^2$, and $z^2$ show that these parameters represent quantum-mechanical mean values):

$$\left.\begin{aligned}\chi_x &= C\left[\overline{y^2} + \overline{z^2} - \frac{(\overline{y^2} - \overline{z^2})^2}{\overline{y^2} + \overline{z^2}}\right] \\ \chi_y &= C\left[\overline{z^2} + \overline{x^2} - \frac{(\overline{z^2} - \overline{x^2})^2}{\overline{z^2} + \overline{x^2}}\right] \\ \chi_z &= C\left[\overline{x^2} + \overline{y^2} - \frac{(\overline{x^2} - \overline{y^2})^2}{\overline{x^2} + \overline{y^2}}\right]\end{aligned}\right\} \tag{24}$$

$$C = -\frac{N_A e^2}{4mc^2} \tag{25}$$

Eq. (24) shows the connection between $\chi_p$ (the third term in the brackets) and the asymmetry of the charge distribution.

The connections between the Tillieu wave functions (17) and the London-type gauge-invariant atomic orbitals (GIAO) (15) have been discussed by *Raychaudhuri* and *Sinha*[12]. *Hameka*[13] and *Karplus*[14] have recently developed some SCF–GIAO methods, representing today the most accurate approximations for the calculation of diamagnetism.

In the case of the noble gases (see Table 3), the spherical symmetry of whose electron configuration obviates the difficulties concerning $\chi_p$, the calculated values may now be more accurate than the best observed values. Using a twenty-term Hylleraas wave function, *Glick*[20] obtained $\chi_M = 1.8914 \pm 0.0002$ for helium, and suggested this value as a standard in the measurement of the susceptibility of gases.

Table 3. Experimental and calculated values of $\chi_M$ for the rare gases.

| | He | Ne | Ar | Kr | Xe |
|---|---|---|---|---|---|
| exp. [15] | 2.02 ± 0.08 | 6.96 ± 0.14 | 19.32 | 29.0 ± 0.4 | 45.5 ± 0.7 |
| calc. acc. to: | | | | | |
| *Hartree* and *Stoner* [16] | 1.90 | 8.6 | 24.8 | — | — |
| *Angus* [17] | 1.68 | 5.07 | 16.65 | 29.3 | 44.8 |
| *Kirkwood* [18] | 1.92 | 6.15 | 17.0 | 29.3 | 45.7 |
| *Courty* [19] | 1.913 | 7.167 | 20.218 | 30.005 | 44.600 |

The most accurate empirical value available for $H_2$ is $\chi_M = 4.0051$[21]. Using various wave functions, *Wick*[22], *Hirschfelder*[23], *Steensholt*[24], and *Witmer*[25] carried out calculations on this molecule, the best approximations being obtained by *Ishiguro* and *Koide* (4.0689)[26] and by *Hameka*

(4.045)[27]. Very good approximations were also obtained by *Karplus* and *Kolker*[27a] and by *Hoyland*[27b].

Calculations have also been carried out on $N_2$ by *Bonet* and *Bushkovitch*[28], and on $NH_4^+$ by *Hartmann* [29] and by *Venkatachalam* and *Kabadi*[30]. The calculations for $CH_4$ are collected in Table 4. The great discrepancy between theoretical and experimental values shows that $\chi_p$ is by no means merely a correction factor. *Eschbach* and *Strandberg*[33b], *Wick*[22], and *Ramsay*[33c] recently discussed experimental methods for determining $\chi_p$ for diatomic $\Sigma$ molecules, based on determination of the magnetic moment of molecular rotation, *e.g.* by the microwave Zeeman effect. *Weltner*[34] obtained $\chi_p = 9.3$ for $CH_4$, this value being approximately equal to the difference between the calculated and the observed value of $\chi_M$.

| *Barter, Meisenheimer,* and *Stevenson* [15] | Experiment | 17.4 ± 0.8 |

A different empirical method has been described by *Dorfman*[6]. Assuming that $\chi_d$ is the same as the susceptibility derived from the refractive index[*] *via Kirkwood*'s equation (26), then the difference between this value and the experimental susceptibility $\chi_M$ directly represents the quantity $\chi_p$.

$$\alpha = -\frac{4}{9}\frac{a_0^3}{N_e}(\Sigma\bar{r^2})^2 \qquad (26)$$

where $\alpha$ is the electric polarizability, $N_e$ the number of electrons, and r is in units of $a_0 = h^2/(4\pi^2 me^2)$.

## 2. Diamagnetic Increments due to Localized Electron Pairs

Using the principles of the Guy-Tillieu method, *Baudet*[35] was the first to give a comprehensive treatment of electrons localized at atoms and bonds, arriving at an incremental system. He obtained the eigenfunctions of an electron-pair bond A–B from the atomic wave functions of the atoms A and B by means of Eq. (27)

$$\Psi_o = N(\Psi_{oA} + \lambda\Psi_{oB}) \qquad (27)$$

where N is a normalizing factor, and $\lambda$ is a coefficient expressing the difference between the electronegativities of A and B.

The integrals in Eq. (24) can be calculated relatively easily with the aid of good approximations to the atomic wave functions (*e.g.* by *Slater* or *Coulson*) and experimental values for the averages of the coordinates. Table 5 shows the susceptibilities of the inner-shell electrons of closed s-, p-, and d-orbitals in various atoms. The data in Table 6 refer to the susceptibilities of lone electron pairs in various states of hybridization, the

*Pople* has developed a GIAO-MO method attempting resolution into atomic increments on the basis of some considerable simplifications. Using the Hückel and London approximations for the atomic susceptibility, he obtained [36] $\chi_d$ and $\chi_p$ terms containing matrix components of the charge density (in both terms) and of the bond order (in the $\chi_p$ term). The results are unsatisfactory. *Hameka* [37] has pointed out that it is not permissible to neglect the interatomic two-center integrals in the expression for $\chi_p$. This contribution is manifested in practice in "neighboring-bond effects".

### 3. Neighboring-Bond Effects

The discrepancies evident in Table 9 (especially with ketones) show that correlation effects must be taken into account and that one-electron approximations are inadequate. It has been shown by *Haberditzl* [38], in particular for compounds with adamantane-type structure, that these correlation effects are manifested in the following observations.

The diamagnetism of an electron-pair bond between atoms A and B is essentially determined by the nature and the number of other atoms linked to A and B. The "neighboring-bond effect" is not merely a correlation factor, since it is often of the same order of magnitude as the diamagnetism of a bonding electron pair. Thus similar relationships apply as discussed by *Szabo* [38a] for bond dissociation energies.

The neighboring-bond effect was already observed by *Pascal* on chloroalkanes, but he did not recognize its general occurrence. Phenomena due to this effect were later also found in the structural isomers of alkanes (cf. Tables 10). It was taken into account by *Pacault* [2], *Trew* [39], and by *Angus* [40] using empirical structural increments for the $CH_3$, $CH_2$, and the CH groups. Neighboring-bond effects are also exhibited by compounds containing nitrogen and sulfur [41].

Table 10. Molar susceptibilities of some alkanes and alcohols.

| Compound | $(\chi M)_{exp.}$ | $(\chi M)_{calc.}$ [38] |
|---|---|---|
| n-Pentane | 63.05 | 63.15 |
| n-Hexane | 73.3 | 74.5 |
| n-Heptane | 85.38 | 85.85 |
| n-Octane | 96.93 | 97.20 |
| n-Nonane | 108.13 | 108.55 |
| n-Decane | 119.51 | 119.90 |
| n-Undecane | 131.8 | 131.25 |
| 2,2-Dimethylbutane | 76.24 | 76.0 |
| 2-Methylpentane | 75.26 | 75.2 |
| 2-Methylhexane | 86.24 | 86.55 |
| 2,2,3-Trimethylbutane | 88.36 | 88.25 |
| 2,2,4-Trimethylpentane | 99.1 | 99.4 |
| $C_4H_9OH$ | 56.3 | 56.5 |
| $CH_3-CH(CH_3)-CH_2OH$ | 57.8 | 57.6 |
| $C(CH_3)_3OH$ | 57.3 | 57.3 |

*French* and *Harrison* [42] were the first to introduce "bond-interaction" increments. On the basis of SCF calculations, *Hameka* [43] has put forward a theoretical treatment for the neighboring-bond effect in alkanes.

The differences in the $\chi_M$ values between isomers [*] shown in Table 10 can be explained by the neighboring-bond effect in the following manner: the susceptibility due to a C–H or C–C bond, for example, is decreased by other carbon atoms linked to the carbon in question. If primary, secondary, tertiary, and quaternary carbon atoms are denoted respectively by $C_1$, $C_2$, $C_3$ and $C_4$, we have the following sequences for the $(\chi_M)_{total}$ of the isomers:

$$\chi_{C_1-H} > \chi_{C_2-H} > \chi_{C_3-H}$$

and

$$\chi_{C_1-C_2} > \chi_{C_2-C_2} > \chi_{C_3-C_3} > \chi_{C_4-C_4}$$

[43] *H. F. Hameka*, J. chem. Physics *34*, 1996 (1961).

In isomeric compounds an increase in $\chi_M = \chi_d + \chi_p$ is brought about primarily by a decrease in $\chi_p$ (at constant $\chi_d$). The terms $\chi_d$ and $\chi_p$ have different signs and the inequality $|\chi_p| < |\chi_d|$ invariably holds. Clearly this could be the basis of a semiempirical increment system taking into account this effect. Table 11 shows a system developed along these lines and based on the following concepts [38]:

Table 11. Survey of new inner-electron and bond increments [38].

[*] The subscript gives the number of carbon atoms linked to the atom in question. Other atoms or groups thus bonded are shown in parentheses; the asterisk denotes $sp^2$ hybridization and $\pi$ stands for $\pi$-bond electron pair.

1. For inner-shell core electrons (and for the lone electron pairs) we use increments calculated on a quantum-mechanical basis. These data often can be regarded as more accurate than observed values.

2. The bonding-electron increments are determined empirically (taking into account the neighboring-bond effect), with the aid of the incerements calculated in point 1. above. This is made necessary by the fact that one-electron approximations can be calculated with sufficient accuracy for $\chi_d$, but not for $\chi_p$. (Complete calculations have so far been reported only for a few diatomic molecules [44, 45].)

The use of such an incremental system reveals regularities in the neighboring-bond effect and enables us to carry out incremental calculations [38] (see Tables 10, 12, and 13) which reflect conformational differences, solvent effects, hydrogen-bond formation, *etc.* Incremental magnetochemistry could thus join other techniques of structural investigation, such as infrared and NMR spectroscopy, which require a considerably larger expenditure for equipment.

## 4. Diamagnetic Shielding

The bond susceptibilities $\chi_x$, $\chi_y$, $\chi_z$ generally are different [see Eq. (24)]. An electron-pair bond is thus usually magnetically anisotropic. In NMR spectroscopy, the magnetic shielding of the protons, causing the chemical shift, depends also on the spatial distribution of such anisotropic bonds. When a molecule is placed in a magnetic field $\mathfrak{H}$, an additional magnetic field $\mathfrak{H}'$ will be induced at each atomic nucleus.

$$\mathfrak{H}' = -\sigma \cdot \mathfrak{H} \qquad (28)$$

where $\sigma$ is the magnetic shielding constant [46] and can be split up according to

$$\sigma = \sigma_l + \sigma_w \qquad (29)$$

into $\sigma_l$, the local component due to electrons in atom A to which the proton is attached, and $\sigma_w$, the long-range component encompassing all the effects of the electrons in the neighboring atoms. The following approximate relationship holds between $\sigma_l$ and $\chi_A$ of atom A:

$$\sigma_l \approx 2 \sum_i \left( \frac{\chi_A}{r_i^3} \right) \qquad (30)$$

The accurate determination of the relationship between $\sigma_l$ and $\chi$ is, however, very difficult [48]. Empirical values of $\sigma_l$ are tabulated in ref. [49]. In simple cases, $\sigma_w$ can be traced to a mean magnetic anisotropy, $\Delta\chi = \chi_\perp - \chi_\parallel$. We thus obtain [47]:

$$\sigma_w = \Delta\chi\,(1-3\cos^2\vartheta)/3\,R^3 \qquad (31)$$

where R is the distance between the proton and the center of the bond, and $\vartheta$ is the angle formed by the radius vector R and the axis of the dipole.

If several anisotropic (C–C and C–H) bonds are responsible for $\sigma_w$, then only $\sum\Delta\chi_{C-C} - \sum\Delta\chi_{C-H}$ can be obtained. It is generally assumed that $\Delta\chi_{C-C} > \Delta\chi_{C-H}$ [50,51]. There is still only poor agreement among results on bond anisotropy, owing mainly to the sometimes arbitrary division into local and long-range shielding terms and to the uncertain assignment to the different C–C bonds in the molecule.

*Narasimhan* and *Rogers* [52] give $\Delta\chi_{C-C} \approx 1.5$ to 3 for propane. *Zürcher* [53] found $\Delta\chi_{C-C} \approx 2$ for 5α- and 5β-androstane. *Lonsdale* [54] has determined anisotropy in long-chain paraffins and alkylcarboxylic acids. A value of about 25 was obtained for the total C–C anisotropy of a $C_{18}$ chain.

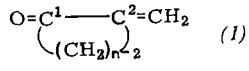
[54] *K. Lonsdale,* Proc. Roy. Soc. (London), Ser. A *171,* 541 (1939).

Using this value and Pascal increments for C–C and C–H bonds, *Davies*[55] obtained $\Delta\chi_{C-C} = 4.0$ and $\Delta\chi_{C-H} = 3.0$. By examining the shielding of axial and equatorial protons in cyclohexane, *Moritz* and *Sheppard*[56] found $\Delta\chi_{C-C} - \Delta\chi_{C-H} = 4.2$. There are some indications[57], however, that other shielding mechanisms must be taken into account in cyclohexanes.

The uncertainty in the molecular parameters R and $\alpha$ are further sources of error in Eq. (31). When R is relatively small (non-aromatic compounds), the $\Delta\chi$ values can be determined with an accuracy of about 20 %. Using the $^{13}C$–H coupling constant of 23 compounds, *Reddy* and *Goldstein*[58] obtained a C–C anisotropy of $10.0 \pm 1.0$, which is considerably greater than the result of any other method. A simpler and more reliable determination of the C–C and C–H anisotropy is possible when the C–C bonds lie in the same plane, as shown for benzene in Section II.5. Reliable values for the bond susceptibility can also be utilized in the reverse manner: for the calculation of $\sigma$ from the anisotropy. Thus the proton shift of the methylene group on $C^2$ in cyclic $\alpha$-methylene ketones



*(1)*

*(1)* (n = 5–10 or 16) has been calculated approximately by *Klose*[59] as a function of the angle of rotation around the $C^1$–$C^2$ bond. Comparison with experimental values shows that the keto-vinylidene group exhibits a fully staggered conformation in compounds with n = 5 to 8 and a fully eclipsed conformation in compounds with n = 9 and 10. Partially free rotation is found when n = 16.

## 5. Molecular Ring Currents

It has long been known that aromatic compounds exhibit two special features of diamagnetism:

1. Aromatic compounds are characterized by strong magnetic anisotropy; the susceptibility $\chi_3$, normal to the plane of the ring, is greater than susceptibilities $\chi_1$ and $\chi_2$ measured in this plane ($\chi_1 \approx \chi_2$).

2. The mean susceptibility as given by Eq. (32) is higher than the value expected on the basis of the incremental system derived theoretically or empirically.

$$\bar{\chi}_M = \frac{1}{3}(\chi_1 + \chi_2 + \chi_3) \qquad (32)$$

The first feature can be demonstrated experimentally only in a few cases, namely when sufficiently large crystals are available. According to *Pauling*[60] and *London*[10], only $\chi_3$ contributes to the high value of the mean diamagnetism, for this term involves the diamagnetic effect of the delocalized $\pi$-electrons which give rise to a molecular ring current in the aromatic system. The quantum-mechanical treatment[10] of this ring current diamagnetism has been developed particularly by *Rebane*[61], *McWeeny*[62], and *Pople*[63].

Using the gauge-invariant wave functions of Eq. (14) and the Hückel approximation, *London* obtained the secular equation

$$\Sigma c_k [\eta_{k,l}\beta \exp\{2\pi i f_{k,l}\} + \delta_{k,l}(\alpha - E)] = 0 \qquad (33)$$

$$\eta_{k,l} = \begin{cases} 1, \text{ when k and } l \text{ adjacent} \\ 0, \text{ when k and } l \text{ not adjacent} \end{cases} \qquad \delta_{k,l} = \begin{cases} 1, \text{ when } k = l \\ 0, \text{ when } k \neq l \end{cases}$$

where $\alpha$ is the Coulomb integral, $\beta$ the exchange integral; k and $l$ denote the atoms of the linear combination; $f_{k,l} = \frac{e}{hc} \Phi S_{k,l}$; $S_{k,l}$ = area of the triangle formed by k, $l$, and the origin of the vector potential.

For various fused aromatic systems, *London*'s method gives only fair approximations. An electron-gas method (the box model) was introduced by *Schmidt*[64] and later also used by *Rebane*[61] (see also [65]). One-electron approximations are again inadequate, and empirical or semi-empirical derivations are unavoidable.

Table 12. Molar susceptibilities of some aromatic compounds. Ring-current diamagnetism was taken into account in the calculations.

| Compound | $(\chi M)_{exp.}$ | $(\chi M)_{calc.}$ [38] |
|---|---|---|
| Toluene | 65.6 | 66.95 |
| *o*-Xylene | 77.8 | 79.1 |

| *o*-(*N*-Methylamino)phenol | 75.7 | 78.8 |
| *o*-(*N*-Ethylamino)phenol | 88.9 | 90.2 |
| *o*-(*N*-Butylamino)phenol | 112.2 | 112.9 |
| *N,N'*-Ethylene-bis(*o*-aminophenol) | 154.8 | 154.6 |
| *N,N'*-Hexamethylene-bis(*o*-aminophenol) | 198.2 | 196.7 |
| *o*-(*N*-Phenylamino)phenol | 119.3 | 116.9 |
| *o*-(*p*-Tolylamino)phenol | 128.4 | 129.1 |
| *N,N'-o*-Phenylenebis(*o*-aminophenol) | 179.0 | 179.0 |
| Benzonitrile | 65.2 | 65.0 |
| 1-Cyano-2-phenylacetylene | 78.2 | 78.2 |
| Phenylacetonitrile | 76.9 | 77.1 |
| Salicylic acid | 75.98 | 76.0 |
| Methyl salicylate | 86.84 | 86.85 |
| Ethyl salicylate | 98.60 | 98.20 |
| Naphthalene | 91.90 | 91.9 |
| Anthracene | 131.0 | 129.0 |
| Naphthacene | 167.0 | 166.1 |
| Biphenyl | 106.0 | 105.6 |
| Triphenylmethane | 167.6 | 166.25 |

The semi-empirical incremental system shown in Table 11 gives $\chi_M = 41.1$ for benzene (experimental value 54.8). For comparison, the values for 1,3-cyclohexadiene are $(\chi_M)_{calc.} = 49.3$ and $(\chi_M)_{obs.} = 48.6$. Thus the $\pi$-conjugation in benzene results in an excess in $\chi$ of $\chi^E = 13.7$. If this value is used as "benzene increment", the susceptibility of aromatic compounds in general can be calculated. Table 12 shows the agree-

ment between observed and calculated values for aromatic systems, this agreement being satisfactory in most cases, despite the expected effect of substituents on the $\pi$-electron system. The agreement is also good for non-condensed polynuclear aromatic systems, and particularly so for fused aromatic compounds in which no separate ring current systems exist in the individual rings. The diamagnetism of a condensed system containing $n$ benzene rings is composed additively of normal bond increments, atomic increments, and $n$ benzene increments. This result suggests a semi-empirical determination of the diamagnetism due to the ring current ("London diamagnetism", $\chi_L$). In accordance with the concepts discussed above under points 1. and 2., and on the basis of a spatial averaging (London diamagnetism is perpendicular to the plane of the benzene ring), we find that $\chi_L = 3\,\chi^E = 41.1$. For a system containing $n$ benzene rings, $\chi_L \approx 3n\chi^E_{benzene}$, indicating approximate additivity of ring currents in individual benzene rings. This result is in agreement with recent modifications of the London theory by *Maddox* and *McWeeny*[66,67], with the aid of which *Memory*[68] showed that approximate additivity of $\chi_L$ holds for the fifteen five-ring systems investigated.

The $\chi_L$ value for benzene (41.1) obtained with the new system exceeds those recently reported by *Davies*[69] and by *Caralp* and *Hoarau*[70] ($\chi_L$ = 33.26 and 33.13 respectively), but is in excellent agreement with *Pople*'s result[71]. The anisotropy caused by the London diamagnetism is increased by the anisotropy of the C–C and C–H single bonds in the plane of the ring. The total magnetic anisotropy of benzene is the sum of the London diamagnetism and the bond anisotropies, *i.e.* $\chi_L + \Sigma\chi^E$.

From measurements on crystalline benzene, *Hoarau*, *Lumbroso*, and *Pacault*[72] obtained: $\chi_1 = 34.9$; $\chi_2 = 34.9$; $\chi_3 = 94.6$[*]. We thus have $\Sigma\chi^E = 18.6$. This value is distributed over the six C–C $\sigma$-bonds, the six C–H $\sigma$-bonds, and the three C–C $\pi$-bonds. As shown above, the anisotropy of the C–C and the C–H $\sigma$-bonds is about 1. *Tillieu*'s calculation gives $\chi^E \approx 2$ for the C–C $\pi$-bond. Accordingly, $\Sigma\chi^E \approx 18$, in good agreement with the estimated value.

Quantum-mechanical calculations show that these considerations cannot be extended to pentalenes and other systems with 4n, instead of (4n + 2), carbon atoms[73,74]. The chemical shift of proton resonance in aromatic systems is particularly suitable for the investigation of ring currents [see, *e.g.*, [46] and Eqs. (29) and (30)].

[*] In the absence of anisotropy one would have

$\chi_1 = \chi_2 = \chi_3 = (\chi M)_{normal}$

Actually, however

$\chi_3 = (\chi M)_{normal} + \chi_L + \Sigma\chi^E$

## III. Use of Diamagnetism in Structural Investigations

### 1. Compounds with Localized Electrons

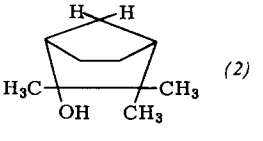
Ample experimental data on diamagnetic susceptibilities are now available for structural investigation; these data have been compiled critically by the International Union of Pure and Applied Chemistry[75].

Some results from our work on complex ring systems are collected in Table 13. They show the applicability of the incremental calculations even to compounds for which this was previously not possible (terpenes, adamantane derivatives).

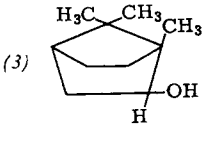
Table 13. Molar susceptibilities of complex ring systems. Experimental values are compared with those calculated with the new increment system [38].

| Compound | $(\chi M)_{exp.}$ | $(\chi M)_{calc.}$ |
|---|---|---|
| Vitamin C | 91.8 | 91.80 |
| Dehydroacetic acid | 75.0 | 75.70 |
| 1,4;5,8-Diethano-1,4,4a,4b,5,8,8a,8b-octahydroanthraquinone | 151.6 | 152.10 |
| Isoborneol *(4)* | 120.3 | 117.10 |
| Camphene hydrate | 115.2 | 115.20 |
| Muscone | 174.8 | 176.30 |
| Tanacetone *(9)* | 109.7 | 104.40 |
| α-Pinene *(5)* | 100.7 | 100.70 |
| β-Pinene *(6)* | 101.9 | 102.20 |
| Menthone | 110.6 | 109.40 |
| 1,8-Cineol *(7)* | 114.5 | 114.33 |
| Fenchol *(8)* | 118.8 | 117.40 |
| (+)-Limonene | 98.0 | 97.20 |
| Dipentene [(±)-Limonene] | 98.6 | 97.20 |
| Adamantane | 94.3 | 94.3 |
| Hexamethylenetetramine | 69.1 | 69.3 |
| Pentamethylenetetraminesulfone *(10a)* | 84.3 | 82.45 |
| Homopentamethylenetetraminesulfone *(10b)* | 94.6 | 93.80 |

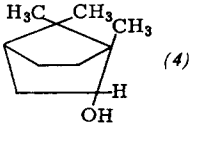
Some bicyclic terpene alcohols, namely camphenol *(2)*, isoborneol *(3)*, and borneol *(4)*, may be selected as examples[38]. The mutual steric hindrance of the OH



*(2)*



*(3)*

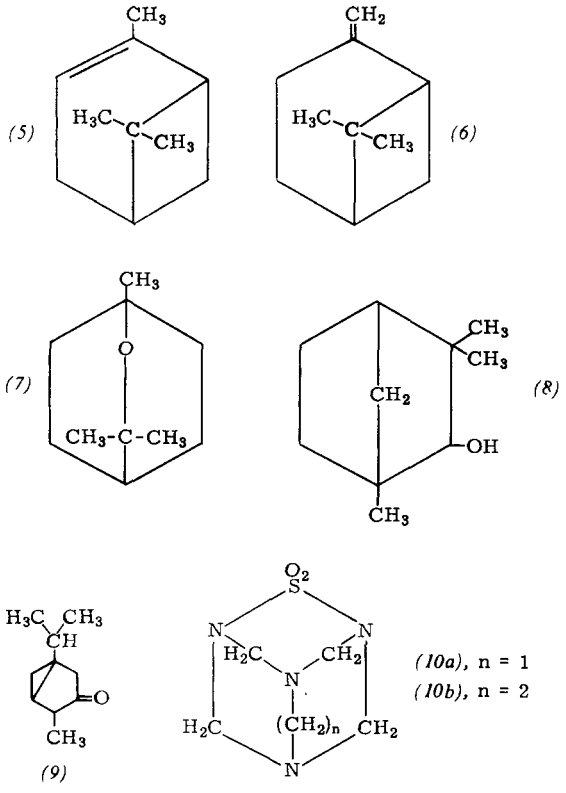


*(4)*

and the $CH_3$ groups decreases from *(2)* to *(4)*, whereas diamagnetism increases in the same direction. Thus diamagnetism reflects also the different molecular conformations caused by steric effects.

Good agreement is also found (see Table 13) between observed values and those calculated by the incremental system for α-pinene *(5)*, β-pinene *(6)*, 1,8-cineol *(7)*, and fenchol *(8)*.

[75] Tables de Constantes selectionnées de diamagnetisme et paramagnetisme. Pergamon Press, Paris 1957.



(5) (6) (7) (8) (9) (10a), n = 1 (10b), n = 2

A similar change in diamagnetism of 1–5 % is observed on formation of betaine structures[76] and hydrogen bonds[38]. The latter can give rise to electron delocalization resulting in $\chi$-anisotropy[77]. The temperature-dependence of this anisotropy leads to a temperature-dependence of diamagnetism, *e.g.* in aliphatic dicarboxylic acids[78]. Similar phenomena are observed in organic sulfur compounds[79]. The diamagnetism of organic compounds of Si, Ge, and Sn has recently been investigated[80,81]. For $XeF_4$, experiment[82] is in good agreement with theory[83].

Much work has been done on the increase of diamagnetism[84] brought about by disappearance of double bonds in addition polymerization. This increase has been observed in polyoxymethylene[85], polyvinyl acetate[86], polymethyl methacrylate[87], polycyclopentadiene, polystyrene[88], and in silicones[89].

$$\chi_{Poly} = \frac{n\chi_{mono} + (n-1)\lambda}{n \cdot M_{mono}} \qquad (34)$$

$\chi_{Poly}$ = weight susceptibility of the polymer; $\chi_{mono}$ = molar susceptibility of the monomer; M = molecular weight; $\lambda$ = diamagnetism of the C–C $\pi$-bond.

Polyethylene oxides have been studied in the liquid, the recrystallized, and in the glassy state, and the change in diamagnetism on melting has been discussed[90]. The magnetic anisotropy of polymers was first measured by *Nilakantan*[91]. Further determinations were carried out on cellulose, silk, keratin, and rubber[92], as well as on polystyrene and polyterephthalate fibers[93].

*Angus* and *Tilston*[94] examined 69 binary mixtures of organic compounds for the validity of *Wiedemann*'s rule [cf. Eq. (1)] for the diamagnetic susceptibility of mixtures. Papers by *Datar* and *Khanolkar*[95], and by *Venkateswarlu* and *Sriraman*[96] may be mentioned among more recent investigations. A comprehensive analysis of the (generally small) deviation from additivity in mixtures is still to be carried out. The largest deviations have been found for the acetone/chloroform[97] and the acetic acid/pyridine[98] systems, caused, in the latter, by salt formation.

### 2. Ring-Current Diamagnetism

*Selwood*[99] has surveyed all aromatic compounds which have been found to exhibit London diamagnetism (see also Table 12). In linearly fused systems, there is a linear relationship between anisotropy and the number of fused rings[100]. It can be shown that hexabenzocoronene is best considered as three fused phenanthrene systems[101]. Several studies[102,103] have been devoted to the effect of *o*-, *m*-, and *p*-substituents on ring-current diamagnetism.

Diamagnetic data have led to the following inferences concerning the aromaticity of pseudo-aromatic compounds. Substituted azulenes exhibit a weaker diamagnetic effect than the corresponding naphthalene derivatives[104–106]. The London diamagnetism of the pyrylium

cation is about the same as that of benzene [106]. Dibenzo[*b*:*f*]oxalene behaves magnetically as two benzene rings and two non-aromatic ring systems [106]. Borazole also exhibits London diamagnetism [107].

A connection between anomalous diamagnetism and carcinogenicity has long been suspected [108]. 3,4-Benzopyrene, for example, has an anomalously low diamagnetic susceptibility. Such a connection has not, however, been proved by investigations on hydrocarbons [109–111] and other carcinogenic substances [112]. The diamagnetism of carcinotherapeutic agents has also been studied [113].

Relationships have been found between changes in diamagnetism (±10 %) on formation of charge transfer complexes of aromatic compounds and the stability of the complexes [38].

Particularly accurate investigations of London diamagnetism have recently become possible by means of its resultant magnetic shielding. *Jonathan*, *Gordon*, and *Dailey* [114] obtained information on the ring-current density in the individual rings of fused aromatic systems (see Table 14); *Memory* determined the ring-current densities of 3,4-benzopyrene, 1,2-benzanthracene, and 1,2:5,6-dibenzanthracene [114a].

Table 14. Ring currents, I, of the individual rings in condensed aromatic systems, calculated from the chemical shift ($I_{benzene} = 1$) [114].

| Molecule | Ring | Ring current I | Molecule | Ring | Ring current I |
|---|---|---|---|---|---|
|  | A | 1.093 |  | A<br>B | 1.111<br>0.747 |
|  | A<br>B | 1.085<br>1.280 | | | |
|  | A<br>B | 1.329<br>0.964 |  | A<br>B | 0.979<br>0.247 |
|  | A<br>B | 1.133<br>0.975 |  | A<br>B | 1.460<br>1.038 |

Large conjugated ring systems such as porphyrins and phthalocyanins represent a transition to compounds with "quasi-free" electrons, such as graphite. These systems have the highest diamagnetic susceptibilities of all organic compounds, partly because of their exceptionally high London diamagnetism [115]. The perimeter of the current in the porphyrin ring can be determined from the experimental London diamagnetism [38] (cf. Fig. 3). It coincides with the conjugated system, whose

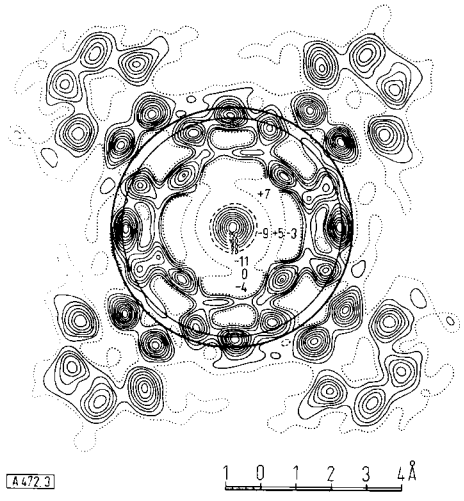

Fig. 3. Electron density contour map of Pt-phthalocyanine [120]. The $\pi$-electron ring current calculated from the diamagnetic effect is drawn to scale. The inner ring is calculated semi-empirically, the outer ring by the Pascal system. The electron densities are given as electrons per Å$^2$; negative values are due to experimental and computational errors.

area has been calculated to be 38 Å$^2$ by *Crute* [116]. Using the radius obtained on the basis of the diamagnetic effect, we find an area of 39 Å$^2$. The diamagnetic ring current of porphyrins and their metal complexes will doubtless attract great biochemical interest, in addition to supplying new information for the theory of diamagnetism of delocalized electrons.

A completely new field of research should be mentioned in conclusion, namely that of orientational and concentration effects in diamagnetic macromolecules in an external field. These have been discussed by *Dorfman* [117] and detected in glutamate dehydrogenase by *Haberditzl* and *K. Müller* [118]. This effect may provide a means of influencing chemical reactions with a magnetic field.

# The Surface Tension of Solids

BY P.-J. SELL AND DR. A. W. NEUMANN

INSTITUT FÜR PHYSIK UND CHEMIE DER GRENZFLÄCHEN
(FRAUNHOFER-GESELLSCHAFT), MARIENTHAL/PFALZ (GERMANY)

*The surface tension of a solid, unlike that of a liquid, cannot be measured directly. After a discussion of the most important methods used so far, all of which are subject to uncertainty, the determination of the surface tension of solids from the wetting equilibrium is described.*

## I. Introduction

There are more methods for the measurement of the surface tension (specific surface free energy) of a liquid than for that of practically any other physical quantity. If we consider only static and quasi-static methods, there are two reasons for this multiplicity. First, the surface area of a liquid can easily be increased in such a way that the work involved is entirely consumed as surface work, which has the dimensions energy per unit area or force per unit length. This is the basis of, *e.g.* the bubble-pressure method and the ring method, in which the surface tension of the liquid is the force per unit length required to detach the ring from the surface of the liquid [1]. Second, owing to the tendency of liquids to minimize, their surface (or interfacial) area, cohesive and adhesive forces give rise to droplets and menisci, from the forms of which the surface tension can be determined [2].

The situation is different in the case of solids. When a surface area is increased, not all the work supplied can reappear as surface free energy. Moreover, solids do not assume shapes that are determined solely by the work of cohesion per unit area (which is equal to twice the surface tension) [*]. Thus the determination of surface tensions is much more difficult for solids than for liquids, with the result that values reported for a given solid may differ by one or two orders of magnitude.

Some of the terms used in the present paper are defined below.

The term surface denotes the phase boundary between a condensed phase and an uncondensed phase. An interface is a phase boundary between two condensed phases.

The surface tension $\sigma$ or interfacial tension $\gamma$ is the change in Helmholtz free energy F accompanying an increase in a surface or interfacial area $\Omega$ at constant volume V, temperature T, and number of moles $n_i$ of component i.

$$\sigma \text{ or } \gamma = (\partial F/\partial \Omega)_{V,T,n_i}$$

The contact angle $\vartheta$ is the angle formed at the three-phase line solid-liquid-gas between a solid and a liquid in contact with each other.

The equilibrium between a solid and a liquid phase, described by Young's equation (3), is known as the wetting equilibrium.

The specific total surface energy $\Sigma$ and the specific total interfacial energy $\Gamma$ are defined as follows:

$$\Sigma = \sigma - T(d\sigma/dT)$$
$$\Gamma = \gamma - T(d\sigma/dT)$$

The work of cohesion, $\zeta_s$ and $\zeta_l$, is twice the surface tension and the work of adhesion, $\zeta_{sl}$, is the sum of the surface tensions of two phases minus their interfacial tension.

$$\zeta_s = 2\sigma_s;\quad \zeta_l = 2\sigma_l;\quad \zeta_{sl} = \sigma_s + \sigma_l - \gamma_{sl}.$$

## II. Methods for the Determination of the Surface Tension of Crystals

### 1. Calculation from the Surface Tension of the Melt

In view of the difficulty of measuring the surface tensions of solids by the methods used for liquids, an obvious route to such data is measurement of the properties of the melt. On the basis of *Jaeger*'s results [3] on the temperature-dependence of the surface tensions of fused alkali metal halides, *von Engelhardt* and *Haussühl* [4] calculated the surface tensions of the {100} faces of these salts at 25 °C. For sodium chloride they obtained $\sigma_s = 170$ dynes/cm.

It is assumed in this calculation that the temperature coefficient of the surface tension is independent of temperature, and in particular that it is the same for the crystal and for the melt; it is also assumed that the surface tensions of the {100} face and of the melt are equal at the melting point. It is reasonable to assume a constant temperature coefficient for each phase, since the order in the surface both of the crystal and of the melt are not different from those in the interior of the phases, and the surface specific heats therefore probably are zero [1]. It is questionable, however, whether the melt and the {100} face have the same temperature coefficient of surface tension, since the crystal face and the surface of the melt do not necessarily exhibit the same state of order. Since the ratio of the surface tension of the melt to that of the solid is approximately the same as that of the heat of vaporization to the heat of sublimation [1]

[1] For details of such methods, see *e.g. K. L. Wolf*: Physik und Chemie der Grenzflächen. Springer, Heidelberg 1957.

[2] See, *e.g., A. W. Neumann*, Dissertation, Universität Mainz 1962; Z. physik. Chem. NF *41*, 339 (1964); *43*, 71 (1964).

[*] Surface tensions cannot be determined easily even for single crystals, where the crystal's habit (on the basis of the Gibbs-Wulff theorem) possibly is determined by surface energies.

[3] *F. M. Jaeger*, Z. anorg. allg. Chem. *101*, 1 (1917).

[4] *W. v. Engelhardt* and *S. Haussühl*, Kolloid-Z. *173*, 20 (1960).

(provided that melting is not associated with a change in order at the surface) the last of the above assumptions appears uncertain.

### 2. Determination from the Dependence of Solubility on Grain Size

From the dependence of solubility on grain size [5, 6], *van Zeggeren* and *Benson* [7] determined the surface tension of the {100} face of NaCl by use of the Thomson-Gibbs equation. To ensure the approximate validity of Ostwald's dilution law (which is used in the evaluation), the experiments were carried out in alcoholic solution, so that the quantity measured is the interfacial tension $\gamma_{sl}$ between sodium chloride and the alcoholic solution. Surprisingly, however, the value obtained (171 ± 12 dynes/cm at 25 °C) agrees well with that for the cubic faces of NaCl obtained from the surface tension of the melt (see Section II, 1).

### 3. Determination from Supercooling of Melts

The interfacial tension between a supercooled liquid and the crystalline phase can be calculated from the frequency of homogeneous nucleation using a theory developed by *Turnbull* and *Fischer* [8,9]. From this theory the interfacial tension between solid and liquid benzene at −60 °C is found to be 20.4 dynes/cm [10]. This value was confirmed [11] by investigation of the relationship between the equilibrium temperature T and the pressure of curvature of the solid/liquid phase boundary. In capillaries,

$$T = T_m - (T_m \gamma_{sl}/q_l \rho_s)(2/r)$$

where $T_m$ is the melting temperature, $q_l$ the heat of fusion per gram, $\rho_s$ the density of the solid, r the radius of curvature of the interface. Supercooling experiments for the determination of crystal/melt interfacial tensions have recently also been carried out on high polymers [12].

### 4. Determination from Abrasion and Grinding

The mechanical energy required to abrade or grind a solid is consumed not only as heat and as work of deformation, but also as interfacial work. This raises the question of whether the surface free energy of the abraded solid can be determined from abrasion or grinding tests. Experiments of two types have been carried out:

On the assumption that the total energy, the frictional energy, and the work of deformation in abrasion experiments with isotypic crystals are as constant as the shape, particle-size distribution, and the number of abraded particles, *von Engelhardt* and *Haussühl* [3] deduced the relationship

$$\sigma_s = \text{const. } V^{-2/3} \qquad (1)$$

for the specific surface free energy $\sigma_s$, where V is the volume of solid ground off under given conditions.

When the surface tensions of the solids, calculated from data of the melts, are plotted against $V^{-2/3}$, two straight lines are obtained, one for lithium and sodium halides, the other for potassium and rubidium halides. The surface tension of any crystal of the two groups of alkali metal halides can thus be determined.

Instead of grinding crystals individually with an abrasive under standardized conditions, *Kusnezow* [13] ground two different crystals against each other. Partly because of the different method used, different assumptions are made, and different results are obtained. It is assumed that, during the mutual abrasion of two crystals, the energy used to increase the surface area is uniformly distributed over the two crystals and that the particles abraded from each of the two substances are equal in size. It follows from these assumptions that the volumes ground off are inversely proportional to the surface energies:

$$V_1/V_2 = \sigma_{s2}/\sigma_{s1} \qquad (2)$$

Therefore, if the surface tension of one of the crystals is known, those of other solids can be determined by abrasion measurements.

The discrepancy between Equations (1) and (2) is probably due to the fact that *Kusnezow* regards the size, but *von Engelhardt* and *Haussühl* the number, of abraded particles as constant. Both methods involve further difficulties: *Kusnezow* uses the value calculated by *Born* and *Stern* [14] for the surface tension of the cubic face of the ideal NaCl crystal, which is not necessarily valid for the real cubic face (see Section II, 6). *Von Engelhardt* and *Haussühl* also use theoretical values for ideal crystals as reference values, as well as the surface tensions of solids found from solubilities and data of the melt. Since the abrasion experiments are carried out in xylene, a further uncertainty is the effect of the interfacial tension between the crystal and xylene on the result.

### 5. Determination from the Work of Cleavage

At first glance it appears possible to determine the surface tension of crystals from their cleavability, since the cohesive energy per unit length, which is equal to twice the surface tension, must be overcome during cleavage. The following distinctions are made [15], according to the experimental arrangement used:

[5] *J. J. P. Valeton*, Ber. Königl. Sächs. Ges. Wiss., Math.-phys. Kl. *67*, 1 (1915).

[15] *H. Tertsch*: Die Festigkeitserscheinungen der Kristalle. Springer, Vienna 1949.

a) In cleavage by impact, a knife-edge is driven into the crystal by a well-defined blow.

b) In cleavage by pressure, a knife-edge is pressed into the crystal.

c) In cleavage by fracture, a wedge with an apex angle of 60 to 90° is used instead of the knife-edge.

d) Cleavage by tension does not require the use of a tool; the crystal is simply pulled apart.

These methods give different values for the work of cleavage for the same crystal; the values are not related. Sometimes the results differ even qualitatively. Thus cleavage of sodium chloride by pressure or by fracture is easier along the {100} face, whereas cleavage by impact occurs more readily along the {110} face [15]. Evidently it is not generally possible to convert the energy required for cleavage directly into surface energy, since, depending on the experimental conditions, varying proportions of the mechanical work done are consumed for the elastic deformation of the cleavage tool or are dissipated as heat or sound. This seems the only possible explanation for the very high values ($10^4$ to $10^6$ ergs/cm$^2$) obtained [16] by impact cleavage for the cubic face of rock salt. In view of these difficulties, reasonably accurate values of surface or interfacial tensions are most likely to be obtained by measurements on readily cleavable crystals at very low temperatures (cf. the tension cleavage experiments carried out by *Gilman* [17] at −196 °C in liquid nitrogen). The method is suitable for only a few solids, and even with these it can only be used for a single direction. However, the work of cleavage of mica probably is an accurate measure of the surface tension of the solid; a value of 315 ergs/cm$^2$ was recently obtained by *Bailey* [18] by fracture cleavage.

### 6. Theoretical Calculations

The surface tensions of crystals of the NaCl type can be predicted by calculations on models. Thus *Born* and *Stern* [14] treated the Coulomb attraction between the ions and the repulsive forces, assumed exponential, and *Born* and *Göppert-Mayer* [19] refined these results by taking into account dispersion forces.

Further refinements included consideration of the polarization of surface ions and of the deformation of the outer crystal layer under the action of surface forces, as well as quantum-mechanical calculations [20–24]. These calculations relate to ideal crystals and give values of 70 to 180 dynes/cm for the surface tension of rock salt, the most widely studied crystal, at room temperature.

*Benson*, *Schreiber*, and *Patterson* [25] calculated a value of 112 dynes/cm at 0 °K for the real NaCl crystal, whereas *van Zeggeren* and *Benson* obtained a value of approximately 190 dynes/cm at 0 °K both from the classical theory of ionic crystals [26] and on the basis of a simple quantum-mechanical model [24]. It appears, therefore, that the commonly accepted value of 150 to 170 dynes/cm for the surface tension of the {100} plane at room temperature may be correct for ideal crystals, but that the surface tension of real crystals is lower.

## III. Physical Chemistry of Interfaces

### 1. Statement of the Problem

In some cases, information about the surface tension of solids has been obtained by analogy with liquid properties that are readily found by experiment. In others, the interaction between a solid and a liquid was used as a basis for conclusions regarding the unknown surface tension $\sigma_s$ and the interfacial tension $\gamma_{sl}$ between the solid and the liquid. Earlier studies of this nature, *e.g.* [27–29], failed to produce any far-reaching results, mainly because Young's equation

$$\sigma_s - \gamma_{sl} = \sigma_l \cos \vartheta, \qquad (3)$$

which was used as the equilibrium condition, yields only the difference between $\sigma_s$ and $\gamma_{sl}$, but cannot be used to find these two quantities separately ($\sigma_s - \gamma_{sl}$ is the work of wetting or the work of immersion). Owing to the lack of success of these investigations and the fact that the reproducibility of contact angles is often poor, interest in the wetting equilibrium subsequently declined.

### 2. The Critical Surface Tension for Wetting

The importance of the wetting equilibrium was recognized by *Zisman et al.* [30–32], who showed the existence of a relationship between the surface tension of a liquid $\sigma_l$ and the contact angle $\vartheta$ between the liquid and a solid surface having a low energy, *i.e.* having a specific surface free energy smaller than that of the liquid in question. In a homologous series of liquids, the contact angle with a given solid decreases almost linearly with decreasing surface tension of the liquid [33] (Fig. 1).

In his earlier publications, *Zisman* stated that, for a given solid, every homologous series of liquids gives a different straight line of $\cos \vartheta$ *versus* $\sigma_l$. These lines were all reported to intersect at a common point with $\cos \vartheta = 1$. The abscissa of this point depends on the solid, and was designated as the critical surface tension of wetting, $\gamma_c$, of the solid. In more recent

papers (*e.g.*[31]), however, the values for non-homologous liquids were found to lie within a certain band, so that the value of $\gamma_c$ is not sharply defined. The values for liquids with reltatively high surface tensions do not lie on the lines obtained for those with relatively low surface tensions, but are displaced towards higher values of cos $\vartheta$; *Zisman* ascribes this to the effect of hydrogen bonds in liquids with high surface tensions (*e.g.* water). In recent years the critical surface tension for wetting, $\gamma_c$, has proved an important aid to the study of wetting, adhesion, and related phenomena, particularly in view of *Zisman*'s extensive work on the relationship between $\gamma_c$ and the chemical constitution of the solid (see also Section IV, 1 and Fig. 2).

### 3. Attempts to Identify the Critical Surface Tension of Wetting with the Surface Tension of the Solid

The fact that $\gamma_c$ is the first surface energy relating to solids alone, together with *Zisman*'s supposition that the critical surface tension for wetting is probably not very different from the surface tension of the solid, $\sigma_s$, suggests that $\gamma_c$ could be identical with $\sigma_s$.

The equality

$$\gamma_c = \sigma_s \tag{4}$$

was proposed almost simultaneously by *Gray*[34,35] and *Wolfram*[36]. *Wolfram*'s point of departure was *Antonow*'s rule:

$$\gamma_{sl} = \sigma_l - \sigma_s \tag{5}$$

He claimed this rule to hold at least when the liquid is just beginning to spread, *i.e.* when $\vartheta = 0$ and $\cos\vartheta = 1$, so that it follows from Equation (3) that

$$\gamma_{sl} = \sigma_s - \sigma_l \tag{6}$$

Comparison of Equations (5) and (6) then shows that

$$\gamma_{sl} = 0 \tag{7a}$$

and

$$\sigma_s = \sigma_l \tag{7b}$$

The proposed expression (4) then follows directly from the definition of $\gamma_c$ and Equation (7b).

The objection to this argument is that the vital Equation (7a) is derived indirectly *via* Equation (5), which probably cannot be proved (cf. Section IV, 1)[37]. In other words, since Equation (5) is supposed to be valid only when $\vartheta = 0$ and hence when $\gamma_{sl}$ becomes zero, it is identical with the proposed Equation (4) because of the definition of $\gamma_c$, and is equally lacking in proof.

*Gray*, on the other hand, started with the analytical equation of the straight line in Fig. 1.

$$\cos\vartheta = 1 + k(\gamma_c - \sigma_l) \tag{8}$$

where k is the slope of the line. He reasoned that if the liquid is replaced by the solid in question (assuming that some means is available for overcoming the cohesive forces of the solid), the liquefied solid spreads upon itself, so that Equations (7) are valid, and comparison of Equation (8) with Equation (3) gives the proposed Equation (4). Despite its plausibility, this reasoning, like the attempts to deduce the surface tension of the solid from that of the melt, is open to the objection that the surface tensions of the solid and of the melt should be different, their ratio being equal to the ratio of the heat of sublimation to the heat of fusion. Moreover, it is well known from crystal-growing practice that, when a crystal is being drawn from the melt, the latter often forms a finite contact angle with the growing crystal.

### 4. The Surface Tension of Solids, Contact Angles, and Intermolecular Forces

By analogy with an equation proposed by *Berthelot*[38], *Good et al.*[39–41] defined an interaction parameter[*]

$$\Phi = (\sigma_s + \sigma_l - \gamma_{sl})/2\sqrt{\sigma_s\sigma_l} \tag{9}$$

which represents the ratio of the work of adhesion and the mean work of cohesion of the two phases. These authors use this function in two ways to obtain information about the surface tension of solids:

1. *Girifalco* and *Good* calculated the interaction parameters[39] for many pairs of liquids from their surface and interfacial tensions. Within a group of chemically similar liquids, the values of $\Phi$ against water lie in a narrow range; *e.g.* between 0.51 and 0.60 for aliphatic hydrocarbons. On the assumption that the interaction parameters between *solid* aliphatic hydrocarbons and water also lie in this range, the surface tension of the solid, $\sigma_s$, can be estimated by measurement of the contact angle, since the interfacial tension, $\gamma_{sl}$, can be eliminated from Equations (9) and (3):

$$\sigma_s = \sigma_l(1 + \cos\vartheta)^2/4\,\Phi^2 \tag{10}$$

2. If the free energies in Equation (9) are replaced by the total specific surface energies $\Sigma_s$, $\Sigma_l$ and $\Gamma_{sl}$, combination of the resulting equation with that defining the heat of immersion or heat of wetting B:

$$B = \Gamma_{sl} - \Sigma_s \tag{11}$$

gives

$$\Sigma_s = (\Sigma_l - B)^2/4\,\Phi^2\Sigma_l \tag{12}$$

[38] *D. Berthelot*, C. R. hebd. Séances Acad. Sci. *126*, 1703, 1857 (1898).

[*] The term interaction parameter was introduced by *J. C. Melrose*; as far as we know, *R. J. Good* did not give the function $\Phi$ any special name.

[39] *L. A. Girifalco* and *R. J. Good*, J. physic. Chem. *61*, 904 (1957).

[40] *R. J. Good*, *L. A. Girifalco*, and *G. Kraus*, J. physic. Chem. *62*, 418 (1958).

[41] *R. J. Good* and *L. A. Girifalco*, J. physic. Chem. *64*, 561 (1960).

Thus if $\Phi$ and $\Sigma_l$ are known, the specific total surface energy $\Sigma_s$ of the solid can be found from the measured heats of immersion [40].

On the assumption that the contributions of intermolecular forces to surface tension are additive, *Fowkes* [42–44] expressed the surface tension of water as

$$\sigma_{l_1} = \sigma_{l_1}^h + \sigma_{l_1}^d \tag{13}$$

where $\sigma_{l_1}^h$ is the contribution due to the hydrogen bonds and $\sigma_{l_1}^d$ that due to dispersion forces. The surface tension $\sigma_{l_2}$ of saturated hydrocarbons, on the other hand, consists only of the contribution due to dispersion forces

$$\sigma_{l_2} = \sigma_{l_2}^d \tag{14}$$

The interactions at the interface between saturated hydrocarbons and water are almost entirely dispersion forces, so that on the tacit assumption that $\Phi = 1$, Equ. (9) can be written

$$\gamma_{l_1 l_2} = \sigma_{l_1}^d + \sigma_{l_2} - 2\sqrt{\sigma_{l_1}^d \sigma_{l_2}} \tag{15}$$

The calculation of $\sigma_{l_1}^d$ from $\sigma_{l_2}$ and $\gamma_{l_1 l_2}$ for several saturated hydrocarbons gives $\sigma_{l_2}^d = 21.8 \pm 0.7$ dyne/cm for the dispersion component of the surface tension of water.

This method can be used to find the dispersion component of the surface tensions of liquids in general. The application of these considerations to solids simply requires the combination of Young's Equation (3) with Equation (15) ($l_1 = s$, $l_2 = l$).

$$\sigma_l^d (\cos\vartheta + 1) = 2\sqrt{\sigma_l^d \cdot \sigma_s^d} \tag{16}$$

Thus the dispersion component $\sigma_s^d$ of the surface tension of a solid can be calculated from contact-angle data and calculated values of the dispersion component of the surface tension of the liquid. *Fowkes* has applied the above considerations to heats of immersion and of adsorption [44].

*Girifalco* and *Good* [39] derived the most general expression for the interaction parameter, on the basis of work by *Fowler* and *Guggenheim* [45]:

$$\Phi = \frac{4(V_1 V_2)^{1/3}}{(V_1^{1/3} + V_2^{1/3})^2} \cdot \frac{A_{12}}{(A_{11} A_{22})^{1/2}} \tag{17}$$

where $V_1$ and $V_2$ are the molar volumes and the A values are the attraction constants in a Lennard-Jones potential. Taking into account the usual intermolecular forces, *i.e.* dispersion and dipole forces, one obtains [46]:

$$\Phi = \frac{4\,(V_1 V_2)^{1/3}}{(V_1^{1/3} + V_2^{1/3})^2} \cdot \frac{{}^3/_4\,\alpha_1\alpha_2[2I_1I_2/(I_1 + I_2)] + \alpha_1\mu_2^2 + \alpha_2\mu_1^2 + {}^2/_3[(\mu_1\mu_2)^2/kT]}{[({}^3/_4\,\alpha_1^2 I_1 + 2\,\alpha_1\mu_1^2 + {}^2/_3(\mu_1^4/kT))\,({}^3/_4\alpha_2^2 I_2 + 2\,\alpha_2\mu_2^2 + {}^2/_3(\mu_2^4/kT))]} \tag{18}$$

where the $\alpha_i$ denote polarizabilities, the $\mu_i$ dipole moments, and the $I_i$ ionization energies.

The surface tensions $\sigma_s$ of a number of solids, were calculated by *Good* with the aid of Equation (10) using the surface tensions of liquids whose contact angles with the solid in question had been determined by *Zisman et al.* The interaction parameters were calculated by means of Equation (18). For polytetrafluoroethylene, the values of $\sigma_s$ varied from 15 to 35 dynes/cm, the mean value being 24 dynes/cm; the dipole moment of the polymer surface was taken to be 1.2 Debye. A dipole moment of zero, which *Good* regards as less likely on physical grounds, would give $\sigma_s = 21$ dynes/cm.

*Good*'s calculations, like those of *Fowkes* and like *Zisman*'s work, are based on the assumption (which is supported by many arguments) that, if $\sigma_l > \sigma_s$, the liquid is not adsorbed on the surface of the solid. The validity of this assumption has recently been questioned by *Melrose* [47], who estimates that the change in surface tension of the solid as a result of adsorption of vapor is of the order of 10 dynes/cm, and thus obtains values for $\sigma_s$ that are distinctly higher than those obtained by *Good*, *Fowkes*, and *Zisman*. According to *Melrose*, for example, the surface tension of polytetrafluoroethylene is 34 dyne/cm.

## IV. The Equation of State for Surface Energies and the Surface Tension of Solids

### 1. Principle

The fundamental object of molecular treatments such as that carried out by *Good* is to obtain information about the various interfacial-energy properties, for example the surface tensions of solids, $\sigma_s$, from the known intermolecular interactions. The capillarity theory, on the other hand, answers [in the form of Young's equation (3)] the question of the nature of the equilibrium between a solid phase having the surface tension $\sigma_s$ and a liquid phase having the surface tension $\sigma_l$ for a given interfacial tension $\gamma_{sl}$. Thus neither of these approaches can provide any other relationship between the three fundamental interfacial energies $\sigma_s$, $\sigma_l$, and $\gamma_{sl}$.

The interfacial tensions between a solid and chemically different liquids of the same surface tension (as is approximately true of lower alcohols and alkanes) were thought to be different because of different intermolecular forces. However the relationship (19) [48] for two immiscible liquids, $l_1$ and $l_2$ has been postulated.

$$\gamma_{l_1 l_2} = |\sigma_{l_1} - \sigma_{l_2}| \tag{19}$$

Comparison with experiment shows that Eq. (19) is not generally valid, even if partial miscibility is taken into account.

Moreover $\sigma_s$, and hence also $\gamma_{sl}$, generally is known to only a crude approximation, so that a functional relationship, if there is one, between the fundamental interfacial energies of a solid and a liquid cannot be established directly.

[42] *F. M. Fowkes*, J. physic. Chem. *66*, 382 (1962).

[43] *F. M. Fowkes*, in [31], p. 99.

[44] *F. M. Fowkes*, Lecture to the 4th International Congress on Surface Active Substances, Brussels 1964.

[45] *R. H. Fowler* and *E. A. Guggenheim*: Statistical Thermodynamics. Cambridge University Press, Cambridge 1939.

[46] *R. J. Good* in [31], p. 74.

[47] *J. C. Melrose*, in [31], p. 158.

Nevertheless it is possible to answer this question by examination of the wetting equilibrium [49,50] between a given solid and various liquids. If we assume, in agreement with *Zisman*, that the surface tension of the solid is not affeced by contact with liquids and their vapors when $\sigma_l > \sigma_s$ [*], the contact angle between the solid and any liquid is a unique function of the interfacial tension $\gamma_{sl}$ because of Equation (3). If there is a functional relationship among the three fundamental interfacial energies $\sigma_s$, $\sigma_l$, and $\gamma_{sl}$, this means that when $\sigma_s$ is kept constant and $\sigma_l$ is continuously varied, the interfacial tension $\gamma_{sl}$, and hence cos $\vartheta$, also change continuously, *i.e.* a plot of the surface tension $\sigma_l$ of any liquid against cos $\vartheta$ for a given solid (or more accurately for a given value of $\sigma_s$) will give a continuous curve. Fig. 2 shows that, contrary to the expectations based on the specificity of intermolecular forces, this is in fact the case, particularly if all the uncertainties associated with contact angles are taken into

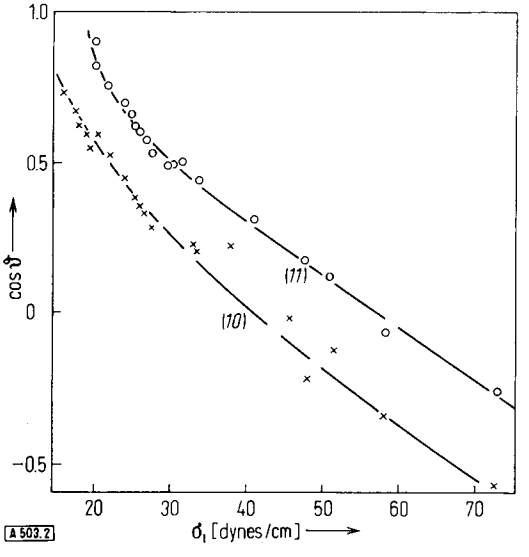

Fig. 2. Isotensosolids at 20 °C against *(10)*: pentadecafluorooctyl methacrylate, $C_7F_{15}-CH_2-OOC-C(CH_3)=CH_2$, and *(11)*: pentafluorononadecanoic acid [$CF_3-CF_2-(CH_2)_{16}-COOH$]. Liquids (examples): For *(10)*: n-alkanes, silicones, perhalogenated hydrocarbons, hydrocarbons. For *(11)*: n-alkanes ($C_7$, $C_8$, $C_{10}$, $C_{11}$, $C_{12}$, $C_{13}$, $C_{14}$, $C_{16}$), water, formamide, diiodomethane, glycol, tricresyl phosphate, bicyclohexyl.

account. Thus Fig. 2 proves that $\sigma_s$, $\sigma_l$, and $\gamma_{sl}$ are related by an equation of state:

$$F(\sigma_s, \sigma_l, \gamma_{sl}) = 0 \qquad (20)$$

(cf. also Fig. 1 and Section III, 2).

A quantitative treatment of such curves of constant solid surface tension ("isotensosolids") is precluded, *inter alia*, by the large scatter of the experimental data; however, if the work of wetting

$$\beta_{sl} \equiv \sigma_s - \gamma_{sl} = \sigma_l \cos\vartheta \qquad (21)$$

is plotted on the abscissa instead of $\sigma_l$, the scatter is greatly reduced (Fig. 3).

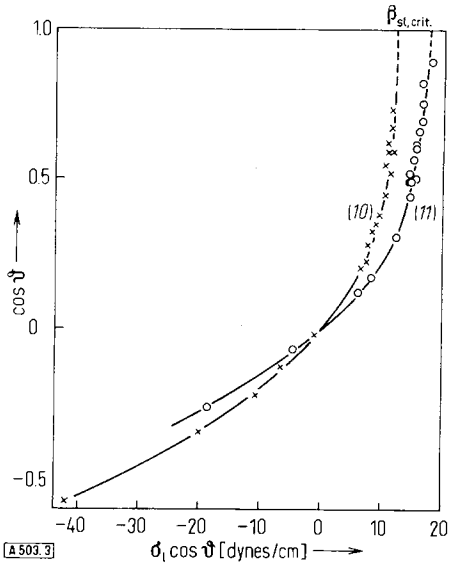

Fig. 3. Relationship between cos $\vartheta$ and $\sigma_l \cos\vartheta$. $\beta_{sl} = \sigma_s - \gamma_{sl}$. Conditions and substances as in Fig. 2.

In order to compare different solids, it is necessary to refer to equivalent points on the isotensosolids. For this purpose we use the maximum value of $\sigma_l$ obtained by extrapolation to cos $\vartheta = 1$, denoted as the critical wetting tension, $\beta_{sl,crit}$. A plot of these solid-specific values $\beta_{sl,crit}$. for various solids against cos $\vartheta$ for a given liquid according to Equation (20) also gives continuous curves (Fig. 4) ("isotensoliquids" [51]).

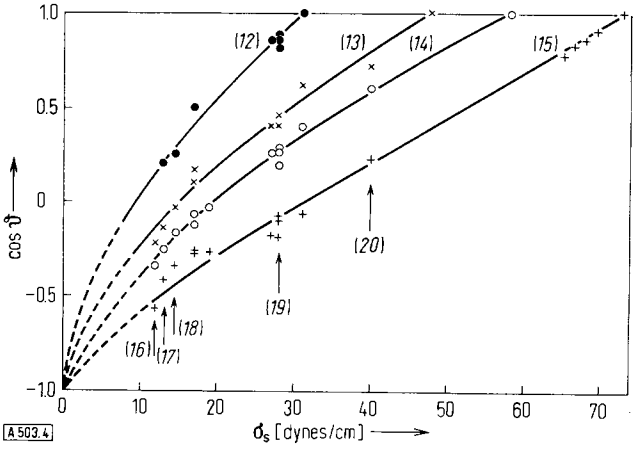

Fig. 4. Relationship between cos $\vartheta$ and $\sigma_s$ (= $\beta_{sl,crit}$), measured at room temperature for several solids against four liquids of different surface tensions (isotensoliquids).

*(12)*: bis-2-ethylhexyl sebacate ($\sigma_l$ = 31.0 dynes/cm), *(13)*: glycol (47.7), *(14)*: formamide (58.2), *(15)*: water (72.8).

$\beta_{sl,crit.}$ (= $\sigma_s$) = critical wetting tension. Some solids are indicated by vertical arrows: *(16)* perfluorolauric acid, *(17)* pentadecafluorotetracosanoic acid, *(18)* undecafluorodocosanoic acid, *(19)* polyethylene (BASF), *(20)* Ultramid (BASF). (See also Table 2).

It can be seen from Fig. 4 that, for a given solid, the contact angle decreases, *i.e.* cos $\vartheta$ increases, with decreasing surface tension of the liquid; Fig. 3 shows that the wetting tension $\beta_{sl}$ also increases with increasing cos $\vartheta$, so

[48] *G. Antonow*, J. Chim. physique *5*, 372 (1907).

[50] *P.-J. Sell*, Z. physik. Chem. NF *39*, 322 (1963).

[*] When $\sigma_s > \sigma_l$, adsorption of the liquid is accompanied by an increase in the free energy of the surface of the solid.

[51] *A. W. Neumann* and *P.-J. Sell*, Z. physik. Chem. NF *41*, 183 (1964).

that, according to Equation (3), the interfacial tension decreases with decreasing surface tension of the liquid.

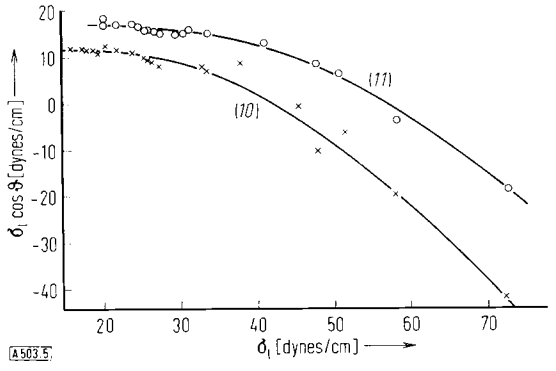

Fig. 5. Isotensosolids at 20 °C against several liquids (for examples see Fig. 2).

The curves of $\sigma_l \cos\vartheta$ *vs.* $\sigma_l$ [52] (Fig. 5) apparently pass through the points $\sigma_l = \beta_{sl,crit}$ parallel to the $\sigma_l$ axis. Since

$$d(\sigma_s - \gamma_{sl})/d\sigma_l = -d\gamma_{sl}/d\sigma_l \qquad (22)$$

it follows from Equation (3) that

$$(d\gamma_{sl}/d\sigma_l) = 0 \text{ for } \sigma_l \longrightarrow \beta_{sl,crit} \qquad (23)$$

*i.e.* $\gamma_{sl}$ assumes a minimum value when $\sigma_l \rightarrow \beta_{sl,crit}$. Since there is no reason why the interfacial tension between a solid and a liquid cannot be zero, whereas it assumes a minimum value for $\sigma_l = \beta_{sl,crit}$, it is reasonable, by analogy with the reasoning leading to Nernst's theorem, to postulate

$$(\gamma_{sl})_{\sigma_l \longrightarrow \beta_{sl,crit}} = 0 \qquad (24)$$

It then follows from Equation (21) that

$$\beta_{sl,crit} = \sigma_s \qquad (25)$$

In order to be able to formulate the interfacial-energy equation of state (20) explicitly [37], it is necessary to find a physically meaningful function of the three fundamental interfacial energies, the form of which is such that all possible values of the function are uniquely assigned to one of the three fundamental energies. Since $\sigma_s$ and $\sigma_l$ are naturally to be regarded as the independent variables, owing to the fact that the solid and the liquid are specified in advance, the dependent quantity that is to be assigned to the values of the function must be the interfacial tension $\gamma_{sl}$.

We examined *Girifalco* and *Good*'s interaction parameter [Equation (9)] to see whether it was suitable for use as a function of state. To test the supposition that $\Phi$ is only a function of $\gamma_{sl}$, the isotensosolids of the solids studied in [50] and [53] were plotted in the ($\sigma_l$; $\gamma_{sl}$) diagram, and $\Phi$ was calculated for various values of $\gamma_{sl}$. Within the scatter of the measurements in the energy range accessible ($10 \leqslant \sigma_s \leqslant 45$ dynes/cm and $20 \leqslant \sigma_l \leqslant 73$ dynes/cm), the $\Phi$ values assigned to one and the same $\gamma_{sl}$ value are constant.

A plot of the average $\Phi$ values against the corresponding $\gamma_{sl}$ values gives approximately a straight line, the equation of which is:

$$\Phi = -0.0075\,\gamma_{sl} + 1 \qquad (26)$$

If we eliminate $\Phi$ from Equations (9) and (26), we obtain the following approximation for the equation of state for the interfacial energies in the interfacial-tension range of 0 to about 40 dynes/cm:

$$\gamma_{sl} = (\sqrt{\sigma_s} - \sqrt{\sigma_l})^2 / (1 - 0.015\sqrt{\sigma_l \sigma_s}) \qquad (27)$$

With the aid of Equations (27) and (3) it is possible, in principle, to calculate the surface tension of the solid and the interfacial tension for any solid/liquid combination (in the energy range given above) from the surface tension of the liquid and the contact angle [54].

## 2. Results

Table 1 shows values obtained in this way for the surface tension of solid perfluorolauric acid, together with the surface tensions and contact angles [55] of some other liquids. There is no dependence of $\sigma_s$ on $\sigma_l$ within the limits of error; the same is found for the $\sigma_s$ values of the solids listed in Table 2. This may be regarded not only as confirmation of the above theoretical considerations, but also as evidence for the correctness of the constants in Equations (26) and (27). Column 3 of Table 2 contains some values of $\sigma_s$ calculated by *Good* from intermolecular force data with the aid of Equations (10) and (18). In view of the large number and uncertainty of the data used by *Good*, the agreement with the values in column 2 of Table 2 is remarkable.

Since the surface tension of a solid can in principle be determined from the surface tension of a single liquid

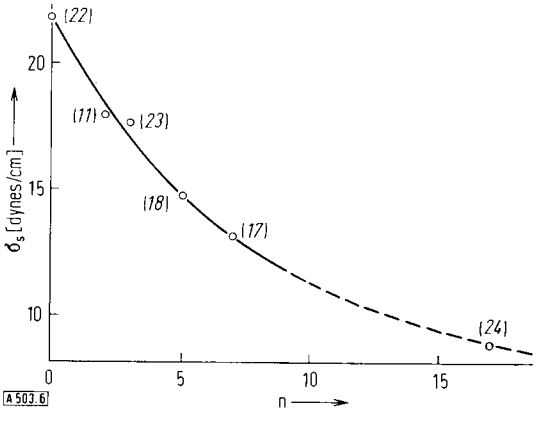

Fig. 6. Surface tensions of a number of solid fluorinated fatty acids as a function of the length of the perfluorinated hydrocarbon chain (for compounds, see Table 2).

[54] For details of the solution of the cubic equation obtained by combination of Equations (3) and (27) see *O. Driedger*, *A. W. Neumann*, and *P.-J. Sell*, Kolloid-Z. u. Z. Polymere *204*, 101 (1965).

[55] *E. F. Hare*, *E. G. Shafrin*, and *W. A. Zisman*, J. physic. Chem. *58*, 236 (1954).

and the corresponding contact angle, it is possible to study the relationships between the surface tension of a solid and its chemical constitution. For example, Fig. 6 is a plot of the surface tensions of solid stearic acid *(22)* and of a number of fluorinated acids against the length of the fluorinated chain. Compounds *(11)*, *(23)*, *(18)*, and *(17)* are stearic acids in which a hydrogen atom on C-18 has been replaced by a perfluoroalkyl group. As expected, it is found that the fluorination of a few C atoms causes a marked decrease in the surface tension,

Table 1. The surface tension, $\sigma_S$, of solid perfluorolauric acid at 20 °C, calculated from that of the liquid, $\sigma_l$, and contact angles, $\vartheta$, from Eqs. (3) and (27) [55].

| Liquids | $\sigma_l$ [dynes/cm] | $\vartheta$ [deg] | $\sigma_S$ [dynes/cm] |

and that $\sigma_S$ converges towards a limiting value for very long perfluorinated chains.

The discussion of the wetting equilibrium has so far related to solids with low energies, in which the contact angle with liquids is a function of the chemical constitution of the solid, which is expressed in the surface tension $\sigma_S$. High-energy solids, *i.e.* those whose surface tensions are greater than that of water, generally are covered with an adsorbed film of atmospheric moisture, since the adsorption is accompanied by a gain in energy. To extend the present examination to cases of this kind, contact angle measurements were carried out on the cubic faces of potassium bromide, sodium chloride, and lithium fluoride against liquid mercury under a pressure of $10^{-4}$ mm Hg[*]. To remove the adsorbed aqueous film, the crystals were heated to about 500 °C at the working pressure before the measurements were carried out. After cooling, all three crystals gave the same contact angle as before (about 132–135 °). It can be concluded, therefore, that the crystal faces, which were undoubtedly cleaned at 500 °C[62], readsorbed some residual gas on cooling.

An attempt to measure contact angles at higher temperatures met with some success. It was found that the contact angles of the three crystals against mercury were not very strongly dependent on temperature between 150 and 200 °C, and showed a rapid increase only below 150 °C. Following *Johnson* and *Dettre*[63], special attention was paid to the receding angles $\vartheta_R$, which in the case of partial coverage of the surface by adsorbed substances characterize mainly the sites of higher surface tension of the solid. The measured values of the contact angle $\vartheta_R$ are listed in Table 3; however, the evaluation cannot be carried out mathematically from the equation of state, since the validity of the latter has only been

established for a relatively narrow energy range. The evaluation is therefore most easily carried out with the aid of the isotensoliquid of mercury.

Table 3. Contact angles of mercury against the {100} faces of alkali halides, and the corresponding solid surface tensions, $\sigma_S$ (measured at 150–180 °C, calculated values refer to room temperature).

| | $\vartheta_R$ [deg] | $\sigma_{SHg}$ exp. [dynes/cm] | $\sigma_S$ calc. [dynes/cm] [3] |
|---|---|---|---|
| KBr | 120 | 120 | 135 |
| NaCl | 115 | 138 | 170 |
| LiF | 104 | 181 | 354 |

As can be seen from Fig. 4, the isotensoliquids become almost linear with increasing surface tension, and exhibit an appreciable curvature only at low solid surface tensions, if at all. To determine any curvature present, the contact angles of mercury against Teflon, polystyrene, and a polyamide (Ultramid) were measured and plotted (Fig. 7) against the known surface tension of these solids. Since the points almost lie on the straight line joining the points (0; −1) and (480; +1), the isotensoliquid of mercury is fixed. It is possible, with the

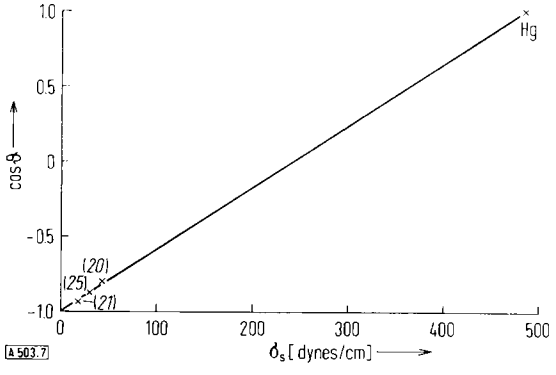

Fig. 7. Isotensoliquid of mercury at room temperature against *(21)* (see Table 2), *(25)*: polystyrene (BASF), *(20)*: see caption to Fig. 4.

aid of this line, to convert the contact angles listed in Table 3 into the desired surface tensions of the solids. The measured values for KBr and NaCl are somewhat lower than those calculated; the difference is slightly less if the temperature at which the measurements are carried out (150–180 °C) is taken into account, since the calculated values refer to room temperature. The discrepancy between the measured and the calculated value for LiF cannot be explained at present; it could be due to strong adsorption of residual gas on cooling.

The above concepts permit the determination of important interfacial energies, and provide an answer to the question of how far the various interfacial phenomena are determined by interfacial energies and to what extent directly by specific actions of intermolecular forces.

Parallels between coefficient of friction and adhesive strength appear to be due to the fact that both phenomena depend on interfacial energy relationships. The adhesive strength increases with decreasing interfacial tension between the adhesive and the adherend [53], just as the coefficient of friction increases with increasing surface tension of the solid [64]. Ordinary liquids and their vapors are surface active on solid surfaces; investigation of the wetting equilibrium permits a quantitative treatment of the phenomena observed [65]. Sedimentation and related phenomena in connection with powdered solids of low energy are dependent primarily on interfacial energies, as shown by the dependence of the sedimentation volume on the surface tension of the liquid in which the sedimentation takes place [66]. The surface tension of solid paints and varnishes evidently plays an important part in the processes of soiling, cleaning, and above all corrosion [67].

Equation (20) relates to the wetting equilibrium between a pure liquid and a solid. It can also be applied to solid/liquid/liquid systems, but it apparently does not characterize these completely [68]. Investigation of the temperature-dependence of contact angles (and of the surface tension of liquids) gives the temperature dependence of the surface tension of solids and solid/liquid interfacial tensions, *i.e.* the corresponding entropies [69, 70]; this makes possible a thermodynamic study of interfacial phenomena.

*We gratefully acknowledge the support of this investigation by the Bundeswirtschaftsministerium.*

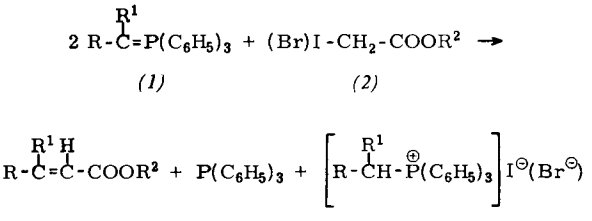
## Reaction of Alkylidenephosphoranes with Halogenoacetic Esters

By Prof. Dr. H. J. Bestmann, Dr. K. Rostock, and cand. chem. H. Dornauer

Institut für Organische Chemie der Universität Erlangen-Nürnberg (Germany)

The halogen atom is decisive for the mode of reaction of alkylidenephosphoranes *(1)* with halogenoacetic esters.

1. On treating compounds *(1)* (salt-free solutions in boiling tetrahydrofuran or benzene[1]) with iodo- or bromo-acetic esters *(2)*, one obtains α,β-unsaturated carboxylic esters *(3)*, triphenylphosphine *(4)*, and a phosphonium salt *(5)*.

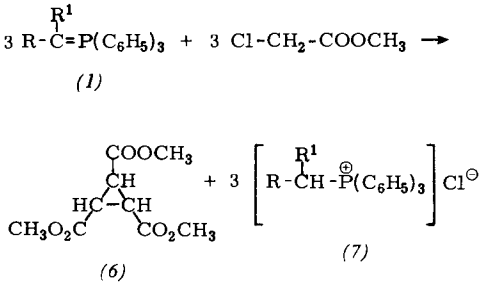


*(1)* *(2)* *(3)* *(4)* *(5)*

| R | $R^1$ | Halogen in *(2)* | Acid in *(3)* | B.p. of *(3)* [°C/mm Hg] | Yield of *(3)* [%] |
|---|---|---|---|---|---|
| $C_6H_5$ | H | Br | Cinnamic | 95/0.3 | 74 |
| *p*-$ClC_6H_4$ | H | Br | 4-Chlorocinnamic | 115/0.3 | 80 |
| n-$C_3H_7$ | H | Br | 2-Hexenoic | 32/0.2 | 50 |
| $C_6H_5CH_2CH_2$ | H | I | 5-Phenyl-2-pentenoic | 150/0.4 | 71 |
| cyclo-$C_6H_{11}$ | H | I | 3-Cyclohexylacrylic | 75/0.3 | 60 |
| $C_6H_5$ | $CH_3$ | Br | β-Methylcinnamic | 127/10 | 59 |

Other α-halogenocarboxylic esters can be used in place of bromo- or iodo-acetic esters. Thus *(1)*, R = $C_6H_5$, $R^1$ = H, and ethyl α-bromopropionate afford the α-methylcinnamic ester in 59 % yield.

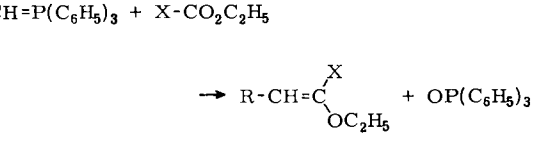
2. Trimethyl *trans*-cyclopropanetricarboxylate *(6)* and the corresponding phosphonium chloride are obtained in 55 % yield from alkylidenephosphoranes *(1)* and methyl chloroacetate in n-pentane at room temperature.



*(6)* *(7)*

The reaction does not involve a carbene intermediate. Presence of cyclohexene does not lead to formation of a norcaranecarboxylic ester. If the reaction mixture is treated with dimethyl fumarate fully deuterated at the double bond, deuterium is found in the product *(6)*.

3. Ethyl fluoroacetate and alkylidenephosphoranes (salt-free in boiling benzene[1]) undergo a Wittig reaction at the carbonyl group[2]. Enol ethers *(8)* of fluoroketones are obtained. Enol ethers *(9)* of trifluoroketones result analogously from ethyl trifluoroacetate and alkylidenephosphoranes.



*(8)*, X = $CH_2F$
*(9)*, X = $CF_3$

| R | X | B.p. of *(8)* or *(9)* [°C/mm Hg] | Yield [%] of *(8)* or *(9)* |
|---|---|---|---|
| $C_6H_5$– | $CH_2F$ | 78/0.4 | 65 |
| $C_6H_5$–$(CH_2)_2$– | $CH_2F$ | 88/0.4 | 45 |
| $CH_3$–$(CH_2)_2$– | $CH_2F$ | 50/13 | 50 |
| $C_6H_5$– | $CF_3$ | 84/13 | 82 |
| $C_6H_5$–$(CH_2)_2$– | $CF_3$ | 111/13 | 71 |
| $CH_3$–$(CH_2)_2$– | $CF_3$ | 36/13 | 59 |
| cyclo-$C_6H_{11}$ | $CF_3$ | 72/13 | 76 |

## One-Step Syntheses of Fused Pyrimidinethiones[1]

By Prof. Dr. E. C. Taylor, Dr. S. Vromen, Dr. R. V. Ravindranathan, and Dr. A. McKillop

Department of Chemistry, Princeton University, Princeton, New Jersey (U.S.A.)

Previously available methods for the preparation of fused pyrimidinethiones involve either laborious and inefficient multistage syntheses, or drastic conditions. We have now found that fused pyrimidinethiones may be prepared from *o*-aminonitriles, ethyl orthoformate, and NaHS in a one-step reaction which proceeds in high yield and under mild conditions. 3.0 g of an *o*-aminonitrile is refluxed either with a mixture of 30 ml of ethyl orthoformate and 30 ml of acetic anhydride, or with 30 ml of ethyl orthoformate alone[2], for 1–3 hours. Evaporation of the reaction mixture under reduced pressure gives the intermediate, crude ethoxymethyleneamino derivative which, without further purification, is treated with 100 ml of a 1.5 N solution of sodium hydrosulfide in anhydrous ethanol. The reaction mixture is refluxed for 10–12 hours, evaporated to dryness and the residual solid taken up in hot water, treated with charcoal, filtered and acidified with glacial acetic acid. The fused pyrimidinethione precipitates in an extremely high state of purity and in yields often in excess of 90 % (see Table).

The effectiveness of this method may be illustrated by the synthesis of 4(5*H*)-pyrazolo[3,4-*d*]pyrimidinethione. This compound has previously been prepared[3] from 3-amino-4-cyanopyrazole by a 4-step sequence involving initial hydrolysis of the nitrile with concentrated sulfuric acid to the amide, cyclization with formamide to 4(5*H*)-pyrazolo[3,4-*d*]pyrimidinone, then to the 4-chloro derivative with phosphorus oxychloride, and finally conversion to the thione with thiourea. Direct conversion of the pyrimidinone to the thione with phosphorus pentasulfide proved even less satisfactory[3]. By

| o-Aminonitrile | Pyrimidinethione | Time [hrs.] | Yield [%] | m.p. [°C] |
|---|---|---|---|---|
| 4-Amino-1-benzyl-3-cyanopiperidine | 2-Benzyl-1,2,3,4-tetrahydro-8(7*H*)-pyridino[4,3-*d*]pyrimidinethione | 1 | 81 | 220–225 (decomp.) |
| 3-Amino-4-cyanopyrazole | 4(5*H*)-Pyrazolo[3,4-*d*]-pyrimidinethione | 3 | 97 | 354–356 (decomp.) |
| 5-Amino-4-cyano-1-methylpyrazole | 1-Methyl-4(5*H*)-pyrazolo[3,4-*d*]-pyrimidinethione | 2 | 91 | 309–311 (decomp.) |
| 5-Amino-4-cyano-1-phenylpyrazole | 1-Phenyl-4(5*H*)-pyrazolo[3,4-*d*]-pyrimidinethione | 2 | 94 | 280–282 (decomp.) |
| 4-Amino-5-cyanopyrimidine | 4(3*H*)-Pyrimido-[4,5-*d*]pyrimidinethione | 2 | 69 | > 360 |
| 2-Aminobenzonitrile | 4(3*H*)-Quinazolinethione | 2 | 73 | 326–330 (decomp.) |
| 1-Amino-2-cyanocyclopent-1-ene | 7(6*H*)-Cyclopenteno-[*d*]pyrimidinethione | 1 | 70 | 275–277 (decomp.) |
| 1-Amino-2-cyanocyclohex-1-ene | 8(7*H*)-Cyclohexeno-[*d*]pyrimidinethione | 0.75 | 68 | 268–274 (decomp.) |

contrast, 4(5*H*)-pyrazolo[3,4-*d*]pyrimidinethione may be prepared from 3-amino-4-cyanopyrazole by our procedure in a single step in 97 % yield; the product is analytically pure as isolated directly from the reaction mixture.

A second one-step synthesis of fused pyrimidinethiones, although less advantageous and involving more strenuous conditions, consists of the reaction of *o*-aminonitriles with phenyl isothiocyanate in acidic medium. Heating 1.2 g of 2-aminobenzonitrile and 1.4 g of phenylisothiocyanate in 15 ml of dimethylformamide (saturated at 0 °C with dry HCl) at 85 °C for 15 hrs. results in gradual dissolution followed by separation of a yellow solid. Evaporation under reduced pressure, trituration of the residue with water, filtration and recrystallization from methanol gives 1.3 g (79 %) of 4(3*H*)-quinazolinethione, m.p. 326–330 °C (decomp.). Similarly, 5-amino-4-cyano-1-methylpyrazole is converted into 1-methyl-4(5*H*)-pyrazolo[3,4-*d*]pyrimidinethione in 67 % yield, and 5-amino-4-cyano-1-phenylpyrazole to 1-phenyl-4(5*H*)-pyrazolo[3,4-*d*]pyrimidinethione in 48 % yield.

With the use of $^{14}C$-labelled dimethylformamide it was shown that the C-2 atom of 4(3*H*)-quinazolinethione originated from the dimethylformamide and not from the phenyl isothiocyanate. The reaction sequence probably involves nucleophilic attack of phenyl isothiocyanate upon the protonated *o*-aminonitrile to give thioanthranilamide, which then undergoes formylation by the dimethylformamide/hydrogen chloride mixture and subsequent cyclization. Strong support for this interpretation was found in the reaction of 4-amino-5-cyanopyrimidine with phenyl isothiocyanate and dimethylformamide/hydrogen chloride to give a 57 % yield of 4-aminopyrimidine-5-thiocarboxamide, which did not undergo subsequent formylation and cyclization, apparently because of decreased nucleophilicity of the 4-amino group.

[2] A mixture of equal volumes of ethyl orthoformate and acetic anhydride is the reagent of choice for the formation of ethoxymethyleneamino derivatives. However, in some cases (3-amino-4-cyanopyrazole, 2-aminobenzonitrile, 1-amino-2-cyanocyclopent-1-ene) acetylation of the amino group may take precedence over formation of the latter derivative and resort must be made to the use of ethyl orthoformate alone.

# A One-Step Synthesis of Fused Pyrimidinedithiones[1]

By Prof. Dr. E. C. Taylor, Dr. R. N. Warrener, and Dr. A. McKillop

Department of Chemistry, Princeton University, Princeton, New Jersey (U.S.A.)

The reaction of aromatic and heterocyclic *o*-aminonitriles with $CS_2$ in pyridine gives fused pyrimidinedithiones (dimercaptopyrimidines). 3.0 g of 2-aminobenzonitrile, 10 ml of $CS_2$, and 10 ml of pyridine were heated for 2 hrs. under reflux. On dilution of the reaction mixture with methanol, 4.82 g (97 %) of quinazoline-2,4(1*H*,3*H*)-dithione separated out. The other compounds listed in the Table were prepared in analogous fashion.

In order to investigate the course of this conversion, 5.00 g of 3-amino-4-cyanopyrazole *(1)*, 50 ml of $CS_2$, and 50 ml of pyridine were heated under reflux for 1 hr., whereupon 10.25 g of a yellow, crystalline pyridinium salt separated. Treatment of this salt with cold, dilute HCl gave 4(5*H*)-imino-6(7*H*)-pyrazolo[4,3-*d*]-thiazinethione *(2)*. The structure of this intermediate was established by microanalysis, by the absence of —CN absorption and the presence of a strong imine N—H band at 3510 $cm^{-1}$ in its infrared spectrum, by its ultraviolet spectrum [$\lambda_{max}^{EtOH}$ = 237, 262, 311, and 382 mμ (ε = 11,160, 12,270, 11,340, and 2,950)] and by its rearrangement in quantitative yield by 1 N sodium hydroxide to 4,6(5*H*,7*H*)-pyrazolo[3,4-*d*]pyrimidinedithione *(3)*.

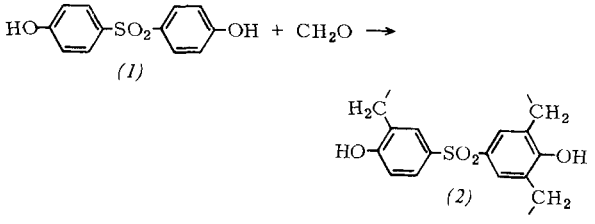
## Syntheses of Peptides by Means of Activated Units Bound to Resins [*]

By Prof Dr. Th. Wieland and Dipl.-Chem. Ch. Birr

Institut für Organische Chemie der Universität
Frankfurt/Main (Germany)

Amino acids can be bound, in ester form, to polymers containing strongly acidic (*e.g.*, phenolic) hydroxyl groups and can then be used as "activated" amino acids for peptide syntheses. We have used a gel *(2)* prepared [2] by cross-linking *p,p'*-dihydroxydiphenyl sulfone *(1)* [1].



*(1)*

*(2)*

The capacity of this new phenoplast for acyl residues is 4.2 mmole/g (calc. 6.7 mmole/g) when loaded by reaction of its lithium salt with benzoyl chloride in tetrahydrofuran (THF). For *N*-benzyloxycarbonylamino acids the capacity is 0.8–1 mmole/g when loaded with dicyclohexylcarbodiimide [3] in THF or dimethylformamide (DMF), or 1.2 mmole/g when activated by the mixed anhydride method [4] in THF, or 0.9–1.1 mmole/g after activation of the resin with thionyl chloride. For the last-mentioned type of activation the $Li^+$ form of the resin, swollen in THF, is allowed to react as two equivalents of thionyl chloride in THF percolate through it, the excess of chloride being then washed out and the acid to be activated then allowed to react in the presence of an excess of triethylamine in THF at 20 °C for about 2 h. The resin can also be activated by reaction with phosgene.

An ester of a carboxylic acid and the phenoplast affords the carboxyamide when percolated in the column by a solution of the amine component in DMF at 20 °C. Thus with L-phenylalanine methyl ester as amine component, the benzyloxycarbonylglycyl resin, the t-butoxycarbonyl-L-alanyl resin, or the t-butoxycarbonylleucyl resin afford, respectively, benzyloxycarbonylglycyl-L-phenylalanine methyl ester (m.p. 97 °C, 56 % yield), t-butoxycarbonyl-L-alanyl-L-phenylalanine methyl ester (oil, 65 %), or t-butoxycarbonyl-L-leucyl-L-phenylalanine methyl ester (m.p. 146 °C, 63 %). Reaction of the benzyloxyglycyl resin with L-valyl-L-phenylalanine methyl ester afforded the tripeptide ester, which on hydrolysis of the ester group gave benzyloxycarbonylglycylvalylphenylalanine in 71 % yield, calculated on the amount of dipeptide ester used. The peptide syntheses could also be effected with the Na salts of the amino acids in formamide.

*Katchalski et al.* [5] recently reported the cyclization of peptides by a method also involving use of carboxyl groups activated on a resin (nitrated poly-*p*-hydroxystyrene).

## Volume Change as Indicator for Reactions in Solution

By Prof. Dr. K. F. Jahr, Dipl.-Chem. E. Gegner [1], Dr. G. Wiese, and Dr. J. Fuchs

Institut für Anorganische Chemie der Freien Universität
Berlin (Germany)

Reactions in solution generally are accompanied by volume changes caused by a change in the nature of the solute particles. Previously it has not been possible to measure these changes continuously during a titration. With the aid of a new apparatus we have succeeded in using the volume change as endpoint indicator of reactions in solution.

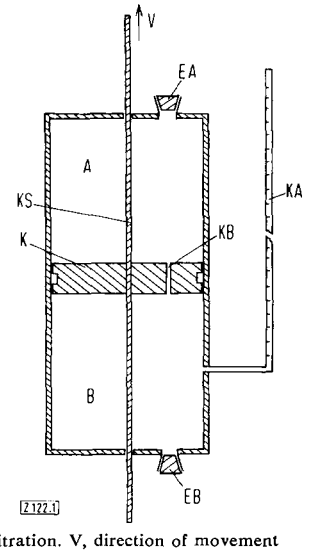

Fig. 1. Apparatus for dilatometric titration. V, direction of movement of piston K; KS, push rod; EA, EB, filling apertures; KA, KB, capillaries.

Figure 1 shows the principle of the apparatus. The initial solution (in compartment B) and the titrant (in compartment A) are gradually mixed in a syringe buret [2] by raising the piston K which contains a capillary hole KB. The volume of titrant solution entering B is proportional to the displacement of the piston K, which is measured mechanically; the proportionality factor is determined by calibration. The volume changes caused by the resulting reaction are indicated by a change in the height of the meniscus in the calibrated measuring capillary KA.

We have used this dilatometric indication for determination of the endpoint in neutralization, precipitation, redox, complex formation, and aggregation reactions. Accuracy, time required, and expenditure for apparatus are comparable to those of the usual physicochemical indicator procedures. An example of a dilatometric titration, the precipitation of sulfate ions by barium ions, is given in Figure 2.

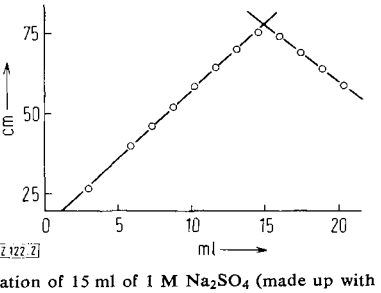

Fig. 2. Dilatometric titration of 15 ml of 1 M $Na_2SO_4$ (made up with water to the initial volume of compartment B) with 1 M $BaCl_2$ (in compartment A).
Abscissa: Consumption (ml) of $BaCl_2$ solution.
Ordinate: Position of meniscus in capillary KA (cm).

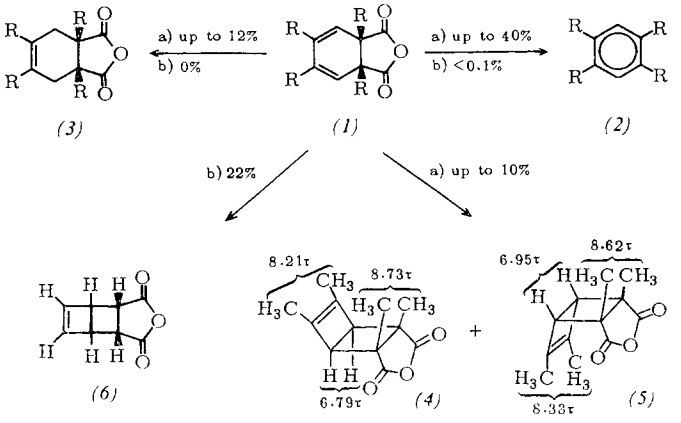
## Excited-State Reactions of 1,2,4,5-Tetramethyl-3,5-cyclohexadiene-cis-1,2-dicarboxylic Anhydride

By Dr. R. N. Warrener and J. B. Bremner

Department of Chemistry, Australian National University, Canberra, A.C.T. (Australia)

Ultraviolet irradiation[1] of the title diene *(1a)*[2] in ether gave the products *(2a)*–*(5a)* together with two unidentified compounds.



a) R = $CH_3$
b) R = H

We consider that the novel fragmentation of *(1a)* into durene *(2a)*, CO, and $CO_2$ is due to a multicenter valence-electron redistribution[3] of the excited-state diene, rather than a consequence of the anhydride group itself. This accounts for the photolytic stability of the reduction product *(3a)*. The source of the hydrogen atoms in *(3a)* is not certain, although solvent participation seems unlikely since *(3a)* is also formed with carbon tetrachloride as solvent.

Disrotatory electrocyclic ring closure, a favored photoreaction in the diene system of *(1a)*[4], accounts for the formation of both valence isomers *(4a)* (m.p. 150–151 °C) and *(5a)* (m.p. 100–101 °C). These structures are supported by thermal reconversion into the initial diene *(1a)*. The stereochemical assignments were based on the NMR spectra of *(4a)* and *(5a)*.

These results are in contrast with the photolysis pattern of the parent dienedicarboxylic anhydride *(1b)*[5]. In this case, photoaromatization is a minor reaction (< 0.1 %), no reduction product *(3b)* is observed and only a single valence isomer *(6)* is formed of unknown stereochemistry.

Vapour phase pyrolysis (800 ± 15 °C at 0.1 mm) of the diene *(1a)* also yielded durene (40 %), CO, and $CO_2$. This reaction may, however, be due to simple thermal anhydride fragmentation[5a]. A preliminary investigation[6] of the mass spectrum of *(1a)* showed that a unimolecular fragmentation of the parent ion (mass 206) to the durene molecular ion with loss of 72 mass units (CO + $CO_2$) is a major decomposition pathway.

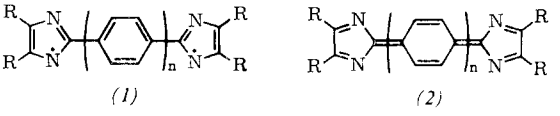
## Biradicals, Quinones, and Semiquinones of the Imidazole Series

By Dipl.-Chem. U. Mayer, Dr. H. Baumgärtel, and Prof. Dr. H. Zimmermann

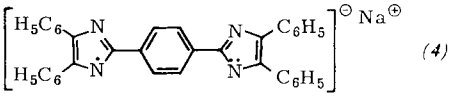
Institut für Organische Chemie der Universität München (Germany)

Biradicals of the imidazolyl series can occur as paramagnetic biradicals *(1)* or as diamagnetic quinonoid molecules *(2)*.

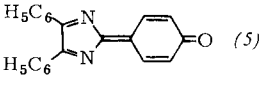


The homologous series of compounds *(2)* can be considered as derived from tetraazafulvalene. The first representative of this class of compound has now been prepared. When the disodium salt *(3)* of 1,4-bis-(4,5-diphenyl-2-imidazolyl)-benzene[1] is treated with bromine in methylene chloride, sodium bromide separates and 3,6-bis(4,5-diphenyl-2-imidazolylidene)-1,4-cyclohexadiene *(2)* (n = 1, R = phenyl), blue crystals, long wavelength absorption in $CHCl_3$ at $\lambda$ = 602 mμ, log ε = 4.95) is formed. This product contains some of the paramagnetic form but consists mainly of the diamagnetic quinonoid form.

Treatment of *(2)* with the disodium salt *(3)* in acetone affords the red, unstable semiquinone *(4)*, whose paramagnetism was detected by ESR spectroscopy in a stop-flow apparatus.

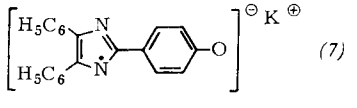


We have also prepared 4-(4,5-diphenyl-2-imidazolylidene)-2,5-cyclohexadienone *(5)* by dehydrogenation of *p*-(4,5-diphenyl-2-imidazolyl)phenol *(6)*[2] with lead dioxide in anhydrous ether. This compound forms red crystals, decomp.



at 155 °C, having long-wavelength absorption in $CHCl_3$ at $\lambda$ = 440 mμ, log ε = 4.64.

Treatment of *(5)* with the dipotassium salt of the phenol *(6)* in dioxane also gives a short-lived, green semiquinone *(7)*, which was detected by ESR spectroscopy.



The quinonoid molecules *(2)* and *(5)* were titrated with hydroquinone, which regenerated the starting materials *(3)* and *(5)*.

## Isosteres of Hexamethyldisiloxane and Tris(trimethylsilyl)amine

By Priv.-Doz. Dr. H. Schmidbaur and cand. chem. W. Wolfsberger

Institut für Anorganische Chemie der Universität Würzburg (Germany)

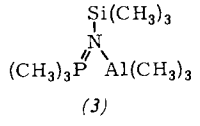
For the preparation of an isostere *(3)* of tris(trimethylsilyl)-amine *(2)* we required *P*-trimethyl-*N*-trimethylsilyliminophosphorane *(1)*. The latter is readily accessible from trimethylsilyl azide and trimethylphosphine[1,2]:

$$(CH_3)_3Si{-}N_3 + (CH_3)_3P \rightarrow N_2 + (CH_3)_3Si{-}N{=}P(CH_3)_3 \quad (1)$$

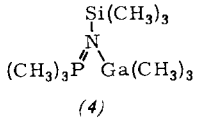
| A B | M.p. [°C] | B.p. [°C/mm] | NMR δ(CH₃)A [cps] | NMR δ(CH₃)B [cps] |
|---|---|---|---|---|
| $(CH_3)_3SiOSi(CH_3)_3$ | −56 | 100.5/760 | 3.5 | −3.5 |
| $(CH_3)_3SiNP(CH_3)_3$ *(1)* | 3–4 | 169/760 | +6.4 [c] | −80.8 [b] |
| $(CH_3)_3AlOP(CH_3)_3$ | +89 | 117/1 | [a] | [a] |

[a] Not measurable in $CCl_4$. [b] $J(^1H{-}C{-}^{31}P) = 12.4$. [c] $J(^1H{-}C{-}^{29}Si) = 6.4$.

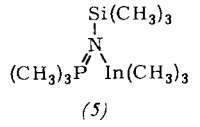
Compound *(1)* is a third[3] isostere of hexamethyldisiloxane. When warmed for a short time with trimethylaluminum etherate it affords *(3)*, in which, for the first time, the three neighbours Al, Si, and P in the Periodic Table are bound to the same nitrogen atom. Compound *(3)* is remarkably stable and does not dissociate even on vacuum distillation. The crystals are sensitive to oxidation and hydrolysis, are readily soluble in organic solvents that do not contain active protons, and give the simple molecular weight in benzene. Three signals of equal area appear in the $^1H$-NMR spectrum, one being a doublet due to $^1H$-C-$^{31}P$ coupling.



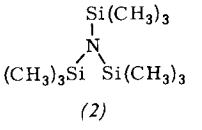
*(3)*



*(4)*



*(5)*



*(2)*

On reaction with trimethyl-gallium or -indium etherate in place of the aluminum compound, *(1)* affords *(4)* and *(5)*, respectively, in quantitative yield. The continuous decrease in chemical shifts and coupling constants along the series *(1)*, *(3)*, *(4)*, *(5)* shows that the bond order of P–N is higher than that of Si–N and that the acceptor strength of organometallic compounds decreases in the order $(CH_3)_3Al > (CH_3)_3Ga > (CH_3)_3In$.

| | *(3)* | *(4)* | *(5)* |
|---|---|---|---|
| M.p. [°C] | 79–80 | 32–34 | 43–44 |
| B.p. [°C/mm Hg] | 120/1 | 56/0.1 (decomp.) | — |
| NMR [4]: δ($CH_3Si$) | − 13.2 | 9.0 | − 6.6 |
| δ($CH_3P$) | −104.0 | −98.2 | −95.6 |
| δ($CH_3M$) | + 61.0 | +36.5 | +32.5 |
| $J(^1H{-}C{-}^{31}P)$ | 12.8 | 12.7 | 12.6 |
| $J(^1H{-}C{-}^{29}Si)$ | 6.6 | 6.55 | 6.5 |

*P*-triethyl-*N*-trimethylsilyliminophosphorane[2] yields, analogously, the *P*-triethyl homologues of *(3)* and *(4)*: *(3)* $(CH_3)_3SiNP(C_2H_5)_3{\cdot}Al(CH_3)_3$, m.p. 169 °C, subl. at 135 °C/1 mm; *(4)* $(CH_3)_3SiNP(C_2H_5)_3{\cdot}Ga(CH_3)_3$, m.p. 114 °C.

## Hydrogallinations

By Priv.-Doz. Dr. H. Schmidbaur and cand. chem. H. F. Klein

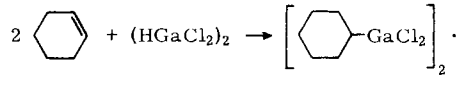
Institut für Anorganische Chemie der Universität Würzburg (Germany)

Addition of boron and aluminum hydrides to olefins is of great practical importance. Analogous addition of gallium hydrides has not previously been observed.

We have found that dichlorogallane $HGaCl_2$[1] reacts with olefins even under mild conditions, forming organogallium dihalides $RGaCl_2$[2]. A solution of $HGaCl_2$ (obtained from gallium trichloride and trimethylsilane) in chlorotrimethylsilane absorbs ethylene rapidly at 0 °C, with evolution of much heat. Ethylgallium dichloride[2] (75–78 %) can be obtained from the reaction mixture by distillation in a vacuum:

$$2\,CH_2{=}CH_2 + (HGaCl_2)_2 \rightarrow (C_2H_5GaCl_2)_2$$

Cyclohexene and a suspension of dichlorogallane in cyclohexane rapidly afford cyclohexylgallium dichloride (73 %), m.p. 67–69 °C, b.p. 142 °C/1 mm:



To determine the position of the entering component we have studied the addition of propene and 1-heptene to $HGaCl_2$. In both cases homogeneous products were formed, namely, n-propyl- and n-heptyl-gallium dichloride, respectively ($C_3H_7GaCl_2$: 88 %, m.p. 39–40 °C, b.p. 120–122 °C/1 mm; $C_7H_{15}GaCl_2$: 72 %, m.p. −30 °C, b.p. 155–160 °C/1 mm). NMR spectroscopy gave no indication of the formation of isopropylgallium dichloride; the structure of heptylgallium dichloride was established by degradation to heptyl iodide by means of iodine. This result proves the anti-Markovnikoff orientation in addition of > Ga-H to the > C=C < group, this being analogous to the results of hydroboration and hydroalanations.

Hydrolysis with HCl and oxidation with $H_2O_2$ convert compounds $RGaCl_2$ into hydrocarbons RH and alcohols ROH, respectively, but the yields are generally unsatisfactory.

Carbonyl compounds are reduced by $HGaCl_2$ to alkoxygallium dihalides. In this way isopropoxygallium dichloride (b.p. 95–97 °C/1 mm) is formed from acetone:

$$2\,CH_3{-}CO{-}CH_3 + (HGaCl_2)_2 \rightarrow [(CH_3)_2CH{-}O{-}GaCl_2]_2$$

Hydrolysis of these compounds leads to the alcohols without difficulty.

## Organogallogermoxanes, Compounds Containing the Structural Unit Ga-O-Ge

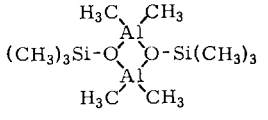
By Priv.-Doz. Dr. H. Schmidbaur and
cand. chem. Brunhilde Armer

Institut für Anorganische Chemie der Universität
Würzburg (Germany)

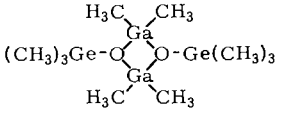
For preparation of the basic member ($R = CH_3$) of the homologous series of gallogermoxanes $R_3Ge-O-GaR_2$ we converted trimethylgallium etherate with ethereal HCl into dimethylgallium chloride: $(CH_3)_2GaCl$, m.p. 48–50 °C, b.p.164 to 165 °C, $^1$H-NMR: $\delta(CH)_3 = -16.0$ cps[1]. Treatment of $(CH_3)_2GaCl$ with lithium trimethylgemanolate in diethyl ether, removal of the separated LiCl, and sublimation afforded high yields of pentamethylgallogermoxane *(1)*:

$$[(CH_3)_2GaCl]_2 + 2\ LiOGe(CH_3)_3 \rightarrow 2\ LiCl + [(CH_3)_2Ga-O-Ge(CH_3)_3]_2 \qquad (1)$$

Compound *(1)* has m.p. 42–44 °C, b.p. 84–85 °C/1 mm, and, according to molecular-weight determinations in benzene, is dimeric. Its $^1$H-NMR spectrum contains the expected singlet signals of $\delta(CH_3Ga) = +25.0$ and $\delta(CH_3Ge) = -20.2$ cps (ratio of areas 2:3). Infrared-spectroscopic analogies to pentamethylalumosiloxane *(2)* permit structure *(3)* containing a four-membered ring to be assumed, and this was confirmed by X-ray analysis[2]; compound *(2)* is accordingly isomorphous with compound *(3)* and there are only slight differences in the dimensions of the unit cells. From this it is concluded that compounds *(2)* and *(3)* are isostructural, having a planar inorganic skeleton[3].



*(2)* Monoclinic, $P2_1/n$
$a = 7.008$ Å, $b = 12.220$ Å
$c \sin\beta = 10.655$ Å



*(3)* Monoclinic, $P2_1/n$
$a = 7.010$ Å, $b = 13.299$ Å
$c \sin\beta = 10.697$ Å

We have found another synthesis of compounds of the type $R_2Ga-O-GeR_3$ in the reaction of compounds $R_3GeOH$ with $GaR_3$:

$$2\ (C_6H_5)_3Ge-OH + 2\ Ga(CH_3)_3 \rightarrow 2\ CH_4 + [(C_6H_5)_3GeOGa(CH_3)_2]_2 \qquad (4)$$

*Ge*-Triphenyl-*Ga*-dimethylgallogermoxane *(4)*, like compound *(2)*, forms colorless crystals, m.p. 175–177 °C, sensitive to moisture. It is dimeric in benzene (by cryoscopy). $[(C_6H_5)_3GeOGa(C_6H_5)_2]_2$: m.p. 219–293 °C.

Received: December 22nd, 1965 [Z 127/959 IE]
German version: Angew. Chem. 78, 305 (1966)

[1] We were unable to confirm the different data of *G. E. Coates et al.* [J. chem. Soc. (London) *1963*, 243)]. All NMR data in this paper are for $CCl_4$ solutions at 30 °C and 60 Mc/s with tetramethylsilane as internal standard.

[2] We thank Dr. *P. J. Wheatley* for these investigations.

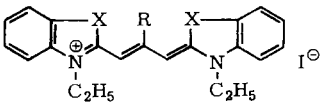
## Detection of the Forbidden Transition in Dimeric Carbocyanines at Low Temperatures

By Prof. Dr. G. Scheibe and Dipl.-Chem. O. Wörz

Arbeitsgemeinschaft für Strukturchemie und Physikalisch-Chemisches Institut der Technischen Hochschule
München (Germany)

The absorption of a dimeric dye cation of carbocyanine type is shifted towards short wavelengths relative to that of the monomer[1–3]. According to a model proposed by *Förster*, the dimerization is accompanied by approximately symmetrical splitting of the principal absorption maximum, although the longer-wavelength transition is forbidden[4]. Prerequisite is that the dimer has symmetry $C_i$ (or $C_2$).



*(1a)*: R = $CH_3$; X = S; *(1c)*: R = $CH_3$; X = Se;
*(1b)*: R = $C_2H_5$; X = S; *(1d)*: R = $C_2H_5$; X = Se.

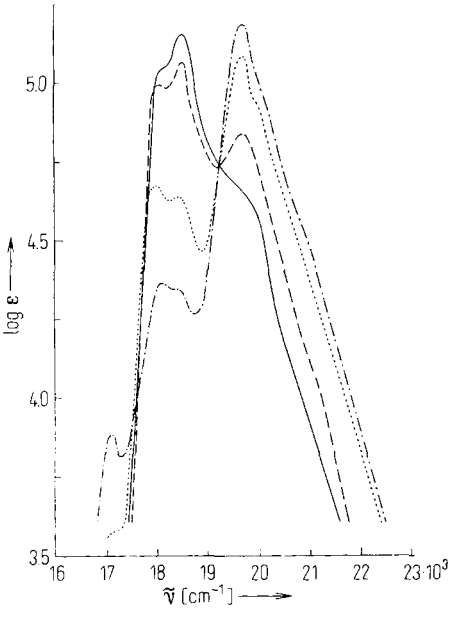


Fig. 1. Absorption spectra of *meso*-methylthiacarbocyanine iodide *(1a)* in ethanol at −180 °C. Concentrations (mole/l): $3.25\times10^{-6}$ (———); $1.33\times10^{-5}$ (– – –); $8.17\times10^{-5}$ (·····); $5.53\times10^{-4}$ (— · — · —).

If an alkyl group is introduced at the *meso*-position of certain thia- or selena-carbocyanines *(1)*, dimerization occurs in solution in 95 % aqueous ethanol at about −100 °C. The figure shows the spectra for various concentrations of *meso*-methylthiacarbocyanine iodide *(1a)* at −180 °C. With increasing concentration the monomer band decreases in intensity, and the short-wavelength, shifted, dimer band increases, but an additional, very weak, long-wavelength band also appears. The concentration dependence of the last-mentioned band, its small extinction coefficient, and its occurence at about the same distance from the monomer band as the short-wavelength dimer band (see table), lead to the conclusion that we have here the forbidden, long-wavelength dimer transition of the *Förster* model. That it can be observed is probably due to the low temperature and the fact that the *meso*-alkyl group somewhat distorts the $C_i$ (or $C_2$) symmetry of the dimer by steric hindrance and thus partly allows the transition.

Earlier attempts, by *Förster*[5] and *Levinson*[6,7], to find this band were apparently unsuccessful.

Wave numbers ($cm^{-1}$) of the absorption maxima of monomeric and dimeric thia- and selena-carbocyanines.

| Dye | Forbidden dimer transition | Monomer all-*trans*-form | Permitted dimer transition |
|---|---|---|---|
| *(1a)* | 17100 | 18500 | 19700 |
| *(1b)* | 16900 | 18300 | 19450 |
| *(1c)* | 16800 | 18150 | 19200 |
| *(1d)* | 16800 | 18000 | 19100 |

Splitting of the monomer bands was also observed; it is attributed to *cis-trans*-isomerism; the band of shorter wavelength is assigned to the all-*trans*-form, that of longer wavelength to a mono-*cis*-isomer that arises by rotation around the C-2/C-8 bond

## Preparation of Fluoromethane in Molten Fluorides

By Dipl.-Chem. W. Verbeek and Dr. W. Sundermeyer

Institut für Anorganische Chemie der Universität Göttingen (Germany)

Fluoromethane is usually prepared from methyl derivatives such as esters or alcohols that are cleaved by anhydrous HF or KF. Treatment of methane with fluorine leads to a difficultly separable mixture of fluorocarbons, containing mainly more highly fluorinated products. A fluorocarbon mixture is also obtained on electrofluorination of methane. Direct halogen exchange has hitherto been obtained only in the reaction of $CH_3I$ with $HgF_2$ or AgF.

We have led chloromethane, with vigorous strirring, into a LiF-NaF-KF melt at 500 °C, using an apparatus described previously[1] but with a nickel reaction vessel, inlet tube, stirrer, and thermoelement supports. $CH_3F$ resulted in 85 % yield with 42 % conversion, and was easily freed from traces of $CO_2$ and unchanged $CH_3Cl$. A yield of 96 % and conversion of 32 % can be attained if $CH_3Cl$ is led into a KF-HF melt at 350 °C. The $CH_3F$, which has thus become easily accessible, can be brominated to afford bromofluoromethanes, and these can be pyrolysed by a known method to yield hexafluorobenzene.

Reaction of $CH_2Cl_2$ with the KF-HF melt leads to $CH_2F_2$ with 82 % yield and 34 % conversion, whereas $CHCl_3$ gives, in the main, a mixture of partially substituted products.

## Desulfuration with Hydroximoyl Chlorides

By the late Prof. Dr. A. Dornow and Dipl.-Chem. H. U. Voigt

Institut für Organische Chemie der Technischen Hochschule Hannover (Germany)

An exchange of sulfur for oxygen in good yield was observed on treatment of hydroximoyl chlorides with compounds containing a thiocarbamoyl group. The preferred hydroximoyl chloride was chlorohydroxyiminoacetic ester because of its stability and accessibility[1]. The reaction was carried out in anhydrous benzene or toluene; 1-methylpyrrolidone proved an excellent solvent for reactions of thioxo compounds, but experiments with dimethylformamide, dioxane, and nitromethane failed.

Equimolar amounts of the components were allowed to react for 5 to 12 hours at 80 to 100 °C, the solutions were concentrated, and the products were precipitated by light petroleum or water. Some examples are given in the Table.

| S-compound | Solvent [a] | Temp. (°C) | Reaction time (h) | Yield (%) of O-compound |
|---|---|---|---|---|
| *N*-2-Naphthylthiobenzamide | Benzene | 80 | 5 | 100 |
| Benzyl *N*-phenyldithiocarbamate | Benzene | 80 | 8 | 85 [b] |
| Methyl benzylidenedithiocarbazinate | Toluene | 110.8 | 10 | 80 [c] |
| Benzimidazole-2-thiol | Benzene | 80 | 10 | 95 |
| 4,5-Diphenylimidazole-2-thiol | NMP | 100 | 12 | 90 |
| 5-Methyl-1,2,4-triazoline-2-thione | NMP | 100 | 12 | 80 |
| 5-Phenyl-1,3,4-oxadiazoline-2-thione | Toluene | 110.8 | 10 | 85 |
| 6-Phenyl-3[4*H*]-thioxo-1,2,4-triazin-5[2*H*]-one | NMP | 100 | 12 | 80 |
| 4-Benzylideneamino-6-methyl-3[4*H*]thioxo-1,2,4-triazin-5[2*H*]-one | NMP | 100 | 12 | 78 |
| 3-Phenyl-2[4*H*]-thioxo-quinazolin-4[2*H*]-one | NMP | 100 | 12 | 90 |

[a] NMP = 1-methylpyrrolidone. — [b] Product: *S*-benzyl thiocarbanilate. [c] Product: *S*-methyl benzylidenethiocarbazinate.

The potential mercapto form of the thiocarbamoyl group is a prerequisite for the reaction; this group may comprise part of a ring (the sulfur being exocyclic), or it may be part of an open chain. The hydroximoyl chloride reacts with the thiol group that is in tautomeric equilibrium with the thioxo group, HCl being evolved, and the oxime group adds intramolecularly to the C=S double bond. The 1,4,2-oxathiazoles formed as intermediates in this way decompose to isothiocyanate and the O-analogue of the starting material[2]. Ready decomposition of 1,4,2-oxathiazoles was observed previously by *R. Huisgen* when he added nitrile oxides to *N,N*-disubstituted thioamides and obtained the O-products directly[3].

We have used this desulfuration repeatedly as a criterion for exocyclic sulfur, *e.g.*, with isomer pairs of 5-methyltriazole-2-thione, 5-methylthiadiazole-2-amine, and the like.

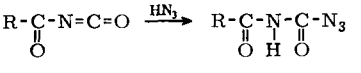
## Acyl- and Sulfonyl-carbamoyl Azides

By Doz. Dr. R. Neidlein

Pharmazeutisch-Chemisches Institut der Universität Marburg (Germany)

Acylcarbamoyl azides *(2)* (as far as we know not previously reported) were obtained by addition of equimolar amounts of hydrazoic acid to acyl isocyanates *(1)*[1] with stirring in cooled benzene solution.

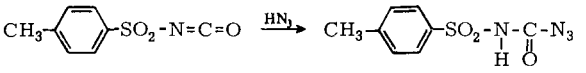


*(1)* *(2)*

| R | M.p. [°C] (decomp.) | Yield [%] |
|---|---|---|
| *(2a)* $C_6H_5-$ | 111—112 | 94 |
| *(2b)* *p*-Cl—$C_6H_4-$ | 141—142 | 88 |
| *(2c)* *p*-$CH_3$—$C_6H_4-$ | 112—113 | 89 |
| *(2d)* *o*-$CH_3O$—$C_6H_4-$ | 115—116 | 93 |
| *(2e)* *m*-$CH_3O$—$C_6H_4$ | 109—110 | 94 |

*p*-Toluenesulfonylcarbamoyl azide *(4)* is formed analogously from *p*-toluenesulfonyl isocyanate *(3)*[2] and hydrazoic acid.

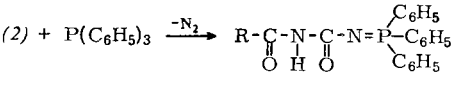
The structures of the compounds are proved by their spectra. Acylcarbamoyl azides have absorption bands characteristic of the $N_3$ group at 2155–2165 $cm^{-1}$, and sulfonylcarbamoyl azides at 2193 $cm^{-1}$. In the $^1H$-NMR spectrum of compound



*(3)* *(4)*

*(2a)* the signal of the NH-proton is at 9.34 ppm and there is a multiplet due to aromatic protons centered at 7.6 ppm (measurements in deuteriochloroform). The compounds are stable at room temperature. Satisfactory elemental analyses were obtained.

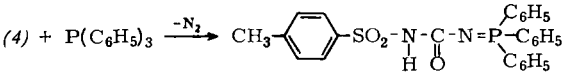
Acylcarbamoyl azides *(2)* react with equimolar amounts of triphenylphosphine in anhydrous tetrahydrofuran with loss of 1 mole of nitrogen and formation of (acylcarbamoylimino)-triphenylphosphoranes *(5)*:



*(5)*

| R | M.p. [°C] | Yield [%] |
|---|---|---|
| *(5a)* $C_6H_5$– | 153–154 | 89 |
| *(5b)* *p*-Cl–$C_6H_4$– | 175–176 | 82 |
| *(5c)* *p*-$CH_3$–$C_6H_4$– | 180–181 | 92 |
| *(5d)* *o*-$CH_3O$–$C_6H_4$– | 59– 60 | 87 |
| *(5e)* *m*-$CH_3O$–$C_6H_4$– | 170–171 | 94 |

(*p*-Toluenesulfonylcarbamoylimino)triphenylphosphorane *(6)*, m.p. 146–146.5 °C (yield 83 %), is obtained analogously from compound *(4)* and triphenylphosphine:



*(6)*

The structures of these products are also verified by their spectra.

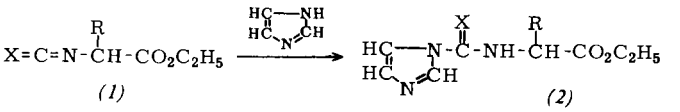
## Peptide Syntheses via N-(1-Imidazolylcarbonyl)- and N-(1-Imidazolylthiocarbonyl)-amino Esters

By Dr. J. Gante

Institut für Organische Chemie der Freien Universität Berlin (Germany)

The previously unknown *N*-(1-imidazolylcarbonyl)amino esters *(2a)–(2d)* are obtained on mixing the ethyl esters *(1a)–(1d)*[1] of α-isocyanato-fatty acids with equimolar amounts of imidazole. Ethyl isothiocyanatoacetate[2] and imidazole give *N*-(1-imidazolylthiocarbonyl)glycine ethyl ester *(2e)* analogously.

Compounds *(2a)–(2e)* are colorless and crystallize well from anhydrous ethyl acetate or ethyl acetate/light petroleum. The reactivity of the imidazolylcarbonyl group attached to an amino group is similar to that in "carboxyl-activated" *N*-benzyloxycarbonyl(Cbo)-amino acids[3], so that compounds *(2a)–(2e)* can be used in peptide syntheses, though only for



*(1)* *(2)*

## Solid Perrhenic Acid

By Prof. Dr. G. Brauer and Dipl.-Chem. G. Sleater

Chemisches Laboratorium der Universität Freiburg (Germany)

Perrhenic acid has hitherto been known only in aqueous solution. We have prepared it in solid form by the reaction of $Re_2O_7$ with a small amount of water at room temperature. The hygroscopic oxide was treated dropwise with water or was allowed to take up water from the air; any excess of water was removed in a desiccator over $P_2O_5$ or $Mg(ClO_4)_2$. The solid acid is pale greenish-yellow, well crystalline, and exceedingly hygroscopic. As a result it gave on chemical analysis 1.2 mole of $H_2O$ per mole of $Re_2O_7$, *i.e.* somewhat more than corresponds to the composition $HReO_4$. The X-ray diagram of the acid contains many lines; it is totally different from that of rhenium heptoxide[1]. When warmed in a vacuum the acid begins to dissociate above about 65 °C into anhydride and water and to volatilize.

## Exchange of Ring Members in Cyclopolyphosphines [1]

By Prof. Ulrich Schmidt, cand. chem. R. Schröer, and Dr. H. Achenbach

Chemisches Laboratorium der Universität, Freiburg (Germany)

When heated with diethyl sulfide, pentaphenylcyclopentaphosphine (the so-called tetraphenylcyclotetraphosphine was recently found to be the pentamer) yields diethyl phenyldithiophosphonite, $C_6H_5-P(SC_2H_5)_2$. This reaction was interpreted as involving insertion of a phenylphosphinidene ($C_6H_5-P$:) into the disulfide linkage [1].

Thermal decomposition of cyclopolyphosphines into phosphinidenes should lead to "disproportionation" of two different symmetrical cyclopolyphosphines. We have now demonstrated such an exchange of ring members between pentamethylcyclopentaphosphine *(1)* and pentaethylcyclopentaphosphine *(2)* [2]:

$$\underset{(1)}{(MeP)_5} + \underset{(2)}{(EtP)_5} \downarrow$$

$$(1) + \underset{(3)}{Me_4EtP_5} + \underset{(4)}{Me_3Et_2P_5} + \underset{(5)}{Me_2Et_3P_5} + \underset{(6)}{MeEt_4P_5} + (2)$$

On simultaneous introduction of compounds *(1)* and *(2)* into a mass spectrometer [3] superposition of the mass spectra of these two compounds is observed. If, however, the mass spectrum is registered under the same conditions for a mixture that has been previously distilled (150 °C bath temperature, 0.1 mm), then ions of mass 244, 258, 272, and 286 are observed, in addition to the molecule ions and fragments of compounds *(1)* and *(2)*. These masses correspond to the molecule-ion weights of the mixed cyclopentaphosphines *(3)* to *(6)*.

[2] Preparation: *W. A. Henderson, M. Epstein*, and *F. S. Seichter*, J. Amer. chem. Soc. *85*, 2462 (1963). According to these authors the product is identical with a cyclophosphine obtained by *K. Isleib* and *B. Mitscherling* [Z. Naturforsch. *15b*, 267 (1960)] for which the tetrameric structure was deduced from cryoscopic measurements. According to mass-spectrometric results the product is pentameric; the most important signals in the spectrum of *(2)* are at m/e = 300 ($Et_5P_5^+$; 70 %) and 271 ($Et_4P_5^+$; 100 %).

## Synthesis of Free Dithiocarbamic Acid, $SC(SH)(NH_2)$ [1]

By Prof. Dr. G. Gattow and Dipl.-Chem. V. Hahnkamm

Anorganisch-Chemisches Institut der Universität Göttingen (Germany)

Although there have been numerous papers concerning esters of dithiocarbamic acid, $SC(SH)(NH_2)$ *(1)*, and their *N*-substituted derivatives, as well as the ammonium salt, only the probable existence of the free acid *(1)* has been shown by *Mulder*'s investigations [2]. We have now prepared the acid *(1)* by a method analogous to that used for synthesis of trithiocarbonic acid, $SC(SH)_2$ [3]:

Concentrated HCl (1.4 ml, 0 °C) was dropped, with stirring, into a solution of 2 g of $NH_4[(SC(S)(NH_2)]$ in 16.5 ml of $H_2O$, previously cooled to 0 °C. The colorless acid *(1)* that crystallized was washed with ice-water, ligroin was poured over it twice, and the product was dried in a desiccator over $P_2O_5$. The yield was about 45 %.

The compound *(1)* [m.p. 35.7 ± 0.4 °C; $d_4^{20} = 1.479_6 \pm 0.001$ g/cm³] is almost insoluble in nonpolar solvents; the solubility increases with the polarity of the solvent. Chemical, kinetic, infrared-spectroscopic, and X-ray investigations showed that thermal decomposition of the acid *(1)* between 20 and 100 °C proceeds in two steps:

$$2\,SC(SH)(NH_2) \rightarrow NH_4[SC(S)(NH_2)] + CS_2$$
$$NH_4[SC(S)(NH_2)] \rightarrow NH_4SCN + H_2S$$

Infrared spectrum of *(1)*: 2170(m), 1551(w), 1519(st), 845(m) $cm^{-1}$ [4].

The equivalent conductivity [5] determined for aqueous solutions between 5 and 25 °C is described by the temperature functions

$$\Lambda_0 = 5.87\ T - 1348 \text{ for } (1)$$
$$\Lambda_0 = 0.918\ T - 222.8 \text{ for } [SC(S)(NH_2)]^-$$

[$\Lambda_0$ in $cm^2(g\text{-equiv})^{-1}$ $ohm^{-1}$; T in °K). The thermodynamic dissociation constant [5] of *(1)* is $K_a = (1.13 \pm 0.03) \times 10^{-3}$ at 20 °C.

Decomposition of the acid *(1)* in aqueous solution follows first-order kinetics, with a half-life of 85.5 ± 1.5 min. at 20 °C and an activation energy of 21.1 ± 0.5 kcal/mole at 20 °C.

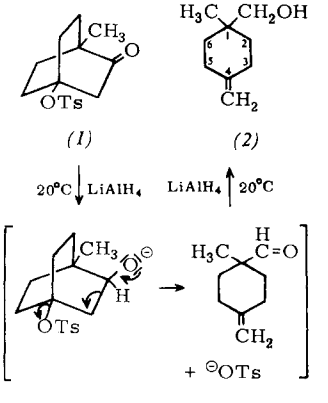
## Reductive Fragmentation of 1-Methyl-4-tosyloxybicyclo[2.2.2]octan-2-one [1]

By Dr. W. Kraus

Chemisches Institut der Universität Tübingen (Germany)

Sulfonic esters of β-hydroxy ketones are fragmented on hydrolysis with KOH [2,3] or treatment with a Grignard reagent [3]. Reductive cleavage of such compounds has not previously been described.

4-Hydroxy-1-methylbicyclo[2.2.2]octan-2-one [5,6], which is readily accessible from 4-acetyl-4-methylpimelic acid [4] by way of 4-acetyl-4-methylcyclohexanone [5,6], was converted into its *p*-toluenesulfonate *(1)*; (Ts = $CH_3C_6H_4SO_2$), m.p. 93.5–94.5 °C. This was stirred with $LiAlH_4$ in ether for 2 h at room temperature, leading to the previously unknown (1-methyl-4-methylenecyclohexyl)methanol *(2)*, b.p. 89 °C/10 mm, in 83 % yield.



Structure *(2)* follows from the NMR spectrum[7], which shows a singlet for the methyl group at $\tau = 9.04$ (3 H) and two unsymmetrical triplets ($A_2B_2$ spectrum) for the methylene groups at $\tau = 8.70$, 8.63, and 8.51 (4 H, at C-2 and C-6), and at $\tau = 7.94$, 7.84, and 7.73 (4 H, allyl protons at C-3 and C-5). In $CCl_4$ solution the singlet signal for the hydroxymethyl group is at $\tau = 6.68$ (3 H), but in dimethyl sulfoxide there are two signals with relative areas 1:2 ($OH/CH_2$). The signal for the vinyl protons occurs at $\tau = 5.42$ (2 H). Infrared spectrum: 880, 1640, 1770, 3070 ($=CH_2$), 1035, 3360 (broad association band), 3630 (primary OH), and 1365 $cm^{-1}$ ($CH_3$). The infrared spectrum of the alcohol *(2)* is identical with that of a sample prepared by reducing 1-methyl-4-methylenecyclohexane-1-carboxylic acid[2] with $LiAlH_4$.

## Explosion of Nitrogen Trifluoride on Active Charcoal. – Reaction of $NF_3$ with Carbon

By Dr. J. Massonne and Dr. R. Holst

Zentrallaboratorium der Kali-Chemie AG.,
Hannover (Germany)

A violent explosion occurred during an attempt to free $NF_3$ from small amounts (less than 2 vol-%) of $N_2F_2$ and $N_2O$ by adsorption on active charcoal at low temperatures.

Active charcoal grains (600 g, previously dried at 120 °C; manufactured by Messrs. Riedel, Seelze) were placed in a 2-liter steel pressure flask. The vessel was cooled to −100 °C and evacuated for a considerable time. About 25 g of $NF_3$ was introduced during about 10 min and then the gas flow was interrupted at a pressure of 1.5 kg/cm² in the adsorption vessel. A short time thereafter an explosion fractured the metal vessel and ejected glowing active charcoal.

According to *Ruff*[1], carbon does not react with $NF_3$ even at red heat. *Gould* and *Smith*[2,3] found that $NF_3$ reacts with petroleum coke in a fluidized bed at 400–500 °C to give $N_2F_4$, $CF_4$, and $C_2F_6$.

The reaction

$$4\,NF_3 + 3\,C \rightarrow 3\,CF_4 + 2\,N_2 \qquad (a)$$

was observed only above 500 °C.

We have heated active charcoal grains in a nickel tube and treated them with $NF_3$ (93.2 vol-% $NF_3$; 2.22 % $N_2$; 0.42 % $O_2$, 1.9 % $N_2O$; 1.31 % $N_2F_2$) at atmospheric pressure. Up to 100 °C no reaction could be observed. At 150 °C the charcoal reacted with incandescence. $N_2$ and $CF_4$ were the sole products found. $N_2F_4$ could not be detected. The reaction (a) is thus energetically preferred to that leading to $N_2F_4$, $CF_4$, and $C_2F_6$, which is bypassed.

We assume that the reaction leading to explosion was initiated by the heat of adsorption, which could not be removed sufficiently rapidly. Experiments with 30 g of active charcoal grains, carried out without thermal insulation, resulted in temperature increases of 40 to 70 °C when gaseous $NF_3$ was led at atmospheric pressure into a vessel containing charcoal and previously evacuated to 1–2 mm.

When impure $NF_3$ is passed through active charcoal at −80 °C, $N_2F_2$ and $N_2O$ are completely retained, but at +20 °C only $N_2O$ is adsorbed.

*Warning: Special precautions are required if $NF_3$ is to be purified over active charcoal.*

## Radiation-Chemical Synthesis of Phosphonium and Arsonium Salts

By Dr. H. Drawe and Dipl.-Chem. G. Caspari

Hahn-Meitner Institut für Kernforschung,
Sektor Strahlenchemie, Berlin (Germany)

γ-Irradiation ($^{60}Co$-source) of mixtures of triphenylphosphine or triphenylarsine with aryl halides gives tetraarylphosphonium (see Table) or -arsonium salts. G-values are in the usual range for one-stage reactions. They are high enough for quantitities of 10 to 100 g to be prepared in one batch if a sufficiently intense source of radiation is used. Yields of arsonium salts are about one-tenth of those of phosphonium salts. The quantum yields are independent of the dosage and

| Starting materials | Mole-% | Phosphonium salt | G (molecules/100 eV) | Yield based on $(C_6H_5)_3P$; dose [a] | M.p. (°C) [b] |
|---|---|---|---|---|---|
| Chlorobenzene | 76 | $[P(C_6H_5)_4]Cl$ | 1.4 | 15 % | 274–278 |

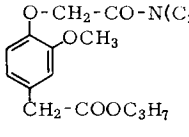
# CONFERENCE REPORTS

## Therapy Congress and Pharmaceutical Exhibition

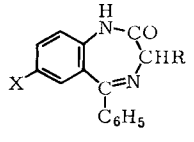
The 17th German Therapy Congress held in Karlsruhe (Germany) from August 29th to September 4th, 1965, was attended by about 6000 people from Germany and abroad. Of the new therapeutic agents only those are listed in the following report which contain new compounds or are marketed now for the first time in Germany.

Epontol®, a short-duration narcotic for intravenous application, has been introduced by Farbenfabriken Bayer. Its active principle is n-propyl 4-(*N,N*-diethylcarbamoylmethoxy)-3-methoxyphenylacetate *(1)* (generic name: propanidide), a colorless to yellow oil, insoluble in water. Epontol is characterized by rapid inception and particularly rapid cessation of the narcotic action. Patients can be released from clinical supervision 20 to 30 minutes after Epontol narcosis, which lasts for 3 to 4 minutes.



*(1)*

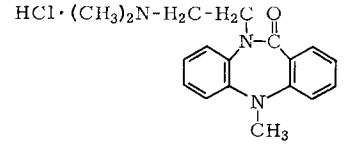
Mogadan®, introduced to the market by Hoffmann-La Roche, is a new soporific resembling the tranquilizers Librium and Valium in structure and properties, and suitable particularly when sleep is disturbed by irritability, overexertion, anxiety, *etc.* Its active agent is 2,3-dihydro-7-nitro-5-phenyl-1,4-benzodiazepin-2(1*H*)-one *(2)*.



*(2)*: R = H, X = $NO_2$
*(3)*: R = OH, X = Cl

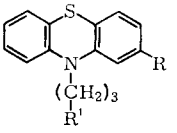
Praxiten®, a psychotherapeutic drug, also has a close structural relation to Librium and Valium. It was developed in the Wyeth Laboratories in USA and is marketed by Wyeth-Pharma GmbH., Münster (Germany). It consists of 7-chloro-2,3-dihydro-3-hydroxy-5-phenyl-1,4-benzodiazepin-2(1*H*)-one *(3)* (generic name: oxazepam), a white crystalline substance that is sparingly soluble in water. Praxiten, which is marketed in USA under the name "Serax", is suitable for relief of anxiety states, strain, agitation, irritability, and sleeplessness.

A new group of psychotropic drugs, the dibenzodiazepines, is represented by Noveril®, which is put forward by Dr. A. Wander GmbH., Frankfurt/M. It is described as an intensely active, broad-spectrum antidepressant, which is active mainly against endogenous depressions. Noveril contains 10-(2-*N,N*-dimethylaminoethyl)-5-methyl-1,4-dibenzodiazepin-11(10*H*)-one hydrochloride *(4)*, a compound readily soluble in water.



*(4)*

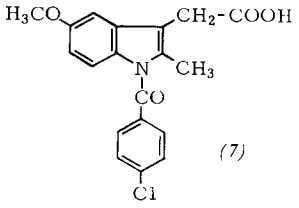
Two further new psychotherapeutic drugs have been introduced. The psychosedative Pasaden®, from Chemiewerk Homburg, contains 10-[γ-{hexahydro-4-(2-hydroxyethyl)-1,4-diazepin-1-yl}-propyl]-2-trifluoromethylphenothiazine dihydrochloride *(5)*, a white crystalline powder (m.p. 210 °C). It is suitable for treatment of disturbances of neurovegetative control, such as vegetative dystony, neurasthenia, nervousness, disquiet, *etc.* The neuroleptic Aolept® from Farbenfabriken Bayer consists of 2-cyano-10-[γ-(4-hydroxypiperidino)propyl]phenothiazine *(6)* (generic name: propericiazin) and is suitable particularly for prolonged therapy of all psychoses of schizophrenic type.



*(5)*: R = $CF_3$,
R' = -N⟨⟩N-$CH_2$-$CH_2$OH · 2 HCl

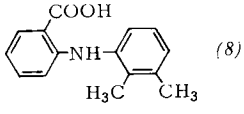
*(6)*: R = CN, R' = -N⟨⟩-OH

A new antirheumatic, introduced some months ago in USA under the name "Indocin", has been placed on the market under the name Amuno® by Sharp & Dohme GmbH, a subsidiary of Merck & Co., Inc., Rahway, USA. It contains the antiphlogistic, analgetic, and antipyretic agent 1-(*p*-chlorobenzoyl)-5-methoxy-2-methyl-3-indoleacetic acid *(7)* (generic name: indometacin), that does not belong to any of the previously known antiphlogistic groups. Indometacin is a pale yellow powder (m.p. 156–160 °C) that dissolves in alcohol, acetone, ethylene dichloride, or acetonitrile but not in water or hydrocarbons.



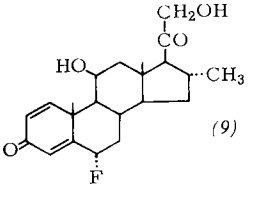
(7)

Parkemed®, from Parke Davis & Co., is an analgetic with antiphlogistic properties, that also belongs to a new group of analgetics, the *N*-phenylanthranilic acid derivatives. The active ingredient is *N*-(2,3-xylyl)anthranilic acid *(8)*, a white powder whose solubility in water is strongly pH-dependent. This preparation is marketed in the USA under the name "Ponstan".



(8)

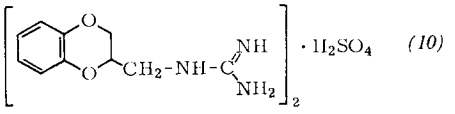
A new corticoid, 6α-fluoro-11β,21-dihydroxy-16α-methyl-1,4-pregnadiene-3,20-dione *(9)* (generic name: fluocortolon), is contained in Ultralan® cream, which is marketed by Schering AG., Berlin, and is suitable for treatment of inflammatory and allergic skin conditions. Whereas the anti-inflammatory steroids hitherto known belong to the hydrocortisone or 21-deoxyhydrocortisone class, fluocortolon is a derivative of corticosterone.



(9)

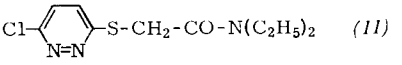
Remarkably, five firms have brought out or announced analgesic or antiphlogistic preparations containing dimethyl sulfoxide (Dolicur from Schering AG., Berlin; DMS-70 and DMS-90 from Sharp & Dohme GmbH., Munich; Hyadur from Chemie Grünenthal, Stolberg; Infiltrina from Chemische Fabrik von Heyden AG., Munich; Somipront from H. Mack Nachf., Illertissen.) The analgesic and anti-inflammatory action of dimethyl sulfoxide was first observed a few months ago and requires clinical evaluation for a further period. The utility of the above preparations can therefore not yet be finally estimated; they have in the meantime been recalled from the market.

Envacar®, developed in the Pfizer Research Laboratories as a new drug for depression of blood pressure, has been placed on the market by Pfizer GmbH., Karlsruhe (Germany). It contains 2-guanidinomethyl-1,4-benzodioxane (generic name: guanoxan), which is suitable for treatment of all cases (mild to severe) of essential and renal hypertony. Envacar contains guanoxan as its sulfate *(10)*, a white crystalline substance of m.p. 204–208 °C.



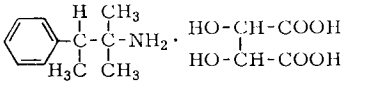
(10)

A new choleretic, α-(6-chloro-3-pyridazinylthio)-*N*,*N*-diethylacetamide *(11)* (m.p. 97–98 °C) is present, with various enzymes, in Oragallin®, a medium for regulation of digestion, from Byk-Golden-Lomberg GmbH., Konstanz (Germany). The active component increases the flow of gall in the manner of a true choleresis and in doses of 400 mg/kg has neither depressant nor stimulating effect on the central nervous system. The choleretic action is said to begin 10 min after application and to last for about an hour.



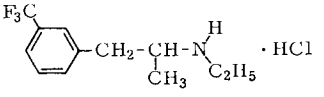
(11)

Modatrop®, an appetite-controller with lipolytic activity, has been brought out by Nordmark-Werke GmbH., Hamburg. Its active ingredient is α,α,β-trimethylphenethylamine hydrogen tartrate *(12)* (m.p. 159–162 °C), which depresses the appetite and the centers in the hypothalamus that control the feeling of hunger, at the same time as controlling the motility of the stomach. Modatrop also mobilises body fat and accelerates its removal.



(12)

Another appetite-controller has been introduced by Byk-Gulden-Lomberg GmbH., Konstanz, under the name Ganal®. This contains the new appetite-depressant *N*-ethyl-α-methyl-3-trifluoromethylphenethylamine hydrochloride *(13)*, a white

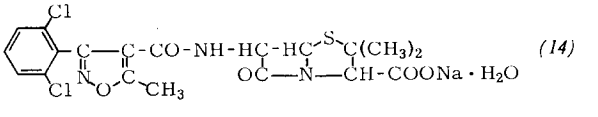


(13)

crystalline substance, soluble in water and ether (m.p. 166 to 168 °C). Ganal does not stimulate the central nervous system and is characterized by its powerful and prolonged action.

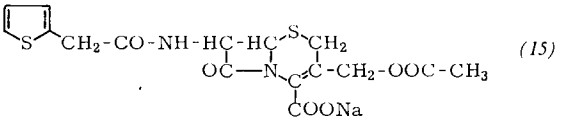
A few further preparations may be mentioned that contain new semisynthetic antibiotics.

A penicillin derivative that is stable to penicillinase and to acid, the sodium salt of [3-(2,6-dichlorophenyl)-5-methyl-4-isoxazolyl]penicillin *(14)* (generic name: dicloxacillin), has been placed on the market under the name Stampen® by the German Beecham GmbH., Biberach/Riss, and under the name Dichlorstapenor® by Farbenfabriken Bayer. Dicloxacillin is a colorless, microcrystalline powder that is readily soluble in water or methanol and decomposes at 222–225 °C. The preparations are suitable for treatment of all types of staphylococcal infections.



(14)

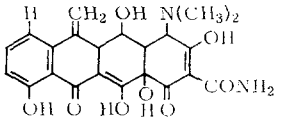
Cefalotin®, introduced by Eli Lilly GmbH., Giessen (Germany), is a semisynthetic antibiotic derived from cephalosporin C. It consists of the sodium salt of 7-[α-(2-thienyl)acetylamino]cephalosporic acid *(15)*, a cream-colored crystalline substance. Cefalotin must be administered parenterally. It is claimed to be particularly useful against severe infections that do not respond to penicillin or other antibiotics.



(15)

Rondomycin® is a new broad-spectrum antibiotic that has been developed from oxytetracyclin and belongs to the semisynthetic tetracyclin series. This substance is 5-hydroxy-6-methylenetetracyclin *(16)* (generic name: methacyclin). It is

absorbed rapidly from the stomach and intestinal tract, but is only slowly excreted through the kidneys. The antimicrobial



(16)

activity of Rondomycin is exerted against both Gram-positive and Gram-negative microorganisms. Its action against staphylococci, streptococci, haemophyllum species, and coli bacteria is particularly strong.

## Stereochemistry and Mechanism of Some Reactions of Ketenes

*H. Pracejus*, Halle (Germany)

Addition of symmetrical alcohols to asymmetrically disubstituted ketenes in the presence of catalytic amounts of optically active bases leads to optically active esters. The influence of the structure and configuration of the catalyst and of temperature on the steric course of the reaction has been studied for the synthesis of methyl 2-phenylpropionate. It was found that the spatial structure of the catalyst can be brought into better relation to the form of the temperature-stereospecificity function measured over a wide range of temperature than to the specificity at only one temperature. In favorable cases the enthalpy and entropy of activation of the two sterically competing reactions [formation of the (+) and of the (−) ester] can be calculated or estimated from the effect of temperature. It was found that $\Delta\Delta H^{\neq}$ and $\Delta\Delta S^{\neq}$ always have the same sign. This explains the finding that not only the degree, but also the direction of the stereospecificity depend on the temperature. Kinetic measurements indicate that the specificity-determining step in the reaction is a proton transfer from an ammonium ion (catalyst-$H^+$) to an ester carbanion formed in the rate-determining step. Consideration of the relative stabilities of the possible conformations of the two diastereoisomeric transition states leads to correct prediction of the sign of $\Delta\Delta H^{\neq}$; the simplest results are obtained when the catalyst molecule is a very rigid one (a bicyclic base with an asymmetric N or a base with an asymmetric carbon atom next to a bridgehead nitrogen). The stereospecificity ($\Delta\Delta H^{\neq}$) of acyclic catalysts with a freely rotating dimethylamino group attached to an asymmetric carbon atom can be evaluated on the Curtin-Hammett principle. This principle is, however, not applicable if the rotation about the C–N bond is hindered by bulky substituents (*e.g.* t-butyl).

The asymmetric synthesis of amides from ketenes and primary amines is suitable in principle also for asymmetric synthesis of dipeptide derivatives, as we have shown for the example t-butylphthalimidoketene (3,3-dimethyl-2-phthalimido-1-buten-1-one) + D-alanine isopropyl ester → *N*-(3,3-dimethyl-2-phthalimidobutyryl)-D-alanine isopropyl ester (D,D/L,D = 85:15 at −60 °C).

## Osmosis, Anomalous Osmosis, and Determination of Molecular Weight

*A. J. Staverman*, Leiden (Holland)

Measurement of osmotic pressure is often used for determination of the molecular weight of polymers. This requires the use of membranes that are strictly semipermeable, *i.e.*, permit no passage at all of the solute. Such membranes can be only approximated and then permit passage of the solvent only with difficulty, so that times required for measurement become very long. In practice, membranes are normally used that permit some passage of the solute, and the experimental osmotic pressure $\pi_{exp}$, *i.e.*, the opposing pressure at which passage through the membranes just ceases, is extrapolated to zero time, *i.e.*, to the time at which no solute has yet passed through.

The author has shown[1] that this procedure is unwarranted because a molecule capable of permeation contributes incompletely to the osmotic pressure, even before it has permeated. Diffusion of the solute can be allowed for in determination of molecular weights by carrying out, alongside the measurement of the osmotic pressure, a second experiment – ultrafiltration – in which a solution of the same concentration, c, is pressed through an identical membrane in another cell, the change in concentration being then measured. The solvent and solute do not flow through the membrane at the same rate. The selectivity of the membrane can be expressed by a reflection coefficient $\sigma$, which is determined from the change in concentration $c' = (1 - \sigma)c$ on ultrafiltration of the dissolved, only slowly diffusing component. According to the theory the measured osmotic pressure $\Pi_{exp}$ is equal to the product of $\sigma$ and the theoretical thermodynamic osmotic pressure $\Pi_{th}$, whence the molecular weight M can be calculated directly: $M = \sigma RTc/\Pi_{exp}$.

The theory has been tested for sucrose solutions on membranes of porous Vycor glass (Corning Glass Works, Corning, N.Y.)[2]. The ultrafiltration experiment gave $\sigma \approx 0.2$, the osmotic pressure was $\Pi_{th}/5$, and the molecular weight determined for sucrose in this way agreed with the correct value within experimental error; $\sigma$ was independent of concentration.

Aqueous solutions of polyethylene glycol showed quite different behavior towards glass membranes. The polymers were strongly adsorbed on the glass membranes and the $\sigma$ values depended greatly on the concentration; at high concentrations ($c \approx 2$ g/*l*) they approached unity (complete reflection), whereas at lower concentrations ($c \approx 1$ g/*l*) $\sigma$ was much lower and sometimes even assumed negative values. These results are in agreement with earlier measurements by *Elias*[3], who found negative osmotic pressures in this system, *i.e.*, the solvent diffused against the concentration gradient. This phenomenon is designated anomalous osmosis. Our method of determination of molecular weight could thus be used also in cases of anomalous osmosis. A theoretical explanation of the strong concentration-dependence of $\sigma$ has been given[4] on the basis of concentration-independent frictional coefficients and strong selective adsorption of the solute on the membrane (as observed experimentally).

[Lecture at Aachen (Germany), November 5th, 1965]

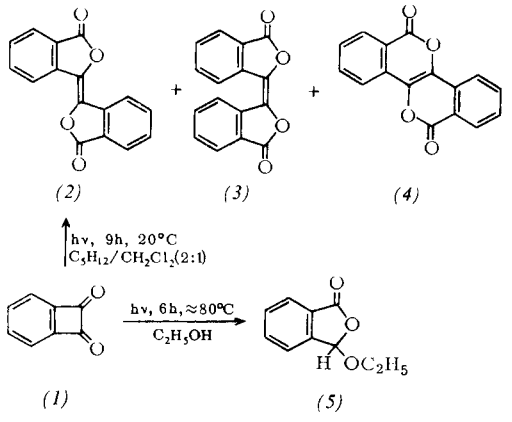
## Photochemical Reactions of Benzocyclobutene-1,2-dione

*H. A. Staab* and *J. Ipaktschi*, Heidelberg (Germany)

Benzocyclobutene-1,2-dione *(1)*[1], on irradiation in inert solvents with a high-pressure mercury lamp, gives the dimers *(2)*, *(3)*, and *(4)*, whereas in ethanol a 39 % yield of compound *(5)* is obtained together with 4 % of *(4)*.



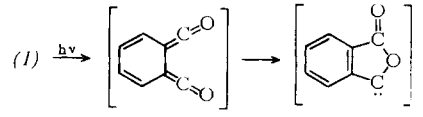
(2) (3) (4)

hν, 9h, 20°C
$C_5H_{12}/CH_2Cl_2$(2:1)

hν, 6h, ≈80°C
$C_2H_5OH$

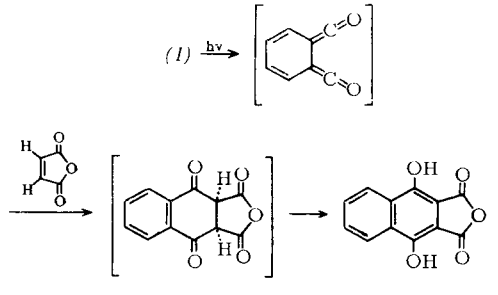
(1) (5)

These results led to the hypothesis that the primary photochemical reaction converts compound *(1)* into the bisketene *(6)*, from which the carbene *(7)* could be formed by aromatization as a second reactive intermediate. The existence of the two intermediates was demonstrated by specific trapping



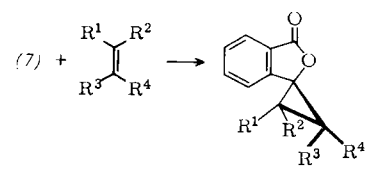
(6) (7)

experiments: On irradiation of the diketone *(1)* in the presence of maleic anhydride, 1,4-naphthalene-2,3-dicarboxylic anhydride was formed in 67 % yield by a Diels-Alder reaction involving the bisketene *(7)*; if 1,4-naphthoquinone is used, 6,11-dihydroxy-5,12-tetracenequinone is obtained.



(8)

If compound *(1)* is irradiated in the presence of an excess of an alkene, compounds are obtained which according to their compositions and molecular weights are 1:1 adducts of compound *(1)* and the alkene and for which the spirolactone structures *(9)* were proved spectroscopically and chemically. Examples: $R^1 = R^3 = H$, $R^2 = R^4 = CH_3$, m.p. 68–69 °C, 65 % yield; $R^1 = R^3 = H$, $R^2R^4 = (CH_2)_4$, m.p. 67–68 °C, 35 % yield; $R^1 = R^2 = R^3 = H$, $R^4 = CH{=}CH_2$, m.p. 101 to 102 °C, 54 % yield. The normal Schönberg reaction, namely, the photochemical reaction of 1,2-dicarbonyl compounds with alkenes to give 1,4-dioxins, was not observed with compound *(1)*; it would have led in this case to a benzocyclobutadiene derivative.



(9)

The results obtained so far confirm our hypothesis that the primary reaction on irradiation of compound *(1)* is conversion into the bisketene *(6)* which is favored by the ring strain in *(1)*; this bisketene rearranges in the absence of a dienophile into the carbene *(7)*, whose presence can be demonstrated by its reactions with alkenes.

[Lecture at Heidelberg (Germany), November 23rd, 1965]

[VB 966/274 IE]

German version: Angew. Chem. *78*, 308 (1966)

## Studies on Formamidines

*M. Seefelder*, Ludwigshafen (Germany)

Many substituted formamidines can be synthesized by reaction of anhydrous hydrogen cyanide with amines. Whereas according to *Stewart* and *Fontana*[1] amines and hydrogen cyanide yield only salts, *Erickson*[2] isolated formamidines after prolonged reaction and subsequent hydrolysis. The assumption of the coupled equilibria

$$RR'NH + HCN \rightleftarrows RR'NH_2^{\oplus} + CN^{\ominus}$$

$$RR'NH + HCN \overset{\text{Slow}}{\rightleftarrows} RR'N{-}CH{=}NH$$

$$RR'N{-}CH{=}NH + HCN \rightleftarrows RR'N{-}CH{=}NH_2^{\oplus}\ CN^{\ominus}$$

*(1)*

affords a plausible explanation of all the products. The amidinium salt *(1)* present in the equilibrium mixture reacts with nucleophilic agents: water affords formamides[2], and $H_2S$ thioformamides[3]. This synthesis of thioformamides has been found to be very useful. Primary amines can replace ammonia in the salts *(1)*, yielding *N,N'*-disubstituted[4] and *N,N,N'*-trisubstituted formamidines *(2)* (R' = H or alkyl).

$$RR'N{-}CH{=}NH_2^{\oplus}\ CN^{\ominus} \xrightarrow{H_2NR''} RR'N{-}CH{=}N{-}R''$$

*(2)*

The trisubstituted formamidines can be obtained from both aliphatic and aromatic amines, sometimes in excellent yield. Analogous reactions with secondary amines afford the cyanides *(3)*, which spectra and molecular-weight determinations indicate as existing in solution in equilibrium with glyoxylonitrile aminals *(4)*, the position of equilibrium depending on the polarity of the solvent. Compounds *(4)*, and not *(3)*, occur in the solids.

$$RR'N{-}\overset{\oplus}{C}H{=}NRR'\ CN^{\ominus} \rightleftarrows NC{-}CH(NRR')_2$$

*(3)* *(4)*

Compounds *(3)* are obtained in good yield on reaction of an excess of strongly nucleophilic secondary cycloalkylamines with hydrogen cyanide. They behave like amidinium salts *(1)* in their reaction with water, $H_2S$, and amines, forming formamides, thioformamides, and trisubstituted formamides.

Contrary to statements in the literature *N,N'*-disubstituted formamidines can be converted smoothly into sulfonyl derivatives in the presence of stoichiometric amounts of a base (*e.g.* NaOH). Reaction of aromatic amines to trisubstituted formamidines and subsequent quaternization and hydrolysis provide a synthesis of very pure aromatic secondary amines that is more selective than all previous methods.

*N,N'*-Disubstituted formamidines are strongly associated in solution. For tetrahydropyrimidine and imidazoline *(5)* molecular-weight determinations and spectroscopic findings suggest equilibria of the type:

## Synthesis of Azide Halides and Nitride Halides and some Related Structural Problems [1]

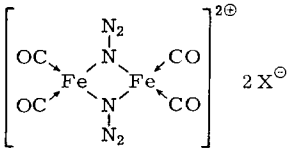
*K. Dehnicke*, Stuttgart (Germany)

Reaction of $WBr_5$ and $BrN_3$ afford the highly explosive compound $WBr_5N_3$ (symmetry class $C_{4v}$), soluble in $CCl_4$:

$$WBr_5 + BrN_3 \rightarrow WBr_5N_3 + {}^1/_2\,Br_2 \qquad (a)$$

An analogous reaction occurs with $UCl_5$ and $ClN_3$, affording an azide chloride, probably $UCl_5N_3$, which loses $N_2$ and $Cl_2$ in boiling $CCl_4$ and thus yields polymeric $UNCl_3$.

$ClN_3$ or $BrN_3$ react with the metal carbonyls $Fe(CO)_5$, $Mo(CO)_6$, and $W(CO)_6$ with formation of well-defined carbonyl azide halides $M(CO)_2N_3X$ (X = Cl or Br). Their infrared spectra and magnetic behavior indicate that a substantially planar four-membered ring occurs in these iron compounds, the halide being ionic:



These compounds show the paramagnetism of the unperturbed $Fe^{2+}$ ion ($\mu$ = 5.29 B.M., $\Theta$ = 0 °K) and are the first examples of paramagnetic iron-carbonyl compounds. The Fe–C linkage appears to be a pure $\sigma$-bond without back-donation. On thermal decomposition at 90 °C in a vacuum the CO-free azide halides $FeClN_3$ and $FeBrN_3$ ($\mu$ = 4.80 B.M., $\Theta$ = 12 °K) are formed. The carbonyl azides and the simple azide halides of $Fe^{II}$ are not explosive; this is attributed to locking of the lone electron pair on the $\alpha$-N atom. The carbonyl azide halides of Mo and W, $M(CO)_2ClN_3$, are polymeric (n = 6), both Cl and $N_3$ acting as bridges. Intense metal-metal interaction results, as shown by the magnetic behavior: $Mo(CO)_2ClN_3$: $\mu$ = 0.93 B.M., $\Theta$ = −20 °K; $W(CO)_2ClN_3$: $\chi_m = -74.9 \times 10^{-6}$ EMU/mole.

$ClN_3$ reacts with organometallic compounds such as $Cd(CH_3)_2$ and $[Al(C_2H_5)_3]_2$ with partial replacement of alkyl by azide:

$$Cd(CH_3)_2 + ClN_3 \rightarrow N_3CdCH_3 + CH_3Cl \qquad (b)$$

Azidomethylcadmium forms colorless crystals that do not melt and for which infrared spectra indicate an ionic structure: $[CdCH_3]^{\oplus}N_3^{\ominus}$. Azidodiethylaluminum is a colorless distillable liquid (b.p. 63 °C/$10^{-3}$ mm Hg), which dimerizes through the azide group; its infrared spectrum indicates a strictly planar four-membered Al–N ring.

[Lecture at Erlangen (Germany), December 2nd, 1965]

[VB 970/277 IE]

German version: Angew. Chem. 78, 339 (1966)

[1] With collaboration of *G. Lange, J. Müller, D. Seybold*, and *J. Strähle*.

## Synthesis of Graft and Block Copolymers

*G. Greber*, Freiburg (Germany)

Addition of dialkylaluminum hydrides to molecules with C=C double bonds in side chains or at chain ends, and treatment of the products with transition-metal halides (*e.g.* $TiCl_4$), afford macromolecular Ziegler catalysts that initiate graft and block polymerization of ethylene and $\alpha$-alkenes. Graft polymers with stereoregular poly-$\alpha$-alkene side chains become accessible in this way.

Macromolecules containing RC=NM linkages are formed on addition of organometallic compounds of lithium (LiR) or magnesium (MgRHal) to the N≡C triple bond in styrene-acrylonitrile copolymers, and they initiate anionic graft polymerization of acrylonitrile (AN), methyl methacrylate (MMA), 2-vinylpyridine (2-VP), and 4-vinylpyridine (4-VP).

Reaction with Na of macromolecules containing O=C, N≡C, or C=C linkages in side chains gives macromolecular radical anions (*e.g.* high-polymeric ketyls in the case of poly-*p*-vinylbenzophenone) or dianions, formed by electron-transfer from the metal to the multiple bond. Both the radical anions and the dianions initiate anionic graft polymerization of AN, MMA, 2-VP, 4-VP, butadiene, and styrene, and in this way pure graft copolymers are formed, free from "backbone molecules" and from homopolymers of the grafted monomer.

Pure graft copolymers are formed also on use of macromolecular organometallic initiators, such as those formed by metalation of poly-4-chlorostyrene or 4-chlorostyrene-styrene copolymers with stoichiometric amounts of naphthalene sodium.

Since the anionic end groups of the growing side chains remain "living" during these processes, second and third monomers can be added to afford graft copolymers whose side chains are block copolymers. If the growing chains are terminated, *e.g.* by chlorosilanes containing functional groups, then reactive end groups are introduced into the side chains.

Finally, graft and, in particular, block copolymers can be obtained when "finished" macromolecules containing very reactive silicon side or end groups (*e.g.* HSi–, ClSi–, HOSi–, $CH_2$=CH–$CH_2$–Si–) are joined together by chemical reactions. These methods open a route to block copolymers having stereoregular blocks. Macromolecules containing suitable functional groups attached to silicon atoms also provide a bridge to anionic processes. For instance, macromolecules containing *p*-vinylphenylsilicon end groups react surprisingly readily with sodium to yield radical anions which effect block copolymerization of vinyl monomers.

[Lecture at Krefeld (Germany), December 16th, 1965]

[VB 972/279 IE]

German version: Angew. Chem. 78, 309 (1966)

## Ammonolytic Processes in Liquid Ammonia

*O. Schmitz-DuMont*, Bonn (Germany)

The hexamminecobalt(III) ion behaves as a cationic ammono acid in liquid ammonia:

$$[Co(NH_3)_6]^{3+} + NH_3 \rightleftarrows [Co(NH_3)_5NH_2]^{2+} + NH_4^+ \qquad (1)$$

Addition of 1 equivalent of $KNH_2$ and then of potassium phenoxide at −20 °C precipitates amidopentamminecobalt(III) phenoxide. At +20 °C the amidopentamminecobalt(III) ion *(1)* undergoes condensation to a binuclear complex $[(NH_3)_4Co(NH_2)_2Co(NH_3)_4]^{4+}$ *(2)*, which reacts further with the ion *(1)* to afford the trinuclear complex *(3)*.

$[(NH_3)_4Co(NH_2)_2Co(NH_3)_3NH_2Co(NH_3)_5]^{6+}$ *(3)*

Products *(2)* and *(3)* are isolated as nitrates. It is thus shown for the first time that ammonolysis of ammine complexes in liquid ammonia proceeds analogously to the hydrolysis of aquo complexes in aquous media.

The ammonolysis of $Si(C_6H_5)_4$, $Sn(C_6H_5)_4$, $Pb(C_6H_5)_4$, $P(C_6H_5)_3$, $As(C_6H_5)_3$, and $Sb(C_6H_5)_3$ in liquid ammonia containing $KNH_2$ has been studied. $Si(C_6H_5)_4$ gives the dipotassium salt of hexaamidocyclotrisilazane *(4)*, which even at 0 °C undergoes polycondensation with loss of ammonia[1]. This product *(4)* is also obtained on ammonolysis of hexaphenylcyclotrisilazane. $Sn(C_6H_5)_4$ is also completely ammonolysed at 0 °C, with formation of $K_2[Sn(NH_2)_6]$[2]. Ammonolysis of $Pb(C_6H_5)_4$ leads partly to a black, very explosive nitride of quadrivalent lead and, with loss of nitrogen, to $K[Pb(NH_2)_3]$. $P(C_6H_5)_3$, when heated in an autoclave at 100 °C (not otherwise), is partly cleaved to yield triphenylcyclotriphosphazane $(C_6H_5PNH)_3$. $As(C_6H_5)_3$ and $Sb(C_6H_5)_3$ are completely ammonolysed to $K[As(NH)_2]$ and $K[Sb(NH)_2]$. Tetracyclohexyltin is completely resistant even at 100 °C, whereas tricyclohexylphenyltin suffers ammonolysis with loss of the phenyl group. Thus ammonolysis is the easier the more polar the M–C bond.

[Lecture at Aachen (Germany), December 17th, 1965]

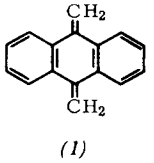
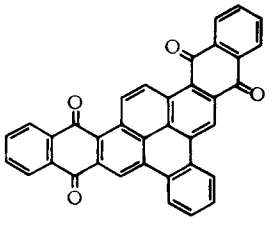
# SELECTED ABSTRACTS

**The homoserine dehydrogenase from Rhodospirillum rubrum** has been found by *P. Datta* and *H. Gest* to show interesting control phenomena. The enzyme, which the authors concentrated by a factor of 1800, catalyses the DPNH-dependent oxidation of homoserine to 2-amino-4-oxobutanoic acid. The enzyme exhibits end-product inhibition by L-threonine. However, this inhibition is eliminated in the presence of L-isoleucine or L-methionine. Both of these amino acids are end-products of another reaction path starting with homoserine. In the absence of threonine, isoleucine and methionine activate the oxidation of homoserine, but not the reduction of 2-amino-4-oxobutanoic acid. The regulating effects of the amino acids are completely reversible. The regulating effect of threonine and isoleucine can no longer be observed in the absence of $K^+$. / J. biol. Chemistry *240*, 3023 (1965) / −Hö. [Rd 405/614 IE]

**Diels-Alder reactions of 9,10-anthraquinodimethane** *(1)* have been studied by *I.T. Millar* and *K. E. Richards.* The compound *(1)* forms adducts with 2 moles of dienophile, whereas other *p*-quinodimethanes react with only 1 mole of dienophile. *Cis-* or *trans*-9,10-dimethyl-9,10-dihydroanthracene-9,10-diol is dehydrated in the presence of excess dienophile, and the compound *(1)* formed reacts with the dienophile to form the diadduct. Aromatization takes place in nitrobenzene. The dimethyl ester of acetylenedicarboxylic acid



*(1)*



*(2)*

reacts with *(1)* to form the tetramethyl ester of benzo[*e*]-pyrene-2,3,6,7-tetracarboxylic acid [m.p. 321 °C, yield 23 % (in boiling nitrobenzene)]. The reaction of *(1)* with maleic anhydride in boiling acetic anhydride leads to the formation of 1,2,3,6,7,8,8a,12b-octahydrobenzo[*e*]pyrene-2,3:6,7-dicarboxylic anhydride (m.p. 230 °C, yield 60 %). *(1)* reacts with 1,4-naphthoquinone in boiling nitrobenzene to form the diquinone *(2)* (m.p. 360 °C, yield 46 %). / Chem. Commun. (London) 1965, 369 / −Ma. [Rd 384/593 IE]

**The specificity of snake-venom protease** has been studied by *G. Pfleiderer* and *A. Krauss.* From the crude poison of *Crotalus atrox* three isoenzymic proteases were separated by chromatography. The substrates are peptides with known amino acid sequences: insulin, the oxidized A and B chains of insulin, and glucagon. Peptide linkages in which the amino group belongs to a leucine or phenylalanine unit are hydrolysed preferentially. High-molecular weight native proteins are not attacked; the digestion must be preceded by denaturation by heat or urea. The substrates must have a chain length of between 5 and 20 amino acid units. / Biochem. Z. *342*, 85 (1965) / −Hö. [Rd 410/619 IE]

**o-Carboranyl derivatives of boron compounds** have been synthesized by *J. L. Boone, R. J. Brotherton,* and *L. L. Patterson* by double decomposition of monolithio-*o*-carborane *(1)* with chlorobis(dimethylamino)borane *(2)* in ether:

$$\underset{(1)}{o\text{-}HCB_{10}H_{10}CLi} + \underset{(2)}{ClB[N(CH_3)_2]_2} \rightarrow \underset{(3)}{o\text{-}HCB_{10}H_{10}CB[N(CH_3)_2]_2} + LiCl$$

Bis(dimethylamino)-*o*-carboranylborane *(3)* is obtained from this reaction in 45 % yield; m.p. 46 °C. This compound undergoes alcoholysis with quantitative formation of dimethylamine according to

$$\underset{(3)}{o\text{-}HCB_{10}H_{10}CB[N(CH_3)_2]_2} + 3\ CH_3OH \rightarrow o\text{-}HCB_{10}H_{10}CH + B(OCH_3)_3 + 2\ (CH_3)_2NH$$

Hydrolysis of *(3)* in ether gives 70 % of the theoretical amount of dimethylamine, together with a viscous, insoluble precipitate. Infrared examination of the non-volatile material showed that the products of this reaction include a small quantity of *o*-carborane (but no dihydroxy-*o*-carboranylborane).

$$\underset{(4)}{o\text{-}(n_4\text{-}CH_9)CB_{10}H_{10}CLi} + \underset{(5)}{(ClBNCH_3)_3}\ KH \rightarrow \underset{(6)}{[o\text{-}(n\text{-}C_4H_9)CB_{10}H_{10}CBNCH_3]_3} + 3\ LiCl$$

*N,N',N''*-Trimethyl-*B,B',B''*-trichloroborazine *(5)* reacts with *C*-monolithio-*C'*-n-butyl-*o*-carborane *(4)* in an ether-heptane mixture to give a 64 % yield of *B,B',B''*-tris-(n-butyl-*o*-carboranyl)-*N,N',N''*-trimethylborazine *(6)*. This last compound is a light yellow, low-melting wax. / Inorg. Chem. *4*, 910 (1965) / −Sch. [Rd 428/637 IE]

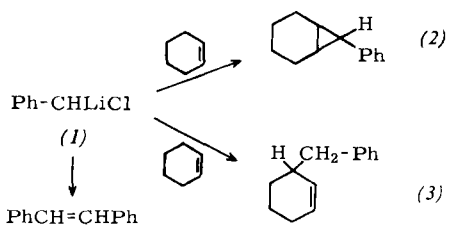
**The synthesis of tetracyanooxirane** *(1)* is described by *W. J. Linn, O. W. Webster*, and *R. E. Benson*. This compound is obtained in yields of from 65 to 70 % when a 30 % solution of $H_2O_2$ is added dropwise to a cooled solution of tetracyanoethylene in acetonitrile. Oxidation of the tetracyanoethylene radical anion with acidic $H_2O_2$ in water also leads to the formation of *(1)* (58 %). The compound (m.p. 177–178 °C) crystallizes in the form of needles, is stable in air, and is slowly decomposed by water.

$$(NC)_2C{=}C(CN)_2 + H_2O_2 \longrightarrow (NC)_2C\overset{O}{\diagup\!\diagdown}C(CN)_2 + H_2O$$
*(1)*

It is attacked at one of the nitrile groups by iodide and bromide ions with formation of cyanogen halide and the tricyanovinylalkoxide anion. Pyridine derivatives and dialkyl sulfides open the ring to form stable dicyanomethylides and carbonyl cyanide. When di-n-butyl sulfide is used, carbonyl cyanide is obtained in a yield of 86 to 91 %. / J. Amer. chem. Soc. *87*, 3651 (1965)] / –Ma. [Rd 381/590 IE]

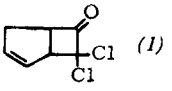
**Automatic equipment for the synthesis of polypeptides** is being operated in the Rockefeller Institute, New York. *R. B. Merrifield* and *J. M. Steward* have succeeded in automating the heterogeneous polypeptide synthesis. The C-terminal amino acid of the polypeptide to be synthesized is anchored to an insoluble particle (polystyrene with 2 % of divinylbenzene, diameter 10 to 80 mμ). The other amino acids are then attached to this first acid by essentially conventional methods. An important advantage of the process is the insolubility of all the intermediates, so that the only purification required at each stage is washing. The particles to which the polypeptide chains are anchored remain in the reaction vessel throughout the process. Thus the process consists simply in the changing of the reactant and wash solutions and in the programming of the amino-acid sequence, all of which are technically simple operations. With the aid of this apparatus, it is possible to lengthen a peptide by 6 amino acids in 24 hours. So far, the peptide hormones bradykinin (9 amino acids), methionylsilylbradykinin (11), and angiotensin II (8) have been synthesized with full biological activities and in yields of about 70 %. / Chem. Engng. News *43*, no. 25, p. 540 (1965) / –Hö. [Rd 400/609 IE]

**The reaction of ω-dichlorotoluene with lithium and cyclohexene** in tetrahydrofuran between 5 and 10 °C has been studied by *P. Mavrikos* and *A. Cheng*. Gas chromatography of the distillate shows that in addition to 26 % of dibenzyl, 11 % of stilbene, and 8 % of benzyl chloride, it also contains 20 % of 7-phenylnorcarane *(2)* (two isomers) and 6 % of 3-benzylcyclohexene *(3)*. It is thought that the carbenoid α-chloro-α-lithiotoluene *(1)* is first formed, and that this is converted into the products *(2)* and *(3)* either directly or *via* free phenylcarbene, by addition across the double bond or by insertion into an allyl C–H bond of the cyclohexene. *(1)* can also be assumed to be a precursor of stilbene. Further, *(1)* undergoes transmetalation to form benzyl chloride, which is probably responsible for the formation of dibenzyl. The



similarity of the product composition to that obtained in the reaction of benzyl chloride with butyl-lithium suggest a common intermediate. / J. org. Chemistry *30*, 1675 (1965) / –Eb. [Rd 424/633 IE]

**A new tropolone synthesis using dichloroketene** is described by *D. R. Brandt, K. R. Fountain, E. J. Gaughan, D. A. Reich*, and *H. C. Stevens*. Dichloroketene is prepared at a low temperature by the dehydrochlorination of dichloroacetyl chloride with triethylamine, and is treated *in situ* with cyclopentadiene to form the 1:1 adduct (yield 70 to 75 %), which probably has the bicyclic structure *(1)*. Hydrolysis of the adduct with aqueous potassium acetate in acetic acid yields tropolone, which can be isolated as the copper complex



*(1)*

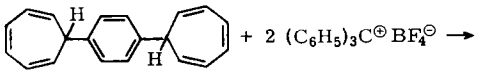
(m.p. 320 °C, yield 52 %). The free tropolone is obtained by treatment of the complex with $H_2S$ in $CHCl_3$. / 150th Meeting Amer. Chem. Soc. *1965*, 62S / –Ma. [Rd 383/592 IE]

**The determination of alcohols in water by the ATR technique** (attenuated total reflection) has been described by *C. P. Malone* and *P. A. Flournoy*. Infrared radiation is passed through a material with a high refractive index, *e.g* AgCl, KRS-5 (TlBr + TlI), or germanium, at an angle slightly greater than the critical angle for total reflection, onto the interface with the absorbing substance (alcohol/water mixture.) The radiation penetrates the material to a depth (fraction of λ) that depends on the angle of incidence, the refractive index of the substance, and the wavelength. Owing to partial absorption, reflection back into the optically denser medium is not total. The radiation, after reflection one or more times, is subjected to a spectrophotometric examination in which it is compared with the totally reflected radiation obtained with air in place of the absorbing sample. Until now it has been practically impossible to determine alcohols in water by infrared spectroscopy, owing to the solubility of the cell windows in water and owing to the difficulty of obtaining layer thicknesses of a few μ with high reproducibility. Alcohol-water mixtures obey the Beer-Lambert law at all alcohol concentrations from 0 to 100 %. / Spectrochim. Acta *21*, 1361 (1965) / –Hz. [Rd 396/605 IE]

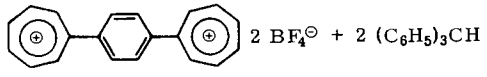
**The gas-chromatographic detection of monosaccharides in the septanose and open-chain forms** has been reported by *E. Bayer* and *R. Widder*. The sugars are converted into glucosides and then permethylated, in order to "freeze in" the forms that exist in the solution. The gas chromatography is then carried out on polyethylene glycol/kieselgur. The permethyl ethers can be separated preparatively. Depending on the methylation conditions, the above procedure yields furanosides, pyranosides, septanosides, and acyclic carbonyl forms (al forms). For example, by direct methylation of galactose with $BaO/CH_3I$, the authors obtained considerable quantities of the septanose form. The al form occurs in proportions of up to 3.4 % in the case of fructose, and up to 2.1 % in the case of galactose, but only up to 0.1 % in the case of glucose. / Liebigs Ann. Chem. *686*, 181, 197 (1965) / –Bu. [Rd 443/265 IE]

**Unsolvated "Grignard compounds"** do not crystallize as such as has been shown by *E. Weiss* for methylmagnesium and ethylmagnesium bromides. Alkylmagnesium halide crystals obtained from ether solutions lose ether of crystallization at 100 to 120 °C/$10^{-3}$ mm Hg; this is accompanied by the disappearance of all the X-ray reflections that suggest the existence of an unsolvated Grignard compound. These are replaced by the diffraction lines for (polymeric) dialkylmagnesium $(R_2Mg)_\infty$ (R = $CH_3$, $C_2H_5$) and for magnesium halide $MgX_2$ (X = Cl, Br). It is uncertain whether all Grignard compounds undergo disproportionation on desolvation, or whether Grignard compounds prepared in non-solvating solutions are disproportionated even in solution. The $MgX_2$ reflections are distinctly broadened, indicating the presence of lattice defects. / Chem. Ber. *98*, 2085 (1965) / –Eb. [Rd 425/634 IE]

**The synthesis of p-phenyleneditropylium difluoroborate** *(1)*, a stable salt of a dicarbonium ion, is described by *R. W. Murray* and *M. L. Kaplan*. The starting material *(2)* is obtained in a poor yield by the thermal or chemical decomposition of 1,4-bis(diazomethyl)benzene in benzene. When a solution of *(2)* in $CH_2Cl_2$ is treated with excess trityl fluoroborate (64 h), the



*(2)*



*(1)*

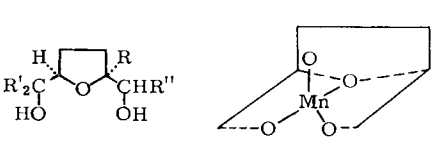
rust-red, crystalline difluoroborate *(1)* separates out in 97 % yield (m.p. < 350 °C). The unusual stability of the dicarbonium ion is due to the presence of the aromatic tropylium system. / Tetrahedron Letters 1965, 2903 / –Ma. [Rd 391/600 IE]

**The synthesis of sulfonates by cleavage of ethers with sulfonic acids** is reported by *D. Klamann* and *P. Weyerstahl*. Dialkyl and alkyl aryl ethers undergo cleavage when heated with anhydrous sulfonic acids such as *p*-toluenesulfonic acid *(1)* and methanesulfonic acid *(2)*; symmetrical aliphatic ethers consume two moles of sulfonic acid to form the ester of the sulfonic acid, while alkyl aryl esters react with one mole of sulfonic acied to form the alkyl sulfonate and the phenol.

$$R{-}O{-}R' + 2\,R''{-}SO_2OH \rightarrow 2\,R''{-}SO_2OR + H_2O$$

The reactions take from 5 to 15 hours at 150 to 180 °C. The reaction is stopped at a moderate yield by the water formed. In the case of high-boiling ethers, the water can be eliminated continuously, and the yield can be increased to about 70 %. Examples: R–O–R′: R = R′ = $C_2H_5$, cleavage with *(1)*, b.p. of ester 79–80 °C/0.05 mm Hg, yield 26 %; R = R′ = n-$C_4H_9$, *(1)*, b.p. 105–106 °C/0.1 mm, yield 55 %; R = $C_6H_5$, R′ = $CH_3$, *(1)*, b.p. 82–84 °C/0.07 mm, yield 74 %; R = $C_6H_5$ R′ = $CH_3$, *(2)*, b.p. 41–42 °C 1 mm, yield 38 %. / Chem. Ber. *98*, 2070 (1965) / –Ma. [Rd 386/595 IE]

**High yields of *cis*-2,5-bis-hydroxymethyltetrahydrofurans were obtained by the permaganate oxidation of 1,5-dienes** by *E. Klein* and *W. Rojahn*. Geranyl acetate gives only the *erythro* form of the tetrahydrofuran derivative (70 % yield),



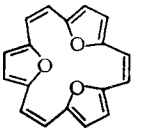
*(3)*

*(1)* R = R′ = $CH_3$
R″ = $CH_2OAc$, m.p. 107–108 °C

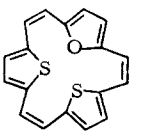
*(2)* R = R′ = R″ = H, $d_4^{20} = 0.944$, $n_D^{20} = 1.4446$

whereas neryl acetate gives only the *threo* form (68 % yield). *(2)* is obtained in 20 % yield from 1,5-hexadiene. The strict stereospecificity has been explained by the authors and by *G. Wilke*, but the explanation does not cover the simultaneous cyclization and oxidation. In the $MnO_4^-$ ion, manganese has the coordination number 4 and a formal valence of +7. A very large number of electrons are withdrawn from the manganese atom, so that its electron affinity should be very high. The complex *(3)* is suggested as an intermediate in the oxidation. / Tetrahedron *21*, 2353 (1965) / –Bu. [Rd 445/654 IE]

**Triepoxy[18]annulene and epoxydiepithio[18]annulene** have been synthesized by *G. M. Badger*, *J. A. Elix*, *G. E. Lewis*, *U. P. Singh*, and *T. M. Spotswood*. Furan-2,5-diacetic acid and methyl *cis*-α,β-bis-(5-formylfur-2-yl)acrylate were condensed in acetic anhydride and triethylamine and the product



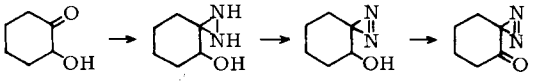
*(1)*



*(2)*

was esterified to form 1,4:7,10:13,16-triepoxy[18]annulene-5,11,18-tris(methyl carboxylate); hydrolysis and decarboxylation of this compound yields the trioxide *(1)* (decomp. 215 to 216 °C, red platelets). 1,4-Epoxy-7,10:13,16-diepithio[18]-annulene *(2)* (m.p. 103 to 103.5 °C, orange needles) was obtained in a similar manner. The NMR spectrum of *(1)* indicates an appreciable ring current, whereas there is no ring current in *(2)*. / Chem. Commun. (London) 1965, 269 / –Ma. [Rd 390/599 IE]

**A diazoketone with a diazirine ring** has been synthesized by *E. Schmitz*, *A. Stark*, and *C. Hörig*. 2-Hydroxycyclohexanone reacts with $NH_3$ and hydroxylamine-*O*-sulfonic acid to form the spirodiaziridine *(1)* (45 % yield), the dehydration of which with $Ag_2O$ yields *(2)* (b.p. 46–47 °C/0.8 mm Hg). Oxidation of *(2)* with t-butyl hypochlorite leads to the diazoketone 1,2-diazaspiro[2.5]octan-4-one (m.p. 6 °C, yield



*(1)* *(2)* *(3)*

36 %). Compounds *(2)* and *(3)* are sensitive to acids, the latter being extremely so. The decomposition of *(3)* yields 2-methylenecyclopentanone and cyclopentanecarboxylic acid. *(3)* reacts with hydrazines to form cyclopentanecarboxylic acid hydrazides, or rearrange to form substituted 1-amino-5,6,7,8-tetrahydrobenzo[*d*]-[1,2,3]triazoles. / Chem. Ber. *98*, 2509 (1965) / –Ma. [Rd 392/601 IE]

**The preparation of ε-caprolactam from cyclohexanecarboxylic acid in liquid $SO_2$** is reported by *N. Tokura*, *T. Kawahara*, and *T. Sato*. In place of the nitrosylsulfuric acid used in the SNIA method, these authors used fuming nitric and fuming sulfuric acids. They assume that nitrosylsulfuric acid is formed *in situ*. Anhydrous $SO_2$, fuming nitric acid, and fuming sulfuric acid were mixed by stirring at 20 °C. Cyclohexanecarboxylic acid was added, and the mixture was heated slowly to 68–70 °C and then poured after an hour into ice-water. ε-Caprolactam (m.p. 68 to 70 °C) was formed in 60 % yield. / Bull. chem. Soc. Japan *38*, 849 (1965) / –Bu. [Rd 444/653 IE]

**The von Auwers-Skita rule** is still a useful means of determining configurations, as is shown by measurements carried out by *H. Feltkamp* and *K. D. Thomas* on methylcyclohexylamines and their *N*-substituted derivatives. This rule states that for *cis-trans* isomers of hydroaromatic compounds, the *cis*-isomer has the higher density and the higher refractive index, but the lower molar refractivity [R]. The rule can also be used in the modified form proposed by *H. van Bekkum*[1] for 1,3-disubstituted cyclohexanes or for polysubstituted rings.

Examples:

| Substance | Form | $d_4^{20}$ | $n_D^{20}$ | [R] |
|---|---|---|---|---|
| 4-t-Butyl-cyclohexylamine | *trans* | 0.8660 | 1.4645 | 49.525 |
| | *cis* | 0.8716 | 1.4670 | 49.435 |
| *N*-Methyl-4-methyl-cyclohexylamine | *trans* | 0.8418 | 1.4511 | 40.704 |
| | *cis* | 0.8500 | 1.4531 | 40.466 |

Liebigs Ann. Chem. *685*, 148 (1965) / –Bu. [Rd 442/651 IE]

[1] *H. van Bekkum*, Recueil Trav. Chim. Pays-Bas *80*, 1310 (1961).

**Brennstoffelemente. Moderne Verfahren zur elektrochemischen Energiegewinnung** (Fuel Cells. Modern Processes for Electrochemical Production of Energy). Monograph No. 82 to "Angewandte Chemie" and "Chemie-Ingenieur-Technik". By *W. Vielstich*. Verlag Chemie, GmbH., Weinheim/Bergstr. 1965. 1st Edit. XV + 388 pp., 267 figs., 31 tables, plastic cover, DM 54.– (about $ 14.–).

In recent years the problems involved in fuel cells, where chemical energy is converted directly into electrical energy, have drawn the attention of an increasing number of technologists and scientists. *W. Vielstich* has chosen the right moment for a comprehensive review of the results and for delineation of unsolved problems.

The introductory chapter lists the cells according to the physical state of the reactant materials. Understanding is made easy for the novice by clear diagrammatic drawings.

In accord with their importance, much space is given to description of methods of electrochemical investigation, to electrode kinetics, and to transport phenomena. Special treatment is accorded to anodic oxidation of hydrogen, mono- and di-hydric alcohols, aldehydes, carboxylic acids, hydrocarbons, ammonia, hydrazine, and borohydrides, as well as to cathodic reduction of oxygen hydrogen peroxide, nitric acid, bromine, and chlorine. This section includes unpublished work by the author concerning, *e.g.*, the pH-dependence of the exchange current density of the $H_2$ reaction and potentiostatic potential diagrams of smooth noble-metal electrodes. The fundamental studies have contributed materially to a better understanding of the effects observed, but it remains for the future to show whether they provide a basis for new, promising technical developments.

The treatment of low-, medium-, and high-temperature cells, and of cells containing dissolved fuel, occupies more than 100 pages. This chapter, completed in 1964, makes it particularly apparent how vigorously development of cells and batteries is progressing. Special types, such as redox cells, and amalgam-oxygen and biochemical fuel cells, receive separate treatment.

Discussion of the conversion of heat and nuclear energy by electrochemical processes is a novel feature for a monograph on fuel cells. Electrochemical energy storage and electrochemical enrichment of deuterium and tritium are included in the border problems that are treated in about 30 pages. For the preparation of individual chapters *W. Vielstich* enlisted collaboration of *A. Küssner* (hydrogen foil electrodes), *R. P. Tischer* (fuel cells at medium and high temperatures), *H. Schmidt* (high-temperature cells with solid electrolytes), and *G. Grüneberg* (heat and nuclear energy converters).

The book is excellently produced and, because of the balanced treatment of the theory and technical status of fuel cells, will certainly receive a good reception by a wide audience. *F. von Sturm* [NB 446/299 IE]

**Trivialnamenkartei** (Card File of Organic Trivial Names). Issued by the Editorial Office of Chemisches Zentralblatt, Berlin. Verlag Chemie, GmbH., Weinheim/Bergstr. 1964. 8000 Cards (72 mm×104 mm) in 3 cartons, DM 280.– (about $ 70.–).

Trivial names are a necessity, but often also a source of annoyance: the latter always when the structure cannot be derived from the name no matter how great one's knowledge of nomenclature and the like. It is the aim of this set of cards, compiled in the Editorial Office of Chemisches Zentralblatt, to offer help in this situation. On each card there is in the center the structural formula, in the top left corner the German trivial name (or names), in the top right corner the English trivial designation, in the bottom left corner the molecular formula, and in the bottom right corner literature references (mostly to Beilstein and to abstracts in Chemisches Zentralblatt or Chemical Abstracts). The cards are numbered consecutively according to their alphabetical order, which facilitates replacement in the correct position. The German and the English forms of the trivial names have independent numbers, so that by simply sorting into rising numbers the cards can be arranged according to the alphabetical order of either the German or the English keywords.

Compounds having several trivial names have a corresponding number of cards. For example, ouabain appears also as acocanthenin and as g-strophanthin at appropriate places. This system is, however, not always followed strictly. Thus diphosphopyridine nucleotide is not to be found under that designation. But a corresponding card appears under DPN, and other trivial designations of this coenzyme are present as separate cards: yet there is no card for NAD, which has recently become the customary abbreviation in place of DPN. It is very welcome that abbreviations are treated here as trivial names. In most cases the cards contain also an explanation of how these abbreviations arose, *e.g.*, NAA = naphthylacetic acid, or DDD = dichlorodiphenyldichloroethane, but occasionally (CMU, PAN) such explanation is omitted.

In addition to references to Beilstein, Chemisches Zentralblatt, and Chemical Abstracts there are literature citations such as "Karrer 2203" or "Negwer 1971", but the inexperienced are not told what these mean (at least not in the set of cards supplied for review).

In some cases the user will fail in his search for a trivial name. This is not surprising for 8000 cards, but regular supplements are envisaged which are to complete the file and also to bring them up to date [*]. The Editorial Office of Chemisches Zentralblatt asks specifically to be informed of further trivial names that should be included and, in the reviewer's opinion, it is to be hoped that this request will find the strongest possible echo, because the cards are and will continue to be a great help to all who possess them; they furnish the information sought quickly, reliably, without long thumbing over, and without ballast. *H. Grünewald* [NB 447/300 IE]

**Struktur und Synthese von Vitaminen** (Structure and Synthesis of Vitamins). *G. Kempter*. WTB-Wissenschaftl. Taschenbücher – Chemie, Vol. 22, Akademie-Verlag, Berlin 1964. 1st Edit., 155 pp., numerous illustrations, DM 8.– (about $ 2.–).

This small volume presents a lucid survey of the structures and syntheses of nearly all the vitamins. The author writes fluently and competently. He describes the efforts of the organic chemists that led to the elucidation of the structures of most of the vitamins in the early 1930's making this one of the highlights of natural product chemistry; the book then shows how the time required for investigations of this nature is greatly reduced nowadays by the application of physical methods, although these methods can only be based on knowledge gained by classical methods

One or two technically important syntheses or syntheses that provide evidence of the structure are appended to the structural elucidation of each vitamin, in a style that betrays the authors detailed technical knowledge The properties of the vitamins and a number of antagonists are described. The chapters on the fat-soluble vitamins are particularly good; however, the stereochemistry of tachysterol is only touched upon. In the case of the water-soluble vitamins, the cofactor form and its synthesis is not generally considered, but this does not form part of the object of the book. In the discussion of vitamin $B_{12}$, the recent attempts to synthesize the corrin ring system are not mentioned.

[*] The first supplement comprising about 1100 cards will appear shortly.

The layout of the book is very clean, and the formulae are particularly clear. The few misprints and biochemical incongruities in the text are of no importance. The book closes with a glossary in German, English, and Russian. The literature survey is unfortunately confined to fairly recent reviews. Onthe whole, however, this is an excellent little book, and contains everything that the student is likely to absorb from very good special lectures. *L. Jaenicke* [NB 440/275 IE]

**Die Oxydation organischer Verbindungen mit Sauerstoff** (The Oxidation of Organic Compounds with Oxygen). By *R. Schöllner*. Wissenschaftliche Taschenbücher, Vol. 23. 1st Edit., Akademie-Verlag, Berlin 1964, 195 pp., 8 tables, 6 illustrations, cardboard DM 12.50 (about $ 3.10).

If one is not disturbed by sentences such as "The rapid development of the chemical industry in the Soviet Union and in the entire socialist camp will greatly favor the application of efficient processes for the oxidation of organic raw materials to form high-quality base chemicals", or by a number of inaccuracies and misprints, this book will provide a good picture of the many reactions of the oxygen molecule with organic substances. In addition to preparative aspects, on which the greatest stress is placed the kinetics of autoxidation also are discussed.

The question arises, however, of the type of reader for whom this book is intended. It contains too many specialized data for the student whereas the number of references to original publications is too small for the research worker (the 22 references given are mainly reviews); the book must therefore be intended primarily for industrial chemists. For this type of reader, in fact, the book may provide many suggestions in the course of a few hours' easy reading.

*R. Criegee* [NB 428/298 IE]

**Silicate Science.** Vol. II. Glasses, Enamels, Slags. By *W. Eitel*. Academic Press, New York-London 1965. 1st Edit., XII + 707 pp., numerous figures, $ 26.–.

This volume, the second of the planned series of five, deals with glasses, enamels, and slags. The chemical and physicochemical properties, such as the viscosities of glass melts, surface tension, electrical conductivity, and changes in density, are discussed in detail. Considerable space is devoted to the structures of glasses and to theories on the subject. Non-silicate glasses are also mentioned. A special chapter is given to the surface structure and surface reactions of glass. The second section deals more fully with industrial glasses, their homogeneity, color correction, reaction residues, gas inclusions, and the relationships between physico-chemical properties and chemical composition than with enamels. The chapter on slags reports recent findings relating to the constitution of slags, and includes sections on the viscosity and corrosiveness of molten slags and on equilibria between molten slags and molten metals.

The literature covered is mainly that published between 1952 and 1962. The section on glass contains 703 references from this period, while that on enamels and industrial glasses contains 458. The chapter on slags contains 186 references. The division into short, numbered chapters makes the book tidy and useful as a reference work. It is regrettable that, in keeping with the publishers' wishes, the contents of the book "Physical Chemistry of Silicates" (1954) are assumed to be known, and that the publications discussed in this earlier work are dismissed with a mere reference in the present volume. Apart from this, the author has been extremely successful in his use of the extensive literature. Misprints (*e.g.* page 511, where a phenylene complex is given instead of a catechol complex) are few.

As a reference book and handbook, this work is practically indispensable for all laboratories and institutes concerned with this field. *Armin Weiss* [NB 443/278 IE]

**Methods in Carbohydrate Chemistry.** Edited by *R. L. Whistler* in collaboration with *J. N. BeMiller* and *M. L. Wolfrom*. Vol. V: General Polysaccharides. Academic Press, New York-London 1965. 1st Edit., XXII + 463 pp., 26 figures, 11 tables. $ 16.50.

The present volume completes the provisional object of this series[1]. Like the previous volume, it contains a collection of reliable procedures. Volume V is devoted to methods in polysaccharide chemistry (cellulose and starch are excluded). 86 procedures are presented by 75 well-known specialists. The text is divided into seven main parts: methods of isolation (18 contributions), preparation of polysaccharides (25 contributions), chemical (4 contributions) and physical (5 contributions) analysis, molecular weight determinations (4 contributions), structural analysis (13 contributions), and the preparation of polysaccharide derivatives (7 contributions).

The first part describes the modern methods of extraction and purification of polysaccharides by chromatography, gel filtration, precipitation, dialysis, ultrafiltration, and zone electrophoresis. Dehydration and freeze-drying of preparations are explained. The second part contains particulars on the isolation of selected polysaccharides from plants, animals, and microorganisms, including mucopolysaccharides and lipopolysaccharides, glycogen, heparin, hyaluronic acid, cellulose, hemicelluloses, inulin, chitin, pectin, dextran, and plant gums. Part III contains only methods for the determination of lignin, acetyl and ester groups in pectin, and primary hydroxyl groups in polysaccharides The physical methods (Part IV) cover only the electrophoretic homogeneity, the optical rotation, the thixotropy and pseudoplasticity, the film properties, and the immunology of the polysaccharides. Part V then deals with molecular weight determinations by end-group analysis with $^{14}CN^{\ominus}$ and periodate, or by osmometry and isothermal distillation.

Methods of hydrolytic and oxidative degradation of polysaccharides and their methylated derivatives for the purpose of structural analysis account for the major part of Part VI. An exhaustive table (44 pp.) of methyl ethers of sugars should be very useful to the practical chemist. The oxidation and reduction of uronic acids, esterification and deacetylation desulfurization (of heparin), and etherification are some of the points dealt with in connection with the preparation of polysaccharide derivatives.

Since the book does not deal exhaustively with the subject "General Polysaccharides," references are made to methods published in earlier volumes of this or other series. The author index is large (18 pp.), since each contribution is followed by an average of 10 to 15 references. On the other hand, the subject index (a 20-page collective index for volumes III to V) is rather meagre, and contains only about 2000 keywords.

Volume V satisfactorily fulfils the purpose for which it is intended, *i.e.* to serve as a handbook for research and practical laboratory work. Both the experienced carbohydrate chemist and the newcomer to the field will quickly realize that "Methods of Carbohydrate Chemistry" is as valuable and as reliable as is "Organic Syntheses" in organic chemistry or "Biochemical Preparations" in biochemistry.

*J. M. Harkin* [NB 444/279 IE]

**The Proteins: Composition, Structure, and Function.** Edited by *H. Neurath*. Academic Press, New York-London. 2nd Edit., Vol. II, 1964, XIV + 840 pp., numerous illustrs. and tables, $ 26.00 (by subscription $ 24.00); Vol. III, 1965, XIV + 585 pp., numerous illustrs. and tables, $ 21.00 (by subscription $ 18.50).

Soon after its publication, the first edition of "The Proteins" (Chemistry, Biological Activity, and Methods), together with the standard monograph by *Cohn* and *Edsall*, became

[1] Review of Vol. IV: Angew. Chem. *77*, 226 (1965).

the standard handbook of every protein chemist. Now, ten years later, the first volumes of the second edition have been published. Owing to the illness and untimely death of the co-editor of the first edition, *K. Bailey*, the second edition is edited by *Neurath* alone.

The second edition, like the first, is to comprise four volumes. However, it is not a new edition in the true sense, but a completely new version oriented along different lines. This is evident from the subtitle: "Composition, Structure, and Function", and from the fact that only three of the contributors to the first edition have also contributed to the second. The principal theme of the work is no longer the question of the chemical structure of the proteins, but the problem of the relationship between the structure of a protein and its specific biological function. Comparison of the new edition with the old will make clear the progress that has been made in this field of biochemistry.

The first chapter of Volume II deals with the conformation of the polypeptide chains of proteins in solution (*J. A. Schellman* and *C. Schellman*), while the last chapter is concerned with the X-ray structure analysis of proteins (*Dickerson*); these two chapters are closely related, and even overlap in part. The general theoretical principles and the experimental methods used in the determination of the structures of proteins are described in detail, and the facts noted are discussed. *Dickerson* gives a list of the proteins that are under investigation by X-ray analysis.

The chapters by *Steinhardt* and *Beychok*, "Interaction of Proteins with Hydrogen Ions and Other Small Ions and Molecules," and by *Nichol, Bethune, Kegeles*, and *Hess*, "Interacting Protein Systems," are devoted to the interactions of proteins with proteins or components of low molecular weight. The first of these two chapters is mainly concerned with the acid-base equilibria of proteins, and so provides a basis for the discussion of the pH-dependence of various protein functions. The chapter on protein-protein interactions has a pronounced physico-chemical bias. This chapter is very informative on the subject of the quaternary structure of many proteins and on the problem of the antigen-antibody reaction. A particularly impressive chapter is "Polyamino Acids as Protein Models" by *Katchalski, Sela, Silman*, and *Berger*, which describes the synthesis and the chemical, physico-chemical, and biological properties of polypeptides, and deals with all the results published in this field. It becomes clear from this chapter how much the elucidation of the structure of proteins, of the genetic code, and of immunological problems owes to studies on synthetic polypeptides.

The first and last chapters of Volume III are of a general nature, while the other four chapters deal with the structures and functions of various proteins. *Sober, Hartley, Carroll*, and *Peterson* give a very instructive treatment of the "Fractionation of Proteins" (solubility, chromatography, electrophoresis, sedimentation, dialysis, ultrafiltration, and immunological methods), and also describe the methods used for the characterization of proteins and the determination of their purity. *Weber* and *Teale* ("Interaction of Proteins with Radiation") discuss the infrared and ultraviolet spectroscopy, fluorescence, light scattering, and optical rotatory dispersion of proteins *Fraenkel-Conrat* gives a brief outline of the structures and functions of virus proteins, and *Putnam* ("Structure and Function of the Plasma Proteins") and *Singer* ("Structure and Function of Antigen and Antibody Proteins") presents a lucid, impressive survey of the plasma proteins and the antigen-antibody proteins. Finally, *Davie* and *Ratnoff* give a clear description of the various factors that effect the coagulation of blood.

The various chapters are well written by competent authors, and special emphasis is laid throughout on the description of the experimental methods. The literature covered includes very recent publications, so that we are shown the latest situation in each field. These reports are indispensable to anyone who is concerned with proteins. There is only one objection to this work: one gains the impression that the arrangement of the chapters is arbitrary (*e.g.* chapters 7, 11 and 17 would be expected to appear together in that order). This gives the volumes a certain "Advances" character. Regrettable omissions include a somewhat more detailed treatment of denaturation and a chapter on the size and shape of protein molecules such as that contributed by *Edsall* in the 1st Edition (which will consequently still have to be consulted as before). Only a few misprints were found, and the print and layout, with the exception of the cover, are good.

*H. Sund* [NB 441/276 IE]

**Coincidence Tables for Atomic Spectroscopy.** By *J. Kuba, L. Kučera, F. Plzák, M. Dvořak*, and *J. Mráz*. Elsevier Publishing Comp., Amsterdam-London-New York 1965. 1st Edit., XXXI + 1136 pp., about $ 18.00

Anyone who is concerned with trace analysis by emission spectroscopy must constantly ask himself what foreign elements could interfere with a detection or even make it doubtful. *Kuba* and his co-workers have now used all the published data to produce a comprehensive book of tables (about 1150 pages) that supplies the answer to this question immediately.

The emission lines of 90 elements (only At, Bk, Cf, Es, Fm, Fr, Md, No, Pm, Po, and Tc are excluded) between 2000 and 10000 Å are presented in 17 tables. Table IV and V give lines that can be used for the analysis of the rare earths, Table VI for a number of actinides, and Tables VII and VIII for gases. Table IX gives the spark spectrum of air, and calibration lines for the secondary standard Fe are given to at least three decimal places in Tables X and XI. Tables XII and XIII contain the emission lines of inorganic molecules and fragments (*e.g.* AlO, BeO, $C_2$, CN, and CaF). Finally, Table XIV gives the ionization energies of the elements and of their ions.

The principal tables – Table XVI for 73 elements, with a total of 683 analytically important lines (*e.g.* resonance lines), and Table XVII for the rare earths – cover 1050 pages, the elements being arranged alphabetically and in order of increasing wavelength of the most important lines. All interfering emission lines there are always a few dozen!) due to foreign elements are also listed on the following basis: the entire coincidence region is assumed to be so wide that the resolution of two lines on a photographic plate must be possible; the coincident lines are then noted according to their relative intensities for three ranges $\pm \Delta\lambda$. To save unnecessary searching on the part of analysts with high-resolution equipment, the coincident lines are given in three types of print bold, normal, and italic (corresponding to linear dispersions of 0.5 to 5, 2 to 30, and $> 30$ Å/mm). A very disturbing fault is the fact that the tables contain practically no legends or explanations for the symbols used, so that the explanations must be sought in the text in the very early part of the book. Thus in Table I (p. XVII) reference should be made to Table XVI (p. 95), and the explanation of the table "Dislocation of Main Lines" (pp. 63–91) is given on p. XVIII. The values given in Tables X and XI for the standard Fe do not agree exactly; no indication of the source of Table X is given. According to the text on p. XVI, Table XI should contain calibration lines for the standards Cd, Kr, and Fe, whereas according to p. 52 these lines refer only to Fe.

On the whole, this is an excellent and important book in a very good and hard-wearing form – a book for the practical analyst.

*W. Jung* [NB 442/277 IE]

**Coordination Chemistry.** By *F. Basolo* and *R. C. Johnson*. W. A. Benjamin, Inc., New York-Amsterdam 1964. 1st Edit., XII + 180 pp., numerous illustrs. and several tables, linen, $ 4.35.

This book is intended as an introduction to coordination chemistry for American chemistry students. A very skilful treatment of molecular orbital methods and ligand field

theory are given in the explanation of the coordinate bond. In view of the purpose of the book and the class of reader for whom it is intended, the mathematical details are kept to a minimum. Nevertheless, the reviewer knows of no German book on coordination chemistry that would provide such a good theoretical background.

A short chapter on stereochemistry is followed by a section on the preparation and reactions of coordination compounds. Owing to the number of reactions and syntheses to be dealt with in a limited space, the material in this chapter is greatly simplified, and appears in fact to be too simple in many cases. Although original in itself, an exhaustive presentation of this kind can offer the beginner too little real information, while at the same time understating the preparative problems. The next chapter deals with the stability of complexes, and is again very well executed The last section, which is concerned with kinetics and mechanisms, deals mainly with substitutions and redox reactions

The book does excellently what it sets out to do, *i.e.* to provide an introduction to the chemistry of coordination compounds, and also in Germany it could serve as a basis for a one-semester lecture course on coordination chemistry. However, it will also be useful to more experienced chemists who wish a rapid grounding in coordination chemistry as an approach to more advanced literature. The illustrations are very clear, and misprints are rare. One unfortunate error in the Index is the mis-spelling "Zeigler" for "Ziegler", particularly noticeable because it is the last entry.

*Ernst Bayer* [NB 438/273 IE]

**The Chemistry of Alkenes.** Edited by *S. Patai*. The Chemistry of Functional Groups. A series of advanced treatises. Interscience Publishers, a Division of J. Wiley & Sons, London-New York-Sydney 1964. 1st Edit., IX + 1315 pp., numerous illustrations and tables, £ 15.15.0.

The olefinic double bond occupies a central position in organic chemistry by virtue of the unsurpassed variety of reactions in which it takes part. It is therefore gratifying to find that in this first volume of a series dealing with the chemistry of functional groups, the alkenes are accorded a treatment, by authorities, in keeping with their importance. The first of the fourteen chapters in the book presents a wave-mechanical discussion of the olefinic double bond (*C. A. Coulson* and *E. P. Steward*, 147 pp.). Three chapters are then devoted to the formation of olefins by eliminations in solution (*W. H. Saunders, jr.*, 53 pp.), in the gas phase (*A. Maccoll*, 38 pp.), and by condensation (*T. I. Cromwell*, 30 pp.). In the chapter on methods for detection and analysis of olefins (*E. J. Kuchar*, 63 pp.), in which physical methods are discussed in detail, mention might have been made of the papers published in 1962 on the quantitative analysis of simple olefins by far ultraviolet spectroscopy. The chapter on complexes with transition metals (*M. Cais*, 49 pp.) is followed by a section on rearrangements of olefins (*K. Mackenzie*, 81 pp ), which, together with the chapter on allyl compounds (*P. H DeWolfe* and *W. G. Young*, 58 pp.), provides a very comprehensive picture. The next three, rather extensive chapters describe the behavior of olefins towards nucleophiles (*S. Patai* and *Z. Rappoport*, 116 pp.) and free radicals and carbenes (*J. I. G. Cadogan* and *M. J. Perkins*, 96 pp.), as well as in cycloadditions (*R. Huisgen, R. Grashey*, and *J. Sauer*, 215 pp.). The peculiarities of olefins in combination with other double bonds are discussed in the articles on conjugated dienes (*M. Cais*, 71 pp.), cumulenes (*H. Fischer*, 135 pp.), and ketenes (*R. N. Lacey*, 67 pp.), the chapter on cumulenes giving a particularly comprehensive description of this class, which generally receives far too little attention. The book ends with a complete author index, the keying of which might advantageously be imitated in other books, and a subject index.

The up-to-date conception of the subject-matter of the individual chapters and the completeness and clarity of the whole make this book a model work, on which the editor and the authors are to be congratulated. An indication of the quantity of material presented in the book may be obtained from the fact that it contains more than 3500 references extending up to 1962/1963. As is pointed out in the preface, two chapters that were to be included, dealing with the important electrophilic reactions of olefins and the biochemical aspects of the carbon-carbon double bond, have been omitted because of late delivery by the authors; this is a regrettable loss in a book that is so much based on teamwork. Other topics that could have been included in the book are the chemistry of vinylmetal compounds and eliminations from olefins, reference to which is restricted to a few scattered examples. It must be admitted, however, that any additions to the text would have made it impossible to keep the book in the form of a single volume.

The book is well presented and, apart from a few printing errors, carefully produced. It is an important reference book that should have a place in every chemical library. Its broad distribution will be subject to the limits imposed by the price, which is unusually high even for a scientific book.

*G. Köbrich* [NB 425/295 IE]

**The Isoquinoline Alkaloids. A Course in Organic Chemistry.** By *K. W. Bentley*. Pergamon Press, Oxford-London- Edinburgh-New York-Paris-Frankfurt 1965. 1st Edit. VII + 264 pp., £ 1.5.0.

The isoquinoline alkaloids form a chemically and pharmacologically important group of natural products, with more than 400 members, including morphine and the tubocurare poisons. A monograph on this subject written by a leading expert in the field is therefore very welcome.

The book begins with a description of the methods of chemical degradation used in the determination of the structures of isoquinoline alkaloids. In the next twelve chapters, the various alkaloids are dealt with in turn, mainly from the point of view of the substances themselves, and a final chapter is devoted to their biosynthesis. This somewhat one-sided presentation may provide useful information for the initiated. Unfortunately, however, the author fails in his aim of producing a well-rounded monograph suitable for chemistry students. Thus the introduction to this book states that "in these days the structures of complex natural products may be elucidated with scarcely a reaction done at the bench, by the application of the modern tools of ultraviolet, infrared, nuclear magnetic resonance and mass spectrometry, and X-ray crystallography . . .", but no further information about these methods is given, despite the fact that they have been particularly useful in the study of the isoquinoline alkaloids.

The complete absence of references gives a false impression of the recent literature, and the reader will sometimes mistake the author's opinions for published findings (*e.g.* p. 65). On page 81, morphinan structures are given for crotonosine and its derivatives, and this is used as a basis for biogenetic conclusions; on page 154, on the other hand, we find that crotondsine is not a morphinan alkaloid. It is assumed that the numbering often used in the text of the sometimes complicated ring systems is known, and no explanation is given on any of the formulae. The amaryllidacea alkaloids with isoquinoline structures are not mentioned. Misprints which could easily cause confusion occur on pages 15, 18, 97, 243, and 247.

Nevertheless, as a valuable source of information, this book is worth a place in the specialist's reference library, and it might be possible to recommend a revised and enlarged second edition to a wider audience.

# The Scientific Work of Hans Meerwein

BY PROF. DR. R. CRIEGEE, KARLSRUHE (GERMANY) [*]

I have been honored with the difficult task of surveying the scientific work of *Hans Meerwein*. I shall base this outline on the 70 or so publications he produced in the course of 63 years (from 1903 to 1965), and on a manuscript prepared by him probably last year, which is to be published in "Chemische Berichte". I am not myself a student of *Meerwein*, but I worked in his institute as senior assistant for five years, from 1932 to 1937, and was therefore able to observe his work during this period from close quarters.

If, of the 70 publications mentioned, we disregard a few short communication, some reviews, and a number of papers on miscellaneous subjects, we are left with about 35 important and fundamental publications, each of which would justify a lecture by itself. Therefore I must confine my remarks to a very small selection.

The first step is to look for the sources of *Meerwein*'s creativeness. In the case of scientists, it is usually the teacher that gives the deciding impulses. However, *Meerwein* did not follow in the footsteps of *Schroeter*, his teacher. His development naturally was strongly influenced by the times in which he lived and by the people he met. Since he mentions nothing about this, even in his notes, we can only suppose that the people who had the greatest influence on him, through their personalities or through their work, were *Anschütz* in Bonn, *Claisen* in Godesberg, *Bredt* in Aachen, and *Werner* and *Pfeiffer*.

Many chemists, and not only the mediocre ones, allow themselves to be led by experiment. They make observations, they follow these up and try to explain them. Attempts to explain lead to new experiments, and these lead in turn to new observations. This was not *Meerwein*'s approach, who started off with deliberation, postulation, and hypothesis. These enabled him to make certain predictions, while experiment served to confirm these predictions – and his predictions nearly always were confirmed. How often, therefore, do we read in his publications that: "The result was as expected". Thus by far the major part of *Meerwein*'s discoveries were not accidental, but the logical outcome of his thinking. Only the discovery of the trialkyloxonium salts fell into his lap unexpectedly in the course of experiments; however, it seems certain that even without this "accident", he would have discovered these compounds later by planned experiments.

Let us now consider a few examples that illustrate *Meerwein*'s method of working, his arguments, and his results.

I shall begin with a field studied by *Meerwein* in his earlier years, namely that of Michael additions and ester condensations. This field is probably not so well known as the others, since the work was completed in 1922. The investigations led to a general method for the preparation of 1,5-dialdehydes and 1,5-ketoaldehydes, and culminated in a simple two-step synthesis of the bicyclo[3.3.1]nonane system from formaldehyde and malonic ester [1].

Two moles of a methylenemalonic ester *(1)* condense with one mole of a methylenebis(malonic ester) *(2)* under the influence of sodium ethoxide; a double Michael addition is followed by double elimination of carbonic ester to form the bicyclic diketotetracarboxylic ester *(3)*. This product could be converted not only into the unsubstituted hydrocarbon *(4)* but also into derivatives of two isomeric tricyclononanes *(5)* and *(6)*. Bicyclo[3.3.1]nonane *(4)* is a strainless hydrocarbon, which can be imagined to be cut out of the diamond

[*] Address given at a memorial service held at Marburg University (Germany) on January 15th, 1966.

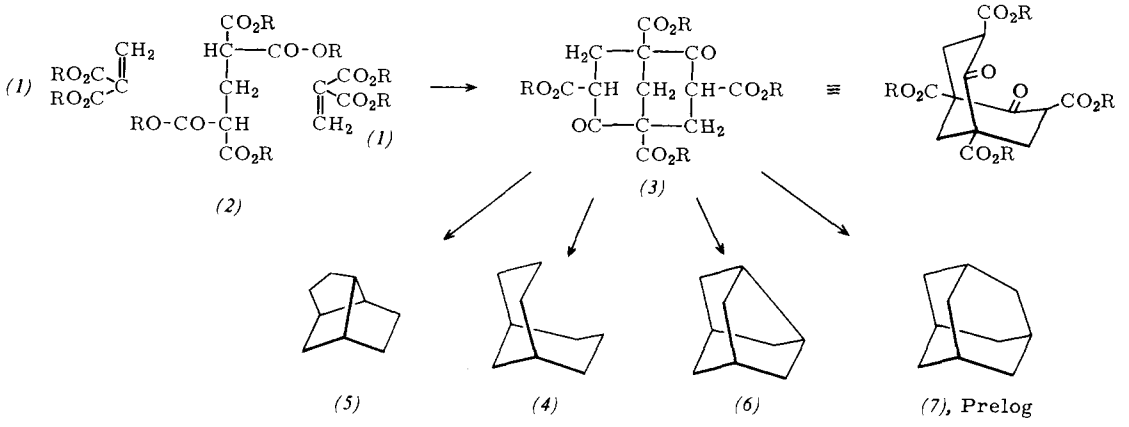
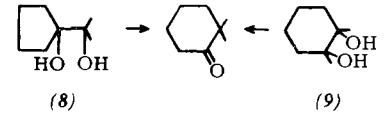
lattice, and in which both six-membered rings are in the chair form. Of the two tricyclic compounds, *(6)* also contains two cyclohexane rings in the chair form, whereas *(5)* contains two somewhat distorted cyclohexane boats. At a time when *Mohr* had just revived *Sachse*'s views on strainless rings, *Meerwein*'s experiments

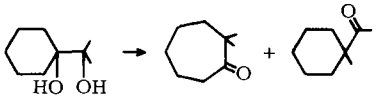


provided one of the earliest proofs. The freedom from strain of cycloheptane and the difference in reactivity of what are nowadays termed axial and equatorial OH groups were also first postulated and demonstrated experimentally by *Meerwein*. However, although he tried to synthesize adamantane *(7)* from his bicyclononane derivative *(3)*, it was not until 20 years later that this synthesis was achieved by *Prelog*.

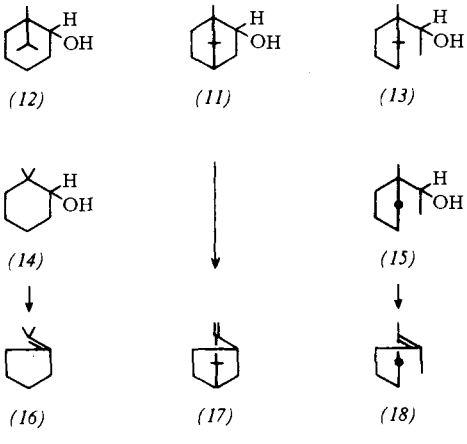
*Meerwein* was interested in the bicyclononane also because of its similarity to bicyclo[2.2.1]heptane (which, however, is strained). The latter system, which according to *Bredt* and others is the basis of camphor and its derivatives, fascinated *Meerwein* at an early stage, not as a structural unit of important natural products (the chemistry of which in the narrower sense remained foreign to him throughout his life), but because of the numerous rearrangements with far-reaching changes in the carbon skeleton that take place in this system. Though the structural relations among pinene, bornyl chloride, camphene, isoborneol, *etc.* were largely elucidated, the nature of the various rearrangements was still obscure.

*Meerwein* entered this field with model reactions on simple cyclic pinacols *(8)–(10)* [2]. He found that the





readily occuring pinacol rearrangement of these compounds is almost always accompanied by a change in the ring system, even though the starting compounds contain strainless rings. The same is true of the retro-pinacol rearrangement, an example of which, according to *Wagner*, is the conversion of borneol into camphene. If we imagine the bicyclic system of borneol *(11)* to be cut open in one of two places, we obtain two monocyclic "pinacolone alcohols" *(12)* and *(13)*. On acid-catalysed dehydration, the somewhat simpler lower homologues



*(14)* and *(15)* of these "model borneols" gave the olefins *(16)* and *(18)*, which differ from camphene *(17)* only in the position of the double bond. This showed that these rearrangements are by no means restricted to the bicyclic systems [3].

The possible occurrence of epoxides or cyclopropanes as intermediates in these rearrangements could be ruled out immediately, since the conversion of these into the end-products obtained proceeds (if at all) more slowly than that of the pinacols or pinacolone alcohols. The formation of "1,1-diradicals" (we would nowadays say "carbenes") by α-elimination, as suggested by *Tiefeneau*, was also ruled out by experiment. Thus camphor hydrazone *(19)* should give the 1 1-diradical on treatment with mercuric oxide. However, the product is not camphene *(17)*, but consists almost entirely of tricyclene *(20)* [4].

The solution of the problem was published in 1922 by *Meerwein* and *van Emster* (an old friend and colleague) in a paper entitled: The Equilibrium Isomerism Be-

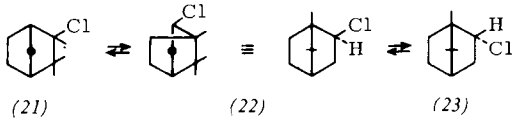
(19) (17) (20)



(21) (22) (23)

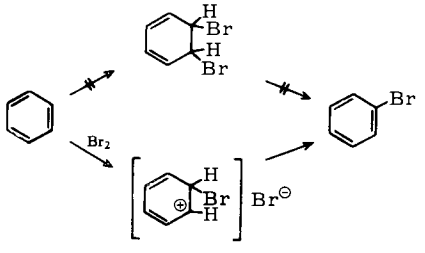
tween Bornyl Chloride, Isobornyl Chloride, and Camphene Hydrochloride [5]. First an analytical method was developed for the determination of the three chlorides *(21)–(23)* in the presence of one another, on the basis of the different reactivities of their chloro-substituents, and it was then possible to follow the rearrangements kinetically. They were all found to be first-order reactions, with rates depending very strongly on the solvent. The extremes were cresol on the one hand, and ether on the other. The effectiveness of the solvent was found to be determined by its "dissociating power", which *Walden* had determined by conductivity measurements on solutions of triphenylchloromethane. The rate of equilibration was affected to an equal or greater extent by complexing agents such as $ZnCl_2$, $FeCl_3$, $SnCl_4$, $SbCl_5$, *etc.* Somewhat later *Hamel*, *Serini*, and *Voster* showed that the rates of the corresponding rearrangements of esters of borneol, isoborneol, and camphene hydrate are also strongly affected by the strength of the esterifying acid.

This led to the now obvious, but then revolutionary conclusion that all these rearrangements are preceded by an ionization, and that the regrouping of carbon atoms takes place in the resulting carbonium ions. Solvents with high dielectric constants, complexing agents, and strong esterifying acids stabilize the ions and so facilitate the heterolysis leading to their formation. Since the ions can only be detected indirectly, *Meerwein* called them "cryptoions".

The idea of ionic reaction mechanisms in organic chemistry was not generally accepted at first, since ionic reactions were held to belong to the realm of inorganic chemistry. It must be remembered that *Lewis*' electronic theory had only just been developed and had not yet found a foothold in Germany, so that concepts such as lone pair of electrons, electron deficiency, sharing of electron pairs, nucleophilic, and electrophilic were still unknown. Nevertheless, *Meerwein* used just these concepts, though in his own terminology derived from complex chemistry.

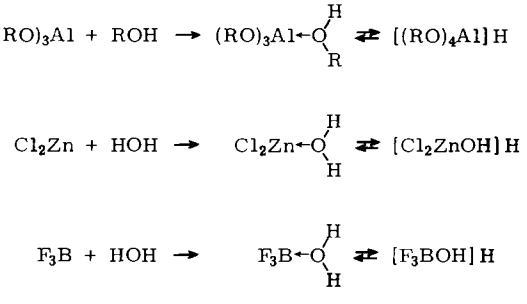
In the meantime, the number of known Wagner-Meerwein rearrangements, as rearrangements proceeding *via* a sextet of electrons on carbon are now generally called, has increased tremendously. To these have been added rearrangements involving sextets on nitrogen and on oxygen. The question now no longer is whether these rearrangements are ionic, but whether they involve classic or non-classic ions, or intimate or solvent-separated ion pairs. It is easy to forget that these are mere questions of detail in comparison with *Meerwein*'s fundamental discoveries.

*Meerwein* was quick to recognize the significance of his ideas, which extended far beyond the rearrangements in the camphor series. In a lecture to the 1925 meeting of the Verein Deutscher Chemiker in Nuremberg on the problem of orientation in substitutions on aromatic compounds [6] he modified the *Thiele-Wieland* theory of substitution *via* addition by assuming that only a single bromine cation was added to the benzene, while the bromide anion remained bound in the "outer coordination sphere". However, this is nothing else but the theory of electrophilic aromatic substitution developed later by *Pfeiffer* and *Wizinger* and perfected by *Ingold*.



(24)

The catalytic action of metal halides such as zinc chloride or antimony pentachloride was also recognized in 1926 as a general principle [7]. These halides, like many other electron-accepting compounds, are ansolvo acids (now known as Lewis acids). "Complex formation", *i.e.* reaction with the nucleophilic centers of water, alcohol, or carboxylic acids, leads to strong protonic acids.



Thus aluminum alkoxides react with alcohols to form alkoxy-acids, the acidic protons of which can be esterified with diazomethane. It is possible in this way to convert alcohols (which do not react as such with diazomethane) into methyl ethers [8]. The catalytic action of zinc chloride in the inversion of sugars or in the elimination of water from alcohols is also explained by the formation of dissociable "esters" of complex zinc acids. Many salts of such acids have been prepared. *Meerwein* also explained the solubility of aluminum hydroxide in

[5] *H. Meerwein* u. *K. van Emster*, Ber. dtsch. chem. Ges. *55*, 2500 (1922).

[6] Angew. Chem. *38*, 815 (1925).

[8] *H. Meerwein* and *G. Hinz*, Liebigs Ann. Chem. *484*, 1 (1931).

alkalis by the formation of salts of complex hydroxo acids.

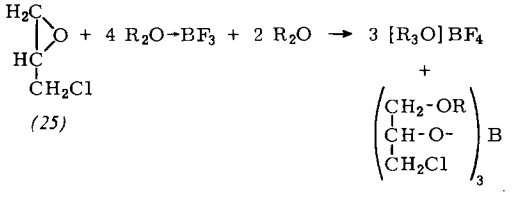
Just as the O–H bond in alcohols can be activated by complex formation with ansolvo acids, so the C=O double bond can be polarized and hence activated by complex formation. Whereas acetone does not react with diazomethane, its molecular complexes with water, alcohols, or lithium chloride react rapidly with diazomethane to form epoxides together with homologous ketones [9]. *Eugen Müller* recently developed these findings into a synthesis of homologous cyclic ketones.

These experiments also led *Meerwein* to study the photochemical decomposition of diazomethane in solution. Together with *Rathjen* and *Werner* [10] he found that the methylene formed can insert into any C–H bond, and so, *e.g.* from diethyl ether, produce a mixture of homologous ethers. This insertion is typical of "hot" carbenes. The formation of tricyclene *(20)* from camphor hydrazone *(19)* is an intramolecular variant of this reaction.

With benzene, on the other hand, the ring is expanded to form tropilidene, a result that prompted several research groups to carry out intensive investigations on the tropilidene-norcaradiene isomerization.

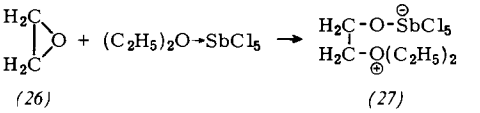
Among the complexing agents mentioned earlier, boron trifluoride occupies a special place because of its small molar volume [11]. Its numerous addition compounds, which were studied by *Meerwein*, are characterized by exceptional stability. The boron trifluoride hydrates and alcoholates behave as strong acids, the compounds with ethers resemble the esters of mineral acids, and those with esters the acid anhydrides. These relations made possible many catalytic reactions such as esterifications, condensations, rearrangements, and polymerizations, but these cannot be discussed here. Instead we shall consider in more detail the role of boron trifluoride in the preparation of tertiary oxonium salts.

Probably one of the most fruitful of *Meerwein*'s discoveries was that of the trialkyloxonium salts, jointly with *Kroning* in 1937 [12]. These long-sought analogues of quaternary ammonium and tertiary sulfonium salts were obtained unexpectedly when epichlorohydrin *(25)* was treated with boron trifluoride etherate.

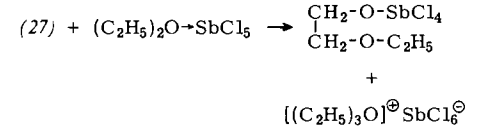


*(25)*

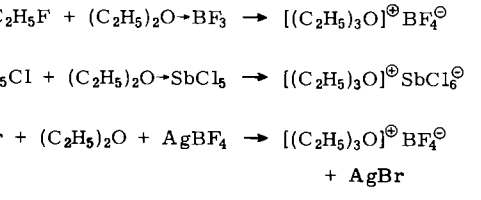
The mechanism of this complex reaction was later elucidated, and will be illustrated here for the somewhat simpler reaction of ethylene oxide *(26)* with the etherate of antimony pentachloride. The first step is cleavage of the oxirane ring to form a zwitterion *(27)*, which transfers an ethyl residue, as a cation, from the oxygen onto a second molecule of $SbCl_5$ etherate.



*(26)* *(27)*



A simpler reaction, but a preparatively less useful one because of its slowness, is that of ethyl fluoride with boron trifluoride etherate. Here, the energy loss on formation of the triethyloxonium ion is compensated by the energy gain accompanying formation of the stable $BF_4^{\ominus}$ anion. Other routes include the reaction of ethyl chloride with $SbCl_5$ etherate, and particularly the reaction of ethyl bromide in ether with silver fluoroborate. The mixture of ethyl bromide and $AgBF_4$ has also proved eminently useful for other alkylations [13].



The trialkyloxonium salts, which superficially are very similar to the tetraalkylammonium salts, are the strongest alkylating agents known. They react as expected for "free" alkyl cations; they are, in fact, stabilized alkyl cations in the same sense that the hydroxonium ion is a stabilized proton. For this reason nearly all simple anions are alkylated immediately, so that trialkyloxonium cations are stable only when accompanied by stable complex anions.

Many paths led to new discoveries from the trialkyloxonium salts. *Meerwein* opened up these paths essentially only after his retirement, *i.e.* at an age when creativity is declining rapidly. Fifteen valuable and lucidly written papers, all published after his 70th birthday, and the last after his 85th, showed that his genius was not dimmed by old age. A few examples may again suffice:

Ethers are alkylated by trialkyloxonium salts to form other oxonium salts. Thus the simplest route to trimethyloxonium salts is *via* the mixed oxonium salt formed by ethylation of dimethyl ether. An alkyl cation also adds readily to the oxygen atom of tetrahydrofuran *(28)*.

[9] *H. Meerwein* and *W. Burneleit*, Ber. dtsch. chem. Ges. *61*, 1840 (1928); *H. Meerwein, Th. Bersin*, and *W. Burneleit, ibid. 62*, 999 (1929).

[10] *H. Meerwein, H. Rathjen*, and *H. Werner*, Ber. dtsch. chem. Ges. *75*, 1610 (1942).

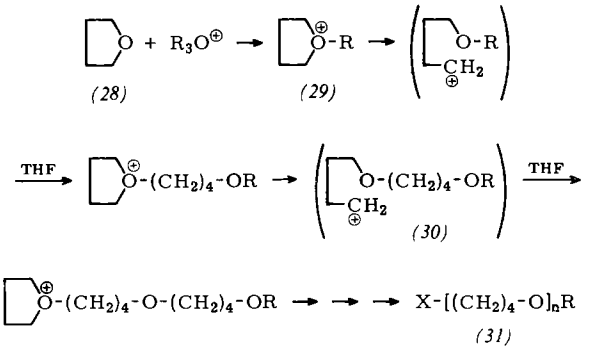
[11] *H. Meerwein*, Ber. dtsch. chem. Ges. *66*, 411 (1933); *H. Meerwein* and *W. Pannwitz*, J. prakt. Chem. [2] *141*, 123 (1934); *H. Meerwein* and *D. Vossen, ibid. 141*, 149 (1934).

[12] *H. Meerwein, G. Hinz, P. Hoffmann, E. Kroning*, and *E. Pfeil*, J. prakt. Chem. [2] *147*, 257 (1937); *H. Meerwein, E. Battenberg, H. Gold. E. Pfeil*, and *G. Willfang, ibid. 154*, 83 (1939).

[13] *H. Meerwein* and *K. Wunderlich*, Angew. Chem. *69*, 481 (1957); *H. Meerwein, V. Hederich*, and *K. Wunderlich*, Arch. Pharmaz. Ber. dtsch. pharmaz. Ges. *291*,581 (1954).

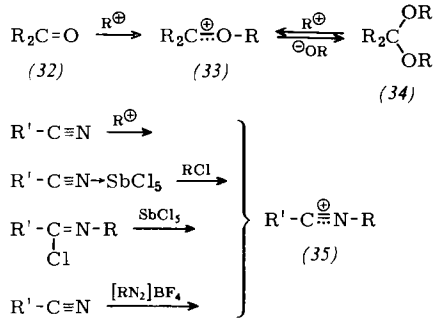
[14] *H. Meerwein, D. Delfs*, and *H. Morschel*, Angew. Chem. *72*, 927 (1960).

The resulting mixed oxonium salt *(29)* can alkylate a second molecule of THF, while itself undergoing ring scission, to form a new oxonium salt *(30)*, which can then alkylate a third THF molecule. The reaction continues in this way with formation of macromolecular ethers. The chain is terminated by addition of a foreign nucleophile, *e.g.* a halide ion derived from the complex anion. The chain lengths of the resulting polyethers therefore depend on the stability of the complex anions present. The trialkyloxonium salts used as initiators may be prepared *in situ*. This is a typical cationic polymerization, all the steps of which have been elucidated [14].



*(28)* *(29)* *(30)* *(31)*

Ketones *(32)* are alkylated by oxonium salts to give carboxonium salts *(33)* [15], the cations of which are stabilized by resonance. Their reactivity is determined by the carbonium limiting form. They react with alkoxides to give acetals *(34)*. Conversely, they can be obtained with trialkyloxonium salts from the acetals; the alkyl cation removes an alkoxide ion from the acetal to form an ether.



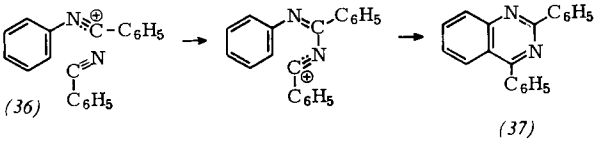
*(32)* *(33)* *(34)* *(35)*

Nitriles can similarly be converted into nitrilium salts *(35)* [16]. *Meerwein* later found further methods for the preparation of this new class of compounds. The antimony pentachloride adducts of nitriles react with alkyl chlorides to form nitrilium salts. These are also formed from *N*-substituted imide chlorides with $SbCl_5$, *N*-arylnitrilium salts being formed when the nitrogen carries an aryl substituent. However, nitriles also can be arylated directly with diazonium fluoroborates. Finally, acylnitrilium salts are obtained when acyl chlorides react with molecular compounds of nitriles with metal chlorides. In most cases, however, two molecules of nitrile react with one molecule of acyl chloride to form salts with very marked resonance stabilization.

[15] *H. Meerwein, K. Bodenbrenner, P. Borner, F. Kunert,* and *K. Wunderlich*, Liebigs Ann. Chem. *632*, 38 (1960).

[16] *H. Meerwein, P. Laasch, R. Mersch,* and *J. Spille*, Chem. Ber. *89*, 209 (1956).

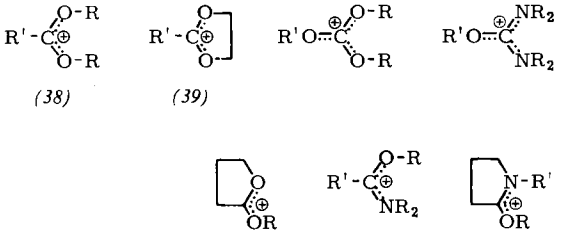
*N*-Arylnitrilium cations *(36)* containing at least one free *ortho* position in the benzene ring react readily with a second molecule of nitrile to form quinazolines *(37)* [17]. The course of the synthesis, in which neither the nitrilium salts nor the imide chlorides used in their production need be prepared as such, can be seen from the following scheme:



*(36)* *(37)*

Diphenylquinazoline is obtained in 86% yield in a single-stage reaction from benzanilide, benzonitrile, thionyl chloride, and aluminum chloride.

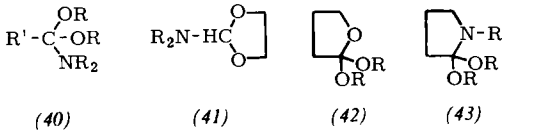
In compounds containing several nucleophilic centers, the alkyl cation, like the proton, reacts in such a way as to give the cation with the greatest resonance stabilization. The most important types of salts prepared from such compounds are shown in Scheme 1 [18]. They are obtained by alkylation of esters of carbonic acid, lactones, amides, lactams, or substituted thioureas with trialkyloxonium salts. The first two types, *(38)* and *(39)*, can also be obtained by abstraction of alkoxide ions from ortho-esters with alkyl cations. The dioxolenium salts *(39)* are particularly stable, probably because of their necessarily planar structure.



*(38)* *(39)*

Scheme 1. Carboxonium salts prepared from compounds containing several nucleophilic centers.

The constitution of these salts was determined by reaction with alkoxide; the products in every case were derivatives of ortho-acids, compounds *(40)–(43)* being of a new type.



*(40)* *(41)* *(42)* *(43)*

The great significance of the numerous reactions with alkyl cations lies in the fact that these are models for acid-catalysed reactions. Whereas the products resulting from protonation of the various substrates cannot usually be isolated, the alkylation products can be readily isolated in the form of stable salts [19].

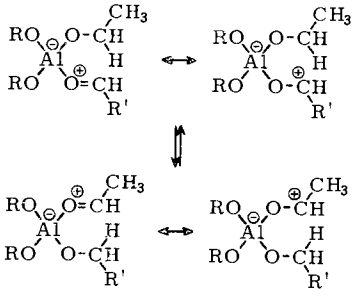
[17] *H. Meerwein, P. Laasch, R. Mersch,* and *J. Nentwig*, Chem. Ber. *89*, 224 (1956).

[18] *H. Meerwein*, Angew. Chem. *63*, 480 (1951); *H. Meerwein, W. Florian, N. Schön,* and *G. Stopp*, Liebigs Ann. Chem. *641*, 1 (1961).

[19] *H. Meerwein*, Angew. Chem. *68*, 356 (1956); *H. Meerwein, P. Borner, O. Fuchs, H. J. Sasse, H. Schrodt,* and *J. Spille*, Chem. Ber. *89*, 2060 (1956).

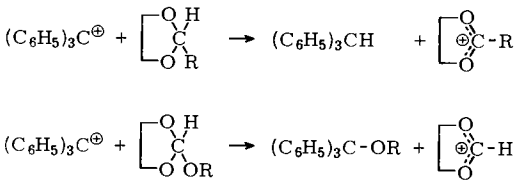
In conclusion let us consider a few reactions having the common feature of the transfer of a hydride ion (and in many cases of an alkoxide or cyanide ion) onto a carbonium ion. These include the well-known Meerwein-Ponndorf reaction, discovered by *Meerwein* and *Schmidt* [20] in 1925 and later extended by *Ponndorf* and *Verley*.

This reaction involves the exchange of oxidation states between an aldehyde or ketone and a primary or secondary alcohol under the catalytic action of an aluminum alkoxide. This forms a complex with the carbonyl component; the "activation by complex formation" consists in the formation of a latent electrophilic center on the carbonyl C-atom, to which the hydride ion migrates, presumably by a cyclic mechanism:



The reverse of this reaction has also become important as the Oppenauer oxidation.

A still more versatile class of reactions is that of the intermolecular anion shifts [21]. The acceptors are carbonium or diazonium ions; on loss of the anion, the donor is converted into a resonance-stabilized cation. The last of these reactions [22] is noteworthy in that the well-known reduction of diazonium salts is carried out with ethers or acetals instead of alcohols. The yields are appreciably better, since no phenol ethers can be formed as by-products.



Much of *Meerwein*'s work has only been hinted at in this survey and much (*e.g.* the Meerwein reaction, *i.e.* the arylation of α,β-unsaturated nitriles, esters, ketones, *etc.*, with diazonium salts [23]) has not even been mentioned. However, it is not the volume, but the substance of his work that is important, *i.e.* the perception of the courses of many reactions, the discovery of ionic processes in organic chemistry, the recognition of the role of complexing agents as catalysts and initiators, and the extension of our knowledge of the carbonium, oxonium, and diazonium ions. *Meerwein* is justifiably regarded as one of the originators of theoretical organic chemistry. He also showed that nothing is of greater practical use than a good theory, since his own theory led him to many new methods, including even industrial processes.

The description of *Meerwein*'s scientific work and the reference to his extensive literary activity also sheds some light on his personality, but the picture gleaned in this way is not complete. To appreciate fully the infectiousness of his enthusiasm one must have discussed with him and listened to his lectures, in which every sentence was clearly formulated, and which held his audience from beginning to end. This is how he will be remembered by all his friends, colleagues, and students. May the flame of enthusiasm for our science that he has kindled in all of them be handed on to future generations like an Olympic flame.

# Hans Meerwein, the Teacher and the Man

BY PROF. DR. K. DIMROTH, MARBURG (GERMANY) [*]

*Hans Lebrecht Meerwein* died suddenly on October 24th, 1965. Among the few personal belongings found in his office at the University Chemical Laboratories of Marburg was a small black notebook. It lay in the drawer of his desk, together with some of the many medals and awards that had been bestowed upon him during the later years of his life.

This notebook relates his association with the family home in Hamburg, an association that flourished to the end of his days. The entries are inscribed in the beautifully clear hand of his father *Wilhelm Emil Meerwein* whom he always held in high regard. They relate

[*] Address given at a memorial service held at Marburg University on January 15th, 1966.

the history of the Meerwein family. The story unfolds like an exciting novel, telling of his father's development from the student of architecture with only a casual interest in his subject, to the highly respected and honored master-builder and citizen of the Hanseatic city of Hamburg. Having begun this chronicle at the age of 59, *Wilhelm Emil Meerwein* laid down his pen when he was 81 years old, having added to the tale at intervals of five or ten years. The last two pages are written in another hand, evidently after his death, and contain additions based on notes which had come to light.

At the beginning we find a sentence which seems to me so typical of the relationship between different generations as to merit quotation:

> Even though today my children show no great inclination to acquaint themselves with their family's history, may the time come one day when one or the other of them will be glad to learn from the past.

*Hans Meerwein* was 26 when his father wrote these words in 1905. At the beginning of that year he had taken up his first position as an assistant lecturer at the Chemische Institut at Bonn, under Professor *Richard Anschütz*. On the subject of this appointment his father wrote:

> Although the salary was modest I advised him to take the post, since I think that he is better suited to a career in science than to the practical life.

Having spent his youth in Hamburg, *Hans Meerwein* always looked upon it as his home town. His father, who came from a southern part of Germany, first settled there in 1873, setting up business as an architect in partnership with *Bernhard Hanssen*, his friend from student days. It was through the latter that he met his future wife, *Hanssen*'s sister-in-law *Mathilde Schmilinsky*, whom he married in 1877. Her maternal grandfather had owned a well-known iron foundry and the family had been long established in Hamburg. Its name is familiar to its citizens through a generous foundation, unfortunately deprived during World War II of the large orphanage built by the elder *Meerwein*, as well as through the Schmilinsky-Strasse, named in honor of the founder, an uncle of *Meerwein*'s mother.

While *Hans Meerwein* was still at school at the Hamburger Gelehrtenschule Johanneum, his father set up for him a small chemical laboratory. Here at home he was able, as he himself related afterwards, to carry out all the fundamental experiments known to chemists of that time. Nevertheless, when he graduated from school in 1898, he did not go immediately to a university, but first spent three semesters at the Wiesbaden College of Chemistry run by *Heinrich* and *Wilhelm Fresenius*, where he studied analytical theory and practice. There he obtained a basis which proved to be invaluable for his later work. The careful development of simple methods of qualitative and quantitative analysis characterizes much of *Hans Meerwein*'s scientific work, and it was precisely this approach which enabled him to gain a clear insight into the often complicated course of chemical reactions.

He enrolled at Bonn University in the summer semester of 1900. Not long afterwards he commenced work for his doctorate with *Georg Schroeter*, who was some ten years older than himself and had only recently qualified as a lecturer. In February 1903, after only six semesters of university work, *Meerwein* successfully defended his thesis "On nitrated β-phenylglutaric acids". After studying for some time in Berlin-Charlottenburg, he returned to Bonn early in 1905, at the invitation of the then director of the Chemische Institut at Bonn, Professor *Richard Anschütz*, to take up the assistant lectureship already referred to.

*Hans Meerwein* remained in Bonn until 1923. For many years he must have moved in a stimulating circle of artists and other high-spirited companions. He frequently looked back with pleasure to this period. Gradually, however, his duties increased. Having qualified in 1908 with his inaugural dissertation "On the condensation reactions of α,β-unsaturated aldehydes", he took over in 1910 the position of his former tutor *Georg Schroeter* who had gone to Berlin as Professor of Chemistry at the Veterinary Academy.

During his years in Bonn *Meerwein* concentrated his work on organic rearrangements, particularly in the terpenes and in camphor derivatives. He taught a great many students, with most of whom he established a firm and lifelong friendship. I shall single out only one of them, *Karl Freudenberg*, who passed the practical laboratory courses under him and who was to be for many years the director of the Chemische Institut at Heidelberg. In honor of *Freudenberg*'s 80th birthday on January 29th, 1966, *Meerwein* dedicated to him a paper entitled "On chlorodimethylsulfonium salts". When sending the manuscript to the editor of Liebigs Annalen der Chemie, Professor *Richard Kuhn*, on January 22nd, 1965 he wrote that it would probably be his last paper. It was published in the 688th volume of Liebigs Annalen on October 7th, 1965, just two weeks before *Hans Meerwein* died. It was indeed the last contribution to this great man's work.

In 1923 *Hans Meerwein* was invited to take the Chair of Chemistry at Königsberg. He accepted the position at a difficult time, when the Institute had become practically ineffectual through the ravages of war and inflation. Nevertheless, he succeeded within a short time in restoring the institute to a high standing. He had a relatively small number of students, many of whom were later to reach high positions in the chemical industry, thanks to the excellent training they had received under him. With their assistance he explored two new domains, and in doing so laid the foundation for his future scientific renown: the theory of "cryptoions" as intermediates of many organic reactions, and the formation of complex ions and acids, the "ansolvo acids", as he called them. The reduction of unsaturated aldehydes, named after him, also dates back to those years; it was developed in collaboration with the chemical industry and for some time used in the production of important pharmaceuticals.

Admittedly, much of *Meerwein*'s work received scant recognition at that time. The great chemists of the period were engaged in the elucidation of natural products. Interest was concentrated on the discovery

of vitamins and hormones and the study of their relationship with the enzymatically catalysed processes in organisms. This may be the explanation for the rejection by a leading scientific journal of one of *Meerwein*'s pioneering papers on the ionic mechanism of many organic reactions, on the grounds that it was too speculative. *Meerwein*, who was never a fighter, yielded, though he never doubted the correctness of his views. He knew that in any case the truth would prevail sooner or later. For many years he published no papers in that periodical and preferred to write for the Journal für Praktische Chemie. Partly for similar reasons, he published his fundamental work on complex anions in the "Abhandlungen der Königsberger Gelehrtengesellschaft," and only parts of this still highly interesting paper appeared in more readily accessible journals at a later date. Consequently, many years passed before he received the recognition that was his due. We must confess with some shame that his work has only been fully appreciated in Germany after the end of World War II, and then largely as a result of the high regard in which he was held by American chemists, who consider him as one of the founders of modern organic chemistry. *Meerwein* was fortunate enough to live to witness this change.

Nevertheless, his reputation even in those early years was such that in 1928 he was almost simultaneously offered a professorship at the Universities of Leipzig and Marburg. It seems typical of the man that he gave preference to the smaller university, where he had fewer distractions to fear from administrative and representative duties.

His scientific achievements as a successor to *Karl von Auwers* in the 23 years during which he was head of the Chemische Institut at Marburg, and in the 13 years which followed his retirement from his chair, are unique. To the very end of his life he continued to develop original ideas, and only three weeks before his death he engaged a new post-doctoral assistant at his laboratory with the intention of approaching an old problem, connected with his dissertation, using new concepts and methods.

The discovery of the oxonium salts, the polymerization of tetrahydrofuran and consequently the discovery of cationic polymerization, the discovery of nitrilium salts, the use of carbonium ions instead of protons, which led to new syntheses and reactions of acetals, lactams, and orthoesters, the reactions of alkyl halides with silver fluoroborate or those of diazomethane and aromatic diazonium compounds, are just some of the many topics he studied.

In his teaching capacity, *Hans Meerwein* introduced generations of students to chemistry and guided their progress in their daily laboratory work. His fascinating lectures, supported by brilliant demonstrations, were an unforgettable experience. He had mastered the knack of building up suspense in his listeners to the point when, usually in a startling and unexpected manner, the solution to the problem struck them as if of its own accord.

He advised his students and co-workers also to use the element of surprise in their lectures. It was better, he said, to lecture less frequently, but then to present to the audience new and unexpected material.

Whenever a chemist attracted *Meerwein*'s attention by his originality and acumen, he invariably received the fullest measure of encouragement. The scientific achievements of many young chemists received his support, frequently even without their being aware of it. He did everything he could to bring on the rising generation of chemists, never hesitating to recommend gifted and even very young men for responsible and challenging positions.

To this period at Marburg also belongs the rebuilding of the Chemistry Laboratory after the last war. A new building had been approved at about the time of his appointment. However, by the time he had completed the plans, prepared with all the talent inherited from his father, it was too late: the political circumstances at the universities after 1933 led to a decline in student numbers, and to the rescinding of the earlier approval. Thus it happened that the bold plans for the building were never put into practice. Nevertheless he did have the opportunity of demonstrating his architectural skill, albeit on a much more modest scale, during the rebuilding of the Institute after its destruction in World War II. Thanks to his splendid planning, the new Marburg laboratory was for many years considered as one of the foremost with regard to design and equipment. Even today, it is only lack of space which necessitates the replacement of the present facilities by a new building at another location.

On numerous occasions *Meerwein* has been concerned with literary work falling somewhat outside his own field. The first instance was when he succeeded *Schroeter* in the preparation of the 11th edition of *Richter-Anschütz*, the most comprehensive textbook of organic chemistry of its day. After the last war he worked with *Eugen Müller*, *Otto Bayer*, and *Karl Ziegler* on the new edition of Houben-Weyl, Methoden der Organischen Chemie. Twenty volumes have appeared to date, and only those intimately involved in the work know the full extent of his own efforts. We are indebted to him not only for many useful suggestions, but also for a number of contributions on his own particular fields of interest. As with all his published work, they are models of clarity and precision. He continued working on this project to the last: on his desk were found new drafts for a chapter on condensation reagents, which never ceased to interest him and which had been the subject of much thought and discussion with others.

I have not yet referred to his last work. It was found hidden among other and quite unrelated papers in his otherwise meticulously ordered office. *Meerwein*, who was always glad to talk about his current work, who never missed an opportunity to discuss the problems which occupied his mind, spoke to no one about this last manuscript. It is a comprehensive account of his own life's work. This account, on which he worked to the last day of his life and the last pages of which, just as his father's chronicle, lay unfinished upon his desk, will be his crowning achievement. It is to appear in

Chemische Berichte, successor to the Berichte der Deutschen Chemischen Gesellschaft, which had once shown a lack of appreciation by rejecting one of his most important papers. In this way the man to whom chemistry was his life and who has more than any other in our time disseminated new ideas among chemists all over the world, has continued his father's work in his own way by dedicating himself to research. In so doing he has created for himself the finest memorial.

# Scrambling Equilibria and Analysis of Labile Mixtures

BY DR. J. R. VAN WAZER AND DR. K. MOEDRITZER

CENTRAL RESEARCH DEPARTMENT, MONSANTO COMPANY, ST. LOUIS, MISSOURI (U.S.A.)

*In this brief review, it is attempted to point up the importance of chemical equilibria in structural inorganic chemistry and to show how the kind and yield of various molecules may be treated quantitatively. Because of the importance of kinetic control in organic chemistry and because the chemistry of carbon compounds is by far the most advanced branch of general and descriptive chemistry, preparative inorganic chemists have often overemphasized the value of reaction-mechanism theory to their studies and have thereby neglected the powerful quantitative approach of thermodynamics which may be used in equilibrated systems. The general theorems for treating in terms of small molecular segments the multitude of equilibria present in families of compounds are surveyed superficially with the hope that the interested reader will turn to the original papers for details. Not only physical-inorganic chemists, but also those interested solely in preparative work can advantageously employ the theoretical ideas discussed.*

## I. Introduction

Reactions involving only carbon compounds are generally kinetically controlled (*i.e.*, the structure of the products is determined by the reaction mechanism). However, compounds having elements other than carbon in the spine of the molecule are often quite labile, so that the amounts and kinds of reaction products may be thermodynamically controlled (*i.e.*, by the position of an equilibrium), with different reaction mechanisms leading to identical products and product distributions. Most oligomeric compounds not based on C–C backbones are easily disrupted and therefore, under suitable conditions, readily undergo "scrambling" reactions involving exchange of parts between the same or adjacent molecules [1]. It is these scrambling reactions that complicate separations, lead to unreliability in elucidation of structure by degradation or synthesis, and cause many preparations of supposedly pure compounds to consist of mixtures of molecules at or near equilibrium with respect to exchange of parts among them.

In these cases the usual postulates as to reaction mechanism are no longer fruitful for explaining reaction products, and must be replaced by the mathematically more complicated approach of thermodynamics and its underlying statistics of molecules (statistical mechanics and stochastic theories of molecular structure and configuration).

[1] *J. R. Van Wazer*, Amer. Scientist *50*, 450 (1962).

Of course, we do not wish to imply that reaction mechanisms are always inapplicable to the rationalization of reaction products in inorganic chemistry. There are a number of areas (*e.g.*, the square-planar platinum complexes) in which the energetics along the reaction coordinate are ideally suited to present-day interpretative techniques of reaction-mechanism theory. However, when reaction products are to be ascribed to kinetic control the examples [2] must be carefully selected when working with compounds based on elements other than carbon.

## II. Techniques of Experimentation and Data Treatment

### 1. Analysis of Mixtures

#### a) Nuclear Magnetic Resonance

During the last 10 years, high-resolution NMR spectroscopy [3] has become a major analytical tool. At present, the most suitable nuclei for quantitative NMR measurements are $^{1}H$, $^{19}F$, and $^{31}P$. Nuclei exhibiting quadrupole moments, such as $^{11}B$, are ill-suited for quantitative assay of mixtures (using the magnetic-field strengths obtainable with non-superconducting magnets) because of excessive line broadening. Problems of line broadening may also be introduced by paramagnetic

[2] *H. Taube*, Chem. Rev. *50*, 69 (1952).

[3] *J. A. Pople, W. G. Schneider*, and *H. J. Bernstein*: High-resolution Nuclear Magnetic Resonance. McGraw-Hill, New York 1959.

impurities, so that the presence of a few p.p.m. of iron in a sample may cause coalescence of important fine structure in the NMR spectrum. The emphasis on hydrogen, fluorine, and phosphorus in practical high-resolution NMR spectroscopy is not as much of a limitation as would appear, since the NMR spectra are often very sensitive to changes in molecular structure occurring many atoms removed from the position of the magnetically active nucleus in the molecule. For example, Fig. 1 shows separate resonance peaks [4] for various values of n in a mixture of dimethyl polysulfates, $CH_3O(SO_3)_nCH_3$. For $n > 9$, resonances for the individual molecules cannot be resolved with the present apparatus. This means that the chemical shift of the hydrogen of a methyl group is appreciably affected by the substitution of carbon for sulfur at a position 21 atoms removed from the hydrogen (one C, then an O, plus nine S alternating with nine O, followed by the sulfur or carbon atom in question).

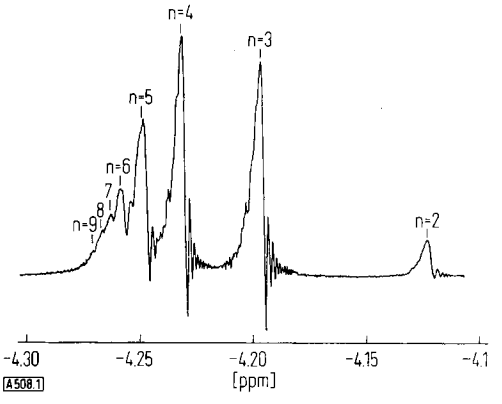

Fig. 1. The $^1$H-NMR spectrum of an equilibrated mixture of dimethyl polysulfates [4], $CH_3O(SO_3)_nCH_3$, taken on a Varian A-60 spectrometer modified to give a sweep width of 25 cps. The composition of this mixture equilibrated at 72 °C is given by a $CH_3$:S mole ratio of 0.22. The resonances for n = 8 and 9 can be reproducibly distinguished.

This ability to see in depth into a molecule [5] enables mixtures of molecules to be assayed in detail if at least some of the monofunctional exchangeable substituents or the molecular backbones or any nonexchangeable groups on the backbone atoms contain hydrogen, fluorine, or phosphorus atoms so arranged that their NMR spectra are not unduly complicated by spin-spin interactions. A methyl group is a particularly valuable substituent in this respect, since all three hydrogens are in chemically equivalent positions and their NMR signals do not show fine structure due to spin-spin splitting by hydrogens within the substituent, such as is found for ethyl or phenyl groups. Likewise, the methylene hydrogens of a benzyl group are suitable for quantitative analysis of mixtures by $^1$H-NMR spectroscopy, since there is inappreciable coupling between these hydrogens and those of the phenyl ring. We have found the following monofunctional substituents, which remain intact throughout most exchange reactions, to be particularly advantageous: H, $CH_3$, $C_6H_5CH_2$, $ClCH_2$, $CH_3O$, $CH_3S$, $(CH_3)_2N$, $(CH_3)_3C$, $(CH_3)_3Si$, F, $F_3C$, and (with poorer results because of the inclusion of an extra intermediate atom) the groups $(CH_3)_3CO$, $(CH_3)_3SiO$, and $CH_3C(O)O$. Certain bridging groups are also very useful in this respect, *e.g.* $CH_3N <$, $CH_2 <$, and $(CH_3)_2Si <$. Since all of the measurements described herein were performed on single-phase liquids or solutions, the resulting data correspond to a total analysis of all the components in the system under study [6].

Equilibria between compounds not containing suitable NMR-active nuclei may be indirectly studied by NMR spectroscopy. Thus the scrambling of, say, isocyano groups with bromine atoms on germanium [*i.e.*, equilibria between compounds of the type $Ge(NC)_iBr_{4-i}$], can be investigated by studying the exchange of these substituents on dimethyl-and monomethylgermanium moieties (which remain intact) and extrapolating the results to the case of methyl-free germanium. By these procedures, it is possible to attack quantitatively such experimentally difficult problems as the molecular constitution of silicate glasses.

The time and temperature required for a particular system to reach equilibrium with respect to scrambling of substituents is determined in a series of pilot experiments. Equilibrium is deemed to be attained when the NMR pattern of the sample remains constant for prolonged times at a given temperature.

NMR spectroscopy may be used to investigate rapidly equilibrating systems, the individual components of which cannot be separated by distillation [7]. However, when the rate of exchange becomes too rapid, the individual resonances coalesce to a single sharp peak which is difficult to interpret in terms of individual components of a mixture [3]. The rates of exchange may, of course, be reduced by lowering the temperature or by dilution with a solvent. Signals separated by about 200 c.p.s. allow a quantitatively analysis for components of short lifetimes (*e.g.* $10^{-3}$ sec) in mixtures. In Fig. 2, $^{19}$F- and $^1$H-NMR spectra are presented for the mixture [7] obtained on equilibrating 1.25 moles of $AsF_3$ with 1 mole of $As[N(CH_3)_2]_3$. This Figure illustrates the good resolution obtained for the widely separated fluorine peaks of the neat liquid as compared to the closely spaced hydrogen resonances which were not resolved sufficiently for quantitative assay until 18–20 parts of a solvent were added. From the widths of the allow a quantitative analysis for components of short of the $^1$H resonances, it is estimated that the rate of exchange of fluorine and dimethylamino groups on arsenic corresponds to an average lifetime of *ca.* $4 \times 10^{-3}$ sec in the neat liquid at room temperature.

### b) Assignment of NMR Signals

There are several general methods for assigning the various NMR peaks of a mixture. First the chemical shifts of the pure starting materials are determined. These data may be

[4] *J. R. Van Wazer, D. Grant,* and *C. H. Dungan,* J. Amer. chem. Soc. *87,* 3333 (1965).

[5] *J. R. Van Wazer* and *D. Grant,* J. Amer. chem. Soc. *86,* 1450 (1964).

[6] *L. C. D. Groenweghe, J. R. Van Wazer,* and *A. W. Dickinson,* Analytic. Chem. *36,* 303 (1964).

[7] *K. Moedritzer* and *J. R. Van Wazer,* Inorg. Chem. *3,* 139 (1964).

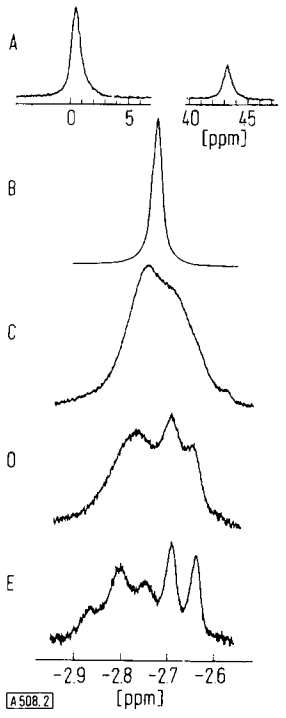

Fig. 2. NMR spectra of an equilibrated mixture [7] of $AsF_2N(CH_3)_2$ and $AsF[N(CH_3)_2]_2$ at 25 °C.

A: $^{19}F$-NMR spectrum of the neat liquid.

B: $^1H$-NMR signals of the methyl groups in the neat liquid.

C: as for B, but with addition of 5 parts $CCl_4$ by volume.

D: as for B, but 10 parts $CCl_4$.

E: as for B, but 18 parts $CCl_4$.

The downfield peak of the $^{19}F$-NMR spectrum and the triplet on the downfield side of the $^1H$-NMR spectra correspond to the $AsF_2N(CH_3)_2$ molecule. The singlet peak at the upfield side in the $^{19}F$ spectrum and the upfield doublet in the $^1H$ spectra correspond to $AsF[N(CH_3)_2]_2$. The doublet and triplet character of the $^1H$ spectra are attributable to spin-spin splitting between the methyl group hydrogens and the fluorine atoms.

Abscissae: Chemical shift relative to trifluoroacetic acid (top) and tetramethylsilane (bottom).

used to identify these compounds when present in a mixture. In a *simple system* involving the exchange of monofunctional substituents only, the chemical shift of a series of related compounds generally changes more or less linearly upon replacement of one substituent by another. In the more complicated systems involving *families* of compounds (*e.g.* in the systems $AsF_3/As_2O_3$ or $(CH_3)_2SiCl_2/[(CH_3)_2SiO]$), NMR signals appear in clusters, which generally indicates that these peaks represent moieties of the same functionality but of different chemical environment. The separations between clusters are often much greater than those between individual peaks within a cluster. In addition, assignments may be based on the order of appearance of new NMR signals when equilibrating large amounts of a compound A with increasing amounts of a compound B. The maximization of the peak areas at certain compositions when comparing a series of spectra of samples having varying mole ratios of the starting components or their increase or decrease with varying over-all composition is also utilized in assigning NMR peaks. In many cases the ratio of the areas of two or more peaks remains constant for different over-all compositions. Peaks exhibiting such a fixed-area relationship generally are readily assignable to certain simple molecules or molecular segments. Kinetic data serve as an additional source of information for peak assignments. In well-filled sealed tubes where no phase separation occurs, the over-all composition must remain fixed from start to finish. Further, in many scrambling reactions certain peaks appear, reach a maximum area, and then disappear at a given over-all composition, whereas at another composition, one of these peaks may be seen under equilibrium conditions.

After all of the resonances have been assigned, one may check the validity of the assignments by material-balance calculations. For single-phase liquids the correct assignments of the NMR peaks will lead to acceptable material balances at any stage of the reaction. In addition, the distribution of atomic or molecular arrangements at equilibrium may be described by a set of equilibrium constants, as exemplified by Eq. (a) below. These constants may be used to calculate a theoretical distribution as a function of the over-all composition.

### c) Other Methods

Raman spectra may also be used for analysis of systems undergoing rapid exchange [8]; however, this method is considerably more restricted than high-resolution NMR spectroscopy and considerable effort is required to obtain quantitative data from the spectra. Gas chromatography [9–11] (see Fig. 3) and mass spectrometry [12, 13]
