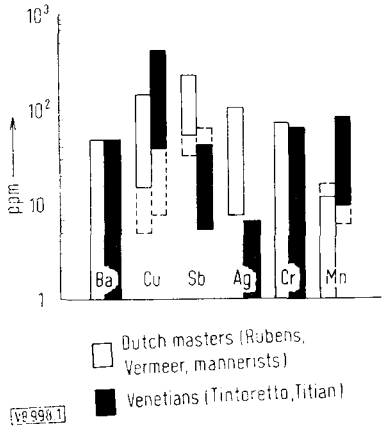
In our work the content of Ag, Ba, Cr, Cu, Mn, and Sb in the white lead was determined. The samples were taken from undoubtedly white parts of the pictures, *e.g.* white spots. Each sample was subdivided into one for short irradiation (irradiation time 4 hr; $^{139}$Ba, $^{64}$Cu, $^{56}$Mn) and another for long irradiation (irradiation time 300 hr; $^{110m}$Ag, $^{51}$Cr, $^{122}$Sb). The samples were irradiated in the research reactor at Munich (FRM) with a flux of $5\times10^{12}$ or $3\times10^{13}$ neutrons $cm^{-2}$ $sec^{-1}$. The individual nuclides were determined by a combination of radiochemical separation and gamma-spectrometric measurement. A 1600 channel pulse-height analyser was used for this measurement. Counting times for the longer-lived nuclides were up to 800 min. The limits of detection were $5\times10^{-10}$ g for Ba, $2\times10^{-10}$ g for Cr, $10^{-10}$ g for Ag and Cu, and $10^{-11}$ g for Mn and Sb. Samples of white lead were taken on the one hand from paintings by Dutch masters of the 16th and 17th century, namely *Rubens*, *Vermeer*, and the mannerists *Hemessen*, *Janssens*, and *Roymerswaele*, and on the other from paintings of the Venetians *Titian* and *Tintoretto*. The results are given in Fig. 1.



They show that the Dutch and the Venetian white leads differ in Ag, Sb, and Mn content. It is thus proved in principle that there is a characteristic distribution pattern for the trace ingredients in white lead of paintings of about the same age.

As regards the recognition of imitations, our studies and the conclusions reached by *Houtman et al.*[2] show that modern white lead differs from the old material in a distinctly lower copper content (<1 ppm) and sometimes in the very marked occurrence of a single trace ingredient, to the extent of some tenths of a percent (*e.g.*, Ba in our work or Zn[2]).

## Spectrochemical Determination of Impurities in Very Pure Aluminum after Removal of the Matrix by Distillation as Organometallic Compound

*K. H. Neeb*, Erlangen (Germany)

Metallic aluminum reacts with ethyl bromide with formation of triethylaluminum tribromide, which can be vacuum-distilled without decomposition, leaving some important impurities as a nonvolatile residue. This simple method of separation can be utilized to determine traces of other elements in very pure aluminum. For evaluation of the behavior of ppm amounts of impurities, control mixtures containing radioactive isotopes were studied; the distillation residue was analysed spectrographically. Recoveries in the residue and the lower limits of determination (for 1 g of aluminum) are shown in the table.

| Impurity | Fe | Cu | Pb | Ag | Cr | Mn | Co | Ni |
|---|---|---|---|---|---|---|---|---|
| Recovery (%) | 99 | 99 | 99 | 99 | 95 | 94 | 98 | 102 |
| Lower lim. of detn. (ppm) | 0.3 | 0.02 | 0.5 | 0.02 | 0.1 | 0.07 | 0.05 | 0.4 |

Low background values were obtained by confining the reagents used to low-boiling liquids such as ethyl bromide, bromine, and nitric acid that are easy to purify by distillation. The process is not limited to final use of spectroscopic determination.

## A Novel Pulse Process with Digital Readout for Automatic Titration

*F. Oehme*, Glattbrugg-Zurich (Switzerland)

Except where the reagent is generated coulometrically, almost all accurate automatic titrators involve use of syringe burets. Induction motors used for control of the buret have the disadvantage, due to inertia of the control mechanism, that the volume added does not correspond to the duration of the dosage command when the latter is short; a further result of the inertia is that a small excess may be added when the cut-off is very sudden.

Step motors do not suffer from these disadvantages. Single impulses delivered as signals by a pulse generator are passed on as defined rotations of the buret control mechanism even if the pulse duration is only $^1/_{100}$ sec. For example, a step motor rotates about 18° per pulse. The motor stops at once when the current stops and remains magnetically arrested.

The step-motor drive and the pulse generator on which it is based have the following advantages:

(a) The volume added is shown directly by counting the pulses, *e.g.* by a mechanical counter.

(b) Very great resolution of the volume used can be achieved by a simple program. For instance, 1 ml can be added in 1000 separate portions.

(c) If the recorder used for drawing a titration curve includes a step-motor drive for advancing the paper, the two motors can be actuated by a single, common pulse generator. A cable connection (impulse conductor) can be used for synchronization of control of the buret and movement of the paper.

(d) The impulse feeder mentioned in (c) can be as long as desired, which opens obvious possibilities for remote control.

(e) The frequency of the impulse generator can be so related to the signal from the servo-generator of a potentiometer recorder that the rate of addition can be related to the steepness of the titration curve.

## Use of Thin-layer Chromatography and Infrared Spectroscopy for Elucidation of the Thermolysis Products of Triphenylphosphine

*H. Schindlbauer* and *F. Mitterhofer*,
Vienna (Austria)

Phosphines and phosphine sulfides can be readily separated on thin-layer chromatograms run on silica gel layers with weakly or moderately polar solvents. The $R_F$ values increase rapidly in the order tertiary > secondary > primary phosphines. Positional isomers of phosphines (*e.g.* the three tritolylphosphines) are best separated on basic alumina with hexane/benzene (5:1 v/v) as solvent; the $R_F$ values increase in the order *p-* > *m-* > *o-*. Phosphine oxides are well separated by use of ether/ethyl acetate. Replacement of a phenyl group by methyl greatly decreases the $R_F$ value of all organophosphorus compounds.

Phosphines can be oxidized to phosphine oxides on the plate before running by spotting with iodine in $CCl_4$; similarly they can be converted with methyl iodide into phosphonium salts, which run in their dissociated form in acetone/HCl but in their undissociated form in acetone/$NH_3$. Phosphines are best made visible by iodine in $CCl_4$ (yellow spots), whereas compounds of quadrivalent phosphorus are well disclosed by permanganate-sulfuric acid (white on pink). The two-dimensional technique and the wedge method make separation of organophosphorus compounds possible.

The decomposition products (66 hr at 400 °C under $N_2$) of triphenylphosphine have been identified by this technique. All the products were also studied by infrared spectroscopy. When no reference sample was available for thin-layer chromatography, the spots of the unknown were isolated on a preparative scale and analysed infrared-spectroscopically, and the assumed product was then synthesized.

The decomposition products of triphenylphosphine were proved to contain substantial amounts of phosphorus, benzene, biphenyl, and *p*-biphenylyldiphenylphosphine,with smaller amounts of *o-*, *m-*, and *p*-terphenyl, *p*-phenylenebis-(diphenylphosphine), *m*-biphenylyldiphenylphosphine, and diphenylphosphine, with only traces of 9-phenyl-9-phosphafluorene detectable.

## New Analytical Separations of Traces of Material on Dextran Gel

*H. Spitzy*, Graz (Austria)

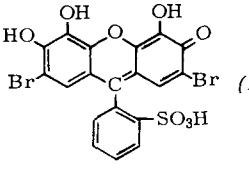
Dextran gels can be used for other analytical purposes besides gel filtration. Reversible adsorption of aromatic and heterocyclic compounds is the basis for a separation of thyroid hormones from blood serum [3].

A further use of dextran gels arises from the fact that the strength of adsorption of solvents varies in accord with their polarities. This effect (known also for ion-exchange resins) has the result that with methanol/water mixtures the water is enriched in the gel phase compared with the mobile outer phase. During passage through a column filled with Sephadex swollen in methanol/water a mixture of alkali chlorides is separated by virtue of the different solubilities of these chlorides in methanol/water mixtures (more correctly, in methanol/water mixtures of different compositions). Under suitable conditions (methanol concentration, 75 vol.-%; column dimensions, 42×1 cm; gel type, Sephadex G-25 fine; rate of addition, 4.40 ml $hr^{-1}$ $cm^{-2}$) all the alkali chlorides can be separated quantitatively at concentrations of $10^{-4}$ M downwards. For an addition of 0.5 ml this corresponds to 340 ng of Li to 6.3 μg of Cs. Yields are 95–100 %. Microgram quantities of Li and K are separated quantitatively from a more than 1000-fold excess of sodium (1600 μg) on a 7.5×1.5 cm column. For Li, Na, and K it is a matter of pure distribution chromatography, but for Cs and Rb adsorption phenomena enter, so that quantitative elution is adversely affected at concentrations below $10^{-4}$ M.

## Photometric Determination of Small Amounts of Tin with Bromopyrogallol Red

*D. Thierig* and *F. Umland*, Münster (Germany)

The 1:1 complex formed by Bromopyrogallol Red *(1)* with Sn(II) or Sn(IV) in acetate-buffered solution of pH 3 is suitable for photometric determination of tin. Direct analysis can be effected in presence of at least a 100-fold molar excess of alkalis, alkaline earths, lead, and mercury(II); interference



*(1)*

by most of the heavy-metal ions can be avoided by separation of the tin as $SnI_4$ before the determination; then there is no interference by 1000-fold excesses of Be, As, Bi, Ti(IV), V(V), Cr(III), Mn(II), Fe(II), Fe(III), Cu, Zn, Ce(III), or W(VI). Only Sb causes a too high and Ag a too low extinction. The extinction coefficient was determined as $\varepsilon = 18000$ *l* $mole^{-1}$ $cm^{-1}$ at 515 mμ. The most favorable concentration limits are 6–90 μg of tin in 25 ml of solution. [VB 998 IE]

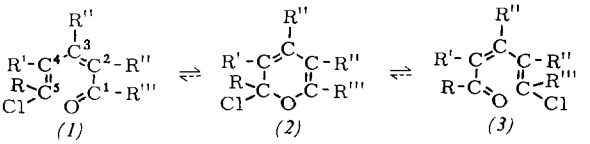
## Pentadiene-1,5-Halogen-Oxygen Exchange

*A. Roedig*, Würzburg (Germany)

Compounds of general structure *(1)* – with the *cis*-configuration at C-2/C-3 – rearrange rapidly and quantitatively in boiling $CCl_4$ into the acid halides *(3)* when R = Cl or Br and R''' = H, $CH_3$, or $C_6H_5$. The term "1,5-pentadiene halogen-oxygen exchange" is proposed to designate this thermal rearrangement. Its mechanism has been largely clarified by radioactive labelling and kinetic measurements [1].

This reaction was discovered with *cis*-perchloropentadienal *(1a)* [2] but is not restricted to perchlorinated pentadienal systems, as has been shown by study of compounds *(1d)* to *(1d)*. The *cis*-compound *(1e)* avoids the pentadiene-1,5-halogen-oxygen exchange by rearrangement to its *trans*-isomer; however, pentadienals containing chloro or bromo substituents on C-3 and C-2 are more stable in the *cis*-form [3].

Furthermore, experiments with [1-$^{14}$C]perchloropentadienoyl chloride *(1f)* have shown that pentadienal 1,5-halogen-oxygen exchange is not restricted to aldehydes and



*(1)* ⇌ *(2)* ⇌ *(3)*

*(a)*: R = R' = R'' = Cl; R''' = H
*(b)*: R = Br; R' = R'' = Cl; R''' = H
*(c)*: R = R' = Cl; R'' = Br; R''' = H
*(d)*: R = Cl; R' = $CH_3$; R'' = Br; R''' = H
*(e)*: R = R' = Cl; R'' = R''' = H
*(f)*: R = R' = R'' = R''' = Cl
*(g)*: R = $C_6H_5$; R' = R'' = Cl; R''' = H

ketones. If *(1f)* is heated for 48 h at 130 °C the radioactivity is distributed equally between C-1 and C-5. However, the data collected up to the present suggest that two halogen substituents on C-5 are essential for complete and irreversible pentadiene 1,5-halogen-oxygen exchange: the *cis*-form of *(1g)* appears merely to enter into an equilibrium with the pyran *(2g)*; the presence of the ketone *(3g)* in the mixture cannot be ascertained.

If complex-forming reagents ($FeCl_3$ or $SnCl_4$) are added to *(1)* during the rearrangement, pyrylium salts can be isolated in good yield[4], a fact that presents strong evidence for formation of the pyrans *(2)* as intermediates.

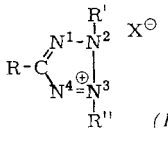
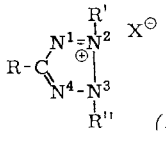
## The Nature of Tetrazolium Salts and Formazans

*C. Schiele*, Ulm (Germany)

The concensus of opinion regarding the nature of tetrazolium salts was summarized by *Nineham*[1] who formulated them as resonance hybrids between the structures *(1a)* and *(1b)*. However, from the observation of $\nu_{C=N(1)}$ and $\nu_{C-N(4)}$ vibrations at 1527–1544 $cm^{-1}$ and near 1150 $cm^{-1}$ we were able to establish that the system is not a resonance hybrid but occurs exclusively in the form *(1a)*.



*(1a)*

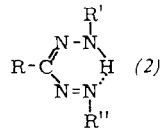


*(1b)*

Furthermore, it could be shown that there is a marked influence of aryl substituents on the carbon atom of the tetrazolium ring upon the ease of reduction of these compounds (measurement of the decomposition potential on Ag/Pt); this effect could even be used occasionally, *e.g.* when R = R′ = *p*-tolyl or *p*-chlorophenyl and R″ = phenyl, or when R = R″ = *p*-tolyl or *p*-chlorophenyl and R′ = phenyl, to differentiate between *N*(2)- and *N*(3)-substituted tetrazolium salts. These findings led to the postulation of a heterocycle with varying bond lengths between the N-2 and N-3 atoms of the ring, depending on the nature of the aryl substituent on the carbon atom in the ring. The occurrence of two modifications with each of eight solid tetrazolium perchlorates indicated the existence of tetrazolium salts which are stereoisomeric with regard to the arrangement of the aryl residue. The infrared spectra of these forms differ in the regions of their skeletal, $\gamma_{C-H}$, and ring deformation vibrations. They also give different Debye-Scherrer diagrams and different extinction coefficients in the ultraviolet and visible regions.

The occurrence of stereoisomers does not, however, explain why crystalline tetrazolium salts turn yellow when exposed to light. This discoloration is attributed by *Nineham*[1] to some structural characteristic of the compounds, but no explanation is given. The new absorption bands that appear between 400 and 450 mμ when layers of tetrazolium salts are irradiated can be interpreted when a photoisomerism caused solely by a change in position of the anion is assumed. This interpretation finds support in the results of infrared spectroscopic investigations.

Formazans *(2)* also exhibit a marked change in frequency of the C–N valence vibration in dependence on the *C*-aryl substituent. If formazans are examined in which only the *C*-aryl substituent is varied, an increase in the extinction of the chromophoric band from log ε = 4.1 to log ε = 4.2 and a



*(2)*

shift in the frequency of the C–N valence vibration from 1226 to 1236 $cm^{-1}$ are observed on passing from a substituent with a (+)-M effect to one with a (−)-I effect. These findings are indicative of an increase in the electron density in the N=C–N portion of the molecule and of an expansion along the N–H···N bonds associated with a weakening of the hydrogen bond. Consequently, the *C*-aryl residue and the "heterocycle" appear to be almost coplanar whereas both the hydrogen bridge and the *N*-aryl residues are not in a coplanar arrangement. In principle, therefore, the same picture is obtained for formazans as for tetrazolium salts, namely that the *C*-aryl substituent exerts a significant influence on the bonding and on the ring parameters in remote parts of the molecule.

[Lecture at Isny (Germany), April 20th, 1966]

[VB 994 IE]

## New Facts about Aroma Essences

*F. Drawert*, Siebeldingen (Germany)

It was established using gas chromatography and radio-gas chromatography that there are considerable differences between the substances that cause the aromas of fruit and those of fruit juices prepared from the fruit. The fruity esters of apples (butyl acetate, amyl acetates, hexyl acetate, *etc.*) are split to varying degrees by hydrolases after damage of the fruit cells. Simultaneously enzymatic oxidations occur in the damaged (homogenized) fruit which lead to the formation of new aroma essences, which include 2-hexenal *(1)* and hexanal *(2)* in predominant proportions; these compounds therefore play a major part in determining the aroma and taste of apple juice. The precursor of *(1)* is linolenic acid, that of *(2)* is linoleic acid[1].

Numerous aroma essences are produced by yeast. The amounts of such substances vary when the sugar content of the fermentation solution is kept constant but its amino-acid content is varied. Model fermentations with *Saccharomyces cerevisiae* in an otherwise uniform culture medium revealed that various amino acids contribute differently to the formation of aroma substances in the yeast. Methionine and proline cause a higher formation of malic and tartaric acids relative to other amino acids.

[Lecture at Freiburg (Germany), April 29th, 1966]

[VB 993 IE]

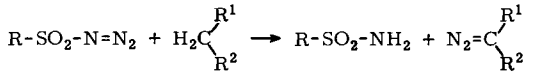
## Transfer of Diazo Groups: Mechanism and Preparative Importance

*M. Regitz*, Saarbrücken (Germany)

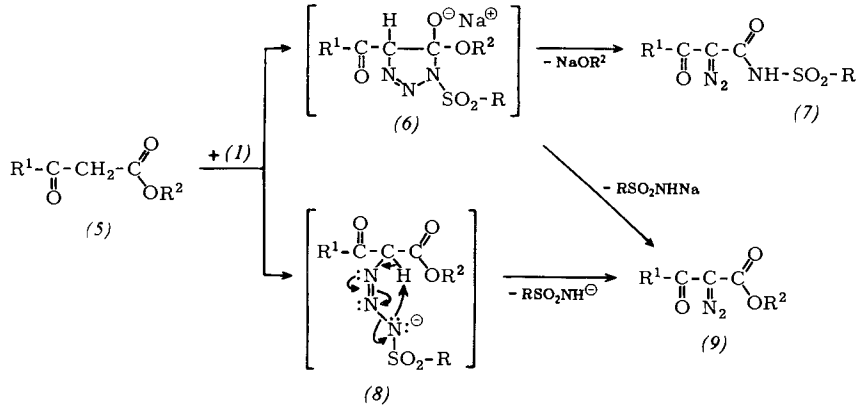
Transfer of diazo groups from sulfonyl azides *(1)* to active methylene compounds *(2)* occurs by exchange of the $N_2$ group of the azide for two H atoms of the methylene com-

pound *(2)*, with formation of sulfonamides *(3)* and diazo compounds *(4)*.



*(1)* *(2)* *(3)* *(4)*

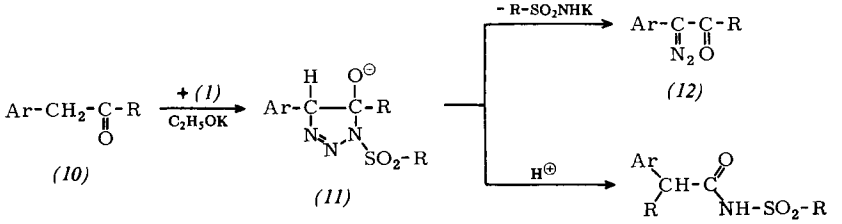
For β-dicarbonyl compounds of type *(5)* and for aryl-activated α-methylene ketones *(10)* some statements can be made about mechanism. Malonic esters *(5)*, $R^1$ = OR, and β-keto esters *(5)*, react with the azide *(1)* in ethanol/sodium ethoxide by loss of an alkoxy group to form diazo-*N*-sulfonyl-carboxamides *(7)*, probably by way of the triazoline *(6)*.



*(5)* *(6)* *(7)* *(8)* *(9)*

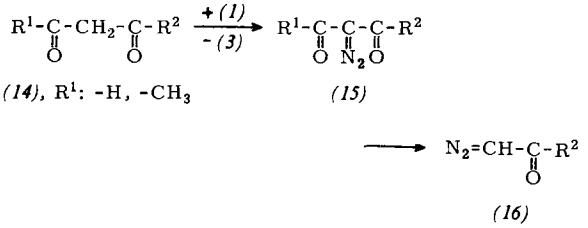
The reaction route *(5)* → *(8)* or *(6)* → *(9)* → *(7)* is excluded because diazo-carboxylic esters *(9)* do not react with sulfonamides *(3)* in ethanol/sodium ethoxide. Esters *(9)* are formed almost quantitatively from compounds *(5)* by transfer of diazo groups in acetonitrile/triethylamine, in which intermediates *(8)* are conceivable.

When aryl-activated methylene compounds *(10)* are used an unstable intermediate can be isolated, whose decomposition indicates its triazoline structure *(11)*: thus in alkaline medium they afford diazo ketones *(12)*, whereas acid hydrolysis yields *N*-sulfonylacetamides *(13)* with evolution of nitrogen and anionotropic migration of the group R.



*(10)* *(11)* *(12)* *(13)*

α-Methylene ketones such as acetophenone and acetic esters have insufficent $H^+$ activity for transfer of diazo groups, so the acylated derivatives *(14)* are treated with the azide *(1)* and after the transfer the activating group is removed solvolytically. If $R^1$ = H in *(14)*, compounds *(16)* can be obtained



*(14)*, $R^1$: -H, $-CH_3$ *(15)* *(16)*

directly, *i.e.* without isolation of the intermediate *(15)*. Diazoacetic esters and diazoacetophenones can be thus prepared[1].

## Structure of Metal Compounds

*K. Brodersen*, Erlangen (Germany)

As part of a systematic study of the structures of platinum-metal halides the crystal structure of palladium(II) bromide has been determined. X-Ray investigations of the dark brown, needle-shaped single crystals (prepared by chemical transport reactions) showed the following dimensions for the unit cell: a = 6.59 Å, b = 3.96 Å, c = 25.22 Å, β = 92.6°. Further elucidation of the structure showed that the palladium atoms are surrounded by four bromine atoms in a distorted square, and that each bromine atom has two palladium atoms as neighbors at distances of 2.34 Å and 2.57 Å, respectively. The coordination squares are joined in zig-zag chains. The compound is diamagnetic.

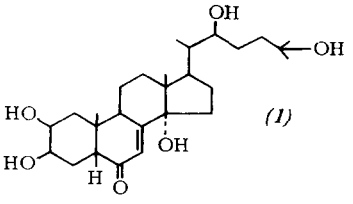
Infrared-spectroscopic studies of the complexes of ethylenediamine with silver(I) cyanide and thiocyanate, which are prepared by treating anhydrous solutions of the corresponding silver salts in pyridine with a solution of ethylenediamine in anhydrous ethanol, showed the diamine to be attached at *trans*-positions.

The compound $FePCl_8$ can be prepared from $FeCl_3$ and $PCl_5$ at 140 °C. The yellow adduct decomposes above 260 °C. Mössbauer spectra (chemical shift + 0.18 mm/sec at 295 °K and +32 mm/sec at 78 °K; quadrupole splitting 0.23 mm/sec) show that the iron(III) ion is surrounded by four chloride ions in a distorted tetrahedron. Infrared-spectroscopic study also indicates the presence of a distorted $FeCl_4$ tetrahedron, as is to be expected from the $d^5$ electron configuration of iron(III).

[Lecture at Kiel (Germany), May 26th, 1966] [VB 995 IE]

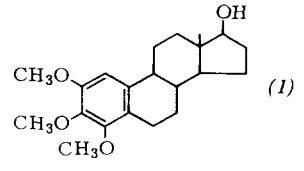
German version: Angew. Chem. *78*, 684 (1966)

**Synthesis of ecdysone** *(1)*, the moulting hormone of insects, was achieved by *U. Kerb, P. Hocks, R. Wiechert, A. Furlenmeier, A. Fürst, A. Langemann*, and *G. Waldvogel*, as well as by a different route by *J. B. Siddall, A. D. Cross*, and *J. H. Fried*, who communicated their results only three days later. The former synthesis starts from methyl 3,3-ethylenedioxy-bisnor-5-cholenate, which was converted into *(1)* in many steps, some of which were stereospecific. *Siddall, Cross*, and *Fried* obtained ecdysone from methyl 14α-hydroxy-2β,3β-isopropylidenedioxy-6-oxo-22,23-bisnor-5β-chol-7-enate in a synthesis that also contained many steps. / Tetrahedron Letters *1966*, 1387 and J. Amer. chem. Soc. *88*, 862 (1966) / –Kr. [Rd 481 IE]



*(1)*

**Polyalkoxyestranes, a new group of analgetic compounds,** have been synthesized by *L. R. Axelrod, P. N. Rao*, and *D. H. Baeder*. 2,3,4-Trimethoxy-1,3,5(10)-estratrien-17β-ol *(1)*, prepared from 3-(2-benzoyl-4-nitrophenoxy)-2-methoxy-1,3,5(10)-estratrien-17β-yl acetate, was particularly effective. It exists in two dimorphic forms. $LD_{50}$ is 175 ± 28 mg/kg mouse intravenously and > 500 mg/kg mouse orally. Intravenously it has 40 and 160 times the analgetic effect of morphine sulfate and meperidine, respectively. No estrogenic action was observed; no side effects were seen after chronic administration to animals. / J. Amer. chem. Soc. *88*, 856 (1956) / –De. [Rd 487 IE]



*(1)*

**The association of potassium bromide in the vapor phase** was studied by *K. Hagemark, M. Blander*, and *E. B. Luchsinger* by vapor density measurements in a liquid-gold isoteniscope. When the small proportion (< 5 %) of trimer present is neglected, least-square analysis of the results in the range 1175–1450 °K and $2.3–7.8\times10^{-4}$ moles/liter gives for the dimerization constant $K_2$ (in liters/mole) and for the vapor pressure p (in mm Hg)

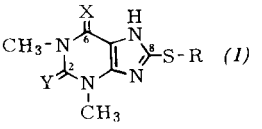
$$\log K_2 = -3.407 + 8378/T$$
$$\log p = 22.159 - 10824/T - 3.966 \log T$$

Dimensional analysis of the partition functions of gaseous salt molecules leads *inter alia* to the relation

$$\ln K_2(Td'/d) + 3 \ln (d'/d) = \ln K'_2 (T)$$

between the dimerization constants $K_2$, $K_2$ and internuclear distances d, d' of the monomers of an arbitrary salt and a reference salt, respectively. With NaI as reference salt, the calculated thermochemical quantities for the dimerization of KBr ($K_2$, $\Delta S^0$, $\Delta U^0$) are in excellent agreement with the experimental values. / J. physic. Chemistry *70*, 276 (1966) / –Da. [Rd 477 IE]

**8-(Alkylthio)thiotheophyllines are a new group of hypnotica,** according to *A. H. Dietz jr.* and *R. M. Burgison*. 8-(Alkylthio)theophyllines *(1)*, in which the oxygen at position 2 or 6 or both is replaced by sulfur were obtained by condensing the corresponding 8-mercaptothiotheophyllines with alkyl halides or sulfates. The hypnotic action of these compounds is comparable with those of thiopental and pentobarbital, but the new compounds are less toxic and cause fewer side reactions. / 151st Meeting, Amer. Chem. Soc. *1966*, I 18 / –De. [Rd 488 IE]

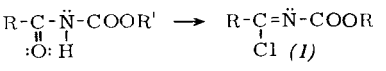


*(1)*

X, Y = O or S

**The stereochemistry of polymerization of methacrylic esters** has been studied by *T. Tsuruta, T. Makimoto*, and *H. Kanai*. They polymerized, *inter alia*, methyl, ethyl, isopropyl, and t-butyl methacrylate by means of radical (benzoyl peroxide) and anionic [$LiAlH_4$, $SrZn(C_2H_5)_4$, $C_6H_5MgBr$, n-$C_4H_9Li$, n-$C_4H_9MgBr$) initiators. The polymers were hydrolysed to polymethacrylic acids which were then esterified with methanol. The tacticities of the products were determined by NMR spectroscopy; calculation of the tacticity parameters shows that the arrangement of the penultimate unit depends on the natures of the ester group, catalyst, and solvent, as well as on the temperature and the polymerization mechanism. Examples: methyl methacrylate with benzoyl peroxide, retention of configuration ($P_{ddd}$, 1.0); with $Sr[Zn(C_2H_5)_4]$, inversion ($P_{dll}$, 0.52). The metal influences the stereochemistry in anionical polymerization. / J. macromolecular Chem. *1*, 31 (1966) / –Hl. [Rd 502 IE]

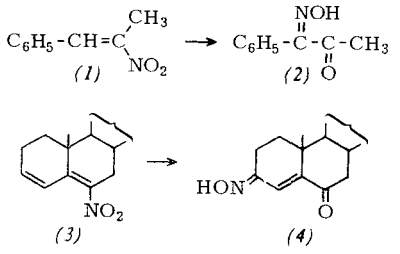
**N-(Alkoxycarbonyl)carbimidoyl chlorides** *(1)* have been synthesized for the first time by *R. Neidlein* and *R. Bottler*. Suspensions of *N*-acylcarbamidic esters, when heated with $PCl_5$ under reflux until HCl evolution ceased, gave the chlorides *(1)* as colorless to pale yellow oils that could be distilled in a vacuum and were stable for several weeks if moisture was excluded. The structure of the products was determined by infrared spectroscopy. Examples: R = $C_6H_5$, R' = $C_2H_5$, b.p. 100–103 °C/0.05 mm Hg, yield 73 %; R = *m*-$CH_3OC_6H_4$, R' = $C_2H_5$, b.p. 110–112 °C/0.03 mm, 53 %; R = $ClC_6H_4$, R' = $C_2H_5$, b.p. 105–108 °C/0.05 mm, 63 %; R = $CH_3C_6H_4$, R' = $C_2H_5$, b.p. 125–127 °C/0.05 mm, 48 %. / Tetrahedron Letters *1966*, 1069 / –Ma. [Rd 476 IE]



*(1)*

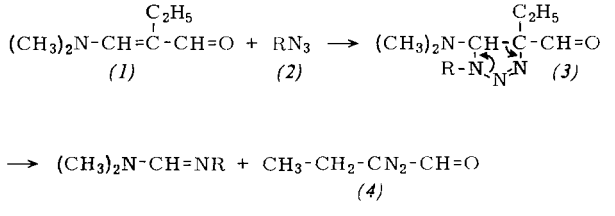
**Synthesis of chloro-, bromo-, and iodo-diacetylene** has been accomplished by *Else Kloster-Jensen* in a two-stage reaction. An ethereal solution of diacetylene is treated with the equivalent amount of butyl-lithium at –80 °C- under nitrogen. Then a solution of the halogen (1 mole) is added at –55 °C. The mixtures are freed from unchanged halogen by distillation at –40 °C and the products are purified by gas-liquid chromatography. Chloro- (m.p. –41 °C, yield *ca.* 30 %), bromo- (m.p. –18 °C, yield *ca.* 18 %), and iodo-diacetylene (m.p. –30 °C, yield *ca.* 59 %) polymerize at room temperature. The iodo-compound may explode. / Tetrahedron *22*, 965 (1966) / –Bu. [Rd 507 IE]

**A new photochemical rearrangement of nitroolefins** is described by *O. L. Chapman, P. G. Cleveland,* and *E. D. Hoganson.* Irradiation of 2-nitro-1-phenylpropene *(1)* in acetone under $N_2$ with light of $\lambda > 290$ mμ gives α-hydroximino-α-phenylacetone *(2)* in 81 % yield, both geometrical isomers being formed. The yields are lower if other solvents are used. A vinylogous rearrangement occurs on irradiation of 6-nitro-3,5-cholestadiene *(3)*, yielding 3-hydroximino-4-cholesten-



6-one *(4)*. Acetone presumably acts as sensitizer. The rearrangement may be intramolecular or may involve a dissociation-recombination mechanism in which the first step in each case is the rearrangement $R-NO_2 \rightarrow R-O-NO$. Chem. Commun. *1966*, 101 / –Ma. [Rd 468 IE]

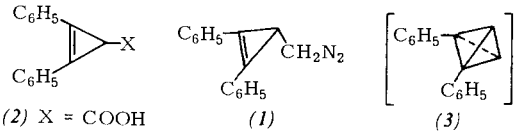
**α-Diazobutyraldehyde (4)**, the first aliphatic α-diazo-aldehyde, was obtained by *J. Kučera* and *Z. Arnold* by treating β-dimethylamino-α-ethylacrolein *(1)* with reactive organic azides *(2)* in an inert aprotic solvent. The reaction presumably involves the unstable intermediate *(3)*. The diazoaldehyde *(4)* is a yellow oil, distillable in vacuum at low



temperature, and can be kept for several days at 0 °C without significant decomposition ($\lambda_{max}$ = 249, 284, 381 mμ). It evolves $N_2$ with dilute acids or traces of Cu. The yields of aldehyde depend on the azide *(2)* used. The authors employed tosyl and picryl azides and cyanogen azide. / Tetrahedron Letters *966*, 1111 / –Ma. [Rd 471 IE]

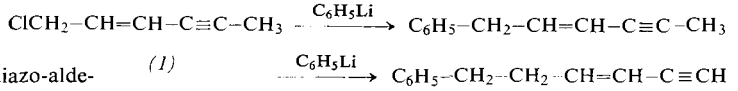
**A radical-pair mechanism of the Wittig rearrangement of anionized ethers** containing a tertiary carbon atom has been postulated by *P. T. Lansbury, V. A. Pattison, J. D. Sidler,* and *J. B. Bieber.* Reaction of methyl-lithium with benzyl t-butyl ether in ether/tetrahydrofuran for 2 days leads to a 51 % yield of 2,2-dimethyl-1-phenyl-1-propanol (α-t-butylbenzyl alcohol). Benzyl 1-norbornyl and 1-apocamphyl benzyl ether do not rearrange under these conditions. Stereochemical investigations have shown that migration of aliphatic ligands from oxygen to the neighboring carbanionic center on the α-benzyl carbon atom that is formed under the influence of the metalating agent involves fragmentation and re-combination. It must be concluded from the new results that the fragments from ligands containing tertiary carbon atoms are radicals. If fragmentation led first to a benzaldehyde/alkyl-lithium pair, then the bicyclic ligands should migrate faster than t-butyl, since 1-norbornyl-lithium is more stable than t-butyl-lithium in iodine/lithium exchange. On the other hand, it is known that the radical state of the bridgehead atom of bicycloheptane is less stable than that of a tertiary carbon atom in acyclic systems (ring strain). / J. Amer. chem. Soc. *88*, 78 (1966) / –Eb. [Rd 501 IE]

**Synthesis and properties of diphenylcyclopropenyldiazomethane** *(1)* were investigated by *E. H. White, G. E. Maier, R. Graeve, U. Zirngibl,* and *E. W. Friend.* The compound *(1)* was obtained in seven steps from 2,3-diphenylcyclopropenecarboxylic acid *(2)*. It is abnormally sensitive to protic solvents such as water and methanol and very sensitive to $O_2$. The half-life in $O_2$-free dilute solution at 25 °C is *ca.* 30 min.



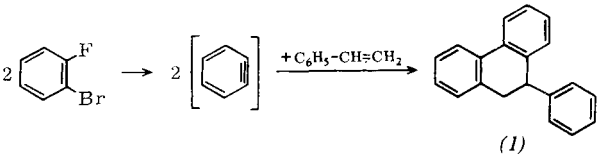
Thermal or photochemical decomposition does not, as was hoped, yield diphenyltetrahedrane *(3)*, but instead diphenylacetylene, benzoic acid, the azine of the aldehyde *(4)*, $N_2$, and polymers. / J. Amer. chem. Soc. *88*, 611 (1966) / –Ma. [Rd 470 IE]

**Rearrangement of *cis*-1-chloro-2-hexen-4-yne, containing a vinylacetylene system,** under the influence of phenyl-lithium has been reported by *J. Cymerman Craig* and *R. J. Young.* With phenyl-lithium at 0 °C, compound *(1)* affords about equal



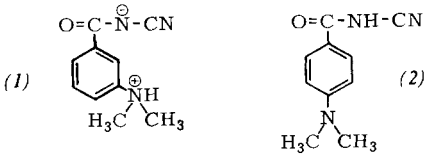
amounts of *cis*- and *trans*-6-phenyl-3-hexen-1-yne *(2)*, b.p. 47–48 °C/0.0004 torr, $n_D^{20}$ = 1.5670, in 3 hr. The structure of the product *(2)* is proved by infrared and ultraviolet spectroscopy. The driving force for the rearrangement, which is initiated by removal of a proton, is held to be provided by the formation of the terminal acetylide anion. / J. chem. Soc. (London) org. *C 1966*, 578 / –Kü. [Rd 499 IE]

**The reaction of benzyne with styrene** has been studied by *W. L. Dilling.* Addition of *o*-bromofluorobenzene to a mixture of Mg turnings and an excess of styrene in tetrahydrofuran at 60 °C, hydrolysis with water, and chromatography on



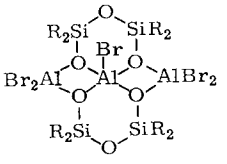
$Al_2O_3$ give 9,10-dihydro-9-phenylphenanthrene *(1)*, m.p. 79–80 °C, in 87 % yield. This compound may arise by a Diels-Alder reaction, loss of a proton, and nucleophilic addition of the second benzyne molecule. / Tetrahedron Letters *1966*, 939 / –Ma. [Rd 469 IE]

**Amino-N-cyanocarboxamides,** a new class of compounds, have been described by *J. C. Howard* and *F. E. Youngblood.* They obtained *e.g. N*-cyano-*m*- *(1)* and *N*-cyano-*p*-(*N,N*-dimethylamino)benzamide *(2)*, m.p. 156–157 °C and 147 to 148 °C, respectively, from reactions of the acid chlorides with sodium cyanamide in dimethylformamide. According to the infrared spectra, the solid compound *(2)* is in the uncharged



form, but the compound *(1)* is an inner salt. Both the corresponding carboxylic acids are uncharged in the solid state. / J. org. Chemistry *31*, 959 (1966) / –Kr. [Rd 504 IE]

**Compounds of aluminum with coordination number five** have been investigated by *M. Bonamico*. Earlier *Ercolani et al.* obtained, from trimethylsiloxyaluminum dichloride and octamethylcyclotetrasiloxane, a crystalline, stable aluminum-siloxane compound of empirical formula $C_8H_{24}Al_3Cl_5O_6Si_4$ *(1)*, which sublimed at 155 °C in a vaccum, as well as a polymer $[(CH_3)_2SiOAlClO]_n$. The bromine analogue *(2)* of *(1)* is monoclinic (space group $P2_1/n$) and colorless. One of



*(2)*, R: $-CH_3$

the 3 Al atoms has the coordination number 5; it is surrounded by four oxygen and one bromine atom; the other two Al atoms are tetracoordinated (2 O, 2 Br). X-Ray analysis gave a = 11.22, b = 13.48, c = 18.76 Å, β = 93 °52′. Z is probably 4. / Chem. Commun. *1966*, 135 / –Kr. [Rd 503 IE]

**Separation of enantiomers by gas chromatography** has been achieved by *E. Gil-Av*, *B. Feibush*, and *R. Charles-Sigler*. The solid carrier and the material to be separated must be chemically similar and interaction must be possible at many points. For this purpose the capillaries (internal diameter 0.25 mm; length 100 m) of capillary columns (75000 theoretical plates for *N*-trifluoroacetylvaline isobutyl ester) were charged with *N*-trifluoroacetyl-L-isoleucine lauryl ester or esters of other *N*-trifluoroacetyl-α-amino acid. The following esters were separated into two or four components (according to whether they contained one or two optically active C atoms per molecule) by using 0.3 to 0.6 μl of ethereal solution in a nitrogen stream at 100 to 200 °C: the isopropyl (retention times in min: 63.7:64.7), butyl (173:175.2), and cyclopentyl (366.8:373.2) ester of *N*-trifluoroacetylalanine; the isobutyl ester of *N*-trifluoroacetyl-alanine (102.9:104.5:108.6:110.7), -valine (171.5:175:180.5:184.7), and -leucine (341.2:34.8:360.8:369.5). Separation is the more successful the larger is the alkyl component; the methyl esters and such "foreign" compounds as 1-methylhexyl acetate are thus not separable. / Tetrahedron Letters *1966*, 1009 / –Jg. [Rd 490 IE]

# BOOK REVIEWS

**Landolt-Börnstein. Zahlenwerte und Funktionen aus Naturwissenschaften und Technik.** Gruppe II. Band 1: Magnetische Eigenschaften freier Radikale (Numerical Values and Functions from Science and Technology. Group II. Vol. 1: Magnetic Properties of Free Radicals). Edited by *K.-H. Hellwege*. Springer-Verlag, Berlin-Heidelberg-New York 1965. 1st Edit., x + 154 pp., DM 68.– (about $17.–).

The definition, production, and magnetic properties of free radicals are treated in a short introduction. Then follow literature references to the theory of ESR spectra (spin Hamilton operator, *g*-factor, coupling parameters, line widths, relaxation, calculation of spin density), and next the tables themselves with ESR data (*g*-factors, *a*-values) for neutral and ionic radicals, organic diradicals, and donor-acceptor complexes. An extensive list of references includes papers which have not been included in the tables (measurement of susceptibility; radicals formed by irradiation, electric discharge, on polymerization, or pyrolysis and in biological systems). The ESR spectroscopist and the "radical chemist" are here offered for the first time – and at a relatively favorable price – the possibility of having the experimental results in his field to his hand on his working desk. This book – presented in two languages – thus needs no further recommendation.

Because of the rapid expansion in the held a supplement or new edition will nevertheless soon be necessary. Then, it is suggested, some results that have not been included (*e.g.* on sulfur radicals) should be added, and references to Chemisches Zentralblatt or Chemical Abstracts should be given for difficultly accessible papers. At the same time factual errors should be corrected: *e.g.* section 2.2.4 alone contains 20 inaccuracies in the tables and literature, and references Ba5, He9, and Mu4 are missing.

*A. Rieker* [NB 474/327 IE]

**Metallkundliche Analyse** (Metallurgical Analysis). By *W. Koch*. Verlag Stahleisen GmbH., Düsseldorf – Verlag Chemie GmbH., Weinheim/Bergstraße 1965. 1st Edit., 497 pp., 394 figs., 80 tables, linen DM 135.– (about $34.–).

The purpose of metallurgical analysis is to clarify the structure of heterogeneous alloys by chemical-analytical investigations. A new book from *W. Koch* is particularly welcome as his name is so closely linked with progress in this field. However, as the author stresses, this progress should not lead to the illusion that metallurgical analysis has passed its first stages.

This book is concerned with the isolation, enrichment, separation, and determination of the structural components. One of its main sections is a detailed chapter on the electrochemical basis for electrolytic analysis of ferrous alloys, which takes into account the predominant importance of this method. For all the experimental procedures recorded in other chapters – whether X-ray analysis, isolation by an extraction-replica process, analysis by emission spectroscopy, or chemical separation of a multiphase material – in all cases the relevant principles of the procedure are briefly but clearly described, the suitability for the work in question is critically discussed, and comprehensive details help the experimental execution. The chapter on the modern method of X-ray microanalysis by means of an electron-beam microprobe is unfortunately rather short, yet the few examples are so chosen that readers can estimate the value of a microprobe for their special purposes. The chapter on characteristic properties of isolated structural ingredients, and the tables of properties, which amount to nearly 200 pages, describe the most important exclusions and inclusions in ferrous and some non-ferrous alloys. Most of these are interpreted with the aid of phase diagrams. The tables of properties contain, not merely various physical properties, but also extensive crystallographic data and Debye-Scherrer diagrams in their original sizes, so that in many cases the reader's own diagrams can be indexed by simple superposition.

Finally it deserves mention that the author has succeeded in conveying his comprehensive knowledge in an easily readable text.

*H. de Laffolie* [NB 475/328 IE]

**Steroid Spektrenatlas** (Atlas of Steroid Spectra) (in German and English). By *W. Neudert* and *H. Röpke*. Springer-Verlag, Berlin-Heidelberg-New York 1965. 1st Edit., viii + 471 pp., 36 illustr., 1111 spectral curves, linen DM 144.– (about $ 33.–).

This atlas characterizes 900 steroids by means of their infrared and ultraviolet spectra, melting points, and specific rotations. NMR spectra of 95 substances are also reproduced. These and other physical methods of characterizing steroids are described, and instructions are given for the preparation of peephole cards for steroids. The whole of the textual material and all the explanations are given in German and in English.

The material consists mainly of steroid hormones, pharmaceutical steroidal products, and intermediates in their synthesis. One looks in vain for an example of the steroid alkalo-

ids, cardenolides, or bufadienolides, and no natural bile acid is included. Even the choice of chromophoric systems is not as complete as is to be expected in a book with claims of this sort [there is, for instance, no 15-ketone or 9(11)-ene-12-one]. However, for the types that are described (170 in the infrared and 101 in the ultraviolet section) there are extensive data concerning band assignments and, above all, the small but significant shifts due to additional substituents; it is just such data which are of particular value in structure determination. For the ultraviolet spectra half-widths are given in each case in addition to $\varepsilon$; these are particularly important for narrow bands; unfortunately there is no indication that both $\varepsilon$ and the half-width are dependent on slit width, though their product is almost independent thereof.

The NMR spectra were measured on a 40 Mc instrument and thus do not show the quality that one has become accustomed to in recent years. Thus the tables contain only the chemical shifts, and spin-spin splitting is hardly ever described. On the other hand, the very valuable section on dipole moments of steroids is rich in tables and practical instructions. In cases where several polar groups are present the experimental dipole moment is always compared with the calculated value and an estimate of the conformation is attempted; for conjugated 3-ketones this is, however, discussed only for the twist form and for one of the two possible half-chair forms of ring A. Collection of data of this sort is a novelty in the steroid field and will induce many to carry out dipole-moment measurements.

Each chapter has a theoretical introduction on techniques; but these introductions often leave much to be desired. For instance, configuration is often confused with conformation, and in the correlation table for infrared bands, which is very clear in other respects, the chromophores are denoted only by numbers. In the ultraviolet section it is noted that polar solvents usually cause a bathochromic shift of the bands, but without indicating that just the opposite is true for $\pi$-$\pi^*$ bands. Remarkably, *Woodward*'s rules for dienes and unsaturated ketones are mentioned only in one short sentence, and are there erroneously assigned to the longest-wavelength ultraviolet bands whereas for enones they are valid only for the short-wavelength K bands. In the NMR section, which was originally written in English, there are uncorrect translations ("integral" values instead of "ganzzahlig", "Feldkonstanz of $10^{-8}$ gauss" instead of "Homogenität of $1:10^8$", *etc.*), and it is claimed, for instance, that a keto group does not influence the position of the signal of a neighbouring $CH_2$ group except with 11-ketones. The region given for the 12-methylene signal of the latter is in general not the correct one – it is correct only for compounds having an oxygen-rich side chain. The existence of long-distance couplings for $\sigma$-bonds is denied, and there is no reference to *Shoolery*'s rule or the *Karplus* equation, to *Zürcher*'s tables of the positions of methyl signals, or the types of spin-spin splitting.

The relation between specific rotation and configuration is regarded as too complex; yet, on the basis of *Klyne*'s and *Barton*'s work (not *Djerassi*'s, as stated), many configuraiotns can be determined by the method of molecular rotation differences (which, like the concept of molecular rotation, is not mentioned). It is unusual that hardly any literature is cited – neither review, nor handbook, nor original paper. Therefore it is very difficult for the user of the atlas to compare its data with those from other laboratories.

If these and other drawbacks could have been avoided, this atlas would have served also as a very good introduction into methods of instrumental analysis. The criticisms of the textual material should not, however, be held to diminish the great value that steroid chemists will find in the tables, which have been constructed with great care from extensive factual material, and in the rules deduced therefrom. Production of the book and reproduction of the illustrations are excellent, which indeed should be expected in view of the price, which unfortunately will be a severe hindrance to wide distribution.

*G. Snatzke* [NB 453/306 IE]

**Chemische Veränderungen von Stoffen durch energiereiche Strahlung.** (Chemical Changes of Materials by Energy-Rich Radiation). By *E. Rexer* and *L. Wuckel*. VEB Deutscher Verlag für Grundstoffindustrie. Leipzig 1965. 1st Edit., 275 pp., 74 figs., 78 tables, bound. MDN 32.– (*ca.* $ 8.00).

This book about radiation chemistry has the usual weakness of most of its predecessors in that, while it reviews a mass of material about the behavior of substances under the influence of ionizing radiation, it usually leaves open the question "Why?" This question is not answered by the many reaction sequences, whose necessity is not evident to the reader because details of experimental methods and methods of investigation are missing. The treatment covers gases, water, aqueous solutions, organic compounds, and polymers.

The introduction into the fundamentals of radiation chemistry is truly unfortunate. Kinetics, mass spectrometry, electron spin resonance, excited molecules, and the like are mentioned only incidentally. This part, written in phraseology that is often imprecise, contains also notable omissions and errors, *e.g.*: 1 curie is seen as the activity of 1 g of Ra in equilibirum with its decomposition products (p. 33), the output of a cobalt source is wrongly calculated since the fact that each $^{60}Co$ atom emits two $\gamma$-quanta is neglected (p. 36), data about mass absorption coefficients would be useful (p. 40), figure 3.2 contains an unexplained parameter (p. 49), the colour of F centers a function of the lattice constants and not the same as the absorption of the free metal atoms (p. 67), and the names of *Franck* and *Rabinowitch* do not appear in the discussion of the cage effect (p. 125). The description of radiation damage to solid bodies seems to have been derived from the secondary literature and is superfluous since crystalline inorganic and organic materials are not treated in the main section; here the omissions abound: for instance, only the least probable of the disorder models, that of *Brinkman*, is described; the problematics of disorder are not discussed at all (p. 79).

The book cannot serve as an introduction to radiation chemistry, and citation of the literature is, of course, incomplete. The production is satisfactory.

*Horst Müller* [NB 480/334 IE]

**Analytical Chemistry of Ruthenium.** By *T. D. Avtokratova*. Series: "Analytical Chemistry of Elements". Academy of Sciences of the U.S.S.R., Moscow 1962. English translation: Israel Program for Scientific Translations, Jerusalem 1963. 224 pp., 36 figs., 54 tables, 13 analytical schemes, $ 14.00

This book is the first of the translations of a series of new Russian monographs. The occurrence, properties, and use of ruthenium and its compounds are reported in an introductory chapter (use as pen points is omitted). Chapter 2 treats qualitative detection (20 pages). Here the expert will be especially pleased with the tables of color reactions with organic reagents that include the limits of detection, and the table of qualitative microreactions where those for the other five platinum metals are also listed In chapter 3 methods of determining ruthenium are described, arranged as gravimetry, titrimetric analysis, potentiometry, and spectrophotometry. Electrochemical methods including polarography, ultraviolet, and *X*-ray spectral analysis, as well as radiochemical methods, complete a rich section.

Chapter 4 contains methods of separation, much space being devoted to methods involving distillation of the tetroxide. The determination of ruthenium in raw materials, concentrates, osmiridium, slurries, slags, *etc.*, is described in chapter 5; the text is completed by 13 schemes for separation. An appendix treats ruthenium fluoride and the preparation of some ruthenium compounds.

Citation of the literature, with 784 references, appears complete up to 1960. In some cases the evaluation could

have been more critical. In addition to the analytical methods, this book contains much non-analytical information about the chemistry of ruthenium. The subject index is too short and makes reference to an individual item difficult. Those interested in platinum and nuclear chemistry will welcome this monograph. *H.-L. Grube* [NB 476a/329 IE]

**Analytical Chemistry of Molybdenum.** By *A. I. Busev*. Series: "Analytical Chemistry of Elements". Academy of Sciences of the U.S.S.R., Moscow 1962. English translation: Israel Program for Scientific Translations, Jerusalem 1964. 1st Edit., vi + 247 pp., numerous figs., $ 15.25.

This book forms part of a series of about 50 volumes being published under the title "Analytical Chemistry of Elements" by the Institute of Geochemistry and Analytical Chemistry of the Academy of Sciences, Moscow. The volumes all follow the same design in respect of content and presentation.

The present monograph begins with a discussion of the properties of molybdenum and its compounds, and continues with a description of the chemical reactions that are of importance for analysis of the metal. Physical, physicochemical, and chemical methods of analysis, and their use for determination of molybdenum in ores, semi-finished materials, and end products (metal, oxides, salts, and compounds), are treated in detail.

The presentation is particularly valuable because the practical importance of individual methods is indicated, which prevents the book from being an uncritical collection. The analyst will be able to obtain much useful information.

*H. Braun* [NB 476b/330 IE]

**High Resolution Spectra of Inorganic and Related Compounds.** Inorganic Spectra with Indexes and Binders. Published by Sadtler Research Lab., Inc., Philadelphia/Pa. 1965. 1st Edit., $160.00.

A card index of vibration spectra of "inorganic" compounds fills a gap in present documentation and can be expected to arouse the critical interest of chemists working in this field.

The first part of the collection, for which yearly supplements are foreseen as for the older "organic" series, is now available either as single sheets (format 21.5×28 cm²), printed on one side and contained in two strong ring binders, or as 16 mm microfilm. An edition on punched cards, which would have many advantages, is, however, not announced.

The 600 infrared spectra illustrated include coordination compounds such as $K_3[Fe(CN)_6]$, $(NH_4)_2[PtCl_4]$, and $[Ni(NH_3)_6]Cl_2$, as well as classical inorganic compounds such as LiF, $NH_4NO_3$, $AlCl_3$, $SiO_2$, $P_4S_{10}$, $CdCO_3$, and $PbCrO_4$. Their choice and arrangement is apparently according to receipt and origin of the material. This has the consequence that many classes of compounds such as halogens, boron hydrides, and simple metal(0) complexes are not considered here at all, whereas on the other hand spectra are given for borates ($MBO_3$) of indium, scandium, yttrium, and lanthanum and for 20 complexes of 2,4-pentanedione. The purity of the substances is described summarily as $> 98\,\%$.

The compounds characterized by vibration spectra in these two volumes are recorded together in three indexes, placed at the beginning: an alphabetical index, a molecular formula index, and – unnecessarily in view of the lack of order in the arrangement – according to the spectrum number. Issue of an index arranged according to functional groups is planned.

The vibration spectra were measured using capillary films, discs, and/or Nujol/Hostaflon suspensions between 4000 and 200 $cm^{-1}$ (2.5 to 50 μ) with a grating spectrograph and are reproduced linear in wave number. Thus a high degree of accuracy is obtained for the short-wave region which, however, is in many cases free from lines for inorganic compounds that contain no water of crystallization. Wave numbers of maxima and assignments of significant bands are not indicated.

The sheets contain the vibration spectrum (format 8×25 cm²), the firm's imprint (format 2×13 cm²), and the spectrum number, then the name, composition, formula weight, and sometimes a schematic structural formula of the substance, the origin of the sample, and the method of measurement. Physical data such as melting point, boiling point, refractive index, and density are given incompletely or not at all; criteria of purity and literature references are totally lacking.

As to detail, a very heterogeneous picture is presented by different sizes and kind of type, even sometimes handwriting, in different positions on the individual sheets. Like other alums (*e.g.* Y 51 S and Y 73 S), sodium aluminum sulfate dodecahydrate (Y 173 S) has the simple formula weight, as given correctly in the molecular formula index. On the other hand, the molecular formula index does not include the water of crystallization of ammonium cobalt hexahydrate that is given on the spectral sheet Y 208 S. It is proved that in nickel bis(biacetyl dioxime) (Y 266 S) coordination is to the nitrogen atoms and not to oxygen. In the reviewer's copy spectrum Y 370 S is missing.

In conclusion it must be stated that the present collection does close the documentation gap mentioned above but that many improvements could be effected. Its utility would in particular be raised by classification of the spectra, by a wider choice of substances, and, in view of the blank reverse pages, by the additions mentioned above.

*H. Bock* [NB 481/335 IE]

**Biology Data Book.** Edited by *P. L. Altman* and *D. S. Dittmer*. Federation of American Societies for Experimental Biology, Washington, D.C., 1964. 2nd Edit., 633 pp., numerous figs., $ 10.–.

In this book are collected data of particular concern to biologists. He who is interested in the pulse frequency of the bat, the expectation of life of the crocodile, or the number of eggs in herring roe, or who is looking for an authoritative comparison of the most poisonous snakes, the highest trees, or the fastest spread of organisms, can occupy himself contentedly with this book for many hours and find in the process a host of the most interesting facts from toxicology, ecology, and the inexhaustible reservoir of the biological collector's treasure. Here are presented to the biochemist most valuable data about the foods essential for every species and genus, about hormones, antibiotics, and antimetabolites, about enzymes and their properties. All in all, however, this industrious book is biological. Even the chapter headings will show, that unless he has wide-ranging biological interests, the chemist will find more satisfaction for his lexical curiosity than directly useful information.

The 155 tables concern the following physiological areas: genetics, cytology, reproduction, development, and morphogenesis; food, nutrition, and metabolism; breathing, life cyle, and blood; biological control, habitat, and adaptation. They are all compiled from the original papers by experts in the field, and contain very exhaustive references. However, as these references disclose, there has been little culling from the most modern literature, for the book is described as an abbreviated and improved version of the "Handbook of Biological Data" of 1956. It is questionable whether the citation of sources, obviously wanted by many readers, need have been quite so extensive. The scholastic was given a scientific alibi by quotation of older authorities. In such quotations the compilers are, however, too easily satisfied by a complicated chemical word – they do not explain it. For instance, among the physical properties of compounds there are none of the more modern characteristics, for the hexoses and pentoses no strucural formulae, for acids and bases no pK values (there are a few of these, but in reference to buffers).

There are some – not many – small blunders in the tables, but these can be set down to the labour of collation. It is misleading to compare, without comment, the height of Englishmen in 1926 with that of the Japanese in 1960. The colored illustration of blood cells can be misunderstood because normal and pathological forms are jumbled together after varied histological staining. The metabolism diagram is not very clear because the typeset photooffset printing is not sufficiently flexible. In the chapter on reaction kinetics everything is missing which the biochemist – or the biologist – expects to find there, from a useful table of buffers to a set of formulae for evaluation and calculation of metabolic results. It is true that a table of antilogarithms is given, but without any introduction to show how to use it in calculating pH values...

The book is extraordinarily wide-ranging in its collection and treatment of facts, and will certainly be useful to the biologist. It will be less valuable to the biochemist. It is probably unjust to review it in a journal designed for chemists.

*L. Jaenicke* [NB 469/322 IE]

**The Chemistry of the Antibiotics Used in Medicine.** By *R. M. Evans*. Pergamon Press, Oxford 1965. 1st Edit., viii + 226 pp., numerous illustr., 25 s (about $ 3.50).

This pocketbook is not aimed at the specialist but is intended to offer students and their teachers a review of the chemistry of the antibiotics used in medicine. This object is attained and the book thus fills a gap in the literature. The antibiotics are arranged from a biogenetic viewpoint, which allows the heterogeneous materials to be handled logically. A few antibiotics with antitumor activity are mentioned as well the compounds used therapeutically.

Short historical remarks and information about the production of the antibiotic are followed in each case by thorough treatment of the chemistry. In this treatment the author succeeds in pinpointing the steps essential for determination of structure; he also describes a few syntheses and partial syntheses. However, the sections on biogenesis are mostly unsatisfactory in that the author is content with mere listing of the results, which are then often interpreted inaccurately; in this section too the literature is very incompletely covered. Relevant references are also missing from the treatment of the stereochemistry of the sugars from macrolide antibiotics. In a short chapter on the mode of action of antibiotics the reader is told of some of the important results and problems in this field.

There is a subject index and the book is well printed and produced; the number of erroneous formulae is small. The main emphasis in the book is on the chemistry of antibiotics; *Zähner*'s excellent pocketbook on the biology of antibiotics may be recommended as compensation.

*H. Grisebach* [NB 460/313 IE]

**Dictionary of Organic Compounds.** Vol. 1–5. Compiled and edited by *Sir I. Heilbron †*, *A. H. Cook*, *H. M. Bunbury*, and *D. H. Hey*. Eyre & Spottiswoode Ltd. and E. & F. N. Spon Ltd., London 1965. 4th enlarged Edit., 3281 pp., 5 Vol. and 1 Supplement £ 100.

The last edition of "Heilbron-Bunbury" appeared in 1953 in four volumes. The new edition now published consists of five volumes and the first supplement. Further supplements are due to appear yearly, keeping the work up to date.

In its present form the work contains more than 40000 entries, 9000 more than in the previous edition. In addition 6000 new cross-references have been included.

A new feature is the inclusion of trade names, particularly for antibiotics, pharmaceuticals, and plant pesticides, and it was a good idea to give also literature references for radioactive and deuterium-labeled compounds. For instance, the entry for toluene includes five deuterated derivatives, one tritiated compound, and three $^{14}C$-compounds.

The entry name of each compound is followed by other possible designations, which, however unfortunately do not always appear as cross-references. Then the structural formula is given, often with all details of the configuration. It is very satisfactory that all the formulae are extremely clear, though the use of dots in place of valence bonds is disturbing, particularly for double bonds and triple bonds. After the molecular formula and molecular weight follow data – very short but kept intelligible – of the physical properties of the substance and its derivatives. For recent material NMR spectral data are included, when other properties are not yet reported in the literature. Next follow characteristic derivatives of the compound described, and, finally, the entry is completed by references to original papers.

This work contains such an unusual wealth of information in such a very short space that one cannot help but admire the editors' achievement. Yet one of the greatest advantages of the new edition of this lexicon is its up-to-dateness: the six volumes now presented contain the results in the chemical literature up to the end of 1964.

# New Methods and Results in the Study of Polyacids

BY PROF. K. F. JAHR AND DR. J. FUCHS

INSTITUT FÜR ANORGANISCHE CHEMIE DER FREIEN UNIVERSITÄT BERLIN (GERMANY)

*The present status of research on condensed vanadic, molybdic, and tungstic acids is reviewed. Information about the structure and formation of polyanions can be obtained by X-ray analysis and from nuclear magnetic resonance, infrared, and Raman spectra, as well as from complex formation in aqueous solution. Salts of the polyacids can be prepared in organic solvents by hydrolysis of esters of the metal oxoacids.*

## 1. Introduction

The chemistry of polyacids still presents many unsolved problems, although numerous compounds of this class have been known and studied for more than 100 years. Whereas preparative and analytical investigations predominated at first, attention later turned mainly to a systematic study of the state of the polyanions in aqueous solution [1, 3]. The measurement of diffusion and dialysis coefficients was used as the principal method for the determination of the pH ranges in which certain polyanionic species predominate, and the ranges in which strong aggregation occurs. The quantitative interpretation of these measurements, *i.e.* the determination of the degree of condensation of the anions, has sometimes led to erroneous results, since the relationships between diffusion coefficient and molecular weight are very complex [2]. Nevertheless, these investigations were of great value to further research in this field. Modern physical methods were later used to check, and in some cases to correct, the results, so that a fairly unanimous view on the size of the dominant particles in the most important polyanion systems has now been reached. However, many points of uncertainty still exist in this respect in the polymolybdate system.

## 2. Methods for the Determination of the Degree of Condensation of Polyanions

A very accurate and universally applicable method for the determination of the size [*] of polynuclear complexes was developed by *Sillén* [4], who showed that for the formation of a polynuclear complex in accordance with Eq. (a)

$$pA + qB \rightleftharpoons A_pB_q \qquad (a)$$

the values of p and q can be calculated from equilibrium data. It is possible to recognize several ionic species existing together, and to determine the equilibrium constants. To obtain the required experimental data, the concentration of one component, *e.g.* $c_A$, is kept constant, and the concentrations of the other components are varied. Series of experiments are carried out with different fixed initial concentrations $c_A$, and the concentration of free A and/or B is found by EMF measurements.

Important results have also been obtained by salt cryoscopy. This method, which was known as early as 1895 [5], has been greatly improved in recent years by the use of thermistors. A comparison of the results of careful salt-cryoscopic investigations with those obtained by other methods shows that very useful

[*] The size of a complex is expressed by the degree of condensation, *i.e.* the number of metal atoms in the polyanion.

[4] *L. G. Sillén*, Acta chem. scand. *8*, 299, 318 (1954); *10*, 186, 803 (1956); *16*, 159 (1962).

[5] *R. Löwenherz*, Z. physik. Chem. *18*, 71 (1895).

results can be obtained by salt cryoscopy. The recent criticism[6] of this method therefore seems unjustified.

Ultracentrifugation has also proved a very successful means of measuring the degree of condensation. This method can also be applied to electrolytically dissociated compounds, provided an excess of a foreign electrolyte[7] is added to ensure complete decoupling of the oppositely charged ions. Like the cryoscopic measurements, determinations using the ultracentrifuge give only average degrees of condensation[*], but this method has the advantage that it is possible[8] to recognize whether the solution studied contains one type of particle or a mixture of particles of different weights.

A selection from the results obtained for polyvanadate, polymolybdate, and polytungstate solutions by various methods is shown in Table 1.

Table 1. Degrees of condensation in a number of polyanionic systems.

[a] The acidification x of a solution is the ratio of the number of hydrogen ions to the number of monomeric oxometalate ions.
[b] Slowly established equilibrium between hexamers and dodecamers.

[6] *R. S. Tobias*, J. inorg. nuclear Chem. *19*, 348 (1961).

[7] *T. Svedberg* and *K. O. Pedersen*: Die Ultrazentrifuge. Steinkopff, Dresden and Leipzig 1940, S. 21.

[*] The ultracentrifuge method gives a weight-average molecular weight $M_w = (\sum_i n_i M_i^2)/(\sum_i n_i M_i)$, whereas salt cryoscopy gives a number-average $M_n = (\sum_i n_i M_i)/(\sum_i n_i)$. The calculation of the average degree of condensation from $M_w$ and from $M_n$ can lead to differences, which are particularly marked for mixtures of particles of different sizes, *e.g.* a mixture of monomeric and hexameric species.

[8] *H. P. Stock*, Z. Naturforsch., *20b*, 933 (1965).

## 3. Some Polyanionic Systems

The polyanionic systems listed in Table 1 are described below in greater detail.

### (a) The Vanadate System

Acidification of a vanadate solution leads first to the formation of $HVO_4^{2-}$ ions, which exist in equilibrium with the dimeric $V_2O_7^{4-}$ ions, the position of the equilibrium depending on the vanadium concentration. Further acidification leads *via* $HV_2O_7^{3-}$ [9] to metavanadate ions $(VO_3)_n^{n-}$ by a route that has not yet been fully elucidated. A concentration-dependent equilibrium[10] exists at this stage between $V_3O_9^{3-}$ and $V_4O_{12}^{4-}$. The trimeric ion is detected only in very dilute solutions. Addition of further $H^+$ leads to the decavanadate ions[11] $V_{10}O_{28}^{6-}$, $HV_{10}O_{28}^{5-}$, and $H_2V_{10}O_{28}^{4-}$, and finally to the free acid $H_6V_{10}O_{28}$. The transition from the metavanadate to the decavanadate also proceeds by an unknown route; a short-lived red intermediate is observed in concentrated solutions[31]. Free decavanadic acid $H_6V_{10}O_{28}$ exists in equilibrium with a compound $V_2O_5 \cdot x\,H_2O$ of higher molecular weight[32]. On further acidification, the monomeric cation $VO_2^+$ is formed by degradation reactions, the details of which are not yet known.

Depending on the acidification, the crystalline compounds obtained from polyvanadate solutions are divanadates $M_4V_2O_7$, metavanadates $(MVO_3)_\infty$, which

have a chain structure, decavanadates $M_6V_{10}O_{28}$, $M_5HV_{10}O_{28}$, and $M_4H_2V_{10}O_{28}$, and "hexavanadates" $(M_2V_6O_{16})_\infty$, which have a layer structure [33,34] (M = univalent metal). Nearly all vanadates contain water of crystallization.

### (b) The Molybdate System

Diffusion experiments and salt-cryoscopic and spectrophotometric measurements show that molybdate solutions contain condensed ions after the addition of even small quantities of acid. The existence of $Mo_7O_{24}^{6-}$ may be regarded as certain; this anion is formed in accordance with

$$7\ MoO_4^{2-} + 8\ H^+ \rightleftharpoons Mo_7O_{24}^{6-} + 4\ H_2O \qquad (b)$$

and hence has its maximum stability when the acidification x is 1.14 ($8H^+/7MoO_4^{2-}$). The average degree of condensation increases rapidly at acidifications higher than 1.50. Figure 1 shows the average degree of condensation P of acidic molybdate solutions as found in our salt-cryoscopic measurements [21].

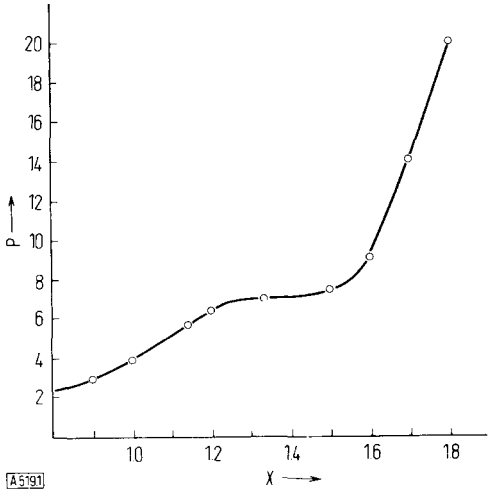

Fig. 1. Average degree of condensation p of polymolybdate ions as a function of the acidification x, from salt-cryoscopic measurements [21].

*Byé* [35], who found that the degree of condensation decreased again at $x > 1.14$, evidently failed to make adequate allowance for the influence of hydrogen ions on the freezing point depression. The main difficulty in the elucidation of the molybdate system is the fact that several polyanionic species exist in every pH range, in rapidly established equilibria.

Crystalline products obtained from acidic molybdate solutions include paramolybdates $3M_2O{\cdot}7MoO_3{\cdot}nH_2O$, "trimolybdates" $M_2O{\cdot}3MoO_3{\cdot}nH_2O$, and metamolybdates $M_2O{\cdot}4MoO_3{\cdot}nH_2O$ (M = univalent metal). Numerous products [36] with still higher molybdenum contents have been isolated from more strongly acidic solutions. However, it is not yet certain whether these are single compounds.

[36] Gmelins Handbuch der anorganischen Chemie, System Nr. 53, 8th. Edit., Verlag Chemie, Berlin 1935, p. 113.

### (c) The Tungstate System

Acidification of tungstate solutions leads first to the rapid formation of a hexameric [38] ion, the paratungstate ion A [39].

$$6\ WO_4^{2-} + 7\ H^+ \rightleftharpoons [HW_6O_{21}{\cdot}x\ aq]^{5-} + (3\text{-}x)\ H_2O \qquad (c)\ [*]$$

This ion slowly comes to equilibrium, *via* at least one intermediate [40] (the paratungstate ion B [40]), with a dodecameric ion [22,29,30] (the paratungstate ion Z [**] $[W_{12}O_{36}(OH)_{10}]^{10-}$ or $[W_{12}O_{40}(OH)_2]^{10-}$). In a still slower reaction, part of the equilibrium mixture is converted into monotungstate $WO_4^{2-}$ and "true" metatungstate $[W_{12}O_{38}(OH)_2]^{6-}$. Rapid addition of 9 $H^+$ to 6 $WO_4^{2-}$ ($x = 1.50$) leads *via* $[HW_6O_{21}{\cdot}x\ aq]^{5-}$ to another hexatungstate ion (the metatungstate ion A [41] $[HW_6O_{20}{\cdot}x\ aq]^{3-}$, which changes very slowly, again *via* at least one intermediate, the Ψ-(pseudo-) metatungstate ion [39,41,41a], into the dodecameric "true" metatungstate ion.

The crystalline products obtained from acidic tungstate solutions are paratungstates $5M_2O{\cdot}12WO_3{\cdot}nH_2O$ and metatungstates $3M_2O{\cdot}12WO_3{\cdot}nH_2O$. A sodium salt having the composition $Na_2O{\cdot}2WO_3{\cdot}5H_2O$ [42] is also known. The addition of $K^+$ or $Ba^{2+}$ to Ψ-metatungstate solutions leads to amorphous precipitates having the composition $K_2O$ or $BaO{\cdot}4WO_3{\cdot}nH_2O$ [39].

## 4. Determination of the Structure

The aim of further investigations must be to determine the structures of the polyions present in solution, and to discover how they are interconverted. Since the structure of dissolved particles cannot be determined directly, except in a few particularly favorable cases, this aim can only be achieved by a combination of methods.

The elucidation of structures in many fields of chemistry has been greatly assisted by models developed on the basis of theoretical considerations. However, attempts to develop a structural model for polyanions generally fail simply because the compositions of the ions are not

[37] Cf. *D. L. Kepert*, Progr. inorg. Chem. *4*, 199 (1962).

[38] *H. Schulz* and *G. Jander*, Z. anorg. allg. Chem. *162*, 141 (1927); *G. Jander*, *D. Mojert*, and *Th. Aden*, *ibid. 180*, 129 (1929); *K. F. Jahr* and *H. Witzmann ibid. 208*, 145 (1932).

[39] *P. Souchay*, Ann. Chimie *18*, 61, 169 (1943).

[*] aq = structural water, cf. Section 4.

[40] *G. Ewald*, Diploma Thesis, Humboldt-Universität Berlin 1951.

[**] The nomenclature used is that proposed by *D. L. Kepert* [37]. Paratungstate B was formerly called paratungstate $A_2$, and paratungstate Z was called paratungstate B.

[41] *G. Jander* and *U. Krüerke*, Z. anorg. allg. Chem. *265*, 244 (1951).

[41a] Ψ-Metatungstate solutions probably contain several species, mainly hexamers in dilute solutions, and mainly more highly aggregated particles, regarded by *C. Jander* and *D. Exner* as dodecamers, in concentrated solution [43]. According to more recent studies [43a], however, the latter are more likely 24-fold aggregates, since particles of ionic weight 6450 have been found in a solution of the amorphous potassium Ψ-metatungstate.

[42] *E. L. Simons*, Inorg. Chem. *3*, 1079 (1964).

accurately known, since the degree of condensation and the charge are not sufficient to give the exact composition of an ion. Since polyanions may contain structural water (aq), which forms neutral OH groups with the oxygen atoms present, the number of oxygen and hydrogen atoms in the ion cannot be found directly. For example, it is impossible to decide from investigations in aqueous solution whether paratungstate A has the composition $[W_6O_{20}(OH)]^{5-}$ or *e.g.* $[W_6O_{19}(OH)_3]^{5-}$ (also written as $[HW_6O_{21}\cdot H_2O]^{5-}$). Even in crystalline compounds, it is often difficult to tell whether or not structural water is present. Even isobaric or isothermal degradation and the study of infrared spectra do not always lead to an accurate answer. Probably the greatest promise is shown by nuclear magnetic resonance measurements [44], but until more experience has been gained, the information obtainable will remain qualitative.

The development of structural models for polyions is further complicated by the fact that the coordination number of the metal ions towards oxygen is unknown. The ionic radii of $V^{5+}$ (0.59 Å), $Mo^{6+}$ (0.65 Å), and $W^{6+}$ (0.65 Å) permit either tetrahedral or octahedral coordination.

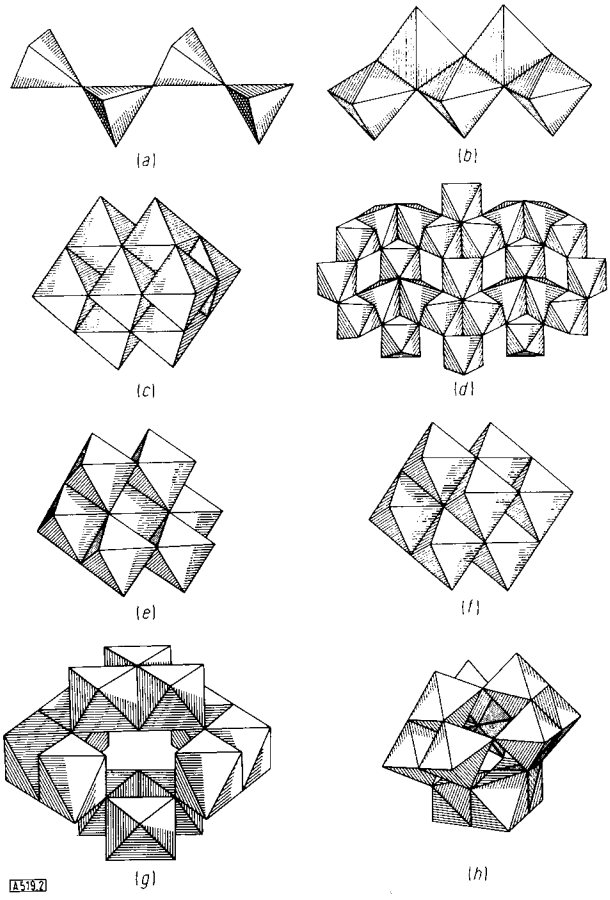
## 5. Importance and Results of X-Ray Structure Investigations

The basis of structure determinations is therefore X-ray studies on crystalline compounds. However, it must be established in every case that the structure of the polyanions in solution is the same as, or at least very similar to, that of the crystalline compounds. This equivalence cannot be assumed. For example, crystalline metavanadates contain long chains of linked $VO_4$ tetrahedra [45] or $VO_5$ units [46] (trigonal bipyramids), whereas the aqueous solution contains tetravanadate or trivanadate ions (cf. Figs. 2a and 2b).

The structures in the crystal and in solution can be compared with the aid of Raman and infrared spectrography and NMR measurements. Thus *Aveston* [26, 29] found close agreement between the Raman spectra of crystalline and dissolved heptamolybdates and paratungstates Z.

The infrared spectra of crystalline and dissolved polytungstates were studied by *Spitzyn et al.* [47, 48]. However, no definite conclusions could be drawn, since agreements were found as well as differences. It was concluded from NMR measurements on decavanadate solutions [49] that three differently bound vanadium atoms were present in the ratio 2:6:2. However, this result cannot be reconciled with the decavanadate structure found by *Evans jr.*, *Swallow*, and *Barnes* [50] for $Ca_3V_{10}O_{28}\cdot 16H_2O$ and $K_2Zn_2V_{10}O_{28}\cdot 16H_2O$. Other investigations (cf. Section 8a) indicate that the structure of decavanadate ions in solution differs from that in crystals. It is also possible that not all the crystalline decavanadates contain the same polyanion [51].

Unfortunately, very few X-ray structure investigations have been carried out on salts of polyacids; moreover, some of the existing investigations are incomplete, since only the heavy metal positions, but not the positions of the oxygen atoms could be determined. The great scattering power of heavy metal atoms (particularly tungsten) for X-rays makes it extremely difficult to locate the oxygen atoms. Other properties of the salts of isopolyacids, *e.g.* large unit cells, poor crystallizing power, and tendency towards twinning, also make them particularly difficult subjects for X-ray structure analysis. Fig. 2 shows the structures of isopolyacids that have been studied by the X-ray method.



A519.2

Fig. 2. Anions of the salts: (a) $KVO_3$ [45], (b) $KVO_3\cdot H_2O$ [46], (c) $K_2Zn_2V_{10}O_{28}\cdot 16H_2O$ and $Ca_3V_{10}O_{28}\cdot 16H_2O$ [50], (d) $K_2V_6O_{16}$ [33], (e) $(NH_4)_6Mo_7O_{24}\cdot 4H_2O$ [52], (f) $(NH_4)_4Mo_8O_{26}\cdot 4H_2O$ [52], (g) $Na_{10}W_{12}O_{36}(OH)_{10}\cdot 23H_2O$ [53]. — (h) "True" metatungstate ion $[H_2W_{12}O_{40}]^{6-}$ (isomorphous with $H_3PW_{12}O_{40}\cdot 5H_2O$) [54].

*Lipscomb* [55] has questioned the correctness of the paratungstate Z structure (Fig. 2g). *Lindqvist* determined only the tungsten positions, and the positions of the oxygen atoms

were estimated on steric grounds. *Lipscomb* showed that the observed X-ray intensities agree equally well with another structural model (Fig. 3) containing fewer oxygen atoms ($W_{12}O_{42}$ instead of $W_{12}O_{46}$).Thus the formula of the crystalline paratungstates Z would be $M_{10}W_{12}O_{36}(OH)_{10}\cdot nH_2O$ according to *Lindqvist*, and $M_{10}W_{12}O_{40}(OH)_2\cdot n\ H_2O$ according to *Lipscomb*. The results obtained in the isobaric degradation of potassium paratungstate $5K_2O\cdot 12WO_3\cdot 11H_2O$ and from the infrared spectra of its degradation products[87] agree more closely with *Lipscomb*'s formula (only one mole of structural water).

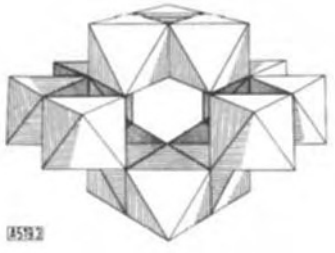

Fig. 3. Structure of the anion of sodium paratungstate $Na_{10}W_{12}O_{40}(OH)_2$, according to *Lipscomb* [55].

The data available at present are insufficient to show how these polyions are formed in solution and how they are interconverted. It is therefore extremely important to detect as many as possible of the intermediates, which must exist, but which are not yet known, since they occur only transiently or only in very low equilibrium concentrations.

## 6. Detection of Intermediate Polyanions

Some possibility of detecting short-lived intermediates is offered by a method described by *Meier* and *Schwarzenbach*[56]. The acidification of vanadate and tungstate solutions was followed potentiometrically in a flow apparatus permitting very rapid mixing of reaction solutions (in about 5 msec). Since condensations proceed much more slowly than protonations and deprotonations, these measurements were intended to detect the protonation stages of anions and polyanions with a minimum of interference from accompanying condensations. Not only known polyanions were detected, but also a short-lived ($10^{-2}$ sec) polytungstate ion, which is probably tetrameric, and which the authors formulate as $H_5W_4O_{16}^{3-}$[57]. It is interesting in this connection to note that *Hüllen*[58] detected a tetratungstate ion as one of the building units in hydrated lithium tungstate $Li_2WO_4\cdot 4/7\ H_2O$ by X-ray structure analysis (see Fig. 4).

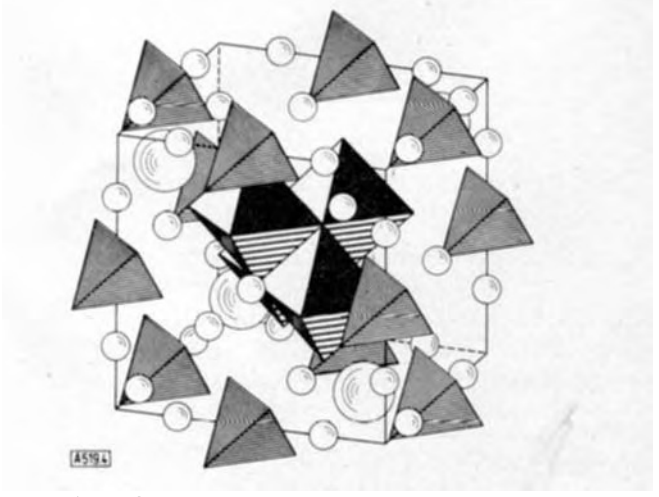

Fig. 4. Structure of $Li_2WO_4\cdot 4/7\ H_2O$ [58]. Large spheres: $H_2O$; small spheres: $Li^+$; tetrahedra: $WO_4^{2-}$; group of four octahedra: $W_4O_{16}^{8-}$.

## 7. Salt Formation in Organic Solvents by Hydrolysis of Esters of Metal Oxoacids

A method for the preparation of salts of polyacids previously not obtainable from aqueous solution was discovered by *Jahr*, *Fuchs*, and co-workers[59]. Complete hydrolysis of an ester of a metal oxoacid dissolved (generally as the monomer) in organic solvents leads normally to a highly condensed metal oxide hydrate. The condensation proceeds *via* the same intermediates as in the acidification of the metalate solution. The intermediate polyacids can be intercepted as salts if the organic solution contains a base, a salt, or a buffer mixture. This method of precipitating salts of polyacids from organic solvents, which involves only very small quantities of water, is very useful not only from the preparative point of view, but also for the investigation of structures, since it is possible in this way to obtain anhydrous compounds. It is then very much easier to determine whether the polyanions contain structural water, and if so, how much. The method also offers new preparative possibilities, since solubility relationships in organic solvents are different from those in water. Polyanions that have been definitely detected in aqueous solution, but of which no crystalline salts have so far been obtained because other polyanions present in the equilibrium form sparingly soluble salts, can be obtained as crystalline salts in this way.

Thus the only previously known crystalline paratungstates were of the Z type, with dodecameric anions. Hydrolysis of tetramethyl tungstate(VI), $WO(OCH_3)_4$, in the presence of piperidine has now led to a pentapiperidinium hexatungstate[59a–61], $(C_5H_{11}NH)_5HW_6O_{21}$, or $(C_5H_{11}NH)_5H_3W_6O_{22}$, the reactions of which show that it contains the paratungstate A ion. The corresponding ammonium and pyridinium salts can also be prepared in this way. We have also obtained salts of paratungstate ions B, which occur as intermediates in the conversion of paratungstate A into paratungstate Z, by hydrolysis of tetramethyl tungstate (VI) in the presence of a solution of potassium or ammonium acetate in methanol[62]. The X-ray diagrams of ammonium paratungstates A, B, and Z are shown in Fig. 5.

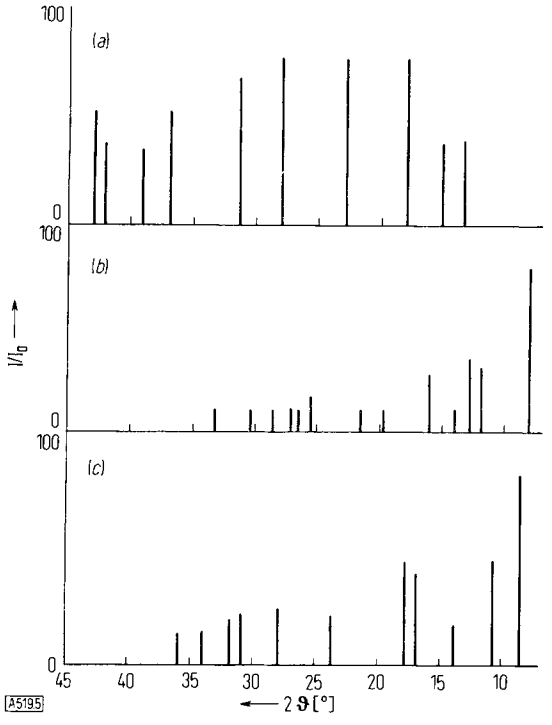

Fig. 5. Relative X-ray intensities ($Cu_{K\alpha}$ radiation) of (a) ammonium paratungstate A, (b) ammonium paratungstate B, (c) ammonium paratungstate Z (Analytical composition: 5 $(NH_4)_2O \cdot 12\ WO_3 \cdot x$ solvent. A and B contain methanol; Z contains water).

Although the compositions are practically identical [$5(NH_4)_2O \cdot 12 WO_3 \cdot x$ solvent; the A and B salts contain methanol, and Z contains water], the compounds differ considerably in their chemical properties. Thus a freshly prepared aqueous solution of ammonium paratungstate Z is neutral, whereas solutions of paratungstates A and B are distinctly acidic. Unlike the other two salts, the paratungstate A is very soluble and reacts vigorously with $H_2O_2$ [63], the resulting solution being strongly acidic.

Salt-cryoscopic measurements indicate that the paratungstate ion B is hexameric, *i.e.* has the composition $[HW_6O_{21} \cdot x\ aq]^{5-}$. It is not yet known whether the difference between paratungstates A and B is due to a change in the content of structural water or to a rearrangement. Interestingly, a further hydrogen in the paratungstate ion B can be replaced by metal ions to give $[W_6O_{21} \cdot x\ aq]^{6-}$. The hydrolysis of tungstate esters in the presence of potassium acetate in ethanol yielded a salt having the ratio 6 $K_2O$:12 $WO_3$; the X-ray diagram of this salt shows that its structure is practically the same as that of the paratungstate B obtained from methanolic solution, in which the ratio is 5 $K_2O$:12 $WO_3$. The infrared spectra of 6 $K_2O \cdot 12\ WO_3 \cdot x\ H_2O$ are so similar to those of the $Na_2O \cdot 2\ WO_3 \cdot 5\ H_2O$ obtained from aqueous solution that we also regard the latter as a salt of the same hexatungstic acid, and denote it by the formula $[Na_6W_6O_{21} \cdot x\ aq] \cdot (15\text{-}x)H_2O$.

Another advantage of the use of organic solvents for the preparation of salts of polyacids is that compounds that are immediately hydrolysed in water can be prepared. For example, *Jahr*, *Fuchs*, and *Oberhauser* [64] prepared a tetra-n-butylammonium tungstate $[N(C_4H_9)_4]_2O \cdot 6\ WO_3$, which is more strongly acidic than any of the polytungstates isolated so far from aqueous solutions, and which is therefore an intermediate stage between metatungstate and the tungsten oxide hydrates. The salt is insoluble in water, but readily soluble in acetone, from which it can be recrystallized. If a little water is added to the acetone solution, the polyanion decomposes and a tungsten oxide hydrate separates out. The degree of condensation of the anion is not yet known. The salt is obtained from acetone as very well-formed, highly refractive crystals [59a].

Interesting results have also been obtained in the study of the hydrolysis of a molybdate ester. Hydrolysis of the diethyl molybdate - ammonia adduct $3\ MoO_2(OC_2H_5)_2 \cdot 2\ NH_3$ [65] in an ethanolic solution of ammonia and ammonium chloride led to an ammonium trimolybdate of the composition $2(NH_4)_2O \cdot 6\ MoO_3 \cdot H_2O$ [66]. The structure of the "trimolybdates" is not yet known. The poor crystallizability of these compounds and their tendency towards twinning have so far made an X-ray structure elucidation impossible. *Lindqvist* [52] believes that the unit cell of the "trimolybdates" contains heptamolybdate $[Mo_7O_{24}]^{6-}$ and octamolybdate ions $[Mo_8O_{26}]^{4-}$ in the ratio 1:1. This structure is certainly not correct for the salt prepared by the hydrolysis of esters, since it must be assumed from the preparation conditions that the water present in the compound, the quantity of which can be accurately determined from the water consumed during hydrolysis, is structural water, *i.e.* that it is present in the form of OH groups. Though the degree of condensation of the polyanion is not given unambiguously by the analytical results (it could also be a multiple of 6), it is very probable from the results of these and other experiments (see Section 8) that the salt is a hexamolybdate $(NH_4)_4[H_2Mo_6O_{21}]$ or $(NH_4)_4[Mo_6O_{19}(OH)_2]$.

A particularly thorough study has been made of the hydrolysis of t-butyl orthovanadate, $(C_4H_9)_3VO_4$, in the presence of bases [67–69]. All types of polyvanadates that can be obtained from aqueous solution can also be prepared in organic solvents. The strength of the base present during the hydrolysis determines whether the product obtained is a divanadate, a metavanadate, a decavanadate, or a hexavanadate, the deciding factor in aqueous solution being the pH. In addition to the above salts, a hydrogen divanadate $K_3HV_2O_7$ [68] has been obtained by the hydrolysis of t-butyl orthovanadate in the presence of potassium t-butoxide; this confirms the existence of the $HV_2O_7^{3-}$ ion, discovered by *Ingri* and *Brito* [9] in equilibrium studies by *Sillén*'s method.

## 8. Complex Formation with Polyanions

### (a) Complex Formation with Polyvanadate Ions

Salt formation is not the only means by which a polyanionic species can be detected in an equilibrium mixture. Many polyanions form complexes with cations

[69] *J. Fuchs*, *K. F. Jahr*, *A. Eberhard*, and *F. Preuss*, Chem. Ber. *98*, 3610 (1965).

in solution. In many cases the polyanion very probably retains its structure and acts as a polydentate ligand, so that information about the size of the polyanion can be obtained from the composition of the complex. Even the fact that complexes are formed at all sometimes gives an indication of their structure. During the titration of a sodium decavanadate solution with a solution of a neutral salt of a bivalent or trivalent cation, for example, we observed [32] that the conductivity of the solution does not increase linearly. Very strong complex formation takes place, particularly with trivalent cations. From the titration curve, formation of a 1:1 complex was deduced. The extent of complex formation depends on the radius as well as the charge of the cation, and increases with increasing ionic radius. A particularly interesting effect is that resulting from the presence of a neutral salt during the titration of free decavanadic acid $H_6V_{10}O_{28}$ with alkalis. Figure 6 shows the course of a conductometric titration of free decavanadic acid with NaOH in the absence and in the presence of strontium nitrate.

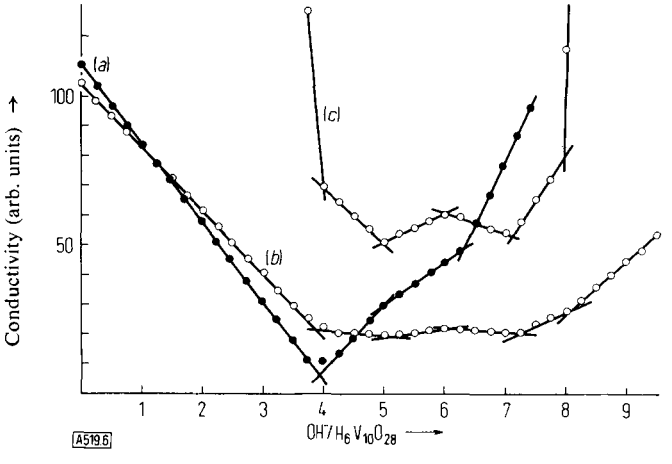

Fig. 6. Conductometric titration of 10 ml of $H_6V_{10}O_{28}$ (0.01 M with respect to $V_2O_5$) with 0.05 N NaOH [curve (a)] [32], and a corresponding titration after addition of 1 ml of 0.1 N $Sr(NO_3)_2$ solution [curve (b)]. Curve (c) shows a section of (b) with a 15-fold increase in sensitivity.

In the presence of $Sr^{2+}$, decavanadic acid consumes but 8 instead of 6 equivalents of $OH^-$. Similar changes in the titration curve are caused by other metal ions. When trivalent cations ($Al^{3+}$, $La^{3+}$, $Ce^{3+}$) or $Be^{2+}$ are present, 9 $OH^-$ are consumed.

Our interpretation of this phenomenon is as follows. The decavanadate ion probably is approximately spherical with a cavity in the center. A hydrated cation can enter this cavity, where it is fixed by complex formation. Owing to the field effect of the oxygen atoms surrounding the cation, protons are removed from the enclosed $[M(H_2O)_x]^{2+}$ and can be neutralized by $OH^-$. This leaves a monomeric hydroxide or an oxometalate ion, *e.g.* $[Be(OH)_3]^-$, in the interior of the complex. On the basis of this interpretation, the titration of $H_6V_{10}O_{28}$ in the presence of *e.g.* $Sr^{2+}$ may be formulated as shown in the following equations:

$$H_6V_{10}O_{28} + 4\ OH^- = H_2V_{10}O_{28}^{4-} + 4\ H_2O$$

$$H_2V_{10}O_{28}^{4-} + Sr(H_2O)_n^{2+} = [Sr(H_2O)_nH_2V_{10}O_{28}]^{2-} \quad (d)$$

$$[Sr(H_2O)_nH_2V_{10}O_{28}]^{2-} + OH^- = [Sr(H_2O)_nHV_{10}O_{28}]^{3-} + H_2O$$

$$[Sr(H_2O)_nHV_{10}O_{28}]^{3-} + OH^- = [Sr(H_2O)_nV_{10}O_{28}]^{4-} + H_2O$$

$$[Sr(H_2O)_nV_{10}O_{28}]^{4-} + OH^- = [Sr(OH)(H_2O)_{n-1}V_{10}O_{28}]^{5-} + H_2O$$

$$[Sr(OH)(H_2O)_{n-1}V_{10}O_{28}]^{5-} + OH^- = [Sr(OH)_2(H_2O)_{n-2}V_{10}O_{28}]^{6-} + H_2O$$

Only a few symmetrical structures are conceivable for a decavanadate ion having the formula $[V_{10}O_{28}]^{6-}$ if the central cavity is assumed to be large. The only structural units possible in this case are $VO_4$ tetrahedra, since $VO_6$ octahedra or $VO_5$ units give only very compact structures with no central cavity. The structure proposed [32] for the decavanadate ion in solution is shown in Fig. 7.

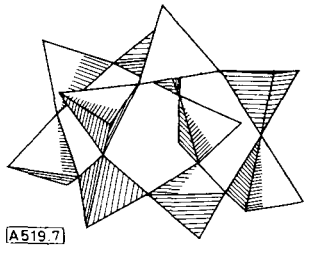

Fig. 7. Proposed structure of $V_{10}O_{28}^{6-}$ in solution [32].

### (b) Complex Formation with Polymolybdate Ions

If a few drops of methyl red are added to a molybdate solution of acidification 1.5, the color of the solution changes from red to yellow after a short time [70,71]. Surprisingly, the solution remains yellow when strong mineral acid is added. Conductometric titrations show the formation of a complex containing methyl red and molybdenum in the ratio 1:12. The yellow color of the methyl red in the strongly acidic solution can be understood only if it is assumed that the indicator molecule is bound in the center of a dodecamolybdate ion, and that the situation is similar to that in conventional inclusion compounds of indicators with cyclodextrins [72, 73], in which the indicator also does not exhibit its normal color.

The formation of complexes thus indicates that molybdate solutions of acidification above 1.5 contain dodecameric anions which, like the decavanadate ion, are approximately spherical, hollow, and can form inclusion complexes. Naturally, nothing can be said about the concentration of polyanions in the solution. It is quite possible that only a small part of the molybdenum is in the form of dodecameric particles, and that it is only the formation of the relatively stable complex that displaces the equilibrium in favor of this polyanion. The rate of formation of the "inclusion complex" is greatest in solutions of acidification x = 1.65 to 1.7. The yellow solution becomes red again on addition of concentrated phosphoric acid, which evidently displaces the indicator anion to form a more stable complex. The methyl red complex is also rapidly destroyed by alkalis, owing to breakdown of the polyanion. It is possible, by very careful addition of $OH^-$, to achieve the apparently paradoxical

result that the color of the solution changes from yellow to red, since the dodecamolybdate ion is destroyed at a pH at which methyl red is normally red. The yellow indicator anion is then formed when an excess of $OH^-$ is added.

We have carried out an intensive study of the complexing power of molybdate solutions of acidification less than 1.50 towards cations and towards acids that can form heteropoly compounds [74,75]. Many cations can react with polymolybdate ions in solution to form complexes, nearly all of which are very unstable. $Al^{3+}$ forms a very stable complex having an Al:Mo ratio of 1:6. The complexes formed by orthotelluric acid and periodic acid are still more stable.

In this case, too, a relation is apparent between the stability of the complex and the ionic radius of the complex former. The radii of $Al^{3+}$ (0.55 Å), $Te^{6+}$ (0.56 Å), and $I^{7+}$ (0.50 Å) are very similar. These complexes, which are formed in relatively weakly acidic solution, require extensive measurements for the determination of their compositions, since the complexing equilibrium depends not only on the concentration of ligand ratio, but also to determine the charge on the hydrogen ion concentration. However, the dependence of the equilibrium on pH also has the advantage that it is not only possible to determine accurately the nucleus: ligand ratio, but also to determine the charge on the complex and to establish the occurrence of protonation stages. We have elucidated these reactions to a large extent [75] by simultaneous thermometric, conductometric, and potentiometric titrations.

The methods used will be illustrated for the complex formation between periodic acid and molybdate ions. When an $HMoO_4^-$ solution (x = 1.00) is titrated with periodic acid, the thermometric and conductometric titration curves contain discontinuities and the potentiometric curve contains inflections at the molar ratios $H_5IO_6/HMoO_4^-$ = 1:7 and 1:3. However, it would be erroneous to conclude that complexes with the ratios I:Mo = 1:7 and 1:3 have been formed. In fact, the discontinuities are due to a 1:6 complex $[IMo_6O_{24}]^{5-}$ which is initially formed by only a part of the molybdenum [reaction (e)].

$$7\ HMoO_4^- + H_5IO_6 \rightleftharpoons [IMo_6O_{24}]^{5-} + MoO_4^{2-} + 6\ H_2O \quad (e)$$

change in slope at I:Mo = 1:7

One-seventh of the molybdate cannot enter into complex formation at first, owing to the deficiency in $H^+$.

An interesting phenomenon is observed in this titration. Owing to the consumption of $H^+$ and the consequent conversion of $HMoO_4^-$ into $MoO_4^{2-}$ the pH initially increases rapidly for a time during the titration, although the titrant is the relatively strong periodic acid.

Since periodic acid itself can supply $H^+$ [*], the remaining molybdate is finally converted into the complex ion [reaction (f)]. If the titration is carried out at different initial acidification, the discontinuities and inflections occur at different values of the ratio $H_5IO_6/MoO_4^{2-}$ [*]. The composition of the complex can be found by mathematical treatment of the results obtained when molybdate solutions of various acidifications are titrated with periodic acid.

$$6\ HMoO_4^- + 2\ H_5IO_6 \rightleftharpoons [IMo_6O_{24}]^{5-} + H_4IO_6^- + 6\ H_2O \quad (f)$$

change in slope at I: Mo = 1:3

The complexing processes can in general be formulated as follows:

$$n\ MoO_4^{2-} + p\ H^+ + m\ H_5IO_6 \rightleftharpoons [I_mMo_nO_s]^{(2s-6n-7m)-} + (5m + p)/2\ H_2O \quad (g)$$

where $s = 4n-(7m-p)/2$

If the acidification x of the molybdate solution is varied and the atomic ratio I/Mo = Z determined for the initially incomplete complex formation (when all the $H^+$ present have been consumed) and for the final complex formation (when all $MoO_4^{2-}$ is converted into complex), it is found that Z = mx/p and Z = −x + (m + p)/n, respectively; it is then possible to establish sets of integral values for m; p; n.

The values found for complex formation with periodic acid are 6; 7; 1 and multiples of this set, such as 12; 14; 2. These sets give Equations (h) and (i).

$$6\ MoO_4^{2-} + 7\ H^+ + H_5IO_6 \rightleftharpoons [IMo_6O_{24}]^{5-} + 6\ H_2O \quad (h)$$

$$12\ MoO_4^{2-} + 14\ H^+ + 2\ H_5IO_6 \rightleftharpoons [I_2Mo_{12}O_{48}]^{10-} + 12\ H_2O \quad (i)$$

The question of whether the mononuclear complex $[IMo_6O_{24}]^{5-}$ or a polynuclear complex is formed cannot be answered on the basis of the titrations; with the ultracentrifuge, however, *Stock* [76] obtained a value of 1110 for the ionic weight of the complex ion ($M_{theor.}$ for $[IMo_6O_{24}]^{5-}$ is 1086.5), showing that the reaction proceeds according to Eq. (h). Other experimental points can be easily interpreted by the formation of the protonation stages $[HIMo_6O_{24}]^{4-}$, $[H_2IMo_6O_{24}]^{3-}$, $[H_3IMo_6O_{24}]^{2-}$, and $[H_4IMo_6O_{24}]^-$.

Complex formation between polymolybdate ions and orthotelluric acid is more versatile than the reaction with periodic acid. Salts having the composition $M_6TeMo_6O_{24}\cdot nH_2O$ have been known for some time [77], complex formation in solution, on the other hand, was first studied in 1963 by *Gross* [74]. Conductivity measurements showed that in addition to the 1:6 complex, other complexes with different Te:Mo ratios occur. By spectrophotometric studies [78] (molar ratio method) and by salt-cryoscopic titrations [79] we found the Te:Mo ratios in these compounds to be 1:7 and 1:12. The charges on the complexes were determined by simultaneous thermometric, conductometric, and potentiometric titrations. The ions found in addition to $[TeMo_6O_{24}]^{6-}$ were $[HTeMo_7O_{28}]^{7-}$ (or $[TeMo_7O_{27}(OH)]^{7-}$) and $[H_6TeMo_{12}O_{48}]^{12-}$ (or $[TeMo_{12}O_{42}(OH)_6]^{12-}$). The ionic weight of the 1:6 complex was determined with the aid of the ultracentrifuge [80] ($M_{exp.}$, 1163; $M_{theor.}$ for $[TeMo_6O_{24}]^{6-}$, 1087.3). Information about the relative stabilities of the complexes was obtained by salt-cryoscopic titrations.

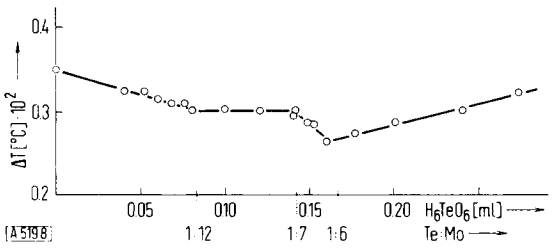

Fig. 8. Relative freezing point depression ΔT in the salt-cryoscopic titration of 2.5 ml of 0.3 M $Na_2MoO_4$ solution having an acidification x = 1.14 with 0.06 M $H_6TeO_6$, measured in the Glauber's salt-ice eutectic.

It can be seen from Figure 8 that the 1:6 complex is the most stable. The freezing-point depressions obtained almost[*] coincided with those expected for $[TeMo_6O_{24}]^{6-}$ although the measurements, which were carried out in the Glauber's salt-ice eutectic, had to be made at a very low concentration ($\approx$ 0.01 g-atom of Mo/l) because of the low solubility of sodium hexamolybdatotellurate. The eutectic freezes at −1.125 °C. The 1:7 and 1:12 complexes are more strongly dissociated than the 1:6 complex. It is very interesting to observe how the stability of the 1:6 complex depends on the acidity of the molybdate solution (Fig. 9).

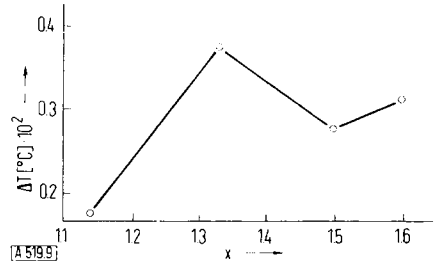

Fig. 9. Relative freezing point depression ΔT produced by $[TeMo_6O_{24}]^{6-}$ in the Glauber's salt-ice eutectic, as a function of the acidification x of the molybdate solution.

The stability of this complex, which corresponds formally to the acidification x = 1.00, increases once more above x = 1.33 (Eq. (j)]. This can be explained by the

$$6\ H^+ + 6\ MoO_4^{2-} + Te(OH)_6 \rightleftharpoons [TeMo_6O_{24}]^{6-} + 6\ H_2O \quad (j)$$

assumption that the concentration of the ligands that react with the orthotelluric acid is lower at x = 1.33 than in more acidic (x = 1.50) and less acidic (x = 1.14) solutions (see below).

This assumption is supported by observations made during the study of complex formation between polymolybdate ions and $Al^{3+}$. The curves obtained by thermometric, conductometric, and potentiometric titrations of acidic molybdate solutions with $Al_2(SO_4)_3$ solution show not only changes in slope indicating completion of complex formation, but also discontinuities and inflections that must be due to other causes. The results can be explained if it is assumed that the $Al^{3+}$ can react only with a certain polyanion, which itself corresponds formally to x = 1.50. Such a polyanion would have to carry one-half of a negative charge per Mo atom, *e.g.* $[HMo_2O_7 \cdot x\ aq]^-$, $[Mo_4O_{13} \cdot x\ aq]^{2-}$, $[HMo_6O_{20} \cdot x\ aq]^{3-}$, $[Mo_8O_{26} \cdot x\ aq]^{4-}$ [Eq. (k)].

$$9\ H^+ + 6\ MoO_4^{2-} + y\ H_2O \rightleftharpoons [HMo_6O_{20} \cdot x\ H_2O]^{3-} + (y - x + 4)\ H_2O \quad (k)$$

The evaluation of the results gives the formula $[H_6AlMo_6O_{24}]^{3-}$ for the aluminum complex.

The results obtained in the investigation of complex formation and hydrolysis of molybdate esters can be readily explained and related to many other facts if it is assumed that the acidification of a molybdate solution leads to consecutive reactions:

The initially formed $HMoO_4^-$ ions rapidly form a cyclic polyanion containing 6 Mo atoms. The $HMoO_4^-$ ions may be held together by hydrogen bonds; the formula of the particle would then be $[H_6Mo_6O_{24}]^{6-}$. In contrast to the tungstate system, in which a polyanion containing 6 W atoms is stable, the hexamolybdate ion is stabilized by combination with an ion of suitable radius. Thus in a pure molybdate solution, the heptamolybdate ion $[Mo_7O_{24}]^{6-}$ is formed. In the presence of $H_5IO_6$ or $Te(OH)_6$, on the other hand, the heterocomplexes $[IMo_6O_{24}]^{5-}$ and $[TeMo_6O_{24}]^{6-}$ or $[H_6TeMo_{12}O_{48}]^{12-}$ are formed. We regard $[H_6TeMo_{12}O_{48}]^{12-}$ as a complex in which the $Te^{6+}$ is situated between two $Mo_6O_{24}$ rings, as in a sandwich compound. The reason for the greater stability of $[TeMo_6O_{24}]^{6-}$ in relation to $[MoMo_6O_{24}]^{6-}$ (heptamolybdate) is probably that the smaller $Te^{6+}$ ion fits into the hexamolybdate ring even better than $Mo^{6+}$.

This view agrees closely with the results obtained by *Evans*[81] in the X - ray structure analysis of $(NH_4)_6TeMo_6O_{24} \cdot 7\ H_2O$, according to which the $Te^{6+}$ ion is situated in the center of a ring of six $MoO_6$ octahedra, whereas in $[Mo_7O_{24}]^{6-}$ the seventh Mo atom lies outside the plane of the ring, so that this particle has a "bowl shape" (Fig. 2e). This shape evidently enables the formation of the complex $[HTeMo_7O_{28}]^{7-}$. In view of the unsymmetrical structure of the heptamolybdate ion, which according to *Aveston*[26] probably has a similar structure in solution to that in the crystal, the tendency towards complex formation is understandable. Many compounds of composition

$$M^I_4M^{II}Mo_7O_{24} \text{ and } M^I_3M^{III}Mo_7O_{24},$$

which could be regarded as purely salt-like, probably are complexes. For example, from the color of $(NH_4)_3Ce^{III}Mo_7O_{24} \cdot 24\ H_2O$, which is orange-yellow even in solution, although $Ce^{3+}$ is colorless, *Barbieri*[82] assumed it to be a complex.

As was also found by *Sasaki*[12,13] with the aid of the Sillén method, the heptamolybdate ion is stable over a wide range of acidifications, and exists in solutions with x > 1.14 as the protonated species $[HMo_7O_{24}]^{5-}$ or $[H_2Mo_7O_{24}]^{4-}$. Complex formation between the heptamolybdate ion and orthotelluric acid (1:7 complex) has been detected even in solutions with x = 1.33 both by the simultaneous thermometric, conductometric, and potentiometric titrations and by salt-

[*] The expected freezing-point depression was $0.259 \times 10^{-2}$. The results of the salt-cryoscopic titration give only the relative change in the number of particles. To find the absolute degree of condensation, series of measurements must be carried out over a wide range of concentrations.

[81] *H. T. Evans jr.*, J. Amer. chem. Soc. *70*, 1291 (1948).

[82] *G. A. Barbieri*, Atti Accad. Lincei (Roma) *17*, 1, 540 (1908).

cryoscopic titrations). However, solutions with x = 1.33 also contain other types of particles, as has been shown by ultracentrifugation experiments [80]. On the other hand, the existence of $(NH_4)_4H_2Mo_6O_{21}$, which is prepared by hydrolysis of molybdate esters, indicates the occurrence of $[H_2Mo_6O_{21}]^{4-}$.

The question of the existence of a definite polymolybdate ion corresponding to an acidification x = 1.33 was disputed for a long time, since no changes in slope were observed in the curves obtained in potentiometric and conductometric titrations of molybdate solutions with acid (except by *R. H. Saxena* and *G. P. Saxena* [83]). A change in slope can, however, be observed in accurate thermometric titrations; we attribute this change to the formation of the $[H_2Mo_6O_{21}]^{4-}$ anion, from which the "trimolybdates" may be derived. We assume that the heptamolybdate ion becomes less stable as a result of protonation, and is partly converted into this hexamolybdate ion (which now has a different structure), possibly according to

$$H_2Mo_7O_{24}^{4-} + H_2O \rightleftharpoons H_2Mo_6O_{21}^{4-} + H_2MoO_4 \quad (I)$$

The complexing reactions in solutions with $x < 1.50$, and particularly the reaction with $Al^{3+}$, can be readily understood if it is assumed that the anion $[H_3Mo_6O_{21}]^{3-}$ is formed in these solutions by protonation of $[H_2Mo_6O_{21}]^{4-}$. This protonation also must be associated with a change in structure, since it would otherwise be impossible to explain the fact that $Al^{3+}$ reacts with $[H_3Mo_6O_{21}]^{3-}$ ($[HMo_6O_{20}\cdot H_2O]^{3-}$), but not with $[H_2Mo_6O_{21}]^{4-}$; the simultaneous thermometric, conductometric, and potentiometric titrations have shown that complex formation with $Al^{3+}$ is preceded by formation of a polymolybdate that corresponds to x = 1.50 (cf. p. 697). Orthotelluric acid also fails to react with $[H_2Mo_6O_{21}]^{4-}$, but probably reacts with $[H_6Mo_6O_{24}]^{6-}$ and $[H_3Mo_6O_{21}]^{3-}$. This provides a simple explanation for the stability minimum of $[TeMo_6O_{24}]^{6-}$ at x = 1.33.

In addition to hexameric polymolybdate ions, the solution with x = 1.50 must contain also dodecameric anions, since it is otherwise impossible to explain the complex formation with methyl red. It is not yet known whether this solution contains appreciable quantities of octamolybdate ions. Many authors believe that the octamolybdate ion $[Mo_8O_{26}]^{4-}$ is the major component of solutions with x = 1.50. The main arguments for this view are the facts that this anion [52] is present in crystalline ammonium metamolybdate, and that the average degree of condensation of the solution is approximately 8. However, no really conclusive evidence has so far been produced. On the basis of our views on the interconversions of polymolybdate ions, an octamolybdate would be quite feasible, since a protonated heptamolybdate ion should condense with an $HMo_4^-$ ion just as with a molecule of orthotelluric acid. No octamolybdate ion has been detected by complex formation. However, this ion probably cannot be expected to form complexes if its structure is similar to that envisaged by us for the $[HTeMo_7O_{28}]^{7-}$ ion, *i.e.* a compact, approximately spherical particle. Thus we can neither confirm nor deny the existence of the octamolybdate ion.

No further details on the relationships in more strongly acidic molybdate solutions ($x > 1.50$) are available at present.

[83] *R. H. Saxena* and *G. P. Saxena*, Z. physik. Chem. N.F. *29*, 181 (1961).

### (c) Complex Formation with Polytungstate Ions

Interesting results [84] have also been obtained in the investigation of complex formation by polytungstates in solution. The paratungstate ions A and B (which can be produced by acidification of $WO_4^{2-}$ solutions to x = 1.167) react with bivalent and trivalent cations to form complexes having the atomic ratio $M^{2+}$ or $M^{3+}$: W = 1:6. The most stable complexes are those formed with cations of radius ≈ 0.75 Å, whereas polymolybdate ions prefer cations having a radius of about 0.5 Å. In solutions containing paratungstate Z, the same complexes are formed only after about 24 hours.

Complex formation with cations ($M^{2+}$:W = 1:12) has also been observed in solutions of free metatungstates, and even in solutions of free metatungstic acid. The intensity of the complex formation depends on the charge and on the ionic radius, and decreases roughly in the order: $La^{3+} > Yb^{3+} > Al^{3+} \approx Ba^{2+} > Cd^{2+} \approx Sr^{2+} > Ca^{2+} \approx Cu^{2+} \approx Zn^{2+} \approx Mn^{2+} \approx Co^{2+} \approx Ni^{2+} > Mg^{2+} > Be^{2+} \approx Cs^+$.

No complex formation has been observed with $Rb^+$ or the lighter alkali metals. Phosphoric acid does not react with metatungstates or metatungstic acid. Metatungstate solutions prepared by acidification of $WO_4^{2-}$ solutions to x = 1.50 react with cations only after boiling for several hours or after prolonged standing (about 200 days), *i.e.* only after "true metatungstate ions" have been formed. On the other hand, freshly acidified solutions react, though only weakly, with phosphoric acid. This result provides further confirmation of *Jander*'s observation [41] that acidification to x = 1.50 does not lead immediately to the pseudotungstate ion, but results first in the formation of metatungstate ion A; recently this observation has been repeatedly questioned. The metatungstate ion and the pseudometatungstate ion evidently differ from the paratungstate ions A and B, not only in the degree of protonation, but also in their structures; otherwise, it would be impossible to explain the failure of the first two to form complexes with cations.

Paratungstate solutions (both A and Z) that have been aged for a long time exhibit the complexing reactions of the "true" metatungstate ion. This confirms again that a slow "dismutation" takes place in paratungstate solutions, with formation of the acidic metatungstate ion and the basic monotungstate ion [85,86]. These two are probably the only thermodynamically stable tungstate ions.

## 9. Closing Remarks

Attempts to obtain information about the nature of the isopolyanions present in a solution from the composition of complexes of the polyanions with cations which have been detected in the solution meet with difficulties similar to those encountered in attempts to apply

[84] *P. Scharner*, Dissertation, Freie Universität Berlin 1965.

[85] *G. von Knorre*, Ber. dtsch. chem. Ges. *18*, 2362 (1885).

[86] *R. Kubens*, Dissertation, Humboldt-Universität Berlin 1952

conclusions based on the crystalline state to the dissolved state. A complex of this nature may be formed in one of two ways:

1. The central cation reacts with monomers or small isopolyanions;

2. The central cation reacts with the preformed isopolyanion.

Only in the second case can reliable conclusions regarding the isopolyanion be based on the structure of the complex.

Both reactions evidently are possible in the formation of hetero-complexes. Thus the fact that "true" metatungstate ions do not react with phosphoric acid shows very clearly that, for example, the dodecatungstatophosphate ion, which is similar to the true metatungstate ion [54], can be formed in accordance with 1; it is formed on acidification of a solution containing monotungstate and phosphate ions. The complexes we have described, on the other hand, evidently are formed in accordance with 2, so that there is a direct relation between these complexes and the isopolyanions originally present in the solution. Some of the many reasons for this conclusion are:

The formation of *different* complexes with cations from paratungstate solutions of the same concentration and pH but of different ages would not be understandable if the heterocomplexes were formed from fragments and not from the different polytungstate ions present in each case.

True metatungstate ions and decavanadate ions are broken down only slowly in alkaline solutions. Since complex formation with these polyanions is instantaneous, it is hardly possible that it could proceed *via* fragments.

The reaction of methyl red with molybdate in the ratio 1:12 could not be explained without assuming the prior existence of dodecamolybdate ions with cavities capable of accommodating the dye.

We have attempted in this paper to outline, with the aid of some examples, the present state of research on polyacids, and to describe a number of new methods that have contributed to progress in this field. New insights into the chemistry of the polyacids will undoubtedly be gained in the future by the use of numerous and versatile chemical and physical methods, and by a logical combination of all the individual results.

# Aryl-$\Delta^2$-pyrazolines as Optical Brighteners

BY DR. ANNEMARIE WAGNER, DR. C.-W. SCHELLHAMMER, AND PROF. S. PETERSEN

WISSENSCHAFTLICHES HAUPTLABORATORIUM, FARBENFABRIKEN BAYER AG., LEVERKUSEN (GERMANY)

*Di- and triaryl-$\Delta^2$-pyrazolines and their derivatives can be used as optical brighteners for synthetic fibers and plastics. The heterocycles are readily obtainable by several methods, e.g. condensation of ß-halogeno- or ß-dialkylaminopropiophenones with phenylhydrazine. A number of relationships can be detected between substitution and optical properties.*

## 1. Introduction

The use of organic fluorescent dyes for the optical brightening of textiles, paper, and plastics and as additives in detergents has shown a rapid increase in recent years. Without additives these materials are not pure white; they absorb in the short wavelength region of the visible spectrum, and consequently appear more or less yellowish. The use of optical brighteners, which emit blue-violet fluorescence, leads not merely to the compensation of this so-called "blue deficiency", but to an increase in the remission of the material above 100 % (relative to magnesium oxide as standard), since the blue-violet fluorescence gives the impression of increased whiteness (cf. Fig. 1).

As with organic dyestuffs, the compounds used in industry for this purpose can be grouped into a small number of types [1]. By far the most important optical

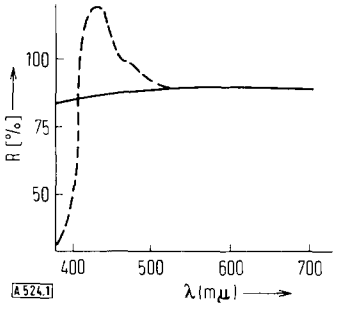

Fig. 1. Re-emission R of unbleached cotton cloth without optical brightener (——) and with optical brightener (– – –) (MgO = 100%).

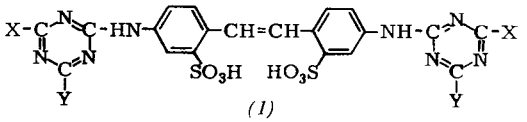
brighteners are derived from 4,4′-diaminostilbene-2,2′-disulfonic acid [2]. The triazine derivatives *(1)* of this compound [3] are particularly suitable.

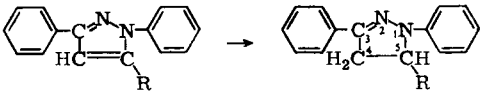


*(1)*

X and Y, *e.g.*: $NH_2$, $NH-CH_3$, $NH-CH_2-CH_2-OH$, $N(CH_2-CH_2-OH)_2$, morpholino, $NH-C_6H_5$, $NH-C_6H_4-SO_3H$, $OCH_3$, Cl.

Substances of other classes [2] which have recently been used for the optical brightening of synthetic fibers and plastics include coumarin derivatives, bisoxazolyl- and bisimidazolylethylenes, and the di- and triaryl-$\Delta^2$-pyrazolines described here.

This class of substances was discovered in 1888 by *Knorr* and *Laubmann* [4], who prepared 1,3,5-triphenyl-$\Delta^2$-pyrazoline *(2a)* and 1,3-diphenyl-$\Delta^2$-pyrazoline *(2b)* [5] by the reduction of the pyrazoles with sodium in ethanol.



*(2a)*, R = $C_6H_5$
*(2b)*, R = H

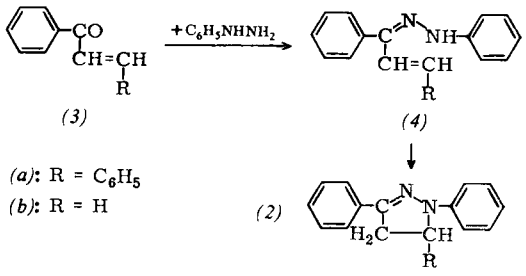
The remarkable fluorescence of the arylpyrazolines in organic solvents was observed already in this first, rather inefficient synthesis. However, it was more than 60 years before any technical use was made of this property.

Many other syntheses have been developed for arylpyrazolines [5a]. With the usual numbering of the pyrazoline ring the syntheses can be arranged according to how the ring members are joined by condensation or addition.

## 2. Syntheses of $\Delta^2$-Pyrazolines

### a) Principle 1,2 + 3,4,5

The reaction of phenylhydrazine with benzylideneacetophenones *(3a)* [4,6] leads initially to the phenylhydrazone *(4a)* of the α,β-unsaturated ketone, which can in some cases be isolated [7]. Ring closure is particularly easy with benzylideneacetophenone derivatives containing electron-donating groups [8]. The reaction, which is very general, is preferably carried out in glacial acetic acid or in a solution containing acetic acid



*(3)* *(4)*

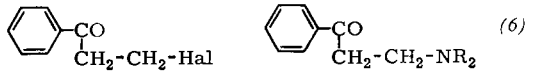
*(a)*: R = $C_6H_5$
*(b)*: R = H

*(2)*

Similarly, the diphenylpyrazoline *(2b)* can be prepared from phenyl vinyl ketone *(3b)* and phenylhydrazine [9]. Any substituted arylhydrazines may also be used instead of phenylhydrazine [10].

Even the cyclization of phenyl vinyl ketone 2,4-dinitrophenylhydrazone, which is opposed by the electron-attracting nitro groups, proceeds in boiling glacial acetic acid in the presence of hydrobromic acid [11].

However, it is not necessary to use the often unstable α,β-unsaturated ketones for the preparation of arylpyrazolines. The synthesis can also be carried out with compounds that behave as aryl vinyl ketones under the conditions of the ring closure. The most important compounds of this type are the β-halogenopropiophenones *(5)* [12] and the Mannich bases *(6)* obtained from acetophenone, formaldehyde, and secondary amines [13]. The reaction of these compounds with arylhydrazines also leads smoothly *via* the hydrazones to the arylpyrazolines.



*(5)* *(6)*

The β-halogenopropiophenones, which may also contain other substituents in the α or β positions, are prepared by Friedel-Crafts acylation of aromatic compounds with β-halogenopropionyl chloride. It should be noted that the simple members of this series, *e.g.* β-chloropropiophenone itself, are powerful skin irritants.

The Mannich bases *(6)* can be prepared from many secondary amines, such as dimethylamine [14], piperidine [15], or morpholine [16]. Ammonia may also be used as the base, and in

this case the product is *(6)* with R = 2-phenoxyethyl [17]. The acetophenones are particularly cheap starting materials. These last two methods are especially useful for the manufacture of pyrazolines.

Moreover, Mannich bases can be prepared, not only from acetophenone, but also from butyrophenone and β-phenylpropiophenone [18]. In these cases the formaldehyde and secondary amines condense on the α-methylene group of the ketone, and the reaction of the product with phenylhydrazine then gives pyrazolines with further substituents in position 4.

For the sake of completeness, mention should also be made of other propiophenones *(7)* that contain replaceable groups in the β position, and which can react with phenylhydrazine to give pyrazoline derivatives *(2)*.

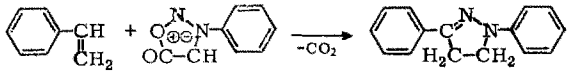
### b) Principle 1,2,5 + 3,4

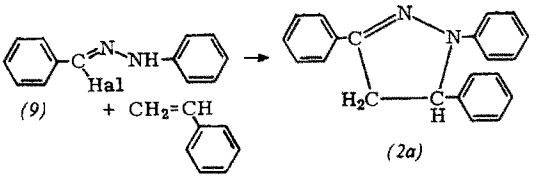
Pyrazoline syntheses based on the principle of 1,3-dipolar addition proceed particularly smoothly. Thus phenylsydnone *(8)* loses carbon dioxide when heated in xylene in the presence of styrene,1,3-diphenylpyrazoline *(2b)* being formed in high yield [26].



*(8)* *(2b)*

### c) Principle 1,2,3 + 4,5

Another example of a 1,3-dipolar addition is the reaction of α-halogenobenzaldehyde phenylhydrazone *(9)* with styrene in the presence of an acid acceptor [27]. The product is 1,3,5-triphenylpyrazoline *(2a)*.

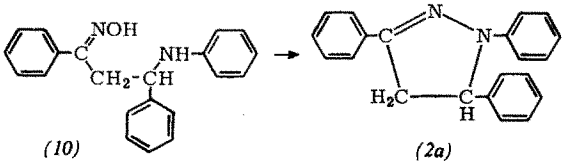


*(9)* *(2a)*

Any substituted arylsydnones or halogenobenzaldehyde phenylhydrazones may also be used as starting materials for the last two syntheses. Substituted styrenes are often difficult to obtain, and styrenes with sulfonic acid, sulfonamide, or nitro groups in the β-position do not react. Olefins such as acrylonitrile, acrylic esters, or butadiene may also be used instead of styrene.

### d) Pyrazoline Ring Closure Between Positions 1 and 2

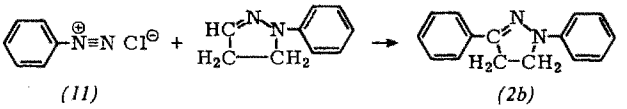
A peculiar synthesis of 1,3,5-triphenylpyrazoline *(2a)* is the elimination of water from β-anilino-β-phenylpropiophenone oxime *(10)* [28]. In this case the N–N ring bond is formed last.



*(10)* *(2a)*

### e) Introduction of Aromatic Substituents into the Preformed Pyrazoline Ring

$\Delta^2$-Pyrazolines with no substituent in position 3 react in this position with aromatic diazonium salts *(11)* [29]. The coupling is carried out in the presence of pyridine or sodium acetate.



*(11)* *(2b)*

Finally, 1-unsubstituted 3-arylpyrazolines can be arylated in position 1 with 2,4-dinitrochlorobenzene [11]. 2,4,6-Trichlorotriazine can also be used in this reaction, and in this case the product is 1-(4,6-dichloro-s-triazin-2-yl)-3-phenyl-$\Delta^2$-pyrazoline.

## 3. Constitution and Fluorescence of Arylpyrazolines

Surprisingly, arylpyrazolines with at least two aryl units in positions 1 and 3 exhibit strong fluorescence, although the molecule *(2)* in its classical formulation does not have continuous conjugation. Benzalacetophenone phenylhydrazone *(4a)* does not fluoresce; however, tri-

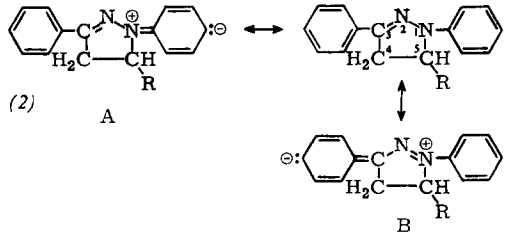
[28] *A. Hassner* and *H. J. Michelson*, J. org. Chemistry *27*, 298 (1962).

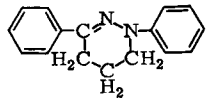
[29] *C. F. Duffin* and *J. D. Kendall*, J. chem. Soc. (London) *1954*, 408; U.S.-Pat. 2610969 (Sept. 16th, 1952), Ilford Ltd., Inv.: *J. D. Kendall* and *C. F. Duffin*.

phenylpyrazoline *(2a)*, derived from *(4a)* through rearrangement, shows a strong blue-violet fluorescence in organic solvents. Thus, pyrazoline ring closure limits the rotational freedom of the phenylhydrazone system; the molecule is fixed in a planar arrangement through action of the ring members 4 and 5. The aromatic nuclei in positions 1 and 3, required for fluorescence, interact by way of mesomeric canonic forms [30].



*(2)* A B

The planarity of the molecule, which is essential for fluorescence [31], is disturbed when the phenyl groups of the arylpyrazolines carry large substituents in the *o*-position. A marked decrease in fluorescence is observed in these cases. We also found that compounds containing one extra ring member, *e.g.* 1,3-diphenyl-1,4,5,6-tetrahydro-1,2-diazine [*] *(12)*, do not fluoresce; *(12)* is non-planar.

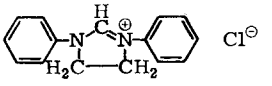


*(12)*

*Neunhoeffer* and *Rosahl* [30] found that it is not possible to formulate a mesomeric ground state in which an aromatic substituent in position 5 of the pyrazoline enters into the conjugated system. In fact, substitution in position 5 has no great influence on the absorption and fluorescence maxima, whereas aryl nuclei in positions 1 and 3 are essential to the fluorescence: thus neither 1-phenylpyrazoline nor 1,5-phenylpyrazoline exhibits fluorescence. The weak fluorescence of 3-methyl- and 3-trifluoromethyl-1,5-diphenylpyrazoline is attributed by *Neunhoeffer et al.* [32] to hyperconjugation.

It should be mentioned that the aromatic substituents on the pyrazoline ring may be replaced by heterocycles or by styryl groups without loss of the ability to fluoresce. However, the extension of the conjugated system by one double bond, as in the styryl group, leads to yellow products with a yellow-green fluorescence, which cannot be used for optical brightening [33]. Compounds of this type are recommended as fluorescent dyes [34].

A compound closely related to 1,3-diphenylpyrazoline is 1,3-diphenyl-$\Delta^1$-imidazolinium chloride *(13)*, which is formally derived from the former by transposition of C and N. No resonance forms with continuous conjugation are possible, and consequently fluorescence does not occur.



*(13)*

Compound *(13)* is formed by elimination of water from *N,N'*-diphenylethylenediamine and formic acid in the presence of hydrochloric acid [35].

## 4. Arylpyrazolines as Optical Brighteners

The use of fluorescent arylpyrazolines for optical brightening of textiles was first proposed by Ilford Ltd. [36], Essex. As in the case of the phthalocyanine dyes, which were modified by substitution to adapt them to the desired technical use, efforts were made to suitably modify the available fluorescent arylpyrazolines.

The simplest change consists in the introduction of substituents into the aromatic rings. However, modifications of this nature are subject to limitations, since many substituents cause a marked bathochromic shift of the absorption and fluorescence maxima; this is the case *e.g.* with an amino or acetylamino group in the phenyl ring on N-1. Substituents that impart color to the compounds cannot be considered. A *p*-nitro group of the phenyl group on N-1 gives a compound that emits orange-yellow fluorescence, while corresponding subsitution of the phenyl ring on C-3 completely extinguishes the fluorescence [37, 33].

The first arylpyrazolines used in practice nad a sulfonic acid group on the phenyl ring on N-1 [38]. These are prepared by the 1,2 + 3,4,5 principle (Section 2a), a phenylhydrazinesulfonic acid being used instead of phenylhydrazine. Owing to the presence of the sulfonic acid group, the molecule is water soluble; it is adsorbed on wool like an acid dye, and thus imparts optical brightening.

Products with other useful properties are obtained when the phenyl nucleus on N-1 also contains a sulfonamide group $SO_2-NH_2$ [39] or a sulfonyl group [40], *e.g.* $SO_2-CH_3$. Compounds of these types are again best prepared from the corresponding substituted phenylhydrazines. These products are not soluble in water. However, they are absorbed from aqueous dispersions onto polyacrylonitrile (Dralon or Orlon), and even when added in small percentages to the spinning solutions of the polymers, *e.g.* in dimethylformamide, they impart to these fibers an outstanding, white appearance. Other synthetic fibers such as polyamide or cellulose acetate can also be brightened. Moreover, these optical brighteners can also be used in detergents for poly-

amides. One disadvantage of these products is that they are not resistant to chlorite.

The color of the fluorescent light depends to some extent on the positions of the substituents. The most useful products are those with electron attracting substituents in the *p*-position of the phenyl ring on N-1. Isomeric compounds with a cyano, sulfonic acid, sulfonamide, or sulfonyl group [12] in the *p*-position of the phenyl ring on C-3 are too yellow for practical purposes. In the first case, the effect of the electron attracting substituents is to increase the contribution of the canonical form A of the pyrazoline ring (see Section 3); the preferred form in the second case, on the other hand, is form B.

A chloro-substituent in the phenyl ring on C-3 has been found to have a particularly favorable influence on the intensity of the fluorescence (cf. Section 3). On the other hand an aryl ring in position 5 simply increases the weight, and does not improve the intensity of the fluorescence.

Useful brighteners are also obtained when a carboxyl group is introduced into the diarylpyrazoline molecule. Since this is an electron-attracting substituent, the above rules regarding its position apply. Thus the 4-(3-aryl-pyrazolinyl)benzoic acids [1-(carboxyphenyl)-3-aryl-pyrazolines] [41] are particularly valuable. Hard soap, which is yellowish in the crude form, appears pure white when these products are added. They are also added during the melt-spinning of polyamide fibers such as Perlon or Nylon. Since they are monofunctional carboxylic acids, they are attached to the polymer chains by predominantly covalent (amide) bonding; therefore, they also act as chain-terminating agents, and may be used in the production of the polyamide. Thus the attachment of the optical brightener to the fiber is particularly firm and resistant to washing.

Esterification of pyrazolines containing carboxyl groups [40,42] leads to products which are insoluble in water. These products can again be used as brighteners to be added during spinning, and they may also be used as additives for detergents and as brighteners for plastics.

A special group are the cationic water-soluble pyrazolines [43], which can be applied in the same way as basic dyes. Possible starting materials for the preparation of these substances include substituted sulfonamides, *e.g.* having the formula pyrazoline $SO_2-NH-(CH_2)_n-NR_2$, or esters containing basic groups, such as parazoline-$CO-O-CH_2-CH_2-NR_2$. The tertiary amino groups in these compounds are subsequently quaternized.

Finally, pyrazolines (and other fluorescent systems) containing polymerizable unsaturated groups [44] have been described; these can be incorporated into plastics by copolymerization. The importance of the arylpyrazolines as brighteners is mainly in connection with the optical brightening of plastics and synthetic fibers.

We conclude with a brief description of a number of relationships between the absorption and fluorescence maxima of simple pyrazolines [45]. The absorption maxima and the fluorescence maxima of nine pyrazolines in methanolic solution were determined, and the fluorescence maxima of these were also determined after absorption on cellulose acetate (cf. Table 1).

[a] Band heights relative to the eighth compound (= 100).
[b] Difference between absorption and fluorescence maxima of the solution spectrum (in wave numbers).

The differences in constitution between these pyrazolines are relatively small. It is, therefore, surprising to find that a number of rules can be deduced from the results: Halogenation in the phenyl ring on C-3 leads to a shift of the absorption maximum toward longer wavelengths, and the absorption and fluorescence maxima are situated closer together. As the number of chlorine atoms in the molecule is increased, the intensity of the absorption maximum as expressed by the molar extinction also increases; this increase is even more pronounced in the case of the fluorescence maximum. A fact not shown by the relative band heights in Table 1 is that the fluorescence maxima on cellulose acetate are about 30 times as intense as in methanolic solution. The unexpectedly weak

fluorescence of the second compound [*(2a)*] on cellulose acetate may be due to decreased absorption or to hindrance on the fiber of the absorption position which most strongly favors fluorescence. The last column in the Table gives the difference (in wave numbers) between the absorption and fluorescence maxima in the solution spectra. The intensity of the fluorescence band increases as this difference in position decreases, and this yields some information about the radiationless energy loss. The differences between the absorption and fluorescence spectra on the fiber were not determined, but it is clear from a comparison of the positions of the fluorescence maxima in solution and on the fiber that the attachment of the pyrazoline molecule to the fiber leads to a decrease in the radiationless energy loss, as is shown by the much higher value of the fiber fluorescence as compared with the solution fluorescence [*].

The facts described here are not sufficient to permit the accurate determination of specific applications of aryl-$\Delta^2$-pyrazolines as optical brighteners. Other factors such as the tint of the brightened article, adsorption, and durability must also be closely examined. – Arylpyrazolines have also found interest as scintillators [24, 26].

# New Methods of Preparative Organic Chemistry VI [*]

## Synthesis of Isocyanates and Carbodiimides

BY DR. H. ULRICH AND DR. A. A. R. SAYIGH

THE UPJOHN COMPANY, CARWIN RESEARCH LABORATORIES,
NORTH HAVEN, CONNECTICUT (U.S.A.)

*The reaction of 1,3-disubstituted ureas and 1-arylsulfonyl-3-alkylureas with phosgene permits the preparation of a number of isocyanates and sulfonyl isocyanates that had not previously been described, or that were difficult to prepare. 1,3-Disubstituted thioureas and 1-aryl-(or alkyl)sulfonyl-3-alkylthioureas give carbodiimides. Thionyl chloride and phosphorus pentachloride react with the urea derivatives in the same way as phosgene. Oxalyl chloride reacts with ureas to form parabanic acid derivatives, whereas with thiourea it gives 2-imino-1,3-thiazolidine-4,5-diones, which can isomerize to parabanic acid derivatives.*

### I. Introduction

It has been known for some time that isothiocyanates [1] and carbodiimides [2] can be prepared from 1,3-disubstituted thioureas and phosgene. The only phosgenation of 1,3-disubstituted ureas that had previously been studied was that of 1,3-diphenylurea above 150 °C, which leads to phenyl isocyanate [3]. The present paper describes the reaction of other 1,3-disubstituted ureas with phosgene to form isocyanates. The authors have developed a simple reaction principle [Equations (a) and (b)], which permits the preparation of a number of mono- and diisocyanates that were not previously obtainable by direct phosgenation of the corresponding primary amines.

In the preparation of an isocyanate RNCO, a primary amine or sulfonamide is converted into the urea derivative by treatment with a readily obtainable alkyl or aryl isocyanate R'NCO; the reaction of the product with phosgene then yields RNCO and the starting isocyanate R'NCO:

$$RNH_2 + R'NCO \rightarrow RNH{-}CO{-}NHR' \quad (a)$$

$$RNH{-}CO{-}NHR' + COCl_2 \rightarrow RNCO + R'NCO + 2HCl \quad (b)$$

R, R' = aryl, alkyl, arylsulfonyl

Thus the overall reaction is equivalent to the phosgenation of an inert amine or of an amine that is not accessible to direct phosgenation.

Another reaction of 1,3 disubstituted ureas and thioureas with phosgene, *i.e.* chlorination, has been described by *Eilingsfeld*, *Seefelder*, and *Weidinger* [4]. This reaction leads to *C,C*-dichloromethylenediamines $RHN{-}CCl_2{-}NHR$ (sometimes formulated as chloroformamidinium chlorides $[RNH{-}CCl{=}NHR]^{\oplus}Cl^{\ominus}$),

[*] The papers in the preceding series have been published in three volumes by Verlag Chemie, Weinheim/Bergstr.; English editions: Academic Press, New York-London. – Volumes IV and V are in preparation.

which give carbodiimides on dehydrochlorination. Thionyl chloride or oxalyl chloride should also be suitable for the chlorination [4].

We have found that the result of the reaction of 1,3-disubstituted ureas with phosgene, thionyl chloride, or phosphorus pentachloride, *i.e.* whether it leads to isocyanates (*via* allophanoyl chloride) and/or to chloroformamidinium chlorides [see Equations (f), (j), and (k)] is largely dependent on the substituents.

## II. Synthesis of Isocyanates

### 1. Elimination of Isocyanates from Substituted Ureas

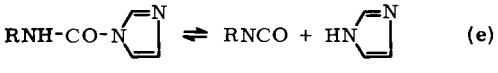
Isocyanates should be easily obtainable from urea derivatives by elimination, *i.e.* without the use of phosgene. In reactions of this type, however, only a part of the molecule can be utilized. The elimination of $NH_3$, which permits the production, *e.g.*, of α-naphthyl isothiocyanate in high yields from α-naphthylthiourea [5], does not occur with all urea derivatives. *Sowa* [6] recently prepared isobutyl isocyanate from isobutylurea by this method.

$$(CH_3)_2CH-CH_2-NH-CONH_2 + BF_3 \rightarrow (CH_3)_2CH-CH_2-NCO + H_3NBF_3 \quad (c)$$

Another example is the preparation of methyl isocyanate from 3-methyl-1,1-diphenylurea [7].

$$(C_6H_5)_2N-CO-NHCH_3 \rightarrow (C_6H_5)_2NH + CH_3NCO \quad (d)$$

Though diphenylamine is a weaker base than 3-methyl-1,1-diphenylurea, this elimination proceeds only at high temperatures (240–290 °C). On the other hand, imidazole-1-carboxamides, which may be regarded as urea derivatives [8], react even at room temperature in suitable solvents.



(e)

The disadvantages of the eliminations (c)–(e) are the possibile recombination of the products and the fact that only part of the urea derivative is used in the formation of the isocyanate [*e.g.* in (d), the formation of one mole of methyl isocyanate (M.W. 57) is accompanied by the formation of one mole of diphenylamine (M.W. 169)].

### 2. The Reaction of 1,3-Disubstituted Ureas with Phosgene [8a]

The phosgenation of 1,3-disubstituted ureas [Equation (b)] could give two moles of isocyanate and two moles of hydrogen chloride (*e.g.* phosgenation of 1,3-diphenylurea [3]), and would, therefore, be much more productive than the elimination method.

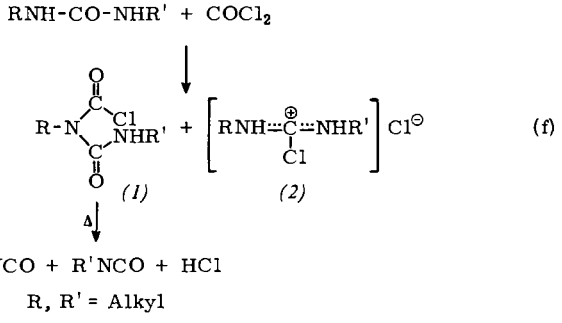
1,3-Diphenylurea reacts with phosgene only above 150 °C. The compound first dissociates, so that the reaction corresponds to the phosgenation of aniline [9,10]:

$$C_6H_5NH-CO-NHC_6H_5 \rightarrow C_6H_5NCO + C_6H_5NH_2$$
$$C_6H_5NH_2 + COCl_2 \rightarrow C_6H_5NCO + 2\,HCl$$

Since 1,3-diarylureas generally form isocyanates on melting, it is reasonable to assume that the reaction with phosgene is generally applicable.

The more strongly basic 1,3-dialkylureas react with phosgene even at room temperature, but this reaction is reported to yield chloroformamidinium chlorides *(2)* [4], which are unsuitable for the preparation of isocyanates.

We have found that the reaction of 1,3-dialkylureas with phosgene at room temperature leads to 2,4-dialkylallophanoyl chlorides *(1)* and/or 1,3-dialkylchloroformamidinium chlorides *(2)* [11].



(f)

R, R' = Alkyl

Among the 1,3-dialkylureas studied so far, it has been found that the reaction leads predominantly to attack on the nitrogen and formation of the allophanoyl chloride *(1)* if the alkyl substituent is attached to the nitrogen by a primary carbon atom. If, on the other hand, the carbon atom adjacent to the nitrogen is secondary, attack on the oxygen leads almost exclusively to the chloroformamidinium chloride *(2)*. The yields of *(1)* and *(2)* obtained from various 1,3-dialkylureas under identical conditions (reaction of RNH–CO–NHR' and phosgene at 2 °C in 1,2-dichloroethane) are listed in Table 1. 1-Butyl-3-phenylurea was also used for comparison.

Table 1. Formation of *(1)* and *(2)* according to Equation (f).

| Comp. | R | R' | *(1)* Yield [%] | *(2)* Yield [%] |
|---|---|---|---|---|
| *(a)* | $CH_3$ | $CH_3$ | 71 | 28 |
| *(b)* | n-$C_4H_9$ | n-$C_4H_9$ | 70.5 (V, 1) [a] | 24 |
| *(c)* | n-$C_{18}H_{37}$ | n-$C_{18}H_{37}$ | 69 | 28 |
| *(d)* | i-$C_3H_7$ | i-$C_3H_7$ | 6.7 | 75.6 [b] |
| *(e)* | c-$C_6H_{11}$ | c-$C_6H_{11}$ | 12.5 | 77.8 |

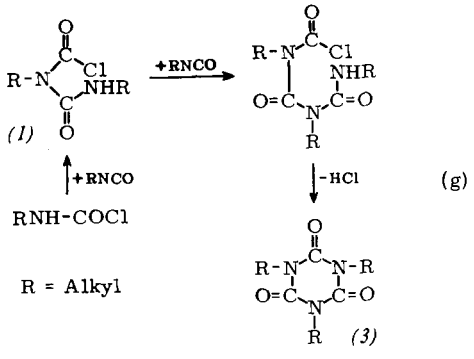
[11] *H. Ulrich, A. A. R. Sayigh,* and *J. N. Tilley,* J. org. Chemistry *29*, 2401 (1964).

Table 2. Physical properties of 2,4-disubstituted allophanoyl chlorides RN(COCl)CO–NHR′ *(1)*.

| Comp. | M.p. [°C] | B.p. [°C/Torr] | $\tilde{\nu}$NH [cm$^{-1}$] | $\tilde{\nu}$C=O [cm$^{-1}$] |
|---|---|---|---|---|
| *(1a)* | 36 | 54/0.15 | 3355 | 1740 |
| *(1b)* | — | 98/0.5 | 3310 | 1718 |
| *(1c)* | 68–69 | | 3345 | 1745 |
| *(1d)* | 63 | | 3310 | 1725 |
| *(1e)* | 127–128 | | 3390 | 1718 |
| *(1f)* | 40–44 | | — | — |

As expected, the compounds *(1)* decompose into isocyanate and HCl when heated above 100 °C in an inert solvent [12]. The yields are almost quantitative (cf. procedure in Section V, 2). If the solution contains more than 10% of *(1)* or if the heating is carried out in the absence of solvent, the products include not only isocyanates, but also isocyanurates *(3)*. These are formed by the reaction of the 2,4-disubstituted allophenoyl chlorides with the isocyanates produced.



Since 2,4-dimethyl- and 2,4-di-n-butylallophanoyl chlorides are obtained in a yield of about 50% when equimolar quantities of the corresponding carbamoyl chloride and isocyanate are heated, the formation of isocyanurates *(3)* during the phosgenation of monoalkylamines is very probably due to reactions (f) and (g). An excess of phosgene should be avoided in reaction (f), since the chloroformamidinium chloride formed as a by-product reacts further to form an *N,N′*-dialkylchloroformamidine-*N*-carbonyl chloride*(4)* [13]. The structure of this product was established by independent synthesis from carbodiimides and phosgene [13, 14].

[13] *H. Ulrich* and *A. A. R. Sayigh*, J. org. Chemistry *28*, 1427 (1963).

[14] *P. Fischer*, German Pat. 1131661; (June 20th, 1962), Farbenfabriken Bayer A.-G.; Chem. Abstr. *58*, 1401 (1963).

Diphenyl carbonate may also be used instead of phosgene. For example, *Morschel* and *Skopalik* [15] recently prepared alkyl isocyanates from 1,3-dialkylureas and diphenyl carbonate. Dialkylureas in which a primary carbon atom is attached to the nitrogen again gave much higher yields of isocyanate than those in which the nitrogen atoms carry secondary carbon atoms.

$$RNH{-}CO{-}NHR + (C_6H_5O)_2CO \rightarrow 2\,RNCO + 2\,C_6H_5OH$$

R = Alkyl

However, the use of carbonates instead of phosgene has the disadvantage that the products readily undergo further reaction with one another.

### 3. The Reaction of 1-Arylsulfonyl-3-alkylureas with Phosgene

The reaction of 1-arylsulfonyl-3-alkylurea with phosgene leads to attack exclusively on the alkyl-substituted nitrogen owing to the acidity of the proton in α-position to the sulfonyl group; the resulting allophanoyl chlorides decompose immediately to give the corresponding isocyanates and hydrogen chloride. Thus, in the reaction of 1-*p*-toluenesulfonyl-3-n-butylurea with phosgene, we obtained good yields of *p*-toluenesulfonyl isocyanate and n-butyl isocyanate (see Section V, 4).

Table 3. Preparation of sulfonyl isocyanates $RSO_2NCO$ and isocyanates R′NCO by reaction of 1-arylsulfonyl-3-alkylureas $RSO_2NH{-}CO{-}NHR'$ with phosgene.

| R | B.p. [°C/Torr] | Yield [%] | R′ | B.p. [°C/Torr] | Yield [%] | Temp. [°C] |
|---|---|---|---|---|---|---|
| *p*-$CH_3{-}C_6H_4$ | 91–92/0.5 | 88.8 | n-$C_4H_9$ | 115 | 85 | 130 [a] |
| *p*-$CH_3{-}C_6H_4$ | 91–92/0.5 | 84.5 | $C_2H_5OCH_2CH_2$ | 140–142 | 76 | 80–150[b] |
| *p*-$Cl{-}C_6H_4$ | 92–93/0.4 | 57.9 | n-$C_3H_7$ | 83–84 | 70 | 130 [a] |

Solvents: [a] chlorobenzene; [o] dichlorobenzene.

$$p\text{-}CH_3{-}C_6H_4{-}SO_2NH{-}CO{-}NHC_4H_9 + COCl_2 \rightarrow p\text{-}CH_3{-}C_6H_4{-}SO_2NCO + C_4H_9NCO + 2\,HCl$$

The reaction takes place above 50 °C; only a small excess of phosgene is necessary for complete reaction. This reaction may be used as the second step in the preparation of isocyanates from amines which cannot be directly phosgenated, and which, therefore, must be converted into urea derivatives. An example is the phosgenation of 1-*p*-toluenesulfonyl-3-ethoxyethylurea, which leads to a good yield of the desired ethoxyethyl isocyanate.

Since alkyl isocyanates have much lower boiling points than sulfonyl isocyanates, they can be easily separated from the latter by fractional distillation. Some examples are given in Table 3.

Difficulties are encountered in the direct phosgenation of sulfonamides to obtain sulfonyl isocyanates. For example, sulfonamides react with phosgene only above 200 °C, and at this temperature the S–N bond is broken, with the result that the yields are unsatisfactory. The yields of more than 80% reported by *Krzikalla* [16] have not been confirmed by other workers [17].

[15] *H. Morschel* and *C. Skopalik*, German Pat. 1154090 (Sept. 12th, 1963), Farbenfabriken Bayer A.-G.; Chem. Abstr. *60*, 2158 (1964).

[16] *H. Krzikalla*, German Pat. 817602 (Oct. 18th, 1951), Badische Anilin & Soda Fabrik; Chem. Abstr. *47* 2206 (1953).

The arylsulfonyl isocyanates, which were formerly difficult to obtain, can now be readily prepared by phosgenation of 1-arylsulfonyl-3-alkylureas. It is even simpler not to use the isocyanates, but to add catalytic quantities of an isocyanate to the sulfonamides.

$$RSO_2NH_2 + COCl_2 + R'NCO \rightarrow RSO_2NCO + 2\,HCl \qquad (i)$$

The sulfonyl isocyanates prepared by this method, most of them for the first time, are listed in Table 4.

Table 4. Preparation of sulfonyl isocyanates $RSO_2NCO$ according to Equation (i). Catalyst: n-butyl isocyanate [18]; solvent: boiling chlorobenzene, and boiling *o*-dichlorobenzene in the case of the nitrobenzenesulfonyl isocyanates.

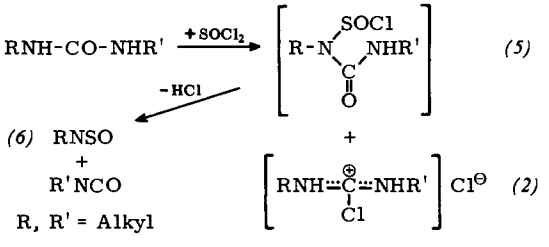
### 4. Reaction of 1,3-Disubstituted Ureas with Thionyl Chloride

The reaction of 1,3-disubstituted ureas with thionyl chloride was found to follow the same pattern as the reaction with phosgene. Ureas containing primary alkyl groups are preferentially attacked on the nitrogen, whereas those containing secondary alkyl groups undergo reaction on the oxygen atom. Since the intermediates *(5)* are dehydrochlorinated even at room temperature, the reaction leads to mixtures that contain isocyanates and sulfinylamines *(6)* as well as chloroformamidinium chlorides *(2)*.

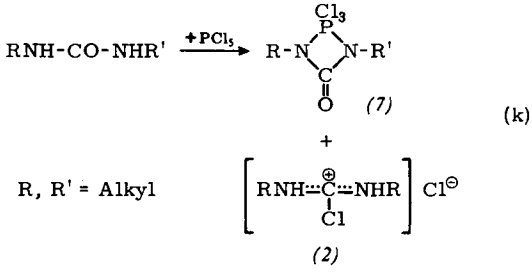


(j)

1,3-Di-n-butylurea gave n-butyl isocyanate with 88% yield. The yields of sulfinylamine are somewhat lower, since part of this product reacts with the hydrogen chloride liberated (cf. Section V, 7).

### 5. Reaction of 1,3-Disubstituted Ureas with Phosphorus Pentachloride

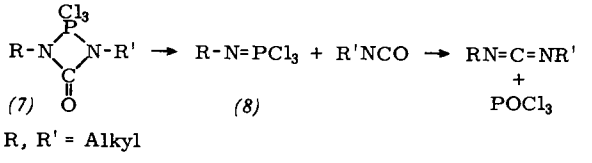
In the reaction of 1,3-disubstituted ureas containing primary alkyl substituents, the attack again takes place preferentially on the nitrogen. Thus, 1,3-diaza-2-$P^V$-phosphetidinones *(7)* were first prepared by this method (cf. Section V, 8)[19,21]. On the other hand, 1,3-disubstituted ureas containing secondary alkyl groups give only minor amounts of this compound, the main products again being chloroformamidinium chlorides *(2)*.



(k)

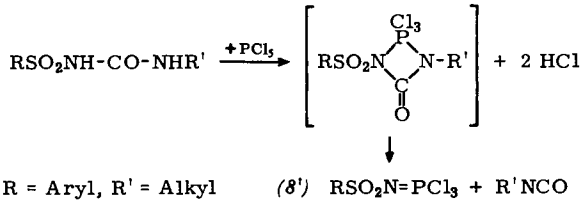
The compounds *(7)*, which contain a strained four-membered ring, have their characteristic C=O absorption at 1785 $cm^{-1}$.

When heated, the 1,3,2-diazaphosphetidinones *(7)* decompose into trichlorophosphazenes*(8)*and isocyanates, which react to form carbodiimides and phosphorus oxychloride[20].



### 6. Reaction of 1-Arylsulfonyl-3-alkylureas with Phosphorus Pentachloride

In the reaction of 1-arylsulfonyl-3-alkylureas, the intermediate containing the four-membered ring could not be isolated, but the decomposition products were obtained in good yields[21]. The sulfonyltrichlorophosphazenes *(8')* do not react with isocyanates (cf. Section V, 9).



### 7. Reaction of 1,3-Disubstituted Ureas with Oxalyl Chloride

For the sake of completeness, the reaction of oxalyl chloride with 1,3-dialkylureas should also be mentioned here. In contrast to the reaction with phosgene, it leads exclusively to 1,3-disubstituted parabanic acids *(9)*; no

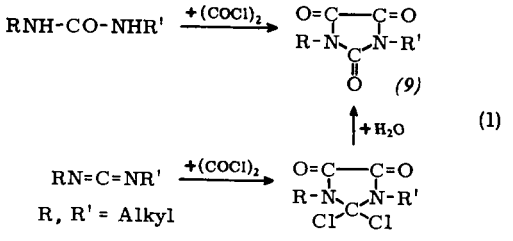
[18] Replacement of the n-butyl isocyanate by phenyl- or cyclohexyl isocyanate leads to approximately the same yield.

[19] *H. Ulrich* and *A. A. R. Sayigh*, Angew. Chem. *76*, 647(1964); Angew. Chem. internat. Edit. *3*, 585 (1964).

[20] *H. Ulrich* and *A. A. R. Sayigh*, Angew. Chem. *74*, 900(1962); Angew. Chem. internat. Edit. *1*, 595 (1962); J. chem. Soc. (London) *1963*, 5558.

[21] *H. Ulrich* and *A. A. R. Sayigh*, J. org. Chemistry *30*, 2779 (1965).

chlorination to form chloroformamidinium chlorides was observed. The structure of the parabanic acid derivatives obtained was established by infrared spectroscopy and by independent synthesis from carbodiimides and oxalyl chloride [22].



As early as 1913, *Biltz* and *Topp* [23] obtained parabanic acid derivatives *(9)* from 1,3-dimethylurea and 1,3-diethylurea. We found that ureas containing secondary and tertiary alkyl substituents also give only parabanic acid derivatives. Acyl isocyanates have recently been obtained by the reaction of amides with oxalyl chloride [24].

The physical properties of the 1,3-disubstituted parabanic acids synthesized are summarized in Table 5.

Table 5. 1,3-Disubstituted parabanic acid derivatives *(9)*, R = R', obtained according to Equation (1).

| R | M.p. [°C] | Yield [%] |
|---|---|---|
| i-$C_3H_7$ | 88–90 | 99 |
| n-$C_4H_9$ | 28–29 | 81.4 |
| t-$C_4H_9$ | 95 | 95.6 (V, 10) |
| c-$C_6H_{11}$ | 174–175 | 96 |

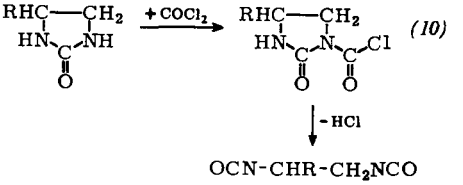
The reaction of 1-arylsulfonyl-3-alkylureas with oxalyl chloride also leads exclusively to 1,3-disubstituted parabanic acids [*(9)*, R = R''$SO_2$]. The reaction takes place on gentle heating, and the yields are almost quantitative [25,26].

## III. Synthesis of Diisocyanates

### 1. Reaction of Cyclic Ureas with Phosgene [8a]

The indirect methods for the synthesis of diisocyanates are of interest only when the diamines cannot be phosgenated directly. We have, therefore, confined ourselves to the synthesis of short-chain alkylene diisocyanates, since short-chain alkylenediamines are converted into polymeric ureas on direct phosgenation [7].

As in the case of the 1,3-dialkylureas, the reaction of five-membered cyclic ureas (2-imidazolidinones) with phosgene takes place almost exclusively on the nitrogen, with formation of cyclic allophanoyl chlorides (2-imidazolidinone-1-carbonyl chloride) *(10)* [11] (cf. Section V, 11). These compounds undergo dehydrochlorination at room temperature in the presence of an HCl acceptor (*e.g.* triethylamine) to give diisocyanates. In contrast to the case of the open-chain allophanoyl chlorides, this reaction can be accelerated with catalytic quantities of Lewis acids, *e.g.* $FeCl_3$, and tertiary amines such as collidine [12] (cf. Section V, 12).



Since the cyclic ureas are readily obtainable from 1,2-alkylenediamines and $CO_2$, this provides a simple method for the industrial production of alkylene diisocyanates.

### 2. Reaction of 1-Arylsulfonyl-3-alkylureas with Phosgene

Difficulties are also encountered in the phosgenation of long-chain alkylenediamines, such as 1,6-diaminohexane. Owing to the low solubility of alkylenediamine dihydrochlorides, a long reaction time and a considerable excess of phosgene are required. Moreover, the long reaction times favor the formation of by-products. For example, ω-chloroalkyl isocyanates are formed in this way, and these can only be removed by careful fractionation [7]. It is essential that the monofunctional by-products are eliminated before the isocyanates are used for the production of polyurethanes.

Alkylenediamines and sulfonyl isocyanates give 1,1'-alkylenebis-(3-arylsulfonylureas) *(11)* in almost quantitative yields [27]. These compounds, unlike the free amines, react readily with only a small excess of phosgene [28].

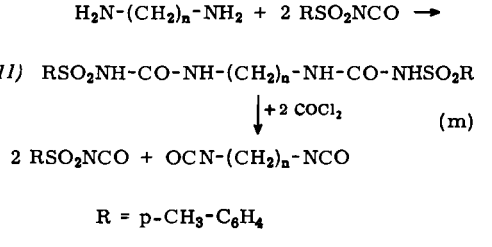


Table 6. Preparation of alkylene diisocyanates according to Equation (m) [*].

| n | OCN–$(CH_2)_n$–NCO Yield [%] | *p*-$CH_3$–$C_6H_4$–$SO_2$NCO Yield [%] | Temp. [°C] |

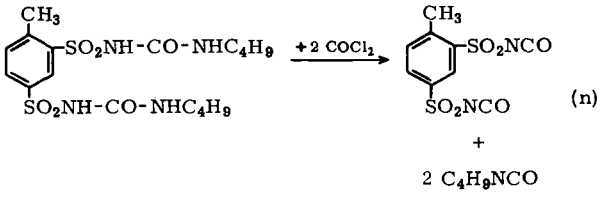
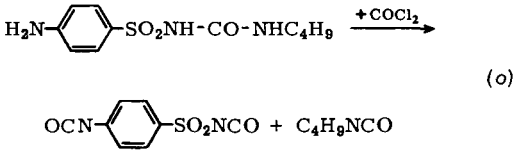
The phosgenation of a bis-sulfonyl compound also permitted the synthesis of the first bis(sulfonyl isocyanate)[29] [Equation (n)].



(n)

Another possibility for the preparation of interesting compounds is offered by the direct phosgenation of sulfanilylureas. This leads to difunctional compounds, in which the sulfonyl isocyanate group is much more reactive than the isocyanate group, despite the fact that the reactivity of the latter is increased by the sulfonyl isocyanate group. The reactivity of the isocyanate group on a benzene nucleus can be still further reduced by substituents (*e.g.* $OCH_3$) on the ring.



(o)

The physical properties of a number of isocyanatobenzenesulfonyl isocyanates are listed in Table 7.

Table 7. Isocyanatobenzenesulfonyl isocyanates *(12)* prepared according to Equation (o).

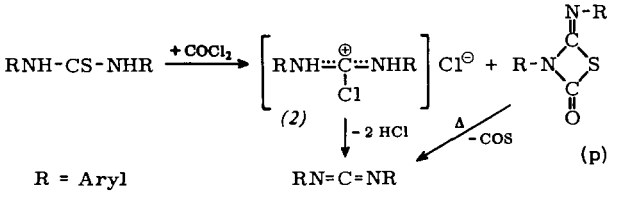
## IV. Synthesis of Carbodiimides

### 1. Reaction of 1,3-Disubstituted Thioureas with Phosgene

The "desulfurization" of 1,3-disubstituted thioureas is the classic method for the preparation of carbodiimides. Phosgene has proved to be a particularly useful desulfurizing agent, since it reacts at room temperature with



(p)

[29] After the completion of our work, *J. Smith jr., T. K. Brotherton*, and *J. W. Lynn*, J. org. Chemistry *30*, 1260 (1965), described the preparation of *p*-isocyanatobenzenesulfonyl isocyanate and of a number of bis(sulfonylisocyanates) by direct phosgenation of sulfonamides in nitrobenzene.

[30] *W. Will*, Ber. dtsch. chem. Ges. *14*, 1486 (1881).

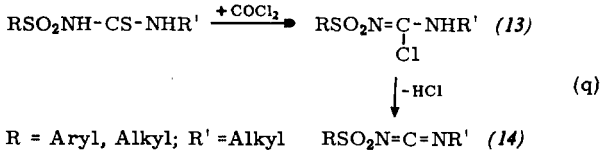
thioureas containing aliphatic and aromatic substituents (cf. Section V, 14). Whereas aliphatic thioureas form chloroformamidinium chlorides *(2)*, aromatic thioureas also give thiazetidinones as by-products[30]. No attack on nitrogen was observed.

Since the basicity of the nitrogen is considerably reduced in the aromatic chloroformamidinium chlorides, these compounds lose hydrogen chloride when heated[31]. Direct phosgenation above 100 °C yields isothiocyanates as by-products. An excess of phosgene must be avoided, since chloroformamidinium chlorides can be readily converted into *N*-carbonyl chlorides in accordance with Equation (h)[13].

Phosphorus pentachloride may be used instead of phosgene for the conversion of thioureas into chloroformamidinium chlorides. However, the reaction in this case yields thiophosphoryl chloride, which, if possible, should be removed before the liberation of the carbodiimides[32].

### 2. Reaction of 1-Aryl(or Alkyl)sulfonyl-3-alkylthioureas with Phosgene

The reaction of 1,3-disubstituted thioureas with acyl chlorides can also be applied to sulfonylthioureas. Thus sulfonylchloroformamidines have been obtained in good yields by the reaction of 1-aryl(or alkyl)sulfonyl-3-alkylthioureas with phosgene (cf. Section V, 15). These can be readily converted into sulfonylcarbodiimides by heating or by the use of an HCl acceptor[33,34] (cf. Table 8). As expected, phosphorus pentachloride reacts in a similar manner.



*(13)*

*(14)*

(q)

Table 8. Sulfonylcarbodiimides *(14)* prepared according to Equation (q).

| R | R' | B.p. [°C/Torr] | $n_D^{24.5}$ | Yield [%] |

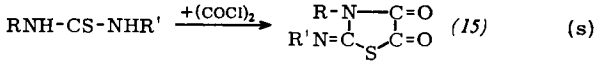
$$RSO_2NH\text{-}CO\text{-}NHR \xrightarrow{+COCl_2} RSO_2N{=}C\langle \text{N(R)}\,\text{S}\,C{=}O \quad (r)$$

$$R = \text{Aryl} \quad RSO_2N{=}C{=}NR + COS + RNCO + RSO_2NCS$$

*(14)*

### 3. Reaction of 1,3-Disubstituted Thioureas with Oxalyl Chloride

The reaction of 1,3-dialkylureas with oxalyl chloride leads only to parabanic acid derivatives [25] (cf. Section II, 7). *Blitz* and *Topp* [23] obtained small yields of 2-thioparabanic acid derivatives from 1,3-disubstituted thioureas and oxalyl chloride. This result is surprising, since in our opinion acyl halides always attack thioureas on the sulfur. We obtained good yields of 2-amino-1,3-thiazolidine-4,5-diones from thioureas and oxalyl chloride [25] (cf. Table 9; RNH–CS–NHR′ was treated with oxalyl chloride in 1,2-dichloroethane with cooling followed by heating at about 84–86 °C for 30 min).



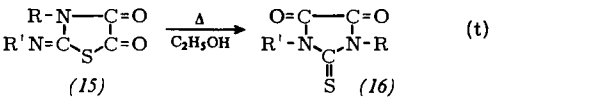
$$RNH\text{-}CS\text{-}NHR' \xrightarrow{+(COCl)_2} R\text{-}N(\text{C=O})\text{-}C(\text{=O})\text{-}S\text{-}C(R'){=}N \quad (15) \quad (s)$$

R = Alkyl, Aryl; R′ = H, Alkyl, Aryl

Table 9. 2-Imino-1,3-thiazolidine-4,5-diones *(15)* prepared according to Equation (s).

| R | R′ | M.p. [°C] | Yield [%] |
|---|---|---|---|
| $n\text{-}C_3H_7$ | H | 208–209 | 63 |
| $i\text{-}C_3H_7$ | H | 204–205 | 49 |
| $c\text{-}C_6H_{11}$ | H | 204–205 | 46.1 |
| $n\text{-}C_4H_9$ | $n\text{-}C_4H_9$ | 130 | 80.6 |
| $C_6H_5$ | $C_6H_5$ | 129–130 | 76.5 (V, 18) |

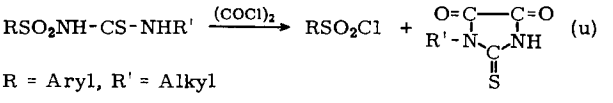
When warmed in alcohol, the 2-iminothiazolidine-4,5-diones *(15)* isomerize to give the thioparabanic acid derivatives *(16)* obtained by *Biltz* and *Topp* [23] and by *Stoffel* [26].



$$R\text{-}N(\text{C=O})\text{-}C(\text{=O})\text{-}S\text{-}C(R'){=}N \quad (15) \xrightarrow[C_2H_5OH]{\Delta} O{=}C\text{-}N(R)\text{-}C(\text{=S})\text{-}N(R')\text{-}C{=}O \quad (16) \quad (t)$$

### 4. Reaction of 1-Arylsulfonyl-3-alkylthioureas with Oxalyl Chloride

The reaction of 1-arylsulfonyl-3-alkylthioureas with oxalyl chloride leads to sulfonyl chlorides and alkylthioparabanic acids, as indicated in Equation (u).



$$RSO_2NH\text{-}CS\text{-}NHR' \xrightarrow{(COCl)_2} RSO_2Cl + O{=}C\text{-}N(R')\text{-}C(\text{=S})\text{-}NH\text{-}C{=}O \quad (u)$$

R = Aryl, R′ = Alkyl

This is probably again due to isomerization of the initially formed iminothiazolidinedione during the working-up of the reaction mixture (cf. Section IV, 3).

## V. Procedures

#### 1. *N,N′-Di-n-butylallophanoyl chloride (1b)* [11]

56 g (0.3 mole) of 1,3-di-n-butylurea in 216 ml of benzene is added dropwise to a solution of 73.3 g (0.74 mole) of phosgene in 300 ml of benzene at 8–10 °C. Nitrogen is passed through the reaction mixture to remove the hydrogen chloride formed. The solution is heated to the boiling point (to remove excess phosgene), and the solvent is then distilled off. The residue (70.7 g) consists of almost pure *N,N′*-di-n-butylallophanoyl chloride (yield 93%). Vacuum distillation of small quantities gives an analytically pure product, b.p. 98 °C/0.5 Torr; $n_D^{23} = 1.4662$ (cf. Section II, 2).

#### 2. *n-Butyl isocyanate from N,N′-di-n-butylallophanoyl chloride* [12]

11.7 g (0.05 mole) of *N,N′*-di-n-butylallophanoyl chloride in 235 g of *o*-dichlorobenzene is heated until the evolution of HCl stops (about 2 hours). Nitrogen preferably should be passed through the reaction mixture to remove the hydrogen chloride. Fractional distillation (to separate the product from the solvent) gives 9 g (91%) of n-butyl isocyanate, b.p. 115 °C (cf. Section II, 2).

#### 3. *N,N′-Di-n-butylchloroformamidine-N-carbonyl chloride* [13]

Phosgene is passed into a solution of 30.2 g (0.16 mole) of 1,3-di-n-butylthiourea in 600 ml of benzene until the exothermic reaction is complete (temperature 21.5–33.5 °C). After the excess phosgene has been removed with nitrogen, the solvent is distilled off *in vacuo*. The residue (39 g; 96.3%) consists of nearly pure *N,N′*-di-n-butylchloroformamidine-*N*-carbonyl chloride, which can be further purified by vacuum distillation of small quantities (b.p. 86 °C/0.5 Torr; $n_D^{23} = 1.4718$) (cf. Section II, 2).

#### 4. *p-Toluenesulfonyl isocyanate and n-butyl isocyanate from 1-p-toluenesulfonyl-3-n-butylurea*

270 g (1 mole) of 1-p-toluenesulfonyl-3-n-butylurea is introduced into 1350 ml of chlorobenzene. Traces of moisture are removed by azeotropic distillation, and 148.5 g (1.5 mole) of phosgene is passed into the solution over a period of about 2.5 hours at 80–100 °C. The solution is heated to boiling, nitrogen is passed through for 30 min, and the n-butyl isocyanate formed is distilled off with the solvent. Vacuum distillation of the residue yields 168.5 g (85.6%) of *p*-toluenesulfonyl isocyanate (b.p. 119–120 °C/4 Torr). The n-butyl isocyanate (b.p. 115 °C, yield 90%) can be separated from the solvent by fractional distillation of the solvent (cf. Section II, 3).

#### 5. *Benzenesulfonyl isocyanate*

78 g (0.5 mole) of benzenesulfonamide is dissolved in 588 ml of chlorobenzene, traces of moisture are removed by azeotropic distillation, and 9.9 g (0.1 mole) of n-butyl isocyanate is added as a catalyst at 75 °C. About 99 g (1 mole) of phosgene is then introduced over a period of 100 min at 129 to 130 °C. Nitrogen is passed through the solution for 30 min to remove excess phosgene, and the solvent, which contains the regenerated catalyst, is distilled off. Vacuum distillation of the residue gives 78 g (85.8%) of benzenesulfonyl isocyanate, b.p. 79–83 °C/0.7 Torr (cf. Section II, 3).

6. *p-Nitrobenzenesulfonyl isocyanate*

3.96 g (0.04 mole) of n-butyl isocyanate is added to a suspension of 20.2 g (0.1 mole) of *p*-nitrobenzenesulfonamide in 200 ml of *o*-dichlorobenzene. 46 g (0.46 mole) of phosgene are then introduced over a period of 46 min at 176–180 °C. The excess phosgene is removed with nitrogen, and the solvent, which contains the catalyst, is distilled off under vacuum. Vacuum distillation of the residue gives 18.5 g (81.1%) of *p*-nitrobenzenesulfonyl isocyanate, b.p. 137–143 °C/0.4 Torr; m.p. 70–73 °C (cf. Section II, 3).

7. *n-Butyl isocyanate and n-butylsulfinylamine (6), R = $C_4H_9$, from 1,3-di-n-butylurea and thionyl chloride*

6.0 g (0.05 mole) of thionyl chloride is introduced into a suspension of 8.6 g (0.05 mole) of 1,3-di-n-butylurea in 50 ml of carbon tetrachloride. The solution is refluxed for 4 hours, and the solvent is then distilled off over a Vigreux column. Distillation of the residue gives a mixture of 4.34 g (88%; determined by titration with di-n-butylamine) of n-butyl isocyanate, b.p. 115 °C, and 4.6 g (77%) of n-butylsulfinylamine, b.p. 116 °C ($\tilde{\nu}_{as}$NSO = 1235 $cm^{-1}$; $\tilde{\nu}_{s}$NSO = 1110 $cm^{-1}$), which cannot be separated by distillation (cf. Section II, 6).

8. *2,2,2-Trichloro-1,3-dimethyl-1,3-diaza-2-$P^V$-phosphetidinone (7), R = R' = $CH_3$* [21]

33.3 g (0.16 mole) of phosphorus pentachloride is introduced into a suspension of 13.2 g (0.15 mole) of 1,3-dimethylurea in 150 ml of carbon tetrachloride. The mixture is refluxed for 1 hour, and after removal of the hydrogen chloride with nitrogen (20 min), the solvent is distilled off. Vacuum distillation of the residue gives 24.1 g (71.9%) of 2,2,2-trichloro-1,3-dimethyl-1,3-diaza-2-$P^V$-phosphetidinone, b.p. 78–79 °C/1.5 Torr (cf. Section II, 5).

9. *p-Toluenesulfonyltrichlorophosphazene (8'), R = $CH_3$–$C_6H_4$, and n-butyl isocyanate from 1-p-toluenesulfonyl-3-n-butylurea and phosphorus pentachloride* [21]

2.7 g (0.01 mole) of 1-*p*-toluenesulfonyl-3-n-butylurea and 2.1 g (0.01 mole) of phosphorus pentachloride in 40 ml of carbon tetrachloride are refluxed for 60 min. Removal of the solvent, which contains 0.8 g (80.8%) of n-butyl isocyanate (determined by titration with di-n-butylamine) and crystallization of the residue from carbon tetrachloride yields 2.35 g (77%) of *p*-toluenesulfonyltrichlorophosphazene, m.p. 88 to 90 °C (cf. Section II, 6).

10. *Di-t-butylparabanic acid (9), R = R' = tert-$C_4H_9$* [21]

6.35 g (0.05 mole) of oxalyl chloride is added dropwise to an ice-cooled solution of 8.6 g (0.05 mole) of 1,3-di-t-butylurea in 86 ml of 1,2-dichloroethane. The mixture is stirred for 30 min at room temperature and then refluxed for 30 min. Removal of the solvent by distillation yields 10.8 g (95.6%) of 1,3-di-t-butylparabanic acid, m.p. 88–89 °C. Recrystallization from ethanol gives white needles, m.p. 95 °C (cf. Section II, 7).

11. *2-Imidazolidinone-1-carbonyl chloride (10), R = H* [11]

Phosgene (*ca.* 0.22 mole) and a solution of 17.2 g (0.2 mole) of 2-imidazolidinone in 220 ml of hot (75–80 °C) 1,2-dichloroethane are added simultaneously to 100 ml of 1,2-dichloroethane at 75–80 °C. After removal of excess phosgene by means of nitrogen, the mixture is filtered. When the filtrate is cooled, 25.6 g (86%) of 2-imidazolidinone-1-carbonyl chloride, m.p. 155–157 °C, separate out in form of colorless crystals. A further 1.6 g of product, m.p. 150–153 °C, can be obtained by concentration of the solution (cf. Section III, 1).

12. *Ethylene diisocyanate* [12]

50.5 g (0.5 mole) of triethylamine is added dropwise to a suspension of 78 g (0.525 mole) of 2-imidazolidinone-1-carbonyl chloride *(10)*, R = H, in 1500 ml of benzene. When the mixture has been allowed to stand for 30 min, 66.1 g (96%) of triethylammonium chloride can be filtered off. Approximately 10 g of phosgene is passed into the filtrate at 70–75 °C to remove any traces of amine. A further 1.3 g of triethylammonium chlorid is filtered off, and the solvent is removed by distillation. Vacuum distillation of the residue gives 38.6 g (66%) of ethylene diisocyanate, b.p. 77–70 °C/16 Torr; $n_D^{23}$ = 1.4472 (cf. Section III, 1).

13. *p-Isocyanatobenzenesulfonyl isocyanate (12), R = NCO, R' = X = H*

27.1 g (0.1 mole) of *N*-sulfanilyl-*N'*-n-butylurea is added in parts to a stirred, ice-cooled solution of 19.8 g (0.2 mole) of phosgene in 270 ml of chlorobenzene at 2 °C. The mixture is slowly heated to boiling with introduction of phosgene. After a further 90 minutes, the addition of phosgene is stopped, and excess phosgene is removed with nitrogen. After filtration, the solvent, which contains 6.8 g (68.7%) of n-butyl isocyanate, is distilled off. Vacuum distillation of the residue gives 14.4 g (64.3%) of *p*-isocyanatobenzenesulfonyl isocyanate, b.p. 115–120 °C/0.4 Torr, m.p. 40–44 °C (cf. Section III, 2).

14. *Di-o-tolylcarbodiimide*

22.5 g (0.22 mole) of phosgene in 100 ml of chlorobenzene at 48 °C is introduced into a suspension of 56.3 g (0.22 mole) of di-*o*-tolylthiourea in 460 ml of chlorobenzene over a period of 37 min. The mixture is heated to boiling, the excess phosgene is removed by means of nitrogen, and the solvent is distilled off. Vacuum distillation of the residue yields 40.7 g (83.4%) di-*o*-tolylcarbodiimide, b.p. 146–149 °C/0.7 Torr (cf. Section IV,1).

15. *N-p-Toluenesulfonyl-N'-n-butylchloroformamidine (13), R = $CH_3$–$C_6H_4$, R' = $C_4H_9$*

A solution of 7 g (0.07 mole) of phosgene in 50 ml of carbon tetrachloride is added dropwise to a stirred solution of 20 g (0.07 mole) of 1-*p*-toluenesulfonyl-3-n-butylthiourea in 150 ml of carbon tetrachloride. The solution is stirred for 90 min at room temperature, and 17.9 g (88.6%) of *N*-p-toluenesulfonyl-*N'*-n-butylchloroformamidine, m.p. 90–95 °C, separate as crystals (cf. Section IV, 2).

16. *Methanesulfonyl-n-butylcarbodiimide (14), R = $CH_3$, R' = $C_4H_9$*

5 g (0.05 mole) of phosgene in 40 ml of chlorobenzene is added dropwise to a suspension of 10.5 g (0.05 mole) of 1-methanesulfonyl-3-n-butylthiourea in 65 ml of chlorobenzene at 5 °C. The solution is stirred for 1 hour at room temperature and then heated to boiling, and the unchanged phosgene is removed by means of nitrogen. Removal of the solvent by distillation, followed by vacuum distillation of the residue, gives 7.0 g (79.5%) of methanesulfonyl-n-butylcarbodiimide, b.p. 103–105 °C/0.3 Torr; $n_D^{24.5}$ = 1.4798 (cf. Section IV, 2).

17. *3-Phenyl-4-p-toluenesulfonylimino-1,3-thiazetidin-2-one*

A solution of 2.8 g (0.028 mole) of phosgene in 35 ml of chlorobenzene is added dropwise to a suspension of 8.5 g (0.023 mole) of 1-*p*-toluenesulfonyl-3-phenylthiourea in

50 ml of chlorobenzene. The mixture is stirred for 1 hour, and the solvent is then distilled off *in vacuo*. Recrystallization of the residue [9 g (97.3%), m.p. 128–131 °C] from ethyl acetate yields analytically pure 3-phenyl-4-*p*-toluenesulfonyl-imino-1,3-thiazetidin-2-one, m.p. 139 °C (cf. Section IV, 2).

18. *2-Phenylimino-3-phenyl-1,3-thiazolidine-4,5-dione (15), $R = R' = C_6H_5$*

3.81 g (0.033 mole) of oxalyl chloride is added dropwise to a stirred, ice-cooled suspension of 6.84 g (0.03 mole) of 1,3-diphenylthiourea in 70 ml of 1,2-dichloroethane. The mixture is refluxed for 45 minutes, and the solvent is then distilled off. Recrystallization of the residue [8.1 g (96.5%), m.p. 124 to 125 °C] from carbon tetrachloride yields 6.49 g (76.5%) of 2-phenyl-imino-3-phenyl-1,3-thiazolidine-4,5-dione, m.p. 129–130 °C (cf. Section IV, 3).

# Some Recent Developments in the Chemistry of Transition Metal Oxocations

BY PROF. J. SELBIN

COATES CHEMICAL LABORATORIES, LOUISIANA STATE UNIVERSITY, BATON ROUGE, LOUISIANA (U.S.A.)

*The range of stability of transition metal oxocations in aqueous solution is discussed. Species with a metal-oxygen bond of order higher than unity are particularly interesting. Bond orders can sometimes be determined from bond lengths and angles, but generally only by infrared spectroscopy. – The frequency range of the metal-oxygen stretching vibration, previously assumed as about 900–1100 $cm^{-1}$, must according to these investigations be extended at least to 780 $cm^{-1}$ if all multiple bonds, particularly those in trans-dioxo complexes, are to be included. Broad bands down to 650 $cm^{-1}$ are ascribed to metal-oxygen bridges. – The existence of cations such as $ZrO^{2+}$ and $VO_2^+$, or of the "well-known" titanyl ion, $TiO^{2+}$, has never been proved. In many cases polynuclear, oxygen-bridged oxometal species must be assumed.*

## Introduction

Of recent theoretical and experimental interest is the general subject of multiple bonds. In the field of metal-oxygen multiple bonds it appears that the experimental science is still well ahead of the theoretical development, and so the former will be the main subject of this review.

No element appears to form multiple bonds with so many other elements as does oxygen. It is well known that oxygen can form multiple bonds with all non-metals, except fluorine and the lighter noble gases, with all metalloids, and apparently with almost all metals to which it bonds covalently [*].

This discussion is limited to oxometal species $MO_x^{n+}$ (where M = transition element; x = 1, 2, or 3; and n = 0–5), which are part of a complex. The other ligands may be strongly or weakly attached to M, while the oxygen is strongly bound and persistent during exchange of the other ligands. Excluded from consideration are the large number of $MO_4^{n-}$ species having only oxygen as ligand, as these have recently been discussed elsewhere [1–3]; the many binary (and most often non-stoichiometric) oxides of the transition metals; and the species $M_2O^{n+}$ [which appear to be quite well established for M = Ti(IV), Cr(III), Fe(III), Mo(V), Re(IV), Ru(IV), Rh(III), and Os(IV)], as in these the oxygen is always bridging, not terminal. The latter species are probably all linear and they are assumed to involve strong M–O–M π-bonding. Theoretical treatments of such entities have appeared [4–10].

Some of the experimental criteria most generally used to establish a bond order greater than one are:

[*] Whatever this may really mean; we exclude here the few ionic oxides such as $Li_2O$, CaO, $La_2O_3$, *etc.*, in which the oxygen is divalent but the bonding is more simply and satisfactory treated electrostatically.

(a) If the bond length is found to be shorter (by at least a few tenths of an Ångstrom unit) than the calculated or an experimentally determined single bond distance; this is the best and most direct evidence.

(b) If the bond angle implies a higher bond order, for example if in an M–O–M unit it exceeds the tetrahedral angle by at least several degrees;

(c) If the bond stretching frequency is considerably higher than is found (or predicted) for a single bond between the same atoms.

This last method is more often relied upon because of its experimental simplicity. Often it provides the only experimental evidence on the multiplicity of a metal-oxygen bond [11–13].

Table 1. Approximate correlation between dominant species in aqueous solutions attaching to a metal ion of formal charge Q, in various pH ranges (after *Jørgensen* [14]).

| | Q | | | | | | | |
|---|---|---|---|---|---|---|---|---|
| pH | +1 | +2 | +3 | +4 | +5 | +6 | +7 | +8 |
| –1 | $H_2O$ | $H_2O$ | $H_2O$ ↓ | $H_2O$ ↓ | $OH^-$ | $OH^-$ ↓ | $OH^-$ ↓ | $O_2^-$ |
| 7 | $H_2O$ | $H_2O$ ↓ | $OH^-$ | $OH^-$ ↓ | $OH^-$ ↓ | $O^{2-}$ | $O^{2-}$ | $O^{2-}$ |
| 15 | $H_2O$ | $OH^-$ | $OH^-$ | $O^{2-}$ | $O^{2-}$ | $O^{2-}$ | $O^{2-}$ | $O^{2-}$ |

Briefly let us consider where we should expect and where we actually find metal oxocations. We might begin by examination of Table 1, which has been patterned after a similar one given by *Jørgensen* [14] and is based on a large number of studies on solutions. It shows the approximate pH intervals in which $H_2O$, $OH^-$, and $O^{2-}$ are the common ligands to central ions oxidation states varying from +1 to +8. Although only qualitative, this table does suggest $O^{2-}$ to be a ligand toward metal ions (in solution) in high oxidation states (+4 to +8), and that the lower the oxidation state the higher must be the pH to prevent this ion from attaching a proton to form $OH^-$.

However, this interpretation of the table suffers from several obvious defects. It does not reflect the important contribution of cationic radius, r, and effective nuclear charge $Z_{eff}$; thus $Z_{eff}/r$ should be considered and not simply the formal charge Q. Also, because it represents an electrostatic picture it does not take into consideration what orbitals of the metal ion may be available for covalent bonding, certainly an important factor as the ionic charge increases and the ionic radius decreases. Further, it does not take into account the differences in covalent bonding capacity among $H_2O$, $OH^-$, and $O^{2-}$, *i.e.* their increasing π-bonding (really π-antibonding) capacities. *Jørgensen*'s [15] optical electronegativities of metal ions are possible measures of this tendency (*i.e.* the tendency for the metal ion to attract π-bonding electrons from oxygen). Finally, in the large intermediate pH ranges both $H_2O$ and $OH^-$ or $OH^-$ and $O^{2-}$ can co-exist as ligands. Indeed, a most remarkable fact is the co-existence within the same coordination sphere of both $H_2O$ and $O^{2-}$. This has been confirmed for $[VO(H_2O)_5]^{2+}$ [13, 16] and $[MO_2(H_2O)_x]^{2+}$ (M = U, Np, Pu, Am) [13, 17]. These are metal ions which have both their σ- and π-antibonding subshells empty, the latter being ideally suited, therefore, to accomodate strongly nucleophilic [*] oxide π-electrons. It is not sur-

[a] Several of the species listed, notably those of molybdenum and titanium, have been shown to be dimeric or polymeric with oxygen-bridged chains (see text and Figure 2).

[b] The underlined species are relatively common and well-established, at least in the solid state; those in parentheses are unstable or of doubtful existence.

[*] It would seem desirable to have a simple semantic way to distinguish nucleophilic groups according to whether their electrons seek to form a σ-bond or π-bond. The author suggests the terms σ-nucleophilicity and π-nucleophilicity.

prising, therefore, that the largest number of complexes have been prepared with the stable ions $UO_2^{2+}$ and $VO^{2+}$.

The requirement that the metal ion possess empty, stable $\pi$-bonding ($\pi$-antibonding) orbitals is pointed up in Table 2, in which are listed oxometal entities according to periodic group number, number of d-electrons, and formal oxidation state. Not all these have been unambiguously established as mononuclear, and many of them are much less common than once believed [12, 13].

Theoretical treatments of bonding and electronic structure in oxocation complexes have appeared for $VO^{2+}$ [18, 19], $UO_2^{2+}$ [17, 20–24], $CrO^{3+}$ [25], and with somewhat less rigor for certain other species $MO^{n+}$, $MO_2^{n+}$ [7–9]. There is not a great deal of agreement among the several workers in the field, and this seems especially true for vanadyl [16] (*vide infra*).

The remainder of this paper will be devoted to a systematic and critical survey of some of the recent experimental developments in oxocation chemistry by periodic group. However, no pretense of exhaustiveness is made; the material selected simply reflects the author's interests and his opinions of what are the most interesting, fruitful, or active of the experimental studies in this area.

## I. Oxocomplexes of Group IVb Elements

### 1. Titanium

There are very few unambiguously established examples of true $MO^{2+}$ species (M = Ti, Zr, Hf, Th), and it may be concluded that these metals, $d^0$ in their quadrivalent state, have a much greater tendency to form either mononuclear hydroxo species, $M(OH)_x^{(4-x)+}$, or chains or rings involving bridging by oxygen or hydroxyl ions.

In spite of the continual reporting in the literature of "titanyl" ions, $TiO^{2+}$, in aqueous solutions, there has never appeared conclusive or even strong evidence to support this mononuclear formulation. The situation with regard to the solid state is somewhat more definitive. Although there is no direct X-ray evidence for a mononuclear entity in any oxotitanium compound, the Ti–O distance in the sulfate, $TiOSO_4(H_2O)$, which consists of (Ti–O–Ti–O) chains, is 1.80 Å [26]. This value is very close to the Ti–O distance of 1.78 Å in $[Ti(C_5H_5)Cl_2]_2O$ [27], which clearly contains the linear, and hence surely multiply-bonded, Ti=O=Ti unit. (The sum of the ionic radii, $Ti^{4+}$ and $O^{2-}$, is 0.60 + 1.45 = 2.05 Å, and the sum of the covalent radii is not very different.) The broad infrared absorption bands centered about 920 and 800 $cm^{-1}$ [11], observed for the sulfate, are probably correctly assigned to metal-oxygen vibrations of bonds with order greater than one, but less than two. Broad bands are found near and below 900 $cm^{-1}$ in the spectra of $TiOF_2(H_2O)$ and $TiOF_2$ [28]; $TiOCl_2$, $TiOCl_2(2C_5H_5N)$ [29]; $TiOI_2$ [30]; some Ti oxide alkoxides [31]; $[TiO(C_2O_4)_2]^{2-}$ [11, 32]; and in products of the reaction of $TiCl_4$ with dioxane or acetonitrile [33].

The assignment [34] of a band at 1149 $cm^{-1}$ in $TiO(OH)_2$ to Ti=O is most likely incorrect. A more probable origin for this band is $\delta$ (Ti–O–H). In fact, on the basis of infrared data alone, mononuclear titanyl species are rare. The most likely compounds, and their possible Ti=O stretching frequencies in $cm^{-1}$, are TiO(β-diketone)$_2$, 1020–1035 [35, 36]; $TiOCl_2 \cdot 2POCl_3$, 1078 [27]; and TiO(phthalocyanine), 965 [37], 978 [38], 972 [39]. An absorption band at 975 $cm^{-1}$, believed to be due to a Ti=O double bond, is observed for $[(C_2H_5)_4N)]_2TiOCl_4$ [38a].

### 2. Zirconium and Hafnium

There are two recent surveys of zirconium chemistry [40, 41]. Both agree that the bulk of the literature on the solution chemistry of Zr(IV) contains no evidence for zirconyl ions, $ZrO^{2+}$. Definitely established instead are such species as $[Zr_4(OH)_8]^{8+}$(aq) and other hydroxo- or oxo-bridged polymeric species, which depend critically upon solution conditions, *viz.* pH, age, temperature, *etc.*

After examining Zr–O bond distances in eighteen solid compounds, *Clearfield* [41] concluded that "the existence of zirconium-oxygen multiple bonds has not been unequivocally demonstrated". This conclusion is based on the very slight deviations in observed bond distances (2,20 Å) from the sum of ionic or covalent radii (2,22 Å). However, recent infrared studies on a series of

"zirconyl" (and "hafnyl") fluorides prepared by thermal decomposition of $ZrF_4 \cdot 3H_2O$ [42], and on the isothiocyanato complexes $ZrO(NCS)_2 \cdot MNCS \cdot 2H_2O$ (where M = K, Rb, Cs, $NH_4$, or pyridinium) [42], have been interpreted as evidence for the existence of the zirconyl entity in such species.

Attempts by the present author [43] to duplicate the work with the fluorides were unsuccessful; the isothiocyanato work was successfully repeated [43] with M = Cs and $(CH_3)_4N$, and strong sharp bands at 916 and 920 $cm^{-1}$ in the respective compounds are tentatively assigned to Zr=O. If these isothiocyanato complexes do turn out to possess this elusive group, it is likely that the analogous hafnium complexes [44] do also.

*Dehnicke* and *Meyer* [45] report a band at 877 $cm^{-1}$ in $ZrOCl_2$ and one at 1083 $cm^{-1}$ in $ZrOCl_2 \cdot 2POCl_3$ which they claim arise from a Zr=O vibration, but neither of these assignments appears to be firmly based. The absence of a Zr=O group has been deduced from infrared data in oxalato, sulfato, and peroxo complexes of zirconium [46] and trichloroacetates of both zirconium and hafnium [47]. A band at 900 $cm^{-1}$ found in $ZrO(C_2O_4) \cdot 1.5H_2O$, but absent from the spectrum of $Zr(C_2O_4)_2$, is attributed to Zr=O, as is a narrow band at 1017 $cm^{-1}$ in $ZrO(NO_3)_2 \cdot 2H_2O$ [48].

Although a few thoryl, $ThO^{2+}$, formulations have been offered, for example ThOX (where X = $F_2$, $Cl_2$, S, Se, Te), no evidence has appeared to support such a mononuclear species.

Work on the crystal structures of some basic salts of Ce(IV), Th(IV), U(IV), Ti(IV), and Zr(IV) has been summarized by *Lundgren* [49] with the conclusion that no M(IV)-O bonds are short enough to be considered multiple bonds.

## II. Oxocomplexes of Group Vb

### 1. Vanadium

Oxocation chemistry in this periodic group is dominated by oxovanadium(IV), $VO^{2+}$. The author has recently surveyed preparative work, ESR, infrared, and visible-ultraviolet spectroscopy, X-ray diffraction, equilibrium, magnetic, and theoretical studies on this stable molecule-ion. With the exception of dioxouranium(VI), $UO_2^{2+}$, this is the most studied of the oxocations and the one for which we have the greatest number and variety of complexes.

Currently the $VO^{2+}$ ion is the center of a controversy over which theoretical model best describes its behavior and in particular its electronic or orbital structure. The apparent simplicity implicit in treating the $d^1$-system is illusory since there is very strong σ- and π-bonding between oxygen and vanadium, and the symmetry of its complexes is never higher than $C_{4v}$, but often lower. Several early (1957) attempts to treat this ion with a crystal field model [50–52] were shown (in 1962) to be inadequate by *Ballhausen* and *Gray* [18], who employed a modified self-consistent Wolfsberg-Helmholtz molecular orbital method in treating specifically the ion $[VO(H_2O)_5]^{2+}$. Their model and energy-level scheme was used by them and by others to interpret optical, ESR, and magnetic properties of $VO^{2+}$ complexes in general, and it was even extended to complexes of $CrO^{3+}$ and $MoO^{3+}$ (also $d^1$-systems) by *Gray* and *Hare* [25]. An analogous, but independent ligand field approach was applied to a generalized species $VOL_4^{n+}$ [53], yielding an energy scheme in approximate agreement with that of *Ballhausen* and *Gray*. Additional experimental work in the author's laboratory with vanadyl(IV) complexes [54,55] and, in particular, low-temperature studies [19,56] led to serious doubt in the universality, if not the specific validity, of the *Ballhausen-Gray* scheme, and a new energy scheme was tentatively proposed for vanadyl(IV) complexes [19]. Recent low-temperature studies [57,58] on vanadyl complexes suggest that none of the previously proposed schemes is acceptable.

Thus the problem of the origin of the visible and ultraviolet spectral bands is largely unsolved, and in its solution should be found important knowledge concerning the validity and usefulness of several modern theoretical approaches. Indeed *Piper* and *Wentworth* [58] are of the opinion that a simple electrostatic model is satisfactory for treating this and similar systems, whereas others, including this author, feel that covalent models must be employed. Additional low-temperature work now in progress, at 4 °K and 77 °K, including polarization spectra, as well as new ESR studies [59] are expected to clear up many of the present inconsistencies.

The mononuclear oxovanadium(V) species may be either $VO^{3+}$ or $VO_2^+$. The former is found more often in solid or liquid compounds such as $VOX_3$ (X = F, Cl, Br, OR, *etc.*) and in most complexes, such as $VO(OR)L_x$, whereas the dioxo ion is reported in relatively few compounds and is postulated in certain concentrated acid solutions.

When vanadate ($VO_4^{3-}$) solutions are acidified, extensive condensation probably gives decavanadate ions of the type $V_{10}O_{28}^{6-}$, $HV_{10}O_{28}^{5-}$, and $H_2V_{10}O_{28}^{4-}$ [60–63].

Upon further acidification a mononuclear cation is formed, but whether that species is $VO_2^+$ is not certain [1, 63–65].

However, several complexes are presumed to contain this elusive dioxo species. Thus $VO_2ClO_4$ (aqueous solution) is said to form $VO_2L_2$ below pH 4, and VO(OH)L above this value, where L = pyridine-2-carboxyl [66]. The same authors report that $VO_2^+$ absorbs at 730 mμ (13,700 $cm^{-1}$). In concentrated $HNO_3$ vanadium(v) is thought to exist as either $VO(NO_3)_3$ or $VO_2(NO_3)$ [67]. A brick-red powder, unstable in moist air, reported to have the formula $VO_2NO_3$ has been prepared [68] by reaction of liquid $N_2O_4$ with metallic vanadium. Infrared data indicate an ionic nitrate (1380 $cm^{-1}$, vs; 820 $cm^{-1}$, vw) and vanadium-oxygen multiple bonding (1020–1000 $cm^{-1}$). However, like the analogous Nb and Ta compounds [69] this nitrate is probably polymeric. Other reports of $VO_2^+$ complexes, for example with EDTA [70] or oxalate [71], do not convincingly demonstrate the presence of this particular ion. Thus the $VO_2^+$ species has never been unambiguously demonstrated either in a solid or in solution. In fact the existence of many complexes containing the $VO(OH)^{2+}$ unit suggests that the $VO_2^+$ species is very readily protonated. However, it is possible that protonation occurs only in the presence of ligands which transfer sufficient charge onto the vanadium to lower its electronegativity so far that it cannot remain multiply bonded to two oxygen atoms.

The $VO^{3+}$ entity is very common in anionic and neutral complexes as well as in covalent molecules. That strong oxygen-metal π-bonding occurs in $VOCl_3$ is reflected in its low dipole moment in $CCl_4$ solution of 0.31 D [72] (which implies a very low V–O bond moment), as well as in the high V–O stretching frequency of 1035 $cm^{-1}$ [73], a value exceeded only by the 1060 $cm^{-1}$ recorded for $VOF_3$ [74]. The value for $VOBr_3$ is lower, 1020 $cm^{-1}$ [75], reflecting probably more the increased mass against which the oxygen vibrates than a weakening of the V–O bond.

$VOCl_3$ reacts with a variety of molecules LH (for example: arenes) to form addition compounds of the types $VOCl_3 \cdot 2LH$ and $VOCl_3 \cdot LH$ [76,77]; or to give complexes of the type $VOCl \cdot L_x$ (x = 1 or 2) [78]; or $VOL_3$ [78–80], where L denotes either a mono- or bidentate ligand such as mono- and di-phenols and monocarboxylic acids.

Another common type of complex is of the general formula $VO(OR)L_x$, where usually x is 2, L is a bidentate ligand (*e.g.* salicylaldoxime), and R is most often H, but may also be alkyl.

*Dutta* and *Lahiry* [81] have prepared and characterized vanadium(IV) and vanadium(v) complexes with unusual bidentate ligands such as quinaldinic acid and its derivatives, hydroxamic acids, hydroxyphenyltriazines, benzimidazoles, benzotriazoles, and oxines. Most of these have the general formula $VO(OH)L_x$. Representative V–O stretching frequencies for the V(v) complexes are: $[VO(OH)Q_2] \cdot 2H_2O$, 939 $cm^{-1}$; $[VO(OH)B_2]$ 968 $cm^{-1}$ (QH = quinaldinic acid; BH = benzhydroxamic acid) which are comparable with the value for the 8-hydroxyquinoline complex $[VO(OH)(oxine)_2]$ of 952 $cm^{-1}$ [82].

### 2. Niobium and Tantalum

There are very few oxometal species of quadrivalent niobium and tantalum (and protactinium). The compounds $NbOCl_2$ [83], $NbOI_2$ [84], and $TaOCl_2$ [83] are the only Nb(Ta)(IV) compounds even formulated as having the oxometal entity. A number of non-oxo Nb(IV) compounds have been recently prepared [85,86], but attempts to obtain the ion $[NbOCl_5]^{3-}$ failed [85b] even though compounds $(RH)_2Nb(OR')Cl_5$ (R = organic amine, R' = alkyl) were readily prepared. Recently dioxo compounds $MNbO_2F$ (perovskites) with M = Li, Na, K, have been described [87] in which there are almost certainly Nb–O–Nb–O linkages with substantial ionic character.

In the quinquevalent state there are several compounds containing the $MO^{3+}$ group, and a few perhaps containing the $MO_2^+$ entity [12]. Examples of compounds formulated as having the latter grouping are $NbO_2Cl$, $K[NbO_2(C_2O_4)]$, $(NbO_2)_2(S_4O_{13})$ [12], $Nb(Ta)O_2NO_3$ [69],

$NbO_2F$ and $NbO_2I$ [88]. Little is known about the structure of these dioxometal compounds; they are most likely polymeric.

Recent reports of $MO^{3+}$ (M = Nb, Ta) compounds include $M'_3[MO(C_2O_4)_3]\cdot xH_2O$, (M' = Na, K, $NH_4$) [89–91]; $[NbOF_5]^{2-}$ [92] and $[MOF_6]^{3-}$ [92–94b], with Nb=O stretching frequencies of 927 and 922 $cm^{-1}$, respectively; $[NbOCl_5]^{2-}$ [96–98]; $MO(SO_3F)_3$ [99]; $NbOCl_3\cdot 2(CH_3)_2SO$ [100] and $MCl\cdot NbOCl_3$ (M = Na, K) [101]; $NbO(NO_3)_3$ (prepared by reaction of $NbCl_5$ with $N_2O_4$); 906 $cm^{-1}$ band assigned to Nb=O [92]; $[NbOCl_2(acac)]_x$, the low frequency (850–800 $cm^{-1}$) and broadness [102] of the infrared bands suggesting that Nb–O–Nb bridging rather than a terminal Nb=O bond is present in the molecule. The possible existence of $PaOF_5^{2-}$ in HF solutions has been reported [95].

In sum, is appears that niobium-oxygen multiple bonds occur in several monooxo compounds, the stretching frequencies of which are found around 900–925 $cm^{-1}$. Lower frequency bands, particularly if they are broad, in the range 850–750 $cm^{-1}$ are indicative of the bond order lower than two found in Nb–O–Nb chains.

## III. Oxocomplexes of Group VIb Elements

There are more possibilities for oxometal species with this family than with the previous two, and indeed more varieties are observed [12].

### 1. Chromium

In the quinquevalent state the chromium species $CrO^{3+}$ is found in very few, but well studied, compounds. For $CrOCl_3$ [103] and the complexes $K_2[CrOCl_5]$ and [isoquinolinium][$CrOCl_4$], magnetic moments of 1.80, 1.92, and 1.82 B.M., respectively, have been recorded [104]. The pentachloro-complex has been studied by ESR [105], visible-ultraviolet [25], and infrared [11, 106] spectroscopy. The Cr=O frequency in $K_2CrOCl_5$ is 950 $cm^{-1}$ [11, 106]. A species believed to be $[CrOF_5]^{2-}$ has also been examined by ESR [105] and magnetic, spectral, and conductivity measurements have been made on Cr(v) species in $H_2SO_4$ solutions [107].

At least two compounds of sexivalent chromium appear to contain the $CrO^{4+}$ group, *viz.* $CrOF_4$ [108] and $CrO(O_2)_2(C_5H_5N)$ [109]. X-ray structure determination on the latter complex reveals a very short Cr–O distance of 1.57 Å, compared to 1.794 for a Cr-(peroxo-O) length [109]. X-ray data on Cr–O distances are available for the following compounds: $K_3CrO_8$ (1.87, 1.97); $CrO_3$ (1.80); $(NH_4)_2CrO_4$ (1.60, 1.98); $(NH_4)_2Cr_2O_7$ (1.63, 1.91) [109]; $CrO(O_2)$(*o*-phen) (1.56, 1.83) [109a].

The much more common dioxo species $CrO_2^{2+}$ is found in $CrO_2X_2$ [12, 109b] (X = F, Cl, Br, $ClO_4$, $NO_3$, $N_3$, $CH_3COO$, NCO, NCS, $BO_2$, $SO_3F$, $^1/_2S_2O_7$), and in $CrO_2ClN_3$ [110].

The Cr=O stretching frequencies are expected in the range 950–1020 $cm^{-1}$, although few data are available [12].

### 2. Molybdenum

After uranium and vanadium, molybdenum has most likely yielded the largest number of oxo complexes. Many of these have been tabulated by the author [12], and a recent review [110a] is devoted entirely to oxo-species of Mo(v) and Mo(vi).

Some compounds of Mo(iv) have been formulated as oxometal species, *e.g.* $MoO_2(acacH)_2$, supposedly containing neutral acetylacetone, and analogous complexes with other neutral diketones [111]; $MoOCl_2$ [112], which has the same X-ray powder pattern as the analogous Nb and Ta compounds [83]; and $[Mo_3O_4(C_2O_4)_4]^{2-}$ [113]. However it seems that only in the first-mentioned of these is a terminal Mo=O bond likely, and even for this there is scant evidence.

At present there is great interest in two problems of oxomolybdenum chemistry: the nature of Mo(v) species in acidic aqueous solutions, and the structural units in the solid state.

From spectrophotometric [114–117], magnetic [118–120], and potentiometric [114] studies of Mo(v) species in hydrochloric acid, it has been concluded that in concentrated HCl (>10 M) the predominant species is monomeric and paramagnetic (1 unpaired electron) $[MoOCl_5]^{2-}$; at intermediate HCl concentrations (2–10 M) two (or more) dimeric forms, one paramagnetic, one diamagnetic, exist in equilibrium; and at low HCl concentrations (<2 M) diamagnetic species predominate, but their nature is not known. The results of a recent spectrophotometric study of Mo(v) and Mo(vi) in HBr solutions [121] have been interpreted in

Table 3. Recently prepared and characterized Mo(v) oxocomplexes.

terms of four dimeric Mo(v) species in aqueous HBr in the concentration range 1.0–8.6 M. At the highest HBr concentration the predominant form is believed to be $[(MoOBr_4)_2]^{2-}$ and no spectral evidence was obtained for $[MoOBr_5]^{2-}$. This is somewhat surprising in view of the fact that salts of $[MoOBr_5]^{2-}$ can be isolated from aqueous HBr solutions [121, 122]. Salts of $[MOX_4]^-$ (M = Mo or W, X = Cl or Br) which is present most likely as bridged dimers, $[M_2O_2X_8]^{2-}$, have been obtained from solutions in $SO_2$ [122].

This brings us to another current problem, *viz.*, the nature of the species of oxomolybdenum(v) in the solid state. Apparently at least four oxo-species can occur in the solid state: $MoO^{3+}$, $Mo_2O_2^{6+}$, $Mo_2O_3^{4+}$, and $Mo_2O_4^{2+}$ (see Fig. 1). The latter two are singly bridged and doubly bridged, respectively, by oxygen. In Table 3 are listed some of the recently prepared and characterized oxo complexes of Mo(v) according to the probable structure [*] of the oxocation.

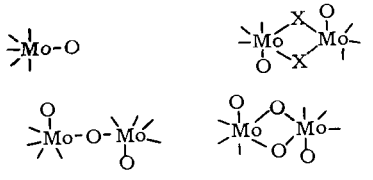

Fig. 1. Possible structures of Mo(v) oxocation species. The strokes simply denote a coordination number of 6.

Recent X-ray structure determination of a xanthate complex, $[Mo_2O_3(C_2H_5OCS_2)_4]$, has revealed a linear Mo–O–Mo bridge, a short M–O bond length of 1.64 Å, and a bridge Mo–O bond length of 1.86 Å [133].

However, the band assignment [133] of 1236 $cm^{-1}$ to Mo=O and either 1046 or 946 $cm^{-1}$ to Mo–O–Mo seems in error. On the basis of the data from Table 2, it would be preferable to assign the 946 $cm^{-1}$ band to Mo=O and bands at about 760 and 765 $cm^{-1}$(shoulder) to Mo–O–Mo. The compound originally formulated as a Mo(v) oxalato complex, $K_2[Mo_2O_4(C_2O_4)_2(H_2O)_2]$ probably is a molybdenum(vi) complex [136], $K_2[Mo_2O_5(C_2O_4)_2(H_2O)_2]$, with bond lengths Mo=O of 1.69 Å, Mo–O (bridging) 1.88, Mo–O (of oxalate) 2.19 and 2.09, and Mo–O (of $H_2O$) 2.33 Å. However, the high value found for the Mo=O stretching frequency, 980$cm^{-1}$, in the compound [126] $[Mo_2O_4(C_2O_4)_2(H_2O)_2]^{2-}$ suggests that there are in reality two nearly identical oxalato complexes, which differ only in the oxidation state of the Mo and in the Mo:O ratio.

The Mo=O frequency in a Mo(vi) complex usually is lower than in a Mo(v) complex by 50–80 $cm^{-1}$. The infrared data available on the $Mo_2O_2^{6+}$ dimers (Table 3) support the bridged structure shown in Figure 1, rather than a structure involving oxygen bridges, since the Mo–O frequencies are all too high to have arisen from the latter. It appears that a coordination number of six is maintained in all series of complexes. The preparation and properties of $MoOCl_3$ have been reported recently [140–142] and the Mo=O stretching frequency has been found as 1020 [141] and 1010 [142] $cm^{-1}$.

Fewer and generally less stable complexes arise with Mo(vi). Compounds derived from $MoO^{4+}$ are few [12], as are those derived from $MoO_3$; the largest number of compounds of Mo(vi) seems to be those of $MoO_2^{2+}$ [12]. Recent work includes a new preparation of $MoOCl_4$ [143], with a value of 990 $cm^{-1}$ recorded [142] for the M=O frequency; preparation [144] and X-ray structure study [145] of $MoO_3$(diethylenetriamine), revealing three mutually *cis* oxygen atoms in an octahedral structure with Mo–O distances of 1.74 Å [145] and only one strong infrared band, at 835 $cm^{-1}$, in the expected region [144]; also an X-ray study of $NaNH_4[MoO_3(C_2O_4)]\cdot 2H_2O$ [146], which consists of infinite Mo–O–Mo–O bent and unsymmterical chains, each Mo being surrounded by a distorted octahedron comprising two terminal oxo oxygens at 1.82 and 1.85 Å, and two oxalato oxygens, in addition to the two bridging oxygens.

The Mo=O stretching frequencies in Mo(vi) compounds (there are as yet few data on the dioxo species) fall in the range 900 ± 10 $cm^{-1}$. That this is lower than the range 960 ± 30 $cm^{-1}$ found for Mo(v) species is due mainly to the presence of two multiply bonded oxygens on the same Mo(vi) atom, which leads to a

mutual lowering of the bond strength and bond order of each oxygen. No Mo(v) compounds are known for sure to have two multiply bonded terminal oxygens, and there are certainly no spectral data to support such species.

### 3. Tungsten

The compounds of W(v) that have been prepared seem quite analogous to the corresponding Mo(v) compounds[12]. For example, $K_2[WO(NCS)_5]$ has been examined by ESR[124], and $M_2[WOX_5]$ and $M[WOX_4]$ (X = Cl, Br, M = K, Rb, Cs, $(CH_3)_4N$) have been studied magnetically and spectrally[122], $Rb_2[WOCl_5]$ showing a W=O band at 970 $cm^{-1}$.

A large number of compounds of W(VI) have been synthesized by reaction of $WOCl_4$ with primary mono- and diamines, substituted phenols, aromatic secondary and tertiary amines, organic acids, *etc.*[147]. The infrared spectrum of $WOCl_4$ shows a strong W=O absorption at 1020 $cm^{-1}$ in the gas phase (1018 $cm^{-1}$ in $SOCl_2$ and 1025 $cm^{-1}$ in $CS_2$)[142]. In the crystalline state $WOCl_4$ and $WOBr_4$ absorb at 882 and 833 $cm^{-1}$, respectively, owing no doubt to a polymeric chain structure[142].

## IV. Oxocomplexes of Group VIIb Elements

With the exception of $MnO_3F$, the $MnO_3^+$ ion in solution, $MnO(C_5H_5N)$phthalocyanine[12], and some oxohalides of Tc, such as $TcO_3X$ (X = F, Cl), $TcOX_3$ (X = Cl, Br), $TcOX_4$ (X = F, Cl)[148], only oxocompounds of rhenium are known in this group[12].

### 1. Rhenium

Rhenium has an extraordinary capacity for forming multiple bonds to oxygen (and also nitrogen); it forms oxo species in the oxidation states +5, +6, +7, and +4, with the number of examples known decreasing sharply in that order. It is possible to find anionic, neutral, and even cationic complexes of rhenium in the oxidation state +5[12]. The bulk of the oxo complexes derive from this oxidation state[149–156b].

Octahedral Re(v) complexes with only one terminal oxygen show Re=O absorptions in the range 930 to 1015 $cm^{-1}$[149,151,154,156b], where, for example, a 978 $cm^{-1}$ frequency[149] corresponds to an X-ray determined Re=O bond length of 1.60 Å[157]. Re(v) complexes with two terminal oxygens per rhenium, most probably in *trans* positions to each other, show O=Re=O bands at 780–830 $cm^{-1}$; the low values derive from anionic complexes such as $[ReO_2(CN)_4]^{-3}$ (780 $cm^{-1}$) and the higher values from cationic complexes such as $[ReO_2(ethylenediamine)_2]^+$ and $[ReO_2(C_5H_5N)_4]^+$. The lower Re=O stretching frequencies of the dioxo compounds is expected from the very strong *trans* effect that a multiply bonded oxygen should show. This effect also explains the observed lowering of the Re=O frequency in a series of complexes $ReOXY_2(R_3P)_2$ as more strongly *trans*-affecting ligands X in the O=Re–X grouping are substituted[151]. (X = Cl, Br, I, Y = Cl, Br, $OCH_3$, $OC_2H_5$, R = $C_6H_5$, $C_2H_5$).

In the dimers $[ReO_2(RCOO)]_2$ it seems possible that the bands at about 934 $cm^{-1}$ are due to terminal Re=O bonds and that there is also bridging by two oxygens as in the $Mo_2O_4^{4+}$ species, although this possibility requires penta- or tetra-coordinated rhenium depending on whether the RCOO group occupies one or two coordination positions. The complexes $[ReOCl(RCOO)]_2$ have similar Re=O frequencies (about 940 $cm^{-1}$) which suggests double chloride bridging, leaving two terminal Re=O groups.

No infrared frequencies are known for oxorhenium(IV) compounds, but those obtained for Re(VII) compounds are: $ReO_3Cl$, 960 $cm^{-1}$ (bond length 1.76 Å); $Re_2O_7$, 910 $cm^{-1}$; and $KReO_4$, 913 $cm^{-1}$.

## V. Oxocomplexes of Group VIIIb Elements

No oxocomplexes of iron, cobalt, nickel, rhodium, palladium, iridium, or platinum of the types considered here appear to exist, with the possible exception of $PtOF_4$[158], about which little is known.

### 1. Ruthenium

There are very few oxometal compounds of ruthenium[12], and none of them have been investigated with the purpose of definitely establishing the existence of a Ru=O multiple bond. For example, $Cs_2[RuO_2Cl_4]$ was prepared in pure form and some of its properties determined[159], but nothing definitive about the $RuO_2^{2+}$ entity is known. However, it should be a relatively stable species, the oxygens in the octahedral

$[RuO_2Cl_4]^{2-}$ ion should be *trans*, and the metal-oxygen vibrations should occur around the 780–830 $cm^{-1}$ region, judging from the data on the analogous osmium(VI) species, $Cs_2[OsO_2Cl_4]$.

### 2. Osmium

The oxometal chemistry of osmium is relatively rich, a few +8, one +7, and many +6 compounds being known [12]. Osmium and rhenium possess the greatest tendency among the metals to form multiple bonds also with nitrogen. Recently infrared data on ten dioxo complexes have been tabulated [160]. In complexes of the types $[OsO_2X_4]^{n+}$ and $[OsO_2X_2Y_2]^{n+}$ one can arrange the X and Y ligands according to the effect on the antisymmetric stretching frequency of the *trans* dioxo species as follows:

| Ligand | $2\,OH^-$ $2\,C_2O_4^{2-}$ | $<4\,OH^-$ | $<4\,HN_3$ | $<2\,C_2O_4^{2-}$ | $<4\,CN^-$ | $<4\,Cl^-$ | $<4\,OCH_3^-$ | $\approx 2\,OH^-$ $2\,NO_2^-$ | $<2\,NO_3^-$ $2\,NO_2^-$ |
|---|---|---|---|---|---|---|---|---|---|
| $\tilde{\nu}_{as}$ (O·M=O) | 796 | 800 | 808 | 824 | 830 | 837 | 840 | 840 | 871 $cm^{-1}$ |

Crystal structure data on $K_2[OsO_2(OH)_4]$ and $K_2[OsO_2(CN)_4]$ reveal Os=O bond lengths of 1.77 and 1.75 Å, respectively [12], and the *trans* positioning of the oxygens is verified.

A discussion of the molecular orbitals and bonding in $OsO_2^{2+}$ complexes [161] has drawn a distinction between the $UO_2^{2+}$ and $OsO_2^{2+}$ groups, from which it is suggested that because of the vacant f-orbitals of uranium, the former can form a triple bond whereas the Os–O bond can only have a multiplicity of two. This may account in large measure for the higher (by 50–100 $cm^{-1}$) antisymmetric stretching frequencies observed for $UO_2^{2+}$ complexes.

Finally, there has recently appeared a review article [161a] on osmium and its compounds.

## VI. Oxocomplexes of Elements with 5f-Electrons

Oxocations in this group include the very stable $UO_2^{2+}$, $NpO_2^{2+}$, $NpO_2^+$, $PuO_2^{2+}$, $AmO_2^{2+}$, and $AmO_2^+$, redox-unstable $UO_2^+$ and $PuO_2^+$, and perhaps $UO^{2+}$ and $PuO^{2+}$. More complexes of $UO_2^{2+}$ have been prepared and characterized than for all other oxocations combined. For over a century and a half uranyl complexes have been investigated, and many hundreds of papers dealing with $UO_2^{2+}$ complexes have appeared in recent years. A book, published in 1964, but containing relatively little information obtained after 1960, deals specifically and thoroughly with the spectroscopy and photochemistry of $UO_2^{2+}$ compounds [17].

There is general agreement that the $O{=}U{=}O^{2+}$ entity is linear with very short bonds (1.60–1.92 Å), that the bond orders are between two and three, and that coordination by other ligands occurs in the equatorial plane with four, five, or six ligands. It is most interesting that five ligands in the equatorial plane is the arrangement found at least as often as four or six, giving the uranium a total coordination number of seven [162]. The linear $UO^{2+}$ species is expected to show three fundamental vibrations, $\nu_1$, symmetric stretching, $\nu_2$, bending, and $\nu_3$, antisymmetric stretching. All three bands have been observed in the infrared, not unusual since crystal and solution distortions can cause $\nu_1$ to be IR-allowed. The $\nu_3$ vibration is generally observed as a very strong band in the 900–1000 $cm^{-1}$ region; $\nu_1$ may be found, with lower intensity, in the 780–900 $cm^{-1}$ region; and $\nu_2$ has been observed a few times in the 210–280 $cm^{-1}$ region [17, 21, 163–168].

Infrared-spectroscopic studies of the transuranium ions yielded the data collected in Table 4 [169, 170]. The decrease of over 100 $cm^{-1}$ from $MO_2^{2+}$ to $MO_2^+$ (for M = Np, Am) must be due primarily to a weakening of the M–O $\pi$-bond by virtue of the presence of an additional electron on the quinquevalent metal ion. This result supports the idea that oxometal bonds will in general be weakened by other ligands capable of transferring charge onto the metal ion. The decrease in frequency of $\nu_3$ from solution to solid state must reflect both the stronger ligand character of acetate over water and the tighter binding in a rigid crystalline lattice.

Table 4. Infrared absorption maxima (in $cm^{-1}$) of some uranium and transuranium oxocations.

| fn | in aqueous $HClO_4$ [169] | $\tilde{\nu}_3$ | Solid [170] | $\tilde{\nu}_3$ | $\tilde{\nu}_1$ [a] |

formulated as follows: $UO(HCOO)_2 \cdot NH_4(HCOO)$, 2 $UO(HCOO)_2 \cdot H_2O$. An acetate complex was also isolated and formulated as 2 $UO(CH_3COO)_2 \cdot NH_4(CH_3COO)$. Earlier formulations of U(IV) oxo species have included a nitrate, sulfate, formate, and halides [171]. However, for none of these compounds is any real evidence presented for a mononuclear $UO^{2+}$ entity. A recent infrared study [172] of compounds obtained by thermal decomposition of $UCl_3(OH) \cdot 6H_2O$ failed to yield conclusive evidence for a terminal U=O bond. Bands observed in the 720–735 $cm^{-1}$ region are assumed to arise from O–U–O bridge stretching vibrations, which implies bond orders greater than one, but lower than two. A band at 960 $cm^{-1}$ was found in one of the compounds at a position where a species such as $U{=}O^{2+}$ might absorb, but this band could also be due to a U–O–H segment of the structure. In sum, no firm evidence has been published (to this author's knowledge) which supports the $UO^{2+}$ (or $PuO^{2+}$) species.

## VII. Appendix

Recent work on oxocations of molybdenum has included structural and ESR studies as well as the preparation of new complexes. X-ray structure analysis of $\{[MoO(C_2O_4)H_2O]_2O_2\}^{2-}$ reveals two octahedrally coordinated Mo atoms sharing an edge, terminal Mo=O bond lengths of 1.70 Å, and bridge bond lengths of 1.88 and 1.93 Å [173]. *Cotton* and *Wing* [174] have discussed metal-oxygen multiple bonds, especially those involving molybdenum, considering specifically the relationships among bond lengths, stretching force constants, and stretching frequencies.

The new complexes of Mo(v) include: $MoCl_3 \cdot 2RCN$ (R = $CH_3$, $C_2H_5$, $C_3H_7$); Mo=O stretching frequency 980 $cm^{-1}$; $MoOCl_3 \cdot A$ (A = *o*-phenanthroline, bipyridyl), $\nu_{Mo=O}$ = 975 $cm^{-1}$; $MoOCl_3 \cdot 2P(C_6H_5)_3$, $\nu_{Mo=O}$ = 950 $cm^{-1}$ [175]; $MoOCl_3 \cdot 2R$ (R = tetrahydrofuran, tetrahydropyran), bands at 1000, 985 and at 995, 985 $cm^{-1}$, respectively); $MoOCl_3 \cdot R^1$ ($R^1$ = 1,4-dioxane, 1,4-oxathiane, ethylene glycol dimethyl ether, dimethyl sulfide, diethyl sulfide, di-n-propyl sulfide) [176].

The ESR spectra of $d^1$ Mo(v) complexes are being studied increasingly [177–180]; recently [180] it was reported that $g_{\|} > g_{\perp}$ in $MOX_n^{3-n}$ (M = Mo, W), which is the opposite of what is normally the case.

Chemical and structural studies of oxo-complexes of Re(v) are increasing rapidly [156a–e, 181–184] so that the oxocation complexes of Re(v) are now among the most thoroughly investigated of the oxometal compounds.

## The Structure of Fulminic Acid, HCNO

By Priv.-Doz. W. Beck and K. Feldl

Anorganisch-Chemisches Laboratorium,
Technische Hochschule München (Germany)

The structure of fulminic acid was hitherto not known with certainty [1]. *H. Wieland* [2] showed that the free acid exists and can be distilled with ether. We have found that the compound, which is liberated from aqueous sodium fulminate by dilute $H_2SO_4$ [2a] and can be sublimed unchanged bellow *ca.* −20 °C/$10^{-4}$ mm, is sufficiently stable in the gaseous state for its IR spectrum to be measured at room temperature. This spectrum [3] indicates that gaseous fulminic acid has the structure of a "formonitrile" oxide, a structure which explains the polymerization and addition reactions of fulminic acid [1]. The spectrum contains a C–H stretching vibration at 3335 $cm^{-1}$ (parallel band); for the form CNOH, however, the O–H stretching vibration is expected at 3600 $cm^{-1}$ [4]. The pseudosymmetric and asymmetric CNO stretching vibrations were found at 1251 and 2190 $cm^{-1}$ (parallel bands). In the region 1000–1400 $cm^{-1}$, the IR spectrum of the form CNOH, however, should contain, besides the $\nu_s$(CNO) band, a second, intense absorption (the NOH bending vibration) [4]. Further, the band at 1250 $cm^{-1}$ is not shifted on deuteration of the compound. The CNO bending vibration at 538 $cm^{-1}$ is a typical perpendicular band with a marked Q branch.

The molecule HCNO may be considered as pseudo-dinitrogen oxide. In fact, the corresponding IR frequencies of HCNO and $N_2O$ show considerable analogy (see table), so that the ground state of fulminic acid can be described approximately by the formulae:

$$H\text{-}C{\equiv}\overset{\oplus}{N}\text{-}\overset{\ominus}{O} \longleftrightarrow H\text{-}\overset{\ominus}{C}{=}\overset{\oplus}{N}{=}O$$

| | $\nu_1$ ($cm^{-1}$) | $\nu_2$ ($cm^{-1}$) | $\nu_3$ ($cm^{-1}$) |
|---|---|---|---|
| $N_2O$ [5] | 1285 | 589 | 2224 |
| HCNO | 1251 | 538 | 2190 |

## Stimulation of RNA Polymerase in Liver Nuclei by Cortisol in vitro

By Dr. I. Lukacs and Doz. C. E. Sekeris

Physiologisch-Chemisches Institut,
Universität Marburg (Germany)

The RNA polymerase in cell nuclei is stimulated by hormones *in vivo* [1]. We have now found that cortisol stimulates RNA polymerase in cell nuclei also *in vitro*; the effect appears within a few minutes. Isolated and purified rat liver nuclei were incubated for 1–15 min with cortisol at 37 °C. From these the DNA-dependent RNA polymerase was isolated as Weiss complex [2]. The activity of the RNA polymerase was measured in a system [1c] that synthesises RNA *in vitro*. This system consists of 0.25 mole each of ATP, GTP, and CTP; 0.1 μCi of $^{14}$C–UTP (spec. act. 145 mCi/mmole), creatine phosphate 2.5 μmole, creatine-phosphokinase 5 μg, 2-mercaptoethanol 3 μmole, $MnSO_4$ 2 μmole, and tris[(hydroxymethyl)amino]methane 12 μmole; final volume 0.15 ml; pH 7.9; the enzyme preparation was added in quantities containing 50–100 μg of DNA; incubation time 4 min.

| System | μμmoles of $^{14}$C–UTP incorporated into RNA/(mg of DNA/min) |
|---|---|
| Controls | 89.7 + 7 |
| Nuclei incubated with 20 γ of cortisol/ml, 1 min | 112 +10 ($p$ <0.01) [a] |
| Controls | 136.9 ± 9 |
| Nuclei incubated with 20 γ of cortisol/ml, 5 min | 214 ± 26 ($p$ <0.02) |
| Controls | 67.5 ± 13 |
| Nuclei incubated with 20 γ of cortisol/ml, 10 min | 93 ± 8.9 ($p$ <0.05) |
| Nuclei incubated with 20 γ of pregnanediol/ml, 10 min | 69.3 ± 12 |

[a] $p$ values according to Fisher's t-test, based on 4–6 individual determinations. Cf. *R. A. Fisher* and *F. Yates*: Statistical Tables for Biological Agriculture and Medical Research. Edinburgh 1949.

The rapid increase in enzyme activity (within a few minutes) is explained by assuming that cortisol increases the matrix activity of DNA, perhaps in the sense of a derepression as envisaged by *Jacob* and *Monod* [3].

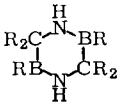
## Synthesis of Derivatives of 1,4-Diaza-3,6-diboracyclohexane and 1,4-Diaza-2-boracyclopentane by Reaction of Hydrogen Cyanide with Alkylboranes

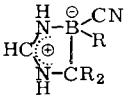
By Prof. G. Hesse, Dr. H. Witte, and H. Haussleiter [*]

Institut für organische Chemie,
Universität Erlangen-Nürnberg (Germany)

When hydrogen cyanide is passed into triethyl- or tri-n-butylborane (molar proportions 6:1) at room temperature, a colorless oil is obtained that can be partially distilled in a high vacuum. Compound *(1)* crystallizes from the lower-boiling fraction [90–100 °C/0.01 mm Hg for *(1a)*, 120–135 °C/0.01 mm Hg for *(1b)*], and compound *(2)* is obtained when the higher-boiling fraction [85–100 °C/$10^{-3}$ mm Hg for *(2a)*, 160–180 °C/$10^{-3}$ mm Hg for *(2b)*] is rubbed with benzene/chloroform.



*(1)*



*(2)*

*(1a)*, R = $C_2H_5$; m.p. 65 °C; 5 %
*(1b)*, R = n-$C_4H_9$; m.p. 71 °C; 14 %
*(2a)*, R = $C_2H_5$; m.p. 118 °C; 10 %
*(2b)*, R = n-$C_4H_9$; m.p. 121 °C; 2 %

All the products are colorless and stable in air. The 1,4-diaza-3,6-diboracyclohexane derivatives *(1a)* and *(1b)* [1] are readily soluble in nonpolar solvents but sparingly so in polar solvents; the 1,4-diaza-2-boracylopentane derivatives *(2a)* and *(2b)* show the opposite behavior.

The structure of the ethyl derivative *(1b)* follows from degradation by chromyl trichloroacetate [2] to di-n-butyl ketone (52 %), ammonia (12 %), and some 1-butanol, as well as from the spectra: $^{11}$B-NMR [in $CHCl_3$, external standard $BF_3 \cdot (C_2H_5)_2O$], −44 ± 2 ppm [3]; $^1$H-NMR (in $CCl_4$, internal standard tetramethylsilane), τ = 6.4 (2 NH).

Compound *(2a)* dissolves in aqueous acid with loss of 1 mole of HCN. After quantitative precipitation of the HCN as AgCN, oxidation with alkaline hydrogen peroxide yields diethyl ketone (47 %), ethanol (32 %), and ammonia (45 %). Oxidation by air gave some ethylboric acid. – The structure of compound *(2a)* is confirmed also by the spectra: $^{11}$B-NMR [in $CH_3OH$, external standard $BF_3 \cdot (C_2H_5)_2O$], 6.5 ppm; $^1$H-NMR (in $CD_3COCD_3$, tetramethylsilane as internal standard), multiplet at τ = 2.1–2.5 (1 NH and 1 CH), τ = 2.6–3.0 (1 NH), multiplet at τ = 9.4–10.0 (B–$CH_2$–$CH_3$); IR (in KBr), 3410 and 3300 $cm^{-1}$ vs ($\nu_{NH}$), 2180 $cm^{-1}$ m ($\nu_{C\equiv N}$), 1618 $cm^{-1}$ vs ($\nu_{\overset{\oplus}{C}=N}$ [4]. The molecular weight was confirmed by mass spectrometry, the chief fragment having mass 152 = molecular mass (179) – HCN (27) [5].

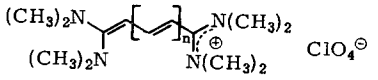
## Vinylogous Guanidinium and ω,ω-Diaminoacrylamidinium Salts

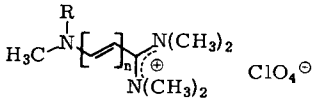
By Doz. Ch. Jutz and E. Müller

Organisch-Chemisches Institut der Technischen Hochschule München (Germany)

Polymethiniminium salts of types *(1)* and *(2)* can be considered as vinylogous ω,ω-diaminoacrylamidinium and guanidinium salts, respectively.



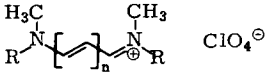
*(1a)*, n = 0; *(1b)*, n = 1; *(1c)*, n = 2; *(1d)*, n = 3



*(2a)*, n = 0, R = $CH_3$;
*(2b)*, n = 1, R = $CH_3$;
*(2c)*, n = 1, R = $C_6H_5$

We have prepared some representatives of the series *(1)* and *(2)* by using the strong nucleophilic base 1,1-bisdimethylaminoethylene *(3)*[1]. This base readily removes methylaniline from the vinylogous formamidinium salts *(4b)* and

$[(CH_3)_2N]_2C{=}CH_2$ *(3)*



R = $C_6H_5$: *(4a)*, n = 0; *(4b)*, n = 1; *(4c)*, n = 2
R = $CH_3$: *(5a)*, n = 2; *(5b)*, n = 3; *(5c)*, n = 4

*(4c)* with double substitution. One mole of the salt *(4b)* and 2 moles of the base *(3)* at 20 °C afford immediately a deep-red solution, from which 7,7-bisdimethylamino-*N,N,N',N'*-tetramethyl-2,4,6-heptatrienamidinium perchlorate *(1c)* crystallizes in 94 % yield on addition of ether 15 min later. This product forms green, shiny leaflets of m.p. 159 °C (from $CH_2Cl_2$/ether), $\lambda_{max}$ = 530 mμ (log ε = 5.20); cf. *(5b)*, 519 mμ (5.30)[2].

Similarly the salt *(4c)* and the base *(3)* afford 9,9-bisdimethylamino-*N,N,N',N'*-tetramethyl-2,4,6,8-nonatetraenamidinium perchlorate *(1d)* in 90 % yield as blue, shiny leaflets of m.p. 138 °C (decomp.) (from $CH_2Cl_2$/ether), $\lambda_{max}$ = 629 mμ (log ε = 5.31); cf. *(5c)*, 625 mμ (5.47)[2].

Compounds *(1c)* and *(1d)* were purified by chromatography in $CH_2Cl_2$ on $Al_2O_3$ (activity III, neutral).

Compound *(4a)* reacts with the base *(3)* in $CH_2Cl_2$ at 20 °C (or in pyridine at 110 °C) giving a 97 % yield of 3-(*N*-methylanilino)-*N,N,N',N'*-tetramethylacrylamidinium perchlorate *(2c)* only. Yellow 5,5-bisdimethylamino-*N,N,N',N'*-tetramethyl-2,4-pentadienamidinium perchlorate *(1b)* is formed only in traces, whereas the reaction of salts *(4b)* and *(4c)* with the base *(3)* (even in a molar ratio of 1:1) cannot be kept at the intermediate stage of vinylogues of compound *(2c)*. Compound *(2c)* forms pale yellow needles of m.p. 113.5 °C (from 2-propanol), $\lambda_{max}$ = 331 mμ (log ε = 4.65). We finally obtained the pentamethine *(1b)* from 1 mole of diethoxycarbonium fluoroborate[3] and 2 moles of *(3)* in $CH_2Cl_2$ at −60 °C, with subsequent conversion into the perchlorate. In this reaction 3-dimethylamino-*N,N,N',N'*-tetramethylacrylamidinium perchlorate *(2b)* is also formed as a result of loss of dimethylamine from *(3)* through the resulting ethanol. Compound *(2b)* could be completely separated by chromatography in $CH_2Cl_2$ on $Al_2O_3$ (activity III, neutral). Compound *(1b)* forms yellow leaflets of m.p. 167 °C (from 2-propanol), $\lambda_{max}$ = 435 mμ (log ε = 5.02); cf. *(5a)*, 416 mμ (5.08)[2].

After treatment of 1 mole of the dimethylformamide-dimethyl sulfate adduct[4] with 1 mole of base *(3)* in $CH_2Cl_2$ at −10 °C we isolated the pure compound *(2b)* in 71 % yield as perchlorate, which formed colorless leaflets, moderately soluble in water, m.p. 128 °C (from 2-propanol), $\lambda_{max}$ = 317 mμ (log ε = 4.62). Treating the tetramethylurea-dimethyl sulfate adduct[5] with base *(3)* under the same conditions afforded, not the trimethine *(1a)*, but tetramethylammonium perchlorate in moderate yield. Attempts to prepare hexamethylguanidinium perchlorate *(2a)* from the tetramethylurea-dimethyl sulfate adduct or *C*-chloro-*N,N,N',N'*-tetramethylamidinium chloride[6] and dimethylamine also failed.

The cations *(1b)*–*(1d)* are strongly basic, being protonated in the carbon chain even by water with decolorization and formation of bis-amidinium ions.

## Synthesis of Isocyanates by Fragmentation of Sulfonylureas

By Dr. H. Ulrich and Dr. A. A. R. Sayigh

The Upjohn Company, Carwin Research Laboratories, North Haven, Connecticut (USA)

We have found a new method of preparing isocyanates in the pyrolysis of 1,3-disubstituted sulfonylureas *(1)*. The sulfonamides formed at the same time react with the isocyanates only very sluggishly or not at all.

The sulfonylureas needed are accessible easily and quantitatively from sulfonyl isocyanates *(2)* and amines. The regenerated sulfonamides *(3)* can be readily reconverted into sulfonyl isocyanates by treatment with phosgene[1].

$$\underset{(2)}{RSO_2NCO} + R'NH_2 \rightarrow \underset{(1)}{RSO_2NHCONHR'}$$

$$\underset{(1)}{RSO_2NHCONHR'} \xrightarrow{\Delta} \underset{(3)}{RSO_2NH_2} + R'NCO$$

$$\underset{(3)}{RSO_2NH_2} + COCl_2 \rightarrow \underset{(2)}{RSO_2NCO} + 2\,HCl$$

Sulfonylureas can be stored in the solid state, so that the isocyanates can be prepared as required by heating sulfonylureas in a distillation apparatus. If the alkyl group is primary, it is advantageous to use a high-boiling solvent such as *o*-dichlorobenzene, 1,2,4-trichlorobenzene, or 2-chloronaphthalene.

| Isocyanate [a] | B.p. (°C/mm Hg) | Yield (%) |
|---|---|---|
| $(CH_3)CH{-}NCO$ | 76/760 | 75 |
| $(CH_3)_3C_2{-}NCO$ | 84–85/760 | 92.5 |
| $C_2H_5O{-}CH_2{-}CH_2{-}NCO$ | 140–142/760 | 43 |
| $CH_3O{-}(CH_2)_3{-}NCO$ | 146–148/760 | 35.1 |
| $CH_2{=}CH{-}CH_2{-}NCO$ [b] | 85–87/760 | 59 |
| $C_6H_{11}{-}NCO$ | 150–155/760 | 88 |
| $C_6H_5{-}NCO$ | 160–162/760 | 58.2 |
| $2\text{-}ClC_6H_4{-}NCO$ | 105/25 | 55.2 |

[a] Prepared from *p*-toluenesulfonylureas.
[b] In 1-chloronaphthalene as solvent.

Since isolation of the sulfonylureas is not essential, the amines can also be converted directly into isocyanates by reaction with arenesulfonyl isocyanates.

*Experimental*:

98.5 g (0.5 mole) of *p*-toluenesulfonyl isocyanate is dropped into a solution of 36.5 g (0.5 mole) of t-butylamine in 500 ml of *o*-dichlorobenzene. When the mixture is heated at 160–180 °C, 38 g (77 %) of t-butyl isocyanate (b.p. 84–85 °C) distils off.

The method described above is particularly suitable for preparation of isocyanates that can react further with hydrogen chloride. For example, ethoxyethyl isocyanate cannot be prepared by treatment of the amine with phosgene directly [2], but is accessible in 43 % yield by our method.

## The Stereochemistry of Pentaaryl Derivatives of Phosphorus, Arsenic, and Antimony

By Dr. D. Hellwinkel

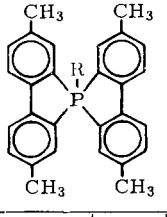
Institut für organische Chemie der Universität
Heidelberg (Germany)

Penta-*p*-tolyl-phosphorane, -arsenic, and -antimony (which can be synthesized by the tosylimine method [1]) at room temperature give only one methyl-proton signal in the $^1$H-NMR spectrum ($CS_2$ solutions), namely at $\delta$ = 2.15, 2.27, and 2.24 ppm, respectively. The singlet for the methyl group in the spectrum of penta-*p*-tolylphosphorane remains unchanged even when the solution is cooled to −60 °C [2]. The equivalence of the five tolyl groups thus demonstrated is compatible neither with the trigonal-bipyramidal structure *(1)* (which has been proved for crystalline pentaphenylphosphorane [3]) nor with the tetragonal-pyramidal structure *(2)* (which is present in solid pentaphenylantimony [4]), since two ligand positions can be differentiated in structures of each of these two types.

The experimental results are, however, intelligible if one assumes that the pentacoordinated molecule in solution undergoes rapid transformation between the structures *(1)* and *(2)*, so that the differentiable ligand positions become averaged [5].

*(1)* *(2)* *(1)*

Further information can be obtained from the series of spirocyclic phosphoranes of type *(3)* [3], whose $^1$H-NMR spectra, measured for $CS_2$ solutions at room temperature, show characteristic differences for the methyl-proton resonances according to the size of the group R.



*(3)*

| R: | Phenyl | 2-Naphthyl | 2-Biphenylyl | 1-Naphthyl | 9-Anthryl |
|---|---|---|---|---|---|
| Nature of signal | Sharp | Sharp | Diffuse [a] | Sharp | Sharp |
| No. of signals | 1 | 1 | — | 2 | 2 |
| $\delta$ [ppm] | 2.14 | 2.09 | 1.85–2.35 | 1.97/2.08 | 1.87/2.10 |

[a] Split into four singlets at −60 °C.

Thus here also rapid intramolecular exchange of positions occurs which is slowed down with increasing bulkiness of the group R until finally, with the 1-naphthyl and the 9-anthryl derivative, the trigonal-bipyramidal structures achieve such a long life that two discrete methyl signals appear in the $^1$H-NMR spectrum, one for the axial and another for the equatorial position of the methyl group. In spirophosphoranes the tetragonal-pyramidal form probably has the character of a transition state [6].

## Conversion of Isocyanates into Isothiocyanates by Reaction with *O,O'*-Diethyl Hydrogen Dithiophosphate

By Dr. G. Ottmann and H. Hooks jr.

Olin Mathieson Chemical Corp., Chemicals Division,
New Haven, Conn. (USA)

We have found that the exothermic reaction of *O,O'*-diethyl hydrogen dithiophosphate *(1)* with aliphatic or aromatic mono- or di-isocyanates leads exclusively to the *N*-alkyl or *N*-aryl derivatives [1] *(2)* of *S*-carbamoyl *O,O'*-diethyl dithiophosphate only if the temperature is kept below 40 °C. At higher temperatures the compounds *(2)* decompose to isothiocyanates and a mixture of sulfur-containing polyphosphoric acids, *O,O',O''*-triethyl thiophosphate, triethyl phosphate, and numerous unidentified products in small quantities. The structures of the products *(2)* were proved by elemental analysis and IR spectroscopy.

*Leber* [2], who studied the thermal decomposition of compound *(2)*, R = $C_6H_5$, found some diphenylurea but apparently did not recognize the isothiocyanates. Under our conditions we did not find dissociation of compounds *(2)* back to *(1)* and isocyanates, though *Leber* observed this in $CH_2Cl_2$ solution. Alkyl derivatives of *(2)* are less stable thermally than the aromatic analogues; thus, compound *(2)*, R = butyl, decomposes at 50 °C, whereas *(2)*, R = phenyl, decomposes appreciably only at 70 °C. Compounds of series *(2)* are stable at room temperature.

We have exploited the decomposition of compounds *(2)* for the conversion of isocyanates into the corresponding isothiocyanates on a preparative scale and in most cases have obtained yields between 50 and 75 %.

$$RNCO + HSPS(OC_2H_5)_2 \rightarrow \underset{(1)}{RNHCO-SPS(OC_2H_5)_2} \xrightarrow{\Delta} \underset{(2)}{RNCS}$$

*Example of Synthesis*:

112.8 g (0.604 mole) of *O,O'*-diethyl hydrogen dithiophosphate is added dropwise to 60 g (0.604 mole) of n-butyl isocyanate with stirring, the temperature being kept at 20 to 25 °C by use of a cooling bath. At the end of the reaction the *S*-butylcarbamoyl *O,O'*-diethyl dithiophosphate (a straw-colored oil) is heated for 2 hours at 125–130 °C. Then, after cooling, the solution is set aside for several hours, and the upper layer is decanted, extracted with ice-water, dried with anhydrous sodium sulfate, and distilled through a 90 cm spinning-band column. Yield: 51 g of n-butyl isothiocyanate.

## Preparation and X-Ray Investigation of Higher Uranium Nitrides

By Priv.-Doz. H. J. Berthold and C. Delliehausen

Institut für Anorganische Chemie und Kernchemie der Universität Mainz (Germany)

Nitrides of uranium have been repeatedly studied in recent years because of the importance of the mononitride as reactor fuel, yet there is no generally accepted opinion about the composition of the various nitrides that can be obtained from metallic uranium (produced from $UH_3$) and nitrogen at 1 atm pressure.

Between 470 and 1000 °C we have obtained the following nitrides $UN_x$:

| Temp. (°C) | 470 | 510 | 580 | 700 | 770 | 830 | 930 | 1000 |
|---|---|---|---|---|---|---|---|---|
| $x$ | 1.74 | 1.76 | 1.68 | 1.67 | 1.64 | 1.63 | 1.58 | 1.55 |

The proportions of nitrogen given are accurate within 1 %. The time for nitrogen uptake was 62 hr at 470 °C, 42 hr at 510 °C, and less than 30 min at 1000 °C. To prevent further nitridation during cooling, the nitrides were either quenched at the end of the reaction time or were cooled slowly under helium.

Decomposition of the $UN_{1.74}$ in a stream of hydrogen (100 ml/min) at 800 °C gave $UN_{1.62}$ after 2 hr, $UN_{1.60}$ after 4 hr, $UN_{1.58}$ after 6 hr, and $UN_{1.45}$ after 20 hr. The nitrogen content fell rapidly as far as $UN_{1.62}$ (the composition of this material corresponds approximately to an equilibrium at 1 atm $N_2$ pressure). Further decomposition as far as $UN_{1.45}$ occurs more slowly and at an almost constant rate. $UN_{1.74}$ is decomposed to pure uranium mononitride within 1.5 hr in an $H_2$ stream at 1200 °C. We found the lattice constant of UN (NaCl type) to be $a = 4.890 \pm 0.002$ Å, in agreement with data in the literature.

The lattice constants of the nitrides $UN_x$ obtained by direct nitridation or by decompositon in an $H_2$ stream decreased linearly with increasing nitrogen content from $10.700 \pm 0.003$ Å for $UN_{1.50}$ to $10.628 \pm 0.008$ Å for $UN_{1.76}$[1]; the wider limit of error is due to increase, at high glancing angle, in the width of the lines and in the background with increasing nitrogen content.

| $x$ | 1.45 [2] | 1.55 | 1.58 | 1.60 | 1.62 | 1.64 | 1.67 | 1.71 [3] | 1.76 |
|---|---|---|---|---|---|---|---|---|---|
| $a$ (Å) | 10.700 | 10.692 | 10.680 | 10.675 | 10.665 | 10.662 | 10.650 | 10.645 | 10.628 |

*Rundle et al.*[4] give lattice constants of $10.700 \pm 0.005$ Å for $UN_{1.50}$ and $10.601 \pm 0.005$ Å (recalculated from kX units) for $UN_{1.75}$.

All the nitrides prepared by us with $x \geq 1.50$ had the body-centered cubic $Mn_2O_3$ structure. The continuous decrease in intensity of the weak diffraction lines characteristic of this structure type that occurred on transition from $UN_{1.50}$ to $UN_{1.76}$ indicates a one-phase transition from the $Mn_2O_3$ structure to the face-centered cubic $CaF_2$ structure of $UN_2$, as was assumed also by *Rundle et al.*[4]. We assume that in this process the nitrogen is taken into the $UN_{1.50}$ lattice statistically. At $UN_{1.76}$ the number of weak lines has been reduced to five[5].

We found no indication in the diffraction patterns for the existence of discrete, stable phases such as have been demonstrated for the $PrO_{1.50}$–$PrO_{2.0}$ system[6].

Received: June 6th, 1966 [Z 261 IE]
German version: Angew. Chem. *78*, 750 (1966)

[1] The values were obtained by extrapolation against $\cos^2\Theta$ (camera diameter 57.3 mm, asymmetrical film position).

[2] The diffraction diagram for this nitride showed some weak lines due to UN as well as the lines due to $UN_{1.50}$.

[3] We obtained this nitride by treatment in an $H_2$ stream for 5 hr at 500 °C.

## An Organometallic Compound with Two-coordinated Fluorine Atoms

By Priv.-Doz. H. Schmidbaur and H. F. Klein

Institut für Anorganische Chemie der Universität Würzburg (Germany)

An X-ray structure analysis[1] recently carried out on the compound $K[(C_2H_5)_3Al$–$F$–$Al(C_2H_5)_3]$ confirmed the suggestion by *Ziegler et al.*[2] that a two-coordinated fluorine atom occurs in the anions of this complex organoaluminum fluoride. Surprisingly, however, it was found that the Al–F–Al bridge is linear. This may be taken as evidence for sp-

hybridized fluorine atoms in strong (p → d)π-interaction with the aluminum atoms. We have now synthesized an electroneutral compound containing the isoelectronic system Si–F–Al and find similarly remarkable bonding relations.

Fluorotrimethylsilane reacts at about 0 °C quickly and completely with an equivalent amount of triethylaluminum, forming a colorless mobile liquid of m.p. −81 to −79 °C. Fluorotrimethylsilane can no longer be removed from this substance at −25 °C in a vacuum. Clearly, under these conditions, the two components undergo complex formation:

$$2\,(CH_3)_3SiF + [Al(C_2H_5)_3]_2 \rightarrow 2\,(CH_3)_3Si{-}F{-}Al(C_2H_5)_3 \qquad (1)$$

The resulting triethylaluminum-fluorotrimethylsilane *(1)* is stable even at room temperature. Its structure follows from the $^1$H-NMR spectrum, which contains a doublet for the Si-bound methyl groups with $\delta = -10.5$ Hz as well as the triplet ($\delta = -46.5$ Hz)[3] and the quartet ($\delta = +20.3$ Hz) with $J(H{-}C{-}C{-}H) = 7.2$ Hz for the ethyl groups. The relative areas of the signal groups are 9:9:6. The doublet signal is accompanied by $^1H{-}C{-}^{29}Si$ satellites, with $J(^1H{-}C{-}^{29}Si) = 7.05$ Hz. It is, however, noteworthy that the coupling constant $J(^1H{-}C{-}Si{-}^{19}F)$ of 9.4 Hz is almost 30 % greater than that of free fluorotrimethylsilane (J = 7.35 Hz)[4]. This indicates an increased s-character of the fluorine orbitals concerned in the Si–F linkage, as is to be expected on hybridization of the fluorine atom in the direction of increasing sp-character. Since the coupling constants $J(^1H{-}^{13}C)$ and $J(^1H{-}C{-}^{29}Si)$ are only very slightly changed on complex formation[4], the increase in $J(^1H{-}C{-}Si{-}^{19}F)$ is to be attributed mainly to changes in the Si–F linkage.

Compound *(1)* should therefore show angle widening at the fluorine atom, corresponding at least to that of the oxygen atom of the isosteric hexaalkyldisiloxanes $R_3Si{-}O{-}SiR_3$ (140 °) or even that in the anions $[R_3Al{-}F{-}AlR_3]^-$ (180 °).

Compound *(1)* decomposes above 30 to 35 °C into ethyltrimethylsilane and fluorodiethylaluminum[5]. These two products can be isolated almost quantitatively (98.8 and 93.5 %, respectively) by distillation. Trimethylaluminum-ether adduct does not react with fluorotrimethylsilane.

## Triorganosilyl Hypochlorites

By Dr. J. Dahlmann, Prof. A. Rieche, and L. Austenat

Institut für Organische Chemie der Deutschen Akademie der Wissenschaften zu Berlin, Berlin-Adlershof (Germany)

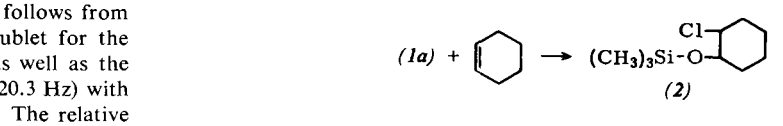
According to *Berry*[1], bistriorganosilyl peroxides are formed by the action of chlorine on sodium triorganosilanolates. Repetition of this work showed that the hitherto unknown triorgaonsilyl hypochlorites, and not silyl peroxides, are formed. On treatment of sodium trimethylsilanolate at −5 to 0 °C, or sodium triphenylsilanolate at −20 °C, with the calculated amount of chlorine in dry $CCl_4$, trimethyl- *(1a)* or triphenylsilyl hypochlorite *(1b)*, respectively, was produced in more than 80 % yield:

$$R_3Si{-}O{-}Na + Cl_2 \rightarrow R_3Si{-}O{-}Cl + NaCl$$

*(1a)*, R = $CH_3$
*(1b)*, R = $C_6H_5$

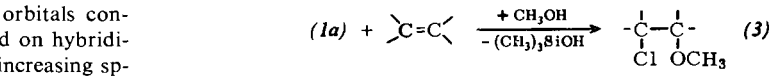
A $CCl_4$ solution of product *(1a)* showed a sharp UV absorption band at 260 mμ characteristic of the hypochlorite group, but this band from *(1b)* was overlaid by the broad, fine-structure bands of the phenyl groups.

Compounds *(1a)* and *(1b)* have not yet been isolated in the pure state, since they decompose even in solution in the dark at 0 °C, with chlorination of the organic substituents on the silicon, and they have strong chlorinating action in general. They undergo electrophilic addition to olefins: *(1a)* and cyclohexene (molar ratio 1:1) in boiling $CCl_4$ containing catalytic amounts of *p*-toluenesulfonic acid give 1-chloro-2-(trimethylsiloxy)cyclohexane *(2)* (yield *ca.* 15 %), which can also be obtained from cyclohexene oxide and chloro(trimethyl)silane[2]. Appreciably better yields of product *(2)*



*(2)*

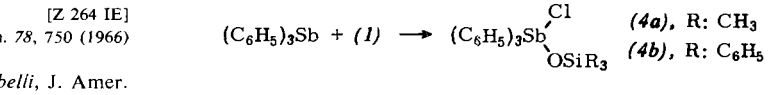
were obtained when *ca.* 1 mole of trimethylsilanol were added. In the presence of methanol, compound *(1a)* reacts with olefins analogously to t-butyl hypochlorite[3], yielding methyl β-chloro-ethers *(3)*: with 1-heptene it gives 1-



*(3)*

chloro-2-methoxyheptane, and with cyclohexene 1-chloro-2-methoxycyclohexane.

Compounds *(1a)* and *(1b)* liberate an equivalent amount of iodine from iodide solutions. Electrophilic addition to triorgano derivatives of elements of Group 5, which is fast even at 0 °C and gives good yields, is particularly suited for detection of hypochlorites. Thus the stibinoheterosiloxanes *(4a)* (m.p. 89–90 °C, from pentane; yield 70 %) and *(4b)* (m.p. > 200 °C (decomp.), from benzene/pentane; yield 84 %) were obtained from *(1a)* and *(1b)*, respectively, and $Sb(C_6H_5)_3$. The arsenic compounds analogous to *(4)* were obtained on use of triphenylarsine.



*(4a)*, R: $CH_3$
*(4b)*, R: $C_6H_5$

## Trifluoromethanesulfonylpentacarbonylmanganese

By Dr. E. Lindner and H. Weber

Institut für Anorganische Chemie der Universität Erlangen-Nürnberg (Germany)

Trifluoromethanesulfonyl chloride *(1)*[1] and the strong Lewis base $[Mn(CO)_5]^\ominus$ *(2)* (molar ratio 1:1) in tetrahydrofuran at −60 °C react according to eq. (a), giving a deep

$$\underset{(1)}{CF_3SO_2Cl} + \underset{(2)}{[Mn(CO)_5]^\ominus} \rightarrow \underset{(3)}{CF_3SO_2Mn(CO)_5} + Cl^\ominus \qquad (a)$$

orange-yellow substance that is stable in air, soluble in most organic solvents, and diamagnetic and melts between 50 and 53 °C. On the basis of elemental analysis and its IR spectrum it is considered to be trifluoromethanesulfonyl-

pentacarbonylmanganese *(3)*. $ClMn(CO)_5$ is always obtained as by-product and can be separated from *(3)* by virtue of its insolubility in diethyl ether.

If, in place of the chloride *(1)*, $FSO_2Cl$, whose fluorine atom is still more electronegative than the $CF_3$ group, is used, then fission to $SO_2$, $F^{\ominus}$, and $Cl^{\oplus}$ occurs in presence of the carbonyl *(2)*; $Cl^{\oplus}$ and *(2)* give $ClMn(CO)_5$ quantitatively.

The IR spectrum of compound *(3)* (in $CH_2Cl_2$), in accord with the pseudo-$C_{4v}$ symmetry, includes four CO absorption bands at very short wavelength: 2158(vs) ($A_1$), 2100(s) ($B_1$), 2045 and 2041(vs) (E), and 2028(m-s) $cm^{-1}$ ($A_1$). The lowering of symmetry causes the IR-forbidden $B_1$ vibration to become active. Because of the electron-attracting $CF_3$ group, the S-O stretching vibrations of compound *(3)* are shifted towards short wavelengths compared to those of $CH_3SO_2Mn(CO)_5$ [2], but quite considerably to longer wavelengths in comparison with the chloride *(1)*, since the Mn atom provides sufficient d-electrons for metal-sulfur back-donation: $\nu_{as}$ = 1217.5(m-s), $\nu_s$ = 1098(m) $cm^{-1}$. This corresponds to a noteworthy weakening of the $(p_\pi-d_\pi)O-S$ bond and simultaneously a strengthening of the bonds to the terminal CO groups. The C–F frequencies appear at 1204(m) and 1154(m) $cm^{-1}$. The weak absorption of the solid in KBr at 807 $cm^{-1}$ can be assigned to the symmetrical stretching vibration of the C–S bond. In the UV spectrum compound *(3)* shows an intense absorption maximum at 280 mμ.

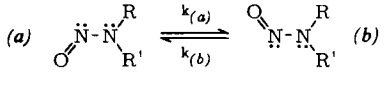
## Separation of Conformational Isomers of a Nitrosamine

By Dr. A. Mannschreck, H. Münsch, and Anne Mattheus

Institut für Organische Chemie der Universität Heidelberg (Germany)

The planar conformations *(a)* and *(b)* of nitrosamines are favored by mesomerism. If R and R′ are different, conformational isomers may arise, but their existence has been indicated merely in equilibrium [1]. Reorientation of the nitroso group in *(1)* requires a free energy of activation of about 23 kcal/mole [2]. This corresponds to the limiting value of $\Delta G^{\ddagger}$, above which *(a)* and *(b)* should be stable in solution at room temperature [3].



*(1)*, R: R′: $CH_3$
*(2)*, R: = $CH_2-C_6H_5$, R′: 2,6-$(CH_3)_2C_6H_3$
*(3)*, R: $CH_2-C_6H_5$, R′: $CH(CH_3)_2$

We have succeeded in separating the isomers of compound *(2)* by two-fold preparative thin-layer chromatography at 6 °C on silica gel (Merck $HF_{254}$) with benzene as the solvent. The mixture of *(2a)* and *(2b)*, m.p. 57–80 °C, was prepared by nitrosation of *N*-benzyl-2,6-dimethylaniline.

The isomers were identified by their $^1$H-NMR spectra in $CCl_4$:

| | τ($CH_2$) | τ($CH_3$) | $R_F$ | M.p. (°C) |
|---|---|---|---|---|
| *(2a)* | 4.59 | 8.36 | 0.4 | 62–63.5 |
| *(2b)* | 5.09 | 8.11 | 0.6 | 86.5–88 |

The nitrosamine structures are also in accord with the infrared spectra, which are similar for both isomers. Elemental analyses and molecular weights correspond to formula *(2)*. The compounds are stable in the solid state. In $CCl_4$ at 36.5 °C an equilibrium mixture [37.5 % of *(2a)*] is formed, starting either from *(2a)* or from *(2b)*, with a half-life of 86 min. Thence can be calculated the rate constants $k_{(2a)} = 8.6 \times 10^{-5}$ and $k_{(2b)} = 5.2 \times 10^{-5}$ $sec.^{-1}$, and $\Delta G^{\ddagger}_{(2a)} = 23.9 \pm 0.2$ and $\Delta G^{\ddagger}_{(2b)} = 24.2 \pm 0.2$ kcal/mole.

Compound *(3a)* can be enriched by crystallization to 75 % purity, and *(3b)* to about 94 % purity [4]. Complete separation was not yet achieved; nor was it achieved for several similar nitrosamines, because they equilibrate somewhat more easily than *(2)*, *e.g.* $\Delta G^{\ddagger}_{(3a)} = 22.3$ and $\Delta G^{\ddagger}_{(3b)} = 23.2$ kcal/mole. Comparison of these values with those for *(2)* shows that the 2,6-dimethylphenyl group contributes little to the conformational stability of compounds *(2a)* and *(2b)*.

Enrichment of rotational isomers that are stabilized by partial double bonds has hitherto been possible only for a thioformamide [5], for mesitylenecarboxamides [6], and for 2,6-dimethylphenylformamides [7]; some rotational isomers of mesitylenethiocarboxamides [4] have been completely separated. It is uncertain whether interconversion of nitrosamines occurs by internal rotation, as inversion on the nitroso-nitrogen atom is possible also.

## A New Principle of Biosynthesis involving Secoanthraquinones [1]

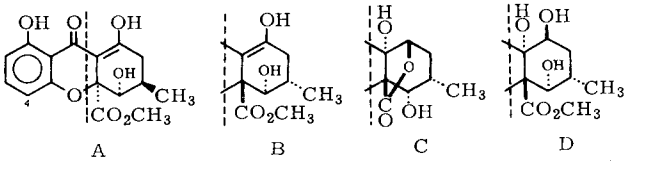
By Prof. B. Franck and F. Hüper

Organisch-Chemisches Institut, Universität Kiel (Germany)

and Doz. D. Gröger and Dr. D. Erge

Deutsche Akademie der Wissenschaften, Institut für Biochemie der Pflanzen, Halle/Saale (Germany)

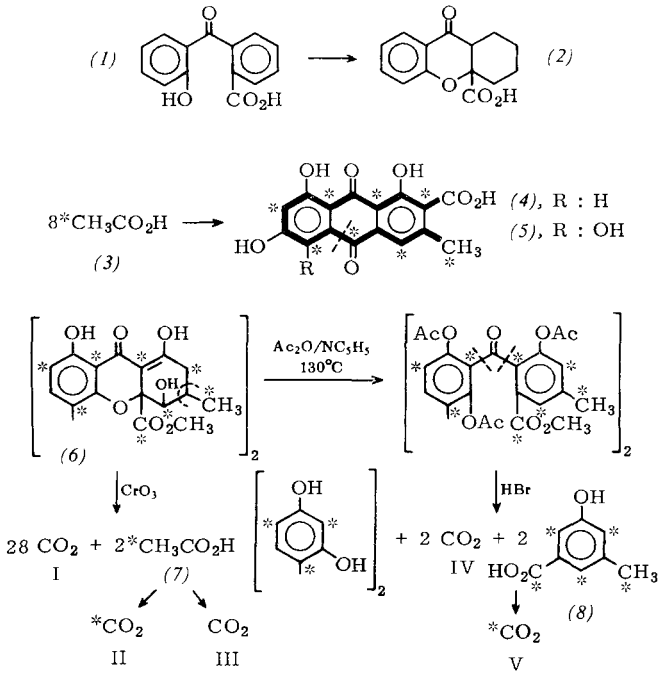
A new principle of biosynthesis can be recognized in the ten ergot dyes (ergochromes) whose structures have recently been elucidated [1–4]. These constitute an unusually complete group of natural products; they comprise all ten dimer combinations of the four monomeric xanthones A to D, the monomers being linked at positions 4,4′ or 2,2′.



The occurrence of the ergochromes in ergot [2, 3] concurrently with the hydroxyanthraquinones *(4)* and *(5)* [5,6], as well as model experiments [7], made it seem possible that the ergochromes are formed from anthraquinones by way of seco-

anthraquinones, in the steps: (a) oxidative fission of the anthraquinone to benzophenonecarboxylic acids of type *(1)*, similar to the Baeyer-Villiger oxidation; and (b) ring closure to xanthone derivatives *(2)* [7].

In agreement with this hypothesis we have found that ergochrome AB *(6)*, as well as the anthraquinones [8], are formed from acetic acid units, the C atoms of the acetic acid being arranged in the ergochrome in accord with the biosynthetic route *(3)* → *(4)* → *(6)*. For the study of this biosynthetic route it is noteworthy that the ergot fungus *Claviceps purpurea* forms the same anthraquinones and ergochromes in liquid cultures [9] as on rye plants – this is generally not the case for ergot alkaloids.



A total of 29 mg of $^{14}CH_3CO_2Na$ (spec. activity 1.41 mCi/mmole) was fed to ten 17-day-old 200 ml liquid cultures of the fungus. The mycelium harvested after a further 17 days yielded 200 mg of ergochrome AB *(6)* [3] after dilution with inactive ergochrome AB; it had a specific activity of $2.495 \times 10^{-3}$ mCi/mmole. By the degradations shown in the formula scheme the activities of the C atoms in the Kuhn-Roth acetic acid *(7)* and in the carbonyl and carboxyl groups of ergochrome AB, which are of particular interest for this investigation, were determined singly, those of others in groups. The number of labeled atoms thus found agreed with that required by our biosynthetic scheme within experimental error (see Table). The distribution of activity in the ergochrome AB obtained after feeding of $CH_3{}^{14}CO_2Na$ also agreed with our biosynthetic scheme.

Measured activities of the degradation products of ergochrome AB *(6)*.

## *N*-Trimethylsilyl-substituted Sulfurous Diamides and Monoimides; *N*-Alkyl-*N'*-phenyl(sulfur diimides)

By Dr. O. J. Scherer and P. Hornig

Institut für Anorganische Chemie, Universität Würzburg (Germany)

Lithium *N*-alkyltrimethylsilylamides [1] add to *N*-sulfinylaniline (molar ratio 1:1) in ice-cooled petroleum ether giving the *N*-lithium derivatives *(1)* of *N'*-(trimethylsilyl)-sulfurous diamides (*ca.* 70 % yield). These products are sensitive to air and insoluble in petroleum ether, but excellently soluble in diethyl ether.

$$(CH_3)_3Si\text{-}\overset{R}{N}\text{-}Li + C_6H_5\text{-}N{=}S{=}O \longrightarrow C_6H_5\text{-}\overset{Li\,O\,Si(CH_3)_3}{N\text{-}S\text{-}N}\text{-}R$$

R : $CH_3$, $C_2H_5$, *(1)*

The compounds *(1)* react *inter alia* with $(CH_3)_3SnCl$ and $AlCl_3$. With $(CH_3)_3SiCl$ (molar ratio 1:1) in petroleum ether at 20 °C they afford in *ca.* 60 % yields the sulfurous diamides

$$(1) + (CH_3)_3SiCl \xrightarrow{-LiCl} C_6H_5\text{-}\overset{(CH_3)_3Si\,O\,Si(CH_3)_3}{N\text{-}S\text{-}N}\text{-}R$$

*(2)*

*(2)* [*(2a)*: R = $CH_3$, m.p. 27–29 °C; *(2b)*: R = $C_2H_5$, m.p. 25–27 °C], whose $^1H$–NMR signals have the calculated relative areas [*(2a)*: calc. 9:9:5:3, found 9:9:5.2:2.8; *(2b)*: calc. 9:9:5:5, found 9:9:5.1:4.9].

Attempts to distil compounds *(2)* led to loss of hexamethyldisiloxane above 100 °C. The sulfur diimides *(3)* formed could be isolated nearly pure and were identified by $^1H$–NMR spectroscopy. The lithium derivatives *(1)* and $AlCl_3$ (molar ratio 3:1) in petroleum ether give *ca.* 50 % yields of *N*-alkyl-*N'*-phenyl(sulfur diimides) *(3)* [*(3a)*: R = $CH_3$, b.p. 52 to 54 °/0.1 mm; *(3b)*: R = $C_2H_5$, b.p. 65–67 °/0.1 mm] as orange liquids which give the expected $^1H$–NMR signals

$$(1) + {}^1/_3\,AlCl_3 \xrightarrow{-LiCl} C_6H_5{-}N{=}S{=}N{-}R + {}^1/_3\,Al[OSi(CH_3)_3]_3$$

*(3)*

with the expected relative areas [*(3a)*: $\tau$ = 6.44 ($CH_3$), $\tau$ = 2.03 (m) ($C_6H_5$), rel. areas 5:3; *(3b)*: $\tau$ = 8.70 (t) and 6.08 (q) ($C_2H_5$), $\tau$ = 2.88 (m) ($C_6H_5$), rel. areas 1:1].

We have synthesized the first *N*-silylated sulfinylamine (sulfurous monoimide), using tris(trimethylsilyl)amine and thionyl chloride (molar ratio 1:1) without a solvent with $AlCl_3$ as catalyst at *ca.* 70 °C, obtaining *N*-(trimethylsilyl)-sulfinylamine *(4)* in *ca.* 50 % yield as a colorless liquid (b.p. 108–110 °C/760 mm; m.p. < –78 °C), which is sensitive to

hydrolysis and gives in its $^1$H–NMR spectrum a sharp signal at $\tau = 9.64$ [$J^{13}$C–H = 120.5 Hz, $J^{29}$Si–C–H = 7.2 Hz; Varian A60 (60 MHz), 5 % solution in $CCl_4$, TMS as internal standard].

$$[(CH_3)_3Si]_3N + SOCl_2 \xrightarrow{70\,^\circ C} (CH_3)_3Si{-}N{=}S{=}O + 2\ (CH_3)_3SiCl$$

*(4)*

In the IR spectrum the two characteristic bands $\tilde{\nu}_{as}$(NSO) = 1297 and $\tilde{\nu}_s$(NSO) = 1122 cm$^{-1}$ are easily assigned [$(CH_3)_3C$–N=S=O (b.p. 98–99 °/760 mm), prepared for the first time from t-butylamine and thionyl chloride, gives wave numbers $\tilde{\nu}_{as}$(NSO = 1250, $\tilde{\nu}_s$(NSO) = 1095 cm$^{-1}$].

The formulae of *(2)*, *(3)*, and *(4)* are confirmed by elemental analyses and molecular-weight determinations.

## Metabolism of Thiodan® in Insects

By Dr. K. Ballschmiter and Priv.-Doz. G. Tölg[1]

Institut für anorganische Chemie und Kernchemie, Universität Mainz (Germany)

So far, the sulfate *(2)*[2] is the sole identified metabolite of the insecticide Thiodan® (1,2,3,4,7,7-hexachlorobicyclo[2.2.1] hept-2-ene-5,6-bismethylene sulfite) *(1a)* + *(1b)*, in houseflies (*Musca domestica*)[3].

We have studied the metabolism of the male imagos of the locust (*Pachytilus migratorius migratorioides*) and have found that after peroral, cutaneous, and subcutaneous application ($LD_{50}$ = 5–10 µg/g[3]) Thiodan *(1a)* + *(1b)* is excreted, partly unchanged, in the feces.

The metabolites *(2)* to *(5)* were identified in the following way[4]. The possible products of assumed hydrolytic, oxidative, and conjugative detoxication reactions of Thiodan were mostly available or were synthesized, and chromatographic data of the metabolites were compared with those of the synthetic compounds. The reference material and the metabolite were considered identical if, after a preliminary separation by thin-layer chromatography, they gave identical retention times on gas chromatography on columns containing various polar liquids (see table).

The configuration of the hydroxyl group in compound *(4)* is uncertain.

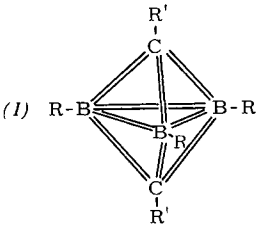
## Preparation of Organocarboranes by Hydroboration of Alkyl-1-alkynylboranes

By Dr. R. Köster, H.-J. Horstschäfer, and Dr. P. Binger

Max-Planck-Institut für Kohlenforschung, Mülheim/Ruhr (Germany)

Hydroboration of non-complexed dialkyl-1-alkynylboranes[1,2] by alkyldiboranes is particularly useful for preparation of carboranes alkylated both on boron and on carbon. For instance, 1 mole of diethyl-1-propynylborane and 2 moles of diethylborane afford pentaethyldicarbaclovopentaborane-(5) *(1a)* (b.p. 84–86 °C/9 mm, m.p. –61.5 °C), whose IR, Raman, and $^1$H- and $^{11}$B-NMR spectra indicate a trigonal-bipyramidal structure in which the two carbon atoms occupy the apices. This product is accompanied by small amounts of higher-boiling organocarboranes with up to five boron atoms in the skeleton.

*(1)*



*(1a)*, R = R' : $C_2H_5$
*(1b)*, R : $C_3H_7$, R' : $C_2H_5$

For the preparation of 1,5-diethyl-2,3,4-tripropyl-1,5-dicarbaclovopentaborane(5) *(1b)*, a solution of "tetrapropyldiborane" (63 g) (containing 1.051 % of hydride H corresponding to 0.662 mole b H[3]) in tripropylborane (275 g) is dropped, with stirring and cooling in ice-water, during 2–3 hr into 42.4 g (0.31 mole) of dipropyl-1-propynylborane (b.p. 50 °C/10 mm, m.p. −63 °C), the mixture becoming slightly warm.

Distillation (up to *ca.* 50 °C/10 mm) removes tripropylborane and "tetrapropyldiborane"; then one obtains 19 g (52 %) of *(1b)* (b.p. 117–118 °C/10 mm; molecular weight 244, determined by mass spectrometry). Alongside *(1b)*, *ca.* 15 % of a second substance is disclosed by gas chromatography; it is probably a *B*-monoisopropyl derivative. Distillation of the residue affords a further 2 g of yellow viscous material (b.p. 70–100 °C/$10^{-3}$ mm), which contains compounds for which mass spectrometry yields molecular weights of 258, 272, and 286, as well as 254, 268, and 282 (up to 5 boron atoms). There remains 5.1 g of highly viscous red residue (18.4 wt.-% of B).

Use of "methyldiboranes" leads with diethyl-1-propynylborane to a series of homologous compounds with molecular weights of 160, 174, 188, and 202.

Compounds with $B_3C$ groups, which disproportionate to $C_2B_3$ carboranes, are indicated as intermediate products by the following equations:

$$R_2B{-}C{\equiv}CR'' \xrightarrow{R_2BH} (R_2B)_2C{=}CHR'' \xrightarrow{R_2BH} (R_2B)_3C{-}CH_2R''$$

$$2\,(R_2B)_3C{-}CH_2R'' \rightarrow 3\,BR_3 + C_2(CH_2R'')_2B_3R_3$$

Triborylated alkanes, $(R_2B)_2CH{-}CH(BR_2)R''$, which may also be formed by hydroboration of $R_2B{-}C{\equiv}CR''$ with alkyldiboranes, can form organocarboranes only after isomerization at higher temperatures:

$$(R_2B)_2CH{-}CH(BR_2)R'' \xrightarrow{>100\,^\circ C} (R_2B)_3C{-}CH_2R''$$

Therefore further carboranes are obtained when the hydroboration mixture is heated. The yields of $C_2B_3$ carboranes are highest when "tetraalkyldiboranes" are used in trialkylborane solution. The hydroboration mixture then consists chiefly of dialkylboron hydrides and thus selective addition of BH is possible[3]. In the present case preferential formation of 1,1,1-triborylated alkanes results.

Organocarboranes can also be obtained by hydroboration of alkyldi-1-alkynylboranes with alkyldiboranes. From isobutyldi-1-propynylborane and "tetraethyldiborane" we obtained two alkylated $C_2B_3$ carboranes with molecular weights 202 *(1a)* and 230 [B-monoisobutyl derivative of *(1)*].

## The Electronic Effect of Phosphorus in *para*-Phosphorus-substituted Anisoles

By Dr. G. P. Schiemenz

Institut für Organische Chemie, Universität Kiel (Germany)

The O–$C_{arom.}$ stretching frequency of alkyl aryl ethers is influenced by the substituents on the aryl ring[1]. The relevant IR bands of *p*-P-substituted anisoles *(1)* to *(4)* should thus provide information about the electronic effect of phosphorus when present as a phosphine, phosphine oxide, phosphine sulfide, or phosphonium group.

$(p\text{-}CH_3O{-}C_6H_4)_nP(C_6H_5)_{3-n}$ *(1)*

$(p\text{-}CH_3O{-}C_6H_4)_nP(X)(C_6H_5)_{3-n}$ *(2)*: X = O; *(3)*: X = S

$(p\text{-}CH_3O{-}C_6H_4)_n\overset{\oplus}{P}(CH_3)(C_6H_5)_{3-n}\ Hal^{\ominus}$ *(4)*

In the alkyl aryl ethers *(1)–(4)*, the values of $\tilde{\nu}$(O–$C_{arom.}$) (see table) exhibit, in general, the same relationships as the half-neutralization potentials of analogously substituted dimethylanilines[2], but there are the following differences. In the anisole series phosphorus as a phosphine group is a "weaker" substituent than as a phosphine oxide group, even when $n = 2$ or 3; the three methoxyphosphines show the same dependence on $n$ as do the phosphine oxides *(2)* and the analogous *p*-(dimethylamino)phenylphosphine chalcogenides[2]. However, in the sulfide series *(3)*, $\tilde{\nu}$(O–$C_{arom.}$) is independent of $n$; in the phosphonium series *(4)* it increases with increasing $n$.

In principle, substituent constants can be obtained from $\tilde{\nu}$(O–$C_{arom.}$), but it is not clear whether $\sigma$ or $\sigma'$ should be used[3]. The values of $\tilde{\nu}$(O–$C_{arom.}$) for the substituted anisoles listed in the top part of the table were plotted against $\sigma$ and $\sigma'$, respectively; in both cases "satisfactory"[3] linear equations [(a) to (d)] were obtained, and thence the Hammett constants given in the table for the phosphorus-containing groups.

The results show that here also phosphorus in all types of compound behaves as an electron acceptor. The $\sigma'$ values generally resemble those for the dimethylaniline series[2]; in three out of four cases $\sigma$ is greater than the Hammett constants derived from the $pK_a'$ values of similarly substituted benzoic acids[4,5].

$\tilde{\nu} = 27.785\,\sigma + 1243.38$ (a) $r = 0.978$, $s = \pm 2.4\ cm^{-1}$

$\sigma = 0.0360\,\tilde{\nu} - 44.750$ (b) $r = 0.978$, $s = \pm 0.09$ σ-unit

$\tilde{\nu} = 19.798\,\sigma' + 1243.09$ (c) $r = 0.973$, $s = \pm 2.5\ cm^{-1}$

$\sigma' = 0.0505\,\tilde{\nu} - 62.789$ (d) $r = 0.973$, $s = \pm 0.12$ σ-unit

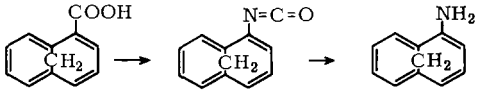
## 1,6-Methano[10]annulen-2-amine and -2-ol

By Prof. E. Vogel, W. Schröck, and Dr. W. A. Böll

Institut für Organische Chemie der Universität
Köln (Germany)

No amino or hydroxy derivative of 1,6-methano-[1] or 1,6-epoxy-[10]annulene[2], 1,2,8,9-tetradehydro[14]annulene[3], or dihydro-*trans*-15,16-dimethylpyrene[4] has yet been described.

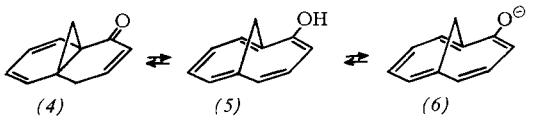
1,6-Methano[10]annulene-2-carboxylic acid[1] *(1)* and thionyl chloride give the acid chloride (b.p. 97–98 °C/0.02 mm Hg; yield 92 %), which in a Curtius reaction with sodium azide in boiling toluene affords the isocyanate *(2)* as a pale yellow liquid (b.p. 69–72 °C/0.01 mm Hg; 90 % yield), whose NMR spectrum (in $CCl_4$) contains a multiplet at $\tau = 2.2$–$3.5$ and an AB system with its center at $\tau = 10.6$ (proton ratio 7:2); the derived methylurethane has m.p. 145–146 °C.



*(1)* *(2)* *(3)*

Treating the isocyanate *(2)* with dilute NaOH (formation of the sodium carbamate) and then with dilute $H_2SO_4$ in amount equivalent to the alkali affords an orange-yellow, air-sensitive, basic substance (yield 85 %), b.p. 97–98 °C/0.07 mm Hg [UV spectrum in cyclohexane: $\lambda_{max} = 254$ ($\varepsilon = 32{,}000$), 270 (21,000)(sh), 342 (5500), and 415 mμ (1100)]. The NMR spectrum of this product in $CCl_4$ contains a multiplet at $\tau = 2.5$–$4.2$ (7 vinyl protons), a broad singlet at $\tau = 6.2$ (2 amino protons), and an AB system at $\tau = 10.0$ and 10.85 with $J_{AB} = 9.5$ Hz ($CH_2$ protons) and thus shows the presence of 1,6-methano[10]annulen-2-amine *(3)*, free from imino tautomers. The amine was characterized as hydrochloride and acetyl derivative (m.p. 204 °C), but attempts to diazotize it had no clear result.

When the aqueous solution of the hydrochloride of *(3)* is heated in the presence of toluene a keto-enol mixture is obtained from which the ketone can be crystallized (m.p. 26 °C). It can be concluded from the NMR spectrum of the ketone (Fig. 1) that the hydrolysis involved not only tautomerization but also cycloheptatriene-norcaradiene valence isomerization, because the AX system at $\tau = 7.9$ and $\tau = 9.8$ with $J_{AX} = 4.5$ Hz can be assigned unambiguously to $CH_2$ protons in a cyclopropane ring[5]. When it is further considered that the UV spectrum (in cyclohexane) with $\lambda_{max} = 215$ ($\varepsilon = 11{,}600$), 274 (2600), and 320 mμ (180) is to be interpreted as superposition of the absorption bands of a norcaradiene system[6] and an α,β-unsaturated carbonyl group (CO band at 1660 $cm^{-1}$), then the ketone must be tricyclo[4.4.1.$0^{1,6}$]undeca-3,7,9-trien-2-one *(4)*.



*(4)* *(5)* *(6)*

In the presence of catalytic amounts of acid or base the ketone *(4)* is equilibrated with the enol, which is proved to be 1,6-methano[10]annulen-2-ol by its NMR spectrum (Fig. 1). The ketone *(4)* is favored ($\approx$ 80 %) in the equilibrium mixture in benzene, but the enol *(5)* preponderates (97 %) in dimethyl sulfoxide. Catalytic amounts of HCl in methanol cause rapid etherification to 2-methoxy-1,6-methano[10]-annulene.

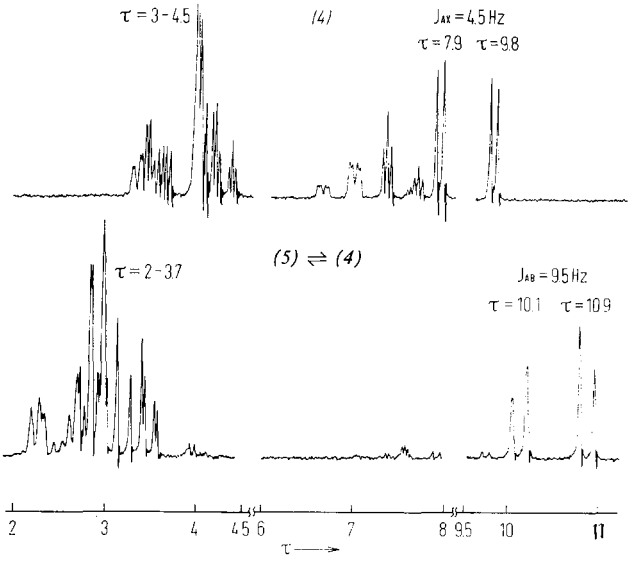


Fig. 1. NMR spectra [60 MHz; in $(CD_3)_2SO$] of the pure ketone *(4)* and of the enol-ketone mixture (97:3) obtained by equilibration with catalytic quantities of trimethylamine (OH absorption at $\tau$ — 0.1).

The ketone and the enol are converted by alkali into the intensely yellow anion *(6)* (NMR spectrum in $(CD_3)_2SO$: multiplet at $\tau = 2.3$–$4.5$ and AX system at $\tau = 9.35$ and 11.05 with $J_{AX} = 9$ Hz) which is sensitive to oxygen but from which a mixture of the tautomers can be regenerated by acidification[7].

## 11-Methylene-1,6-methano[10]annulene and 1,6-Methano[10]annulen-11-ol

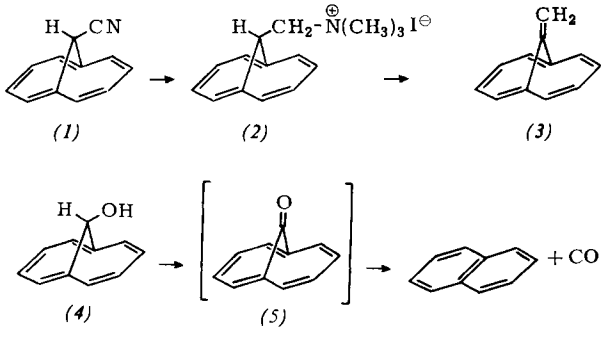
By Prof. E. Vogel, F. Weyres, H. Lepper, and Dr. V. Rautenstrauch

Institut für Organische Chemie der Universität
Köln (Germany)

The possibility that 1,6-bridged [10]annulenes with a trigonal C-11 atom might have a $C_{10}$ perimeter[2] even more nearly planar than 1,6-methano[10]annulene[1] aroused our interest in 11-methylene-1,6-methano[10]annulene *(3)* and 1,6-methano[10]annulen-11-one *(5)*. The geometry of these

compounds prevents normal conjugation of the π-electron systems of the peripheral ten-membered ring and the bridge (orthogonal $p_z$-orbitals on C-11 and C-1 or C-6). It is still an open question whether the two chromophores influence each other in other ways.

The synthesis of compound *(3)* started with 11-cyano-1,6-methano[10]annulene *(1)*[3] [m.p. 100–101 °C; NMR spectrum in $CCl_4$: multiplet at $\tau$ = 2.4–3.0 and singlet at $\tau$ = 9.4 (proton ratio 8:1)]. With $LiAlH_4$ this gave 11-(1,6-methano-[10]annulene)methylamine (b.p. 87–90 °C/0.08 mm Hg; yield 82%; benzoyl derivative, m.p. 163–164 °C), which with $CH_3I$ yielded the methiodide *(2)* [m.p. 224–226 °C; yield 70%; NMR spectrum in $DCCl_3$: multiplet at $\tau$ = 2.3 to 3.1, singlet at $\tau$ = 7.0, doublet at $\tau$ = 7.8 with $J$ = 6 Hz, and broad triplet at $\tau$ = 10.2 with $J$ = 6 Hz (8:9:2:1)].



Although fragmentation to naphthalene, acetylene, and trimethylamine occurs on reaction of the methiodide *(2)* with potassium amide[4], a 4:1 (wt.-proportion) mixture of naphthalene and a pale yellow hydrocarbon $C_{12}H_{10}$ (m.p. 85 to 86 °C) is obtained on pyrolysis of the ammonium base derived from *(2)* at 100–140 °C/0.1–1 mm Hg.

The NMR spectrum of this compound $C_{12}H_{10}$ contains only an $A_2B_2$ system (as two identical $A_2B_2$ systems) at $\tau$ = 2.8 and a sharp singlet at $\tau$ = 6.8 (8:2); thus the compound is 11-methylene-1,6-methano[10]annulene *(3)*. The absorption of the olefinic bridge protons at unusually high field is to be expected for a structure *(3)*, since these protons should be strongly shielded by the 10π-electron system. The compound *(3)* has an UV spectrum that is almost superposable on that of 1,6-methano[10]annulene [$\lambda_{max}$ in cyclohexane = 258 (ε = 67,500), 300 mμ (6700), bands with 7 maxima between 360 and 410 mμ (ε between 130 and 190)], whence it follows that the geometries of the $C_{10}$ perimeters of the two compounds do not differ appreciably and that in compound *(3)* there is no noteworthy interaction between the π-electron systems of the perimeter and the bridge.

It was hoped to obtain the ketone *(5)* by conversion of 11-bromo-1,6-methano[10]annulene[5] into the alcohol *(4)* and subsequent oxidation. We succeeded in converting the bromide by silver acetate in boiling glacial acetic acid into 11-acetoxy-1,6-methano[10]annulene [m.p. 92–93 °C; yield 60%; NMR spectrum in $CCl_4$: multiplet at $\tau$ = 2.5–3.2, singlet at $\tau$ = 7.9, singlet at $\tau$ = 8.5 (8:1:3)] and thence, by $CH_3MgI$, into 1,6-methano[10]annulen-11-ol *(4)* [m.p. 71–72 °C; yield 50%; NMR spectrum in $CCl_4$: multiplet at $\tau$ = 2.5–3.2, singlet at $\tau$ = 8.6, broad singlet at $\tau$ = 9.9 (8:1:1)]. However, naphthalene (yield 80 and 75%, respectively) was always the sole product on oxidation of the alcohol *(4)* with $CrO_3$ or lead tetraacetate in pyridine; on use of aqueous chromic acid or of manganese dioxide in hexane the naphthalene was accompanied by α-naphthaldehyde [which is isomeric with *(5)*].

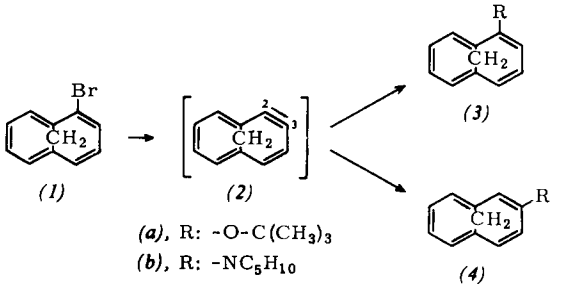
## Concerning the Existence of 2,3-Didehydro-1,6-methano[10]annulene

By Dr. W. A. Böll

Institut für Organische Chemie der Universität Köln (Germany)

Numerous electrophilic reagents convert 1,6-methano[10]-annulene into substitution products where the substituent has entered only at the 2-position[1]. A possible route to 3-substituted derivatives appeared to be reaction of 2-bromo-1,6-methano[10]annulene *(1)* by way of the 2,3-didehydro compound *(2)*, which with nucleophiles should give a mixture of the position isomers *(3)* and *(4)*.



Metalation and base-catalysed deuterium exchange of 1,6-methano[10]annulene showed that the hydrogen on C-2 is appreciably more acidic than that on C-3[2], whence it was to be expected that the negative charge in the transition state resulting from addition of a nucleophile to *(2)* should be better stabilized on C-2 and that thus the 3-isomers should be formed preferentially[3].

When *(1)* was heated for 12 hr at 90 °C with potassium t-butoxide in dioxane containing 1 mole/l of t-butyl alcohol, a 5:95 mixture of 2- and 3-t-butoxy-1,6-methano[10]-annulene, *(3a)* and *(4a)*, was obtained in 40% yield.

The structure of *(4a)* (m.p. 27 °C) follows from the UV spectrum [in cyclohexane, $\lambda_{max}$ = 262 (ε = 70000), 304 (6900), and 383 mμ (330)] and from the NMR spectrum (in $CCl_4$, multiplet at $\tau$ = 2.5–3.5, singlet at $\tau$ = 8.65, and AB system at $\tau$ = 10.43 and 10.57; $J_{AB}$ = 8.8 Hz; intensity ratio 7:9:2). Fine splitting of the AB doublets of the $CH_2$– protons into triplets ($J \approx$ 0.8 Hz), which is a consequence of stereospecific long-range coupling with the protons in positions 2 and 5, and 7 and 10, respectively, confirms the position of the t-butoxy group on C-3. The isomer *(3a)* (b.p. 76 to 78 °C/0.01 mm Hg) was synthesized independently by reaction of the Grignard compound from *(1)* with t-butyl perbenzoate[4] (yield 85%); it is differentiated from its isomer *(4a)* by its longer-wavelength UV absorption [$\lambda_{max}$ = 260 (ε = 49000), 316 (6000) and 403 mμ (470)] and by the larger NMR shift of the $CH_2$ protons forming the AB system ($\tau$ = 10.28 and 10.72; $J_{AB}$ = 9.4 Hz); fine splitting of the A part into triplets and of the B part into doublets ($J \approx$ 0.9 Hz) is as expected for substitution in position 2.

When the reaction of the bromide *(1)* with potassium t-butoxide at 90 °C was carried out in presence of piperidine (1 N in dioxane) in place of t-butyl alcohol, compounds

*(3b)* and *(4b)* were obtained in a total yield of 93 % and a ratio 6:94. Replacement of the $KOC(CH_3)_3$ by the stronger base lithium piperidide altered this ratio to 60:40. This reversal, and the marked dependence of the isomer ratio on temperature, piperidine concentration, and solvent, suggest that reaction by way of the dehydro compound *(2)* is in competition with direct exchange of substituents to give *(3b)*; this is being studied further.

The viscous reddish-yellow mixture (b.p. 114–116 °C/ 0.04 mm Hg) of isomers *(3b)* and *(4b)* was separated by column chromatography. The UV spectrum of *(3b)* [$\lambda_{max}$ = 255 ($\varepsilon$ = 31000), 275 (19500, sh), 353 (8200), and 410 mμ (1400, sh)] is very similar to that of 1,6-methano[10]annulene-2-amine[5], whereas that of *(4b)* is shifted towards shorter wavelengths. This observation and the fine splitting of the AB doublets in the NMR spectrum unambiguously prove the structure shown.

Experiments designed to trap the postulated intermediate 2,3-didehydro-1,6-methano[10]annulene *(2)* in Diels-Alder reactions[6] were successful on use of tetracyclone (tetraphenylcyclopentadienone): we obtained – again by dehydrohalogenation of *(1)* with potassium t-butoxide – a *ca.* 30 % yield of 1,2,3,4-tetraphenyl-7,12-methanobenz[10]annulene *(5)* (m.p. 258 °C).

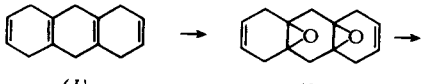
## 1,6:8,13-Diepoxy[14]annulene

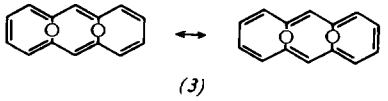
By Prof. E. Vogel, Dr. M. Biskup, A. Vogel, and Dr. H. Günther

Institut für Organische Chemie, Universität Köln (Germany)

We recently reported some experiments on the synthesis of bridged [14]annulenes[1] with an "anthracene perimeter". Whereas *anti*-1,6:8,13-dimethano[14]annulene has hitherto been obtained only as 7,14-dihydro derivative, the analogous 1,6:8,13-diepoxy[14]annulene *(3)* (probably the *syn*-form) can be prepared surprisingly easily.



*(1)* *(2)*



*(3)*

Treatment of 1,4,5,8,9,10-hexahydroanthracene *(1)*[1] with two equivalents of peracetic acid gives almost quantitatively 4a,9a:8a,10a - diepoxy - 1,4,5,8,9,10 - hexahydroanthracene *(2)*[2], the NMR spectrum of which indicates that it is a mixture (*ca.* 60:40) of *syn*- and *anti*-isomers, since the four central $CH_2$ protons give rise to an AB system (*syn*-form) as well as a singlet (*anti*-form). If compound *(2)* (*syn-anti*-isomer mixture) is allowed to react with two equivalents of *N*-bromosuccinimide in $CCl_4$ and the crude bromination product is treated with potassium t-butoxide in tetrahydrofuran, a carmine-red substance (leaflets from methanol) of m.p. 230 °C is formed in 5 % yield; it can be isolated readily by chromatography[*]. Analysis and the mass-spectrographic molecular weight ($M^+$ = 210) lead to the molecular formula $C_{14}H_{10}O_2$.

The NMR spectrum (Fig. 1a)[3] proves the compound to be 1,6:8,13-diepoxy[14]annulene *(3)* (*syn*- or *anti*-form). It shows a singlet at $\tau$ = 2.06 ppm (relative intensity 2) due to the protons H-7 and H-14 and an AA'BB' system ($\tau_A$ = 2.25 and $\tau_B$ = 2.40 ppm[4]; relative intensity 8) arising from the protons H-2 to H-5 and H-9 to H-12.

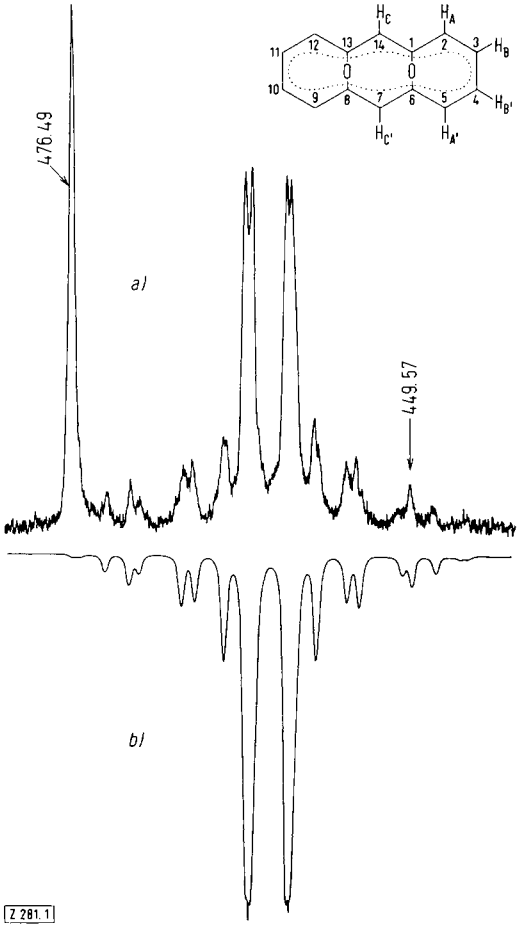


Fig. 1. a) Experimental NMR spectrum for compound *(3)* at 60 MHz (0.19 M in $CDCl_3$); values are in Hz relative to tetramethylsilane as internal standard.
b) Calculated AA'BB' system of protons H-2 to H-5 and H-9 to H-12.

The fact that H-2 to H-5 and H-9 to H-12 have identical NMR parameters (appearance of only one AA'BB' system) excludes an olefinic structure with fixed double bonds. A fluctuating structure is consistent with the symmetry of the spectrum, but does not account for the positions of the proton resonances, whose paramagnetic shift evidently is caused by a ring current due to the π-electrons. If 1,6-epoxy[10]annulene *(4)*[5] is taken as reference substance, calculations for *(3)* by the *Pople* point dipole model[6] give $\tau_C$ = 1.92, $\tau_A$ = 2.27, and $\tau_B$ = 2.65 ppm, in good agreement with experiment. Coupling parameters for *(3)* are identical with those for *(4)*[7], namely:

$$J_{AB} = 9.0;\ J_{BB'} = 9.2;\ J_{AB'} = 0.3;\ J_{AA'} = 1.1 \text{ Hz}.$$

The fact that the vicinal coupling constants $J_{AB}$ and $J_{BB'}$ are almost identical indicates that there is no appreciable alternation in the corresponding C–C bond lengths[8].

The UV spectrum is also compatible with structure *(3)*. It shows $\lambda_{max}$ = 306 ($\varepsilon$ = 169000), 345 (14400), 382 (8500), and 555 mμ (775), the last-mentioned band having fine structure (in cyclohexane).

The aromatic structure of *(3)* that follows from the spectra is manifested by the remarkable thermal stability of the compound and by its insensitivity to oxygen. Preliminary experiments suggest, moreover, that compound *(3)* is amenable to electrophilic substitution.

## Isolation of Protease Inhibitors [1]

By Dr. H. Fritz, H. Schult, M. Neudecker, and Prof. E. Werle

Klinisch-Chemisches Institut, Chirurgische Klinik, Universität München (Germany)

A 1:1 maleic anhydride-ethylene copolymer (mol. wt. range 13500–135000; type DX 840–21 EMA–M) in aqueous buffer solutions (0.2 M phosphate; pH 7.5) reacts with the ε-amino groups of the lysine residues in trypsin (EC 3.4.4.4) [1 g of EMA–M binds *ca.* 5 g of trypsin]; in the presence of hexamethylenediamine as crosslinking agent an insoluble trypsin-maleic acid-ethylene copolymer is formed[2]. The portion (*ca.* 20 %) of the trypsin covalently fixed on the insoluble carrier that retains its enzymatic acivity is subject to trypsin inhibitors such as Kunitz inhibitor from pancreas or soybean inhibitor[2].

We have used the trypsin resin for selective absorption, in the neutral pH region, of trypsin inhibitors from crude organ extracts. After all the accompanying materials have been washed out of the trypsin resin by 0.1 M triethanolamine buffer + 0.1 M NaCl (pH 7.8), the inhibitors are eluted by 0.2 M KCl/HCl buffer.

The previously characterized[1,3] trypsin inhibitors shown in the Table were isolated in pure form and high yield in one step from organ extracts that had been freed from protein with 3 % perchloric acid.

The inhibitor from pig pancreas was separated electrophoretically[*] into three fractions that were active as inhibitors[1,3]; the middle fraction was found to have the composition[3a] 4 Lys, 2 Arg, 4 Asp, 5 Thr, 6 Ser, 6 Glu, 5 Pro, 4 Gly, 1 Ala, 6 Cys½, 4 Val, 3 Ileu, 2 Leu, 2 Tyr. Absence of the amino acids tryptophan, methionine, and histidine is remarkable.

Inhibitors and enzymes isolated by means of a maleic anhydride-ethylene copolymer.

| Copolymer plus | Isolation from | Yield (%) of pure enzyme or inhibitor |
|---|---|---|
| Trypsin (EC 3.4.4.4) | Trypsin inhibitor from: | |
| | Pig pancreas | 90 |
| | Dog pancreas | 82 |
| | Ox pancreas | 95 |
| | Seminal vesicles of mice | 75 |
| Chymotrypsin (EC 3.4.4.5) | Kunitz inhibitor from ox pancreas | 90 |
| Kallikrein (EC 3.4.4.21) | Trypsin-kallikrein inhibitor from ox organs | 70 |
| Tryspin-kallikrein inhibitor Trasylol® | Trypsin | 95 |
| | Chymotrypsin | 90 |

In addition, the water-insoluble enzyme-maleic acid-ethylene copolymers of chymotrypsin (EC 3.4.4.5) and kallikrein (EC 3.4.4.21) were prepared. Use of the chymotrypsin or kallikrein resin led to the isolation, from ox pancreas extracts, of the Kunitz inhibitor, and subsequent use of the trypsin resin afforded the specific trypsin inhibitors remaining in the extract. There was quantitative separation of the two inhibitors, which have similar molecular weights [Kunitz inhibitor: $M$ = 6513; spec. trypsin inhibitor: $M$ = 6000 (from the amino acid composition), 6800 (by *Andrews'* molecular-sieve method[4])].

We have also used the process for purification of enzymes. The kallikrein inhibitor[5] bound to the copolymer adsorbs trypsin, chymotrypsin, or kallikrein specifically from protein-containing solutions. Trypsin and chymotrypsin were eluted in 90 to 95 % yield from the kallikrein inhibitor resin by acid buffer solutions such as 0.2 M KCl–HCl (pH 2).

The enzyme- and inhibitor-maleic acid-ethylene copolymers retain their specific activity on repeated use (tested for up to 60 operations) for isolation of inhibitors or enzymes provided the experiments are carried out at 4 to 8 °C.

## 5'-*O*-Methylthymidine

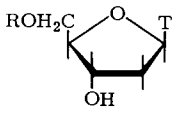
By Dr. G. Kowollik, K. Gaertner, and Dr. P. Langen

Institut für Biochemie der Deutschen Akademie der Wissenschaften zu Berlin, Berlin-Buch (Germany)

Direct nucleophilic replacement of a primary sulfonyloxy group by methoxy has hitherto been observed only for a few pentose[1] and hexose derivatives[2]. We have applied

to a deoxyribonucleoside the methods used in those cases (reaction of the sulfonyl derivative with $CH_3ONa/CH_3OH$ under reflux or in a closed vessel at 100 °C).

Under these conditions 5'-*O*-tosylthymidine *(1)* gives 5'-*O*-methylthymidine *(2)* (60 % yield) and thymidine *(3)* in a molar ratio of 7:3 to 8:2; the products *(2)* and *(3)* can be separated by partition chromatography on Hyflo Super-Cel[3] with ethyl acetate/propan-2-ol/water (12:1:6 v/v) as running solvent and are obtained analytically pure by recrystallization from 96 % ethanol. If 3'-*O*-acetyl-5'-*O*-methanesulfonylthymidine is used in place of *(1)*, the same products *(2)* and *(3)* result in the same amounts.



T: 1-Thymyl
*(1)*, R: p-$CH_3$-$C_6H_4$-$SO_2$-
*(2)*, R: $CH_3$
*(3)*, R: H

*(2)*: m.p. 170.5 °C; UV spectrum ($H_2O$), $\lambda_{max}$ = 265.5 mμ, $\lambda_{min}$ = 234.5 mμ, $\varepsilon_{max}$ = 9500; IR spectrum (KBr), 1090 $cm^{-1}$ ($OCH_3$); $R_F$ = 0.63 in butan-1-ol/water/conc. aq. $NH_3$ (86:14:15 v/v). 3'-*O*-Acetyl derivative: m.p. 154 °C; $R_F$ = 0.75.

In contrast to thymidine *(3)*, the ether *(2)* is not cleaved by uridine deoxyuridine phosphorylase (EC 2.4.2.3) or thymidine phosphorylase (EC 2.4.2.4) and does not inhibit the cleavage of thymidine by this enzyme.

## Isopolyanions of Molybdenum(VI)

By Prof. O. Glemser and W. Höltje

Anorganisch-Chemisches Institut,
Universität Göttingen (Germany)

The chief products of aggregation of $MoO_4^{2-}$ caused by protons in aqueous solution were found by *Glemser et al.*[1] and by *Aveston et al.*[2] to be $MoO_7$ and $MoO_8$ complexes (at $p$ = 1.14 and 1.50, respectively[3]), whereas *Sasaki* and *Sillén*[4,5] arrived at a different reaction scheme in terms of species $Mo_7O_{24}^{6-}$ ($p$ = 1.14), $HMo_7O_{24}^{5-}$ ($p$ = 1.29), $H_2Mo_7O_{24}^{4-}$ ($p$ = 1.43), $H_3Mo_7O_{24}^{3-}$ ($p$ = 1.57), and a larger complex at $p$ = 1.79.

To clarify this discrepancy we have studied the chemical relaxation of acidified molybdate solutions ($10^{-2}$ M + 0.3 M $NaNO_3$) at acidifications[3] $p$ = 0.2, 0.6, 1.14, 1.31, 1.50, and 1.56, using the temperature-jump method[6]; ancillary measurement of pH-indicator equilbria with very short equilibration times (Chlorophenol Red, Methyl Red, Bromocresol Green, Bromochlorophenol Blue, Benzyl Orange) allowed spectrophotometric recording. The temperature jump was from 18 °C to 25 °C; the measuring cell was brought to thermal equilibrium before each experiment.

At $p$ = 0.2, 0.6, 1.14, 1.31, and 1.50 relaxation effects with only one time constant in the msec region were observed (*e.g.* for $[Mo]_t = 1.5\times10^{-2}$ at $p$ = 1.41, $1/\tau = 1.71\times10^3$ $sec^{-1}$, and at $p$ = 1.50, $1/\tau$ = 257 $sec^{-1}$). However, solutions with $p$ = 0 and $p$ = 1.56, and indicator control solutions without molybdate, gave no relaxation in the time interval 0.1 sec to 50 μsec.

The occurrence of a single relaxation time indicates an equilibrium between *two* species having different degrees of aggregation. If no relaxation signal is obtained, then either only a single species is present (limits of detection 3–5 %) or the equilibria are protolytic and therefore too rapidly established to be registered.

Since, at the concentrations used, the equilibria are almost entirely on the side of the polyanions, the scheme of *Sasaki* and *Sillén*, which involves only protonation stages between $p$ = 1.14 and 1.57, cannot be correct[7]. On the other hand, there is agreement with our earlier results[1]: aggregation occurs up to formation of the $Mo_8$ complexes at $p$ = 1.50; at higher $p$ values ($p$ = 1.56) only protolytic reactions occur.

The nature of the primary aggregation step was also studied by means of relaxation measurements (indicator: Chlorophenol Red). At not too high $H^+$ and Mo concentrations the observed extinction curves were characterized by a single time constant. At pH 5.50 the reciprocal of the relaxation times is related to the third power of the monomolybdate concentration (*e.g.* $[Mo_1] = 6.7\times10^{-3}$ M, $1/\tau$ = 12.2 $sec^{-1}$; $17.7\times10^{-3}$ M, 64.8 $sec^{-1}$); when the Mo concentration is kept constant ($1.0\times10^{-2}$ M), $1/\tau$ depends on the fifth power of $[H^+]$ (*e.g.* at pH 5.6, $1/\tau$ = 12.4 $sec^{-1}$; at pH 5.36, $1/\tau$ = 55.6 $sec^{-1}$). Thus the first polyanion to be formed on acidification of a $MoO_4^{2-}$ solution is a tetramolybdate[9], formation of which consumes six $H^+$ ions. Di- and trimolybdates do not exist in aqueous solution. Accordingly the overall equation is

$$4\,MoO_4^{2-} + 6H^+ \rightleftarrows [Mo_4O_{10}(OH)_6]^{2-}.$$

This formula for the new isopolymolybdate species[10] is also in agreement with the fact that all the hepta- and octamolybdates known so far[2] are built up from octahedral $MoO_6$ units. Moreover, in such fast reactions addition seems more probable than condensation[11].

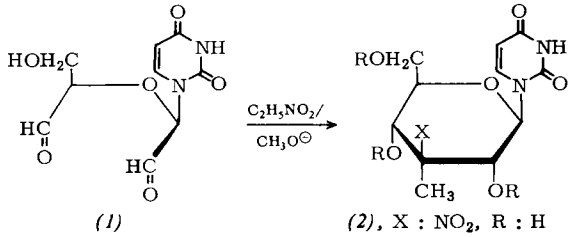
## Synthesis of *C*-Methyl Branched Uracil Nucleosides

By Doz. F. W. Lichtenthaler and H. Zinke

Institut für Organische Chemie, Technische Hochschule Darmstadt (Germany)

Extension of the reaction whereby "nucleoside dialdehydes" are cyclized by nitromethane[1,2] to nitromethane homologues[3] would be expected to produce branched nucleosides of pharmacological interest.

2-*O*-[(*R*)-Formyl-(1-uracilyl)methyl]-(*R*)-glyceraldehyde ("uridine dialdehyde") *(1)*, obtained by oxidation of uridine with periodate, is converted by nitromethane/sodium methoxide in methanol into a crystalline mixture of isomers (yield 79.7 % based on uridine), from which 1-(3′-deoxy-3′-*C*-methyl-3′-nitro-β-D-glucopyranosyl)uracil *(2)*, m.p. 226 to 240 °C (decomp.), $[\alpha]_D^{20} = +25.5°$ ($H_2O$), can be separated as main product by fractional crystallization. Acetylation of this product in acidic solution gives the tri-*O*-acetate *(3)*, m.p. 228 °C, $[\alpha]_D^{20} = -8°$ ($CHCl_3$); hydrogenation in presence of Raney nickel gives 1-(3′-amino-3′-deoxy-3′-*C*-methyl-β-D-glucopyranosyl)uracil *(4)* as monohydrate, m.p. 146–148 °C, $[\alpha]_D^{20} = +39°$ ($H_2O$). With acetic anhydride/methanol the amine affords the acetamido compound *(5)*, m.p. 248–250 °C (decomp.), $[\alpha]_D^{20} = +72°$ ($H_2O$), which is converted by further acetylation into the tetraacetate *(6)*, m.p. 133 °C, $[\alpha]_D^{20} = +21°$ ($CHCl_3$).



*(1)*

*(2)*, X : $NO_2$, R : H
*(3)*, X : $NO_2$, R : Ac
*(4)*, X : $NH_2$, R : Ac
*(5)*, X : NHAc, R : H
*(6)*, X : NHAc, R : Ac

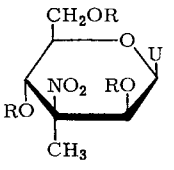
The 3′-*C*-methyl-D-*gluco*-configuration of the nitro compound *(2)* and the derived products *(3)* to *(6)* follow from NMR spectroscopic data:

1. In $(CD_3)_2SO$ the nitro-compound *(2)* gives a 1 H doublet at $\tau = 4.02$ with $J = 6$ Hz, which proves the diaxial arrangement of the 1′- and 2′-protons and thus the equatorial orientation of the 2′-hydroxyl group[5].

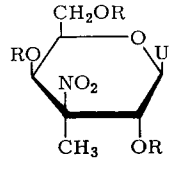
2. The NMR spectrum of the nitro acetate *(3)* in $CDCl_3$ contains around $\tau = 8$ two signals with the intensity ratio 2:1 that indicate equatorial acetoxy groups at positions 2′ and 4′ ($\tau = 7.93$; 6 H) as well as the primary 6′-acetoxy group ($\tau = 8.02$; 3 H). The signals (in $CDCl_3$) of the acetoxy groups of the tetraacetate *(6)* must be interpreted analogously: 6′-OAc at $\tau = 7.99$, equatorial 2′- and 4′-OAc at $\tau = 7.90$ and 7.93.

3. The configuration at the tertiary C-3′ can be determined by comparison of the acetamido and acetoxy signals with those of analogous compounds[6]. The 3 H singlet at $\tau = 8.15$ in the $CDCl_3$ spectrum of the tetraacetate *(6)* is thus due to an equatorial 3′-acetamido group. The corresponding orientation is to be assumed for the nitro group in *(2)*.

Fractional crystallization, from water, of the mixture remaining after separation of the main product yields two further nitrohexosyluracil isomers: *(7)*, m.p. 186–190 °C, $[\alpha]_D^{20} = +121°$ (methanol), and *(8)*, m.p. 157–160 °C, $[\alpha]_D^{20} = +50°$ (methanol), as monohydrates in low yield; on acetylation in acidic solution these afford tri-*O*-acetates *(9)*, m.p. 106–109 °C, $[\alpha]_D^{20} = +124°$ ($CHCl_3$), and *(10)*, m.p. 107 to 110 °C, $[\alpha]_D^{20} = +24°$ ($CHCl_3$), respectively. According to their NMR spectra compounds *(7)* and *(9)* have the D-*manno*- and compounds *(8)* and *(10)* the D-*galacto*-configuration.



U: 1-Uracilyl



*(7)*, R : H
*(9)*, R : $CH_3CO$

*(8)*, R : H
*(10)*, R : $CH_3CO$

In the present case our total yields of isomer mixture (79.7 %) exclude the epimerization at C-5 observed by *Baer*[4c] for nitroethane cyclization of 2-*O*-[(*S*)-formyl(methoxy)methyl]-(*R*)-glyceraldehyde.

# CONFERENCE REPORTS

## Preparative and Kinetic Aspects of Radiation Chemistry

The Nuclear, Radio, and Radiation Chemistry Section of the Gesellschaft Deutscher Chemiker and the Hahn-Meitner-Institut für Kernforschung, Berlin, held a symposium from April 5th to 7th in Berlin (Germany), on the chemical effects of energetic radiation. The following is a selection of the abstracts of papers read.

### γ-Radiolysis of Liquid Ammonia in the Presence of *p*-Nitrophenol

*M. Dobó* and *D. Schulte-Frohlinde*, Karlsruhe (Germany)

On γ-irradiation of *p*-nitrophenol in liquid ammonia, *p*-aminophenol, 2-amino-4-nitrophenol, hydrazine, nitrogen,

and hydrogen are formed by reactions of the radiolysis products of $NH_3$ with one another or with the trapping agent. The 2-amino-4-nitrophenol is produced by addition of the $\cdot NH_2$ radical to *p*-nitrophenol, with subsequent dehydrogenation of the cyclohexadienyl radicals formed. It is remarkable that this introduction of an amino group into an aromatic compound by way of a free radical occurs selectively.

Aminophenol arises from the action of $\cdot H$ and $e^{\ominus}$ on nitrophenol through intermediate stages. Hydrogen and hydrazine are formed from ammonia even if the nitrophenol concentration is high (*ca.* 1 mole/l); the precursors of these products are thus not trapped by nitrophenol. At dosages greater than $3\times10^{20}$ eV/ml the $N_2H_4$ concentration becomes stationary, *i.e.* hydrazine is formed as rapidly as it is degraded to nitrogen.

For a study of the kinetics $G_{2\text{-amino-4-nitrophenol}}$, $G_{\text{hydrogen}}$, and $G_{\text{nitrogen}}$ were measured in relation to dosage and to the concentration of *p*-nitrophenol. At concentrations exceeding 1.0 mole/l $G_{2\text{-amino-4-nitrophenol}}$ is constant ($G \approx 1.80$). If it is assumed that in this region each amino radical that is formed is recovered in the 2-amino-4-nitrophenol and that one nitrogen molecule is formed from two molecules of hydrazine (for which there is some evidence), then the following stoichiometry results for the γ-radiolysis of liquid ammonia in the presence of *p*-nitrophenol:

$$3.0\ NH_3 \xrightarrow[100\ eV]{\gamma} 1.8\ \cdot NH_2 + 1.74\ (H\cdot + e^{\ominus}) + 0.5\ 8N_2H_4 + 0.61\ H_2$$

## Labeling of Aromatic Halides by Radiation-Induced Isotopic Exchange

*H. Elias*, Darmstadt (Germany)

Aliphatic halides RX are in general easily labeled by homogeneous, nucleophilic isotopic exchange in solution:

$$R{-}X + {}^*X^- \rightleftarrows R{-}{}^*X + X^- \qquad (1)$$

or by heterogeneous isotopic exchange in gas chromatography columns[1]:

$$R{-}X_{\text{mob. phase}} + [(Butyl)_4N]\ {}^*X_{\text{stat. phase}} \rightleftarrows R{-}{}^*X_{\text{mob. phase}} + [(Butyl)_4N]\ X_{\text{stat. phase}} \qquad (2)$$

Both methods fail for aromatic halides such as $C_6H_5I$, $C_6H_5Br$, and $C_6H_5Cl$ in which there is no group next to the halogen that favors substitution.

On radiolysis and photolysis of organic iodides or bromides in the presence of radioactive iodine or bromine a radiation-induced isotopic exchange occurs:

$$R{-}X + {}^1/_2\ {}^*X_2 \longrightarrow R{-}{}^*X + {}^1/_2\ X_2 \qquad (3)$$

The *G* value for this exchange is usually greater than for the radiolysis products. Thus radiation-induced isotopic exchange can be used for labeling organic iodides and bromides. The method is of particular interest for aromatic halides that cannot be labeled in accordance with equation (1) or (2).

A study has been made of the radiation-induced isotopic exchange of iodobenzene *(1)*, *o*-iodobenzoic acid *(2)*, and *o*-iodohippuric acid with $^{131}I_2$ in the presence of oxygen by means of a $^{60}Co$ source (dose rate: $0.71\times10^6$ rad/hr) at about 30 °C [benzene/1,4-dioxane was used as solvent for *(2)* and *(3)*]. Radiolytic formation of iodine from *(1)*, *(2)*, and *(3)* was also measured.

*System iodobenzene/*$^{131}I_2$: With a radiation dose of $5\times10^{20}$ eV/g at $c_{I_2} = 0.02$ mole/l, the value of $G_{I_2}$ was 0.90. For the isotopic exchange the following values were found: $G_{IE}$ = 8.2 for $c_{I_2} = 0.17$ mole/l; $G_{IE} = 6.7$ for $c_{I_2} = 0.038$ mole/l; and $G_{IE} = 5.1$ for $c_{I_2} = 0.0056$ mole/l. Thermal isotopic exchange was not observed even when the solutions were kept standing for a longer time.

Iodobenzene is easily labeled at $c_{I_2} = 0.0056$ mole/l with a dose of $2.4\times10^6$ rad, under which conditions the exchange amounts to 86 %. The irradiated iodobenzene contains a total of only about 0.1 mole-% of organic radiolysis products and these can be easily separated.

*System o-iodobenzoic acid/*$^{131}I_2$: $G_{I_2} = 0.85$ for a solution of *(2)* ($c_{(2)} = 0.1$ mole/l) in a benzene/dioxane mixture (1:3). For a 1:1 benzene/dioxane mixture (as solvent) with $c_{(2)} = 0.66$ mole/l and $c_{I_2} = 10^{-3}$ mole/l, $G_{IE} = 1.5$ (exchange amounts to 90 % with a dose of $3\times10^6$ rad). The proportion of radiolysis products is larger for *(2)* than for *(1)*.

*System o-iodohippuric acid/*$^{131}I_2$: The exchange behavior of *(3)* and the radiolytic formation of iodine from *(3)* are similar to those for *(2)*.

## Study of the Radical Anion $SO_4^-$ by Pulse Radiolysis [2]

*E. Heckel*, Berlin (Germany)

OH radicals formed on radiolysis of water react with $HSO_4^-$ ions with formation of the radical anion $\cdot SO_4^-$. These particles have maximal extinction ($\varepsilon = 1.05\times10^3$ l mole$^{-1}$ cm$^{-1}$) at 4500 Å. The rate constant for the reaction of OH with $HSO_4^-$ amounts to $8\times10^5$ l mole$^{-1}$ sec$^{-1}$. In the presence of reducing substances the extinction at 4500 Å is reduced owing to scavenging of OH radicals; the reaction of OH with $HSO_4^-$ can thus be used for determination of the rate constants of reactions of the OH radical. The following rate constants have been found:

| Reaction | $k$ (l mole$^{-1}$ sec$^{-1}$) |
|---|---|
| $Fe^{2+} + \cdot OH$ | $5.0\times10^9$ |
| $Fe^{2+} + \cdot SO_4^-$ | $9.9\times10^8$ |
| $CH_3OH + \cdot SO_4^-$ | $2\times10^7$ |
| $C_2H_5OH + \cdot SO_4^-$ | $3\times10^7$ |

## Investigations, by Pulse Radiolysis, of the Reactivity of Catalase towards Hydrated Electrons and Free OH Radicals

*W. Karmann*, Berlin (Germany)

Catalase reacts in aqueous solution with the hydrated electron and with the OH radical with rate constants of $3.7\times10^9$ and $8.3\times10^{10}$ l mole$^{-1}$ sec$^{-1}$, respectively[3]. The reaction of OH with catalase is diffusion-controlled, although some of the amino acids of catalase do not, when in the isolated state, react with an OH radical at each encounter. A diffusion coefficient of $2.3\times10^{-5}$ cm$^2$ sec$^{-1}$ can be calculated for the OH radical from these measurements. The results are of interest in relation to the decomposition of catalase on irradiation in aqueous solution and in relation to the influence of catalase on the sensivity of biological systems to radiation. It is further suggested that reactions of small radicals with monomers, which although fast are not exclusively diffusion-controlled, may become diffusion-controlled if the reaction partner is a macromolecule consisting of the same monomer units.

## Depolymerization of Cellulose by $^{60}Co$-γ-Radiation

*H.-G. Klippel*, Hamburg (Germany)

In 1954 *Charlesby* reported that dry cellulose was degraded to a powdery material when irradiated with about $10^8$ rad in a reactor or with a γ-source. From the change in viscosity

[1] *H. Elias* in: Proceedings of the International Symposium on the Preparation and Biomedical Application of Labeled Molecules, Euratom 2000e, p. 467 (1964).

[2] *E. Heckel, A. Henglein*, and *G. Beck*, Ber. Bunsenges. physik. Chem. *70*, 149 (1966).

[3] *A. Henglein, W. Karmann, W. Roebke*, and *G. Beck*, Makromolekulare Chem. *92*, 105 (1966).

of Cu(II)-ethylenediamine solutions it was deduced that $10^6$ rad caused liberation of 0.16 % of the glucose units [4].

Increase in the swelling capacity of the cellulose parallels an increase in the rate of hydrolysis and can be explained as activation of the bonding (uptake of energy by the bonding electrons). Increasing the dose deepens the yellow color of the irradiated material, and this may be made the basis of a method for determining doses of the order of $10^{6.25}$ to $10^8$ rad (with an accuracy of ± 2 %) [5].

Medicinal cotton wool (prepared as described by *v. Bruns*), was irradiated in a circular isodose arrangement by a Co unit with a dosage of *ca.* 150 Ci, *i.e.* $1.5\times10^6$ rad/hr (distance from the $^{60}$Co cylinder 1 cm; diameter 1 cm). The irradiated cellulose was stored for five months in the dark under nitrogen; the degree of polymerization was then determined by *Jayme-Bergmann*'s method with EWNN, *i.e.* in an aqueous solution of hexasodium tritartratoferrate at defined $OH^-$ concentration, as solvent [6]. Use of this solvent in two stages of increasing EWNN concentration permits relatively rapid dissolution of the cellulose for the determination of viscosity. The viscosity was measured in a constant-temperature Ubbelohde viscometer.

Before irradiation the pre-treated, bleached cellulose had a degree of polymerization of *ca.* 20000. γ-Irradiation with a dose of $5\times10^6$ rad resulted in fission of the cellobiose chain into three fragments; increasing the dose to $10\times10^6$ rad reduced the degree of polymerization to about half its initial value; and further increase to $30\times10^6$ rad caused the cleavage of five hexose units per $10\times10^6$ rad. At higher doses not only does the chance of recombination increase but, in the presence of water, so does the rate of reaction with atmospheric oxygen and nitrogen oxides.

## Radiation Chemical Reduction of Aromatic Nitro Compounds

*E. Koerner von Gustorf*, Natick, Massachusetts (U.S.A.)

Direct reduction of aromatic nitro compounds to nitroso compounds can be achieved radiation chemically with the aid of $Fe(CO)_5$ in benzene solution according to the overall equation (1):

$$2\ Ar{-}NO_2 + 2\ Fe(CO)_5 \xrightarrow[\text{benzene}]{^{60}CO-\gamma} [Ar{-}NOFe(CO)_3]_2 + 2\ CO + 2\ CO_2 \quad (1)$$

The nitroso group is shielded from further reduction by formation of an iron tricarbonyl complex.

The mechanism of this reaction can be written as in (2)–(6):

$$C_6H_6 \rightsquigarrow C_6H_6^* \quad (2)$$

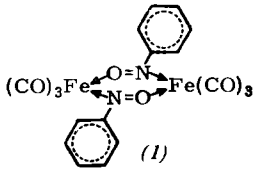
$$Fe(CO)_5 + C_6H_6^* \rightarrow C_6H_6 + Fe(CO)_5^* \quad (3)$$

$$Fe(CO)_5^* + Ar{-}NO_2 \rightarrow Ar{-}NO_2Fe(CO)_4 + CO \quad (4)$$

$$Ar{-}NO_2Fe(CO)_4 + C_6H_6^* \rightarrow Ar{-}NOFe(CO)_3 + CO_2 + C_6H_6 \quad (5)$$

$$2\ Ar{-}NOFe(CO)_3 \rightarrow [Ar{-}NOFe(CO)_3]_2 \quad (6)$$

Nitrobenzene gives only dimeric nitrosobenzene-tricarbonyliron of structure *(1)* [7], but *para*-substituted nitrobenzene derivatives give monomeric or dimeric complexes. Electron-repelling substituents favor formation of monomeric complexes, electron-attracting substituents favor that of dimeric complexes, as indicated by the Hammett σ-values. The relative electron density on the iron can be estimated from the position of the C≡O bands in the infrared spectra and is related to the σ-constants of the substituents [8].



*(1)*

Multiply substituted nitro compounds, *e.g.* 2-chloro-6-nitrotoluene, can also be reduced in accord with equation (1); with 2,2′-dinitrobiphenyl selective reduction of one nitro group can be achieved.

The *G* values for formation of $X{-}C_6H_4{-}NOFe(CO)_3$ lie in the range 0.1 to 2.0, depending on the substituent (X = *p*-$OCH_3$, *p*-$CH_3$, *p*-Cl, *p*-$COOCH_3$, *o*-$CH_3$, *o*-Cl, *m*-$CH_3$, *m*-Cl).

Tricarbonyliron complexes of aromatic nitroso compounds react, for instance, with aromatic amines, yielding azo compounds [7], and can replace the free nitroso compounds in preparative chemistry.

## Pulse Radiolysis of Dimethyl Sulfide in Aqueous Solution

*G. Meissner*, Berlin (Germany)

The hydrated electron hardly reacts at all with dimethyl sulfide, in accordance with mass-spectroscopic results. The OH radical reacts with dimethyl sulfide by removal of either an H atom or an electron. The absorption spectra of the products $CH_3SCH_3^+$ ($\lambda_{max}$ = 470 mμ) and $CH_2SCH_3$ ($\lambda_{max}$ = 290 mμ) have been measured. Both particles disappear from solution in a reaction of the second order. The rate of the reaction between $CH_3SCH_3^+$ and $CH_3SCH_3^+$ is increased by addition of an inert salt *e.g.* $NaClO_4$. A second sulfide molecule is required for formation of $CH_3SCH_3^+$; a complex of $CH_3S(OH)CH_3$ with $CH_3SCH_3$ occurs as intermediate.

## Degradation and Cross-Linking of Polydimethylsiloxane in Solution under the Influence of $^{60}$Co-γ-Radiation

*W. Schnabel*, Berlin (Germany)

Polymers that form a three-dimensional network when in the pure state are mainly degraded on irradiation in solution provided that the polymer concentration is less than the critical concentration [9]. With respect to previous measurements of the weight-average molecular weight it was not possible to relate the specific degradation density $p_o$ to the specific cross-link density $q_o$ [*] or to determine the dependence of $p_o/q_o$ on the polymer concentration.

The following facts have been established for the polydimethylsiloxane/toluene system by the use of weight- and number-average molecular weight data: $p_o/q_o$ (= 0.02 for the homogeneous polymer) increases with addition of toluene, equals 2 at the critical concentration, and tends to infinity at a mole fraction of polymer base units $x_p \leqslant 0.03$. The *G* value for cross-linking bonds decreases with decreasing polymer concentration and is zero in very dilute solutions, but the *G* value for main chain scissions increases from *ca.* 0.1 (homogeneous polymer) to *ca.* 0.8 ($x_p$ = 0.03). These results confirm *Henglein*'s theory in principle: according to this theory $p_o$ should be independent of the polymer concentration and $q_o$ should become continuously smaller with increasing dilution. The relatively small

[*] $p_o$ and $q_o$ are the fractions of monomer units degraded and crosslinked, respectively, by a dose of 1 Mrad.

increase in $p_o$ with increasing dilution is probably due to transfer of energy from the solvent to the polymer.

### γ-Radiolysis of 5-Bromouracil in Oxygen-Containing Aqueous Solutions

*O. Volkert, W. Bors, E. Gilbert,* and *D. Schulte-Frohlinde,* Karlsruhe (Germany)

5-Bromouracil can be incorporated into the DNA of bacteriophages in place of thymine. Phages containing 5-bromouracil are more sensitive to radiation than are normal phages, consequently a study of the radiochemistry of 5-bromouracil seemed important for clarification of this phenomenon.

Hydrogen, hydrogen bromide, hydrogen peroxide, isodialuric acid (main product), alloxan, isobarbituric acid, diisobarbituric acid, urea, and an unstable hydroperoxide are formed on irradiation of 5-bromouracil in oxygen containing aqueous solution. In order to elucidate the mechanism of the decomposition of 5-bromouracil the $G$ values for these products were determined and related to the dose and the concentration of 5-bromouracil. In dilute solutions ($<10^{-4}$ mole/l) only the OH radical reacts with 5-bromouracil. At increasing concentrations the reducing radicals formed by radiolysis of water begin to attack the 5-bromouracil. At concentrations greater than $2\times10^{-3}$ mole/l the $G_0$ value (initial value) for disappearance of 5-bromouracil equals the sum of the $G$ values of all the radicals resulting from the radiolysis of $H_2O$. Quantitative analysis of the kinetics showed that it is not only the concurrent reactions of the solvated electron with 5-bromouracil and with oxygen that are responsible for the increase in the $G_0$ value, but that at higher concentrations the $O_2^-$ radical also reacts with 5-bromouracil.

The first step in the reaction of the solvated electron with 5-bromouracil leads to separation of bromide ions, but the OH radical adds to the C=C double bond. Addition at the 6-position, with subsequent addition of $O_2$, leads to a peroxy radical, which by reaction with a $HO_2$ radical yields 4-hydroxy-5-uracilyl hydroperoxide. The hydroperoxide decomposes in solution by a second-order reaction, with loss of $O_2$ and formation of isodialuric acid. Addition of the OH radical at position 5 leads to an intermediate that cannot be isolated and at once reacts further, by ring opening, to yield a second intermediate, which is sensitive to hydrolysis; urea and mesoxalic acid were identified as secondary products.

### Radiation Chemical Formation and Optical Absorption Spectra of Organic Sulfur Radicals in Organic Glasses at —196 °C

*J. Wendenburg,* Berlin (Germany)

Organic disulfides, sulfides, mercaptans, and hydrogen sulfide have been exposed in tetrahydro-2-methylfuran or nydrocarbon glasses to γ-iradiation at −196 °C. The absorption spectra and extinction coefficients of the following radicals of uni-coordinate sulfur have been determined: $CH_3S$, n-$C_4H_9S$, t-$C_4H_9S$, $CH_2{=}CH{-}CH_2S$, $C_6H_5S$, $C_6H_5CH_2S$, and $SH(\lambda_{max} \approx 4200$ Å, $\varepsilon \approx 1.05 \times 10^4$ l mole$^{-1}$ cm$^{-1}$).

The disulfides form radicals by dissociative capture of electrons formed by ionization of the vitreous solvent. Mercaptans yield sulfur-containing radicals only as the glass warms up, the reaction being H abstraction by the radicals that result from radiolysis of the solvent. HS is formed when irradiated glasses containing $H_2S$ are warmed. Benzyl mercaptan and dibenzyl disulfide (the latter to a smaller extent) yield benzyl radicals by electron capture. Several new absorption bands were observed and have been ascribed to negative ions: $C_6H_5SH^-$ (8100 Å) from phenyl mercaptan, $C_6H_5SC_6H_5^-$ (broad absorption in the visible region) from diphenyl sulfide, $C_6H_5CHS^-$ and $C_6H_5CH^-SH$ from dibenzyl sulfide (*ca.* 3900 Å). Carbon tetrachloride, if present, inhibits all the reactions of free electrons in the glass, but the reactions that free radicals undergo on warming are not suppressed.

Glassy mixtures of methylcyclohexane and isopentane, containing olefins, give strong absorption bands between 7000 and 9000 Å, which are derived from positive ions. Olefin cations and protonated olefins absorb at longer wavelength the fewer H atoms are attached to the doubly bonded C atoms. Absorption by positive ions has also been observed for diphenyl disulfide (8500 Å) and diallyl disulfide (6840 Å). Small additions of readily protonated substances such as isopropyl alcohol and tetrahydromethylfuran weaken the absorption bands of positive ions.

### Radiation Chemical Synthesis of Dichloro-2-chloroalkylphosphines

*K. Wunder,* Berlin (Germany)

γ-Irradiation of mixtures of olefins and phosphorus trichloride affords the corresponding dichloro-2-chloroalkylphosphines by a chain reaction. The $G$ values reach *ca.* 2000 during irradiation at *ca.* 100 °C. Several new compounds 2-Cl−R−$PCl_2$ have been isolated in gram quantities (*e.g.* R = cyclopentyl, b. p. 238 °C; R = cyclohexyl, b. p. 256-260 °C; R = cycloheptyl, b. p. 286–288 °C).

At temperatures above 150 °C another chain reaction occurs, which leads to dichloro(alkyl)phosphines and β-chloroalkenes. Several olefins that have rather large groups attached at the double bond undergo the second reaction more often than the first, even at room temperature.

### γ-Irradiation of 3-Phenyl-1,4-cyclohexadiene in Benzene

*B. Zimmerli,* Lausanne (Switzerland)

3-Phenyl-1,4-cyclohexadiene (P), which is formed on radiolysis of benzene, is rapidly destroyed again. Solutions of P in benzene (B) show on irradiation a decrease in the concentration of P that can be expressed as a pseudo-first order reaction, in which $c_p = c_{p_0} \cdot e^{-kD}$ where $k$ is a constant and $D$ the radiation dose.

At 25 °C 17 % (24 % at 85 °C) of the P consumed in the radiolysis appears as biphenyl (Q). The following simplified scheme satisfactorily accounts for these results:

$$\text{(1)}\quad B \xrightarrow{k_1} B^*$$

$$\left.\begin{array}{ll} \text{(2)} & B^* + P \xrightarrow{k_2} \\ \text{(3)} & B^* + Q \xrightarrow{k_3} \\ \text{(4)} & B^* + B \xrightarrow{k_4} \end{array}\right\} \text{Products, deactivation}$$

If a stationary amount of excited benzene (B*) is assumed, this scheme leads to a linear relation between $1/k$ and the initial concentration $c_{p_0}$. $G$ values [$k_1 c_B = G(B^*)$] and the ratios $k_4/k_2$ and $k_3/k_2$ can be calculated from the intercept on the axis and the slope.

| Temp. [°C] | Q [μmole/g] | G(B*) [μmole/g·Mrad] | $k_4/k_2$ | $k_3/k_2$ |
|---|---|---|---|---|
| 25 | — | 2.2 ± 0.2 | (5.6 ± 1) × $10^{-3}$ | — |
| 85 | — | 1.8 ± 0.2 | (1.6 ± 0.3) × $10^{-2}$ | — |
| 25 | 340 | 1.9 ± 0.2 | — | 1 ± 0.2 |

Within the range 25 to 85 °C the $G$ value for excited benzene seems to be independent of temperature. The two values of $k_4/k_2$ permit a difference in activation energies of 4 ± 2 kcal/mole to be estimated; *i.e.* the activation energy of reaction (4) is about 4 kcal/mole greater than that of reaction (2). The ratio $k_3/k_2$ indicates that Q and P react equally readily with B*. The present measurements do not permit any conclusion about the nature of B*. [VB 1000 IE]

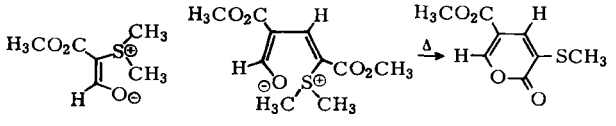
## Heterocycles from Acetylene Derivatives

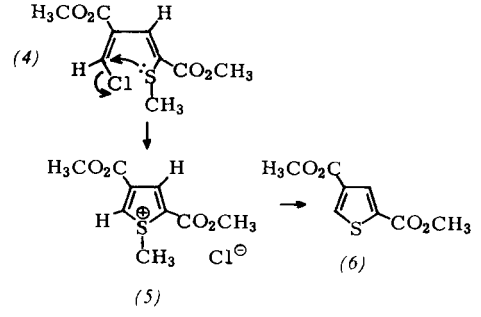
*E. Winterfeldt*, Berlin (Germany)

The betaine-like compounds *(1)* and *(2)* can be prepared from methyl propiolate and dimethyl sulfoxide. When high concentrations of the ester are used, only compound *(2)* can be isolated, but at high dilution the 1:1 adduct *(1)* is obtained at 125°C.



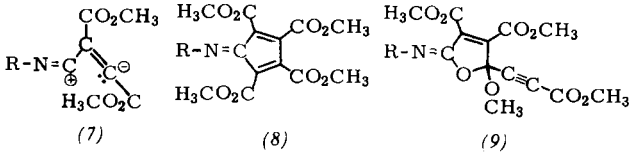
*(1)* *(2)* *(3)*

Both substances are crystalline and quite stable. When compound *(2)* is heated at 150°C in a vacuum the main product is the 2-pyrone *(3)*, and dimethyl 2,4-furandicarboxylate is formed only to a small extent. Thionyl chloride converts compound *(2)* quantitatively into dimethyl 2,4-thiophenedicarboxylate *(6)* at room temperature, by way of the stages *(4)* and *(5)*.



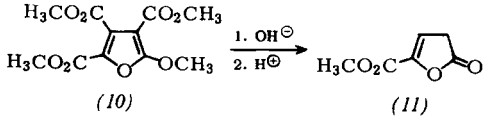
*(4)* *(5)* *(6)*

Reaction of dimethyl acetylenedicarboxylate with isocyanides usually leads to a large number of products, but if a large excess of isocyanide is used at −10°C the main products – probably formed from a primary product *(7)* – are the 1:2 adducts *(8)* and *(9)*; their structures are proved by infrared, ultraviolet, and NMR spectroscopy, by elemental analyses, and by molecular-weight determinations.

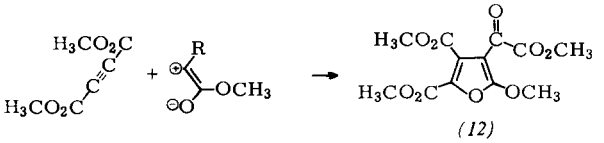


*(7)* *(8)* *(9)*

Heating dimethyl acetylenedicarboxylate in a sealed tube at 150–180°C in the presence of copper as catalyst and oxygen leads to a 50% yield of the furan derivative *(10)*, whose structure is supported by ultraviolet, infrared, and NMR data as well as by its mass spectrum and conversion into the enol lactone *(11)*. Alongside *(10)* carbon monoxide is evolved, and the reaction occurs only in the presence of oxygen.



*(10)* *(11)*



*(12)*

R = −CO−$CO_2CH_3$; −C̈−$CO_2CH_3$ + O

These results do not agree with a reaction mechanism recently proposed[1]. Instead, formation of an α-oxo-ester *(12)* by cycloaddition and oxidation is discussed. Trapping experiments with tolan and with sulfur support this hypothesis. The order of the two steps, uptake of oxygen and condensation, remains an open question.

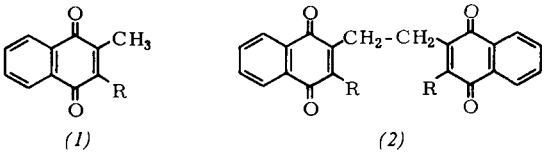
## Recent Advances in the Chemistry of Quinones

*R. H. Thomson*, Aberdeen (Scotland)

2-Hydroxy-1,4-naphthoquinones can be prepared by autoxidation of α- and β-tetralones in t-butyl alcohol/potassium t-butoxide. The reaction probably proceeds *via* a 1,2-diketone which aromatizes to a 1,2-dihydroxynaphthalene whose semiquinone anion combines with a further mole of oxygen at position 4. Under the same conditions 1,2-dihydroxynaphthalenes rapidly absorb 1 mole of oxygen, giving 2-hydroxy-1,4-naphthoquinones. Autoxidation of 5,7,8-trimethoxy- and 5,6,7,8-tetramethoxy-1-tetralone, followed by demethylation, gives 2,5,7,8-tetrahydroxy- and 2,5,6,7,8-pentahydroxy-1,4-naphthoquinone. These products are identical, respectively, with mompain, a metabolite of *Helicobasidium mompa* Tanaka and spinochrome D, a pigment found in the spines of several species of sea urchin.

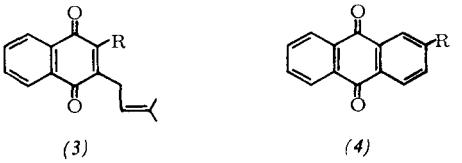
In the Dam-Karrer test for vitamin K and other allylnaphthoquinones (treatment with ethanol/sodium ethoxide) a blue mesomeric anion is formed by removal of a proton from the methylene group adjacent to the quinone ring. The colour is transient, changing to red-brown as a consequence of cleavage of the side chain to form phthiocol(2-hydroxy-3-methyl-1,4-naphthoquinone). 2-Benzyl-1,4-naphthoquinone behaves similarly, giving first a blue and then a red solution with the formation of lawsone (2-hydroxy-1,4-naphthoquinone) and benzaldehyde. The reaction is considered to be a special case of ketone autoxidation, the quinone behaving as a vinylogous benzyl ketone. If a methyl group is also present in the quinone ring [*(1)*, R = $CH_2C_6H_5$] cleavage of the benzyl group is accompanied by dimerization, and in



*(1)* *(2)*

general 2-methyl-1,4-naphthoquinones of type *(1)*, R = $C_2H_5$, iso-$C_3H_7$, $CH_2CH{=}CMe_2$, $CH_2C_6H_5$, $CH(C_6H_5)_2$, *p*-$CH_3C_6H_4$ Cl, Br dimerize at the methyl group (preferential formation of a primary carbanion) to give the corresponding diquinones *(2)* together with the quinhydrone of *(1)*.

Re-examination of lapacho wood (*Tabebuia ipé*, Bignoniaceae), a well-known source of lapachol *(3)*, R = OH has shown it to contain *inter alia* the naphthoquinones *(3)*, R = H, $CH_3$, OH, $OCH_3$ and anthraquinones *(4)*, R = $CH_3$, $CH_2OH$, $CH_2OAc$, CHO, $CO_2H$), several of which also



*(3)* *(4)*

occur in teak wood (*Tectona grandis*, Verbenaceae). The unusual coexistence of these two groups of quinones suggests a biogenetic relationship which is supported by a simple

*in vitro* conversion of deoxylapachol *(3)*, R = H into tectoquinone *(4)*, R = $CH_3$, by treatment with boron trifluoride in acetic acid. Another compound present in lapacho wood in small amount belongs to both groups and probably has structure *(5)*.

## Biosynthesis of Methionine by Bacteria

*L. Jaenicke*, Cologne (Germany)

The biosynthesis of methionine involves reaction between tetrahydrofolic acid and vitamin $B_{12}$. The central step is condensation of homocysteine with a methyl group bound to folate. This methyl group comes from the one-carbon reservoir of the cell and is transferred by way of 10-formyl- and 5,10-methylene-tetrahydrofolic acid to give 5-methyltetrahydrofolic acid.

Methionine synthetase from *S. faecalis* was enriched 800 times and appeared homogeneous by the usual criteria (particle weight 135000). It contains 1 molecule of a corrin derivative that, however, does not posses the full growth activity of complete vitamin $B_{12}$. In its properties it rather resembles a cobyric acid derivative.

The combining reaction requires a reductant (*in vivo* an FAD-containing reductase, which was also purified to homogeneity), but it requires neither ATP nor metal ions. A further activating factor is *S*-adenosylmethionine (SAM). Whereas with catalytic amounts of the enzyme 5-methyltetrahydrofolate (5-$CH_3$-folate) seems to donate its methyl group undiluted to homocysteine, with substrate amounts of the reactants the methyl group of SAM appears undiluted in the cobalt cofactor and hence in the newly formed methionine. 5-$CH_3$-folate dilutes its specific activity 1 : 1.

The results exclude a reaction course in which the cobalamine derivative is converted by ATP into the coenzyme, whose deoxyadenosyl residue is replaced by methyl which is then transferred. Instead, in model experiments with cobinamide and 5-methyltetrahydrofolic acid spectral changes were found indicating formation of a complex in which the folic acid derivative takes the position occupied by the dimethylbenzimidazole portion in the complete cofactor. In this way the tertiary methyl group is labilized sufficiently for transfer.

## The Kerr Effect at High Pressures and its Relation to the Structure of Molecules and Liquids

*E. Kuss*, Hannover (Germany)

According to the Langevin-Born theory[1] electrical birefringence depends on the fact that a dipole moment is induced in a molecule by an electric field and that, because of the anisotropy of the polarizability, this moment does not lie in the direction of the field. Molecules without a permanent dipole moment thus also become oriented in the field and in such a way that the major axis of the polarizability ellipsoid lies in the direction of the electric field.

This orientation effect is, however, very small and with the fields used in practice its macroscopic result is equivalent to one in every ten thousand molecules being aligned with the field, the rest remaining randomly oriented. This partial orientation of the molecules causes a difference in the ninth decimal place of the refractive index for light polarized parallel to, or perpendicular to, the direction of the field.

When measured on gases or dilute solutions, the electrical double refraction can be used, on the basis of the Langevin-Born theory, to draw conclusions about molecular structure, as has been shown for 1,2-dichloroethylene[2]. The Kerr effect measured for liquids or compressed gases is, however, usually smaller than that expected theoretically, owing to restriction to rotation as well as change in local field strength. The differences from the expected values[3] permit conclusions about quantities characteristic of liquid structure, such as the anisotropy of the local field and the restriction potential.

Few measurements of birefringence at high pressure[4] have previously been made because the very small Kerr effect is overlaid by a considerably greater background birefringence of the high-pressure cell windows, which varies with time and distance across the window. Therefore a new apparatus has been developed for pressures up to 2000 atm, based on the application of an alternating instead of a direct voltage to the Kerr cell; the Kerr effect is thus modulated. The transmitted light is received on a photomultiplier where it generates an alternating signal, which after amplification passes to a ring demodulator. The demodulator receives a reference signal exactly equivalent in frequency and phase to the signal to be measured. It is generated by means of a supplementary optical path through another Kerr cell containing phenyl isothiocyanate, a photodiode, an amplifier, and a peak limiter, and because of the rapid response of the Kerr effect and the frequency doubling it matches the sought effect in frequency and phase. It has been shown by deliberate introduction of spurious birefringence that this method eliminates the latter completely. The Kerr constants are determined either from a galvanometer deflection or by using the galvanometer as a null instrument with a second, "crossed" Kerr cell that compensates the path difference to be measured[5].

With this technique the pressure-dependence of birefringence has been investigated for $CCl_4$, n-heptane, and benzene. The first two substances show a pressure-dependence smaller than expected from the Langevin-Born theory, but benzene shows an abnormally large pressure effect. Up to incipient solidification (600 atm at 25 °C) the double refraction increases by 84%; the pressure dependence is 7.3 times as great as expected theoretically.

This large influence of pressure cannot be explained by the theories of *Peterlin* and *Stuart* and of *Klages* and *Buckingham*[6] without additional assumptions. Presumably at high densities a deformation of the π-electron cloud occurs which is more noticeable by the Kerr effect than by any other method. According to these results the component of the polarizability perpendicular to the plane of the molecule decreases by 19.5% under the influence of pressure, and those in the plane increase by 4.4%.

## Solubility in, and Reaction with, Alkali Chloride/$AlCl_3$ Melts, of Metal Oxides and Oxide Halides

*H. Kühnl*, Hannover (Germany)

Molten $NaAlCl_4$ at 200 °C dissolves up to 7 atoms-% of oxygen (as oxide). Thus addition of arsenic-(III) oxide leads to replacement of chloride ions by oxide ions, and arsenic trichloride distils off quantitatively:

$$As_2O_3 + 6\,Cl^- \rightarrow 3\,O^{2-} + 2\,AsCl_3$$

In all alkali chloride/$AlCl_3$ melts, $AlCl_3$ acts as a strong acceptor for oxide ions, so that $CO_2$ is liberated from carbonates, and $NO_2$ and $O_2$ are liberated from nitrates.

Oxides of Fe(II), Co(II), and Ni(II) dissolve at 400 to 500 °C and, on cooling, the anhydrous chlorides crystallize; $CoCl_2$ and $NiCl_2$ are isolated from the melts by filtration and have been identified by analysis and Debye-Scherrer diagrams. $Sb_2O_3$ reacts with the melts, yielding $SbCl_3$, and $V_2O_5$ gives $VOCl_3$. $K_2Cr_2O_7$ reacts differently, according to the temperature and composition of the melt; with a $LiCl/AlCl_3$ melt at 120 °C a solution is formed from which $CrO_2Cl_2$ distils; in $NaAlCl_4$ at 160–180 °C principally $CrCl_3$, which is insoluble in the melts, is formed, with evolution of $Cl_2$; above 350 °C chromium(III) oxide is also formed; the oxide is obtained as main product if the dichromate is added to an $NH_4Cl/AlCl_3$ melt; both in the alkali-metal and the ammonium halide melts the proportion of $Cr_2O_3$ in the product is the greater the coarser is the potassium dichromate added; passing in $CrO_2Cl_2$ always leads to formation of chromium(III) chloride.

On reaction of $MoO_3$ or $Na_2MoO_4$ with melts containing more than one mole of $AlCl_3$ per mole of alkali-metal chloride, aluminium-molybdenum(VI) oxide chlorides are formed from 140 °C; these materials, which are volatile and very sensitive to moisture, can be obtained in four zones on vacuum sublimation in a temperature gradient. However, reaction with $NaAlCl_4$ at 400 °C gives a sublimate of $MoO_2Cl_2$. After addition of $Na_2WO_4$ or $WO_3$ to $LiAlCl_4$ containing an excess of $AlCl_3$ at 120 °C, $WOCl_4$ was isolated; in $NaAlCl_4$ at 400 °C pure $WO_2Cl_2$ is formed.

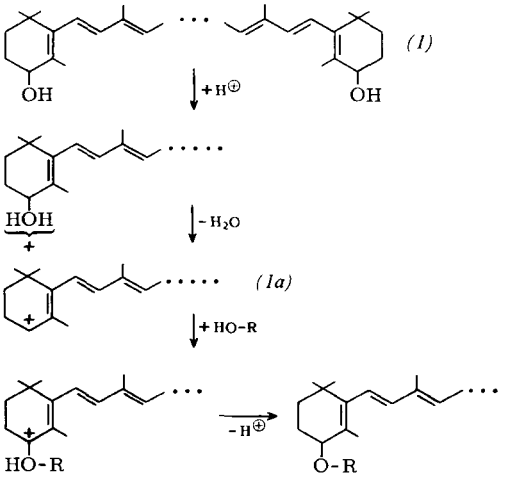
## Recent Results in Carotenoid Chemistry

*E. C. Grob*, Bern (Switzerland)

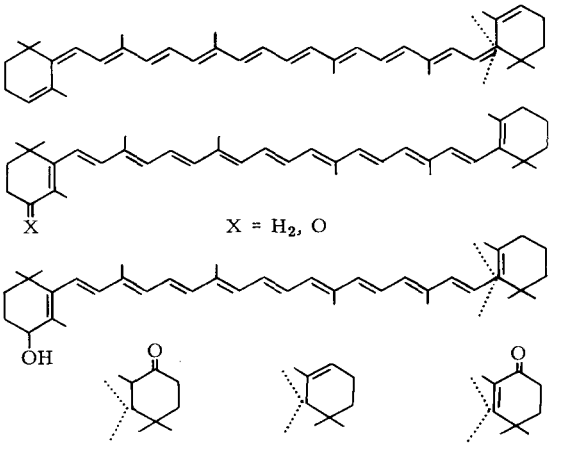
Certain carotenoids are extremely sensitive to acids. *Karrer* [1] has pointed out changes undergone by xanthophylls containing allylic hydroxyl groups when they are treated in chloroform solution with dilute mineral acids. For instance, hydroxyl groups are removed from eschholtziaxanthin by acid catalysis, a carotene hydrocarbon with two additional double bonds resulting.

We find non-allylic as well as allylic hydroxyl groups are eliminated under these conditions. However, if alcohols, ether, benzene, or light petroleum is used in place of chloroform as solvent, selective elimination of allylic hydroxyl groups can be achieved. Zeaxanthin, which does not contain an allylic hydroxyl group, is unchanged in alcoholic solution by 0.01 M HCl. Only the one allylic hydroxyl group is removed from lutein, the second group remaining unaffected. Both the allylic hydroxyl groups are removed from isozeaxanthin by treatment with acid. The chief product from lutein was shown to be a monoethoxy-monoalcohol. Isozeaxanthin gives the monoethoxy-monoalcohol as well as the diether, these ethers being apparently formed in accordance with Scheme 1 (formation of the monoether by the steps shown is repeated at the other end of the molecule, this leading to the diether).



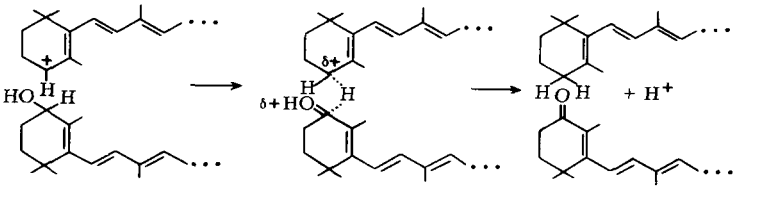
Scheme 1.

In the reaction of isozeaxanthin *(1)* in alcoholic solution a small amount of a monoalkoxy-monoketone is formed as well as the mono- and di-ether. If this reaction is effected in an inert solvent, *e.g.* benzene, seven products can be identified (see Scheme 2), including carotenoid ketones and hydrocarbons.



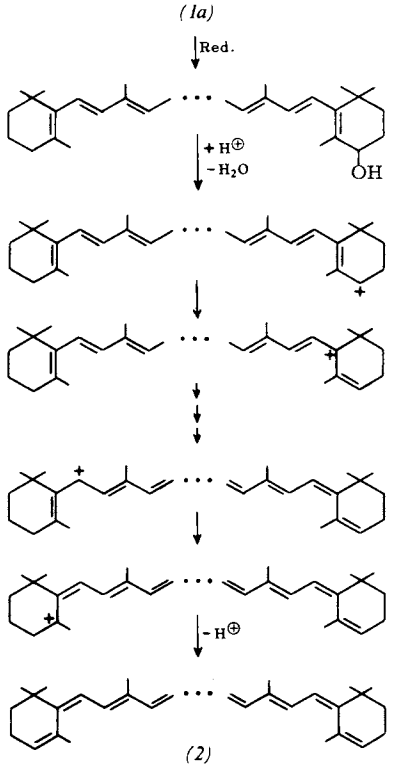
Scheme 2.

Their formation from isozeaxanthin must therefore be ascribed to redox reactions. According to *Steward* and *Bartlett* [2] carbonium ions can act as oxidizing agents towards *e.g.* alcohols, in that, after transfer of a H atom to the carbonium ion and loss of a proton, the alcohol is converted into the corresponding carbonyl compound: the carbonium ion thus affords a hydrocarbon. Transferring this reaction logically to isozeaxanthin leads to Scheme 3 for the formation of carotenoid ketones and β-carotene.



Scheme 3.

Formation of dehydroretro-β-carotene *(2)* proceeds by a somewhat different route. Since an additional double bond is formed in this case, the carbonium ion cannot have been stabilized by taking up a H atom; the new double bond must have arisen by loss of a further proton. Scheme 4 provides a representation of the course of this reaction.



Scheme 4.

Carotenoids are thus susceptible, in principle, to redox reactions. Whether they really are involved in redox reactions in the living cell cannot at present be decided.

## Spectroscopic Studies of Transition-Metal Fluorides

*D. Oelkrug*, Tübingen

In ionic complexes of Cr(II), Mn(III), and Cu(II) with coordination number 6 the ligands are in octahedral arrangement that is strongly distorted tetragonally (Jahn-Teller effect). Thus, in place of the one ligand-field transition ($E_g \rightarrow T_{2g}$) customary for octahedral symmetry, three transitions can occur ($B_{1g} \rightarrow A_{1g}$, $B_{1g} \rightarrow B_{2g}$, and $B_{1g} \rightarrow E_g$ for an octahedron extended in the $z$-direction), and these can be recognized in the reflectance spectra of most of the compounds as three absorption maxima. The assignment is ensured in particular through the Mn(III) fluorides, where because of the larger $Dq$ values two bands are shifted to higher energies whilst the position of the third is barely affected.

When the metal-ligand distances are known [*e.g.*, for Cu(II) fluorides] the term positions can be calculated by means of the electrostatic model[1], though the results may agree only approximately with the experimental values because of the approximations necessary. Comparison is best made for the fluorides, since they have the most marked ionic character. First the $B_{1g} \rightarrow B_{2g}$ band is used, with the asumption of 3d-radial functions similar to those for hydrogen to yield the effective nuclear charge number $Z_{eff}$ 6.35 for Cu(II), and then the positions of the other two maxima are determined. Except for $K_2CuF_4$, which is the only example yet proposed of a compressed octahedron[2], this method gives sensible term energies. The spectrscopic findings for $K_2CuF_4$, like those for other Cu(II) fluorides, can be better explained on the basis of an elongated octahedron.

Experimental and calculated position of bands ($cm^{-1}$) and experimental ligand-field parameters ($cm^{-1}$).

| Fluoride | $B_{1g} \rightarrow A_{1g}$ | $B_{1g} \rightarrow B_{2g}$ | $B_{1g} \rightarrow E_g$ | $Dq$ | $Ds$ | $Dt$ |

# SELECTED ABSTRACTS

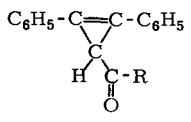
**Xenon dichloride,** $XeCl_2$, has been prepared by *H. Meinert* by high-frequency excitation (25 MHz, 150–350 mA) of a mixture of xenon, fluorine, and silicon tetrachloride or carbon tetrachloride [1:1:1 (v/v)] at a xenon pressure of *ca.* 10 Torr. The crystals can be purified by resublimation under reduced pressure. They decompose at 80 °C or in a high vacuum. The dichloride is presumably formed by way of $XeF_2$, which with $SiCl_4$ or $CCl_4$ or their radicals exchange fluorine for chlorine. / Z. Chem. *6*, 71 (1966) / −Ma

[Rd 498 IE]

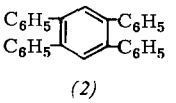
**Hydrocarbon solutions of Grignard reagents** can be prepared by using equivalent amounts of triethylamine, according to *E. C. Ashby* and *R. Reed*. For instance, dropping a benzene solution of an alkyl halide on to Mg turnings in benzene/triethylamine (reaction started by gentle warming) gives clear and usually colorless solutions. The temperature is kept at 40–50 °C. These Grignard reagents, which are readily soluble in benzene, contain Mg, halogen, and N in the atomic ratios 1:1:1. / J. org. Chemistry *31*, 971 (1966) / −De.

[Rd 510 IE]

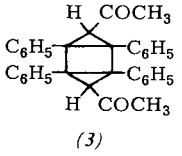
**Interesting photochemical rearrangements of 3-acylcyclopropene derivatives** are reported by *N. Obata* and *I. Moritani*. Ultraviolet irradiation of the compound *(1a)* in tetrahydrofuran at 65 °C affords 1,2,4,5-tetraphenylbenzene *(2)* in 25 % yield. Under the same conditions the analogue *(1b)* gives the new tricyclohexane derivative *(3)* as well as compound *(2)* and biacetyl, yields of the first two being 6.7 % and 20.6 %, respectively. On further irradiation, product *(3)* is converted into *(2)* in 43.4 % yield. Thus the cyclopropene *(1b)* dimerizes preferentially to the tricyclohexane *(3)*, which



*(1a)* R: $C_6H_5$
*(1b)* R: $CH_3$



*(2)*



*(3)*

rearranges to the benzene derivative with α-fission and formation of a diradical. / Tetrahedron Letters *1966*, 1503 / —Ma. [Rd 491 IE]

**β-Lactams with exocyclic methylene groups** are obtained by the reaction of allenes with chlorosulfonyl isocyanates, according to *J. F. Kelly* and *E. J. Moriconi*. 3-Methyl-1,2-butadiene, cyclohexylideneallene, and 1,2-cyclononadiene afford the *N*-chlorosulfonyl-2-azetidone derivatives *(1a)*, *(2a)*, and *(3a)*, respectively. Their reduction by thiophenol/pyridine in acetone leads to the β-lactams *(1b)*, *(2b)*, and *(3b)*. The allenes appear to be sufficiently polarized in the

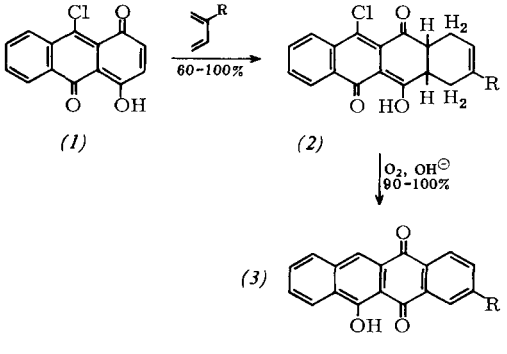
*(3)*

ground state for reaction with the isocyanate to occur. / Amer. Chem. Soc. 151st Meeting *1966*, Abstr. K 76 / —Ma. [Rd 492 IE]

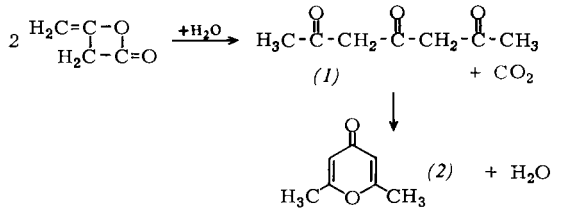
**A new three-stage synthesis of substituted naphthacenequinones** has been devised by *R. Winkler*. 1,4-Dihydroxyanthraquinone derivatives are converted by $SOCl_2$ into derivatives of the dienophilic 9-chloro-4-hydroxy-1,10-anthraquinone *(1)*, which adds 1,3-dienes, *e.g.* butadiene, isoprene, chloroprene, 2,3-dihalobutadienes, 2,3-dialkylbutadienes, 1-acetoxybutadiene, and 1-dimethylaminobutadiene, under relatively mild conditions, affording linear Diels-Alder monoadducts such



*(1)* *(2)* *(3)*

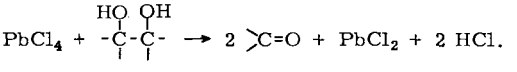
as *(2)*. These are dehydrogenated in alkaline solution by air to hydroxynaphthacenequinones *(3)*. Yields are usually high, and the products very pure. / Chimia *20*, 122 (1966) / —Ma. [Rd 496 IE]

**A new reaction of diketenes with water** has been described by *E. Marcus, J. K. Chan*, and *C. B. Strow*. Reaction in presence of a tertiary amine as catalyst affords 2,4,6-heptanetrione *(1)*, 2,6-dimethyl-4*H*-pyran-4-one *(2)*, and $CO_2$ as main products. Use of 1 mole of water per 2 moles of diketene is required if good yields of compounds *(1)* and *(2)* are to be obtained. The proportion *(1)*:*(2)* varies between 3:1 and 2:3 according to the reaction conditions. Under optimal conditions, with 1,4-diazabicyclo[2.2.2]octane as catalyst,



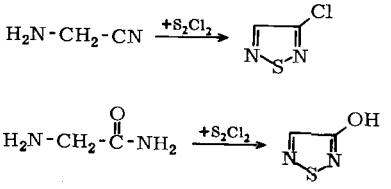
the total yield amounts to 78 %. / Amer. Chem. Soc. 151st Meeting *1966*, Abstr. K 80 / —Ma. [Rd 493 IE]

**The reaction of lead (IV) chloride with vicinal diols** has been studied by *I. May, D. Schreiber*, and *G. G. Schlesinger*. $PbCl_4$, prepared by decomposition of pyridinium hexachloroplumbate, was dissolved in $CCl_4$ and added to a suspension of the diols in $CCl_4$:



The reagent is more selective than lead tetraacetate. Ethylene glycol and *meso*-1,2-diphenylethyleneglycol undergo the expected C—C fission to formaldehyde and benzaldehyde, respectively, and 2,3-diphenyl-2,3-butanediol is chlorinated and cleaved to ω-chloroacetophenone. The butanediol, as well as pinacol and tetraphenylethyleneglycol, give 1:1 adducts of various stabilities with $PbCl_4$. *Cis*- and *trans*-cyclohexanediol and 2,3-butanediol do not react. / Amer. Chem. Soc. 151st Meeting *1966*, Abstr. K46./Ma. [Rd 494 IE]

**A new general synthesis of 1,2,5-thiadiazoles** is described by *L. M. Weinstock, P. Davis, B. Handelsman*, and *R. Tull*. Compounds containing an acyclic N—C—C—N group, such as α,β-diamines, α-amino-amides, α-amino-amidines, α-amino-nitriles, cyanoformamide, α,β-dioximes, and dicyanogen, react with $S_2Cl_2$ or $SCl_2$ in dimethylformamide at room temperature with formation of the 1,2,5-thiadiazole derivatives.

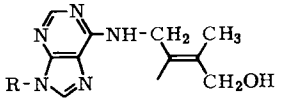


Yields amount to 50—90 %. 1,2,5-Thiadiazole itself can be obtained from ethylenediamine and $S_2Cl_2$. / Tetrahedron Letters *1966*, 1263 / —Ma. [Rd 495 IE]

**2-Diazo-1,1,1-trifluoropropane** *(1)* has been prepared by *R. A. Shepard* and *P. L. Sciaraffa* by several routes, *inter alia*, by oxidation of 1,1,1-trifluoroacetone hydrazone, which is obtained from 1,1,1-trifluoroacetone, hydrazinium dichloride, and sodium acetate. The product *(1)* is intermediate in its reactions between the unstable 2-diazopropane and the stable 2-diazoperfluoropropane. Its solutions are very stable at room temperature but react with acids. The compound is a volatile, orange-red liquid which must be kept at 0 °C since it explodes at room temperature. / J. org. Chemistry *31*, 964 (1966) / —Kr. [Rd 506 IE]

**A sparingly soluble compound of NaCl and racemic 2,3-bis-(*p*-aminophenyl)butane** [1,2-dimethylethylenedi(aniline)] is precipitated from an aqueous solution of the components, according to *N. P. Marullo* and *R. A. Lloyd.* The precipitate, which is considered to be a coordination compound of sodium with a donor nitrogen ligand, melts at 200 °C. It contains three molecules of the diamine per molecule of NaCl. X-Ray analysis and the infrared spectrum are compatible with the assumption that the sodium is surrounded octahedrally by amino groups. The *meso*-isomer of diamine does not give a precipitate with NaCl. The salts NaBr, NaI, $NaNO_3$, and $NaN_3$, but not $Na_2CO_3$, $Na_2SO_4$, $Na_2S$, or $CH_3COONa$, react like NaCl. Some halides of other alkali and alkaline-earth metals are similarly precipitated. / J. Amer. chem. Soc. *88*, 1076 (1966) / –Kr. [Rd 505 IE]

**A synthesis of zeatin** (a factor from maize, similar to kinetin, that activates cell division) has been described by *G. Shaw, B. M. Smallwood,* and *D. V. Wilson.* *trans*-4-Amino-2-methyl-2-buten-1-ol sulfate is treated with 6-(methylthio)- or 6-chloro-purine or with 6-chloro-9-β-D-ribofuranosylpurine in presence of triethylamine in warm butanol, whereby pure zeatin *(1)* or, in the last case, zeatin riboside *(2)* crystallizes out in excellent yield after 1 hr.

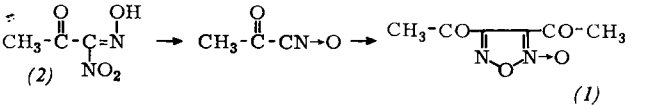


*(1)*, R = H

*(2)*, R = 
The zeatin [6-(4-hydroxy-3-methyl-*trans*-2-butenylamino)-purine], which forms needles (from water), m.p. 207–208 °C, is identical in melting point, mixed melting point, paper and thin-layer chromatography, $^1H$–NMR, mass, and UV spectra, and biological activity with the natural material which is thus unambiguously proved to be the *trans*-form. / J. chem. Soc. (London) (C) *1966*, 921 / –De. [Rd 508 IE]

**Synthesis of tetramethylammonium tetranitratoborate,** $[(CH_3)_4N][B(NO_3)_4]$, was effected by *C. R. Guibert* and *M. D. Marshall.* They mixed tetramethylammonium tetrachloroborate with liquid dinitrogen tetroxide ($N_2O_4$: $BCl_4^- > 8:1$) at –78 °C and allowed the temperature to rise to 0 °C in 2 hr. After removal, at room temperature, of the excess of $N_2O_4$ and the NOCl produced there remained a white residue from which the tetranitratoborate could be extracted with $NH_3$. The structure was proved by, *inter alia*, infrared and $^{11}B$–NMR spectroscopy. The product is stable at room temperature and is neither dissolved nor hydrolysed by cold water, but dissolves in methanol, acetonitrile, or dimethylformamide. Almost complete dissociation into two ions was shown to occur in acetone. / J. Amer. chem. Soc. *88*, 190 (1966) / –Kr. [Rd 482 IE]

**Furazan 2-oxides (furoxans)** have been synthesized by *L. I. Peterson* by reaction of aliphatic or aromatic methyl ketones with dinitrogen tetroxide. Acetone and anhydrous $N_2O_4$ at 0 to 5 °C give an unstable compound that decomposes explosively on attempted distillation and, when heated at 50 °C. slowly decomposes (NO evolution) affording diacetylfuroxan *(1)* as a yellow liquid, b.p. 100 °C/1 Torr (yield 93 %). The reaction presumably proceeds by way of the labile



*(2)* *(1)*

intermediate *(2)* which is transformed into *(1)* by thermal fission and dimerization. Acetophenone and pinacolin can be similarly converted into furoxan derivatives. / Tetrahedron Letters *1966*, 1727 / Ma. [Rd 497 IE]

**Metal/halogen exchange between aryl-metal and aryl-halogen compounds** has been studied by *H. J. S. Winkler* and *H. Winkler.* The ligands in the system

$$ArBr + Ar'Li \rightleftarrows ArLi + Ar'Br \quad (Ar, Ar': \text{aryl})$$

in ether are exchanged at a measurable rate at room temperature. For analysis the mixture is treated with trimethylsilyl chloride, the aryl-lithium yielding the aryltrimethylsilane rapidly and quantitatively. The exchange can be followed by quantitative gas-chromotagraphic analysis. The equilibrium constants, but not the rates of establishment of equilibrium, are largely independent of the medium, added salts, and temperature. Exchange is 100- to 1000-fold faster in tetrahydrofuran than in ether. "Salt-free phenyl-lithium" [from $(C_6H_5)_2Hg + Li$] reacts faster than the "salt-containing" reagent (from $C_6H_5Br + Li$). At equilibrium lithium prefers aryl ligands containing electron-attracting groups. The measured equilibrium constants and known substituent effects σ afforded the reaction constant $\rho = 5.5$. Reaction between phenyl-lithium and substituted bromobenzenes is accelerated by electron-attracting substituents in the bromide ($\rho = 4.0$). Although detailed interpretation of the process is made difficult by aggregation of the aryl-lithium compounds, it can be concluded that the aryl bromides behave as bromonium salts and that the equilibrium constants can serve as a measure of the stability of substituted phenyl anions. / J. Amer. chem. Soc. *88*, 964, 969 (1966) / –Eb. [Rd 500 IE]

# BOOK REVIEWS

**Biochemie der Nebennierenrinden-Hormone** (Biochemistry of the Adrenal Hormones). Monograph in the Series "Biochemie und Klinik". By *H. J. Hübener* and *H. W. Staib.* Georg Thieme Verlag, Stuttgart 1965. 1st Edit., 253 pp., 35 figs., 37 tables, cardboard, 58.– DM (about $ 15.–).

After a description of the chemistry of the steroids, the biosynthesis of steroid hormones is reviewed. The chapter on the control mechanism of adrenal hormone secretions is of particular interest to endocrinologists since it describes, not merely the physiology and therapeutic use of adrenocorticotropic hormone (ACTH), but also the pharmacological influence of the hypophysis-hypothalamus system, the metopiron test, and the biochemical basis of functional disorders of the suprarenal gland. The control of aldosterone secretion, the Conn syndrome, and secondary aldosteronism are reviewed in a separate chapter. The metabolism of the adrenal hormones is reported from the point of view of the enzymology of individual metabolic steps, so that this chapter is of special value to the steroid biochemist. The section on the physiological function of adrenal hormones as enzyme inductors is confined mainly to reproduction of the findings and theories of *H.-J. Hübener* The chemist interested in the development of new corticoids, and the pharmacologist will read the chapter on Synthetic Analogues of Steroid Hormones" with particular interest.

In accord with the aim of the book, therapy by means of adrenal hormones is merely indicated. The steroid analyst will

warmly welcome the detailed description of analytical methods for adrenal hormones.

There are a few printing errors, and some sentences sound unusual to the chemist, but these are only minor blemishes. The book is at once textbook, laboratory guide, and reference work, and with its 1275 literature citations is a rich source of references.

*E. Gerhards* [NB 466/319 IE]

**Stoffwechsel der Galaktose und ihrer Derivate.** (Metabolism of Galactose and its Derivatives). From the series "Biochemie und Klinik". By *W. Fischer* and *H. Weinland.* Edited by *G. Weitzel* and *N. Zöllner.* Georg Thieme Verlag, Stuttgart 1965. 1st Edit., xii + 256 pp., 51 figs., 82 tables, cardboard DM 59.– (about $14.50).

Anyone who does not already know it will be convinced by reading this book that galactose is one of the most widely distributed constituents of living systems. It is a component of the oligosaccharides that occur in high concentration in the capillary fluids of plants and are responsible for transport of the products of assimilation from the leaves to those parts of the plant that do not assimilate. It is a component of the cell walls and membranes of the most varied organisms. It contributes to the formation of cerebrosides and gangliosides, and as galactolipids constitutes a notable proportion of the lipid fraction of green leaves. Also it plays an almost unique role as a constituent of lactose in the milk of mammals. Its importance is evident also from the dynamics of formation and decomposition of galactose-containing compounds. On infusion into the circulation it is resorbed much faster than any other monosaccharide, and as a component of the lipid fraction of green algae it is the fraction that takes up radioactivity from $^{14}CO_2$ fastest and to the greatest extent. The great importance of galactose metabolism in man is shown by the catastrophic results that follow a defect in the enzyme system responsible for utilization of galactose in the suckling (galactosemia).

All these and many other aspects of the metabolism of galactose and galactose-containing compounds are carefully and comprehensively reviewed and discussed in the present book. There are more than 3000 references, partly extending to 1965. Thus this book will be most warmly welcomed by all who work in this field or might like to do so: it will save them much literature searching; and in particular it is a rich source for the less accessible, older literature that is often forgotten.

If the reviewer were asked how an ideal book on galactose would differ from the present one, the following points would arise. 1. It would not contain linear projections for all structural formulae of sugars, as these give no indication of reactivity 2. It would have a chapter on the detection and determination of galactose, galactose derivatives, and galactose-affecting enzymes. There is, it is true, a reference, in two lines of small type to an enzymic method of determining galactose, but paper- and gas-chromatographic analysis are not mentioned, nor is diagnosis of galactosemia or determination of galactose loading. 3. The ideal book would lay less emphasis on some statements from the literature, just because of its greater emphasis on analytical aspects. For instance, it depends on the method of determination whether or not free galactose is "completely absent" from blood on failing exogenic addition. The high content in *Forsythia* pollen mentioned in "Occurrence of Lactose in Plants" has been found to be erroneous [Chem. Ber. *93*, 1009 (1960)], fission of *O*-methylated galactosides by galactosidase depending on the nature of the aglycone. The tables showing acceleration of mutarotation by mutarotases are useless without statement of the experimental conditions and the quantities of enzymes. Some rules can be laid down for acceptor specificity in transfer reactions, and in the framework of induction of the lac-operon of *E. coli* there is a biological meaning to the transgalactosidation, lactose → allolactose – at least in the coli bacterium. In sum, however, this monograph is to be rated a valuable addition to the literature.

*K. Wallenfels* [NB 472/325 IE]

**Lignin Biochemistry.** By *W. J. Schubert.* Academic Press, New York-London 1965. ix + 131 pp., 17 figs., 26 tables, linen $8.–.

The size of this little monograph is already enough to show that it provides only a somewhat superficial discussion of its subject. The value of the book residues in the fact that it is primarily a review of the numerous contributions made to the biochemistry of lignin from the Laboratories of Organic Chemistry and Enzymology of the Fordham University in New York which endeavors to show how these results fit into the overall picture of the current knowledge of lignification and its associated phenomena. This approach is necessarily accompanied by limitation of the extent to which the work of other groups is evaluated, if at all, and consequently irregularities in the overall perspective may result. The user of the book who is not a thorough expert in this field must bear this in mind, otherwise he may obtain only a somewhat incomplete and slightly distorted picture of the present status of knowledge on the processes of lignification. For instance, there is no mention of the numerous studies of lignification that have been carried out with plant tissue cultures, whereas the metabolism of methyl *p*-methoxycinnamate in a single microorganism is discussed at length, even though this has no direct connection with lignification.

The text is divided into four main sections: a short introduction to the chemistry of lignin (37 pp.), a description of the biogenesis of aromatic compounds in microorganisms (12 pp.) because of its significance for the corresponding processes in higher plants (described on 20 pp.), and a discourse on the microbiological degradation of lignin. The treatment is concise and readily understandable throughout. A subject index with about 450 entries and an author index containing about 270 names combine with the attractively presented formulae to make a most useable volume.

*J. M. Harkin* [NB 482 IE]

**Conformation Theory.** By *M. Hanack.* Transl. from the German manuscript by *H. C. Neumann.* Vol. 3. Organic Chemistry, a Series of Monographs[1]. Edited by *A. T. Blomquist.* Academic Press, New York-London 1965. 1st Edit., ix + 382 pp., numerous figs. and tables, bound $14.50.

Evidently there is a need for textbooks and monographs giving a comprehensive survey of the development of organic stereochemistry, for after a long period of quiet there now appear numerous books concerned with this subject at various levels. One of the most important recent advances in stereochemistry is the widespread and logical use of the concept of conformation, with the theoretical prediction and the experimental determination of the properties of the different conformations of a molecule that are termed conformational analysis.

"Conformational Analysis", the comprehensive monograph by *E. L. Eliel, N. L. Allinger, S. J. Angyal,* and *G. A. Morrison,* and the present book, "Conformation Theory"[2] by *Hanack* have been published within a short interval.

In a field that is in rapid development it is no simple task to keep a due proportion between the importance and the quantity of the material discussed, and it is interesting to compare these two new books on conformations in this respect. *Hanack's* book is less comprehensive and goes less deep than that of *Eliel et al.* and will be preferred mainly by those or-

[1] Cf. Angew. Chem. *73*, 304 (1961).

[2] This title seems unfortunate, for there is no question of a theory here.

ganic chemists who, without much previous knowledge, wish to learn from the beginning about conformational analysis.

Two of the eight chapters are devoted to a short general introduction to stereochemistry, four treat in detail the conformations of alicyclic and one each the conformations of heterocyclic and aliphatic compounds.

The numerous references (some even up to 1964) will help those who wish to form their own opinion about this field, which is of the utmost importance in many areas of organic chemistry.

*V. Prelog* [NB 489a IE]

**Fundamentals of Carbanion Chemistry.** By *D. J. Cram.* Organic Chemistry – A Series of Monographs. Edited by *A. T. Blomquist.* Vol. 4. Academic Press, New York-London 1965. 1st edit., viii + 289 pp., numerous figs. and tables, bound, $ 9.50.

In spite of the apparent antipodal relation between carbanions and carbonium ions, carbanion chemistry is much less well defined and is much younger than carbonium ion chemistry as a field of work in its own right within organic chemistry. To carbanion chemistry belong molecules whose negative charge lies mainly or wholly on carbon. It includes therefore above all the chemistry of organic derivatives of the alkali metals, and extension of the acid-base concept to other carbon acids than the classical "active methylene compounds". Since there is no comprehensive treatment of this heterogeneous, rapidly developing field, one is eager to turn to *Cram*'s book.

The critical survey of the thermodynamic and kinetic acidity of carbon acids given in the first section is so good that it alone would justify purchase of this book. A discussion of the structure and stability of carbanions is followed by three chapters on the stereochemistry of carbanions and electrophilic substitution reactions, which make up half of the book. Their center of interest is the author's own fundamental work in this field. The conclusion is a racily written, brief summary of molecular rearrangements that proceed by way of carbanions.

Perusal of this monograph is strongly recommended to all who are interested in reaction mechanism. The author's repute is guarantee for a competent and clear treatment of the material. However, the book has some regrettable gaps. Important papers on the stereochemistry of simple carbanions are omitted and there is no mention of, for instance, the class of high acidic hydrocarbons or of radical ions. Work on organic compounds of the alkali metals, which is of such supreme importance to carbanion chemistry, is mentioned only in passing, showing the almost complete failure to evaluate, in particular, the German literature, and without that a standard textbook of carbanion chemistry would be unthinkable. This does not diminish the value of *Cram*'s book; it is indeed questionable whether a comprehensive text on the whole topic can yet (or still) be written. The reader lays down the book with the wish that an equally good one on other aspects of carbanion chemistry were available.

*G. Köbrich* [NB 489b IE]

**Symmetry in Chemistry.** By *H. H. Jaffé* and *M. Orchin.* John Wilev & Sons, Inc., New York-London-Sydney 1965. 1st edit., x + 191 pp., several figs. and tables, bound, £2.2.–, paperback £1.10.– (about $ 6.– and $ 4.20).

A few years ago there was a dearth of textbooks on group theory that presented this field in a way suitable for chemists or molecular physicists, but today there is a large choice of such books. *Jaffé* and *Orchin*'s monograph is distinguished by the simplicity of the presentation

After a lightly philosophical introduction on "Symmetry and Beauty" the authors introduce the terms symmetry operations, multiplication of symmetry operations, symmetry groups, and symmetry species clearly and convincingly with the aid of examples familiar to chemists. Although it is a good idea to try an essentially non-mathematical treatment it does not seem possible to follow this idea to the end. Reference to "reducible" and "irreducible representation" is avoided as long as possible; therefore arguments in which these terms are nevertheless needed are not very convincing.

A reader who is not interested in mathematics and in understanding symmetry thoroughly, but who rather wants to get an idea of how group theory can be used in practice, will probably appreciate this book more than others on the same topic.

*W. Kutzelnigg* [NB 491 IE]

**Quantum Mechanics in Chemistry.** By *M. W. Hanna.* W. A. Benjamin, Inc., New York-Amsterdam 1965. 1st Edit., 253 pp., numerous figs. and tables, paperback $ 4.35, bound $ 7.70.

This book is intended for undergraduates.

Mathematical methods and concepts that go beyond school mathematics but are essential for an understanding of modern theoretical chemistry are presented clearly and intelligibly in an introductory chapter. The fundamentals of quantum theory are introduced axiomatically. It is didactically wise to treat rotations and vibrations of molecules as the first applications of quantum mechanics, and only thereafter the electronic structure of atoms and the theory of the chemical bond. Therefore the book can be recommended also – and in fact particularly – as an introduction to molecular spectroscopy.

The author is concerned mainly with defining the fundamental concepts precisely and in an understandable way. The mathematical formulations are compact and conform to international usage. The reader is not embarassed with lengthy derivations. The well chosen problems allow him to find the easier proofs himself, whereas for more complicated ones he finds references to more detailed monographs. Each chapter has a summary.

One should not expect from a textbook intended for beginners a survey of quantum chemistry. In fact it offers the minimum of what a modern chemist should know about quantum mechanics. It is recommended particularly for those young students who do not mind some mathematics and are ready, not just to read a textbook, but to study it carefully.

The printing is agreeable and clearly arranged. The only error the reviewer found is the value of 1.37 Å instead of 1.06 Å for the equilibrium distance in $H_2^+$.

*W. Kutzelnigg* [NB 492 IE]

**Chemistry of the Iron Group Metallocenes: Ferrocene, Ruthenocene, Osmocene.** Part I. By *M. Rosenblum.* Interscience Publishers, New York-London-Sydney 1965. 1st Edit., xv + 241 pp., numerous figs., bound, £4.15.–.

The development of the chemistry of organometallic compounds during the last ten years justifies the metaphor "explosive". Consequently an attempt at a new edition of a book such as *E. Krause* and *A. von Grosse*'s "Die Chemie der metallorganischen Verbindungen", which contained all the metallorganic compounds known in 1937, would appear utopian. Interscience Publishers have now begun to cover the most important sections of organometallic chemistry by a series of monographs edited by *D. Seyferth.* The first of these is devoted to the metallocenes of the iron group, with particular emphasis on ferrocene as the prototype of dicyclopentadienylmetal compounds.

The first three chapters of present volume deal with the preparation, electronic structure, bonding, and physical properties of metallocenes. The bonding, which has in the past been the subject of controversial discussion, is purposely not treated in full detail; only the important results based on MO treatment are presented. Chapters 4, 5, and 6 deal with the acyl-, alkyl-, and aryl-metallocenes that were obtained by replacement of ring protons, their preparation illustrating

also the reactivity of the starting materials $M(C_5H_5)_2$ (M = Fe, Ru, or Os). The mechanisms of the replacement reactions are discussed in detail, whereby attention is directed to the problem of the "aromatic character of metallocenes". At the end of each of these chapters all the known derivatives and their most important properties are tabulated.

The author has contributed to the development of this field from its very beginnings. He has managed to extract what is most worthwhile from more than 1000 papers and he has given fair consideration to the contributions of the various schools. The literature is almost completely covered up to the middle of 1963, and many results are included that had not then been published. The outward appearance of the book is very pleasing but it is unfortunate that some misprints have escaped correction.

The reviewer hopes that the second Part will turn out as well as the present Part I, so that there will then be a standard work on the chemistry of the metallocenes of the iron group.

*H. Werner* [NB 486 IE]

**The Chemistry of the Vitamins.** By *S. F. Dyke*. J. Wiley & Sons Ltd., London-New York-Sydney 1965. 1st Edit., 363 pp., several figs., bound, £3.7.–.

This book is the sixth in the series "The Chemistry of Natural Products" edited by *K. W. Bentley*. It treats the well-known vitamins or vitamin groups, and in particular the elucidation of their structures and their synthesis. It describes also relations between structure and activity of the vitamins, and their biosynthesis and biological function, but not their isolation which is often so troublesome and in which the natural products chemist would probably be interested. The material is arranged in a useful and clear manner; understanding is facilitated by the numerous formulae and figures. At a first, superficial examination one is glad to have found a short introduction that may be useful for lectures and for student use. Closer scrutiny shows, however, that the book is not intended as an introduction or a textbook. It contains mainly references to original papers, including some from the previous century, and it is not clear to the reader on what basis they were chosen. Wherever the chemistry (determination of structure and synthesis) of the vitamins is complete, citation of an appropriate review would have sufficed. On the other hand there are very few references to papers later than 1960: the reader is given the impression that the chemistry of the vitamins came to a standstill in that year. No indication is given of the aims of present-day vitamin chemistry or of the properties and reactivity of vitamins in the molecular-biological sense. So one is left in the dark as to the audience for which the book is intended. Further, the subject matter overlaps extensively with that of "Vitamins and Coenzymes" by *A. F. Wagner* and *K. Folkers* which was published a year previously.

*K. Bernhauer* [NB 485 IE]

**Constantes Sélectionnées Pouvoir Rotatoire Naturel** (Selected Values of Optical Rotatory Power). By *J. Jacques, H. Kagan, G. Ourisson*, and *S. Allard*. Tables de Constantes et Données Numériques. No. 14. Ia. Stéroïdes. Pergamon Press, Oxford-Paris 1965. 1st Edit., 1031 pp., about $54.

In 1956 there appeared the first collection of specific rotations of about 8000 steroids included in the literature up to 1952. In the present volume the literature is covered up to 1960 inclusive, and data are given for more than 21000 steroids. This, incidentally, provides an impressive picture of the growth of the literature in this field.

The introduction, in French and English, describes in readily intelligible form the arrangement adopted and the nomenclature. The recommendations of the IUPAC Nomenclature Commission for Steroids have been followed strictly, with extensions, where necessary, in the same spirit. In the main part of the work the compounds are arranged according to molecular formula, and the systematic name (French), melting point, and molecular weight follow. For each substance the specific rotation, conditions of measurement (wavelength, temperature, concentration, and solvent) are then given, with references. The list of references is very clearly arranged according to year and journal at the end of the Tables. An author index and an alphabetic index of substances, including all the trivial names, close this comprehensive volume. Skilful arrangement of the tables and indexes make it a simple matter to find any required compound in spite of the new systematic and often unfamiliar names used.

The specific rotations are generally given as averages of the published data, together with their range of variation. In this respect the literature is considered critically and the less certain values are designated as such. Revised formulae are included up to 1963 inclusive, and occasionally the authors themselves suggest new structures on the basis of the specific rotations. This, of course, admits the danger of correct formulae being changed, *e.g.* because of an erroneous measurement or a misprint in the original paper. Restriction of space prevented curves or table of optical rotatory dispersion from being reproduced, but when such measurements exist the appropriate paper is cited. Such citations are often as "personal communications"; presumably, however, these data have meanwhile all been published.

A comprehensive set of tables such as this is of value only if truly complete and essentially free from error. As a test the reviewer undertook a large number (about 50) of random tests. As luck hat it, in the first case a page number was wrong, in the second a reference was missing and in the third an incorrect reference was given – but all the others were correct. One cannot but admire the authors' achievement in not merely providing a complete collection of the published [α] values for the steroid field but also, as a by-product as it were, an excellent review of the literature for most of the steroids recorded to date. Since the specific rotation is often a better criterion than the melting point it is cited by almost all authors. Instead of searching several Collective Indexes of Chemisches Zentralblatt or Chemical Abstracts for a particular compound one can use these tables to cover at least 95 % of the literature up to 1960. In this connection it is particularly valuable that the derivatives are listed immediately after the parent compound in the alphabetical index.

The "Pouvoir Rotatoire Natural" is thus of the greatest value to steroid chemists, not merely because of the specific rotations collected therein, but also especially as a source of references. This fact justifies the very high price; though this price will certainly prevent very wide distribution, each group of steroid chemists, at least, should possess a copy of this standard work; the saving in time as a source of references will soon have reimbursed the cost.

*G. Snatzke* [NB 484 IE]

**Condensation Polymers: By Interfacial and Solution Methods.** By *P. W. Morgan*. John Wiley & Sons, New York-London-Sydney 1965. 1st Edit., xviii + 561 pp., numerous figs., several tables, bound, £9.10.–.

*Paul W. Morgan*'s book is the tenth volume of a series on polymers edited by *H. F. Mark* and *E. H. Immergut*. Its aim is to present an up-to-date review of polymer chemistry. The author has limited his treatment to condensation polymerization and has collected his material under several main headings. First he treats polycondensation methods which below 100 °C generally lead to linear polymers and in which the components react at an interface. The preparation of polyamides, polyureas, polyurethanes, polysulfonamides, polyphosphonamides, and polyesters is described in detail.

The preparative procedures are accompanied by very clear descriptions of the unusual properties of the products obtained by interfacial-polymerization and these are compared, where appropriate, with polymers obtained in the classical way. Noteworthy is the large number of monomers that the author describes as suitable for low-temperature condensation.

*Morgan* makes little use of mathematics; evidently low-temperature polycondensation has so far been studied mainly in a qualitative way. Presumably future investigations will be concerned above all with mathematical treatment of these relatively simple polymerization systems.

The author's aim to acquaint the reader with both the methods and the products of polycondensation at low temperatures can be considered completely successful. Moreover, more than 1000 references help to introduce the beginner to the field and the specialist to orient himself more quickly – the more so as the literature is considered up to 1965.

This volume is a valuable enrichment of the literature for all polymer chemists.

*R. Zimmermann* [NB 483 IE]

**Einheitliche Schreibweise in naturwissenschaftlichen Werken** [Uniform Spelling in (German) Scientific Writing]. By *R. Herrmann*. Neumann Verlag, Radebeul 1965. 2nd Edit., 148 pp., linen, DM 14.– (about $3.50).

The first edition of this book appeared in 1957. Particularly its first part "Spelling, Nomenclature, and Technical Terms") was at that time strongly criticized [1]. The same criticisms apply to the second edition. As before, we are presented with "Ribonucleinsäurenucleotid"; as before, the formula of D-glyceraldehyde is ascribed to the L-compound and *vice versa*; as before, the entries are listed at random in the singular or the plural. The statement about the revised spelling "Oxid" is attached to the word "Oxycain" (probably the author himself could not say why) and ingeniously remarks that this spelling applies only in inorganic chemistry. The principle on which the choice of entries is based remains obscure, but meeting words such as "50-ml-Becherglas", "Citrone" [*sic*!], and "Collapsus" indicates that it must have been a very amusing principle. Incidentally, is it not remarkable that although one is told to write "Cytochrom", one must also write "Zytochromoxydase"?

[1] Cf. Angew. Chem. *72*, 146 (1960).

The list of criticisms could be extended. But since this would presumably not prevent the issue of a third edition with the same defects, a warning will suffice. It is not worthwhile buying this book, even though the publishers describe it as "essential".

*H. Grünewald* [NB 487 IE]

**Titrations in Non-Aqueous Solvents.** By *J. Kucharsky* and *L. Šafařik*. Elsevier Publishing Company, Amsterdam-London-New York 1965. xi + 286 pp., 29 figs., 33 tables, linen DM 39.– (about $ 9.50).

This volume is an expanded English edition of the Czech edition published in 1961. It is written by analysts for chemists working in analytical laboratories, with the emphasis strongly on acid-base titrations in non-aqueous media. Redox titrations and titrimetric determinations of equivalent weights of some classes of compound are treated, but only to a very modest extent. The authors devote about 40 pages to an introduction into the theory of acid-base equilibria and the influence of the solvent. To this theoretical preface is added a more practical part dealing with solvents, determination of end points, media for titration, acidimetric standards, techniques of titration, and titration of various classes of compound. Here, however, more recent theoretical aspects are missing: for instance the discussion of curves obtained on titration in acetic acid and of the effect of water on them does not mention the fundamental and generally recognized papers by *Kolthoff* and *Bruckenstein*.

A comprehensive chapter (more than 100 pages) on acid-base titrations of 21 classes of compound forms the nucleus of the book and is particularly valuable in that it contains procedures that have been tested in the authors' laboratories. The literature cited in this and other chapters is complete up to 1963.

This book will interest mainly the analytical chemist and will be of value to him in his daily work.

# Electron Pyrolysis, a New Method of Organic Microanalysis

BY PROF. H. SCHILDKNECHT
BASED ON STUDIES BY DR. F. ENZMANN, K. GESSNER, K. PENZIEN, F. RÖMER, AND DR. O. VOLKERT

ORGANISCH-CHEMISCHES INSTITUT, UNIVERSITÄT HEIDELBERG (GERMANY)

*Organic compounds incubated with tritiated water of specific activity 5 Ci/ml are specifically fragmented. The β-active fragments can be detected in very small quantities by chromatographic separation. Chemical identification of these fragments provides information about the original compounds, as has been shown by experiments with amino acids, esters, lactones, amides, quinones, terpenes, nitrogen-sulfur heterocycles, and natural products.*

## 1. Introduction

"The object and the chief aim of all chemistry is skilfully to break down substances into their components, to discover their properties, and to combine them in various ways". With these words, *Scheele* placed analysis in the forefront of all the chemist's activities.

The earliest method used to decompose organic substances was simply to heat them, *i.e.* to *pyrolyse* them. Several methods are now known to supply the energy leading to cleavage of chemical bonds. Thus we observed that β-resorcylic acid is decarboxylated not only when heated at 150 °C, but also at room temperature in tritiated water. We called this process *Elektronenbrenzen* ("electron pyrolysis") [1]; it was not known at that time that often not only the β-radiation, but also the water itself or its radiolysis products, such as hydrated electrons or OH-radicals [2], can be of use in the fragmentation. However, we were aware of the fact that the unavoidable labeling with tritium greatly facilitates detection of fragments formed only in traces, and is often the only means of detection.

Succinic acid also is decarboxylated on electron pyrolysis, forming tritium-labeled propionic acid [3]. Decarboxylation of mandelic acid yielded benzaldehyde as a result of the oxidation of the initially formed benzyl alcohol by the oxidizing components of the tritiated water. The formation of n-hexanal from n-hexanol and of cyclohexanone from cyclohexanol in tritiated water confirmed this assumption. All carbonyl compounds could be detected as active 2,4-dinitrophenylhydrazones. At the beginning of our investigations we could thus already define electron pyrolysis as the breakdown of organic molecules into smaller, readily detectable complementary fragments involving reduction, oxidation, and labeling.

It was still necessary to determine whether it is possible to establish fragmentation rules by means of which a structure could be suggested on the basis of the fragments obtained. This question can now be partly answered in the affirmative, though many investigations will still be necessary to make electron pyrolysis a generally useful method for the elucidation of the structures of organic compounds.

## 2. Experimental Procedure

Samples varying in size from a few μg to several mg are sealed in glass tubes some 5 cm long and having an internal diameter of 3 mm, together with 2.5 to 50 mg of tritiated water of specific activity 5 Ci/ml. The solution or suspension is left at or above room temperature for several days to a few weeks, until the contents of the tube become discolored. The products are separated chromatographically.

In thin-layer chromatography, the fractions are recorded by means of a thin-layer scanner, and in gas chromatography by a flow detector. This gives activity curves which resemble spectra, the bands of which can often be assigned to chemi-

[1] *H. Schildknecht*, Kerntechnik *6*, 249 (1964). We suggest the application of the German term *Elektronenbrenzen* in English as well, rather than "electron pyrolysis" or "fragmentation by electron impact".

[2] Basic Mechanisms in the Radiation Chemistry of Aqueous Media, Radiat. Res. Suppl. *4*, 1–217 (1964).

[3] *H. Schildknecht* and *O. Volkert*, Z. analyt. Chem. *216*, 97 (1966).

cally identifiable products. We have, therefore, included the thin-layer chromatographic distribution of the fragments in each figure showing "electron pyrolysis spectra". This shows which fragments were detected chemically and which were detected only on the basis of their radioactivity or of their fluorescence. The tritiated fragments were also identified in every case by comparative thin-layer chromatography on Kieselgel G plates, using at least three different solvent systems. The active spots were eluted from the plate and chromatographed once more, and in most cases the ultraviolet and infrared absorption spectra of the eluted compound were determined.

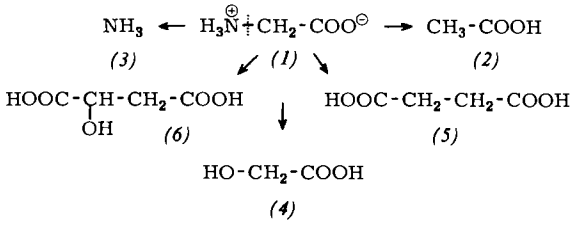
Electron pyrolysis with tritium gas is carried out as follows:

As a precaution the tritium is bound to uranium powder. Uranium hydride is decomposed at 450 °C and $10^{-3}$ mm Hg to hydrogen and uranium powder. The tritium gas (3 Ci, 97.7 %) is adsorbed on the latter at room temperature; it is regenerated as needed at 450 °C. The tritium is pumped into a reaction vessel (5 ml) containing the substance to be analysed. The powdered sample is continuously stirred in the dark with a glass-coated magnetic wire.

## 3. Electron Pyrolysis of Known Compounds

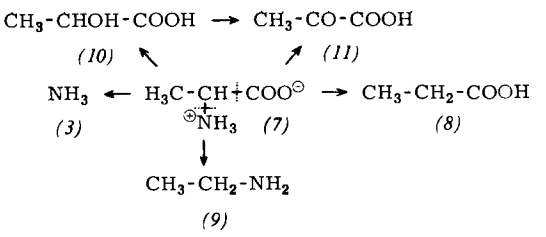
### 3.1. Electron Pyrolysis of Amino Acids [4]

In the electron pyrolysis of glycine *(1)* we obtained only two products, formed by simple cleavage of bonds with no secondary reactions. In the paper radiochromatogram we found the ammonium salt of acetic acid, which was used as an eluent, and in another chromatogram acetic acid *(2)*. Here and in subsequent electron pyrolysis schemes, the bonds which are broken are indicated by dotted lines. No indication is given that part of the hydrogen in all compounds is replaced



by tritium. This labeling is a direct result of the saturation of the $\cdot CH_2-CO_2H$ radical with tritium atoms. OH (OT) radicals also can react with $\cdot CH_2-CO_2H$, as is shown by the formation of glycolic acid *(4)* and malic acid *(6)*. In agreement with literature reports [5] on the radiolysis of organic compounds in water with $\gamma$-rays, the formation of succinic acid *(5)* can be explained only on the basis of intermediate free-radical fragments.

In view of these results on glycine, we were not surprised to find lactic acid *(10)* and pyruvic acid *(11)* on chromatographic analysis of the solution obtained on electron pyrolysis of alanine *(7)*. According to *Garrison* [5], OH radicals are also involved in the radiolytic formation



of pyruvic acid; however, *(11)* may also be formed directly from *(10)*. As can be seen from the thin-layer radio-chromatogram (Fig. 1), the main product apart

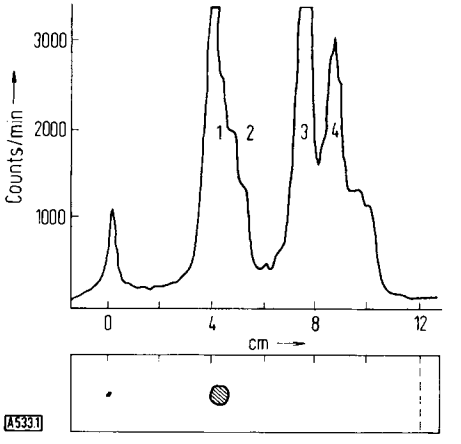


Fig. 1. Thin-layer radio-chromatogram of the solution obtained on electron pyrolysis of 5 µg of alanine *(7)*. Solvent system: ethanol/$NH_3$/$H_2O$ (80:4:16 v/v).

1, alanine *(7)*; 2, lactic acid *(10)*; 3, propionic acid *(8)* + pyruvic acid *(11)*; 4, alanine ethyl ester.

from *(11)* was propionic acid *(8)*. The cleavage of the C–N bond is understandable in view of the fact that in amino acids in solution, the distance between the protonated N atom and the C atom is 1.50 Å, as compared with the normal value of 1.32 Å [6]. Thus the C–N bond is weakened in the zwitterion. If the compound is not in the form of the zwitterion, as in the gas

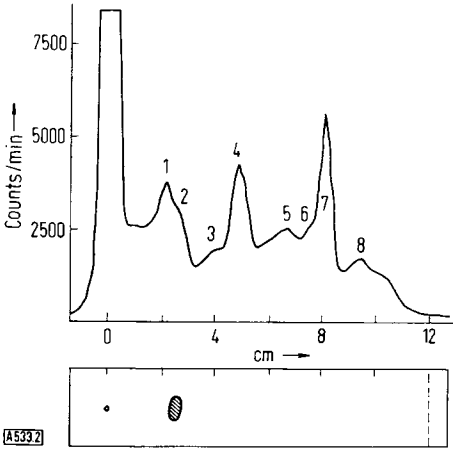

Fig. 2. Thin-layer radio-chromatogram of the solution obtained on electron pyrolysis of 5 µg of aspartic acid *(12)*. Solvent system: ethanol/$NH_3$ (7:3 v/v).

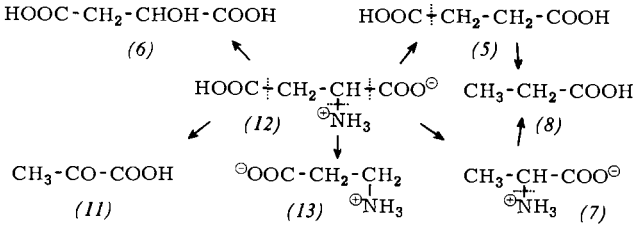
1, malic acid *(6)*; 2, aspartic acid *(12)*; 3, succinic acid *(5)*; 4, β-aminopropionic acid *(13)*; 5, alanine *(7)*; 6, propionic acid *(8)*; 7, pyruvic acid *(11)*; 8, diethyl aspartate.

[4] *K. Geßner*, Diploma Thesis, Universität Heidelberg, 1966.
[5] *W. M. Garrison*, Radiat. Res. Supp. *4*, 158, (1964).
[6] *R. B. Corey* and *J. Donohue*, J. Amer. chem. Soc. *72*, 2899 (1950).

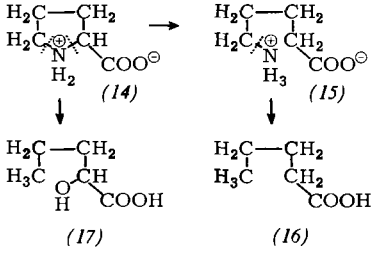
phase in the mass spectrometer, cleavage occurs preferentially in the next-weaker C–CO bond [7]. However, decarboxylation with formation of ethylamine *(9)* can also be observed to a minor extent in solution.

Decarboxylation is particularly pronounced in the electron pyrolysis of aspartic acid *(12)*. As can be seen from the corresponding thin-layer radio-chromatogram (Fig. 2), alanine *(7)*, β-aminopropionic acid *(13)*, and propionic acid *(8)* could be unambiguously detected even when *(12)* was simply allowed to stand at room temperature with tritiated water. This result emphasizes clearly the specific action of the tritiated water.

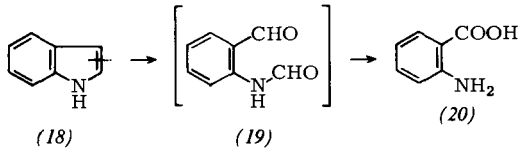
The products again contained succinic acid *(5)*, formed by reductive deamination, and propionic acid *(8)*, formed from the succinic acid, while malic acid *(6)* and pyruvic acid *(11)* were formed by oxidation; *(8)* may have been formed also from *(7)*.



In the electron pyrolysis of proline *(14)*, the ring was opened in a particularly simple manner, and *(14)* was degraded to valeric acid *(16)*. Activity measurements showed that the yields were lower than in the pyrolysis



of alanine *(7)*. The compounds containing 5-membered rings (as is also shown in mass spectrometry [8]) are probably more stable than open-chain compounds, or else chain degradation may be preceded by hydrolytic ring cleavage. Thus tryptophan *(21)* is degraded slightly to indole *(18)* when simply heated with water. The electron pyrolysis of *(21)* also leads to the formation of *(18)*, which, when itself pyrolized, gives anthranilic acid *(20)*, probably *via (19)*.



This fragmentation is quite unimportant in the electron pyrolysis of tryptophan *(21)*, since according to the thin-layer radiochromatogram (Fig. 3), relatively many primary cleavage products are formed.

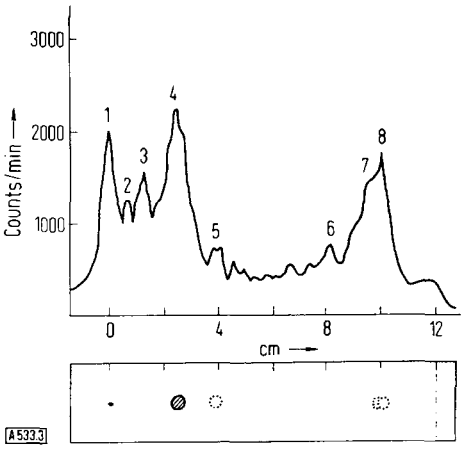


Fig. 3. Thin-layer radio-chromatogram of the solution obtained on electron pyrolysis of 10 μg of tryptophan *(21)*. Solvent system: butanol/$NH_3$ (7:3 v/v).

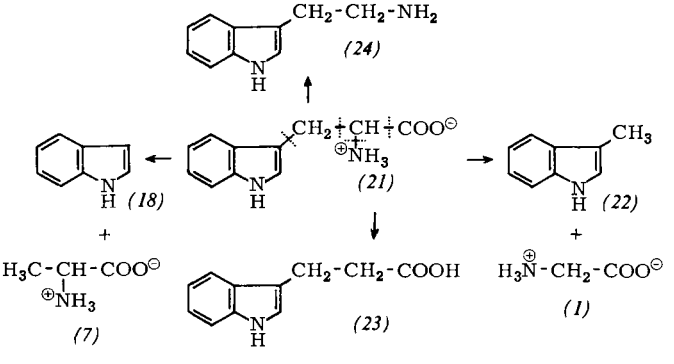
1, starting peak; 2, glycine *(1)*; 3, alanine *(7)*; 4, tryptophan *(21)*; 5, 3-indolyl-β-propionic acid *(23)*; 6, tryptamine *(24)*; 7, indole *(18)*; 8, skatole *(22)*.

Radiolysis of *(21)* with X-rays [9] also yields several cleavage products resulting from decarboxylation and changes in the carbon skeleton. No deamination is found, as on mass spectrometry [8]; the strongest mass peak occurs at $m/e = 130$, suggesting that fragmentation tends to stop at the skatole *(22)* stage. The same result is found in electron pyrolysis, where the greatest activity, apart from the band for the starting material *(21)*, was obtained for the skatole fraction. The complementary fragment, glycine *(1)*, was also found. The structure of the starting material can, however, be deduced from the fragments *(18)* and *(7)*, as well as from the above fragments.



As in the case of tryptophan *(21)*, we obtained indole *(18)* and skatole *(22)* as well as acetic acid in the electron pyrolysis of the growth hormone 3-indoleacetic acid.

### 3.2. Electron Pyrolysis of Esters, Lactones, and Amides [10]

The principal product in the electron pyrolysis of benzyl benzoate was benzoic acid which, like the former, was strongly labeled, but which could not be detected

[7] *G. Junk* and *H. Svec*, J. Amer. chem. Soc. *85*, 839 (1963).
[8] *K. Biemann*: Mass Spectrometry. McGraw-Hill, New York 1962, pp. 260–296.
[9] *G. Peter* and *B. Rajewsky*, Z. Naturforsch. *18b*, 110 (1963).
[10] *H. Schildknecht* and *F. Enzmann*, Z. analyt. Chem., in press.

chemically on the thin layer either with Bromocresol Purple or with Bromophenol Blue. *p*-Hydroxybenzoic acid was formed in addition, though this was naturally absent when tritium gas was used instead of tritiated water; benzaldehyde, on the other hand, was formed in both cases. Owing to the high radioactivities of the fragments, it was possible to characterize as little as 0.1 μg of benzyl benzoate.

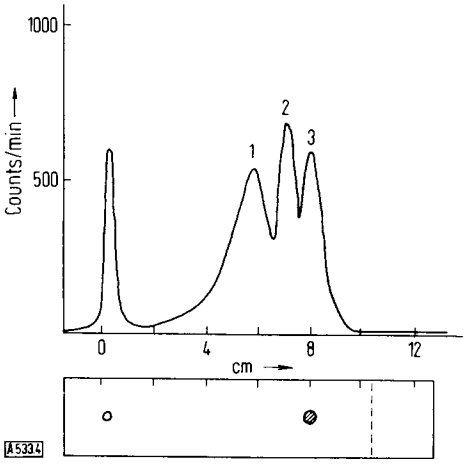


Fig. 4. Thin-layer radio-chromatogram of the electron pyrolysis products of 4 μg of benzyl benzoate in tritium gas. Solvent system: benzene/dioxane/glacial acetic acid (90:25:4 v/v).

1, benzoic acid; 2, benzaldehyde; 3, benzyl benzoate.

In the formulation of the radiolytic reaction, it is conceivable that the O-benzyl bond is broken, in agreement with considerations by *McLachlan*[11,12] and with *Emery*'s mass-spectrometric results[13], but this does not explain the high activity of the benzoic acid. It could be due to labeling in the phenyl nucleus, which could in turn point to the presence of a resonance-stabilized benzoyl radical. The radical combines with hydrogen to form benzaldehyde, which is partly oxidized to benzoic acid by the oxygen in the tritium gas.

The electron pyrolysis of phenyl salicylate in tritiated water or tritium gas yields salicylic acid, and phenol has also been detected. The acid is evidently not formed by hydrolysis, but by nucleophilic displacement at the C=O carbon atom by thermal electrons.

Attempted electron pyrolysis of dibenzyl succinate under the above conditions was unsuccessful at first. The radio-chromatogram shown in Figure 5 was obtained only after the addition of uranium dioxide powder to the reaction mixture. The ester was then degraded, *via* succinic acid, to propionic acid or benzyl propionate. The benzyl group again gave benzaldehyde, which could be detected as the 2,4-dinitrophenylhydrazone.

The large number of fragments formed in the electron pyrolysis of tributyrin *(25)* with tritiated water can be seen from Figure 6. A surprising feature is that the butyric acid residue is degraded primarily to the acetic acid residue, as is shown in the following scheme.

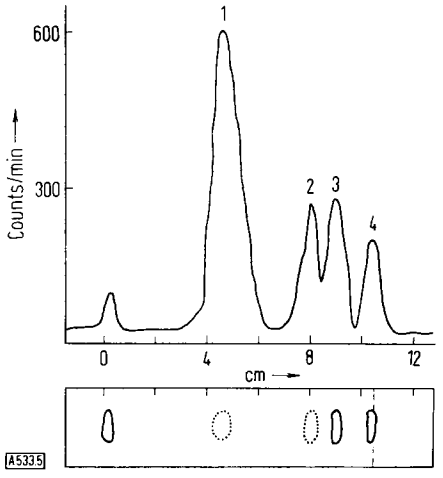

Fig. 5. Thin-layer radio-chromatogram of the solution obtained on electron pyrolysis of 5 μg of dibenzyl succinate in tritiated water with added $UO_2$. Solvent system: ethanol/ammonia/water (100:16:12 v/v).

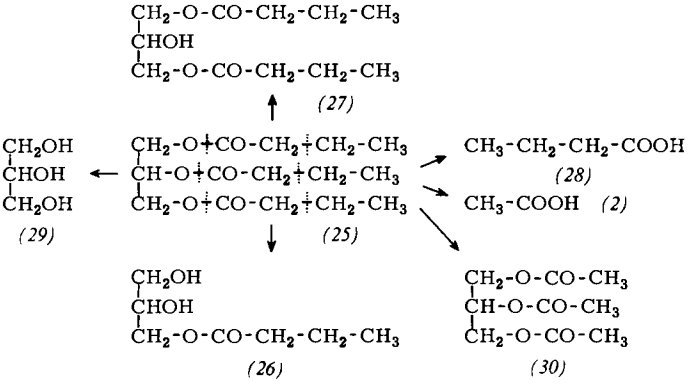
1, succinic acid; 2, propionic acid; 3, dibenzyl succinate; 4, benzyl propionate.



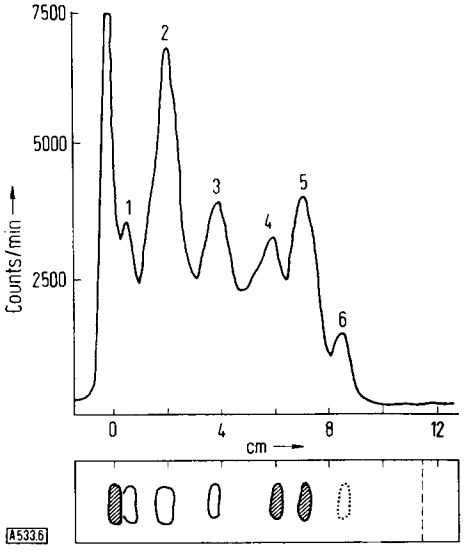


Fig. 6. Thin-layer radio-chromatogram of the solution obtained on electron pyrolysis of 10 μg of tributyrin *(25)*. Solvent system: benzene/dioxane (90:25 v/v).

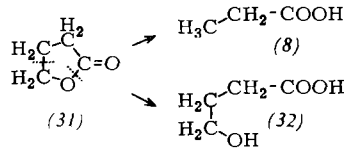
1, monobutyrin *(26)*; 2, butyric acid *(28)*; 3, acetic acid *(2)*; 4, dibutyrin *(27)*; 5, triacetin *(30)*; 6, tributyrin *(25)*.

Though we were unable to distinguish chromatographically between 1,3- and 1,2-dibutyrin, it may be assumed from the secondary products that the electron pyrolysis of *(25)* yields 1,3-dibutyrin *(27)*. Glycerol *(29)* also could be separated from the other components in a second chromatogram. The

[11] *A. M. McLachlan*, J. Amer. chem. Soc. *82*, 3309 (1960).
[12] *A. M. McLachlan*, J. org. Chemistry *29*, 1598 (1964).
[13] *E. M. Emery*, Analytic. Chem. *32*, 1495 (1960).

radio-chromatogram in this case contains practically no activity maximum, since the labile tritium is almost completely exchanged during the development of the chromatogram. However, glycerol can be made visible with $KMnO_4$/$H_2SO_4$.

γ-Butyrolactone *(31)* is only partially hydrolysed by water to hydroxybutyric acid *(32)*, and only on prolonged heating. With tritiated water, however, *(32)* is formed even at room temperature and in higher yields.



*(31)* *(8)* *(32)*

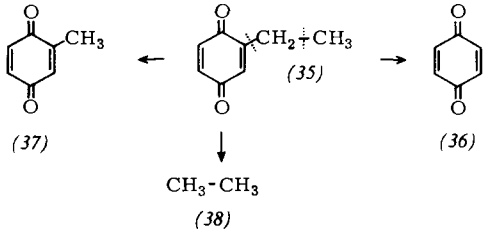
In addition to *(32)*, propionic acid *(8)* is formed. A $C_3$ fragment is formed also in the mass spectrometry of γ-butyrolactone, and is recorded as the $C_3H_4O^{\oplus}$ ion [14].

In order to avoid hydrolysis, sulfanilamide *(33)* was incubated for 10 days with 3 Ci of tritium gas. The fragmentation led to aniline *(34)*, ammonia, and probably sulfur dioxide.

*(34)* *(33)*

### 3.3. Electron Pyrolysis of Quinones [15]

The behavior of quinones on electron pyrolysis was of interest to us, because the defensive substances of arthropods [16] and also of plants [17], which we were studying, quite often are *p*-benzoquinones. Particularly when only a few μg of such a compound are available for analysis, the nature and position of side chains in alkylated *p*-benzoquinones can be found only with great effort. We therefore applied the new fragmentation procedure to quinones of this type. Already in the first example studied, ethyl-*p*-benzoquinone *(35)*, we observed that the ethyl group is split off in stages; benzoquinone and toluquinone were found by thin-layer chromatography, and tritium-labeled ethane by radio-gas chromatography.



*(37)* *(35)* *(36)* *(38)*

In addition to the tritium-labeled quinones *(35)*, *(36)*, and *(37)*, labeled hydroquinones are also formed in every case. This agrees with *Vermeil*'s findings [18], according to which hydroquinone is formed as a principal product on γ-irradiation of *p*-benzoquinone in water. The formation of hydroxyquinones, which react further to humic acids, can be avoided if benzene, toluene, or ethanol is added to the tritiated water as a solubilizing agent. Moreover, when an organic solvent is present, the temperature can be raised from 40 to 80 °C without danger of formation of large quantities of polymers during the electron pyrolysis.

After electron pyrolysis of n-propyl-*p*-benzoquinone, thin-layer chromatography revealed the presence of toluquinone *(37)* in addition to the expected hydroquinones. Benzoquinone was detected only as hydroquinone. After electron pyrolysis of thymoquinone *(39)*, only half of the active pyrolysis product could be stained on the thin layer by spray reagents (Fig. 7). The

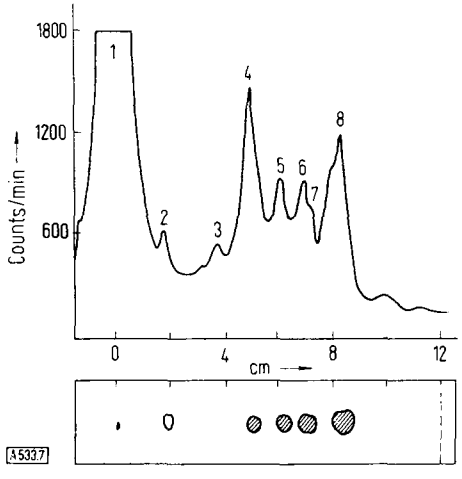


Fig. 7. Thin-layer radio-chromatogram of the solution obtained by electron pyrolysis of 40 μg of 2-isopropyl-5-methyl-*p*-benzoquinone *(39)*. Solvent system: petroleum ether (60—70 °C)/ethyl acetate (6:4 v/v). 1, humic acids; 2, dithymoquinone; 3, toluhydroquinone; 4, 2,5-dimethylhydroquinone; 5, thymohydroquinone; 6, toluquinone *(37)*; 7, 2,5-dimethyl-*p*-benzoquinone *(40)*; 8, thymoquinone *(39)*.

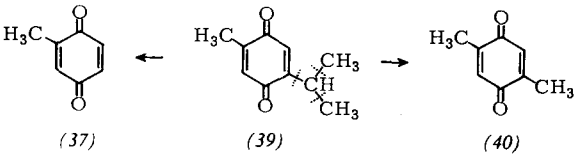
presence of toluquinone *(37)* and 2,5-dimethylquinone *(40)* showed that the isopropyl side chain had been split off and fragmented. 2-Ethyl-5-methyl-*p*-benzoquinone must have been formed as intermediate, the ethyl group then being further degraded, as described above. The methyl group, on the other hand, appears to be more stable, as was shown by the electron pyrolysis of toluquinone *(37)* itself. Thus degradation occurs mainly at the longer and possibly branched side chains. In the electron pyrolysis of phenyl-*p*-benzoquinone, even the phenyl group is readily split off, with formation of benzoquinone.



*(37)* *(39)* *(40)*

[18] *C. Vermeil*, *G. Roquet*, and *L. Salomon*, J. Chim. physique *60*, [5], 659 (1963).

In the study of the defense substances of arthropods we had encountered methoxy-*p*-benzoquinones [19], which we also examined by electron pyrolysis. We found that the methoxy group is readily eliminated. This is particularly significant in the elucidation of the structures of complex methoxyquinones, which can be converted by electron pyrolysis into simpler, and hence in most cases known, alkylated *p*-benzoquinones. Not only methoxy-*p*-benzoquinone *(42)*, but also 2,6-dimethoxy-*p*-benzoquinone *(41)* gave labeled benzoquinone *(36)*, again together with the corresponding hydroquinones, when treated with tritium (cf. Fig. 8).

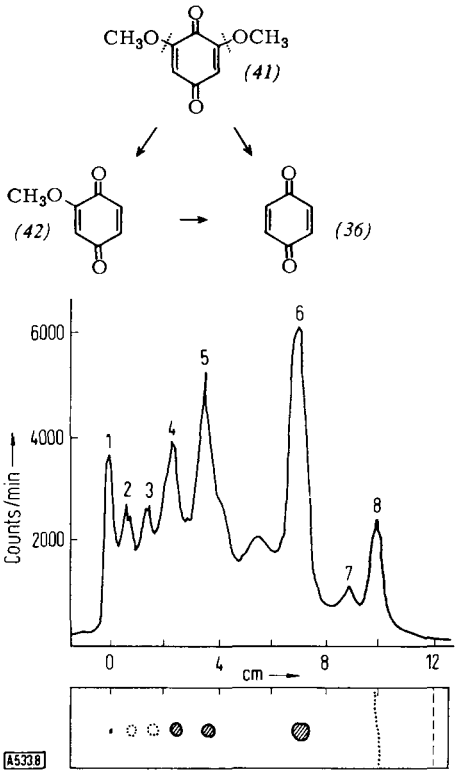

Fig. 8. Thin-layer radio-chromatogram of the solution obtained on electron pyrolysis of 50 µg of 2,6-dimethoxy-*p*-benzoquinone *(43)*. Solvent system: chloroform/petroleum ether (60—70 °C)/ethanol (60:37:4 v/v).

1, polymer; 2, hydroquinone; 3, methoxyhydroquinone; 4, 2,6-dimethoxyhydroquinone; 5, 2,6-dimethoxy-*p*-benzoquinone *(41)*; 6, methoxy-*p*-benzoquinone *(42)*; 7, *p*-benzoquinone *(36)*; 8, second solvent front.

In the electron pyrolysis of the isomers 2-methoxy-5-methyl-*p*-benzoquinone *(43)* and 2-methoxy-6-methyl-*p*-benzoquinone *(44)*, only toluquinone *(37)* is found in addition to benzoquinone. Thus the methoxy group is removed more readily than the methyl group.

### 3.4. Electron Pyrolysis of Menthol and Thymol[20]

We used menthol *(45)* purified by zone melting. The starting band in Figure 9 is due to adsorbed tritiated water and hydroxylated menthol. Band 2 was assigned to *cis*-3-methylcyclohexanol *(49)*, which we prepared by reduction of 3-methylcyclohexanone with $LiAlH_4$. The *trans*-isomer *(50)* was also formed in the electron

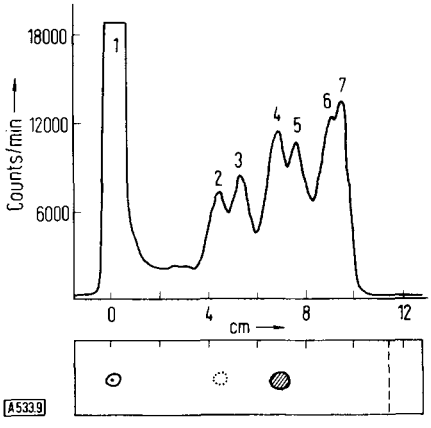

Fig. 9. Thin-layer radio-chromatogram of the solution obtained on electron pyrolysis of 15 µg of menthol *(45)*. Solvent system: chloroform/petroleum ether (60—70 °C)/ethanol (60:37:3 v/v).

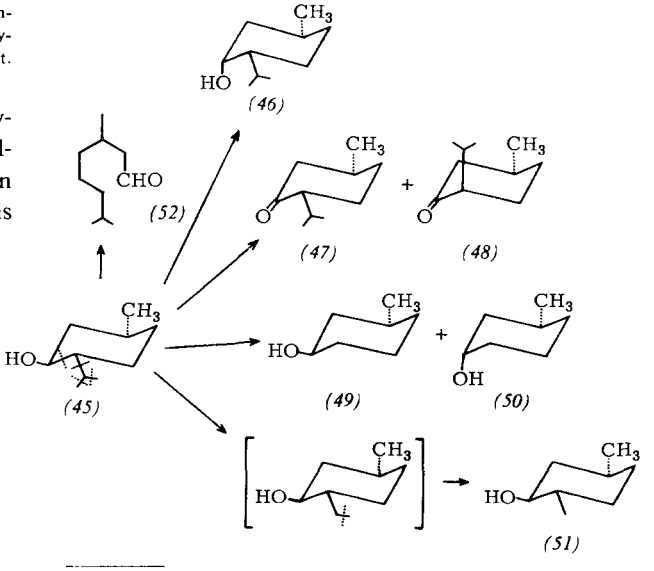
1, hydroxylated menthol; 2, *cis*-3-methylcyclohexanol *(49)*; 3, *trans*-2-*cis*-5-dimethylcyclohexanol *(51)*; 4, menthol *(45)*; 5, neomenthol *(46)*; 6, menthone *(47)*; 7, 3,7-dimethyloctanal *(52)*.

pyrolysis, but with weaker labeling. Band 3 corresponds to *trans*-2-*cis*-5-dimethylcyclohexanol *(51)*. The formation of this isomer during the electron pyrolysis is in agreement with *Hückel*'s findings [21], according to which *(51)* is the predominant species in equilibrium mixtures with its isomers. It corresponds to menthol in its configuration. Owing to the equality of the $R_f$ values of menthol and isomenthol, band 4, and of neomenthol and neoisomenthol, band 5, it was not possible to assign these bands to a particular isomer. A second chromatogram (solvent system: methylene chloride) showed the



[20] *H. Schildknecht* and *K. Penzien*, Z. analyt. Chem. *219*, 102 (1966).

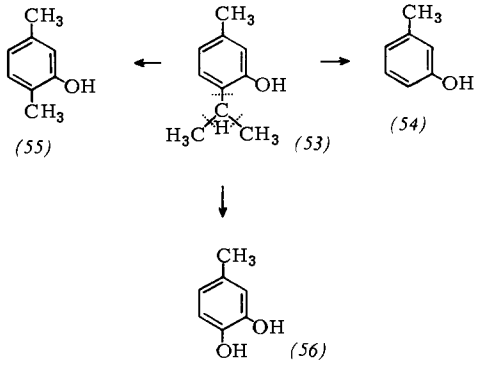
presence of isomenthone *(48)*, menthone *(47)*, and 3,7-dimethyloctanal *(52)* among the products of the electron pyrolysis of menthol.

As in the fragmentation of thymoquinone *(39)*, the isopropyl group of menthol *(45)*, too, is split off. This cleavage is probably favored by the high stability of the isopropyl radical presumably formed. The fact that no removal of the methyl group attached to the ring in menthol was observed supports this interpretation. It is still remarkable that 2,5-dimethylcyclohexanol *(51)* is found, but no 2-ethyl-5-methylcyclohexanol, since it is unlikely that the cleavage of two C–C bonds takes place simultaneously. Thus *Hentz*[22] found, *inter alia*, benzene, ethylbenzene, and toluene in the $^{60}$Co-γ-radiolysis of isopropylbenzene. The 3,7-dimethyloctanal *(52)* obtained from menthol in tritiated water is probably formed because the bond between the C atom carrying the hydroxyl group and that carrying the isopropyl group is the weakest of the C–C bonds in the ring. The dissociation energy of a C–CO bond is smaller than that of a C–C bond. As far as the mechanism is concerned, the dealkylation is best explained by the attack of a solvated electron. However, the oxidation, reduction, and ring cleavage reactions may be initiated by the other radiolysis products of water, particularly by the OH radicals.

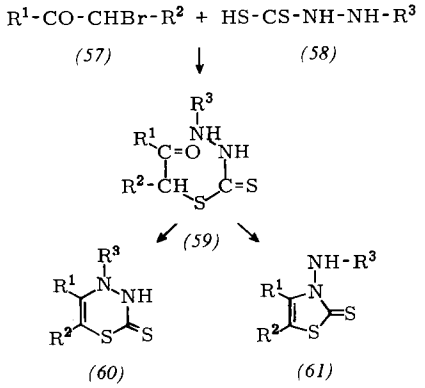
The results of the electron pyrolysis of thymol *(53)* agreed closely with the fragmentation observed in the case of menthol. Of particular interest to the natural



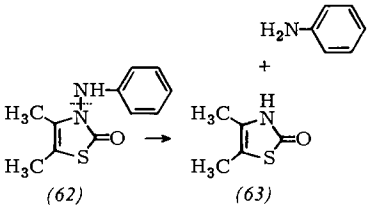
products chemist may be the fact that the isopropyl group again is successively and preferentially split off.

## 4. Elucidation of the Structures of Thiazoles and Thiadiazines by Electron Pyrolysis [23]

The derivatives *(59)* obtained from α-halogenoketones *(57)* and *N*-substituted hydrazides of dithiocarbonic acid *(58)* can undergo ring closure to form either a 3,4-dihydro-2*H*-1,3,4-thiadiazine-2-thione *(60)* or a 1,3-thiazole-2-thione *(61)*.



For $R^3$ = H, the presence of the 5-membered ring in *(61)* can be readily demonstrated by deamination, if detection of the amino group by the formation of a Schiff base is not sufficient in itself. However, this proof is no longer possible when $R^3$ is an organic group. For $R^3$ = CO–$C_6H_5$, *Sato*[24] formulated a 6-membered ring, since compounds of this type are soluble in alkali and this property can be explained by thiol formation. However, *Ege*[25] found that solubility in alkali is not a criterion for the 6-membered cyclic structure. The 5-membered cyclic structure could not be proved either chemically or spectroscopically (NMR, ultraviolet, infrared) in the case of 3-anilino-4,5-dimethyl-2*H*-1,3-thiazol-2-one *(62)*.



The electron pyrolysis of *(62)* should lead to the formation of aniline. In fact, the two complementary fragments aniline and 4,5-dimethyl-2*H*-1,3-thiazol-2-one *(63)* could be detected both chemically and with the thin-layer scanner in the thin-layer radio-chromatogram of the solution obtained on electron pyrolysis of 20 μg of *(62)* (cf. Fig. 10).

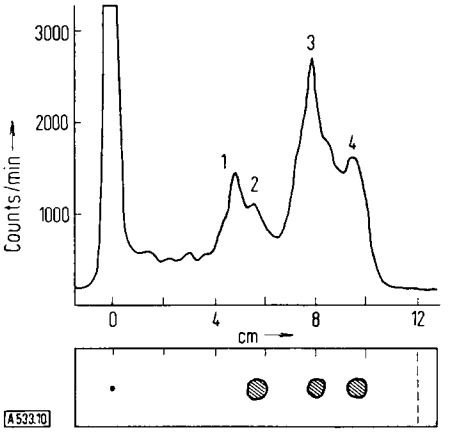


Fig. 10. Thin-layer radio-chromatogram of the solution obtained on electron pyrolysis of 20 μg of *(62)*. Solvent system: $CHCl_3/CH_3OH$ (95:5 v/v).

1, uncertain; 2, 4,5-dimethyl-2*H*-1,3-thiazol-2-one *(63)*; 3, aniline; 4, 3-anilino-4,5-dimethyl-2*H*-1,3-thiazol-2-one *(62)*.

Electron pyrolysis of the compounds *(64)* and *(65)* also confirmed the 5-membered cyclic structure established by *Ege*, since *(66)* and *(67)* were detected in the thin-layer chromatogram. Similarly, the electron pyrolysis of 3-benzoylamido-4-phenyl-2*H*-1,3-thiazol-2-thione *(68)*

[22] *R. R. Hentz*, J. physic. Chem. *66*, 1622 (1962).

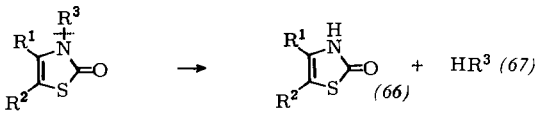
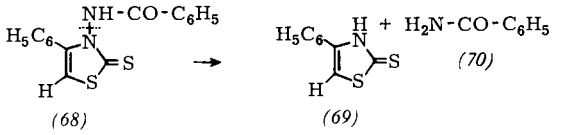
[25] *G. Ege*, unpublished.



*(64)*, $R^1$: $C_6H_5$; $R^2$: H; $R^3$: HN-CO-$C_6H_5$
*(65)*, $R^1 = R^2$: $CH_3$; $R^3$: HN-CO-$C_6H_5$

with methanol as a solubilizing agent led to the formation of benzamide *(70)* and 4-phenyl-2*H*-1,3-thiazol-2-thione *(69)*.



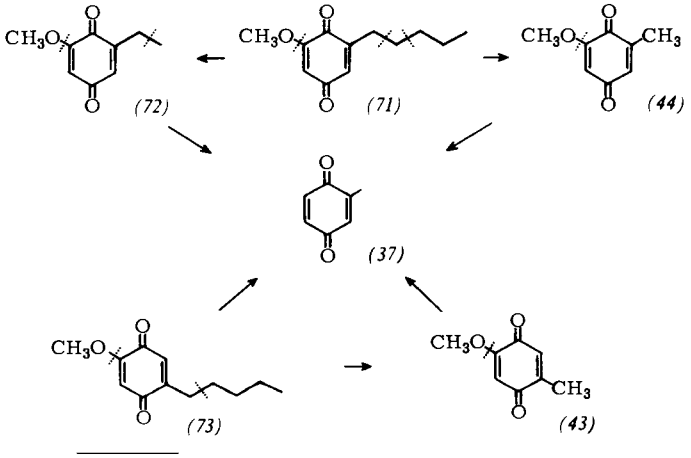
*(68)* *(69)* *(70)*

In the electron pyrolysis of thiazoles and thiadiazines, the mode of fragmentation remarkably often led to conclusive structure proofs, conclusive in that the thiadiazines do not rearrange to the corresponding 5-membered compounds, but are degraded into as yet unidentified fragments. It is likely that during the electron pyrolysis the hydrolytic action of water is superposed on the specific fragmenting action of the hydrated electron.

## 5. Elucidation of the Structures of Natural Products by Electron Pyrolysis

The results obtained with model substances encouraged us to use electron pyrolysis in order to confirm structures proposed for unknown natural products.

For example, we had found by a comprehensive spectroscopic analysis that the poison of the primrose, which *Karrer* had named primin, is a methoxy-n-pentyl-*p*-benzoquinone [26]. Several synthetic quinones had to be used as reference substances in order to show that primin is 2-methoxy-6-n-pentyl-*p*-benzoquinone*(71)* [27]. We later found that the two possible isomers can be easily distinguished by electron pyrolysis, since the known compounds 2-methoxy-5- and 2-methoxy-6-methyl-*p*-benzoquinones, *(43)* and *(44)*, are formed as fragments. This is shown in the following scheme:



*(72)* *(71)* *(44)* *(37)* *(73)* *(43)*

[26] *H. Schildknecht, I. Bayer*, and *H. Schmidt*, Z. Naturforsch. in press.

[27] *H. Schildknecht* and *H. Schmidt*, Z. Naturforsch., in press.

In agreement with the observations made in the electron pyrolysis of other substituted *p*-benzoquinones, the alkyl side chain fortunately is broken down only to such an extent that the positions of the substituents on the quinone nucleus of primin are fixed by the remaining methyl group and by the methoxy group still present. The alkyl group is satisfactorily characterized by the detection, by radio-gas chromatography, of n-butane among the volatile components.

It was mentioned at the beginning that, hopefully, structures can be proposed by properly arranging the electron-pyrolysis fragments like the pieces of a jig-saw puzzle. This hope may yet be realized. Certainly, the identification of the fragments of the arthropod alkaloid glomerine [28] has required much more time than did the rational combination to give the proposed structure [29]. Glomerine, a 1,2-dimethylquinazol-4-one *(74)*, was fragmented by electron pyrolysis to anthranilic acid *(20)*, *N*-methylanthranilic acid *(76)*, *N*-methylanthranilamide *(75)*, and acetic acid (cf. Fig. 11).

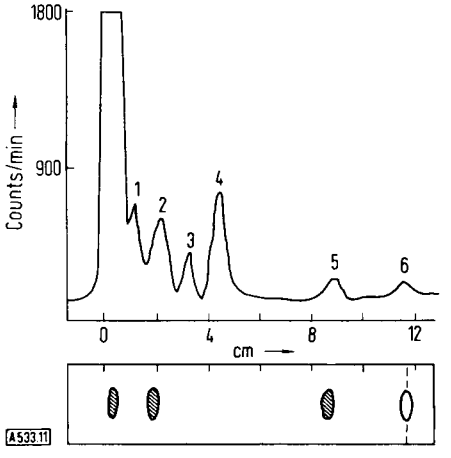


Fig. 11. Thin-layer radio-chromatogram of the solution obtained on electron pyrolysis of 5 µg of glomerine *(74)*. Solvent system: petroleum ether (60—70 °C)/ether/pyridine (1:1:1 v/v).

1, unidentified; 2, anthranilic acid *(20)*; 3, unidentified; 4, acetic acid *(2)*; 5, *N*-methylanthranilamide *(75)*; 6, *N*-methylanthranilic acid *(76)*; start, glomerine *(74)*.

The synthesis of glomerine was a reversal of the fragmentation, since anthranilic acid was converted *via (76)* into *(75)*, which in turn was converted into *(74)* by means of acetic acid. The biosynthesis of glomerine probably also starts from anthranilic acid.

The composite proanthocyanidins [30] are condensation or dehydrogenation products of two flavonoids, a monomolecular proanthocyanidin, and a catechol. The two halves of the molecule may be linked either by an ether oxygen, by a C–C linkage, or by a ketal linkage. In order to clarify the structure, therefore, *Weinges* and *Ebert* [31] examined model substances corresponding to the composite proanthocyanidins with a C–C linkage, and attempted to achieve an informative cleavage by

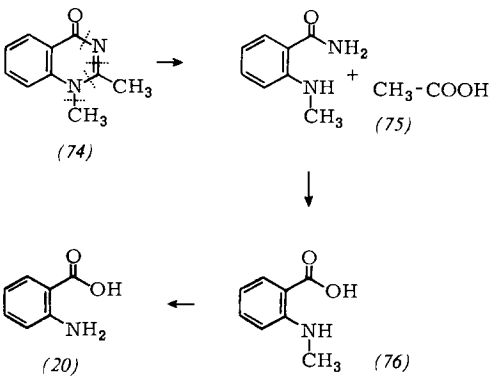
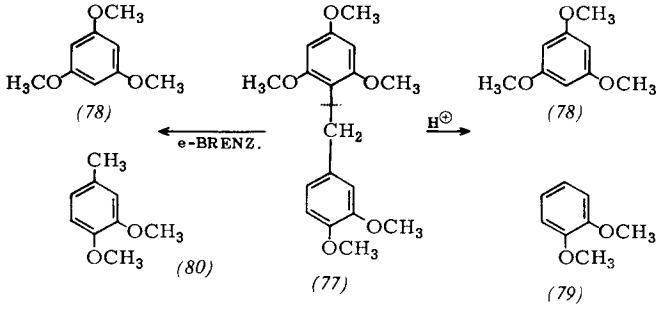
[31] *W. Ebert*, Diploma Thesis, Universität Heidelberg, 1965.



chemical methods. In the presence of acids, however, 2,4,6,3′,4′-pentamethoxydiphenylmethane *(77)* was broken down to phloroglucinol trimethyl ether *(78)* and veratrole *(79)*, with loss of the central methylene group. Consequently, the substitution position in the veratrole residue could not be established in this way. In the thin-layer radio-chromatogram of the solution obtained on electron pyrolysis of *(77)*, on the other hand, one fraction could be satisfactorily assigned to homoveratrole *(80)*.



## 6. Prospects

In all chemical methods of structural elucidation it should be known *which* bonds in the unknown molecule are attacked by the reagent. In reactions with tritiated water, the attack usually takes place on the weakest bonds, and C–N, C–C, C–O, and C–H bonds can be broken oxidatively and reductively. Of great advantage in this case is that part or all of the alkyl side chain is removed from the basic structure, *e.g.* a quinone nucleus, so that information is obtained not only about the nature of the side chain, but also about the substitution site.

The selectivity observed in the fragmentation by electron pyrolysis is surprising, since the β-decay energy of tritium is higher by a factor of $10^3$ than the dissociation energies of the above-mentioned bonds. It must therefore be concluded that the interaction leading to fragmentation occurs between the molecule and an energy-transfer agent, the energy of which is comparable to the bond energy. Whether the energy is transferred *via* H atoms, OH radicals, electrons, radiation, or even excited water molecules is of no importance to the above argument. Nevertheless, efforts will be made to find a mechanistic interpretation of electron pyrolysis, simply to permit the prediction of the course of fragmentation. The growing understanding of the radiolysis of organic compounds in aqueous solution with X- and γ-rays is particularly valuable in this connection.

We believe that solvated electrons may be assumed to be particularly important in the fragmentations observed by us. Consequently, the fragmentation in the mass spectrometer often can be used for comparison. However, whereas only one half of the complementary fragments is recorded in mass spectrometry, both parts can be expected to be detected in electron pyrolysis. Further, the fragments formed in electron pyrolysis are "frozen" by saturation with H (or T) atoms or OH (OT) radicals and by reaction with the tritiated water, whereas the primary radicals formed in the mass spectrometer are stabilized intramolecularly, with further fragmentation. This often leads to a spectrum with a large number of peaks. Moreover, it is not always possible to distinguish between isomeric ions by mass spectrometry, whereas after electron pyrolysis the isomeric fragments can be separated by chromatography and identified.

Concerning the future of radio-gas chromatography, we hope that it will not only become possible to detect all fragments as a result of the development of more sensitive radiation detectors, but also that these will often be sufficiently well characterized by their retention times alone. The long incubation periods ranging from a few days to some weeks will then no longer be necessary if tritiated water having a specific activity of 25 Ci/ml instead of 5 Ci/ml is used. This requires particularly careful work, which can be guaranteed better in gas chromatography than in thin-layer chromatography.

*These experiments, sometimes not entirely without danger, and the unconventional and, to an organic chemist, somewhat unfamiliar techniques required great diligence and idealism on the part of my doctorate candidates, for which I express my sincere thanks. The investigations would not have been possible without the generous support of the Ministerium für wissenschaftliche Forschung, the Deutsche Forschungsgemeinschaft, and the Fonds der Chemischen Industrie. We are grateful to Prof. W. Hückel and to the Dragoco-Werke for the donation of chemicals.*

# Silicon-Nitrogen Heterocycles

BY DR. W. FINK

MONSANTO RESEARCH SA., ZÜRICH (SWITZERLAND) [*]

*Great progress has recently been made in the chemistry of the silicon-nitrogen bond* [1–5]. *Whereas attention was formerly concentrated on open-chain silazanes and silylamines, growing interest is now being shown in the cyclic SiN compounds. A major factor which has contributed to the rapid development in this field is the need for better polymers and liquids for use above 350 °C* [6]. *The present article deals with monomeric cyclic compounds containing at least one silicon-nitrogen bond in the ring, as well as the polycyclic compounds derived from these.*

## 1. Heterocycles with SiN Bonds in the Ring

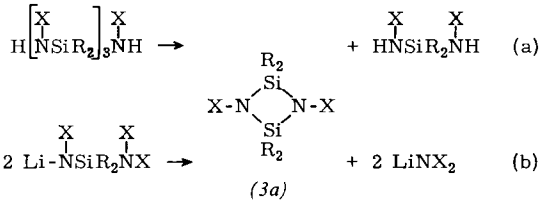
### 1.1. Cyclodisilazanes [7, 8]

For a long time the existence of 4-membered silazane rings with alternating Si-N bonds was doubtful. *Pflugmacher* and *Dahmen* [9] isolated a cyclic perchlorinated silazane *(2)*, formed *via* the condensation of tris(trichlorosilyl)amine *(1)*, from the products of the glow discharge of $SiCl_4/N_2$ mixtures. By analogy with the results obtained by *Schumb* and *Towle* [10], these authors postulated a cyclotetrasilazane structure (n = 4) for their product. They ruled out 4-membered silazane rings because of the high ring strain expected.

$$n\ N(SiCl_3)_3 \rightarrow (Cl_2SiNSiCl_3)_n + n\ SiCl_4$$
*(1)* *(2)*

However, the compound appears to have the structure of a cyclodisilazane [11].

In 1961, 1,3-bis(trimethylsilyl)-2,2,4,4-tetramethylcyclodisilazane *(3a)* was obtained in accordance with equations (a) [12] and (b) [12] by thermolysis of long-chain metalated silazanes [13] [see *(27)*] and of *N*-trimethylsilylated and permethylated cyclotri- and cyclotetrasilazanes [14, 15]. The elucidation of the structure of this

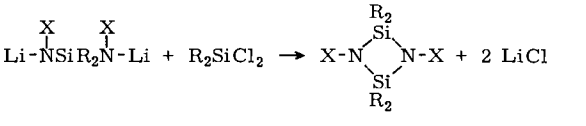


*(3a)*

$R = CH_3$, $X = (CH_3)_3Si$

compound [16] established the existence of 4-membered silazane rings, and a number of methods have recently been developed for the preparation of such rings [*].

The cyclodisilazane ring can be formed in good yields by the reaction of doubly metalated octamethyltrisilazane *(4a)* with organodi- and -trichlorosilanes or with silicon tetrachloride [12, 14]. The products are 1,3-bistrimethylsilyl compounds.



*(4a)* R = $CH_3$, X = $(CH_3)_3Si$ *(3a)* R = $CH_3$, X = $(CH_3)_3Si$
*(4b)* R = X = $CH_3$ *(3b)* R = X = $CH_3$

*Lienhard* and *Rochow* [17, 18] applied this method to doubly metalated bis(methylamino)dimethylsilane *(4b)* (R = X = Me), and isolated cyclodisilazanes *(3)* with methyl substituents on the nitrogens. Other *N*-alkylated and *N*-arylated

rings *(3)* have been prepared in a similar manner from the dilithium compounds of the corresponding silylamines *(4)* [19,20]. The direct reaction of the dilithium compounds of primary (preferably aromatic) amines with diorganosilicon dichlorides can be used for the synthesis of *(3)* [19].

$$2\,XN{-}Li_2 + 2\,R_2SiCl_2 \rightarrow (3) + 4\,LiCl$$

The pyrolysis of diaminodiorganosilanes *(5)* at 200–450 °C is particularly useful for the preparation of *N*-alkylated and *N*-arylated compounds *(3)* [19].

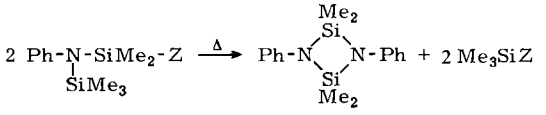
$$\underset{(5)}{2X{-}NHSiR_2HN{-}X} \xrightarrow{\Delta} (3) + 2\,XNH_2 \qquad (c)$$

This method, in which (particularly by use of compounds *(5)* with X = aryl) yields of 90% and more are not unusual, is restricted to compounds *(5)* which decompose below their boiling points. A variant of reaction (c) which makes use of transamination [21] is useful when the removal of the (high-boiling) amine is difficult [19,22].

$$\underset{(5)}{2\,X{-}NHSiR_2HN{-}X} \xrightarrow[-2\,XNH_2]{+2\,X'NH_2} 2\,X'{-}NHSiR_2HN{-}X \xrightarrow[-2\,XNH_2]{\Delta} (3)$$

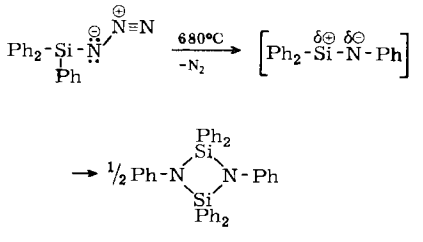
The reaction occurs only when the boiling point of $X'NH_2$ is higher than that of $XNH_2$. Some examples of substituted cyclodisilazanes are given in Table 1.

The formation of *N*-phenylated rings *(3c)* [Z=Cl, $C_6H_5{-}N{-}Si(CH_3)_3$] is also based on pyrolysis [19].



*(3c)*

*Reichle* [23] reported the formation of hexaphenylcyclodisilazane *(3d)* in the decomposition of triphenylsilyl azide at 680 °C.



*(3d)*

A reaction of particularly wide scope is the silylation of primary aliphatic and aromatic amines and of triorgano silanamines with disilanes to form *(3)*, between 0 and 100 °C in the presence of alkali metals or their hydrides as catalysts [equation (d)] [24]. This reaction, which is generally spontaneous and very fast, can be carried out in polar (tetrahydrofuran, 1,2-dimethoxyethane, diethyl ether) or non-polar (benzene, hexane) solvents, or even without a solvent, and proceeds almost quantitatively.

$$2\,XNH_2 + 2\,H_2SiR^1R^2 \xrightarrow{-2\,H_2} \underset{H\ H}{2\,XN{-}SiR^1R^2} \xrightarrow{-2\,H_2} (3) \quad (d)$$

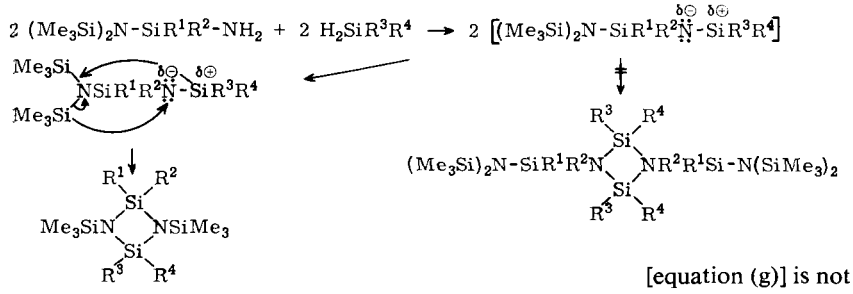
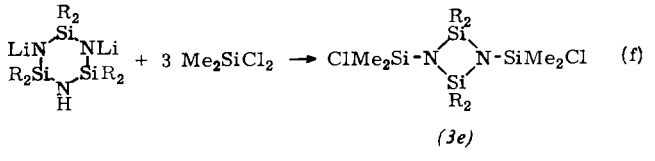
[24] Belg. Pat. 665774 (1965), Monsanto, inventor: *W. Fink*.

The intermediate *(6)* can be used directly in the reaction [24]. Compounds *(3)* with dissimilar substituents on the two ring silicon atoms and compounds with X = trimethylsilyl can be obtained by reaction (e), in which the intermediate is stabilized, not by dimerization, but by migration of the $(CH_3)_3$ Si group [24].



(e)

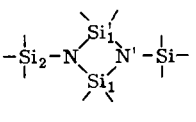
Cyclodisilazanes *(3e)* with chlorodimethylsilyl groups on the nitrogen atoms are used to synthesize linear polymers with cyclodisilazane units in the chain. Compound *(3e)* is synthesized by the reaction of at least doubly metalated cyclotri- or -tetrasilazanes with diorganosilicon dichlorides [25], *e.g.*:



(f)

*(3e)*

The structure of 1,3-bis(trimethylsilyl)-2,2,4,4-tetramethylcyclodisilazane *(3a)* was determined by X-ray analysis [16]. It crystallizes monoclinically in the space group $P2_1/n$ (a = 6.75 ± 0.02, b = 13.18 ± 0.04, c = 11.22 ± 0.03 Å; β = 104° 23′ ± 0.5′, V = 968.7 Å$^3$, d = 0.998).

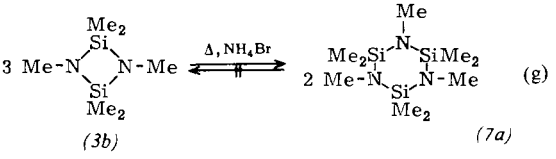


Bond angles and bond lengths in *(3a)*:

| | | | |
|---|---|---|---|
| Si(1)NSi(1′) | 91.7°; | Si(1)N | 1.725 Å |
| N′Si(1)N | 88.3°; | Si(1′)N | 1.724 Å |
| Si(1)NSi(2) | 135.4°; | Si(2)N | 1.707 Å |
| Si(1′)NSi(2) | 132.8°. | | |

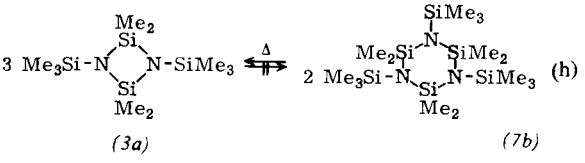
The Si-N bonds in the ring are shorter than those in hexamethylcyclotrisilazane (1.78 ± 0.03 Å) [26,27], but somewhat longer than the exocyclic Si-N bonds. The ring skeleton is highly strained in comparison with that of hexamethylcyclotrisilazane (117 ± 4°) or octamethylcyclotetrasilazane (123 ± 4°) [26,27]. Compound *(3a)* has a planar Si-N framework, as is also indicated by proton magnetic resonance measurements [28], which show unusually strong π-bonding in the exocyclic Si-N bonds.

The deformation of the nitrogen bond angle in cyclodisilazanes to approximately the angle between pure p orbitals can be seen in the weakening of the ring Si-N bond from *(3b)* to *(3a)* [18,28]. The reactivity of this bond should increase in the same direction, but the reverse is true. Whereas hexamethylcyclodisilazane *(3b)* is readily solvolysed [18], *(3a)* is stable towards water and alkali [29]. The stability of the cyclodisilazanes towards acids increases (for R = $CH_3$) in the order X = alkyl < trimethylsilyl < aryl. The hydrolysis is further hindered by large groups on the silicon. The quantitative catalytic ring expansion of *(3b)* (and other *N*-methylated cyclodisilazanes) [17,18] to form a 6-membered ring *(7)* [equation (g)] is not possible in *(3a)* or in *N*-phenylated compounds.



(g)

*(3b)* *(7a)*



(h)

*(3a)* *(7b)*

Compound *(3a)* does not react with ammonium bromide; *N*-phenylated cyclodisilazanes react only above 400 °C, and then only very slowly, with formation of nonuniform products, which do not include the trimer [29]. 1,3,5-Tris(trimethyl)silylated cyclotrisilazanes such as *(7b)*, on the other hand, tend to undergo ring contraction at 400 to 425 °C in accordance with equation (h); this reaction cannot be brought about even at 450 °C with 1,3,5-trimethylated cyclotrisilazanes such as *(7a)*.

The difference in stability between the various types of cyclodisilazanes can be explained on the basis of different electron density distributions (Scheme 1). The electrons of the silazane nitrogen are partly delocalized. Owing to the marked deformation of the Si-N-Si bond angle in the small rings, the electron density on the nitrogen is higher than in the acyclic silazanes. A substituent on the nitrogen may cause either a further increase or a decrease in the electron density as a result of inductive effects, as is shown by the τ values of the rings. Reactions involving the Si-N bond, *e.g.* hydrolysis, normally proceed by protonation of the nitrogen, the ease of which increases with increasing nucleophilic character The

## 1.2. Cyclotrisilazanes and Cyclotetrasilazanes

### 1.2.1. Preparation by Ammonolysis

When the classic route to the silazanes, *i.e.* the ammonolysis of the silicon-halogen bond, is applied to difunctional halogenosilanes (preferably chlorosilanes), the main products are largely strainless 6- (n = 3) and 8-membered (n = 4) silazane rings *(7)* and *(8)*.

$$n\ R_2SiCl_2 + 3n\ NH_3 \rightarrow \underset{(7),(8)}{(R_2SiNH)_n} + 2n\ NH_4Cl \qquad (i)$$

Separation of the ammonium salt by means of aqueous alkali gives *(7)* and *(8)* almost quantitatively [31–35]. Some examples of cyclotri- and -tetrasilazanes are given in Table 2. Whether trimeric or tetrameric cyclosilazanes, mixtures of the two, polysilazanes, silanediamines, or diaminodisilazanes are formed depends on the substituents R and on the reaction conditions.

In reaction (i), diorganosilicon dichlorides $RR^1SiCl_2$ with $R = R^1 = H$ give only polysilazanes [36]; when R = H, $R^1 = CH_3$, cyclic silazanes are formed as well as polysilazanes [37], while the combination R = H, $R^1 > CH_3$ gives both cyclotri- and -tetrasilazanes [38, 39]. A tert-butyl group (with $R^1 > H$) [40] or two α-naphthyl [41], tert-butoxy [42,43], isopropoxy [44], or phenoxy groups [45] favor the formation of silanediamine [42,43] and diaminodisilazane [42,44]; this does not appear to be entirely due to steric factors, since a diaminodisilazane has been isolated with $R = CH_3$, $R^1 = CF_3-CHF-CF_2$ [47]. Except in the case of the very stable di-t-butyldiaminosilane [40], however, these intermediates can be forced to cyclize by the use of heat [44,45] or acidic catalysts (*e.g.* ammonium sulfate) [43,46].

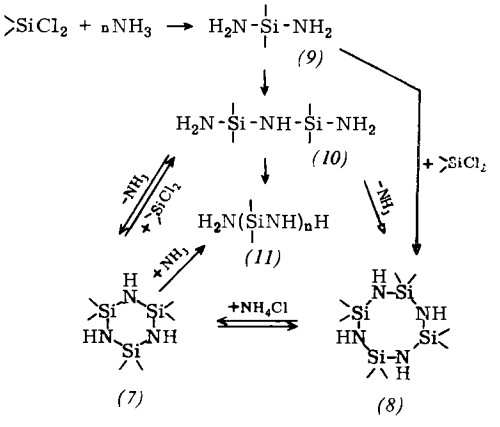
[a] M.p. 63–64 °C.

The formation of cyclosilazanes in accordance with equations (i) and (j) is complicated, and probably involves a series of simultaneous reactions and equilibria[67].

The intermediates *(9)* to *(11)* and their condensation to form *(7)* and *(8)* are known[43–46], as are condensations between halogenosilanes and silanamines[69]. A reaction of diorganodichlorosilane with *(9)* or *(10)* to form the trimer or tetramer is not impossible. The reverse reaction of $R_2SiCl_2$ with *(7)*, which leads to the equilibrium between cyclotrisilazane and longer-chain SiCl-terminated silazanes[70], equilibria between cyclotri- and cyclotetrasilazanes[71], and the ring-cleavage of *(7)* by the action of ammonia to form *(11)* are possible[68]. The direction of the reaction is very strongly influenced by the reaction conditions.



## 1.2.2. Preparation by Aminolysis

The aminolysis of $R_2SiCl_2$ with primary amines does not lead to *N*-alkylated or *N*-arylated cyclotri- and cyclotetrasilazanes. In these cases the reaction generally stops at the stage of the *N*-substituted diaminodiorganosilane *(5)*.

$$n\ R_2SiCl_2 + 4n\ R^1NH_2 \xrightarrow[-2n\ R^1NH_2\cdot HCl]{} n\ R^1NHSiR_2HNR^1 \quad (k)$$

*(5)*

$$\downarrow -n\ R^1NH_2$$

$$(R^1NSiR_2)_n \quad (l)$$

*(7), (8)*

The preparation of *(7)* and *(8)* by reactions (k) and (l) succeeds for reactions of $RR^1SiCl_2$ with R = H, $R^1$ = $CH_3$, $C_2H_5$[72], or $NHC_2H_5$[73] and methylamine or ethylamine. *Andrianov et al.*[76] obtained the compounds *(7)* and *(8)* also at low temperatures (−30 °C) under suitable conditions. Prolonged heating of *(5)* with an excess of diorganodichlorosilane is not very effective[74] and, as was shown with nonamethylcyclotrisilazane *(7a)*, leads only to the equilibrium between cyclic and linear silazanes[75] [cf. equation (q)]. The cyclization of *(5)* to give *(7)* as main product can sometimes be carried out at high temperatures and under pressure (with moderate

yields)[77]. The ring closure is best forced by heating *(5)* in the presence of acidic catalysts such as ammonium salts[77–79] [equation (l)]. The yields depend strongly on steric factors; they decrease with increasing bulk of the substituents on the silicon and on the nitrogen. The influence of the nitrogen substituent dominates [*e.g.* in *(5)* with R = $CH_3$: $R^1$ = $CH_3$, 93%; $C_2H_5$, 66%, $CH_2=CH-CH_2$, 21%; $C_6H_5-CH_2$, 19%; $C_6H_5$, 0% of *(7)* or *(8)*[79]]. Examples of *N*-alkylated cyclotri- and cyclotetrasilazanes are given in Table 4.

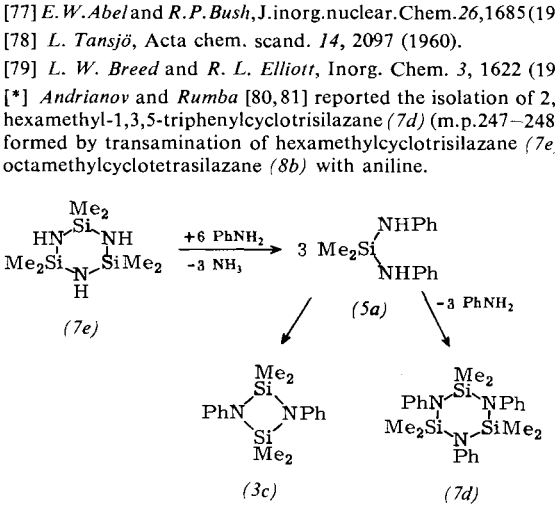
Whereas the thermolysis of *(5)* in the absence of catalyst leads to 4-membered silazane rings [cf. equation (c)], it yields 6- or 8-membered ring systems when carried out in the presence of a catalyst (except in the pyrolysis of *N*-arylated *(5)*, which leads to cyclodisilazanes in both cases[*] [79,29]). Thus it is possible to fix the direction of the reaction by the addition of a catalyst.

[77] *E. W. Abel* and *R. P. Bush*, J. inorg. nuclear. Chem. *26*, 1685 (1964).

[78] *L. Tansjö*, Acta chem. scand. *14*, 2097 (1960).

[79] *L. W. Breed* and *R. L. Elliott*, Inorg. Chem. *3*, 1622 (1964).

[*] *Andrianov* and *Rumba* [80,81] reported the isolation of 2,4,6-hexamethyl-1,3,5-triphenylcyclotrisilazane *(7d)* (m.p. 247–248 °C) formed by transamination of hexamethylcyclotrisilazane *(7e)* or octamethylcyclotetrasilazane *(8b)* with aniline.



These authors assume that *(7e)* is completely broken down to *(5a)*, which then condenses to *(7d)*. However, the infrared spectra and debyeograms of the products obtained in accordance with equation (c) [compound *(3c)*] and by transamination [compound *(7d)*], as well as the molecular weights found from X-ray data[82], are identical [*(7d)* and *(3c)*: space group 61 Pbca (orthorhombic), a = 11.65, b = 8.60, c = 16.88, d = 1.2 Å, M = 298].

Since *N*-alkylated cyclodisilazanes can be catalytically rearranged to cyclotrisilazanes [cf. equation (g)], it may be assumed that the catalytic condensation of *(5)* proceeds *via* the initial formation of cyclodisilazanes, which (apart from the *N*-phenyl compounds, which do not undergo rearrangement) then undergo ring expansion under the influence of the catalyst to form the trimer *(7)*.

### 1.2.3. Other Methods of Preparation

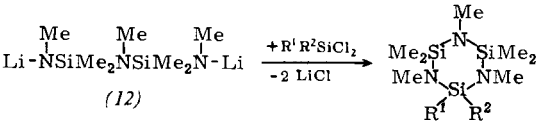
The cyclotri- and cyclotetrasilazane skeleton can also be built up by reaction of amino-Grignard compounds with dichlorosilanes[77],

$$3\ R^1N(MgBr)_2 + 3\ R_2SiCl_2 \rightarrow (R^1NSiR_2)_3 + 6\ MgClBr, \quad (m)$$

the condensation of methylsilylamine at 400 °C[84],

$$4\ MeN(SiH_3)_2 \rightarrow (MeNSiH_2)_4 + 4\ SiH_4$$

and the reaction of *N*-(triethoxysilyl)aniline with magnesium/tetraethoxysilane[83]. *Lienhard* and *Rochow*[85] synthesized *N*-methylated cyclotrisilazanes *via* dilithium bis(methylamino)pentamethyldisilazane *(12)*.



*(12)*

(o)

*(7)*

silyl)amide [89], or, in the case of *(7)* where R = $C_6H_5$, directly with potassium [90].

Single and double silylations of *(7)* and *(8)* proceed readily and in good yields. Triple silylations proceed only with difficulty, and do not go to completion [*(7)*]. The yields are also reduced by lithium-catalysed fragmentations, which are probably favored by steric factors. The complete silylation of cyclotetrasilazanes yields only cyclodisilazanes *(3)* [15].

The introduction of triorganosilyl groups into *(7)* and *(8)* (which can also be accomplished in good yields with triorganosilanes and sodium, potassium, or their hydrides [29] [equation (o)]) leads, particularly with the trimethylsilylated compounds, to a marked depression of the melting point, and to a sudden increase in the stability of the ring towards hydrolysis and heat, particularly with doubly silylated compounds.

Mention should also be made of the isolation of octachloro-1,3,5,7-tetrakis(trichlorosilyl)cyclotetrasilazane from the products of the reaction of silicon tetrachloride with ammonia at 825 °C [10] and the preparation of cyclotrisilazane, $(H_3Si-N-SiH_2)_3$ [91], by the condensation of trisilylamine in the liquid phase in accordance with reaction (m) or by reaction of monochlorosilane with ammonia. Some examples of $(R_2Si-N-SiR_3)_{3 \text{ or } 4}$ are given in Table 5.

## 1.2.4. Structure of the Cyclotri- and Cyclotetrasilazanes

Electron diffraction measurements [26, 27] indicate that hexamethylcyclotrisilazane *(7e)* has a puckered ring structure (Si-N = 1.78 ± 0.03 Å, Si-C = 1.87 ± 0.05 Å, SiNSi = 117 ± 4 °, NSiN = 111 ± 5 °). From infrared measurements, on the other hand, a planar configuration was deduced [92]. Calculations of the SiNSi angle in *(7e)* (118.5 °) [*] appear to confirm the results of the electron-diffraction measurements [93].

A careful X-ray analysis has been carried out on octamethylcyclotetrasilazane $[(CH_3)_2SiNH]_4$ *(8b)* [94]. The compound forms monoclinic crystals of the space group P2/c in the "chair" (A) and "boat" (B) forms (in the ratio 1:1 in the crystal).

*Yokoi* and *Yamasaki* [26, 27] found a value of 123 ± 4 ° for the SiNSi angle in *(8b)* (electron diffraction).

Hexamethyl-2,4,6-triphenyl- *(7f)* and hexamethyl-2,4,6-tri-*p*-anisylcyclotrisilazane *(7g)*, like the structurally similar silicon/sulfur and silicon/oxygen rings [95–97], occur as two structural isomers, for which the structures A and B have been deduced from proton magnetic resonance data [79].

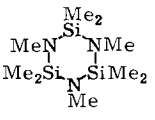
925–950 $cm^{-1}$, with a slight increase in frequency on transition from trimeric to tetrameric and from *N*-unsubstituted to *N*-substituted rings. $\nu_{sym}$-SiNSi occurs at 618–620 $cm^{-1}$. *N*-Silylated or *N*-alkylated cyclotrisilazanes exhibit strong infrared absorption between 1005 and 1055 $cm^{-1}$ [15,79,87], which has not so far been assigned. (For NMR spectra of hexamethylcyclotrisilazane, see [100]).

*Osthoff* and *Kantor* [57] measured the dipole moment of *(7e)* as well as other electrical properties. The ability of *(7e)* and *(8b)* to act as electron donors was studied by *Jarvie* and *Lewis* [101].

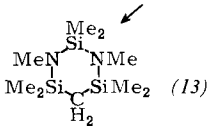
An interesting question, which has not yet been conclusively answered, is that of a pseudoaromatic resonance effect of the nitrogen $\pi$ electrons in cyclotrisilazanes, *i.e.* a displacement of the $\pi$ electrons, which are already partly delocalized in the silazane linkage ($d_\pi$-$p_\pi$ bond) [102,103], through the silicon [104].

*Lienhard* and *Rochow* [85] have demonstrated the absence of aromaticity in nonamethylcyclotrisilazane *(7a)*. They found that the chemical shifts of the proton resonance of the $Si(CH_3)_2$ group in *(7a)* and that of the $Si(CH_3)_2$ group indicated in *(13)* are the same.

*(7a)*



*(13)*



Since the resonance of the $\pi$ electrons in *(13)* is interrupted, there should be a marked difference in the chemical shifts.

Thermodynamic considerations oppose a quasi-aromatic bond system [105]. The electronic structure of the cyclosilazanes can best be explained in terms of localized 3-center $\pi$ bonds. The ultraviolet spectra of cyclotrisilazanes with vinyl substituents on the silicon atoms indicate that the $Si_3N_3$ ring skeleton cannot participate in the conjugation of groups attached to the silicon atom [48]. *Gaidis* and *West* [106] recently reported evidence of the participation of the Si-N bond in the aromatic system in 10,10-dimethyl-9,10-azasiladihydrophenanthrene *(59)*.

### 1.2.5. Properties and Reactions

Cyclotri- and -tetrasilazanes are thermally very stable, apart from compounds having the formula $(RHSiNH)_{3\text{ or }4}$ wich are stable only up to about 200 °C [107]. Decomposition, polymer and oligomer formation, or rearrangements are observed only above 300 °C [107]. The thermal stability is considerably increased by substitution of the silazane hydrogen by alkyl or trialkylsilyl groups.

Cyclosilazanes are relatively stable to water and alkali (cf. [31]), but they are sensitive to acids and alcohols, which cause rapid breakdown into silanol and ammonia or amine, the trimers reacting faster than the tetramers [108].

The stability of the compounds generally increases with the size of the groups attached to the silicon [109]. Cyclosilazanes with mixed substituents are less stable than peralkylated compounds, even when large groups are present [79,110]. The stability is considerably increased by the replacement of NH by NR [79].

Reactions carried out on cyclotri- and -tetrasilazanes have so far been largely confined to acid- and base-catalysed cleavage of the SiN ring structure, which proceeds rapidly and generally in high yields.

Alcohols [33,111–114] and organic acids cause ring cleavage with formation of dialkoxy- or diaryloxytrisilazanes or -disilazanes, or else complete breakdown [112,113,115] of the cyclic silazane to give bisorganyloxy- and bisacyloxysilanes.

Cleavage of cyclotri- and -tetrasilazanes in ether or benzene by stoichiometric quantities of hydrogen chloride leads to 1,3-dichlorosilazanes [33]. Diols react to give low-melting polymers, which are stable up to about 300 °C [116]. An excess of alcohol causes breakdown of the silazane skeleton into nitrogen-free –SiOC– polymers [117].

Transamination of *(7e)* and *(8b)* with aniline leads to bisdianilinodiorganosilane [59] *(5a)* and 1,3-diphenyl-2,2,4,4-tetramethylcyclodisilazane *(3c)* [80,81,29]. The reaction with n-amylamine stops at the stage of 1-amyl-2,2,4,4,6,6-hexamethylcyclotrisilazane (b.p. 85–87 °C/1 mm Hg), whereas the simultaneous action of aniline and ammonia on dimethyldichlorosilane [intermediate formation of *(7e)* and *(8b)*] leads to the 1-phenyl analogue (m.p. 37 °C) [80]. *Andrianov et al.* [118] obtained a (probably linear) polymer of low molecular weight by single ring cleavage in *(7e)* with an aromatic diamine.

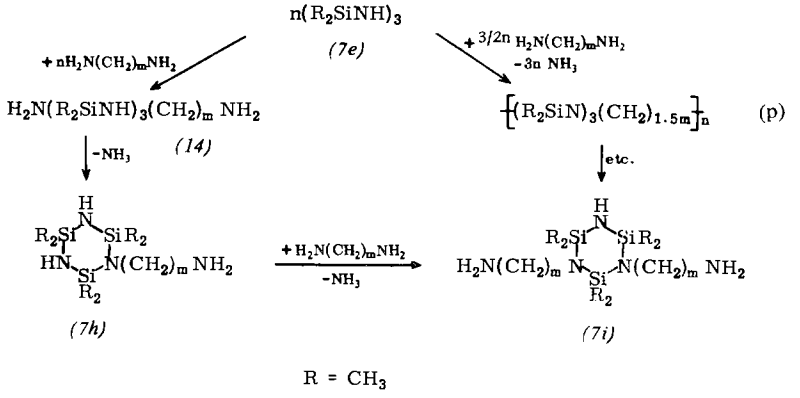
*Morgunova et al.* [119,120] synthesized cross-linked polymers by transamination of hexamethylcyclotrisilazane *(7e)* with aliphatic diamines (m = 2 to 6), in accordance with equation (p).



These authors assume that the reaction proceeds by repeated cleavage of the $Si_3N_3$ ring skeleton to form a silazane chain *(14)*, and subsequent ring closure to form *(7h)*; after renewed cleavage, this reacts with further amine *via (7i)* to form the polymer [121].

Ring cleavage in hexamethylcyclotri- *(7e)* and octamethylcyclotetra-silazane *(8b)* can be brought about by a number of other compounds. Metal and metalloid halides react with *(7e)* in the same manner as with disilazanes [122–126], with cleavage of the Si–N bonds. Diorganoboron chloride can open the ring in *(7e)*, or can break it down completely [122].

The reaction of *(7e)* with $Al_2Cl_6$ leads to products containing Si–N and Al–N bonds, which have not been characterized in any detail [33]; $CuCl_2$ and $CoCl_2$ also react [127], but the results reported are contradictory [128]. Whereas dimethyldichlorosilane degrades doubly metalated *(7e)* to 1,3-bischlorosilylcyclodisilazane [25] [cf. equation (f)], the reaction with *(7e)* or *(7a)* leads to equilibria [70,75] [*e.g.* equation (q)].

$$Me_2SiCl_2 + (MeNSiMe_2)_n \leftrightarrows ClMe_2Si(NMeSiMe_2)_{n-1}NMeSiMe_2Cl \qquad (q)$$

The equilibration of *(7e)* with hexamethylsilazane [37] (with ammonium chloride as catalyst) leads to octamethyltrisilazane *(15)*, R = $(CH_3)_3Si$, n = 1. Ammonia at 140 °C/4 atm [68] gave a linear silazane (R = H, n ≈ 15).

$$R_2NH + (Me_2SiNH)_3 \rightarrow RNH(SiMe_2NH)_nR$$
*(7e)* *(15)*

Organic isocyanates also react with *(7e)* and *(8b)* causing complete degradation of the rings [129] (see Section 4.4).

Base- and acid-catalysed polymerization of cyclosilazanes, with ring cleavage, to give linear polysilazanes generally are impossible [68]. Rearrangement and polycondensation leads to the formation of cross-linked polymers.

*Zhinkin et al.* [130,131] and *Andrianov* and *Rumba* [71] have achieved ring expansions in hexamethylcyclotrisilazane *(7e)*. The compound is quantitatively rearranged to octamethylcyclotetrasilazane *(8b)* by small quantities of concentrated sulfuric acid [0.5 mole-%, based on *(7e)*] [130,131], and in poorer yields by $(CH_3)_3SiCl/NH_3$, ammonium chloride, iodine [71], and other electrophiles [131a]. Remarkably, hexaethylcyclotrisilazane cannot be rearranged with acids.

Ring expansions occur as side reactions in transaminations [80,81], in the reaction of *(7e)* with organic acids and alcohols [121,116], and in the reaction of *(7e)* with ammonia [68].

Ring contractions are also known. Thus *(8b)* undergoes rearrangement at 350 to 450 °C to give an 80% yield of *(7e)* [107,132], and poorer yields of *(7e)* are obtained by rearrangement with $H_2SO_4$ or $AlCl_3$ [131a]. Permethylated *N*-trimethylsilylated cyclotri- and cyclotetrasilazanes also tend to ring contraction, as well as rearrangement and disproportionation, at high temperatures and/or under the influence of lithium chloride [15].

The polycondensation of 2,2,4,4,6,6-hexaphenylcyclotrisilazane at 450 °C without catalyst, with elimination of benzene, was reported by *Groszos* and *Hall* [133]. The

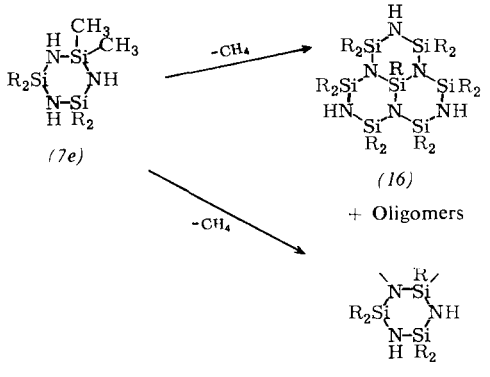
polymer is highly cross-linked, is stable up to 500 °C, and suffers little attack by acids [134].

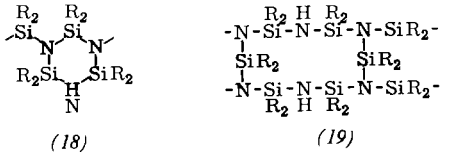
The elimination of methane was observed [135] during attempts to obtain linear polysilazanes by heating *(7e)* and *(8b)* with 1% of solid KOH. Sometimes crystalline polycyclic oligomers (of which the tricyclic compound *(16)*, m.p. 165–167 °C, has been isolated [136]) were obtained at 160 to 260 °C, and partially cross-linked, brittle polymers *(17)*, for which a structure containing intact $Si_3N_3$ units was postulated, at 330 °C.



*(7e)* *(16)* + Oligomers *(17)*

R = $CH_3$

Waxy polymers of unknown structure are obtained by elimination of ammonia from cyclosilazanes having the formula $(C_6H_5HSiNH)_{3 \text{ or } 4}$ in the presence of Pd/C catalysts above 200 °C [39]. *Krüger* and *Rochow* [137–138a] studied the polycondensation of hexamethylcyclotrisilazane *(7e)* and octamethylcyclotetrasilazane *(8b)* with ammonium salts, *e.g.* $NH_4Br$. When equimolar quantities of catalyst are used, the reaction above 160 °C is complete within 6 to 7 hours, and yields a polymer *(18)* or *(19)*, which is cross-linked *via* tertiary nitrogen (oligomers are also formed).



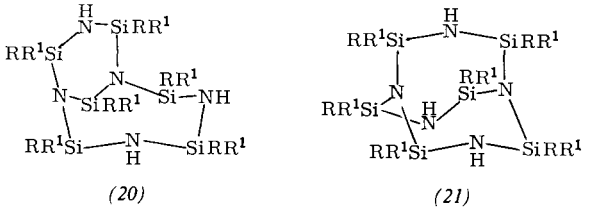
*(18)* *(19)*

R = $CH_3$

Structure *(18)* is more likely, owing to the tendency of the silazanes to undergo ring contraction. The preferred catalysts are ammonium halides (effect: Cl < Br < I). Trimeric cyclosilazanes react more readily than the tetramers.

The waxy to polyethylene-like polymers, which have a maximum crystallinity of 50%, are thermally stable up to 400 °C. Their molecular weight is over 10000. They are resistant to alkali solutions, but are rapidly broken down by acids. The freedom of rotation in these polymers is greatly reduced by "back-coordination" between silicon and nitrogen, formation of small rings, and a high degree of cross-linking in comparison with that in siloxanes [139].

Polymers assumed to have the structure *(18)* [140], as well as bicyclic compounds [38, 140], have been isolated as by-products in the preparation of cyclosilazanes [reaction (i)]. The bicyclic compounds are thought to have the structure *(20)*, though the structure *(21)* is also possible.



*(20)* *(21)*

*(20a)* R=R¹=$CH_3$; b.p. 250–275 °C; $n_D^{20}$ = 1.4684 [140]

*(20b)* R=H, R¹=$CH_3$; b.p. 116 °C/1.5 mm; $n_D^{20}$ = 1.4860 [38]

## 2. Heterocycles with SiN–N Linkages in the Ring

### 2.1. 1,2,4,5-Tetraza-3,6-disilacyclohexane

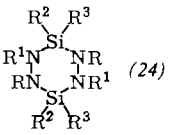
Substituted hydrazines *(22)* react with diorganodichlorosilanes *(23)* at high dilutions in ether to give substituted diorganodihydrazinosilanes *(25)*, which are not particularly stable, and which readily condense to form *(24)* [143, 144].

$$2\ R^2R^3SiCl_2 + 8\ HR^1N\text{-}NRH \longrightarrow$$

*(23)* *(22)*

$$2\ HR^1N\text{-}NR\text{-}SiR^2R^3\text{-}NR\text{-}NR^1H + 4\ HR^1N\text{-}NHR \cdot HCl$$

*(25)*



*(24)*

| R | R¹ | R² | R³ | M.p. (°C) | Ref. |
|---|---|---|---|---|---|
| H | H | Ph | Ph | 168–172 | [143, 144] |

As in ammonolysis, cyclic products are formed by hydrazinolysis in preference to linear ones. If the N–H bonds do not react with the silicon-halogen bond, ring closure can be effected *via* the metalated hydrazines [144, 145] (M = Li, Na).

$$2\ M\text{-}NR\text{-}NR^1\text{-}M + 2\ R^2R^3SiCl_2 \rightarrow (24) + 4\ MCl$$

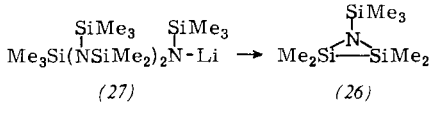
Compounds *(24)* with $R = R^1 = H$ are very readily solvolysed, and are sensitive to oxidation, whereas those with $R = R^1 = C_6H_5$ are more stable[144]. The compounds *(24)* are characterized by an infrared absorption at 890 $cm^{-1}$ [144].

## 3. Heterocycles with Si–SiN Linkages in the Ring

### 3.1. 1-Trimethylsilyl-2,2,3,3-tetramethyl-1-azadisilacyclopropane

An azasiliridine derivative *(26)* (yield 7–12%) has been obtained among other products by the pyrolysis of the lithiosilazane *(27)* at 180–195 °C/100–110 atm[13].

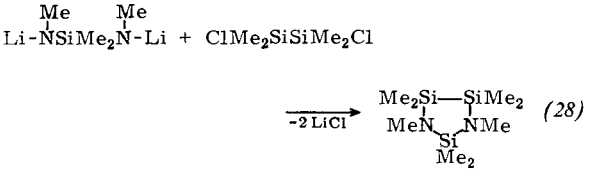


*(27)* *(26)*

Compound *(26)* (b.p. 172 °C, m.p. −37 °C, $n_D^{20} = 1.4375$, $d_4^{18} = 0.827$) has a remarkable thermal stability; the ring is cleaved by bromine at the disilane bond. The ring Si–N bond is weaker than that in cyclodisilazane *(3a)* (ring strain), and the exocyclic Si–N bond is very strong[28]. Compound *(26)* is probably planar.

### 3.2. Octamethyl-1,3-diaza-2,4,5-trisilacyclopentane

The compound was synthesized *via* doubly metalated bis(methylamino)dimethylsilane with 1,2-dichlorotetramethyldisilane (b.p. 70 °C/13 mm, m.p. −18 °C)[146].



*(28)*

### 3.3. 2,2,3,3,5,5,6,6-Octamethyl-1,4-diaza-2,3,5,6-tetrasilacyclohexane

The compound *(29)*, which is isosteric with 1,4-dioxa-2,3,5,6-tetrasilacyclohexane[147], was obtained by *Wannagat* and *Brandstätter*[148] (who also isolated the 1,4-dithia compound[149]) by ammonolysis of 1,2-dichlorotetramethyldisilane in petroleum ether (b.p. 61 °C/2 mm, m.p. 1 °C, $n_D^{20} = 1.4760$, $d_4^{20} = 0.8458$).

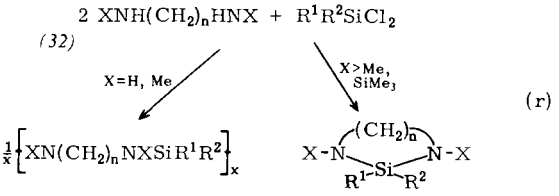
## 4. Heterocycles with N–SiN–$(C)_n$ Linkages in the Ring

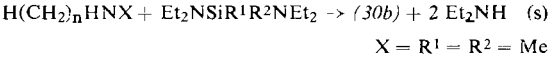
### 4.1. 1,3-Diaza-2-silacyclopentanes and -hexanes

Ethylenediamine *(32)* n = 2, X = H, and *N,N'*-dimethylethylenediamines *(32)*, n = 2, $X = CH_3$, react with polyfunctional organochlorosilanes to form polydiorganosilylethylenediamine. *N,N'*-Disubstituted ethylenediamines with X > Me, on the other hand, tend to form cyclic silylamine derivatives with the 1,3-diaza-2-silacyclopentane skeleton *(30)* [Scheme (r)].



*(30)* n = 2
*(31)* n = 3

Attempts to isolate *(30a)* with X = H[151] and to prepare *(30b)* with $X = R^1 = R^2 = CH_3$ in accordance with Scheme (r) have been unsuccessful. However, the latter compound can be obtained by transamination [equation (s)] (b.p. 132–133 °C/747 mm)[152]. (When $R^1 = R^2 = H$, $X = CH_3$, only polymers are isolated. Ring closure to *(30)* is possible when $R^1 = R^2 = H$ beyond $X = C_2H_5$[84]).



The formation of *(30)* is strongly favored when $X = SiR_3$. No polymers are formed in this case.

The ring in *(30)* is planar with either trigonally hybridized or rapidly inverting nitrogen[150].

The influence of the substituent X on the nitrogen is undoubtedly not only steric in nature. It is surprising that the ring closure of *N,N'*-dimethylethylenediamine *(32b)* does not occur in accordance with equation (r), but can be achieved by transamination in accordance with (s), *i.e.* in a system containing no ammonium salts. From a comparison with the permethylated cyclodisilazane *(3b)*, it appears that the stability principle observed with the cyclodisilazanes is also valid for the 1,3-diaza-2-silacyclopentanes. It is not impossible that the first step in Scheme (r) is ring formation, and that this is followed by ring cleavage by ammonium salts and polymerization.

*Henglein* and *Lienhard*[152] isolated a 1,3-diaza-2-silacyclopentane *(30c)* ($R^1 = R^2 = CH_3$, $X = (CH_3)_3Si$) which has high thermal stability.

Compounds *(30)* in which the ring silicon atom and/or the silyl groups are peralkylated or partially or completely phenylated can be prepared from ethylenediamine and triorganosilanes between 80 and 240 °C[153]. The reaction is catalysed

[150] *D. Kummer* and *J. D. Baldeschwieler*, J. physic. Chem. *67*, 98 (1963).

[151] *D. Kummer* and *E. G. Rochow*, Z. anorg. allg. Chem. *321*, 21 (1963).

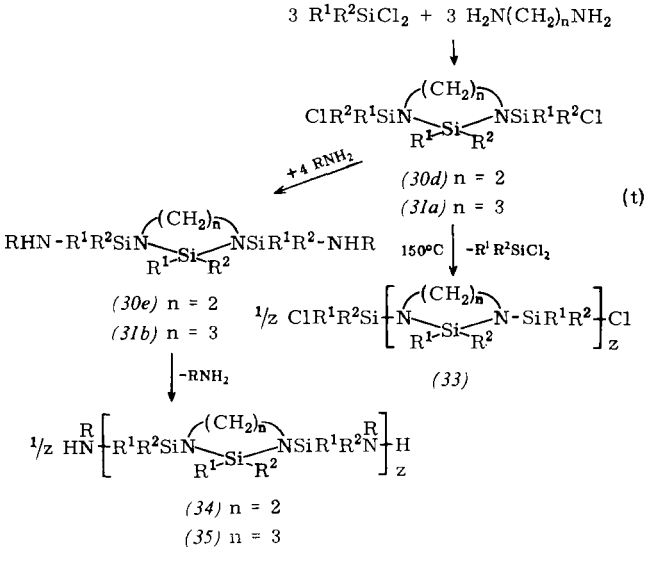
[152] *F. A. Henglein* and *K. Lienhard*, Makromolekulare Chem. *32*, 218 (1959).

[153] *W. Fink*, Chem. Ber., *99*, 2267 (1966).

by NaH. The closure of the 1,3-diaza-2-silacyclopentane ring is accompanied by the cleavage of an Si-phenyl or Si-alkyl bond (elimination of RH).

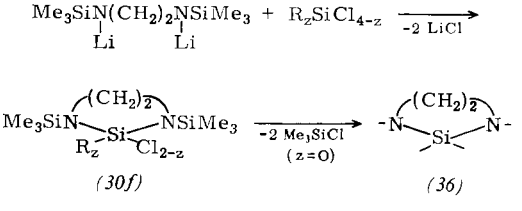
*Henglein* and *Lienhard*[152] and *Breed et al.*[154,155] have described 1,3-diaza-2-silacyclopentanes *(30d)* with monochlorinated silyl groups in positions 1 and 3. Ethylenediamine reacts with excess dialkyl- or alkylaryldichlorosilanes to give good yields of *(30d)* [Scheme (t)]. The reaction with diaryldichlorosilane leads only to disubstituted amines[155].

At higher temperatures the compounds *(30d)* condense, with loss of chlorosilane, to give polymers *(33)*[152,*]. Ammonolysis and aminolysis of *(30d)* leads to the amino compounds *(30e)*[154,155]. These condense at 140 °C in the presence of acidic catalysts (preferably ammonium sulfate) to give polymers with 1,3-diaza-2-silacyclopentane units *(34)*[154,155]. The polymers are soluble in organic solvents, have low melting points, and are sometimes rather elastic; they have molecular weights of up to 15000[154].



(t)

*Kummer* and *Rochow*[151] prepared compounds such as *(30f)* [equation (u)].



(u)

When heated, they condense (particularly readily in the presence of LiCl) to highly cross-linked polymers *(36)*[151], *e.g. (30f)* with z = 0, possibly in accordance with equation (u). The compounds *(30f)* can react further with ethylenediamine. When z = 1, two heterocycles condense *via* an ethylenediamine bridge[151].

1,3-Diaza-2-silacyclopentanes give a pronounced infrared band at 1340 $cm^{-1}$, which is assigned to the 5-membered ring[151,152].

Table. 6. 1,3-Diaza-2-silacyclopentanes *(30)*, (n = 2) and -hexanes *(31)*, (n = 3).

[a] $n_D^{20}$ = 1.4432, $d_4^{20}$ = 0.8623 [152]; [b] $n_D^{20}$ = 1.5343 [153]; [c] $n_D^{20}$ = 1.4383, $d_4^{20}$ = 0.8260 [152; [d] $n_D^{25}$ = 1.4620, $d_{20}^{25}$ = 0.9530 [155]; [e] $n_D^{26}$ = 1.4582, $d_{20}^{26}$ = 0.9304 [155]; [f] $n_D^{28}$ = 1.4566, $d_{20}^{28}$ = 0.9108 [155]; [g] $n_D^{28}$ = 1.5431, $d_{20}^{28}$ = 1.0434 [155]; [h] $n_D^{28}$ = 1.4848, d = $d_{20}^{28}$ 0.9676 [155]; [i] $n_D^{26}$ = 1.4689, $n_D^{26}$ = 0.9672 [155]; [j] $n_D^{26}$ = 1.4671, $n_D^{26}$ = 0.9542 [155]; [k] $n_D^{28}$ = 1.4615, $d_{20}^{28}$ = 0.9243 [155].

The reactions leading to the 1,3-diaza-2-silacyclopentanes are also suitable for the preparation of 1,3-diaza-2-silacyclohexanes *(31)*[153]. Chlorodimethylsilylated compounds *(31a)* can be obtained in moderate yields in accordance with equation (t)[154,155]. The derivatives *(31a)* occur as intermediates in the synthesis of polymers *(35)*, which are obtained from the diamino compounds *(31b)* by condensation with ammonium sulfate[154,155].

Some examples of 1,3-diaza-2-silacylopentanes *(30)* and -hexanes *(31)* are given in Table 6.

### 4.2. 2-Silabenzimidazolines

Compounds *(37)* with readily hydrolysed Si–N bonds are obtained[158] *via* *N,N'*-bis(trimethylsilyl)-*o*-phenylenediamine *(38)* by reaction with polyfunctional chlorosilanes. Whereas the ring closure with methyldichlorosilane is accompanied by elimination of HCl, the reaction of dialkyldichloro- and alkyltrichlorosilanes leads to cleavage of the N–$Si(CH_3)_3$ bond [equation (v)] [*(37a)*,

[154] *L. W. Breed, R. L. Elliott*, and *A. F. Ferris*, J. org. Chemistry *27*, 1114 (1962).

[155] *L. W. Breed, R. L. Elliott*, and *A. F. Ferris*, J. Polymer Sci. *A 2*, 45 (1964).

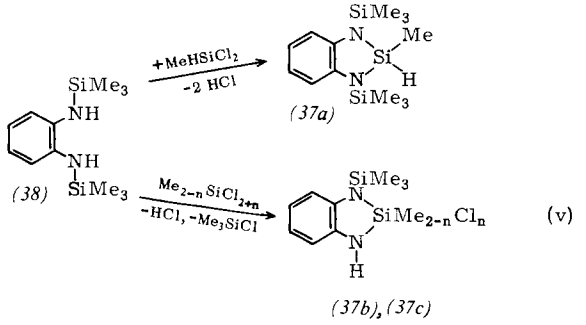
[*] Polymers of similar structure have been synthesized [156,157] by condensation of ethylenediamine with dimethyldichlorosilane. The polymer is at first largely linear but rearranges *via* several intermediate stages to give *(33)* as a result of aging or heat treatment or, more rapidly, by the elimination of ethylenediamine with catalysis by copper salts.

[156] *E. G. Rochow* and *R. N. Minné*, J. Amer. chem. Soc. *82*, 5625, 5628 (1960).

[157] US-Pat. 3098830 (1963), General Electric Co., inventor: *E. G. Rochow*.

[158] *D. Kummer* and *E. G. Rochow*, Angew. Chem. *75*, 207 (1963); Angew. Chem. internat. Edit. *2*, 152 (1963).

b.p. 86 °C/1 mm, $n_D^{20} = 1.5278$; *(37b)*, n = 0, m.p. 91–93 °C; *(37c)*, n = 1, m.p. 99 °C].

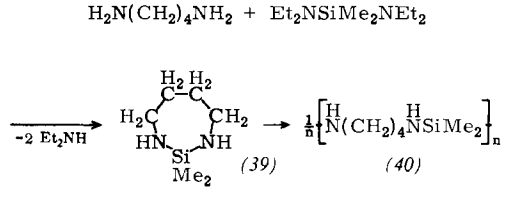


(v)

The *Si*-phenylated compounds *(37)*, which cannot be obtained in this way, can be prepared in good yields by the catalytic silylation of *(38)* or of *o*-phenylenediamine with one or three moles, respectively, of phenylsilane [29,153].

### 4.3. 1,3-Diaza-2-silacycloheptane

Rings with more than six members and containing Si–N bonds are unstable (apart from the stable rings containing only alternating Si and N atoms), and tend to undergo polymerization with ring cleavage. This is clearly seen with compound *(39)* (b.p. 57.5 °C/16 mm), which polymerizes even at room temperature to form polydimethylsilyltetramethylenediamine *(40)* [152].

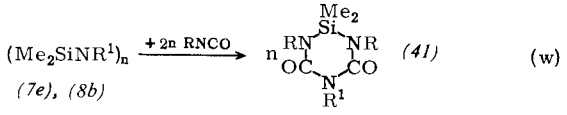


### 4.4. 2,2-Dimethyl-1,3,5-triaza-2-silacyclohexane-4,6-diones

The reactivity of the Si–N bond towards organic isocyanates, reflected in easy cleavability and formation of silylureas [159–162], can be utilized in the synthesis of the 1,3,5-triaza-2-silacyclohexane-4,6-dione.

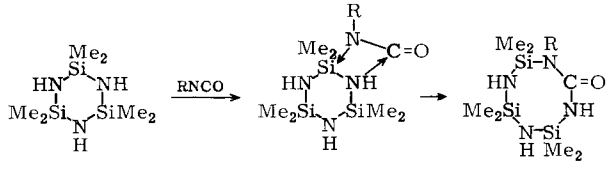
Hexamethylcyclotri- *(7e)*, n = 3, and octamethylcyclotetrasilazanes *(8b)*, n = 4, react with organic isocyanates in solution at 60 to 90 °C to give derivatives of 1,3,5-triaza-2-silacyclohexanedione *(41)* [129,163]. [*(41a)*, R = $C_6H_5$, $R^1$ = H, m.p. 188–190 °C; *(41b)*, R = *p*-Br–$C_6H_4$, $R^1$ = H, m.p. 215 °C].

The structure of *(41)* was found by hydrolysis (which leads to 1,5-diphenylbiuret when $R^1$ = H, R = $C_6H_5$), $^1$H–NMR studies, and X-ray analysis [164].



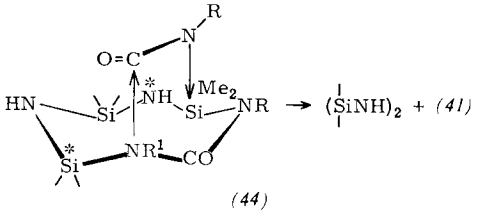
(w)

The reaction (w) can be formulated as a cycloaddition of one molecule of isocyanate (the silazane ring is degraded in stages) to an SiN bond in *(7e)* or *(8b)*.



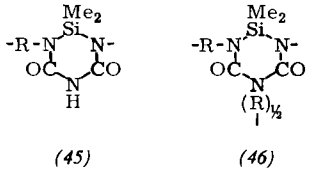
The cleavage of the bond and the ring expansion are facilitated by the weakening of the Si-N bond (suppression of the $d_\pi$-$p_\pi$ bond component owing to occupation of the silicon d orbitals by electrons from the isocyanate nitrogen).

The 8-membered ring *(43)* can add another isocyanate molecule [*(44)*], whereupon the transannular interaction between *silicon and *nitrogen leads to constriction of the ring and to the formation of *(41)* and a cyclosilazane with one less Si-N unit (*i.e.* in this case n = 2), which can then repeat the sequence of reactions.



The reaction of isocyanate with 1,3-disubstituted *(41)* at 120 to 160 °C leads *via* large, unstable rings to 1,3,5-trisubstituted 2,2-dimethyl-1,3,5-triaza-2-silacyclohexane-4,6-diones [129] (*e.g. (41c)* with R = $R^1$ = $C_6H_5$, m.p. 213–215 °C; *(41d)* with R = $R^1$ = $C_2H_5$, m.p. 92–93 °C; *(41e)* with R = $R^1$ = n-$C_4H_9$, b.p. 110–118 °C/0.015 mm).

Transparent, elastic, essentially linear polymers *(45)* containing *(41)* as a structural unit can be synthesized by the reaction of hexamethylcyclotrisilazane *(7e)* with (preferably aliphatic) diisocyanates below 110 °C [29].



Above 110 °C, these rearrange with elimination of $(HNCO)_x$ to form highly cross-linked polymers *(46)* which possess excellent stability towards acids.

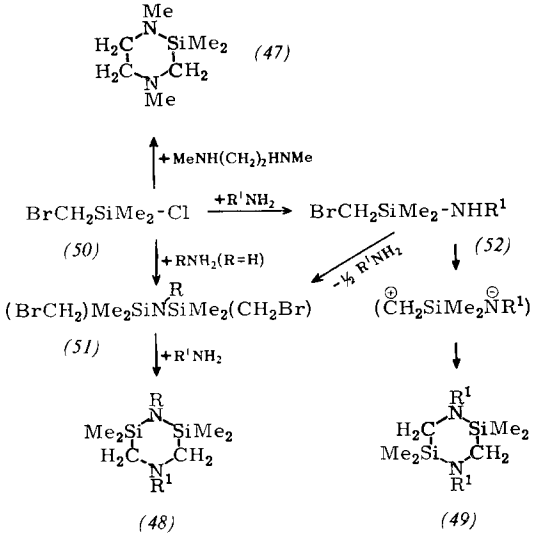
## 5. Heterocycles with C–SiN–Si or C–SiN–C Linkages in the Ring

### 5.1. Silapiperazines

The mono- *(47)* and disilapiperazines, the second of which can occur as 2,6- *(48)* and 2,5-isomers *(49)*, are derived formally from the piperazine ring structure [*(47)*: b.p. 64 °C/53 mm; $n_D^{20} = 1.4508$].



*Simmler*[165] obtained 1,2,2,4-tetramethyl-2-silapiperazine *(47)* in small yields by dropwise addition of bromomethyldimethylchlorosilane *(50)* to an excess of *N,N'*-dimethylethylenediamine at 0 °C.

The 2,6- and 2,5-disilapiperazines have also been synthesized from *(50)*[166]. 1,3-Bisbromomethyl-1,1,3,3-tetramethyldisilazane *(51)* [from the ammonolysis of *(50)*, which also yields *(48)* with R = $R^1$ = H] reacts with primary amines to give 4-alkyl-2,6-disilapiperazines *(48)*, and with an excess of amine (transamination) to give 1,4-dialkyl-2,6-disilapiperazines. The direct reaction of *(50)* with excess of primary aliphatic amines leads to inseparable mixtures of 2,6- and 2,5-isomers. (For the preparation of pure *N,N'*-bis-(2-methoxyethyl)-2,2,5,5-tetramethyl-2,5-disilapiperazine, b.p. 115–117 °C/4 mm, $n_D^{21.5} = 1.4605$, cf.[167]).

The proportion of 2,5-isomer *(49)* increases with the size of the group attached to the nitrogen. This indicates that owing to steric factors, the 2,5-disilapiperazines are formed *via* the silylamine *(52)*. Table 7 shows some examples of 2,6-disilapiperazines.

Table 7. 2,6-Disilapiperazines *(48)*.

| R | $R^1$ | B.p. (°C/mm) | $n_D^{20}$ |
|---|---|---|---|
| H | H | [a] | |

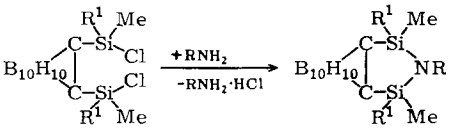
| All | All | 113/15 | 1.4740 |

[a] Decomp. p. of hydrobromide 270 °C.

### 5.2. 2'-Aza-1',3'-disilacarboranes

These compounds, which are remarkable for their thermal and hydrolytic stability, were obtained by ammonolysis or hydrazinolysis of bis(chlorodimethylsilyl)- *(54a)* or bis[(dichloro)methylsilyl]carboranes *(54b)* [168, 169].



*(54a)*: $R^1$ = Me
*(54b)*: $R^1$ = Cl

*(53)*

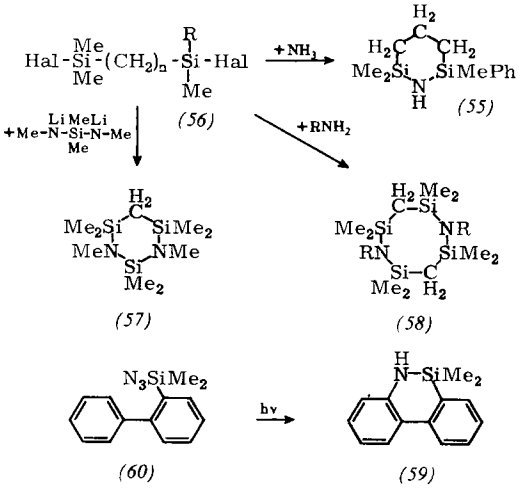
| Derived from: | $R^1$ | R | M.p. (°C) |
|---|---|---|---|
| *(54a)* | Me | H | 190–192 |
| *(54a)* | Me | $NH_2$ | 163–165 |
| *(54a)* | Me | Me | 156–158 |
| *(54a)* | Me | Ph | 183–185 |
| *(54b)* | $NH_2$ | H | 189–191 |
| *(54b)* | NHMe | Me | 128–129 |

The compounds *(53)* are stable up to 500 °C; the Si–N bond, which is normally readily solvolysed, is surprisingly stable in *(53)*.

### 5.3. 1-Aza-2,6-disilacyclohexane and Similar Compounds

2,2,6-Trimethyl-6-phenyl-1-aza-2,6-disilacyclohexane *(55)* (b.p. 100 °C/3 mm, $n_D^{20} = 1.5194$, $d_4^{20} = 0.9736$), which is isosteric with the 1-oxa-2,6-disila compound[170], has been prepared by ammonolysis of the chlorosilyl derivative *(56)* (n = 3, R = $C_6H_5$)[170].

Octamethyl-1,3-diaza-2,4,6-trisilacyclohexane *(57)* (b.p. 46 °C/3 mm, m.p. −18 °C, $n_D^{20} = 1.4573$) and octamethyl-1,5-diaza-2,4,6,8-tetrasilacyclooctane *(58)* (R = H: b.p. 82 to



[165] *W. Simmler*, Chem. Ber. *96*, 349 (1963).

84 °C/3.5 mm, m.p. 35 °C; R = $CH_3$: b.p. 97 °C/3 mm, m.p. 44–45 °C) were synthesized [17,85,171] by the reaction of *(56)* (n = 1, R = $CH_3$, Hal = Br) with *N,N'*-dilithiodi(methylamino)dimethylsilane [for *(57)*] and with ammonia or methylamine [for *(58)*].

10,10-Dimethyl-9,10-dihydro-9,10-azasilaphenanthrene *(59)* (m.p. 143 °C) can be prepared by photolysis of 2-(azidodimethylsilyl)biphenyl *(60)* [106]. The ultraviolet spectrum of *(59)* is remarkably similar to that of phenanthrene; this similarity has been interpreted as resulting from aromatization of the ring containing the Si-N bond.

n = 1 [172–181], 2 [172,175,176,178,179], 3 [175,176,179], 4 [178,179], and 5 [178,179]. Some examples are shown in Table 8.

Compounds with n = 6 to 10 do not give cyclic siloxazanes, but instead form polymeric siloxazanes with low thermal stabilities [180].

The cyclization of *(67)* to form *(65)* and *(66)* proceeds very readily for $R^2$ = H and n < 6 [*(67)* cannot be isolated]. When $R^2$ = alkyl, *(67)* is stable [175–179], but can be cyclized to *(65)* or

Table 8. Cyclic siloxazanes.

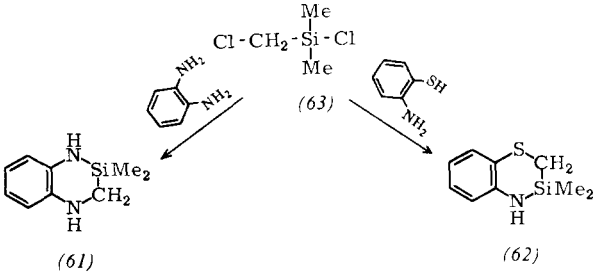
2,2-Dimethyl-1,2,3,4-tetrahydro-1,4-diaza-2-silanaphthalene *(61)* (b.p. 142–144 °C/4 mm, m.p. 52 °C) and 3,3-dimethyl-1,2,3,4-tetrahydro-1-thia-4-aza-3-silanaphthalene *(62)* (b.p. 151–154 °C/8 mm) have been prepared by the reaction of *o*-phenylenediamine and *o*-aminothiophenol with chlorochloromethyldimethylsilane *(63)* [171a].



*(61)* *(62)*

## 6. Heterocycles with O–SiN–Si Linkages in the Ring

### 6.1. Cyclosiloxazanes

Rings with O–SiN–Si linkages [172,173] are generally prepared by ammonolysis or aminolysis of α,ω-dichloro-α,ω-tetraorgano(preferably methyl)siloxanes *(64)* with *(66)* with the aid of acidic catalysts (*e.g.* ammonium sulfate [179]) if the amine formed is simultaneously removed from the equilibrium. The conversion of *(65)* or *(66)* into *(67)* with cleavage of the siloxazane ring is also known. With excess of ethylamine in the presence of $C_2H_5NH_2 \cdot HCl$, the reaction proceeds almost quantitatively even at –20 °C, *e.g.* when $R^2 = C_2H_5$, R = $R^1$ = $CH_3$, n = 2 [178]. Compound *(67)* is probably not formed strictly in accordance with equation (x), but *via* cyclic siloxazanes, which immediately undergo ring cleavage under the conditions of the reaction (excess of amine).

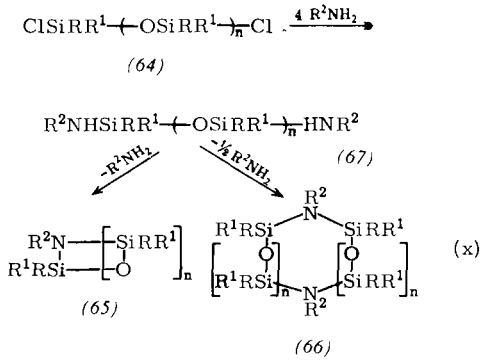
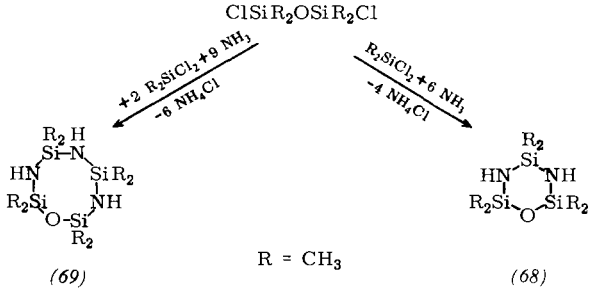
[180] *K. A. Andrianov*, *L. M. Volkova*, and *V. N. Talanov*, Izvest. Akad. Nauk SSSR, Otd. Khim. Nauk *1963*, 2045; Chem. Abstr. *60*, 5534 (1964).

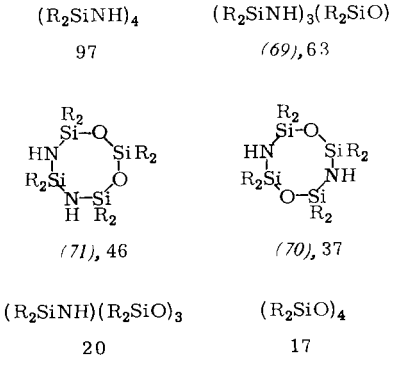
[181] *K. A. Andrianov*, *I. Haiduc*, and *L. M. Khananashvili*, Zh. obshch. Khim. *33*, 2790 (1963); Chem. Abstr. *59*, 15300 (1963).



*Andrianov et al.*[181,182] prepared 6-membered *(68)* and 8-membered *(69)* cyclic siloxazanes by co-ammonolysis of 1,3-dichlorotetramethyldisiloxane and dimethyldichlorosilane (ratio 1:1 and 1:2, respectively) [*(68)*, R = $CH_3$, m.p. 47 °C; *(69)*, R = $CH_3$, m.p. 63 °C].



The same authors[182] isolated the 1,3-dioxa-5,7-diaza isomer *(71)* of 2,2,4,4,6,6,8,8-octamethyl-1,5-dioxa-3,4-diazacyclooctane *(70)*[173–176] from the products obtained by ammonolysis of a 1:1 mixture of 1,5-dichlorohexamethyltrisiloxane and dimethyldichlorosilane (Scheme 3).



Scheme 3. Transitions between cyclotetrasilazanes and cyclotetrasiloxanes. The figures under the formulae are the melting points (°C); R = $CH_3$.

Siloxazanes can be polymerized with ammonium halides, with partial decomposition, to siloxanes, and with alkaline catalysts to polymers and oligomers which are cross-linked *via* triply silylated nitrogen[176,176a]. The N–H bond in siloxazanes is not metalated by organometallic compounds or $NaNH_2$, but the Si–O bonds are broken instead[176].

Whereas the SiOSi bond angle in *(65)* with n = 2 (R = $R^1$ = $CH_3$, $R^2$ = H) corresponds to that in hexamethylcyclotrisiloxane, the angle of the SiNSi bond (133 °C) is considerably larger than in hexamethylcyclotrisilazane (117 °C)[176]. The abnormally low hydrolytic stability of 6-membered cyclosiloxazanes [*(65)* with n = 2] may be due to the ring strain in these compounds. The Si-N bonds in 8-membered cyclosiloxazanes [*(66)* with n = 1], on the other hand, are appreciably more stable than those in cyclosilazanes[179]. Cyclosiloxazanes [*e.g. (66)* with n = 1, R = $R^1$ = $CH_3$, $R^2$ = H] combine outstanding thermal stability with a wide liquid range. They are more stable at 450 °C than cyclotetrasiloxanes or cyclotrisilazanes[183,185].

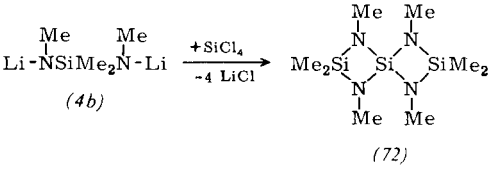
The relative thermal stabilities of a number of heterocycles containing Si, N, or O at 450 °C[183,184] are listed below

| Compound | *(66)*, n = 1 R = $R^1$ = $R^2$ = Me | *(7a)* $(MeNSiMe_2)_3$ | *(7e)* $(HNSiMe_2)_3$ | $(OSiMe_2)_4$ |
|---|---|---|---|---|
| ml of gas/g [*] | 0.10 | 0.24 | 0.58 | 0.82 |

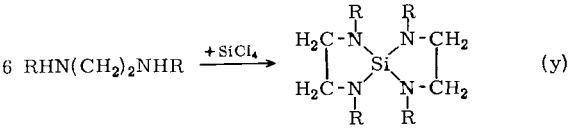
[*] ml of gas formed in 1.5 h/g of substance.

## 7. Spiranes with SiN Linkages

Spirosilazanes can, in principle, be prepared by condensation of a tetrahalogenosilane with a diamine or diaminosilane (possibly in the form of the dilithium compound). Thus octamethylspiro[3.3]trisilazane *(72)* (b.p. 39 °C/4 mm, m.p. 34 °C) is obtained in this way from silicon tetrachloride and *(4b)*[18]



and 1,4,6,9-tetraza-5-silaspiro[4.4]nonane *(73)*, like the 5-germaspiranes, is obtained in accordance with equation (y).



| R | B.p., °C/mm (M.p., °C) | $n_D^{28}$ |
|---|---|---|
| *(73a)* Me | 75/8 | 1.4640 |
| *(73b)* Et | 123/7 | 1.4677 |
| *(73c)* p-Toy | (300–304) | |
| *(73d)* $Me_3Si$ | (206) [151] | |

Whereas *N,N'*-dialkylethylenediamines react smoothly in benzene at 40 to 60 °C to give *(73)*, the arylated diamines react only with difficulty, and give poor yields. It is concluded from NMR data that the rings in the alkylated 1,4,6-tetraza-5-silaspiro[4.4]nonanes *(73)* are planar[185].

The spiro compound *(74)* (m.p. 200 °C), in which only two nitrogen atoms are trimethylsilylated, can be pre-

# The Hormonal System of Plants

BY PROF. H. LINSER

INSTITUT FÜR PFLANZENERNÄHRUNG DER UNIVERSITÄT GIESSEN (GERMANY)

*Higher plants generate active substances, termed phytohormones, having the character of tissue hormones. Some of these compounds have been isolated and identified, namely ethylene, heteroauxins, and gibberellic acids. Cell-elongation inhibitors have been detected, but not yet isolated or identified. Natural and synthetic substances with hormone-analogous effects and those with a hormone-antagonistic effect have become known; evidently, they act on the hormonal system of plants which regulates growth, differentiation, and development and can serve as model substances for as yet unknown phytohormones. Certain physiological phenomena suggest the existence of additional phytohormones.*

## I. Introduction

Since 1904 the term hormones has been used to designate substances produced as internal secretions by an organ of an organism and carried in the bloodstream to a different organ, where they act even at very low concentrations, and which are essential for normal metabolism and development [1]. This concept was restricted for about 25 years to animal organisms; however, the discovery in 1929 [2] of similar substances which are transported by the plant tissue juices to the sites of

[1] *W. M. Bayliss* and *E. Starling*, Proc. Roy. Soc. (London) Ser. B *73*, 310 (1904).

[2] *F. W. Went*, Recueil Trav. bot. néerl. *25*, 1 (1929).

action led to an extension to plants. Although many animal hormones are produced by glands, some are formed by tissues (aglandular hormones). Because higher plants, with few exceptions, have no gland organs, plant hormones (phytohormones) must be regarded as aglandular secretions.

There are also noteworthy analogies in regard to hormone action. Animal hormones regulate the intensity of metabolic changes[3] such as the rates of protein, fat, carbohydrate, and basal metabolism (thyroxin), production of other hormones or internal secretions (thyreotropin), production of pigments (pigment-forming hormones), secretion of certain glands, *e.g.* lactation (prolactin), water balance and salt excretion (adiuretin), displacement of substances into certain organs or storage in these (glycogen storage in liver by insulin), contractions of certain tissues (constriction of blood vessels, tachycardiac stimulation of the heart by adrenalin), development of genitalia and secondary sexual characteristics (estradiol, testosterone), and growth and rate of growth (somatotropin, whose absence leads to dwarfing and cessation of development). Analogously in plants, phytohormones control the intensity of metabolism, the production of other phytohormones, production and decomposition of pigments, displacement of certain substances into certain organs or storage in them, elongation of the cell wall, the development of flowers, and also growth and growth rate (with absence of individual hormones leading to dwarfing and inhibition of development). No information is available yet about hormonal control of water balance, salt secretion, and formation of secretions in plants, except that the water uptake of individual cells is influenced by the cell-elongation hormones.

## II. Methods of Detection

The discovery and study of phytohormones (or of synthetic substances with analogous behavior) requires methods allowing investigation of the generation and measurement of hormonal action in numerous plants (to ensure statistical significance), available throughout the year (under standardized conditions) and over the shortest possible period. The test plants are susceptible to hormones only during a certain stage in their development, the determination of which in general is tedious. In addition, the specimens must be deprived as much as possible of their native hormones.

These conditions are given in growth reactions which become evident very soon after the hormone takes effect. An example of such a reaction is the epinastic downward movement of leaves under the influence of gases which promote the longitudinal growth of cells; the upper side of the leaf stem is stimulated to an increased rate of growth (the top surface of the stem is more susceptible than the underside; curving occurs even if the concentration of active agent, *e.g.* tobacco smoke[4] or ethylene[5] is the same on either side). One-sided application of a substance promoting cell elongation to a uniformly reactive organ, *e.g.* cereal coleoptiles, also can produce measurable curving and permits a quanitative evaluation of the activity. This is the basis of *Went*'s auxin test[6] and numerous analogous methods[7]. More expedient is a measurement of length after uniform exposure to the test solution[9], because transport of a component applied on one side to the untreated side can produce errors[8].

Measurable effects are obtained at a similar rate during germination of various plant seeds. Inhibition of germination[10] or inhibition of root growth of the germinated seed[11] are possible test criteria. Since nonspecific or toxic substances can also produce inhibition, the use of an inhibition test to detect phytohormones is not as convincing as a stimulation test.

Slower methods of detection, suitable for higher hormone concentrations, are based on the influencing or initiation of callus formation, root formation, bud formation on grafted plants or rhizome disks[12] on transplants, or on callus tissue of plant tissue cultures[13] and also on the emergence of morphological changes (or malformations) especially in dicotyledons[14]. Retardation of the degradation of chlorophyll in leaves can also serve for the detection of hormones[15]. Certain hormonal effects influence the overall habit of the plant (rosette or elongated form), *i.e.* the internodal length[16–19].

## III. Historical

*Küster*[20] showed as early as 1909 that substances formed by plant organisms can exert physiological effects on other plants, but this effect is due partly to the action of nutrients or vitamin-like substances or of metabolites of one organism on the metabolic system of another.

The observations of *Molisch*[4] showed that certain plants respond very sensitively to tobacco smoke with epinastic growth. Subsequently, *Ricinus communis* leaves, for example, were found to react epinastically to

[20] *E. Küster*: Vorträge und Aufsätze über Entwicklungsmechanik der Organismen. Engelmann, Leipzig 1909, Vol. 6, p. 1.

ethylene ($1:10^7$ in air)[5]. It was further established that ripening apples can cause potatoes stored in the same room to form sprouts with inhibited longitudinal growth but of increased thickness[21], to increase their sugar content, and to increase the catalase and oxidase activity. Moreover, ripening apples were observed to produce ethylene (in mesocarp and endocarp) and to eliminate it into the air[22]. It therefore seemed reasonable to assign hormonal character to ethylene.

Meanwhile, in 1929, *Went* had demonstrated with *Avena* coleoptiles[6] that during phototropic growth the coleoptile tip liberates substances which regulate the longitudinal growth of the underlying cells. The auxin subsequently obtained by *Kögl* from urine[23] could not be re-isolated later. The cell-elongating hormone (for which the term auxin was retained) of plants is indole-3-acetic acid (heteroauxin)[24]. Cell-elongation inhibitors[23] with as yet unknown structures were also found. In addition, numerous synthetic substances with cell-elongation promoting or inhibiting action are known (cf.[7]).

In 1926 it was discovered that cell-free filtrates of *Gibberella fujikuroj* culture media cause the same Bakanae disease in rice plants as the fungus itself[16]. In 1938 the active component was isolated and its constitution elucidated. Since then the term gibberellins, originally introduced in 1935, has been employed to designate this compound and similar substances.

## IV. Ethylene

Ethylene is formed above all by ripening fruit, but leaves[26] (rhubarb, calla, marshmallow, peony, asparagus) and flowers (dandelion) also liberate gases which can produce epinasty[27,28].

The formation of ethylene during metabolism is inhibited by respiratory poisons[28a]. It is considered to be related to the citric acid cycle[28b], but pyruvic acid is a better starting material than fumaric acid[28c]. Ethylene can be formed enzymatically also from linolenic acid and from methionine in the presence of copper and ascorbate[28d]. The degradation of lipids of the mitochondria caused by age likewise yields ethylene[28e].

The formation of ethylene in plant organs is induced or stimulated by auxins, the rate of formation depending on the promoter content of the relevant organ. Asymmetric distributions of auxin, as in tropisms, are also expressed in the rate of production of ethylene[29].

*Crocker et al.*[25] found an epinastic reaction in 80 out of 202 investigated species when ethylene was allowed to act on the stem. Further effects of ethylene are inhibition (in very small concentrations promotion) of the longitudinal growth of elongating organs, stimulation of root formation, acceleration of fruit ripening (respiration, chlorophyll degradation, color changes, *etc.*), chlorophyll degradation in leaves and shedding of leaves and flowers, promotion (in higher concentrations inhibition) of the sprouting of buds, promotion of callus formation, and inhibition of anthocyanin formation[28].

Ethylene chlorohydrin, acetylene, propylene, and carbon monoxide act similarly to ethylene, but the latter is 500 times more active than acetylene and propylene, and about 5000 times more active than carbon monoxide[30]. The opposite action, retardation of ripening and aging, is shown by ethylene oxide, which inhibits the formation of ethylene in the plant and acts as an ethylene antagonist[31].

Fresh, pure ethylene behaves somewhat differently towards the plant than does aged material (after storage or after regeneration following adsorption on mercury(II) perchlorate). The plants absorb ethylene stomatally, cuticularly, lenticellularly, and through other surfaces, and experiments with $^{14}C$-ethylene have shown that aged ethylene is taken up in larger quantities than the fresh gas[32].

Referred to 1 g dry substance, older plants take up more ethylene than younger ones, but the youngest leaves absorb more ethylene than older ones. More ethylene is also absorbed when the plant is kept in the dark. About two-thirds of the absorbed amount (which reaches a maximum after about 2 hours) can be removed by heating the plant. Eighteen metabolites have been detected in the residue by radiochromatography[33]. Three of these appear in the ether-soluble fraction together with carotenes[34]; the bulk of the reaction products are alcohol-soluble and are contained in the cell wall. Products of esterification with phosphoric acid are probably present[31], but there is no indication that the ethylene causes decoupling of the oxidative phosphorylation[31].

The ripening-promoting action of ethylene is utilized in the banana trade. Unripe bananas treated for 5 days with $10^{-4}$ parts of ethylene in air at 20–22 °C ripen 20 days sooner than untreated fruit. The yellow, mature color of harvested tobacco leaves can likewise be produced by treatment with ethylene (1:5000)[35].

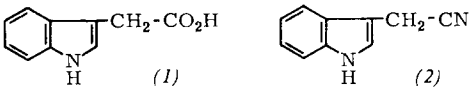
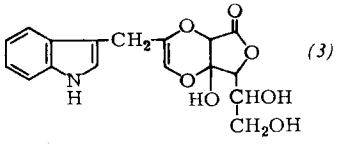
## V. Auxins

Auxins occur in all plants. They are found predominantly in pollen seeds, in the developing seedling, in the latter's endosperm, coleoptile and root tips, and also in the bud vegetation points of older plants. The most important auxin, invariably present, is heteroauxin [36], indole-3-acetic acid *(1)* [37,38]. Many plants also contain indole-3-acetaldehyde, indole-3-butyric acid, indole-3-acetonitrile *(2)* and further indole derivatives [39] such



as 2-hydroxyindole-3-acetic acid and ethyl indole-3-acetate, with similar cell-elongating action. Indole-3-acetonitrile is ten times as active as indole-3-acetic acid in the paste test. Indole-3-acetic acid is formed from tryptophan *via* ascorbigen *(3)* [39,39a].



Numerous authors produced evidence that cell-elongation hormones other than indole derivatives exist, but did not isolate them. Mixtures of unsaturated and saturated $C_{20}$ and $C_{22}$ fatty alcohols with cell-elongating action have been found in tobacco plants [40].

The physiological effects of indole-3-acetic acid are [41–43]:

1. In small concentrations promotion, in large concentrations inhibition of longitudinal cell growth and the related water absorption of the cells;
2. Promotion of cell division of the meristematic tissue (stem, hypocotyl);
3. Promotion of root formation even on tissues which do not normally form roots, but inhibition of root growth, except in smallest concentrations;
4. Promotion of callus formation and callus growth;
5. Inhibition of budding and growth of auxiliary buds and bud formation;
6. Influencing of leaf, flower, and fruit shedding;
7. Influencing of flower formation;
8. Formation of parthenocarpic fruit (infertile seedless fruit) [43a];
9. Promotion of respiration and protein formation.

The concentration *vs.* activity curves exhibit a maximum [7,8], *i.e.* there is promotion at small concentrations, and inhibition at larger concentrations (Fig. 1). The optimum concentration for root growth is $10^{-10}$, for bud growth $10^{-8}$, for stem growth $10^{-5}$, and for flower promotion $10^{-4}$ M [44]. Optimum root formation occurs at concentrations which almost completely inhibit the longitudinal growth of the roots formed.

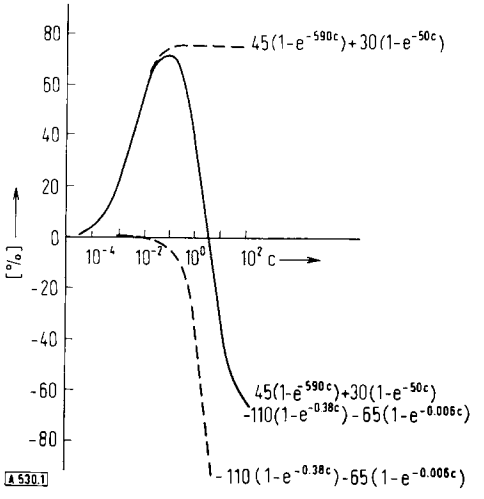


Fig. 1. Concentration—activity curve of indole-3-acetic acid (full line) and the derived promotion (top) and inhibition components (bottom, broken lines).
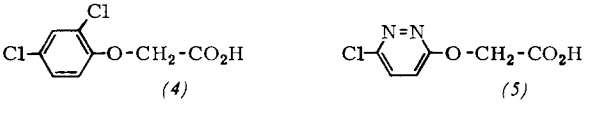
Ordinate: Increase in coleoptyl length in % relative to untreated coleoptyls;
Abscissa: Concentration of indole-3-acetic acid, wt-%.

Certain synthetic substances have an effect similar to that of the auxins; these include α-naphthylacetic acid, 2,4-dichlorophenoxyacetic acid *(4)* and other phenoxyacetic acid derivatives, 6-chloropyridazine-3-yloxyacetic acid *(5)*, and carboxymethyl *N,N*-dimethyldithiocarbamate [44].



Like indole-3-acetic acid, these compounds show maxima in their concentration-activity curves. In contrast, eosin, tetrachlorofluorescein, tetraiodofluorescein, 2 3,5-triiodobenzoic acid, β-naphthoxyacetic acid, and 2,4,6-trichlorophenoxyacetic acid yield decreasing concentration *vs.* activity curves without a maximum [45].

In order to show auxin activity a molecule evidently must possess certain dimensions [46]; a distance of 5.5 Å is postulated to be necessary between the hydroxyl oxygen in the carboxyl group and an atom in the phenyl or indolyl ring or in a corresponding radical able to take up a positive charge [47] (Fig. 2).

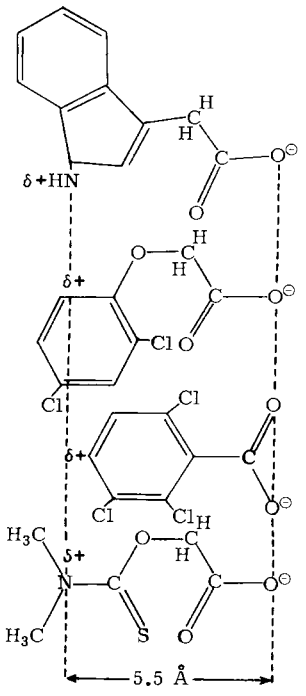

Fig. 2. Distance between atoms of opposite charge in indole-3-acetic acid and in the most active auxins of three other series.

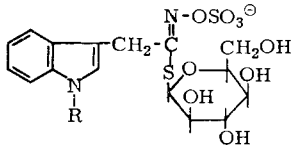
In structure and size, bis-(2,4-dichlorophenoxy)acetic acid resembles eosin, tetrachlorofluorescein, and tetraiodofluorescein, and possesses an inhibitory character [48]. The recently discovered active substance methyl 2,7-dichloro-9-hydroxyfluorene-9-carboxylate [49] has a similar molecular structure. Despite numerous attempts, the relationship between constitution and activity has not yet been elucidated.

Since longitudinal growth is linked closely with protein synthesis, inhibitors of the latter, such as chloramphenicol, also inhibit the former [49a].

All parts of the plant rapidly take up auxins from external sources. Absorption is frequently augmented when the side-chain of the molecule is esterified with a lower alcohol, *e.g.* with butanol. Evidently, the auxins can then also be absorbed from the cell boundary layers *via* the lipid phase. The distribution in the plant is predominantly in the basal direction and is faster at 25 to 30 °C than at 15 °C [50]; apical transport is small and little hormone is moved transversally. This is the reason for the curving observed after one-sided application of the growth agent. Changes in the magnitude of the transverse transport lead to so-called tropistic growth curvatures. On this basis, phototropism can be interpreted as the action of light not on auxin itself but on its distribution downwards from the coleoptile tip, with the auxin content of the illuminated side remaining smaller than that of the unexposed side [51].

During metabolism indole-3-acetic acid is decarboxylated by an indole-3-acetic acid oxidase and loses its activity. Auxin oxidase is inhibited by chlorogenic acid [52]. Indole-3-acetic acid taken up from outside was found partly as *N*-indolylacetyl aspartate and partly as 1-(indolylacetyl)-β-D-glucose. Analogous derivatives are formed after absorption of α-naphthylacetic acid [51a]. Binding to protein has also been observed [52]. Indolylacetylglucose is formed from indole-3-acetic acid and uridine diphosphoglucose. In the biosynthesis of indolylacetyl aspartate an energy-rich compound, perhaps indolylacetyl-CoA, is a likely intermediate [53]. In *Brassica* species, large quantities of indole-3-acetic acid [8] are present in the inactive form as glucobrassicin *(6)* and neoglucobrassicin *(7)* [53]. At pH 4 these are rapidly split enzymatically into indole-3-acetonitrile, glucose, sulfate, sulfur, and hydrogen sulfide, and at pH 7 glucose, sulfate, thiocyanate, and 3-hydroxymethylindole are formed. The last-named compound combines with ascorbic acid to form ascorbigen *(3)* [54].



*(6)*, R = H
*(7)*, R = $OCH_3$

Synthetic substances of the auxin type have been used in agriculture since 1941 in England and the United States, and since 1946 also in continental Europe to combat weeds (cf. [55]). In particular, 2,4-dichlorophenoxyacetic acid and some of its derivatives and analogues have been used successfully to combat dicotyledous weeds in cereal cultures. In horticulture, auxins are used to promote root formation on grafted plants and to produce parthenocarpic fruit, and in orchards for thinning out flowers and fruit and for prevention of premature fruit dropping.

## VI. Gibberellins

Gibberellins are produced not only by fungi but also by higher plants. For example, gibberellins $A_1$, $A_5$, $A_6$ and $A_8$ [*(8)*, *(12)*, *(13)*, and *(15)*] have been isolated from the seed of *Phaseolus multiflorus* [56]. Substances with gibberellin-like action but of unknown structure have been detected in numerous plants and plant organs [57].

Rapidly growing tissue always contains particularly high concentrations of gibberellins [58], but unripe seeds contain about 100 times as much [59] and also form these substances during growth [60].

2. Promotion of hypocotyl growth [65];

3. Promotion of germination, particularly of light germinators in the dark [66];

4. Promotion of the sexual development of flowers [67];

5. Promotion of flower formation [68];

6. Formation of parthenocarpic fruit and promotion of fruit flesh growth [69];

7. Interruption of the rest period of buds and underground storage organs [70, 73a];

8. Influencing of flower formation [71] and the photoperiodic behavior of flowering plants [72];

9. Influencing of the shape and size of the leaves [73, 73a];

10. Promotion of cell division in the cambial zone [74];

11. Influencing of the activity of α- and β-amylase, protease, and catalase [75], lessening of the activity of indole-3-acetic acid oxidase [76].

Ten gibberellins are known [77, 78], the activities of which differ in different plants and in different physiological systems (Table 1). Evidently, the gibberellins are

Table 1. Relative effectiveness of gibberellins $A_1$—$A_9$ relative to $A_7$ = 100 % [80].

| Gibberellin | Dwarf pea, stem growth | Dwarf maize, leaf shedding | Lettuce, hypocotyl | Cucumber, hypocotyl | Lettuce, seed germination in the dark | Cucumber, formation of male flowers on female plants | Tomatoes, parthenocarpy |
|---|---|---|---|---|---|---|---|

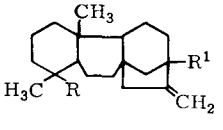
Gibberellins are formed from mevalonic acid [62, 63]. Kaurene *(18)*, kauranol, and steviol *(19)* are metabolized to gibberellic acid [63a,b].



*(18)*, R = $CH_3$, $R^1$ = H
*(19)*, R = $CO_2H$, $R^1$ = OH

The essential physiological effects of the gibberellins (0.05–0.5 ppm) are [61]:

1. Increase of the internodal length of growing plants even in hereditary rosette or dwarf growth, so that the plants attain the normal elongated habit [64];

not only species-specific but also system-specific. Methods of detecting gibberellins are given by *Knapp* [79a].

The acetyl, diacetyl, monobenzoyl, and butyryl derivatives of gibberellin, as well as the sodium, potassium,

and calcium salts are particularly active when administered *via* the leaves. Ethyl, butyl, isopropyl, and octyl gibberellates, which are effective when administered to the roots, develop no activity when given *via* the leaf[79]. The plant absorbs gibberellins from aqueous solutions and lanolin pastes, and distributes them in their tissues also in the apical direction, *i.e.*, translocates them in a nonpolar manner[82].

Synthetic substances with analogous effects are not yet known. 2-Chloroethyltrimethylammonium chloride (chlorocholine chloride) reduces the internodal length[81], and therefore seems to represent a gibberellin antagonist but probably inhibits its synthesis[81a,b].

Longitudinal growth of pea seedlings growing in complete darkness is not promoted by gibberellins[83], but the latter do eliminate the inhibitory effect of red light[84] and also that of infrared light in tomatoes[85]. Red light inhibits the lengthening of the stem and the hypocotyl but is a requisite for growth promotion by gibberellins[86]. Inhibitions by blue or green light are also eliminated by gibberellins[87].

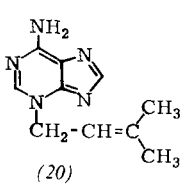
Little is known about the metabolism of the gibberellins and about possible inactive representatives.

General application of gibberellins in agriculture and horticulture is limited by their high cost. They accelerate germination of barley, reduce the malting process by 48 hours, and decrease shrinkage during malting by 1 %[88,89]. After the sowing of grasses characterized by early competition, gibberellins are able to prevent disadvantageous effects on individual species and to eliminate their summer cessation of growth[90], but practical successes have been small[91]. Widespread use is made of gibberellins in dwarf plant culture[61,92–94] (improvement in flower quality, number of flowers, time of flowering) and in fruit growing and horticulture for parthenocarpic fruit formation (*e.g.* pears) or modifying the size of the fruit[95,96].

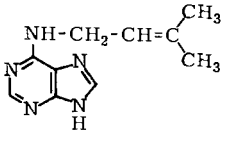
## VII. Kinins

Kinins are phytohormones which initiate cell division in tissues, including those whose cells do not divide in the absence of kinins even when optimally nourished and supplied with other phytohormones[97]. Since the term kinin has a different meaning in animal physiology, *Thimann* proposed the name cytomin, but this has not been adopted.

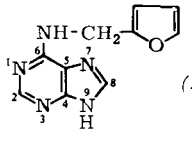
Kinins occur in the endosperm of maize[98] and coconut[99,100], and in other plant organs[97]. Studies by *Mothes* and *Engelbrecht*[101] have demonstrated that these substances are formed in the root and are only then transported to the leaves. Pea seedlings were found to contain a substance which on chromatography behaves like kinetin[102]. The growth factor in maize was found to be 6-(4-hydroxy-3-methyl-2-butenyl)aminopterine and was termed zeatin[103]. An inactive compound, triacanthine, 6-amino-3-(γ,γ-dimethylallyl)-purine *(20)*[104,105], occurs in *Gleditschia triacanthos*. On being heated in an autoclave *(20)* rearranges to 6-(γ,γ-dimethylallylamino)purine *(21)*, which is about 10 times as active as kinetin, 6-furfurylaminopurine *(22)*[107,108], which is formed from nucleic acid-containing material[106] and has not yet been found in



*(20)*



*(21)*



*(22)*

plants[97]. Kinetin can be prepared in large quantities, and its effects, which have been studied in detail, are[109]:

1. Acceleration of cell division and the related DNA synthesis;

2. Acceleration [110–112] or inhibition [113,114] of cell enlargement in leaves;

3. Promotion of leaf bud formation [115, 116] and elimination of the related polarity [117], as well as the mutual inhibition of longitudinal growth [118];

4. Promotion of root growth and root formation; occasionally inhibition;

5. Influencing of leaf shape [119] and leaf pigments [120, 121];

6. Promotion of germination [109];

7. Interruption of the rest period [122, 123];

8. Increase in respiration [112] and of RNA and DNA synthesis [124, 125];

9. Inhibition of protein degradation, rejuvenation of the leaves [126];

10. Translocation of low-molecular nitrogen compounds [127] but not of inorganic ions [128].

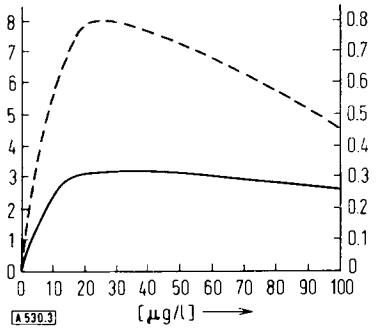

Fig. 3. Concentration–activity curves of kinetin (kinetin callus test after [129]).

Abscissa: Kinetin concentration, µg/l;
Left-hand ordinate and broken curve: Fresh substance (g/callus);
Right-hand ordinate and continuous curve: Dry substance (g/callus).

The sometimes contradictory results on the cell elongation response and the course of the concentration-activity curves (Fig. 3) [129] show that the promoting effect at low concentrations is countered by inhibition of the same processes at high concentrations. Tests for kinins are described by *Miller* [129a].

No kinetin antagonists are known; chloramphenicol inhibits protein synthesis and hence kinetin action, but the relation is probably indirect.

Adenine has similar effects to kinetin on bud formation [130], suggesting that the intact purine ring is essential to the activity. However, 8-azakinetin has also been found to be active [131, 132]. The amino group is not essential, and can be replaced by sulfur [109]. Moreover, the furan ring of the kinetin can be replaced by a benzene ring without loss in activity. Tetrahydrofurfuryl, pyridyl, naphthyl, cyclohexyl, piperidyl, and other rings also yield active compounds, and even 6-alkylaminopurines are active [109]. It is therefore reasonable to assume that the side chain and its ring linked to the amino group impart lipid affinity to the molecule. The methylene group between the amino group and the furan ring can also be dispensed with. The position of the amino group on C-6 seemed to be essential, but 1-benzoylaminopurine and 1-(γ,γ-dimethylallylamino)-purine are also active [133].

No reliable evidence is available whether triacanthin [134], an alkaloid of *Holarrhena floribunda* and *Chidlovra sanguinea* occurring in amounts of up to 0.7 % of the dry substance [129], can be converted enzymatically into an active kinin. Possibly it plays a role similar to that of glucobrassicin in the case of auxins.

## VIII. Morphological Regulators

One effect produced by synthetic auxin analogues of the 2,4-dichlorophenoxyacetic acid type was omitted from the discussion of this class of compounds, because it is absent in natural auxins or at any rate has not been achieved with indole-3-acetic acid. This property is the change in the shape of leaves, flowers, or fruit [14], which can lead to malformations but frequently also to regular and more balanced forms. The process involves an alteration of the morphological characteristics which are normally used to characterize and demarcate species, and which are considered as genetically fixed. In *Erodium*, leaf shapes are produced that are not species-characteristic and could belong to a new species [135]. Substances which produce this effect are

called morphological regulators. They include 2,4-dichlorophenoxyacetic acid, 2,4,5-trichlorophenoxyacetic acid, 2,3,5-triiodobenzoic acid, and some similar substances; also, because of their action on the species- and type-conditioned habit, the gibberellins and their antagonists. Although no morphological regulators have so far been obtained from plants, it is reasonable to assume that the plant normally uses hormones to produce its characteristic leaf and flower form.

## IX. Hormones of Unknown Constitution

The sex of fungi and flower formation in higher plants presumably is determined by hormonal factors. Sexual process-regulating glucoproteins acting as hormones have been found in the alga *Chlamydomonas* [136]. *Raper* [137] has shown that four hormones (A,B,C,D) are involved in the sex differentiation of *Achlya*. The number and growth of the antheridial hyphae is determined by hormone A. The male hyphae then produce hormone B which causes formation of oogonia or primordial ova of the female sexual organs. For some time, the mature oogonia form hormone C, which stimulates the male hyphae to chemotropic growth and results in formation of the gametangium. The fully differentiated antheridium finally forms hormone D, which in turn causes formation of female gametes. This interplay of hormones in lower plants suggests that several hormones may be involved also in flower formation. Grafting tests also indicate the existence of flower-forming hormones. Flowers have been produced in plants in the non-flowering state with extracts of plants about to flower [138–144], but so far no specific flower-forming hormone is known.

Hormones probably participate in the photoperiodic behavior of plants, being formed in dependence on the lighting conditions with their relative quantities determining the physiological effect. Possibly, short-day conditions lead to the formation of a substance K, while long days lead to a substance L [145]. It seems that K is formed and decomposed more quickly than L, and that the K:L ratio governs flower formation. In many respects, gibberellins act similarly to substance L, but the identity of the two factors has not been proved.

## X. Outlook

The great expectations of increased crop yields raised by the term "growth substances" have not been fulfilled. Auxins can accelerate certain development processes, but these accelerators generally produce no effect on the overall yield. Any aggregate increase in the yield of cultured plants by phytohormones is due not so much to an influence on growth, but to control of the differentiation steps by which the yield-determining factors (assimilated area, organ formation, habit, life span of leaves) or morphological and physiological properties of the plants are altered.

Externally applied hormones are subject to widely different conditions in the individual types of plants in regard to absorption and endogenic hormone relations, so that widely varying reactions can ensue. A precise study of these relationships before application of phytohormone-analogous substances is necessary.

Absence of suitable tests makes the detection and study of individual hormones, particularly those participating in differentiation processes, very difficult and in some cases impossible. Study of the effect of synthetic hormone analogues is simpler than that of native plant hormones, but it is the investigation of these latter substances which is essential for the elucidation of the mechanism of plant development with respect to shape and yield.

# Multienzyme Complexes

BY DR. U. HENNING[1]

INSTITUT FÜR GENETIK, UNIVERSITÄT KÖLN (GERMANY)

In 1948 *D. E. Green*[2] termed the mitochondrial enzymes the *cyclophorase complex*, in order, as he later commented[3] "... to signify that the complex was a unit of enzyme action and not a chance mixture of several hundred enzymes. ... this complex was visualized as an organized mosaic of enzymes in which each of the large number of component enzymes was uniquely located to permit efficient implementation of consecutive reaction sequences".

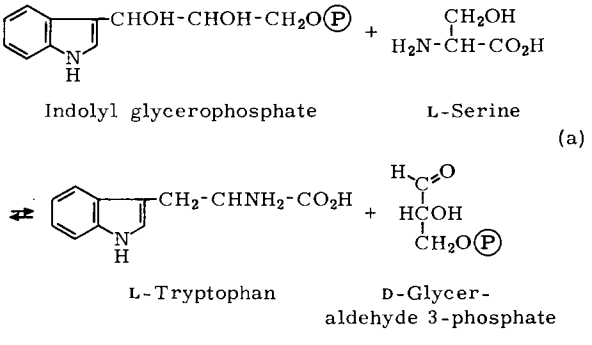
These words contain the concept of the multienzyme complex: ordered association (not involving peptide linkages) of various enzymes that catalyse successive steps in a reaction sequence. The present paper deals with recent findings regarding the properties of such complexes, and the question whether the concept represents a biological principle is discussed.

Predominantly protein-chemical aspects of the association of enzymes were recently described by *Sund* and *Weber*[4], and the "macromolecular organization of enzyme systems" by *Reed* and *Cox*[5].

## I. Multienzyme Complexes in a Narrower Sense

### 1. Tryptophan Synthetase

A clear and relatively simple example is the tryptophan synthetase from *Escherichia coli*. In the presence of pyridoxal phosphate, the enzyme catalyses the last step [Eq. (a)] in the reaction chain leading to the biosynthesis of tryptophan:



It can also[6,7] bring about the cleavage

indolyl glycerophosphate $\rightleftarrows$ indole + D-glyceraldehyde 3-phosphate (b)

and the condensation

indole + L-serine $\rightleftarrows$ L-tryptophan (c)

The extensive investigations by *Yanofsky* and coworkers, which made this enzyme a component of one of the best-known gene enzyme systems, also showed that the synthetase consists of two sub-units, the proteins A and B. The isolated crystallizable protein A (molecular weight about 30000[8]) consists of only one polypeptide chain $\alpha$[9], while the protein B ($M$ = 117000) consists of two chains ($\beta_2$)[10].

The physiological reaction (a) can take place only when the proteins A and B are in contact with each other; indole does not occur as a free intermediate[6,11].

Isolated protein A is inactive in reactions (a) and (c), but can bring about reaction (b) (not requiring pyridoxal phosphate, as expected) with about 1 % of the activity exhibited in the presence of B[12]. On the other hand, isolated B containing pyridoxal phosphate (2 moles of coenzyme per mole of protein) does not catalyse reactions (a) and (b), but catalyses the condensation (c) with 3 to 10 % of the activity exhibited in the presence of A[12]. It was later found that protein B can also act as an L-serine deaminase[13]

L-serine $\rightleftarrows$ pyruvate + $NH_3$ (d)

Addition of A causes almost complete inhibition of B in reaction (d).

There is strong evidence that the catalytically active centers of the respective complementary proteins are not involved in the activation of A in reaction (b) and in that of B in reaction (c). Protein B which has lost its enzymatic activity as a result of mutation can activate A in reaction (b) in the same way as unaltered protein B, while the reverse is true of A which has been inactivated by mutation. Moreover, the activity of B in reaction (c) is increased by a factor of about 20 in the presence of a high concentration of $NH_4^+$ ions[14]. Finally, *Hatanaka*

and *Crawford*[15] have isolated a mutant of *E. coli* producing a defective protein B, which by itself is inactive in reaction (c); in the presence of A, however, the activities of all three tryptophan synthetase reactions are observed.

The two proteins are only loosely associated[16]. L-Serine and pyridoxal phosphate are essential to the complex formation between A and B. Centrifugation of a mixture of A and B in a sucrose density gradient leads to practically complete separation of the components A (2.7 S) and B (5.1 S), while the associated A–B complex (6.4 S) appears after incubation of the mixture with L-serine and coenzyme[16]. The completely associated A–B complex, tryptophan synthetase, contains two moles of A to one mole of B, and its probable polypeptide-chain formula is therefore $\alpha_2\beta_2$[16,17].

The enzymatic activities of the components change, by several orders of magnitude in some cases, on complex formation. The activation by $NH_4^+$ and the behavior of the various proteins which have become inactive as a result of mutation provide very strong evidence that complex formation *per se* is responsible for the change in enzymatic activity. Association presumably involves changes in the conformation of the proteins, for which the active site of the complementary component is not directly responsible.

It is interesting to compare the tryptophan synthetase of *E. coli* (or other enterobacteria) with that of *Neurospora*. The neurospora enzyme[18,19] ($M$ = 135000) so far has not been dissociated into enzymatically active sub-units. On reduction with mercaptoethanol in 5 M guanidinium chloride, the protein dissociates into four sub-units, possibly made up of two identical pairs[19]. This result led *D. M. Bonner*[20] to assume that the two tryptophan synthetases represent two different stages of evolution. It is conceivable that the tryptophan synthetase reaction initially proceeded in separate steps, with indole as a free intermediate. With the development of the association of the two proteins, indole is no longer liberated; the binding of the two proteins may have become "tighter" during the further evolution.

## 2. Pyruvate and α-Ketoglutarate Dehydrogenases

In animal tissues, as well as in many fungi and bacteria, the principal route for the degradation of the two α-keto acids is by oxidative decarboxylation:

$$R{-}COCO_2H + CoASH + NAD^+ \rightarrow R{-}COSCoA + CO_2 + NADH + H^+ \quad (e)$$

It is now known[5,21] that this overall reaction (e) proceeds *via* the steps (f) to (k).

$$R\text{-}CO\text{-}CO_2H + TPP\text{-}E1 \rightleftarrows R\text{-}CHOH\text{-}TPP\text{-}E1 + \underline{CO_2} \quad (f)$$

$$R\text{-}CHOH\text{-}TPP\text{-}E1 + \text{S—S (E2)} \rightleftarrows TPP\text{-}E1 + \text{SH S-CO-R (E2)} \quad (g)$$

$$\text{SH S-CO-R (E2)} + CoA\text{-}SH \rightleftarrows \text{SH SH (E2)} + \underline{R\text{-}CO\text{-}SCoA} \quad (h)$$

$$\text{SH SH (E2)} + FAD\text{-}E3_{ox.} \rightleftarrows \text{S—S (E2)} + FAD\text{-}E3_{red.} \quad (i)$$

$$FAD\text{-}E3_{red.} + NAD^+ \rightleftarrows FAD\text{-}E3_{ox.} + \underline{NADH + H^+} \quad (k)$$

The best-known case is that of the pyruvate dehydrogenase of *E. coli*, which has been isolated as a homogeneous protein ($M = 4.8\times10^6$)[22]. Electron micrographs[23] of the complex show (Fig. 1) a polyhedral structure with a diameter of 300 to 350 Å.

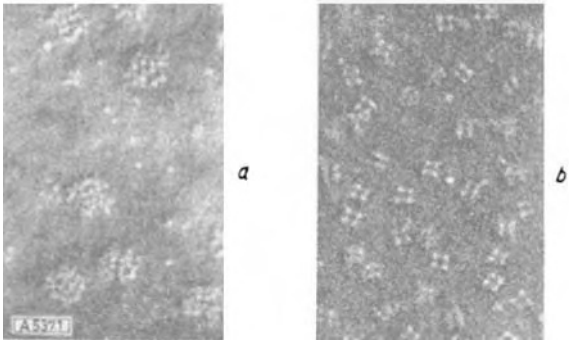

Fig. 1a). Pyruvate dehydrogenase complex from *E. coli*. Magnification factor 260000. b) Lipoate reductase transacetylase component of the enzyme complex, same magnification. The tetrad structure of the component is visible in the center of the complex (1a). In these projections, the diameter of the complex is about 300 Å and that of the components is about 120 Å. Both samples were obtained by negative staining with phosphotungstic acid.

The complex can be dissociated, under mild conditions, into three proteins[24], to which the activities of reactions (f) to (k) could be assigned with the aid of model reactions: the thiamine pyrophosphate(TPP)-dependent pyruvate decarboxylase (E1), the lipoate reductase transacetylase (E2) containing lipoic acid, and the flavoprotein dihydrolipoate dehydrogenase (E3). The proteins re-associate spontaneously *in vitro*[24]; E1 does

not associate with E3, but E2 binds both E1 and E3. One molecule of the complex contains about twelve molecules of the decarboxylase ($M$ = 1.83×10⁵), one molecule of E2 ($M$ = 1.6×10⁶), and about six molecules of the flavoprotein ($M$ = 1.12×10⁵) [5]. The lipoate reductase transacetylase is probably centrally situated (cf. Fig. 1), and surrounded by the two other enzymes.

The lipoate reductase transacetylase has also been reversibly dissociated; it dissociates at pH 2.6 into subunits having $M \approx 7\times10^4$ [5]. The enzyme contains one mole of lipoic acid per 3.5×10⁴ g of protein, and may therefore consist, not of about 24, but of about 48 polypeptide chains having $M$ = 3.5×10⁴. The composition of the decarboxylase is not yet known; that of the flavoprotein will be discussed below. The lipoic acid is covalently bound to the ε-amino group of a lysine residue [25]. The dithiolan ring of the coenzyme must react with (a) the hydroxyethyl TPP of the decarboxylase, (b) the flavin-adenine dinucleotide (FAD) of the dihydrolipoate dehydrogenase, and (c) the coenzyme A. Since the intermediates of the overall reaction remain bound to the enzyme, there appear to be steric difficulties opposing the interaction of one and the same lipoic acid residue with all the prosthetic groups mentioned. The lipoic acid:FAD ratio in the complex is about 4:1. The lipoic acid linkage forms a "flexible arm" (about 14 Å long), and the coenzyme may be able to rotate about the α-C atom of the lysine residue in the enzyme complex [24, 26]. It was shown that all the lipoic acid residues can take part in the oxidation of pyruvate. It was therefore suggested [24] that different lipoic acids could participate in the various reaction steps (Fig. 2), which indeed would be a remarkable type of electron transport in a protein molecule.

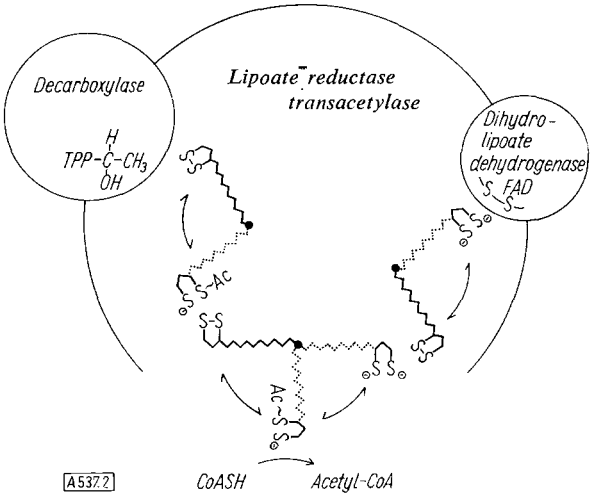

Fig. 2. Scheme of the hypothetical interaction between the coenzymes of the pyruvate dehydrogenase [24]. The lipoic acid residue pivots about the α-C atom of a lysine residue.

[26] *R. M. Bock* and *R. S. Criddle,* quoted in *D. E. Green,* Comparat. Biochem. Physiol. *4,* 81 (1962).

A similar situation is found with the α-ketoglutarate dehydrogenase of *E. coli* ($M$ = 2.4×10⁶) [22, 24]. This also could be reversibly dissociated into α-ketoglutarate decarboxylase, lipoate reductase transsuccinylase, and dihydrolipoate dehydrogenase. The flavoproteins of the two α-ketoacid dehydrogenases are functionally interchangeable, that of the pyruvate dehydrogenase being bound by the lipoate reductase transsuccinylase and *vice versa*; no "hybrid" binding of the decarboxylases takes place [27].

It is possible that the two flavoproteins are identical [5, 28]. If this were the case, it would raise an interesting problem in connection with the regulation of the synthesis of the dihydrolipoate dehydrogenase, since the syntheses of the pyruvate and α-ketoglutarate dehydrogenases are not regulated by the same mechanism [29].

It is not yet known whether the structure of the enzyme complex in the cell is the same as that in which it is obtained after purification. However, since the intermediates of the overall reaction (e) remain bound to the enzyme, some form of association of the enzymes is necessary. It is conceivable that the large complex isolated is an artifact resulting from the aggregation of smaller complexes that were bound to other structures in the cell. There are several arguments against this view; *e.g.*, mutants in which the decarboxylase component has lost its enzymatic activity were found to contain a "partial" complex consisting of the lipoate reductase transacetylase and the flavoprotein [30]. This partial complex appears to be the same as that obtained by the removal of the decarboxylase from the pyruvate dehydrogenase complex *in vitro*.

Concerning the α-keto acid dehydrogenases from animal cells in which the enzymes are components of mitochondria, the reader is referred to the review by *Reed* and *Cox* [5].

### 3. Fatty Acid Synthetase

A similar organization of structure and function is found in the synthesis of unbranched saturated fatty acids. Investigations by *Lynen et al.* [31] have shown that the overall reaction (l)

$$CH_3{-}CO{-}SCoA + n\ HO_2C{-}CH_2{-}CO{-}SCoA + 2n\ NADPH + 2n\ H^+ \rightarrow CH_3(-CH_2-CH_2-)CO{-}SCoA + n\ CO_2 + n\ CoASH + 2n\ NADP^+ + n\ H_2O \quad (n = 7 \text{ for palmityl-CoA}) \quad (l)$$

in yeast is catalysed by a homogeneous protein ($M$ = 2.3×10⁶), the principal products being palmityl and stearyl CoA. The net reaction takes place on the fatty acid synthetase in the following steps. The acetyl transfer [Eq. (m)] is the initiation reaction.

[27] *B. B. Mukherjee, J. Matthews, D. L. Horney,* and *L. J. Reed,* J. biol. Chemistry *240,* PC 2268 (1965).

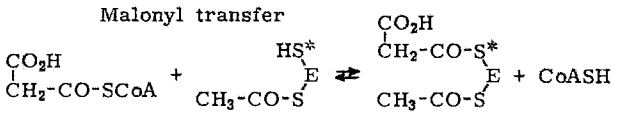
[31] *F. Lynen,* Angew. Chem. *77,* 929 (1965).

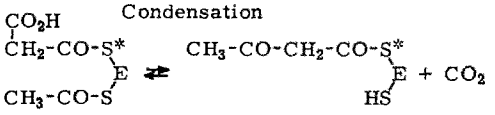
The five subsequent reactions lead to lengthening of the chain; they begin with the malonyl transfer [Eq. (n)].

Malonyl transfer



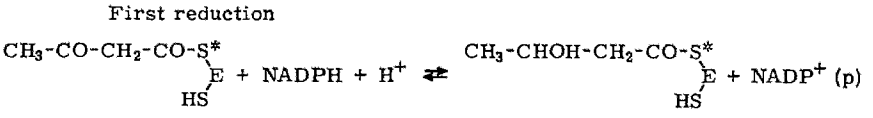
(n)

Condensation



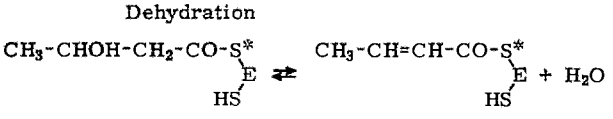
(o)

First reduction



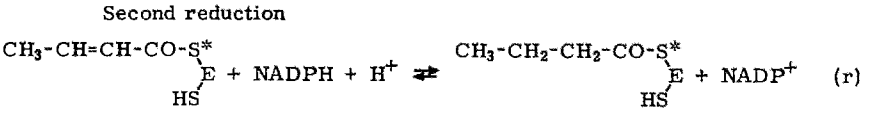
(p)

Dehydration



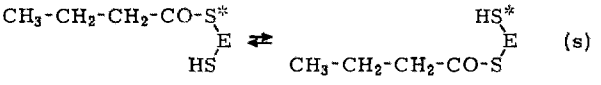
(q)

Second reduction



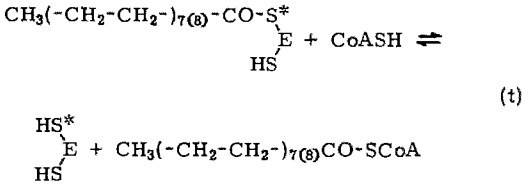
(r)

The SH group which accepts the malonyl residue is then liberated by the butyryl transfer [Eq. (s)].



(s)

Finally, when the chain length becomes $C_{16}$ to $C_{18}$, the stearyl or palmityl CoA is formed.



(t)

The existence of the functionally different SH groups (HS*-, HS–) has been demonstrated [32]. As with the other enzyme complexes, all intermediates remain enzyme-bound.

The seven reaction steps (m) to (s) apparently correspond to seven sub-units in the synthetase; however, dissociation of the enzyme into enzymatically active sub-units has not been achieved. An electron micrograph [33] of the synthetase (Fig. 3) shows its ordered structure in particles having a diameter of 200 to 250 Å. As in the case of tryptophan synthetase, the enzyme system from *E. coli* which carries out the fatty acid synthesis easily can be separated into enzyme fractions with different functions [34].

Details of bacterial and animal systems cannot be discussed here. The electron micrographs, and the fact that the synthetase from yeast can be dissociated into inactive sub-units only under fairly drastic conditions strongly indicate that the isolated enzyme is not an artifact produced during purification.

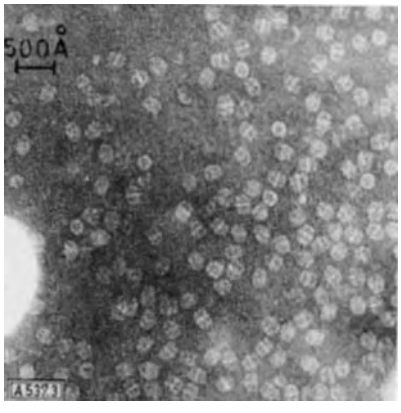


Fig. 3. Fatty acid synthetase from yeast [33]. (Preparation as in Fig. 1, magnification factor 250000).

## 4. Other Multienzyme Complexes

The examples described undoubtedly are not special cases of little general importance. There is evidence that a number of other reaction sequences are catalysed by a functional complex. This is true of the four enzymes that synthesize valine from pyruvate and isoleucine from pyruvate and α-ketobutyrate in *Neurospora* [35,36], and also of the synthesis of isoleucine in *Salmonella* [37].

[36] *R. P. Wagner, A. Bergquist*, and *T. Barbee*, Biochim. biophysica Acta *100*, 444 (1965).

[37] *C. S. Cronenweit* and *R. P. Wagner*, Proc. nat. Acad. Sci. USA *54*, 1643 (1965).

Three enzymes involved in the biosynthesis of tryptophan appear to act as a functional unit in *Neurospora* [38], as do three enzymes involved in the biosynthesis of histidine in *Neurospora* [39]. In the last case, since the three enzymes in question correspond, not to consecutive reaction steps, but to the second, third, and tenth steps, it is reasonable to suspect that *all* relevant enzymes *in vivo* are associated in a functional unit.

The features common to all these examples are readily recognized, and have been characterized by *Lynen* [32] as "strict compartmentalization in the smallest possible space". If enzymes that operate in sequence are also physically adjacent, the activity of the overall reaction sequence presumably may be greater than if these enzymes were separated. In the latter case the action would be optimal only when the concentrations of diffusing intermediates reach certain values. Moreover, reaction chains in which the intermediates are bound to the enzyme avoid competition between different enzymes for the same intermediate.

The specific activities of the fatty acid synthetase from yeast and of the pyruvate dehydrogenase are high; one synthetase complex can catalyse the conversion of $2.4\times10^3$ molecules of malonyl CoA per minute into fatty acid [32], and one pyruvate dehydrogenase complex at 30 °C can produce at least $1.25\times10^4$ molecules of acetyl CoA per minute from pyruvate.

One might conclude that the concept of the multienzyme complex represents an example of the biological principle of "increasing the efficiency". However, this view probably is still too narrow. In higher organisms at least, the large enzyme complexes discussed are localized in the mitochondria. The same is true of the above mentioned enzymes of the biosyntheses of valine and isoleucine in *Neurospora* [35, 36]; the isoleucine system in *Salmonella* [37] occurs in the membrane fraction. It appears reasonable to combine enzyme systems physically when they are bound to large cell structures, even if they are not also components or "supply" enzymes of further processes (*e.g.* the respiratory chain). Another interesting speculative aspect [39a] is that the structure-bound enzymes could greatly increase their surface if the substrate can be retained by the structure (*e.g.* membrane) and can migrate along the latter to the enzyme.

## II. Extension of the Concept: Homofunctional and Heterofunctional Enzyme Complexes

With regard to the enzyme protein, the definition of the multienzyme complex as described in the introduction is really teleological, and therefore is too specialized. This can be seen particularly well with hemoglobin and myoglobin [41–43], which *Frieden* [40] aptly described as "perfect" enzymes, since they permit the study of the enzyme-substrate interaction without the formation of interfering products. The four heme groups, and hence the four active sites, corresponding to the four polypeptide chains of hemoglobin, are situated in "pockets" in each of the two $\alpha$ and $\beta$ chains on the surface of the molecule, without being in contact with one another. The tertiary structure (and also the position of the heme) of myoglobin, which consists of only one polypeptide chain, is extremely similar to the tertiary structure of each of the hemoglobin chains, and in this sense myoglobin may be regarded as a naturally-occurring sub-unit of hemoglobin. The activities of all the polypeptide chains are the same. In contrast to myoglobin, however, the binding of $O_2$ by hemoglobin leads to a heme-heme interaction, *i.e.* a co-operation of the binding sites [44–46]. The rate of reaction of a heme with $O_2$ depends on the state of loading of the other hemes with $O_2$, and increases with the amount of $O_2$ already bound. Thus the association of different sub-units leads (in a wider sense) to an increase in efficiency.

The question arises whether the fact that a protein molecule consists of several sub-units, *i.e.* the presence of a quarternary structure, is enougn to constitute a multienzyme complex. It may be assumed that this is not the case, but that the cell also makes use of the association to *produce* an active site. This appears to be the situation with the dihydrolipoate dehydrogenase [cf. reactions (i) and (k)], as *Massey*'s investigations [47,48] have shown in the case of the pig's heart enzyme.

The enzyme consists of two probably identical polypeptide chains, each with $M = 50000$; 2 moles of FAD and 4 moles of cystine units (as well as 12 cysteine units) are present per mole of enzyme. The intermediate is the reduced enzyme [reaction (i)], in which, in contrast to several other dehydrogenases containing FAD, the flavin coenzyme takes up only one electron. The difference spectrum of the resulting reduced enzyme is similar to that of the semiquinoid form of FMN which occurs as a charge-transfer complex in an equilibrium mixture of FMN and $FMMH_2$. This form ("red" enzyme) has been obtained by the action of NADH or dihydrolipoic acid on stoichiometric quantities of the dehydrogenase. However, spectrophotometric titration of this last reaction with either of the substrates shows that the red form of the protein corresponds to the uptake of two electrons per FAD. This discrepancy was resolved when a disulfide was discovered as a second prosthetic group of the enzyme, and it was found by amperometric titration that the addition of NADH leads to the formation of a dithiol. When the NAD formed in a mixture of NADH and enzyme is removed with an NADase (which does not attack NADH), the enzyme is completely reduced and becomes colorless; four electrons are taken up per FAD. The colorless enzyme can react with NAD to give again the red form.

The dihydrolipoic dehydrogenase in the oxidized yellow state is unusually stable towards urea (in 6.5 M urea at 0 °C only

about 30 % of the enzyme activity is lost after one month); the red form of the enzyme also retains its activity in urea. In the presence of excess NADH or dihydrolipoic acid in 6.5 M urea, the spectrum is initially that of the semi-reduced enzyme, but this soon gives way to that of the fully reduced protein. The completely reduced enzyme is unstable in the urea solution. The $FADH_2$ (or FAD after the admission of air) becomes separated from the protein and dialysable; the protein becomes insoluble when the urea concentration is decreased to less than 2 M, and the molecular weight of the resulting reduced dehydrogenase falls to half that of the native protein.

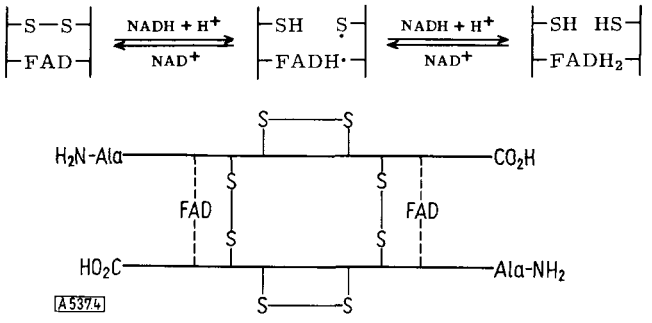

Fig. 4. Scheme of the dihydrolipoate dehydrogenase [47]. Model representation of the steps of the enzyme reduction as described in the text.

Figure 4 shows the model derived by *Massey* from these and other data. Both polypeptide chains appear to be involved, with the disulfide bridges, in the catalysis. The active sites literally are situated *between* the polypeptide chains, since at least cystine residues of both chains act as components of one active site. However, it is not known whether other amino acid residues belonging to one active site originate from both chains.

The example described is not intended to show implicitly that enzymes of this type must necessarily consist of identical polypeptide chains. An association of different polypeptide chains can give almost the same catalytic activity, as is well known from various forms of lactic dehydrogenase [49,50]. These can consist either of four identical chains (the so-called isozymes I and V, consisting of chains H and M) or mixtures of integral molar quantities of chains H and M (isozymes II, III, and IV: 1H2M, 2H2M, 1H3M). *Holbrook* [51] recently reported results that led him to conclude that the active sites in this case also are composed of parts of adjacent sub-units. A similar possibility exists for aldolase, which has only one active site, but consists of at least three (or six) polypeptide chains [52–55].

However, the direct participation of several sub-units of an enzyme molecule in one active site is hypothetical. If this hypothesis is true, it remains to be seen whether it is correct to classify such enzymes separately, since the transition to proteins of the tryptophan synthetase type may be continuous. (Incidentally, it would not be easy to give a good account for the biological evolution of enzymes with "mixed"centers of activity, as dihydrolipoate dehydrogenase).

From the examples described, it appears that a protein may be regarded with certainty as a multienzyme complex if the centers of activity for various steps in an overall reaction chain are situated on different sub-units. As far as the protein is concerned, however, there is no fundamental difference between such complexes and enzymes in which similar active centers are also present in their sub-units and are not formed only by the combination of the sub-units in such a manner that two or more sub-units contribute in forming an active site. If a classification is desired, it appears more reasonable to distinguish between *homofunctional* and *heterofunctional* multienzyme complexes, depending on whether the sub-units and active centers are identical or different.

The so-called allosteric effect [56,57], for which association is evidently a prerequisite, fits in easily with the "heterofunction" on association. An example is the heme-heme interaction in hemoglobin described earlier. Another extreme case was reported in the aspartate transcarbamylase (ATC) of *E. coli* [58].

The enzyme initiates the biosynthesis of cytidine triphosphate (CTP) with the reaction: carbamyl phosphate + aspartate → carbamyl aspartate. It is regulated by feed-back, its activity being inhibited by CTP. The ATC ($M \approx 3\times10^5$) consists of enzymatically inactive regulatory sub-units ($M \approx 3\times10^4$) and enzymatically active sub-units ($M \approx 9\times10^4$); only the first type binds CTP. The enzymatically active sub-unit, when dissociated from the regulating sub-unit, is not inhibited by CTP.

It may be concluded that multienzyme complexes as defined initially do not occupy a special position in enzyme structures. It remains to be seen whether the concept of homofunctional and heterofunctional complexes provides a better insight, since the organization of enzymes is more elaborate than has been described here. We have not considered systems which act at the level of large cell structures, *e.g.* the vectorial enzymes of the transport system on membranes or the mechanochemical systems of contractile or other mobile structures.

# Complex Formation and Flower Colors

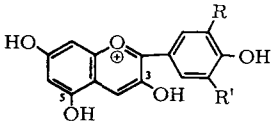
BY PROF. ERNST BAYER [*]
IN COLLABORATION WITH DR. H. EGETER [1], A. FINK, K. NETHER [2], AND K. WEGMANN
CHEMISCHES INSTITUT, UNIVERSITÄT TÜBINGEN (GERMANY)

*The pigment of the blue cornflower, protocyanin, is a complex of high molecular weight. Iron(III) and aluminum ions combine with the anhydro base of the cyanin to form deep-blue complexes, which are stable in the physiological pH range. Complexes of this type also have been synthesized. Alkali metal salts play no part in blue flower pigments. Formation of blue complexes can be prevented by sequestration of the metal ions with stronger complexing agents, e.g. flavonols. The variation of flower colors can be explained to a large extent on the basis of the complex formation of anthocyanins. In delphinidin glycosides, the color base or anhydro base is stable even in slightly acidic media.*

The majority of flower colors are produced by a surprisingly small number of pigments. Apart from the betacyanins, which are confined to a few groups of plants, and the carotenoids, which are important in yellow and orange flowers, mainly the anthocyanins are responsible for the color range from orange to deep blue. Anthocyanins are glycosides of anthocyanidins.

The principal aglycones found in Nature are *(1)* to *(6)*, which occur as their glycosides with sugars on the OH groups attached to C-3 and C-5. The position of the longest-wavelength maximum [3] in the absorption spectra of the aglycones and their glycosides differ at the most by 38 mμ. This difference is not sufficient to explain all the color shades found in Nature. Since *Willstätter*'s classic work, therefore, several hypotheses have been proposed to explain the colors of flowers.

Thus in the investigation of the red rose and of the blue cornflower, *Willstätter* [4] found an example of the



| Compound | R | R' | Name | λmax (mμ) [a] |
|---|---|---|---|---|
| *(1)* | H | H | Pelargonidin | 520 |
| *(2)* | OH | H | Cyanidin | 535 |
| *(3)* | OH | OH | Delphinidin | 544 |
| *(4)* | $OCH_3$ | H | Päonidin | 532 |
| *(5)* | $OCH_3$ | OH | Petunidin | 543 |
| *(6)* | $OCH_3$ | $OCH_3$ | Malvidin | 542 |

[a] In 0.01% methanolic HCl.

presence of the same anthocyanin both in blue and in red flowers. He isolated the same pigment, cyanin, which is a 3,5-diglucoside of cyanidin *(2)*, from the flowers of roses and of cornflowers, and ascribed this to the fact that the red oxonium salts of the anthocyanins, which are stable in the acidic range, are converted into blue-green salts in alkaline media (pH > 8). *Willstätter* concluded that the cornflower, and blue flowers in general, must contain alkali metal salts of anthocyanins in an alkaline medium, whereas red flowers contain the oxonium salts, which are stable only in acidic media (pH < 4). This view was adopted in textbooks of organic chemistry and botany as an established fact, and is found even in a few recent textbooks [5–8].

An unclear point in this hypothesis was the requirement of an alkaline medium in the petals. It has long been known that, owing to the presence of dicarboxylic acids of the citric acid cycle, flower petals are slightly acidic, so that in them phenoxides cannot be stable. This fact was pointed out by *K. Shibata et al.* [9], and later by *G. M.* and *R. Robinson* [10], who therefore assumed that in blue flowers the anthocyanins are fixed or stabilized by colloidal bonding or "copigmentation" with other substances present, whereas *Shibata* and *Hayashi* [9, 11] postulated that the blue color is due to alkaline earth compounds of the anthocyanins.

Two observations led us to check the causes of the blue pigmentation of flowers by anthocyanins: The press juices of blue flowers, *e.g.* cornflowers (*Centaurea cyanea*) have a pH between 3.8 and 5.0. The blue color remains stable in this acidic medium, though no pure

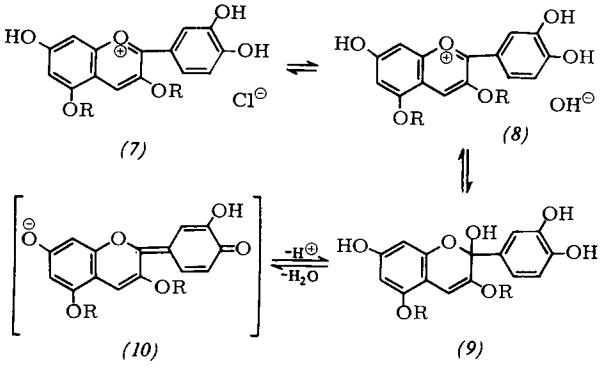
anthocyanin is blue in this range. According to investigations by *Kuhn* and *Sperling*[12], cyanin gives a blue resonance-stabilized anion *(10)* only in alkaline media (pH > 8). At pH ≈ 4, the oxonium salt *(7)* of the cyanin changes *via* the unstable color base *(8)* into a pale yellowish pseudo-base *(9)*. Thus the stability of the blue pigment of cornflower in acidic media refutes *Willstätter*'s alkali salt hypothesis.



*(7)* *(8)* *(10)* *(9)*

Another observation shows that a special bonding state, and not simply an alkali metal salt of cyanin, occurs in the blue pigment of the cornflower. Thus an enzyme that degrades anthocyanins, cyanin oxidase, has been isolated from *Coleus hybridus*[13]. This enzyme occurs in the green parts of the leaves and is absent from the red parts (the existence of red varieties of plants could be due to the mutative loss of this enzyme[13,14]). Cyanin oxidase attacks only anthocyanins having at least two adjacent free hydroxyl groups on the benzene ring, *i.e.* the glycosides of cyanidin *(2)*, delphinidin *(3)*, and petunidin *(5)*.

Cyanin is degraded by cyanin oxidase in the pH range 5 to 9, *i.e.* also in the range in which the alkali metal salts can exist (Fig. 1). However, the blue cornflower pigment is not degraded, even though it contains cyanin. It may therefore be concluded that the cyanin in the cornflower pigment must be in a special bonding state involving the adjacent hydroxyl groups in the phenyl group.

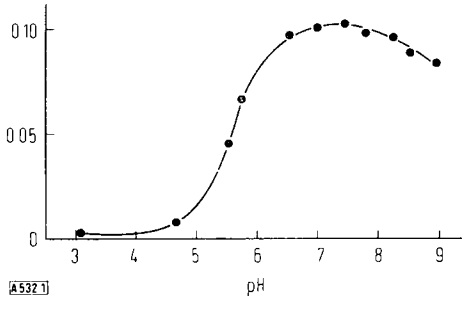


Fig. 1. pH dependence of the activity of cyanin oxidase in the degradation of cyanin. Activity determined in accordance with [13].

[14] *K. Paech* and *F. Eberhardt*, Z. Naturforsch. *7b*, 664 (1952).

The only possible solution to this problem was the isolation of the native pigment, which we named protocyanin. The name cyanin (Κυάνεος = blue) was originally derived by *Willstätter* from the color of the cornflower, though cyanin chloride was the pigment from red roses.

In the isolation of protocyanin from garden cornflowers (*Centaurea cyanea polyphemus*), the use of strong acids must be avoided, since the pigment would otherwise be destroyed. This instability of the blue compounds towards acids probably is the reason for the fact that the extraction of the flowers in the earlier work with dilute mineral acids always gave only the oxonium salts, so that the existence of the protoanthocyanins remained undetected.

The isolation of protocyanin was facilitated by two surprising properties: The dye is not dialysable, and it migrates to the anode in an electric field at pH 4.6, *i.e.* it can be separated from accompanying anthocyanins by electrophoresis. Cyanin does not migrate in an acetate buffer at pH 4.6, as is shown by the paper electropherogram in Fig. 2. This fact is a further argument

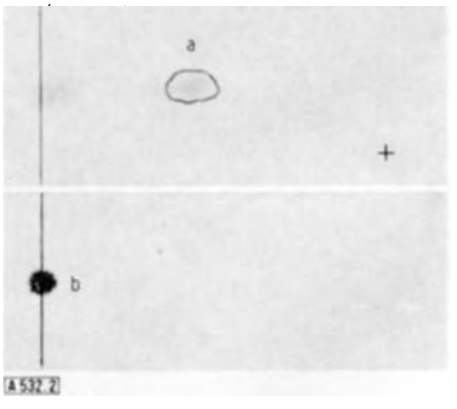

Fig. 2. Paper electropherogram of protocyanin (a) and pure cyanin (b) in 0.2 M acetate buffer (pH 4.45). Voltage: 110 V; migration time: 6 hours; rate of migration of protocyanin: 0.7 cm/hour.

against the presence of alkali metal or alkaline earth metal salts. Electrophoresis generally is a simple method for the detection of blue, complex anthocyanin compounds, since, under the conditions mentioned, the only other flower pigments that migrate are the betacyanins discovered by *Dreiding et al.*[15]. However, since these are yellow to red, they can easily be distinguished from the protoanthocyanins. To isolate the protocyanin, crushed cornflower blooms are pressed, and the resulting ink-blue solutions (pH 4.6) are mixed with alcohol. The blue floccules deposited after a short time are separated from the almost colorless solution. The blue substance, which is soluble in distilled water, is reprecipitated several times with alcohol. The solution is then saturated with ammonium sulfate to remove small quantities of proteins. After a further precipita-

[15] *T. J. Mabry, H. Wyler, G. Sassu, H. Mercier, I. Parikh*, and *A. S. Dreiding*, Helv. chim. Acta *45*, 640 (1962).

tion with alcohol, the product is dialysed against distilled water for 36 hours to remove components of low molecular weight, and the sample is finally purified by preparative electrophoresis without a carrier. The isolation can be simplified by chromatography on Sephadex columns. This procedure gives electrophoretically pure protocyanin as deep-blue platelets. The molecular weight at pH 4.0 is 6200 according to ultracentrifuge measurements, which yield a diffusion coefficient of $11.9 \times 10^{-7}$ cm²/sec at 20 °C.

Protocyanin contains 19.2 % of cyanin and a total of 1 equivalent [*] of iron(III) and aluminum(III) per mole of cyanin [16]. Spectral analysis showed that our product contained only traces of other metals. Protocyanin also is stable towards heat. The macromolecular substance that accounts for about 80 % of protocyanin is therefore not a protein, but a polysaccharide, the main component of which, apart from arabinose and glucose, is galacturonic acid. Thus the macromolecular component is a pectin-like substance. This discovery confirms the hypothesis of *G. M.* and *R. Robinson* [10] that the anthocyanins are bound to macromolecular "carrier substances" [16a].

The color depends, however, on the presence of the metal ions in protocyanin, probably in the form of iron and aluminum chelates. It probably will not surprise gardeners that blue flower colors are due to iron and aluminum complexes of cyanin, since an old gardening trick is to sprinkle red hydrangeas with aluminum or iron alum solution to change their color to blue.

In order to clarify further the bonding of the metal ions, it was necessary to prepare model complexes and to compare their properties with those of protocyanin.

## Chelate Formation of Anthocyanins

Anthocyanins containing at least two hydroxyl groups in the phenyl group can be qualitatively recognized by the blue color that arises on reaction with iron(III) salts. The molar ratios of anthocyanin to metal ion at which complex formation occurs can be established by the method of continuous variation [17]. Spectroscopic measurements have shown that various types of complexes are formed with both aluminum and iron(III) ions at the metal ion: anthocyanin ratios of 1:1, 1:2, and 1:3 [16]. No intensely colored chelates are formed with bivalent ions of transition metals, and no complex can be isolated. If the synthetic and the natural complexes are the same, the synthetic ones containing iron and aluminum ions should also be stable at pH 4 to 6, and must be intensely colored. Figure 3 shows the absorption of the synthetic metal complexes at 590 mμ and at various pH values in comparison with the absorption of protocyanin. Measurements on complexes containing bivalent cobalt, nickel, calcium, magnesium, and barium ions are also shown. It can be seen from the diagram that neither the alkaline earth metal nor the cobalt or nickel complexes of cyanin are stable and blue at pH 4 to 6. Their extinctions are almost 100 times lower, *i.e.* blue complexes are not formed. This is also true of the bivalent ions of other transition elements. The synthetic iron and aluminum complexes, on the other hand, are deeply colored, and their behavior with variation of the pH is similar to that of protocyanin (cf. Fig. 3). Deep-blue chelates stable at pH 4 to 7 are formed, not only with iron(III) and aluminum, but also

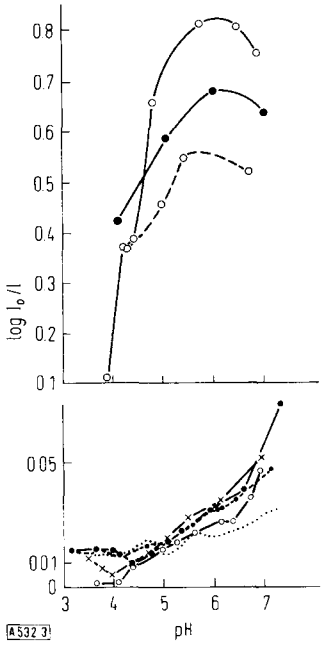

Fig. 3. Top: pH-stability of iron(III) and aluminum complexes of cyanin (o---o) and o—o) and of protocyanin (●—●).

Bottom: Behavior of cyanin in the presence of nickel(II) (x—x), cobalt(II) (●—●), calcium (---), barium (●---●), and magnesium (o—o) acetates.

The concentration of the protocyanin was 0.97 mg in 1 ml of 0.2 M acetate buffer. Cyanin was mixed with the metal salts in the molar ratio of 1:2. The mixtures were taken up in 0.2 M acetate buffer so that the cyanin concentration was $5 \times 10^{-4}$ M.

Ordinate: Extinction at 590 mμ.

by Sn(IV), Ti(III), Cr(III), and $UO_2^{2+}$. However, tin, titanium, chromium, and uranium occur in plants only as trace elements. It is therefore unlikely that any metals other than iron and aluminum are involved in the formation of blue flower pigments.

The complexes of cyanin and cyanidin with iron and aluminum have also been isolated on a preparative scale [18]. The tricyanidinoiron(III) or aluminum complexes *(11a)* and the dicyanidinoiron(III) or aluminum complexes *(12a)* are relatively easy to obtain. In the case of cyanin, the 2:1 complex, which also contains an anion, is formed preferentially. Analysis and structural elucidation show that the complexes are derived from

[*] While the ratio Fe:Al in the protocyanin of garden cornflowers is about 2:1, the protocyanin of wild cornflowers contains mainly Fe together with a little Al.

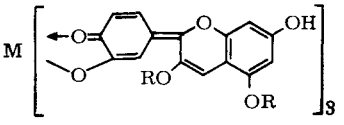
[16] *E. Bayer*, Chem. Ber. *91*, 1115 (1958).

[16a] *Note added in proof*: The presence of the macromolecular component in the protocyanin of the wild cornflower has been confirmed recently by *N. Saito* and *K. Hayashi*, Sci. Rep. Tokyo Kyoiku Daigaku Sect. B *12*, 39 (1965).

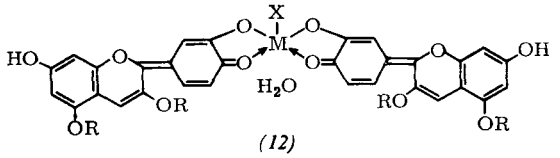
[17] *P. Job*, Ann. Chim. Phys. *9*, 113 (1928).

[18] *E. Bayer, K. Nether*, and *H. Egeter*, Chem. Ber. *93*, 2871 (1960).

the anhydro-base of the anthocyanin. Complex formation involves the two adjacent hydroxyl groups in the phenyl group, since anthocyanins that do not contain two adjacent hydroxyl functions in the phenyl group do not form complexes. This agrees with the facts observed in the enzymatic degradation of protocyanin. Since the



*(11)*



*(12)*

M = $Al^{3+}$, $Fe^{3+}$ *(11a)*, R = H *(11b)*, R = Glucosyl
X = $OH^-$, $Cl^-$ *(12a)*, R = H *(12b)*, R = Glucosyl

metal ion:cyanin ratio in natural protocyanin is 1:2, compound *(12b)* is a synthetic model for the cornflower pigment. The iron complex can be prepared by a simple method that is suitable as a lecture demonstration.

A solution of 16.2 mg of anhydrous iron(III) chloride in 2 ml of water and exactly 52 ml of 0.1 N NaOH are added to a solution of 65 mg of cyanin chloride in 50 ml of 0.1 N HCl. About 150 ml of acetone is added to the resulting blue solution. Blue-black chlorodicyaninoiron(III) precipitates and is filtered off and washed with a very small quantity of methanol. The substance dissolves readily in water to give a deep-blue solution. Yield: 25 mg.

*R. Kuhn* [19] has prepared the aluminum complex *(12a)* as a lacquer in a simple demonstration experiment using our procedure:

100 ml of a thick slurry of $Al(OH)_3$ in methanol is added to 32 mg of cyanidin chloride in 800 ml of methanol. When the mixture has been shaken, the cornflower-blue aluminum complex separates, and the supernatant becomes colorless. The $Al(OH)_3$ should be precipitated from a hot aqueous solution of aluminum sulfate with concentrated ammonia and washed with water until the washings remain neutral. The color of the Al complex then persists for many hours.

The synthetic complex *(12b)* differs from natural protocyanin in the absence of the macromolecular component. Nevertheless, the absorption spectra of the two complexes agree closely (Fig. 4). The weak shoulder at 640 mμ in the spectrum of protocyanin is also hinted at by the marked broadening of the band at 570 mμ in the spectrum of the model complex. The polygalacturonic

[19] *R. Kuhn*, Naturwissenschaften *49*, 1 (1962), cited p. 6.

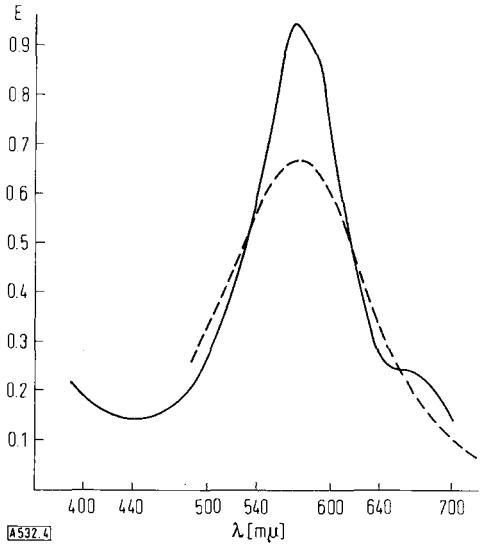


Fig. 4. Absorption spectra of protocyanin (1.25 mg/ml) (—) and of the dicyaninoaluminum complex (0.4 mg/ml) (---) in 0.2 M acetate buffer, pH 6.1.

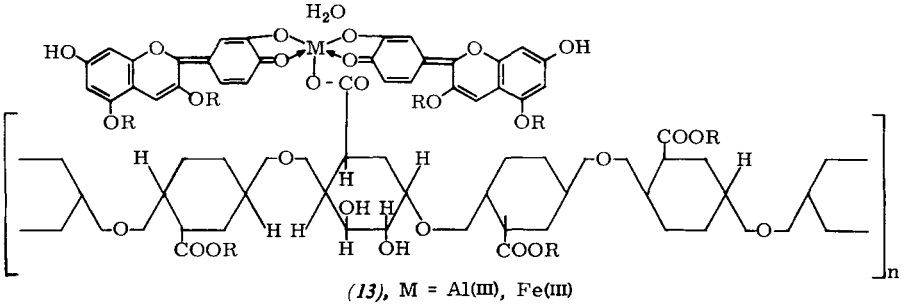
acid is probably coordinatively bonded by its carboxyl groups to the iron atom in place of the residue X in formula *(12)*, giving the structure *(13)* (molecular weight about 6200). A deep-blue complex containing no chloride can in fact be obtained from apple pectin, cyanin, and iron(III) or aluminum chloride.

As far as we know, protocyanin is the first naturally occurring metal chelate in which the macromolecular carrier has been found to be a polysaccharide instead of a protein. Thus, in addition to the chromoproteins and metal proteides, we now have the chromosaccharides.



*(13)*, M = Al(III), Fe(III)

## The Possibility of the Existence of Blue Roses

According to the investigations on the cornflower pigment, the existence of blue flower pigments can be explained by complex formation, whereas red flower pigments are the oxonium salts. It should therefore be possible, in theory, to produce the cornflower-blue rose that rose-growers have sought in vain, by causing the cyanin in the rose to undergo chelate formation. In the case of hydrangeas, the red variety need only be sprinkled with alum solution to bring about a color change from red to blue. However, this method is unsuccessful with roses. The change to blue in the petals of the hydrangea accompanies the increase in the aluminum content, as can be seen from Table 1. In roses, on the other hand, the aluminum content of the petals does

Table 1. Iron and aluminum content of the petals of hydrangeas and roses.

| | Normal plants | | Cut flowers placed in alum soln. (24 hr) [a] | | Plants sprinkled with alum soln. (7days) [a] | |
|---|---|---|---|---|---|---|
| | Al | Fe | Al | Fe | Al | Fe |
| Hydrangea | 0.17% | 0.12% | 0.52% | 0.20% | 0.35% | 0.15% |
| Rose | 0.41% | 0.12% | 0.59% | 0.14% | 0.43% | 0.11% |

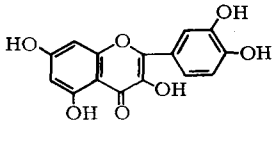
[a] 0.1% aqueous solutions of aluminum alum or iron alum were used.

not increase as a result of this treatment. Roses must therefore possess a "safeguard" which prevents the excessive concentration of metal ions in the petals. However, even the 0.12 to 0.4% of aluminum and iron already present, without further accumulation, should in principle be sufficient for the formation of cyanin complexes. Why, then, does this not occur?

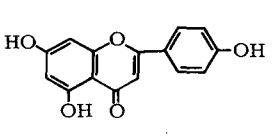
This question could be avoided if it were postulated that the metal ions and the anthocyanin oxonium salts occur in different cell areas. However, it is also conceivable that the Al and Fe in the petals are not free, but are already in the form of complexes. If other complexing agents gave more stable complexes, the failure of the blue color to develop would be understandable. We have now to find such complexing agents in roses. We thought that the most likely substances would be the acids of the citric acid cycle and phenolic components.

Citrate forms more stable complexes than cyanin with iron, as can be shown by the failure of the blue color to develop when cyanin chloride and iron(III) chloride are added to an acetate buffer containing citrate at pH 4.6. However, no notable quantities of citric acid could be detected in the flowers of various types of roses studied by us. Nevertheless, of all the many types of roses that exist, some may contain appreciable quantities of citric acid. For example, *Karrer*[20] reported the presence of 2% of citric acid in one variety. The iron complexes formed by the dicarboxylic acids of the citric acid cycle are less stable than those formed by cyanin.

It has been known for some time that glycosides of flavonols occur in petals as well as anthocyanins. *G. M.* and *R. Robinson*[10,21] assumed that these substances could play some part in determining the tint. These authors[21] made special mention of flavonols in their "copigmentation hypothesis", but did not investigate the matter further. *Karrer*[20] has detected a glycoside of quercetin *(14)* in red roses, but gave no further details about the sugar component. We have confirmed the presence of quercetin glucosides in various types of roses. We also found glycosides of kaempferol *(15)* in red rose petals.



*(14)*



*(15)*

[20] *P. Karrer* and *K. Schwarz*, Helv. chim. Acta *11*, 916 (1928).

[21] *R.* and *G. M. Robinson*, Biochem. J. *25*, 1687 (1931); *26*, 1663 (1932).

The formation of anthocyanin chelates with $Al^{3+}$ and $Fe^{3+}$ is actually suppressed in the presence of quercitrin, and metal ions that have already been incorporated into natural protocyanin can be displaced by the addition of quercitrin, as is shown in Figure 5 by the decrease in intensity of the blue color on addition of

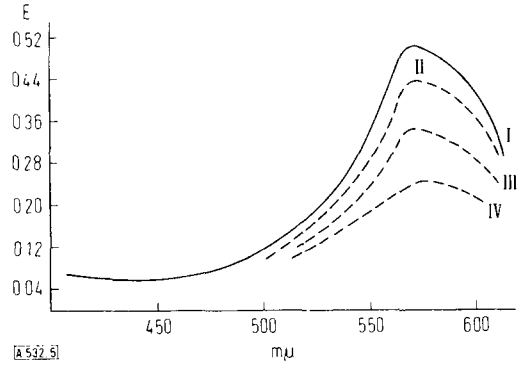


Fig. 5. Exchange of metal ions between blue protocyanin (I) and quercitrin in acetate buffer, pH 4.5. Cyanin concentration: $3.7 \times 10^{-4}$ M. Curves: II: addition of $3.7 \times 10^{-4}$ M quercitrin; III: $1.11 \times 10^{-3}$ M quercitrin; IV: $1.85 \times 10^{-3}$ M quercitrin.

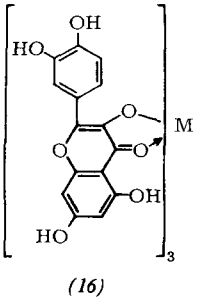
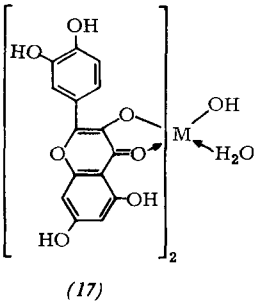
quercitrin. The metal ions are bound by the flavonol glycosides, and the pseudo-base *(9)* is formed. Thus flavonol glycosides could also mask the aluminum and iron ions in the rose, so that, in order to obtain blue roses, it would be necessary to breed plants that do not contain flavones and citric acid. The stronger tendency of flavonols towards complex formation than anthocyanins is due to the presence of the hydroxyketo grouping. *Hörhammer* and *Hänsel*[22,23], who studied the composition of the flavonol chelates by the continuous variation method[17], found that flavonols having a free hydroxyl group in position 3 form both 1:1 and 2:1 chelates, whilst flavonols with a sugar residue attached to C-3 give only 1:1 complexes. We have isolated the Al and Fe chelates of kaempferol, quercetin, and quercitrin and, in agreement with the results obtained by *Hörhammer* and *Hänsel*[22,23], we found three types of complexes for the aglycones *(16)* to *(18)*, and only the 1:1 complex *(21)* for the 3-glycosides. Owing to steric hindrance by the sugar residue adjacent to the carbonyl function, only one flavone molecule can be attached to the central atom in the



*(16)*



*(17)*

[22] *L. Hörhammer* and *R. Hänsel*, Arch. Pharm. *285*, 438 (1952); *288*, 315 (1955).

[23] *L. Hörhammer* and *R. Hänsel*, Z. analyt. Chem. *148*, 251 (1955).

3-glycosides. The same effect is found even with a methyl group. Thus 3-hydroxy-5,7,3′,4′-tetramethoxyflavone *(19)*, like quercetin, gives three types of complexes, whereas only the 1:1 type can be isolated for 5-hydroxy-3,7,3′,4′-tetramethoxyflavone *(20)*, as with the 3-glycosides rutin *(21)*, R = $C_{12}H_{21}O_9$, and quercitrin *(21)*, R = $C_6H_{11}O_4$.

## Variation of Flower Colors

The question now arises of whether the variation of flower colors in general can be explained by complex formation. It is conceivable that all the hues between deep blue and red are produced by a mixture of blue chelates with red oxonium salts.

We have already mentioned that only the glycosides of cyanidin *(2)*, delphinidin *(3)*, and petunidin *(5)* form deep olue chelates. Glycosides of pelargonidin *(1)*, peonidin *(4)*, and malvidin *(6)* are unable to do so, and should therefore occur as principal components only in red to violet flowers. This is in agreement with the results obtained by *Werckmeister* [24] in chromatographic studies on the anthocyanin contents of various flowers. A few examples are given below.

The cornflower occurs in a red variety as well as in blue. *R.* and *G. M. Robinson* [10] assumed that the red color is due to "copigmentation" with chlorogenic acid. However, the anthocyanin present in the red cornflower is not cyanin, but pelargonin [25], a glycoside of pelargonidin *(1)* with only one hydroxyl group in the phenyl ring, which cannot form blue complexes.

The various types of shrub lupin (*Lupinus polyphemus*) show every shade from pink to violet and deep blue in their flowers. The pigment obtained from the press juices of blue lupins cannot be dialysed and, like the protocyanin of the cornflower, must therefore have a high molecular weight. The pigment of red lupins, on the other hand, passes through the dialysis tube in 30 to 60 minutes [26]. When the press juices of violet lupins are dialysed, the inner solution becomes blue within an hour, *i.e.* the color of violet lupins is produced by a mixture of macromolecular, blue chelates with red, dialysable oxonium salts.

The anthocyanins found in lupins of different colors are shown in Table 2. The red varieties contain only pelargonidin glycosides, which do not form blue complexes. The blue lupins contain glycosides of cyanidin and delphinidin, *i.e.* strong complexing agents. Violet flowers contain the pelargonidin glycosides as well as the delphinidin and cyanidin glycosides.

Table 2. Lupin anthocyanins.

| Anthocyanin | RF in butanol/ $CH_3COOH$/ $H_2O$ (4:1:5) | Lupins red | blue | violet |
|---|---|---|---|---|
| Delphinidin monoglucoside | 0.19 | − | ++ | + |
| Pelargonidin monoglycoside | 0.39 | ++ | − | + − |
| Pelargonin | 0.35 | ++ | − | + |
| Cyanidin glycoside | 0.24 | − | ++ | + |
| Unknown | 0.29 | − | − | + |

The colors of various other flowers can similarly be explained by complex formation. Table 3 shows the properties of the press juices of some flowers; the presence of non-dialysable complexes and the direction of migration in an electric field are indicated.

Table 3. Dialysability and electrophoretic mobility of some flower pigments.

| Plant | Color | Dialysis of press juice | Electrophoretic mobility [a] | pH of press juice |
|---|---|---|---|---|
| Crocus *(Crocus spec.)* | blue | No dialysis in 10 hr | to cathode | 5.75 |

[a] In 0.2 M acetate buffer, pH 4.62, 400 V.

## Limits of the Complex Formation Theory

Complex formation has been proved for cyanin by the isolation of protocyanin. In the case of delphinidin glycosides, as was already observed by *Willstätter* [27], the decoloration to the leuco-base in dilute solution does not occur so readily as in the case of cyanin. Thus

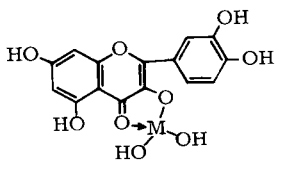
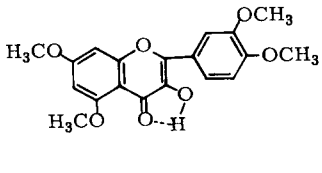
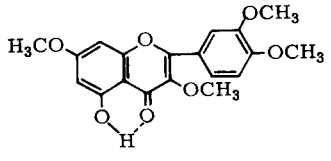
the violet quinoid anhydro-bases *(22)* of delphinidin glycosides could be stable in weakly acidic to neutral media [12].



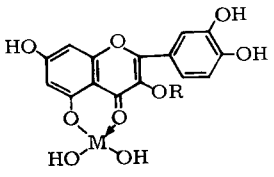
*(18)*



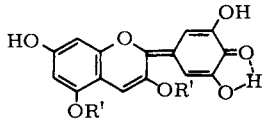
*(19)*



*(20)*



*(21)*



*(22)*

We have therefore studied the question of whether the pigment of the larkspur is an aluminum or an iron complex. This pigment is sparingly soluble in water, and can be extracted from the flowers only with dimethylformamide/water (2:1). Comparison of the absorption spectra (Fig. 6) of a synthetic delphinin-aluminum complex and of the larkspur pigment shows

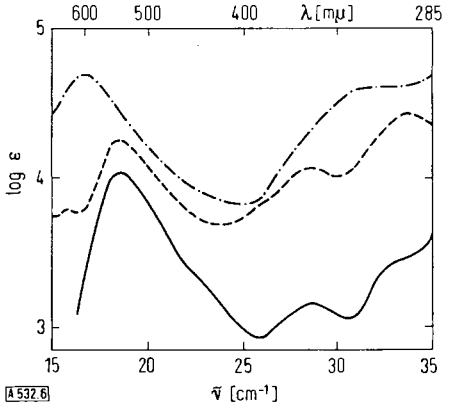


Fig. 6. Absorption spectra of delphinin chloride in 0.01% methanolic hydrochloric acid (—), larkspur pigment in acetate buffer, pH 4.7 (---), and chlorodidelphininoaluminum (·····).

that the latter absorbs at a wavelength 40 to 50 mμ lower, and has a lower maximum extinction than chlorodidelphininoaluminum. The addition of an aluminum salt to the pigment of the larkspur causes a shift towards longer wavelengths and an increase in extinction, owing to complex formation (Fig. 6). Thus the larkspur pigment does not consist primarily of an iron or aluminum complex. Like protocyanin, the pigment of larkspur cannot be dialysed, and so has a high molecular weight. A polysaccharide is again involved. In addition to glucose and arabinose, it contains galacturonic acid. The pigment contains metal ions only in traces, the quantity being about ten times smaller than the stoichiometric amount for chelate formation. Thus the pigment of the larkspur is a compound of a pectin-like polysaccharide and the neutral "anhydro-base" *(22)* of delphinin, without metal ions. This linking of delphinin to pectin to give a non-dialysable molecular complex can also be brought about artificially. When 400 mg of purified apple pectin is added to 19.5 mg of pure delphinin, isolated from larkspur, in 50 ml of water, less than 2% of the delphinin passes through the dialysis tube after dialysis for 20 hours. As the pectin is added, the extinction increases, as shown by Fig. 7. Moreover, the position of the maximum extinction agrees with that of the larkspur pigment maximum. Details of the bonding of the anhydro-base of delphinin to the pectin are not known; hydrogen bonds possibly are involved. Cyanin does not form blue-violet non-dialysable complexes with

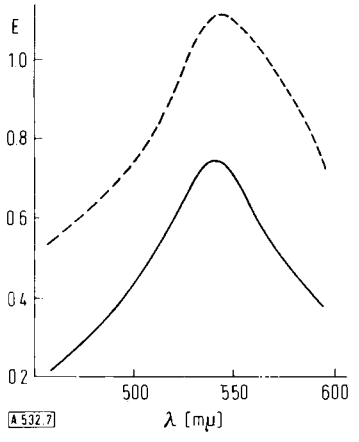

Fig. 7. Increase in the extinction of delphinin in acetate buffer, pH 4.7 (—), on addition of purified apple pectin (---).

Delphinin chloride (18 mg) was dissolved in 6 ml of 0.1% methanolic hydrochloric acid and 2 ml of distilled water. The solution was made up to 50 ml with 0.2 M acetate buffer (pH 4.7), and pectin in acetate buffer (pH 4.7) was then added (40 mg of pectin to 18 mg of delphinin). Before the measurements were made, the reference solution and the samples containing added pectin were allowed to stand for 1 day, and were then centrifuged.

pectins. Moreover, the aglycone delphinidin exhibits neither a deepening of color nor the formation of a macromolecular non-dialysable compound when pectin is added.

These results may explain the observation of *K. Hayashi et al.* [28], who isolated a blue compound containing 1 atom of magnesium per 4 molecules of delphinidin glucoside from *Commelina communis*. This is opposed by the fact that, as with the cyanidin derivatives, spectroscopic studies and attempted isolation have failed to reveal any tendency for delphinin or delphinidin to form complexes with alkaline earth ions at pH 2 to 9 [16, 18, 29]. The attachment of four bidentate anthocyanin ligands would result in a coordination number of 8 for magnesium. Thus this theory is im-

[28] *K. Hayashi, Y. Abe,* and *S. Mitsui,* Proc. Japan Acad. *34,* 373 (1958); *35,* 169 (1959).

[29] *E. Bayer,* Chimia *16,* 333 (1962).

probable from the chemical point of view. However, this conflict would be resolved if the blue color in the commelin, as in the larkspur, were due to the combination of a polysaccharide with the anhydro-base of the delphinidin glycoside, and if the magnesium were simply an impurity that is difficult to remove. It is probable, therefore, that *Hayashi et al.* [28] are the first to have isolated a member of this class of macromolecular pigments.

The bonding of anthocyanins to pectins is probably also involved in the coloring of fruits. Thus it has been known for some time that the pigment of red grapes can be dissolved more easily in order to obtain an intensely red wine if an enzyme that attacks pectins, *e.g.* vinibon [30], is added.

# Evolutionary Aspects of the Structure of Proteins

BY PROF. R. ACHER

LABORATOIRE DE CHIMIE BIOLOGIQUE, FACULTÉ DES SCIENCES, PARIS (FRANCE)

*The evolution of protein structures is discussed using cytochrome c, hemoglobin, and neurohypophyseal hormones as examples. Although these substances have different biological functions, their evolution is controlled by the same general rules: their primary structures vary at the level of the species, order, or class, but this variation is restricted by the fact that the biological activity of the protein must not be impaired. Alterations (i.e. substitutions, deletions, or additions of amino acid residues) can therefore occur only in certain positions of the peptide chains, although with different frequencies. The total number of alterations thus represents only the final state of a protein and does not take into account successive substitutions which may have taken place at the affected sites. It can therefore give only a rough indication of the phylogenetic distance between two species. The nature of the substituting residues, on the other hand, is a useful guide to zoological cognateness, since it allows the identification of transition molecules which simultaneously contain amino acid residues from the protein of the evolutionary ancestor and from the protein of the evolutionary descendant.*

Although normally observed on the morphology of organisms, evolution must ultimately be due to changes at the molecular level, since every hereditary modification in the phenotypes results from a genetic mutation, *i.e.* a change in deoxyribonucleic acid (DNA). This does not mean, however, that the "laws" of the evolution of organisms apply to molecular evolution. Thus, whilst genetic mutations are random and anarchic, the evolution of organisms seems to be oriented in a certain direction by natural selection, which filters the multitude of genetic mutations and makes new beneficial characteristics dominant. The question, however, is to what extent is morphological "orthogenesis" connected with molecular "orthogenesis", *i.e.* to what extent is morphological evolution parallelled by chemical changes. This question can be answered only by selecting the operative molecules from various species and by arranging them in the order attributed to phylogeny. If we can then recognize a stepwise change in the molecules that can be correlated with the steps of anatomical evolution, we can begin the more direct, biochemical investigation of the mechanism of evolution.

The new task in this connection is to examine the chemistry of the genes, which are responsible for the transmission of existing characteristics and for the appearance of new characteristics through mutations. It is now accepted that genes are deoxyribonucleic acids and that their specific action depends on the sequence of the constituent nucleotides. If these deoxyribonucleic acids could be isolated and analysed, we could directly compare the genetic materials of various species. While this is not yet possible, we can isolate and characterize the "products" of the genes, *i.e.* enzymes and, more generally, proteins. It has emerged from the experiments of *Yanofsky et al.* [1] that the sequence of the amino acid residues in proteins corresponds to the sequence of nucleotides in DNA (concept of colinearity). We may therefore study mutations as reflected in the corresponding proteins.

Proteins are characterized not so much by the number and the nature of the constituent amino acids, as by their sequence. Mutational changes in this structure can occur by insertion, deletion, or substitution of the amino acid residues. A unit change can therefore be defined as one which affects a single residue in the chain. We can also determine the variation coefficient,

[1] *C. Yanofsky, B. C. Carlton, J. R. Guest, O. R. Helinski*, and *U. Henning*, Proc. nat. Acad. Sci. USA *51*, 266 (1954).

*i.e.* the ratio of the number of changed residues to the number of unchanged residues. Comparison of homologous proteins of fishes, amphibians, reptiles, and mammals shows that a structural pattern remains unchanged in all these classes. This usually involves the length of the peptide chain, the prosthetic group, and the nature of the amino acids in certain positions. This unchanged structural pattern is probably linked with the biological role of the particular protein.

Interestingly, the length of the peptide chain of homologous proteins is the most stable parameter. All the cytochromes c of the vertebrates so far investigated consist of a chain with 104 amino acid residues, and all the neurohypophyseal hormones of fishes, amphibians, birds, and mammals contain nine amino acid residues. Evolutionary changes seem, therefore, to be restricted to substitutions of amino acid residues in the chain, insertion and deletion occurring only rarely.

Furthermore, investigations of the mutations of tryptophan synthetase[1], hemoglobins[2], and tobacco mosaic virus (TMV)[3] have shown that a genetic change generally affects only one amino acid residue at a time. We may therefore consider an amino acid substitution as a unit evolution. If this is correct, the evolution of the vertebrates should be accompanied by an increase in the number of substitutions. Substitutional similarity will then be a criterion of interspecific kinship, and a scheme of evolution can be based on the number of substitutions (Fig. 1, left), provided that

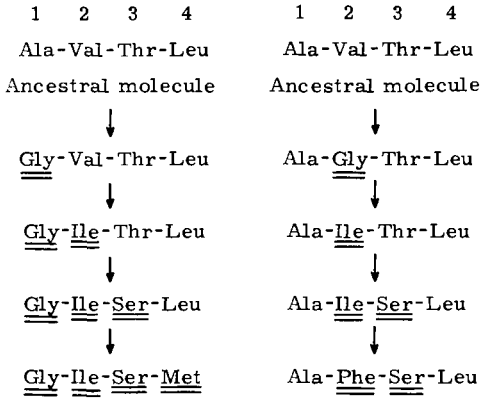

Fig. 1. Evolution of proteins having equal (left) or unequal (right) frequencies of substitution at various sites in the chain (schematic).

mutation affects all positions of a peptide chain with equal probability. However, this is not the case, since in the proteins of vertebrates some positions are never affected while others are involved with various frequencies. The biological function of the molecule does not allow just any substitution, and it is probably the position in the chain which determines whether an amino acid will be a permanent feature or substitutable, and if so, with what probability. The number of immutable positions often is equal to or exceeds the number of the mutable sites. Thus it is not the total number of substitutions in the chain, but the nature of the amino acids on sites with frequent variations that enables us to trace the evolution of a protein, and it should be possible to characterize in certain zoological groups transition molecules with structures intermediate between those of proteins of more primitive species on the one hand, and of more highly evolved ones on the other (Fig. 1, right).

Since the evolution of the vertebrates is the best known, and since proteins from vertebrates are relatively easy to obtain, they have been the subject of most studies. For practical reasons, the proteins selected must be produced by the organisms in sufficient amounts, they must be amenable to rapid purification, and they must have a relatively small molecular weight permitting complete structural analysis in a reasonably short time. Hemoglobins and cytochromes c (abundant and easy to purify), and the neurohypophyseal hormones (structurally simple) fulfil these conditions. Although they have different biological functions, they agree in that their molecules vary from species to species or from class to class.

## I. Cytochrome c

Among the proteins involved in the respiratory chain of aerobic organisms, cytochrome c is one of the easiest to purify, since it is easily soluble and, like most basic proteins, easy to process on cation exchangers. Cytochrome c has been isolated from vertebrates, invertebrates, microorganisms, and some plants. In a number of cases it has been crystallized. Cytochrome c of the heart of vertebrates has been investigated in particular, since this organ contains a relatively large amount of the enzyme. The cytochromes c from various classes of vertebrates all contain 104 amino acid residues, a single prosthetic group (heme), have an isoelectric point close to pH 10 and a redox potential close to +250 mV. Furthermore, they all react with mammalian cytochrome oxidase. Obviously their function has suffered no change in the course of evolution, although their structures have been modified by amino acid substitutions. It has not yet been possible to relate the steps of chemical change with the steps of morphological evolution, although the number of amino acid substitutions increases as we approach the top of the evolutionary ladder.

### 1. The Structural Pattern

We denote by the term "structural pattern" the totality of structural features that do not show any interspecific variation. The structural pattern of the cardiac cytochromes c of 12 species belonging to three classes of vertebrates[4,5] is characterized by a chain of 104 amino

[5] *E. L. Smith* and *E. Margoliasch*, Fed. Proc. *23*, 1243 (1964).

acid residues, about half of which are identical in all the proteins in question, and by a heme prosthetic group fixed in the 14,17-positions, so that the two thioether bridges of the chain are always separated by two amino acids (see Fig. 2). Though the chain length varies slightly in invertebrates and microorganisms, it is constant in vertebrates, so that evolution operates here only through amino acid substitutions.

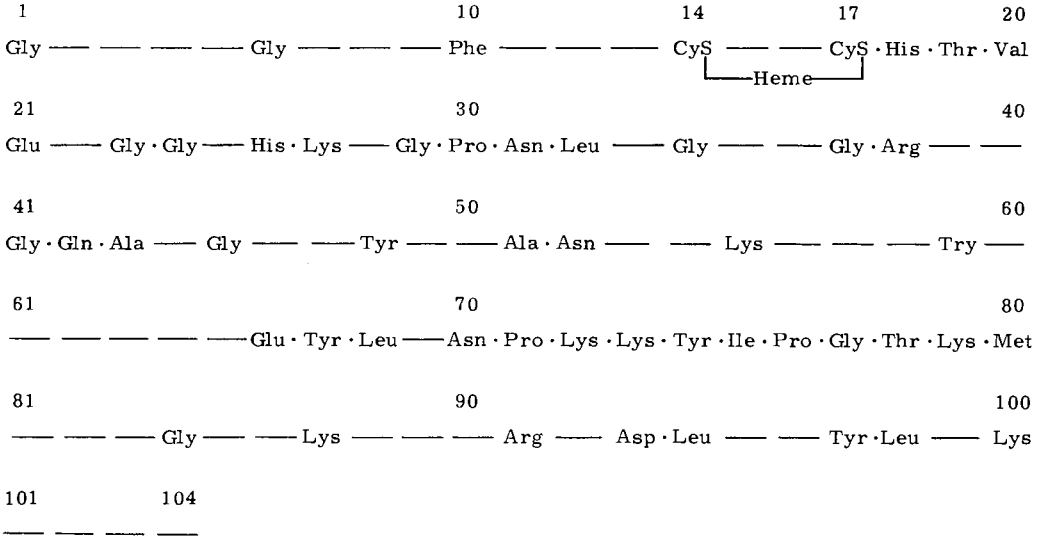

Fig. 2. Structural pattern of the cytochromes c of vertebrates: The dashes represent mutable sites (after [4]).

## 2. Substitutions

### a) Total Number of Substitutions

Figure 2 shows that positions 70 to 80 on the peptide chain are exempt from substitution. This may be because mutations have never affected this region, or because this region is indispensable to the enzymatic activity and the molecules inactivated by substitutions were eliminated during evolution. On the other hand, the substitutable positions outside this region are fairly regularly distributed along the peptide chain, indicating that substitutions affect the sites singly.

Table 1 shows that the difference in the number of substitutions in the cytochromes c is small between mammals of the same order, but significantly greater between mammals of different orders. However, the total number of substitutions is not sufficient for establishing a kinship among various species of vertebrates. Thus, the cytochrome c of the tunny, a bony fish, differs from that of mammals only by 17 to 21 residues, the difference between those of man and horse being as high as 12 residues. Such a comparison takes into account only the "final" states and gives the minimum number of substitutions that must have taken place. The actual number is surely considerably higher, for some sites may have suffered a series of substitutions in the course of evolution, only the last one of which is detected. The observed minimum number of substitutions is thus only a rough indication of interspecific kinship, having a greater validity only within small zoological groups.

Table 1. Number of substitutions in the cytochromes c of some mammals.

| Species compared | Orders compared | Number of substitutions |
|---|---|---|
| Man — ape | Primates — primates | 1 |
| Cow — pig — sheep | *Artiodactyla-Artiodactyla* | 0 |
| Cow — horse | *Artiodactyla — Perissodactyla* | 3 |
| Man — cow | Primates — *Artiodactyla* | 10 |
| Man — horse | Primates — *Perissodactyla* | 12 |
| Man — dog | Primates — *Carnivora* | 10 |
| Man — rabbit | Primates — *Rodentia* | 11 |

### b) Nature of the Substitutions

Depending on whether the substitution involves two chemically equivalent or non-equivalent amino acids, we distinguish between substitutions which preserve and others which alter the chemistry of the chain [4]. Chemically equivalent amino acids are, for example, isoleucine and valine, serine and threonine, or lysine and arginine. Substitution between any of these pairs generally does not change the chemical properties of the protein, its biological properties being changed only to a very small extent. By contrast, the replacement of a charged residue by a hydrophobic residue such as that of lysine by isoleucine, represents a considerable modification and may lead to a molecule with novel properties. Both preserving and modifying substitutions are detectable in the cytochromes c.

Since the prosthetic heme group plays an important part in the electron transfer, substitutions in its neighborhood are of particular interest [6]. Figure 3 shows the preserving and the modifying substitutions affecting these positions in the cytochromes c of 12 vertebrates, in yeast, and in the invertebrate *Samia cynthia* [4].

[6] *S. Paleus* and *H. Tuppy*, Acta chem. scand. *13*, 641 (1959).

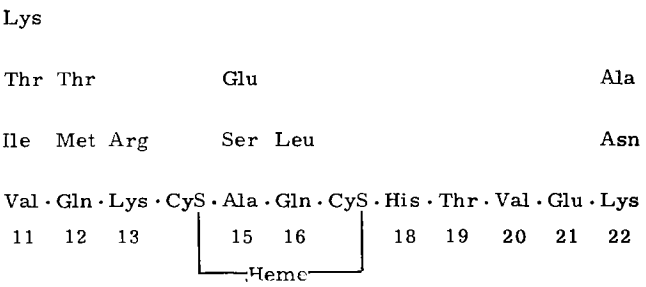

Fig. 3. Substitutions near the heme group in a series of 14 cytochromes c. The base line shows the sequence as found in seven species (after [6] and [4]).

## II. Hemoglobins

Hemoglobin is an abundant protein which can be easily purified and which constitutes almost the entirety of the soluble proteins present in the red cells of the blood. For its isolation the erythrocytes are separated from the plasma by centrifuging, washed with an isotonic solution, and finally lysed with distilled water. Unlike the red cells of mammals, those of lower vertebrates are nucleated, and the purification must then involve the elimination of the nucleic acids. The molecular weights of the hemoglobins of numerous species belonging to different classes of vertebrates were determined by ultracentrifugation. The values found are between 64000 and 68000, except in the case of *Cyclostomata*, the most primitive vertebrates, where it is 17000 [7]. It appears, therefore, that the hemoglobin molecule increased in size at the very beginning of the evolution of the vertebrates.

Study of the primary structure of hemoglobin, *i.e.* of the amino acid sequence, received a new impetus when it was found that the protein is a "tetramer" formed from four peptide chains each having a molecular weight of 17000, and that the molecule can be dissociated simply by lowering the pH. Horse hemoglobin has been separated by electrophoresis and chromatography at pH 2 into two types of peptide chain, $\alpha$ and $\beta$, native hemoglobin containing two of each. This has led biochemists to consider two independent gene-protein systems (corresponding to the $\alpha$ and the $\beta$ proteins) and to postulate the duplication of an ancestral molecule.

### 1. Multiplicity of Chains

The chains of the hemoglobins of mammals have been generally separated by ion-exchange chromatography on Amberlite IRC-50, a carboxylic acid resin, at pH 2.1 with a urea buffer gradient. In the case of the hemoglobins of lower vertebrates, however, it is better to use countercurrent distribution with sec-butanol and dilute dichloroacetic acid as the mobile and the stationary phases, respectively [8]. Two types of chain have been found in the hemoglobins of various species, such as the horse, the rabbit, the pig, the llama, and the cow [8], a great number of primates [10], and the carp [9].

The hemoglobin of adult man contains 90 % of hemoglobin $A_1$, consisting of two $\alpha$ and two $\beta$ chains, and 2–3 % of hemoglobin $A_2$, consisting of two $\alpha$ and two $\delta$ chains. The human fetus has hemoglobin F, consisting of two $\alpha$ and two $\gamma$ chains. The human body thus produces four hemoproteins ($\alpha$, $\beta$, $\delta$, $\gamma$). The amino acid sequence in the $\alpha$, $\beta$, and $\gamma$ chains is now fully known [7–11]. The $\alpha$ chain contains 141 residues, the other three contain 146. Comparison between the $\beta$ and the $\gamma$ chains shows that only 39 out of the 146 sites differ, *i.e.* the degree of homology is 73 %. The 39 substitutions seem to be randomly distributed along the chains without forming blocks. Chains $\beta$ and $\delta$ are likewise similar. As mentioned above, the $\alpha$ chain, which is always present in human hemoglobin, differs from the other three by containing only 141 amino acid units. Although the homology between the $\alpha$ and the $\beta$ chains is only 44 % (64 identical sites), it is still sufficiently great to indicate a common ancestry. In this case the variations are not restricted to substitutions but also involve deletions and insertions.

Detailed investigations on ten apes [10] have revealed the presence of two $\alpha$ and two $\beta$ chains. The simian $\alpha$ chain differs from the human $\alpha$ chain by 0 to 6 substitutions, but the simian $\beta$ chain differs from the human $\beta$ and fetal $\gamma$ chains by 3 to 23 and by 9 to 36 substitutions, respectively.

The two hemoglobins found in the erythrocytes of the horse may be considered to be homologous with the human $A_1$ and $A_2$ types. As in humans, the $\alpha$ chains of both hemoglobins contain 141 residues and are identical. The $\beta$ chains, on the other hand, contain 146 residues and are different. More than one type of hemoglobin has been found in the cow, the sheep, and the mouse [9], and this plurality appears to be the rule.

As in humans, the hemoglobins of all the adult mammals investigated (cow, horse, sheep, rabbit, pig, and llama) consist of two $\alpha$ chains and two $\beta$ chains, and can be represented by the general formula $\alpha_2\beta_2$. As in man, the fetal hemoglobin found additionally in *e.g.* cow, sheep, and goat, consists of $\alpha$ chains, identical to those in the adult hemoglobin, and $\gamma$ chains which differ from the adult $\beta$ chains. The general formula of fetal hemoglobin is therefore $\alpha_2\gamma_2$.

In each group the chain length seems to be the most stable property (see Table 2). On the other hand, the $\alpha$ chain exhibits appreciably fewer substitutions than the

β and γ chains. This is illustrated in Fig. 4 for the amino end of the chains.

Table 2. Number of residues in the α, β, and γ chains of the hemoglobins of some mammals.

| Species | α | β | γ |
|---|---|---|---|
| Man | 141 | 146 | 146 |
| Horse | 141 | 146 | |
| Cow | 141 | 145 | 145 |
| Lemur | | 146 | |
| Camel | | 146 | |

common hemoglobin. The hemoglobin of the lamprey has been isolated in pure form. It contains only one peptide chain consisting of 160 amino acid residues. Its structure is more like that of mammalian myoglobin than that of the α or the β chain of vertebrate hemoglobin [9].

## 2. The Theory of Duplication

Inspection of the number and the sequence of amino acid residues in the hemoglobin chains suggests that

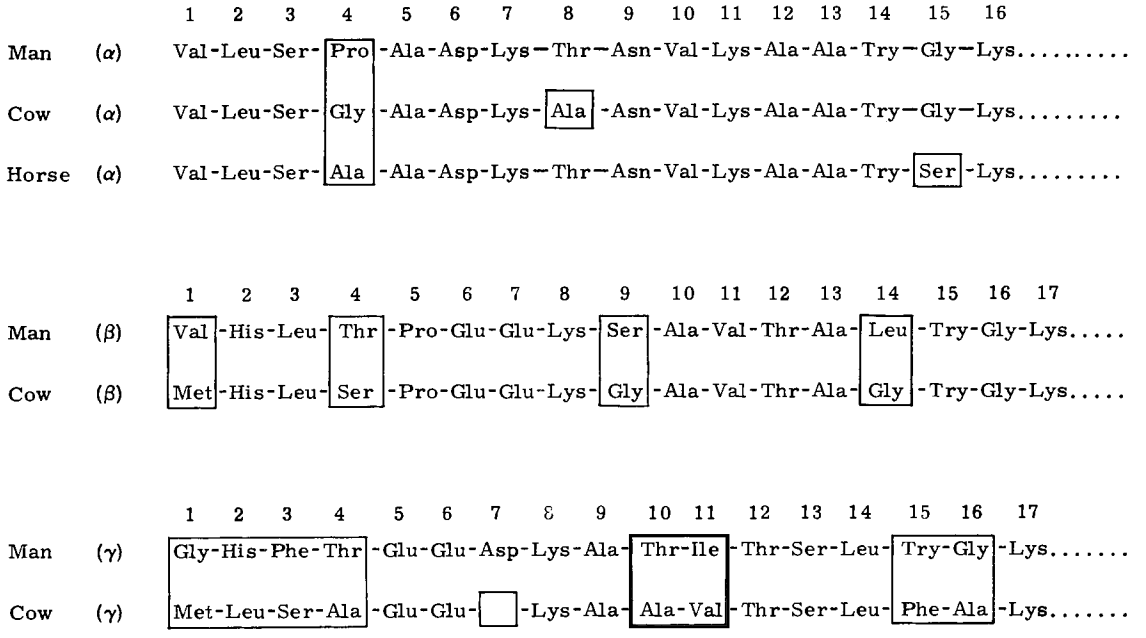

Fig. 4. Comparison of the amino ends of the α, β, and γ chains in human, bovine, and equine hemoglobins. Boxes denote substitutions, empty boxes deletions.

Similar remarks seem to apply to other classes of vertebrates in that the adults frequently contain two or more hemoglobins formed by two types of chain, so that the general formula $\alpha_2\beta_2$ still applies. Thus, in the classes *Aves* and *Pisces*, the hen [12] and the carp [13] have two and three hemoglobins separable by electrophoresis or chromatography. Unlike the β chain, the α chain in the predominant hemoglobin of the carp has an acetylated amino group at one end [13] and, unlike the mammalian α chain (141 residues) contains 142 residues [9]. As with the cytochromes c of the vertebrates, the length of the peptide chains is probably the most constant feature.

Since the *Cyclostomata* constitute the most primitive class of vertebrates, their proteins should be closest to the ancestral type. The lamprey is one of the few remaining representatives of this class. The molecular weight of its hemoglobin is about a quarter of that found in vertebrates [14]. In this respect, it is closer to myoglobin found in the muscles of vertebrates than to they are derived from a single ancestral molecule. Gene duplication is the simplest way to explain the formation of new genes. *Ingram* [8] has advanced this explanation to account for the four types of chain in normal human hemoglobins. As regards their molecular weight, amino acid sequence, *etc.*, these chains resemble the myoglobin of muscles. Accordingly, the gene controlling the biosynthesis of myoglobin should be the oldest and the ancestor of the genes now controlling the biosynthesis of the α, β, γ, and δ chains (Fig. 5).

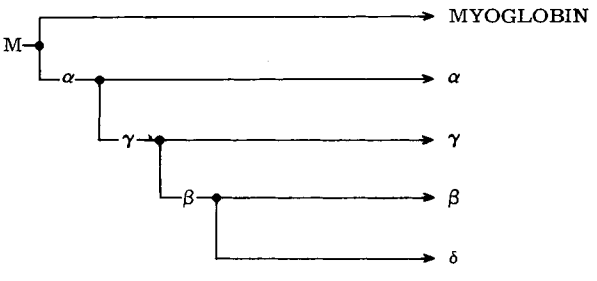

Fig. 5. Evolution of the hemoglobin chains. The dots denote gene duplications (after [8]).

Differentiation of the myoglobin gene M would have given rise to two genes, one of which continues to control the synthesis of myoglobin, the other leading *via* mutations to the formation of the α chain. Duplication of the α gene would give two daughter genes, one

[12] *Cl. Paul, A. G. Schnek*, and *J. Léonis*: Chromatography Symposium II, 1962, p. 133.

[13] *K. Hilse, V. Sorger*, and *G. Braunitzer*, Hoppe-Seylers Z. physiol. Chem. *344*, 166 (1966).

[14] *T. Svedberg* and *I. B. Eriksson-Quensel*, J. Amer. chem. Soc. *56*, 1700 (1934).

form of which continues to control the production of the $\alpha$ chain, the other after modification causing the synthesis of the $\gamma$ chain. The same mechanism would operate in the successive formation of the $\beta$ and $\delta$ chains. This scheme accounts for certain genetic and chemical observations: as implied by the similarity in the amino acid sequences of the corresponding proteins, genes $\gamma$, $\beta$, and $\delta$ are seen to be derived from one another, in that order, while the $\alpha$ gene, which is the most stable, is considered as the oldest of the four. The only reason for placing the $\gamma$ gene before the $\beta$ and $\delta$ genes is that it occurs in the fetus, the other two being found only in the adult.

the amino acid sequence of the corresponding protein. As time proceeds, the two protein structures become more and more dissimilar.

Investigations on the pathological variations of human hemoglobins have revealed a great number of abnormalities. Genetic studies on several generations have shown that these abnormalities result from mutations. The number of the abnormal hemoglobins (B, C, D) has turned out to be so large (about 40) that now a combination of letters (B, C, D) and places of origin is used for denotation. An important feature is that mutation affects almost always only one amino

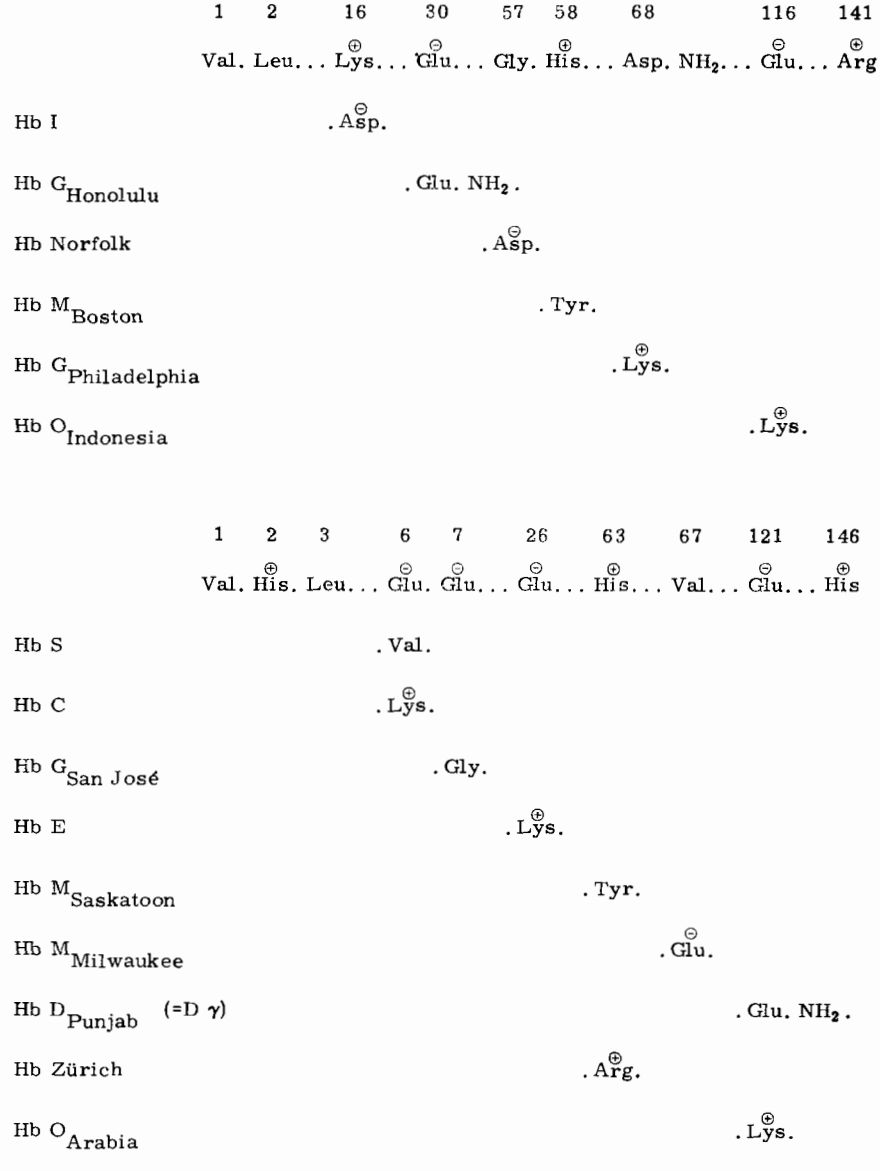

Fig. 6. Substitutions in abnormal human hemoglobins due to the mutations in the genes $\alpha$ (above) and $\beta$ (below) (after [8]).

### 3. Mutations

The hypothesis of duplication explains the formation of two twin genes, each controlling the synthesis of one protein. Initially, the two proteins were also twins. However, each gene suffers some mutations independently of the other. These mutations result in changes in acid residue at a time. Gene $\beta$ is characterized by an appreciably greater number of mutations than gene $\alpha$. The substitutions induced in the protein molecules by mutations are randomly distributed along the chains (see Fig. 6). Furthermore, insertions and deletions must be very rare, since the chain length has been found to be constant.

## III. Neurohypophyseal Hormones

The neurohypophysis produces hormones which have relatively simple structures. For this reason, they were among the first peptide hormones to be characterized. Oxytocin and vasopressin were isolated from cattle [15–17].

### 1. Duality of the Hormones

Tests for oxytocic and pressor activities in the hypophyseal extracts give positive results with all vertebrates, though the levels of activity may differ considerably (Table 3). The neurohypophyseal (NHP) hormones have been isolated from six mammals (man, cow, pig, horse, sheep, and whale), one bird (hen), one amphibian (frog), five bony fishes (bib, pollack, silver hake, cod, and carp), and four cartilaginous fishes (rays). Purification was always carried out by selective adsorption of the hormones onto a protein, neurophysin. The resulting complex was then isolated by fractional precipitation and dialysis. Treatment with trichloroacetic acid precipitated the protein, the hormones remaining in solution. The last step was chromatography on Amberlite CG-50. Some of the chromatographic results are shown in Figures 7a to 7d.

Table 3. Biological activities of posterior pituitary powders from various species of vertebrates.

| Species | | Oxytocic activity [units/mg dry powder] | Vasopressin activity [units/mg dry powder] |
|---|---|---|---|
| Mammals: | Cow | 1.0 | 1.1 |
| | Pig | 1.4 | 1.4 |
| | Horse | 0.9 | 0.8 |
| | Sheep | 0.8 | 0.8 |
| | Whale | 0.5 | 2.5 |
| Birds: | Hen | 0.4 | 0.4 |
| Amphibians: | Frog | 1.2 | 1.0 |
| | Toad | 1.0 | 0.8 |
| Bony fishes [a]: | Bib | 0.6 | 0.5 |
| | Pollack | 0.5 | 0.5 |
| | Hake | 0.5 | 0.3 |
| | Cod | 0.? | 0.2 |
| | Carp | 0.05 | 0.04 |
| Cartilaginous fishes [a]: | Ray | 0.005 | 0.001 |
| | White skate | 0.007 | 0.001 |

Two neurohypophyseal hormones were found in each of the five classes of vertebrates investigated. The purity of the substances was checked by amino acid analysis. In the case of the lower vertebrates, the small size of the hypophysis necessitated the processing of a great number of glands to obtain sufficient material for the determination of the chemical structure. To isolate 1 to 5 mg of hormones, about 5000 to 10000 glands must be extracted. Analysis has shown that mammals contain oxytocin and vasopressin, amphibians mesotocin and vasotocin, bony fishes isotocin and vasotocin, and cartilaginous fishes glumitocin and probably vasotocin. On the various chromatograms, oxytocin, mesotocin, isotocin, and glumitocin occupy the same position. They are the first to be eluted, and are followed by vasotocin or arginine-vasopressin (Fig. 7).

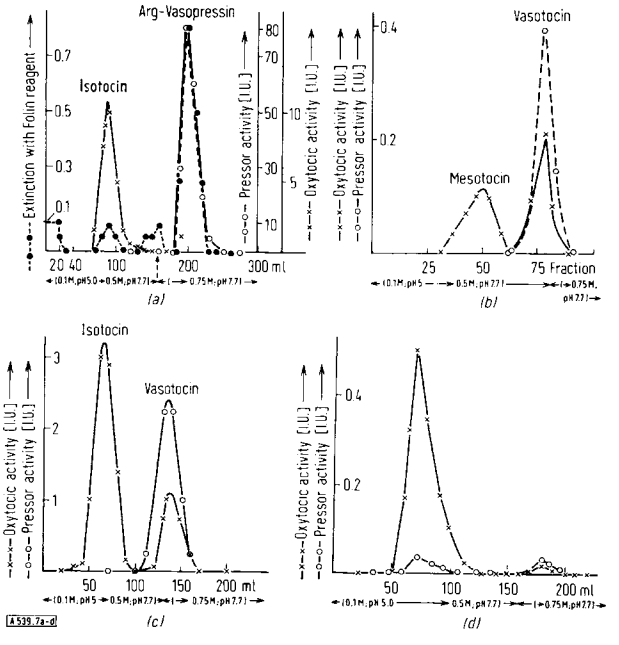

Fig. 7. Chromatograms of the neurohypophyseal hormones of vertebrates (Amberlite CG-50, ammonium acetate gradient) (after [18]). (a) mammals (whale); (b) amphibians (frog); (c) bony fishes (hake); (d) cartilaginous fishes (ray).

### 2. Characterization of the Hormones

All these hormones are peptides having nine amino acid residues (Table 4).

*Mammals*: The NHP hormones of the cow and the pig have been known since 1953, those of the horse, sheep, whale [18], and man [19] having been characterized more recently. All species contain the same oxytocin, five of the six containing the same arginine-vasopressin. Lysine-vasopressin, in which a lysine residue takes the place of an arginine residue, has been found only in the pig.

*Birds and amphibians*: The neurohypophysis of the hen, the only bird investigated, contains oxytocin and vasotocin, that of the edible frog (*Rana esculenta*) containing mesotocin and vasotocin [18].

*Bony fishes*: Isotocin and vasotocin are the two NHP hormones found in four marine species of *Teleostei*: the bib (*Gadus luscus*), the pollack (*Pollachius virens*), the hake (*Merluccius merluccius*), and the cod (*Gadus morhua*), and in one freshwater species of the *Teleostei*, the carp (*Cyprinus carpio*).

*Cartilaginous fishes*: Glumitocin and probably vasotocin are the two NHP hormones found in four species of Elasmobranchs (*Raia clavata*, *Raia batis*, *Raia fullonica*, and *Raia naevus*). The first hormone has been characterized chemically, the second only by pharmacological methods.

## 3. Phylogeny of the Hormones

Although the number of species investigated (about 20) is very small in comparison with the 50000 or so known vertebrates, the following general conclusions may be drawn since almost all the classes of vertebrates were represented:

(i) The neurohypophysis of each species contains two dominant hormones.

(ii) All these hormones have a common structural pattern characterized by nine amino acid residues with a disulfide bridge connecting the amino acids in positions 1 and 6.

(iii) The structure is the same within a given zoological class, and varies by only one or two residues between the classes.

(iv) The changes or mutations seem to affect preferentially "privileged" positions on the chain, in particular positions 4 and 8.

### a) The Ancestral Hormone

The twofold nature of the hormones of the neurohypophysis recalls the chain multiplicity of the hemoglobins and suggests a gene duplication. It must be assumed that this duplication occurred at a very early stage during evolution, since even the *Pisces* contain two hormones. In this connection, the *Cyclostomata*, and especially the lamprey, are of interest. Column-chromatographic and paper-electrophoretic experiments on the pituitary glands of the lamprey revealed only one neurohypophyseal hormone [20], which gave a positive result in pharmacological tests for vasotocin. In addition the lamprey may contain a second hormone, but one which is not detectable by the pharmacological test used. However, this hormone would have to differ greatly from those so far identified, since it is not adsorbed onto neurophysin. Apart from this, it seems

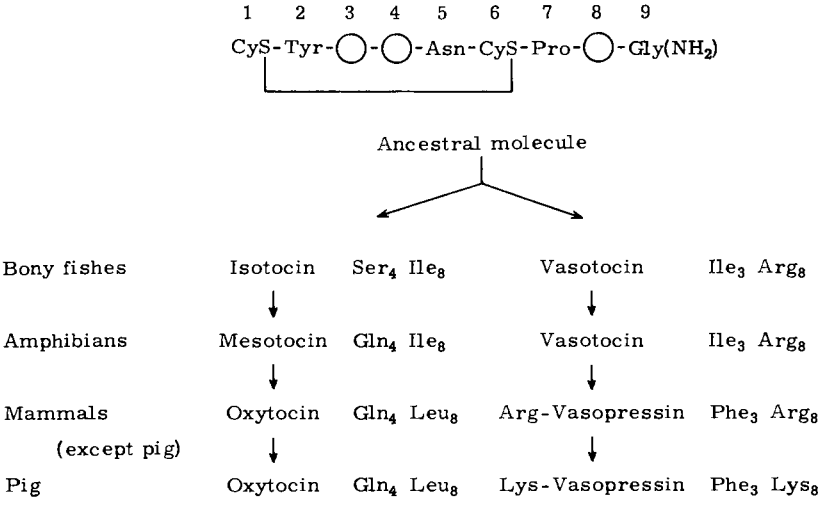

Fig. 8. Hypothetical scheme of the evolution of neurohypophyseal hormones. One gene duplication and a series of subsequent single substitutions in positions 3, 4, or 8 produce two molecular "lines".

feasible to envisage the gene duplication taking place somewhere between the *Cyclostomata* and the fishes. This would mean that two "lines" of molecules are formed, which then undergo diversification independently of each other. One line (isotocin, mesotocin, oxytocin) seems to be specialized in reproduction, the other (vasotocin, vasopressin) being specialized in the regulation of the salt and water balance (see Fig. 8).

b) Molecular Lines

Assuming that the hormones are derived from one another in the same chronological order as the species to which they belong, we can draw up the genealogy of these molecules in juxtaposition to the phylogenealogy proposed by *Simpson*[21]. The cartilaginous fishes and the bony fishes appeared at about the same time some 300 million years ago. However, while the cartilaginous fishes gave rise to no other class of vertebrates, the bony fishes gave rise to the amphibians, these to the reptiles, and these to the birds on the one hand and mammals on the other. It must therefore be examined whether molecular evolution as manifested by the chemical structure of the neurohypophyseal hormones follows the order: bony fish – amphibians – mammals. Considering the NHP hormones involved in the regulation of the water and mineral balance, we note that vasotocin is present in all the vertebrates, with the exception of mammals which contain vasopressin instead. The transformation of vasotocin into vasopressin requires only the substitution of phenylalanine for isoleucine in position 3 (cf. Fig. 8). Although chemically this is merely an interchange between two hydrophobic groups, it precipitates great biological changes: Vasotocin increases the water permeability of the frog bladder, exerts a contracting action on the rat uterus, and stimulates the re-absorption of water at the renal level. When vasotocin is transformed into vasopressin by the substitution $Ile_3 \rightarrow Phe_3$, the first two actions disappear almost entirely, while the third one increases considerably, so that in mammals vasopressin is a powerful antidiuretic.

In addition to the above substitution, porcine vasopressin contains lysine instead of arginine position 8. This second substitution causes practically no chemical change, and only a small biological change. In fact, lysine-vasopressin is the antidiuretic hormone in the pig, just as arginine-vasopressin is in other mammals.

More numerous – and thus more informative – transformations are found in NHP hormones in reproduction. Thus the bony fishes contain isotocin, the amphibians mesotocin, and the mammals oxytocin. The formation of mesotocin from isotocin involves a single substitution in position 4 (glutamine for serine); the formation of oxytocin from mesotocin involves the substitution of leucine in position 8 (see Fig. 8). Mesotocin in amphibians thus represents biochemically an intermediate stage between isotocin and oxytocin: the isoleucine in position 8 is still a piscine feature, but glutamine in position 4 is a mammalian one. From a general point of view, this mixed chemical structure is the molecular equivalent of mixed anatomical structures used by evolutionists to establish the connection between two zoological groups, and mesotocin may therefore be called a "transition molecule", *i.e.* a molecule forming a chemical and, ultimately, a phylogenic link between two genera, orders, and classes.

Although it involves an inference from the above particular case to the general, it seems reasonable to assume that proteins have evolved by a series of single substitutions of amino acids. In fact, this is in agreement with findings on the mutations of various proteins (hemoglobins, tryptophan synthetase, TMV protein), where the changes generally affect only one residue at a time. The transition molecules should provide a clue to the steps of transformation of proteins. It seems logical that the probability of molecular changes increases with time and with increasing chain length. This means that the larger the peptide or protein in question, the more one must restrict the size of the zoological group to be investigated, as otherwise one is confronted with undecipherable complexity.

# The Chemistry and Biochemistry of Insulin

BY DR. H. KLOSTERMEYER

DEUTSCHES WOLLFORSCHUNGSINSTITUT, TECHNISCHE HOCHSCHULE AACHEN (GERMANY)

AND DR. R. E. HUMBEL

BIOCHEMISCHES INSTITUT, UNIVERSITÄT ZÜRICH (SWITZERLAND)

*The protein hormone insulin occurs widely in the animal kingdom. Although its biological function is always the same, its amino-acid composition varies widely. Insulin consists of two polypeptide chains, which are linked by three cystine residues to form a bicyclic system with a 20-membered and an 85-membered ring. The protein crystallizes in various forms with foreign ions. In solution, insulin normally forms aggregates of 2n molecules. The hormone can be regenerated from the separated polypeptide chains, and its total synthesis has been achieved in a similar manner from synthesized peptide chains. In the biosynthesis of insulin, the two chains are evidently built up separately and subsequently linked together. Insulin promotes the synthesis of glycogen, fat, and protein in the organism; insulin deficiency leads to an increase in the blood-sugar level. At the molecular level, the mechanism of action of the hormone is still unknown. Current hypotheses are discussed. No specific active center has so far been detected in the insulin molecule, which contains several antigenic regions.*

## Introduction

In 1788, the physician *Cowley* [1] observed a connection between disturbance of the pancreas function and diabetes mellitus; *von Mering* and *Minkowski* [2] showed in 1889 that diabetes mellitus could be induced experimentally by extirpation of the pancreas. In 1900, *Schulze* [3] and *Ssobolew* [4] realized that the pancreatic substance responsible for lowering the blood-sugar level was formed in the Langerhans islet cells, and for this reason the unknown substance was named "insulin" in 1909 [5]. The extraction of insulin from the pancreas was achieved as early as 1911 [6], but it was only in 1920 that this extraction was carried out consistently by *Banting* and *Best* [7], with the collaboration of the biochemist *Collip*. Thus began the chemistry of insulin, which has since then progressed through the isolation of pure insulin by *Abel* (1926) [8] to the determination of its constitution by *Sanger* (1955) [9] and its synthesis (1963) [10, 11]; the determination of its steric structure, which was begun 30 years ago [12], will soon be completed.

Little is known as yet about an active center in the insulin molecule, its site of action, and its mechanism of action in the cell. Insulin occurs in organs of higher organisms including fish. Evidence has recently been found of its presence in starfish [13].

## Isolation and Purification

Insulin can be isolated in quantities of up to 5 mg [14] by methods based on the pioneering work of *Collip* [15] and of *Somogyi*, *Doisy*, and *Shaffer* [16]. The hormone is extracted from fresh or deep-frozen glands with 60 to 80 % ethanol at a pH of 1 to 3; this treatment inactivates the exocrine proteases of the pancreas. The extract is evaporated under vacuum and freed from fats; the insulin is then salted out, redissolved and finally precipitated isoelectrically at pH 5.3 to 5.4. It can also be precipitated directly from a more strongly acidic solution by seeding with insulin fibrils [17]. In a more recent

process, which avoids the evaporation of the alcohol, the inert proteins are precipitated at pH 8, and residual enzymes are destroyed by brief warming in the acidic solution; the insulin can then be adsorbed on large-mesh ion exchangers (alginic acid [18], DEAE-cellulose, and CM-cellulose [19]) and eluted. This method leads to a 20 to 30 % improvement in yield [18]. From ox pancreas 2000 I.U./kg of gland are obtained, from calf's pancreas up to 10000 I.U. (≈400 mg)/kg, since the exocrine function of the pancreas is not yet developed in the new-born [20], and about 75000 I.U./kg from fish pancreas, since the endocrine part is separate from the exocrine in this case [21].

Methods have been found recently for the isolation of small quantities of insulin, as from single glands of test animals [22]. The pancreas extract can be freed from alcohol under very mild conditions by extraction with ether [23], and the insulin is usually separated by ion-exchange chromatography [19,21] and/or gel filtration [21,24]. Very small quantities of insulin can be isolated by precipitation with antibodies [25].

Crude insulin is most easily purified by repeated crystallization. This procedure gives products with constant biological activity, which were long thought to be absolutely pure. However, more accurate analytical methods showed that even repeatedly recrystallized insulins are not homogeneous [26]. Apart from the insulin antagonist glucagon [27], the most frequent impurity was a deamidoinsulin [28], though insulin-like proteins with little or no biological activity [29] and antigenic substances [30] have also been found.

The preparative final purification of insulin can be achieved by counter-current distribution [26], and chromatographic methods [31] and gel filtration [32] have also been used successfully. Even in highly purified insulins, however, it is generally still possible to detect a few foreign components by electrophoresis [33].

Pure insulin crystals are difficult to obtain [34,35], but when suitable substances are added the hormone crystallizes fairly readily. Numerous crystalline insulin preparations are known, all of which contain water of crystallization and usually also relatively small quantities (in relation to the size of the molecule) of foreign ions; these are all called "crystalline insulin." The crystals are often externally similar, but they may differ when the insulin components are obtained from different animals [36,37].

Insulin was originally crystallized from buffered solutions in the isoionic range at pH 5.5 to 5.6 without the addition of metal ions [34,38], until *Scott* [39] found zinc in these crystals and showed that bivalent metal ions such as $Zn^{2+}$, $Ni^{2+}$, $Co^{2+}$, or $Cd^{2+}$ are essential to the crystallization of the hormone. $Cu^{2+}$, $Mn^{2+}$, and $Fe^{2+}$ ions [36] fulfil the same purpose, and half of the zinc can be replaced by magnesium or calcium [40]; after extraction with ethylenediaminetetraacetic acid, the zinc can be completely replaced by lead [41].

Since the metal content of the insulin crystals is directly proportional to the atomic weight of the metal [42] (0.52 % Zn, 0.77 % Cd, *etc.*), true compounds must be formed. However, crystals with lower metal contents (0.33 % Zn) are now also known [36], whereas in the other direction the zinc content can be increased to 5 % [43]. These compounds are regarded as double salts of the type 2 $M^{2+}$ insulin$^{4-}$·$n$ $MX_2$ [40,44]. The metal ions can be removed from insulins containing metals without destruction of the crystals [36,45].

In addition to zinc chloride, anions such as acetate, citrate, phosphate, or carbonate must also be present for the crystallization of insulin [46]. Insulin is only slightly associated in acidic solutions (pH 2 to 2.5) of low ionic strength, and it crystallizes from such solutions in the absence of metal [47,48] as the sulfate (2 insulin·12 $H_2SO_4$) in two forms, and as the selenate, phosphate, chloride, formate, acetate, and citrate. Crystalline salts of insulin with organic bases, free from zinc but containing metals, have long been known [49].

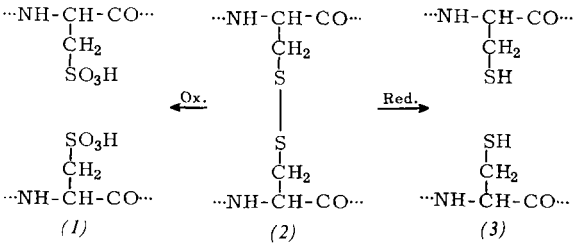
The acidic salts are orthorhombic, and are probably built up from insulin dimers[50]. The cubic metal-free form gives very small rhombododecahedra, in which six insulin dimers[51] appear to form an aggregate. In the monoclinic zinc insulin (from solutions containing phenol) the unsymmetrical unit cell contains aggregates of six insulin molecules and two zinc ions[51]. In the two rhombohedral insulins, the unit cell contains two or four zinc ions in the insulin hexamer, depending on the halide content of the mother liquor[51,52]. The insulin molecules in the dimers are parallel[50,84].

Insulin crystals contain from 30 to 51 % of water of crystallization, depending on the modification[51]. The crystals shrink in air to a water content of 10 %. Part of the water (8 %, *ca.* 30 moles per mole of insulin) is not released even on drastic drying[53]. The zinc can be removed by dialysis or gel filtration[54], and particularly readily when glycine is added.

## Structural Formula

Although *Wintersteiner*, *du Vigneaud*, and *Jensen*[55] recognized insulin as a pure protein as early as 1928, many attempts were made to prepare "protein-free insulin" or to detect a cofactor. However, seventeen different amino acids were repeatedly found in insulin hydrolysates and determined quantitatively[56].



Oxidation of the molecule with performic acid[61] yields two fractions, which can be fractionally precipitated on the basis of the different charges (Acidic and Basic)[62]. The separation can also be carried out by counter-current distribution[63], zone electrophoresis[63] and ion-exchange chromatography[64]. Each of the fractions A and B is homogeneous, insulin therefore consists of the two polypeptide chains A and B.

*Sanger* and his co-workers[65] determined the overall structural formula of bovine insulin (Fig. 1); they first determined the sequences of the 30 and 21 amino acids in the B-[66,67] and A-chains[66,68], respectively, and then the positions of the amide groups[69] and of the three disulfide bridges[9]. The molecular weight was

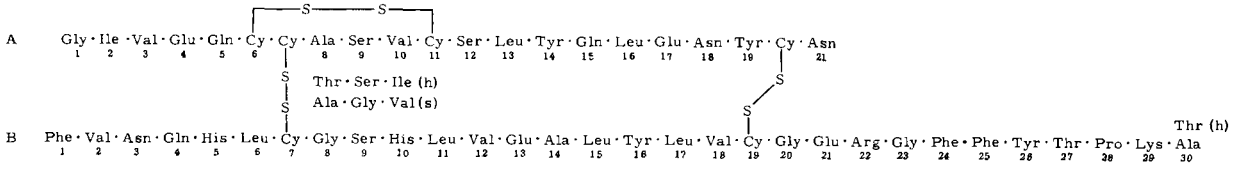


Fig. 1. Primary structure of bovine insulin. Human (h) and sheep (s) insulins differ from this in positions $A_{8-10}$, and human insulin also in position $B_{30}$.

Insulin contains an unusually large amount of sulfur (3.3 %), all of which is present in the form of cystine[57] (methionine has recently also been found in rat and fish insulins). *Freudenberg* and *Wegmann*[58] concluded from this that active (SS) insulin must consist of at least two parallel protein chains held together by SS bridges. This conclusion was confirmed by *Sanger*, who in 1945 found not only phenylalanine[59], but also glycine[60] as an N-terminal amino acid, these two terminal acids being present in the ratio 1:1. Thus it must be possible to break down insulin into polypeptide chains by oxidative or reductive cleavage of the disulfide bridges:

found to be 5734, so that the value of 12000 that had previously been most widely accepted as the lowest molecular weight of insulin must be that of the dimer.

*Sanger* found differences in the amino-acid composition of the A-chains of ox, sheep, and pig insulin, the differences occurring in the $A_{8-10}$ region[70]. The structures of more than 20 insulins have now been elucidated, particularly as a result of the work of *L. F. Smith*[21,71];

the hormone occurs in numerous variants, all having the same biological activity. The differences between the insulins increase with the phylogenetic difference between the species. Some fish [72] and rats [73,74] produce insulins with different sequences even in the same pancreas [74]; it is not yet known how widely this phenomenon occurs.

## Steric Structure

The steric structure of the insulin molecule is determined primarily by the positions of the disulfide bridges. From the differences in behavior of insulin films at water/air and water/oil interfaces, it was concluded [75] that the steric structure of insulin depends to a much greater extent on forces of the van der Waals type than that of hemoglobin. Deuterium exchange [76] shows that insulin in solution contains fewer hydrogen bonds than solid insulin. The helical content of the chains is reported to be only 50 % [77], and scarcely exceeds 65 % even in anhydrous media. This must be due to the positions of the disulfide bridges, since under the same conditions the isolated B-chain almost completely forms a right-handed α-helix [78]. *Slobin* and *Carpenter* [79] found that removal of the C-terminal amino acid $B_{30}$ has no effect on the conformation and biological activity of insulin. However, if the terminal group of the A-chain ($A_{21}$) is also removed, the conformation of the molecule changes, and the hormone becomes inactive. A certain steric structure thus appears to be essential to the hormone activity.

Many attempts [50,77,80] have been made to explain experimental results in terms of models. The extent to which these models correspond to the true structure will be shown by three-dimensional X-ray analysis [51,52,81–83] of insulin. Since intramolecular reaction of insulin with 1,5-difluoro-2,4-dinitrobenzene leads to cross-linkage between glycine ($A_1$) and lysine ($B_{29}$) [84] (Fig. 2), it was postulated [85] that the chains are folded back on themselves. This assumption appears to have been confirmed [41].

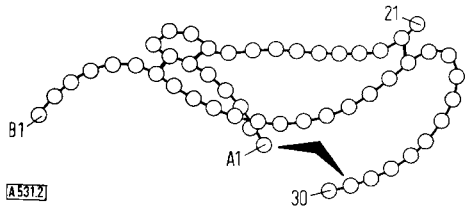

Fig. 2. The intramolecular reaction of insulin with 1,5-difluoro-2,4-dinitrobenzene leads *inter alia* to the formation of a bridge between the α-amino group in $A_1$ and the ε-amino group in $B_{29}$. Consequently the distance between these groups must be about 5 Å.

From the optical rotatory dispersion [86] it was inferred that the conformation of fibrillar (F-insulin) differs greatly from that of dissolved insulin. The reduced iodine uptake [87] of the fibrils and the result that only one of the two histidine units in F-insulin reacts with fluorodinitrobenzene [88], but cf. [89], also suggest a change in the steric structure, but cannot be taken as concrete evidence since these phenomena could be due to diffusion and surface effects. X-ray diagrams [90] show no essential difference between the monomers in F-insulin and in acidic insulin crystals.

## Aggregation and Complex Formation

The particle weight of insulin in solution depends on the pH, temperature, ionic strength, concentration, and foreign ions (Fig. 3). Taking hydration into account, it should be about 6000. This value is found in acidic solutions (pH ≤ 2) at low insulin concentrations [91,92]. As the concentration and alkalinity are increased, the molecule dimerizes. Above pH 4, complexes are formed in the presence of suitable metal ions ($Zn^{2+}$), and between pH 4 and pH 7 these complexes precipitate as

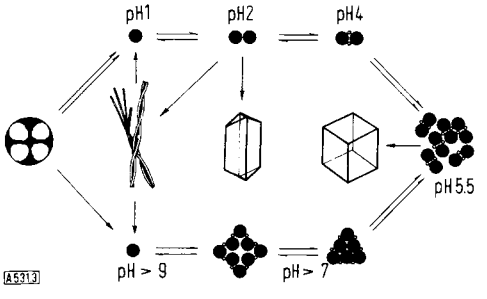

Fig. 3. Behavior of zinc insulin in solutions (greatly simplified). In the middle row from left to right: spheres, fibrils, insulin chloride, zinc insulin, isoelectric precipitation. The large black circles represent insulin molecules and the small white circles $Zn^{2+}$ ions.

amorphous, highly aggregated products (Fig. 4). In solutions with high zinc contents, the hormone takes up increasingly large amounts of metal as the pH is increased (*e.g.* 2.2 % at pH 7.2), and the solubility in the neutral range (pH 6 to 8) decreases sharply [93]. The amorphous precipitate slowly crystallizes at pH 5.6 to 6.0 [94].

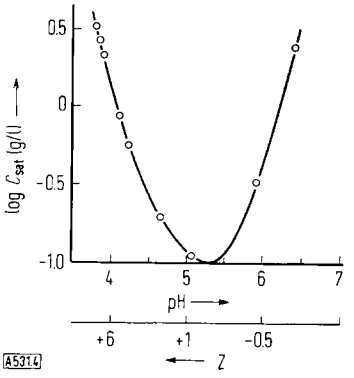

Fig. 4. Solubility of insulin in 0.1 N NaCl; the values of the charge $Z$ relate to the dimer (after *Fredericq* and *Neurath* [91]).
Ordinate: Logarithm of the saturation concentration in g/l.
Upper abscissa: pH; Lower abscissa: Charge $Z$.

Despite numerous investigations [95], the nature of the binding of zinc by insulin has not yet been elucidated. One of the two imidazole groups of the hormone is certainly involved [96]; the participation of the amino groups is not impossible [97], and that of the carboxyl groups has been stated to be necessary on theoretical grounds [80]. X-ray diagrams of crystalline zinc insulin, in contrast to those of lead insulin, can be interpreted in several ways. Possibly the zinc ion can occupy different positions in the insulin aggregates [41].

Zinc insulin in solution at pH > 7 has a particle weight of 36000 [98] to 48000 [99], *i.e.* it is present as a hexamer or octamer, in contrast to the metal-free hormone, which dissociates into the monomer to various extents under these conditions, depending on concentration [100]. Zinc insulin dissociates only at pH > 9 [101], and this process appears to be associated with a change in the conformation of the monomer [102]. At the same time, the hormone is inactivated [103]. Guanidinium chloride [104], urea [105], some salts [91], organic solvents [106], and detergents [107] deaggregate insulin.

Whereas the dimer predominates in acidic solutions (pH 2) at 20 °C, a thixotropic gel is formed at 80 to 100 °C, the micelles of which consist of fibrillar insulin [108]. The fibrils are up to 20000 Å long and about 80 Å in diameter [109, 110], and appear to be composed of four filaments having a diameter of 25 to 30 Å and a period of 1200 Å [110]. The width of 25 to 30 Å corresponds roughly to the diameter of the insulin dimer.

At pH 1, the fibrils form spherical aggregates [111], from which the "heat precipitate" is formed on continuous heating [112]. Fibrillar insulin is biologically inactive, but can be largely converted into crystallizable, active hormone by treatment with alkali at 0 °C and pH 11 to 11.5 [113, 114] or by dissolution in cold 20 % hydrochloric acid [115], or in phenol [116] or urea solutions [117]. The basic fish insulins cannot be precipitated [118], whereas the bis-S-sulfonate of the B chain of bovine insulin readily forms fibrils [119].

Since fibrils are also formed from acetylated and esterified insulin [90], and since no disulfide exchange occurs [120], the association must be due to non-polar forces [121].

Insulin forms compounds with many substances; for example, the well-defined mixed complexes with zinc and protamine [122].

## Stability

Pure insulin is remarkably stable, and remains active for years in a sterile solution at pH 4 and 2 °C. The activity of a crystalline sample was found to be unchanged after storage for two years at 0 °C, whereas a 20 % loss of activity occurred after one year at 20 to 25 °C [124].

Insulin is rapidly decomposed in alkaline solutions, as a result of hydrolysis of the amide linkages and degradation reactions on cystine. Dilute acids cleave the hormone into several components [48], hydrolysis occurring preferentially at the asparagine and glutamine residues [125]. In non-aqueous media, an N → O peptidyl shift also occurs in serine and threonine residues [126]. On acidic and basic ion exchangers, bonds at the carboxyl end of the B-chains appear to be preferentially hydrolysed [127], while concentrated urea cause carbamylation [117, 128] without reduction of activity. Reducing agents such as hydrogen sulfide and cysteine rapidly inactivate the hormone.

Insulin is very sensitive to high-energy radiation. Thus sterilization with $^{60}Co$ $\gamma$-rays leads to rapid inactivation [130] as a result of changes in the polar and the aromatic groups [129]. X-rays and deuterons have a similar effect [131]. Ultraviolet light breaks down the cystine groups; the tyrosine units are also decomposed, though more slowly [132]. Photooxidation, on the other hand, leads to preferential breakdown of the imidazole group of histidine [133]. Ultrasonic degradation is less specific [134]. Insulin can form monomolecular layers at interfaces [135]; unlike other globular proteins, it is not denatured in the process.

## Analysis

A gravimetric method for the determination of insulin makes use of fibril formation [17]; physico-chemical and chromatographic analyses [136–138] have been reported, but these are suitable only for concentrated insulin. Biological methods are preferred for crude products, body fluids, *etc.*, since these, and particularly the immunological methods, permit the determination of insulin at concentrations down to 0.1 ng/ml.

The biological activity of insulin is expressed in international units (I.U.). Crystalline bovine insulin has an activity of 25 to 27 I.U./mg. Insulins from different animal species appear to have the same activity in spite of their different amino acid sequences. For example, insulin from the fish *Lophius piscatorius* has an activity of 26 to 27 I.U. determined on rat adipose tissue [21]. An exception appears to be guinea-pig insulin, which differs from bovine insulin in 17 amino acids, and has a higher activity in guinea pigs than in mice [74].

The activity of pure insulin is determined by the mouse convulsion test [139] or by the rabbit blood-sugar method [140]. Several biological and immunological methods have recently been described. Owing to their greater sensitivity these can also be used to determine very small quantities of insulin in plasma. The biological *in vitro* method now most commonly used is that described by *Renold et al.* [141], in which the stimulation of the conversion of [1-$^{14}C$]glucose into $^{14}CO_2$ in epididymal rat adipose tissue is measured. The most commonly used immunological method is that described by *Yalow* and *Berson* [142]. A useful combination of biological and immunological methods has been described by *Froesch et al.* [143]; the precipitation in the two-antibody system [144] proceeds rapidly and easily, but does not appear to be absolutely specific (cf. the review by *Renold et al.* [145]). Biological *in vitro* methods for plasma insulin generally give higher results than immunological methods; it is not yet known whether the biological methods determine insulin *and* insulin-like factors, or whether the immunological method covers only part of the plasma insulin, the so-called "unbound" [146] or "typical" [147] insulin or "antibody-nonsuppressible insulin-like activity" [143]. Recent results on nonsuppresible insulin [148] cast doubt on its physiological importance. The insulin content of human plasma probably varies between about 20 $\mu$U/ml (immunological method) to 100 $\mu$U/ml (biological method with adipose tissue from the rat), *i.e.* 1 l of plasma contains about 1 $\mu$g of insulin.

## Substitution Reactions

In 1927, *Freudenberg* began a systematic study of the action of various reagents on insulin and the resulting changes in activity. More recently this work has been

continued particularly by *Fraenkel-Conrat* [149]. In this way it was hoped to gain an insight into the relationship between chemical structure and biological activity. If it is assumed that a functional group is not essential to the action of the hormone if chemical modification of this group has no influence on the activity, the three amino groups, the aliphatic hydroxyl groups, and the guanidine residue are unnecessary, whereas the amide, phenolic hydroxyl, imidazole, and carboxyl groups are essential to the activity [133, 149–151].

No consideration is given the fact that substitutions also cause a marked change in the pK and solubility of a protein. Thus with increasing degree of esterification, the isoionic point of insulin is diplaced from 5.6 to 13.0. Changes in solubility should be accompanied by parallel changes in activity [152]. On sulfation, a progressive loss of activity is observed as the sulfate content increases, *i.e.* as the isoionic point decreases [151]. The fundamental error possible in estimating the "value" of a group from substituent effects is shown by *du Vigneaud's* work on oxytocin (activity of oxytocin: 546 I.U./mg, that of acetyloxytocin: 1.7 I.U./mg, but that of deaminooxytocin: 803 I.U./mg.).

Two substitution reactions of insulin are of practical importance: iodination and sulfation. Insulin is sulfated on amino, tyrosine, and histidine groups by the pyridine-sulfur trioxide complex [151], and by chlorosulfonic acid in pyridine [153]. Concentrated sulfuric acid at low temperatures causes preferential esterification of the aliphatic hydroxyl groups, with less attack on the aromatic hydroxyl groups [154]. Slightly esterified insulins are hypoglychemically active and not very strongly antigenic, and are scarcely bound by antibodies already present [155]; they are now produced for the treatment of insulin-resistant diabetics.

The iodination of insulin occurs *ortho* to the hydroxyl groups in the four tyrosine residues. Thus it is possible to obtain $3^4-1 = 80$ different iodoinsulins, and more by additional reaction with the histidine residues [157]. The iodinating agents normally used are $I_3^-$,$I^-$/Chloramine T, and ICl. No conditions leading exclusively to mono- or diiodoinsulins (more highly iodinated insulins are biologically inactive [158]) are known as yet, though the ease of reaction should differ for the four tyrosine residues [87, 159] ($A_{19} > A_{14} > B_{16} > B_{26}$ [160]). The mixture of iodoinsulins can be fractionated by density-gradient electrophoresis [156].

Insulins labeled with $^{131}I$ and $^{125}I$ [138, 161] are the most important indicators for small quantities of insulin. Strongly radiating samples (>10 mCi/mg) undergo rapid self-decomposition [142, 162], but the rate of this decomposition is reduced by dilution with foreign protein, *e.g.* human serum albumin [157]. Despite its wide use it is not yet known whether iodinated insulin behaves in the organism in the same manner as the native hormone.

Insulin labeled with $^{82}Br$ [163] is too short-lived, and the hormone sulfated with $^{35}S$-labeled $H_2SO_4$ is probably more interesting [164]. Insulins containing $^{35}S$, $^{14}C$, and $^{3}H$ are obtained by biosynthesis with labeled amino acids, and are significant for biochemical studies of insulin. Their isolation is tedious, and the specific activities, even of the directly tritiated hormone, are low [165]. Several authors have acylated the amino groups of insulin with $^{14}C$-labeled amino acids, but there is no evidence that these products behave like the native hormone. It is preferable to synthesize insulin with labeled amino acids [166].

## Enzymatic Degradation

The native hormone is very highly resistant towards hydrolysing enzymes *in vitro*, the zinc content appearing to be particularly important in this respect (*e.g.* leucine aminopeptidase digests only metal-free insulin [168]). Native insulin is cleaved only slowly by trypsin and chymotrypsin [169]; however, as soon as one bond has been broken, the remainder of the hydrolysis proceeds rapidly [170]. Insulin is most strongly attacked by subtilisin [171].

Careful degradation with carboxypeptidase [79] is interesting in that fully active dealanine-insulin can be

obtained by removal of only the C-terminal amino acid from the B-chain [172]. On further digestion with carboxypeptidase, the amide linkage in the C-terminal asparagine $A_{21}$ is broken. The activity of the resulting dealanine-deamido-insulin is about two-thirds that of insulin [173–175]; however, if the aspartic acid unit is also removed, the product (dealanine-deasparagine insulin) in inactive [175, 176].

Trypsin cleaves only the B-chain, slowly between $B_{22}$ and $B_{23}$, and rapidly between $B_{29}$ and $B_{30}$ [174]. "Deoctapeptide-insulin" is inactive [175, 177].

Leucine aminopeptidase rapidly breaks down the B-chain from the hydrophobic N-terminal end. The first six amino-acid residues are supposed to be unnecessary for the hypoglycemic action of insulin [168].

Enzymatic reduction of the disulfide bridges is insignificant *in vitro* [178], but is apparently the first step in the *in vivo* degradation of insulin.

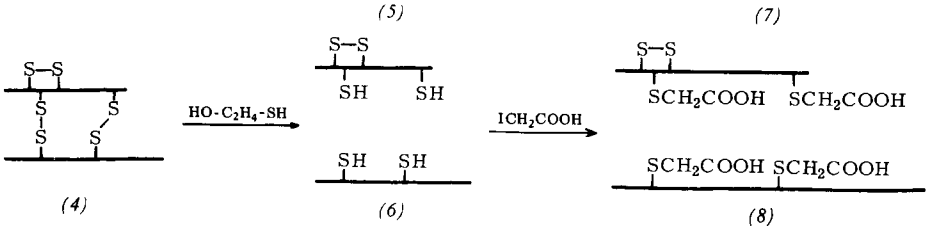
## Non-Enzymatic Degradation Reactions

The primary β-amide group in the C-terminal asparagine residue ($A_{21}$) is particularly sensitive to hydrolysis [173]. Therefore, during the acidic extraction of the pancreas, insulin is already partially degraded to deamidoinsulin, which is still almost fully active [26], and which can be isolated by countercurrent distribution [26] and by ion-exchange chromatography [179].

Peroxyacids break all three disulfide bridges in insulin, each cystine residue giving two cysteic acid residues. The so-called "oxidized chains" are stable, hypoglycemically inactive compounds, which cannot be selectively reduced, but which are degraded by proteases [167].

The chemistry of the reductive and sulfitolytic cleavage of insulin is much more interesting. When the protein is treated with hydrogen sulfide or thioglycollic acid [180] in acidic media, the reduction occurs slowly, whereas rapid reduction takes place in alkaline media. The reduction with mercaptoethanol shows practically no pH-dependence. The hormone becomes inactive as soon as one of the three cystine bonds is broken [181]. Alcohols and heavy-metal ions accelerate the reduction [182], which proceeds only incompletely in the absence of denaturing agents [180]. To ensure cleavage of all three disulfide bonds, therefore, the reaction is generally carried out in 6 to 8 M urea solution [183] or with a many-hundredfold excess of mercaptoethanol [184]. Since thiol groups in the reduced chains are oxidized even in air, they are usually irreversibly blocked in preparative work by carboxymethylation ($RS-CH_2COOH$) with iodoacetic acid [21, 184, 185], amidomethylation ($RS-CH_2CONH_2$) with iodoacetamide [180, 186], or aminoethylation ($RS-CH_2CH_2NH_2$) with 2-bromoethylamine [123], or reversibly blocked by conversion into the *S*-sulfonates (Bunte salts, thiosulfates, $RS-SO_3^-$).

Electrochemical measurements show that the two disulfide bridges linking the chains are easier to reduce than the intrachain bridge [187]; however, owing to the disulfide exchange reaction, it is difficult to use this effect for the preparation of a 7,20-dithiol-6,11-disulfide A-chain *(5)*. On the other hand, if insulin is treated for only a short time with eight equivalents of mercaptoethanol, followed by blockage of the SH groups with



iodoacetic acid, the compound *(7)* can be isolated in a yield of about 65 % [188], *i.e.* the $A_{6-11}$ disulfide bridge is more difficult to attack than the other two S–S bridges.

This is also confirmed in the oxidative sulfitolysis in accordance with

$$RS-SR' + 2\,SO_3^{2-} \rightleftharpoons RS-SO_3^- + R'S-SO_3^- + 2\,e^-,$$

in which air, $Cu^{2+}$ [189], air with traces of $Cu^{2+}$, 1,2-diiodoethane [190], *o*-iodosobenzoate, or sodium tetrathionate [191] can be used as oxidizing agent.

The reaction goes to completion in the presence of urea and guanidine [192, 193, 206, 207], but in their absence it leads to a complex mixture, which has recently been resolved and characterized [194]. The compounds isolated from the mixture included several that were not expected to exist under the conditions of the reaction, *e.g.* disulfides of the A-chain of the type $[A(SS)_2]_n$ where $n$ = 1,2(3,4?). The most interesting product, the 7,20-bis-*S*-sulfonate with the 6,11-disulfide ring intact, is formed in a yield of up to 30 % [192, 195]. This substance, like the A-chain disulfides, was stated to have a low insulin activity [196], but these findings have not been confirmed [193, 197]. It is relevant in this connection that sulfur dioxide poisoning in animal experiments leads to inactivation of the insulin [198].

The two *S*-sulfonates are the most important derivatives of the insulin chains from the preparative point of view. On the one hand they are sufficiently stable for easy isolation [190–192, 199, 207, 209], and on the other they can be readily converted into the reactive thiol chains by excess of thiol [205–207, 210], and can also be useful for the synthesis of disulfides:

$$RS{-}SO_3^{\ominus} + H{-}SR' \rightleftharpoons RS{-}SR' + HSO_3^{\ominus}$$

$$RS{-}SR' + H{-}SR' \rightleftharpoons RS{-}H + R'S{-}SR'$$

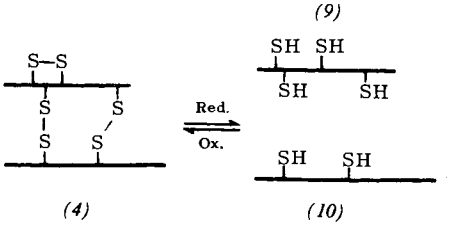
$$R'S{-}SR' + HSO_3^{\ominus} \rightleftharpoons R'SH + R'S{-}SO_3^{\ominus}$$

The thiosulfate chains play an important part in synthetic studies on insulin.

## Regeneration and Resynthesis

Of the many attempts to regenerate native hormone from chemically modified insulin, only a few have been successful. *Freudenberg* and *Dirscherl* [200] recovered part fo the biological activity from acetylated insulin by treatment with alkali. Insulin denatured with hot acids can be reactivated [113–117]. However, the product could be deamido-insulin, since elimination of ammonia is to be expected during precipitation [201].

The oxidative regeneration of insulin from reduced samples is difficult and has been successfully carried out only with partially reduced products [58, 202]; however, the results of these studies have been questioned [203]. One argument against the possibility of resynthesis is the fact that the linkage of the insulin chains during the oxidation can lead to a very large number of products. If the SH chains *(9)* and *(10)* are oxidized in very dilute solutions, intramolecular reactions should, in accordance



with the Ruggli-Ziegler principle, lead to three monomeric bisdisulfides of the A-chain *(11)*, *(12)*, *(13)* and the disulfide *(14)* of the B-chain. These conditions are ideal for the $A_{6-11}$ ring closure, but extremely unfavorable for the formation of the $A_7{-}B_7$ and $A_{20}{-}B_{19}$ bridge, which should occur only at higher protein concentrations. In this case, however, eleven isomers *(15)* to *(25)* of the hormone, as well as an infinite number of oligomers and polymers of the individual chains and of both chains, are to be expected in addition to insulin *(4)* itself. Thus the probability of the formation of insulin by the simultaneous oxidation of the SH chains is small [204, 205].

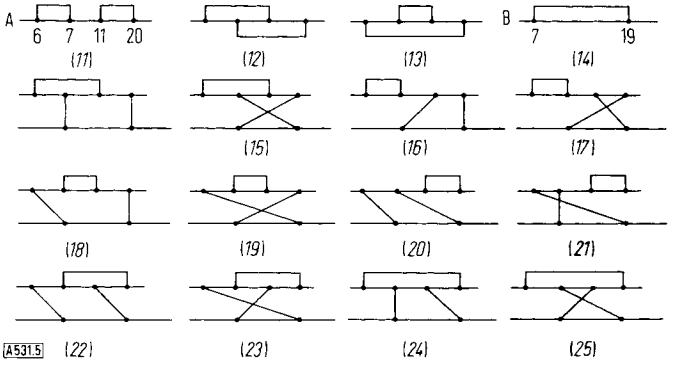


Fig. 5. Schematic representation of the A- and B-chains of insulin with intrachain disulfide bridges (top line) and the isomers of insulin that can result from the formation of different interchain disulfide bridges. Native insulin is shown at the beginning of the second line.

[205] *K. M. Pruitt, B. S. Robison*, and *J. H. Gibbs*, Biopolymers *4*, 351 (1966).

It was therefore even more surprising that *Dixon* and *Wardlaw* [206] and *Tsou et al.* [207] in 1960 were able to resynthesize insulin from polypeptide chains that had previously been completely separated. The chains were separated as S-sulfonates and purified. The inactive chains were reduced with an excess of thiol and precipitated as the SH chains *(9)* and *(10)*. When the precipitates were mixed and oxidized with air at pH 8.5 to 9.0, they gave products having an insulin content of 1 to 2 %.

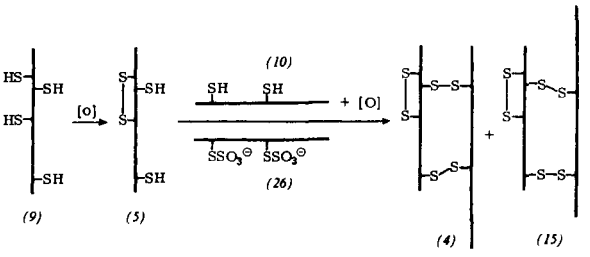
The fact that the activity of the oxidation products is due to insulin was shown by the reaction with insulin antiserum [206] and by the isolation of crystallizable insulin from the resynthesis products by extraction with acidified butanol [207].

By variation of the reaction conditions, the yield was increased initially to 5 to 10 % [205, 208, 209], and then by *Tsou et al.* [210] to 50 %. However, the authors of a recent paper [211] still report yields of only 10 to 20 % (cf. [205]); on repeating this work, *Zahn et al.* obtained a maximum yield of 25 %.

In the method used by *Tsou et al.*, the A-chain is used in a 50 % excess, and the reaction is carried out at the unusual pH of 10.6. Under these conditions insulin [101], and probably also the individual B-chains, does not aggregate. On resolution of the insulin resynthesis mixtures by gel filtration, electrophoresis, or countercurrent distribution [212], a substance having the amino-acid composition $[AB_2]_n$ was isolated as the main product, together with $[AB]_n$ (insulin) and $[A]_n$, but very little $[B]_n$. $[AB_2]_n$ may be formed by two routes: by reaction of the poly-B-chain and by the recently discovered [194] reaction of the thiol-B-chain with insulin.

The simultaneous oxidation of the chains, therefore, does not necessarily lead to a statistical mixture. *Zahn et al.* [213, 214] also obtained maximum insulin yields of 50 % when they first oxidized the A chains alone in the thiol form *(9)* until 50 % of the SH groups had been converted into disulfide groups, then added the equivalent quantity of thiol-B-chain *(10)* and completed the oxidation (pH 8.9).

In this procedure, the more stable [187, 192] $A_{6-11}$ disulfide ring *(5)* may be formed first. On subsequent combination with the B-chain, practically the only product, apart from native insulin, should be the isomer with the antiparallel chain arrangement *(15)*. The insulin yields could be further increased (maximum 70 %) [214, 215] by reaction of the B-chain in the form of its *S*-sulfonate *(26)* with preoxidized A-chain *(5)*; in this case the formation of $[B]_n$ and $[AB_2]_n$ is probably prevented.



Insulin resyntheses using oxidizing agents other than air, *e.g.* diiodoethane and dimethyl sulfoxide [216], or the glutathione disulfide/triphosphopyridine nucleotide [216] and glutathione disulfide/glutathione insulin transhydrogenase systems [217], gave a maximum insulin yield of 11 %.

The resynthesis of insulin from natural chains has also been used for the preparation of "hybrid insulins" of immunochemical interest, in which the A- and B-chains are obtained from different species [209, 218].

## Synthesis

The general progress in peptide chemistry encouraged several research groups to synthesize peptide sequences of insulin after the publication of its formula. The main obstacle to a total synthesis appeared to be the linking of the chains. As soon as it was found possible to solve this problem, albeit only in low yields [206, 207], the way was open for a synthesis of insulin: it should be possible to synthesize the two polypeptide chains separately on the basis of *du Vigneaud*'s work [219], using *S*-benzylated cysteine residues and with permanent blocking of functional groups in the side chains, then to remove all the protective groups with sodium in liquid ammonia and link the resulting SH chains by oxidation. Though this total synthesis would not provide proof of the structure (for which the three disulfide bridges would have to be formed individually and in simple reactions), it would be the simplest route to synthetic insulin.

The plan of synthesis was correct; at the end of 1963 *Zahn* and his co-workers [10], and at about the same time *Katsoyannis* in collaboration with *Dixon* [11], succeeded in preparing sheep insulin. In 1965, research groups working in China under Professors *Niu*, *Wang*, *Hsing*, *Tsou*, and *Tsao* synthesized bovine insulin [220] which differs from sheep insulin in the amino acid (serine

instead of glycine) in position $A_9$ (Fig. 1). This hormone was also synthesized with a $^{14}C$-labeled glycine residue in position $A_1$ [166].

Human insulin (Fig. 1) differs from bovine insulin in having threonine instead of alanine in positions $A_5$ and $B_{30}$, and isoleucine instead of valine in position $A_{10}$. Whereas the synthesis of the chains [221–223] and of the peptide sequences that differ from those of sheep insulin [224, 225] proceeds normally, removal of the *S*-benzyl protective groups from the B-chain of human insulin has so far always led to destruction of the C-terminal threonine unit [222, 223]. As the amino-acid analysis shows, this also appears to apply to the product [221] described in 1966 as "synthetic human insulin". However, the $B_{30}$ unit is not essential to the hormone action [175].

The insulin syntheses published so far differ only in details of the method, and a scheme of the synthesis of *Zahn et al.* is shown in Fig. 6. The synthesis of the A-chain required 89 reaction steps, that of the B-chain 132 steps, while a further 3 steps were required to link the two chains. All reaction sequences were so chosen that changes in the 48 asymmetric centers were practically impossible [226].

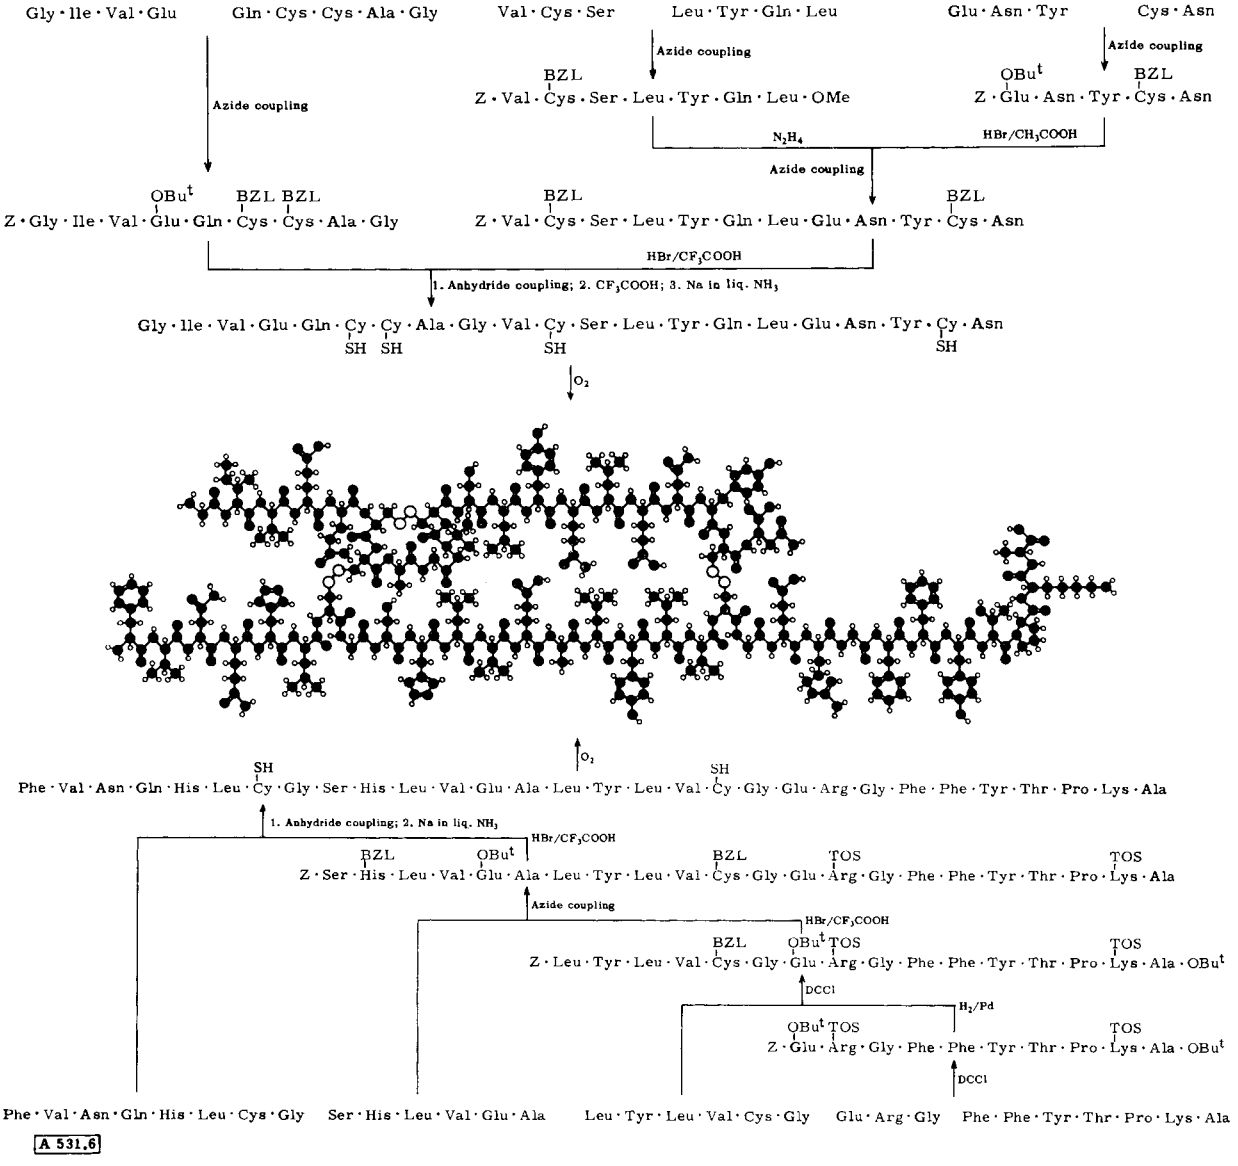

Fig. 6. Projection formula of sheep insulin (middle) and synthetic route, after *Zahn et al.* [10]. The chain fragments were synthesized by stepwise elongation by one amino-acid residue.
Abbreviations: BZL = benzyl, DCCI = dicyclohexylcarbodiimide, OBut = tert-butyl ester, OMe = methyl ester, TOS = *p*-toluenesulfonyl, Z = benzyloxycarbonyl.

Linkage of the chains was surprisingly easy. A stoichiometric mixture of the protected polypeptide chains was dissolved in liquid ammonia and treated with sodium; after evaporation of the solvent, the residue was dissolved in a buffer (pH 9.0), dialysed against water that had not been deaerated, and freeze-dried. The insulin content of the product was found by various methods to be 0.2 to 1.0 % (0.05 to 0.25 I.U./mg), and its activity could be completely neutralized with insulin

antiserum[227]. The yield obtained in the linking of the chains was of the same order as that obtained in the recombination of natural chains by the usual method at that time (no intermediate purification of the chains).

The combination of synthetic chains to native chains of the other type to give "semi-synthetic insulins" showed that the synthetic A-chains[11,228] give more insulin than the synthetic B-chains[11,229]. Since the discovery in 1961[208] that natural insulin chains that have been treated with sodium in liquid ammonia give less insulin than untreated chains, it is known that on removal of the final protective groups, the B-chain in particular is degraded very rapidly, mainly between positions 27 and 28 (–Thr-Pro–)[230]. For this reason, repetition and attempted improvement[222,231,232] of *Zahn*'s synthesis have not led to an increase in yield, but simply demonstrate the reproducibility of the synthesis.

After removal of the protective groups the synthetic chains can be freed from cleavage products and other impurities *via* the *S*-sulfonates[211]. Material purified in this way must be equivalent to the Bunte salt chains obtained from natural insulin and should, on purification, give products containing at least 0.25 I.U. of insulin/mg (Table 1). The isolation of pure crystalline insulin from synthetic material[220,222,232] is simpler if the insulin chains are purified before being combined, but the overall yield is then lower.

The yields (based on the C-terminal amino acids) in one synthesis of *Zahn et al.* were 2.9 % for the protected A-chain, 7.0 % for the protected B-chain, and 0.25 to 0.55 % for the insulin content of the final product. Similar yields were probably obtained in the Chinese and American work. An economical synthesis of insulin is probably impossible by this route.

Table 1. Biological activities of synthetic insulin preparations

| Product | Activity (I.U./mg) | Authors |
|---|---|---|
| Sheep insulin | 0.05–0.25 [a] | 1963 *Zahn et al.* [10] |
| Sheep insulin | 0.005–0.017 [b] | 1964 *Dixon* [11] |
| Bovine insulin | 0.30–0.60 [b, c] | 1965 *Niu, Wang, Hsing, et al.*[220] |
| Human insulin | *ca.* 0.48 [b] | 1966 *Katsoyannis et al.* [221] |

[a] Not corrected for water and salt contents.

[b] Chains purified *via* the *S*-sulfonates before being linked.

[c] The insulin was isolated in the crystalline form (>20 I.U./mg) from this material.

A solution to this problem may be offered by the peptide synthesis on solid supports[233] developed by *Merrifield*. The A- and B-chains of human, bovine and sheep insulins were synthesized in a few weeks by this method[223,234]. The yields of purified protected B-chains, for example, were 45 to 60 %. Since *S*-benzylated cysteines were also used in these recent studies, so that the protective groups had to be removed by treatment with sodium, the activity of the insulin obtained was only of the usual order of magnitude.

*Zervas et al.*[235] have started development of selectively cleavable protective groups for sulfur, and the progress made in the next few years will probably allow removal of the protective groups under mild conditions.

## Biosynthesis

Insulin is synthesized and stored in the β-cells of the Langerhans islets. The islets are scattered over the entire pancreas, of which they amount to only about 1 %. Investigations on the biosynthesis of insulin in the pancreas of mammals with labeled amino acids are therefore difficult. Insulins biosynthetically labeled with $^{3}H$ and with $^{14}C$ have been isolated from ox, calf, and rat pancreases[236–241]. Investigations are easier on the isolated islet tissue of some types of fish, the exocrine pancreas of which is physically separate from the endocrine pancreas. The metabolism of isolated islet tissue was first studied in fish islets[242,243]. Owing to the absence of exocrine tissue, it was also possible, after incubation with labeled amino acids, to isolate insulin of high specific activity[244,245].

The biosynthesis of insulin appears to follow the general pattern of protein biosynthesis. Thus it has been shown[246] that insulin is synthesized in the endoplasmatic reticulum (by the ribosomes). Puromycin, an inhibitor of protein biosynthesis, also inhibits the biosynthesis of insulin[247,248]. Results on labeled insulin from fish islets[248] indicate that the synthesis of the insulin B-chain begins at the N-terminal end, in agreement with results obtained for other proteins such as hemoglobin, lysozyme, or ribonuclease.

A special problem in the biosynthesis of insulin is the linking of the two chains *via* disulfide bridges. There are two fundamental possibilities. A single-chain precursor of insulin containing all the amino acid residues of

the molecule and possibly also a hypothetical link may be formed first. The disulfide bridges could be formed in this precursor, as in ribonuclease or in lysozyme, as intrachain bridges, whereupon hydrolytic cleavage at one or more points would lead to the two-chain insulin molecule. This is the route followed in the synthesis of chymotrypsin, in which the single-chain chymotrypsinogen is formed first, and this is then split into the three chains of chymotrypsin. The second possibility for the biosynthesis of insulin involves the separate synthesis of the two chains followed by the formation of the correct interchain disulfide bridges.

*Wang* and *Carpenter* [249] sought a single-chain precursor of insulin in fractions of pancreas extracts, but found none. *Givol et al.* [250] incubated insulin with a microsomal enzyme from liver that catalyses the exchange of sulfhydryl and disulfide groups in ribonuclease. From the fact that this enzyme could inactivate insulin, *Givol et al.* concluded that the correct disulfide bonds are not favored thermodynamically, and that the synthesis of insulin *in vivo* from the two chains is therefore unlikely. However, the high yields obtained in the *in vitro* recombination of isolated A- and B-chains (see above) now suggest that the combination of separately synthesized chains *in vivo* would be possible. The separate biosynthesis of the A- and B-chains has been demonstrated in doubly-labeled insulin from fish islets [248], so that a single-chain precursor of insulin can very probably be ruled out.

If *Humbel*'s results [248] can be confirmed, a further question is whether linkage of the two chains *in vivo* occurs spontaneously, or whether the process is catalysed by an enzyme ("insulin zipase" [246]). A glutathione insulin transhydrogenase [252] that can split insulin into the A- and B-chains by reduction of the disulfide bridges [253, 254] has been isolated from liver. The reverse process, *i.e.* the synthesis of insulin from the two reduced chains, could also be catalysed by the enzyme, but the extent of the resynthesis was low [217]. *Kotoulas*, *Morrison*, and *Recant* [255] detected glutathione insulin transhydrogenase activity in isolated islets from rat pancreas, and *Varandani* and *Tomizawa* [256] isolated the enzyme from ox pancreas. Thus an enzyme capable of reductive cleavage of insulin appears to be present not only in the liver, but also in the pancreas; it is not yet known whether the function of this enzyme is the catalysis of the combination of the separately synthesized insulin chains or the cleavage of insulin.

Little is known about the regulation of the biosynthesis of insulin. *Smith, Taylor*, and *Parry* [239] discovered that the synthesis of insulin in ox pancreas is slightly stimulated by glucose, whereas glucose has no effect in fish islets [243, 244]. It can be calculated from the rate of *in vivo* incorporation of leucine into insulin in fish islets [242, 245] that about 12 days are required for the synthesis of the amount of insulin normally present in the pancreas. The human pancreas contains about 250 I.U. of insulin (10 mg), *i.e.* five to ten times the daily consumption of insulin.

## Secretion

After its biosynthesis in the endoplasmatic reticulum, insulin is stored in the secretory granules, which can be selectively stained with insulin antibodies coupled with fluorescein [257]. β-Granules have been isolated from fish islets by centrifugation in a density gradient [258]. Insulin forms about 10% of the granule protein [258]. Thus insulin may be stored in the form of a complex with other proteins. *Lindner* [122] first described such a complex ("native insulin") of insulin with a basic protein of low molecular weight. *Antoniades et al.* [259] postulated a similar complex, since pancreatic insulin is bound by a cation exchanger at pH 6.6, whereas the isoelectric point of crystalline insulin is 5.3. On the basis of the difference in solubility of crystalline and pancreatic insulins, *Meade et al.* [260] also support a special form for pancreatic insulin, though they were unable to confirm the findings of *Antoniades et al.* [259].

The islet cells contain large quantities of zinc [261, 262], which could be important in the storage of insulin. Recent investigations on the behavior of zinc, β-granules, and extractable insulin after glucose infusion [263] indicate that the role ascribed to zinc in the secretion of insulin is open to question [262].

The transport of insulin from the synthesis site in the ribosomes to the granules and the actual secretion process, *i.e.* the fusion of the granule membrane with the cell membrane, with simultaneous liberation of insulin into the blood capillaries, has been studied [264] electron-microscopically, and appears to be similar to the secretion process in the exocrine pancreas [265].

The secretion of insulin is regulated mainly by the glucose and insulin levels in the blood [266]. Recent work on pancreas tissue *in vitro* shows a direct dependence of the rate of secretion on the sugar concentration [267, 268]. Simultaneous inhibition of the insulin synthesis by dinitrophenol has no effect on the secretion [269]. The secretion is inhibited by addition of insulin to the pancreas preparation [270]. On the basis of experiments with substances that inhibit the degradation of glucose [271, 272], it is thought that the secretion is stimulated, not by glucose itself, but by a degradation product. Preliminary results indicate that intestinal glucose resorption increases the glucagon level, which in turn stimulates insulin secretion [251].

## Mode of Action

Insulin is an anabolic hormone in the intact organism, *i.e.* it promotes the synthesis of glycogen, fat, and protein. An elegant method by which all the symptoms of insulin deficiency can be produced is the injection of guinea-pig bovine-insulin antiserum [273] into rats or mice. In addition to an increase in blood sugar concentration, other symptoms of acute diabetes such as increased plasma fatty acid concentration, elimination of glucose and ketones in the urine, negative nitrogen balance, and increasing blood acidosis are observed [274].

The action of insulin has been studied *in vitro* mainly on isolated muscle and adipose tissue. Insulin effects in cell-free systems have been described, but it appears that only its effect on the swelling of the mitochondria is reproducible [275], and this seems to be a general property of disulfides.

There are a number of theories in which most of the effects of insulin are attributed to one primary effect. The best known of these is the permeability theory proposed by *Levine* and *Goldstein* [276], which is still used, though not in its original form [277]. *Levine* and *Goldstein* postulated that the primary effect of insulin is to promote the entry of glucose into the cell. The increased synthesis of glycogen and fat, the increased oxidation of glucose, the decreased degradation of protein and fat, and the prevention of ketone formation can be easily explained on this basis. This theory is supported by numerous results obtained *in vivo* and *in vitro* (cf. [277]).

However, an increasing number of insulin effects observed recently can no longer be explained by increased glucose transport. For example, insulin also promotes the transport of some amino acids [278, 279] and of $K^+$ [280], even in the absence of glucose. Insulin also inhibits the liberation of free fatty acids and of glycerol from adipose tissue, again in the absence of glucose [281, 282]. *Rodbell* [283] also showed in work on isolated fat cells that all the effects of insulin on adipose tissue can be imitated by phospholipase C. He postulated that the action of insulin on the plasma membrane is due to modification of the membrane lipids. This would expand the original glucose permeability theory into a general membrane permeability theory, but some of the effects of insulin cannot be explained even with the aid of this extended theory. These include the stimulation of protein synthesis [284], which is clearly distinguished from the influence on the amino-acid transport [279], the stimulation of RNA synthesis [285, 286], the stimulation of glycogen synthetase [287], and the induction or repression of a number of enzymes [288, 289].

In order to preserve the unitary concept of the mode of action of insulin, *Krahl* [290] and *Hechter* [291] suggested that the change occurring during the primary reaction of the hormone with the cell membrane could propagate itself into the cell. The experiments carried out by *Cadenas et al.* [292] and by *Carlin* and *Hechter* [293] suggested a disulfide-sulfhydryl exchange between insulin and the cell membrane. A similar process had previously

been postulated for the action of adiuretin [294], but this theory had to be abandoned [295] when it was shown that analogues of adiuretin that do not contain disulfide bridges are also active, though to a smaller extent.

Hormones are now often regarded as allosteric effectors, which can either suppress or induce the transcription of genetic information [296]. This theory is so general and flexible that it is difficult to refute. An important objection in the case of insulin is probably the fact that even when the synthesis of RNA is strongly inhibited, the effect of insulin on transport processes through membranes remains unchanged [297].

We are still a long way from finding a satisfactory explanation of the mode of action of insulin. A promising means of clarifying this question appears to be the investigation of the active center of insulin. Once the active group in the insulin molecule is known, it will be possible to make a more systematic search for a suitable receptor at the cell membrane.

## Biological Inactivation

From the pancreatic vein, insulin first passes into the liver, where approximately half of it is degraded and removed from circulation [298,299]. The half-life of insulin is about 30 minutes in man [300]. The two principal breakdown sites are the liver and the kidneys. The insulinase described by *Mirsky* [301] is probably identical with insulin glutathione transhydrogenase [217,252–254,256,302], which catalyses the reductive cleavage of the interchain disulfide bridges of insulin, the chains then being hydrolysed to smaller fragments [303,304]. The enzyme has no absolute substrate specificity, and vasopressin and oxytocin are also degraded, though more slowly [217].

*Ensinck et al.* [305] concluded from studies on $^{131}$I-insulin, which was incubated with partially purified glutathione insulin transhydrogenase, that the reduced insulin B-chain is bound to albumin and circulates in the plasma, where it competitively inhibits the action of insulin on muscles [306]. These results have not yet been confirmed (cf. [307]), nor has the inhibition of the glutathione-insulin transhydrogenase by the reduced B-chain reported by *Langdon* [308]. It is unlikely [193,197] that the partially reduced A-chain [196,215,309] or the reduced B-chain [308] have any residual biological activity.

Not only the liver, but also the pancreas [255,256,310,311], muscle tissue [312], and adipose tissue [312,313] appear to have the ability to cleave insulin reductively [255,256] or proteolytically [310–313].

## Immunochemistry

The antigenic nature of insulin was established by *Banting et al.* [314], who detected insulin-neutralizing antibodies in the serum of a schizophrenic patient who had been treated with insulin. *Moloney* and *Coval* [315] showed that guinea-pigs form antibodies that neutralize pig, bovine, sheep, mouse, and rabbit insulins. The electrophoretic behavior of $^{131}$I-insulin in normal serum is similar to that of albumin, whereas $^{131}$I-insulin in the serum of diabetics that have been treated with insulin is bound to the γ-globulins [300]. Fortunately for all diabetics, who rely on insulin from another species, insulin is a weak antigen, but the existence of specific insulin antibodies has now been established by these and other investigations (cf. [316]).

Insulin-binding and insulin-neutralizing antibodies exhibit no pronounced species specificity. Thus bovine and pig insulin antibodies react not only with bovine and pig insulins, but also with mouse [315], whale, dog, rabbit [317], sheep, horse, monkey [318], and human insulins [300,319]. However, quantitative differences do exist [320], these differences increasing with the differences in the primary structures of the insulins. Thus the reaction of cod insulin [321] or bonito insulin [317] with anti-bovine-insulin serum is weaker than that of bovine insulin.

When bovine insulin is injected into guinea-pigs, antibodies can be detected in the serum after a time, but the guinea-pigs do not become diabetic. On the other hand, their serum neutralizes mouse insulin, and mice become diabetic when such a guinea-pig serum is injected into them [274,315,316,318]. In general, insulin antibodies do not appear to react with circulating insulin of the test animal that produces the antibody [322]. *Moloney* [318] therefore postulated a special form of endogenous insulin, which differs from extracted insulin (from the pancreas or from serum) used for immunization.

This appears to be supported by the results obtained by *Renold et al.*[323], who detected antibodies for extracted bovine insulin in cattle after injection with bovine insulin. Other authors[324, 325] have reported antibodies for extracted pig insulin in a pig.

*Berson* and *Yalow*[326] observed antisera that could distinguish between sperm whale and pig insulins, even though the amino-acid sequences of these two insulins are thought to be identical. *Berson* and *Yalow* concluded that the tertiary structure of proteins can differ even when the amino-acid sequences are the same. However, this result should be viewed with caution until absolute proof of the purity and of the identical amino-acid sequences of the two insulins is available.

The groups in the insulin molecule that are involved in the binding of antibodies are probably neither the N-terminal amino acids[327] nor the C-terminal sequence $B_{23-30}$[328]. *Arquilla*[327] has discussed the possibility that $^{131}$I-insulin differs immunologically from uniodinated insulin, since iodination of insulin occurs mainly in the tyrosine residues of the A-chain[329], which are probably important to the antigenic action. By hybridization of the chains of bovine and cod insulins, *Wilson, Dixon,* and *Wardlaw*[209] showed that the immunologic specificity of insulin is determined primarily by the A-chain. The immunologic behavior of bovine-A-cod-B insulin towards anti-bovine insulin is similar to that of bovine insulin, whereas cod-A-bovine-B insulin behaves like cod insulin. *Yagi, Maier,* and *Pressman*[330] prepared antibodies against *S*-sulfonated ($S-SO_3^-$) A- and B-chains. Antibodies against such A-chains reacted only with A-chains, whereas antibodies against such B-chains reacted with B-chains and with insulin. Insulin antibodies reacted with insulin, weakly with the B-chain, and not at all with the A-chain. It was concluded that the insulin molecule contains several (three?) antigenic regions. This conclusion was recently confirmed by investigations[327] on insulin antibodies from pure guinea-pig strains, by cross tests with numerous insulins and their antisera, as well as with *S*-amidomethylated insulin chains and their enzymatic hydrolysates[186]. Surprisingly, even a relatively small synthetic cystine peptide of the insulin B-chain reacts as a complete antigen[331].

Insulin binding antibodies frequently occur in the serum of diabetics who have been treated with large doses of insulin, but there is no strict correlation between insulin-binding capacity and insulin requirement. The antibodies in the serum of diabetics appear, above, all to retard the degradation of insulin[332].

# Methods and Applications of Quantum Chemistry

## Part I: Physical and Mathematical Basis

BY DR. W. KUTZELNIGG

THEORETICAL CHEMISTRY GROUP, UNIVERSITÄT GÖTTINGEN (GERMANY)

*After an introduction to the fundamental concepts of quantum mechanics it is shown how to describe a chemical system in the language of theoretical physics. The equations which one obtains can not, in general, be solved in closed form. Approximate numerical methods that furnish sufficiently accurate solutions for many problems of interest are, however, available. The most important of these are presented briefly, and are given physically visualizable interpretations as far as this is possible. Special attention is devoted to more modern methods of quantum chemistry, to the basic assumptions underlying them, their scope, and their limitations. Treatment of the theory of the chemical bond is reserved for Part II.*

### 1.1. Introduction

Although chemists nowadays use many concepts derived from quantum theory, they often do not know their real meaning and the conditions under which they can be identified with quantities and ideas derived from chemical experience.

The first part of the present article is concerned with the principles on which current quantum-chemical methods are based. Its aim is to aid chemists towards a more critical appreciation of particular applications of quantum chemistry.

In principle, quantum chemistry enables us to calculate bond energies, dissociation energies, ionization potentials, electron affinities, frequencies and intensities of spectral transitions, electron densities, spin densities, dipole moments, polarizabilities, equilibrium internuclear distances, force constants, potential barriers for internal rotations, basicity constants, and many other properties of molecules, ions, and atoms without knowledge of empirical data of these systems. It is further possible to treat intermolecular forces and chemical reactions.

Different applications require a different amount of effort. For example, electron density distributions may be accounted for accurately enough with approximate methods that are much too crude for the calculation of electronic spectra. Bond lengths are obtained to an accuracy of a few percent by methods that would lead to errors of more than 100% for bond energies. Certain expectation values, on the other hand, require much more accurate wave functions than those that are good enough if one wants to calculate energies. The question of which simplifications may be introduced, and hence often of whether the computational effort can be reduced to a reasonable level, depends to a very large extent on the type of problem.

It should, in principle, be possible to calculate the properties of any known or unknown, stable or unstable compound or to predict theoretically the result of any chemical experiment, irrespective of whether this experiment can actually be carried out. That numerical *ab initio* quantum chemistry is still concerned with comparatively modest problems is due to the extreme complexity of the quantum-mechanical equations. A few molecular species, like $H_3$ and $H_2^+$, are, however, better known from theory than from experiment. The best value available for the electron affinity of the H atom is that obtained from theoretical calculations [1]. The existence of the stable cation of cycloheptatriene and of the stable anion of cyclopentadiene was deduced from theory [2] and was later confirmed experimentally.

There have been many other examples of theoretical predictions that were later confirmed by experiment. Collaboration of theory and experiment has proved very successful in many fields of research, including ultraviolet spectroscopy, nuclear magnetic and electron-spin resonance spectroscopy, and the study of metal complexes of aromatic compounds, and will undoubtedly play an even greater role in the coming decades.

The methods used in theoretical chemistry include, besides quantum theory, also statistical mechanics, which bridges the gap between molecular processes and macroscopic properties of matter. There is also some overlap between quantum chemistry and theoretical solid-state physics. The present paper will be confined to quantum chemistry in the restricted sense, *i.e.* to the theory of molecules and their interactions. As far as is possible within the framework of an elementary review, special attention will be given to such problems and results that are topics of current research and still outside the scope of textbooks.

Quantum chemistry is not limited to numerical solutions, with the aid of computers, of highly complicated equations referring to very particular systems. Its scope is rather to help us to understand and to systematize in terms of very general theorems the diversity of chemical facts.

## 1.2. Physical Formulation of a Chemical System

A chemically interesting system may be an atom, an ion, a molecule, a complex, or a whole crystal, or it may consist of several like or unlike atoms, molecules, *etc.* in stationary interaction with one another, moving relative to each other, or taking part in a chemical reaction. From the physical point of view, each of these systems consists of a number of atomic nuclei and electrons, which exert electrostatic (coulombic) forces on one another, and the movements of which are described by the laws of quantum mechanics.

If the laws of classical mechanics were valid on the atomic level, it would be necessary to set up and solve the equations of motion for such a system, and certain initial conditions would have to be known in order to establish the solutions [3]. These solutions would then give the position and momentum of each individual particle (nuclei, electrons) as a function of time, *i.e.* its trajectory. In closed systems, certain physical quantities, such as energy, momentum, and angular momentum, would remain invariant with time; they are called *constants of motion.*

Whereas in the equations of classical mechanics the physically measurable quantities, *i.e.* the *observables*, such as position, momentum, and energy, are directly related to one another, the equations of quantum mechanics do not contain the observables themselves but rather "operators" assigned to them. To each solution of the classical equations of motion, there corresponds in quantum mechanics a *state* of the system; this state is described by a wave function $\psi$, which is a function of the coordinates of all the particles (*i.e.* for a system of $n$ particles, a function of $3n$ position coordinates and $n$ spin coordinates, though the latter may be ignored for the moment). The square of the wave function (or when $\psi$ is complex, the product of $\psi$ with its complex conjugate $\psi^*$) can be regarded as the *probability density* that the first electron will be found at the point $x_1$, $y_1$, $z_1$, the second at the point $x_2$, $y_2$, $z_2$, *etc.* Since the total probability is unity, $\psi$ is *normalized* to unity, *i.e.*

$$\int_{-\infty}^{+\infty}\int_{-\infty}^{+\infty}\cdots\int_{-\infty}^{+\infty}\psi^*(x_1,y_1,z_1,x_2,y_2,z_2\ldots)\,\psi(x_1,y_1,z_1,x_2,y_2,z_2\ldots)\,dx_1dy_1dz_1dx_2dy_2dz_2\ldots = 1, \quad (1)$$

or in an abbreviated notation:

$$\int\psi^*(1,2,\ldots n)\,\psi(1,2,\ldots n)\,d\tau_1\,d\tau_2\ldots d\tau_n \equiv \int\psi^*\psi\,d\tau = 1 \quad (2)$$

where the subscript 1 denotes the coordinates of the first particle and

$$d\tau_1 = dx_1dy_1dz_1$$

denotes the volume element of the first particle, *etc.* and the integration is carried out over the entire space for each particle. This is a $3n$-fold (or $4n$-fold with spin) integral, but it is usual to write just one integral sign.

The two basic concepts of quantum mechanics are the *wave function* and the *operator.* An operator has an explicit meaning only if it precedes a wave function. It then indicates that a certain mathematical operation is to be applied to the wave function. Operators may be multiplicative or differential operators [4].

The operator $\mathbf{x}_1$ of the position coordinate $x_1$ is a multiplicative operator, and it simply means: "$\psi$ is to be multiplied by the coordinate $x_1$", *i.e.*

$$\mathbf{x}_1\psi = x_1\psi \quad (3)$$

On the other hand the operator $\mathbf{p}_{x_1}$ of the $x$-component of the momentum of the first electron is a differential operator, and signifies: "$\psi$ is first to be differentiated with respect to $x_1$, and the derivative is then to be multiplied by the constant $h/\mathrm{i}$" ($h = h/2\pi$, where $h$ is Planck's constant and $\mathrm{i} = \sqrt{-1}$), *i.e.*

$$\mathbf{p}_{x_1}\psi = \frac{h}{\mathrm{i}}\frac{\partial\psi}{\partial x_1} \quad \text{or} \quad \mathbf{p}_{x_1} = \frac{h}{\mathrm{i}}\frac{\partial}{\partial x_1} \quad (4)$$

If in the equations of classical physics one replaces coordinates and momenta by the corresponding operators, one obtains the quantum-mechanical counterparts. Just as in classical physics the kinetic energy $T_i$ of a particle is equal to the square of the momentum divided by twice the mass, the same is true in quantum mechanics. Thus the operator of the overall kinetic energy is

$$\mathbf{T} = \sum_i \mathbf{T}_i = \sum_{i=1}^{n}\frac{\mathbf{p}_{x_i}\mathbf{p}_{x_i} + \mathbf{p}_{y_i}\mathbf{p}_{y_i} + \mathbf{p}_{z_i}\mathbf{p}_{z_i}}{2m_i}$$

$$= -h^2\sum_{i=1}^{n}\frac{1}{2m_i}\left[\frac{\partial^2}{\partial x_i^2} + \frac{\partial^2}{\partial y_i^2} + \frac{\partial^2}{\partial z_i^2}\right], \quad (5)$$

*i.e.* a differential operator. The potential energy is a function of the position coordinates, and therefore a multiplicative operator, as are those of the position coordinates themselves.

$$\mathbf{V} = \frac{1}{2}\sum_{ij=1}^{n}{}' \frac{Z_iZ_je^2}{r_{ij}} \quad (6)$$

Equation (6) is the well-known expression for the Coulomb energy of a system of point charges. The prime by the summation sign means that the term for $i = j$ is to be omitted. $Z_i$ is the charge, including sign, on the $i$-th particle in units of electronic charge, and $r_{ij}$ is the distance between the $i$-th and $j$-th particles.

$$r_{ij} = \left[(x_i - x_j)^2 + (y_i - y_j)^2 + (z_i - z_j)^2\right]^{1/2} \quad (7)$$

The total energy operator, *i.e.* the sum of the kinetic and potential energy operators, is called the Hamiltonian operator or simply the Hamiltonian, $\mathbf{H}$.

$$\mathbf{H} = \mathbf{T} + \mathbf{V} \quad (8)$$

[3] A discussion of classical mechanics as a basis for quantum mechanics can be found, *e.g.*, in *L. Pauling* and *E. B. Wilson*: Introduction to Quantum Mechanics, with Applications to Chemistry. McGraw-Hill, New York 1935; now available as a paperback. Another good introduction to quantum mechanics for chemists is *M. W. Hanna*: Quantum Mechanics in Chemistry. Benjamin, New York 1965.

[4] Integral operators also play a certain role. For example, the "effective potential" of the Hartree-Fock theory (see Section 1.6) is an integral operator. An operator of this type is defined by an integral kernel $A(x,x')$: $\mathbf{A}\varphi(x) = \int A(x,x')\varphi(x')\,d\tau'$.

The link between the abstract operators and the observables is established through the concept of *expectation values*[5]. The expectation value $< \mathbf{A} >$ of the operator **A** for a system in a state described by the wave function $\psi$ is the mean value to be found in a measurement of the quantity $A$. Various notations (9) are used for the expectation value:

$$\overline{A} \equiv < \mathbf{A} > \equiv (\psi, \mathbf{A}\psi) \equiv < \psi | \mathbf{A} | \psi > = \int \psi^* \, \mathbf{A} \, \psi \, d\tau \qquad (9)$$

Any of these expressions means that **A** is to be applied to $\psi$, and the result is to be multiplied by $\psi^*$ and integrated over the entire space occupied by all the particles.

Suppose we know the wave function of a system in a certain state and we want to know the dipole moment $\mathfrak{M}$ of the system; the dipole moment operator $\hat{\mathfrak{M}}$ is

$$\hat{\mathfrak{M}} = e \sum_{i=1}^{n} Z_i \, \mathfrak{r}_i$$

($e$ = unit charge)

and its expectation value $< \hat{\mathfrak{M}} > = (\psi, \hat{\mathfrak{M}} \, \psi)$[6] or the $x$, $y$, and $z$ components of $\hat{\mathfrak{M}}$:

$$< \hat{\mathfrak{M}}_x > = e \sum_{i=1}^{n} Z_i \int \psi^* \, x_i \, \psi \, d\tau$$

*etc.* are then obtained simply by integration.

The concepts presented in this section and their relations are summarized in the following table.

| | Related by equations | Measurable | Relation |
|---|---|---|---|
| Classical | Observables *e.g.* $A$ | Observable, *e.g.* $A$ | Identical |
| Quantum-mechanical | Operators, *e.g.* **A** | Expectation value, *e.g.* $< \mathbf{A} >$ | *via* the wave function |

The properties of a state are evidently known if its wave function is known. This can be obtained as a solution of the *Schrödinger equation*, namely of the time independent one (10) for "stationary" systems, and the time-dependent Schrödinger equation (11) for substantially time-dependent ones. In a stationary state all expectation values of operators that do not explicitly depend on time are constant with time.

$$\mathbf{H}\psi = E\psi \qquad (10)$$

$$\mathbf{H}\psi = -\frac{\hbar}{i}\frac{\partial \psi}{\partial t} \qquad (11)$$

Equation (10) is simply the quantum-mechanical formulation of the statement that the total energy $H$ of a closed system (not interacting with its surroundings) is a constant $E$. While the constant $E$ in classical mechanics can have any value, equation (10) has solutions $\psi$ that can be normalized in the sense of equation (1) only for certain values of $E$. The allowed values of $E_i$ are known as the *eigenvalues* of the equation (or as those of the Hamiltonian **H**), and the corresponding functions $\psi_i$ are called the *eigenfunctions*.

It is very important that a system in a stationary state can assume only certain discrete energy values. The lowest energy eigenvalue is always finite, and the corresponding state of the system is called the *ground state*, while the other discrete energy levels refer to *excited states*. At higher energies generally a *continuum* follows, which corresponds to continously distributed instead of discrete eigenvalues. Physically this means ionized or dissociated states. Zero energy is – by definition – that of a state in which all the nuclei and electrons are at rest at an infinite distance from one another. The total energy of an atom or molecule in the ground state is therefore the energy necessary to ionize and dissociate it completely, which for heavy atoms or large molecules amounts to many thousands of electron volts. Bond energies, on the other hand, are of the order of a few electron volts or even less. This indicates how extremly accurate quantum-chemical calculations must be in order to reproduce chemically interesting quantities correctly[7].

If the energy eigenvalues of a system are known the frequencies $\nu_{ij}$ of the spectral transitions are given by *Bohr*'s relation:

$$h\nu_{ij} = E_i - E_j. \qquad (12)$$

The intensity of the transition is determined by the transition moment $\mathfrak{M}_{ij} = (\psi_i, \hat{\mathfrak{M}}\psi_j) = \int \psi_i^* \hat{\mathfrak{M}} \psi_j d\tau$ where $\hat{\mathfrak{M}}$ is the dipole moment operator already defined, and $\psi_i$ and $\psi_j$ are the wave functions of the two states between which the transition occurs. If $\mathfrak{M}_{ij}$ vanishes, the transition is "forbidden". Certain $\mathfrak{M}_{ij}$ vanish for symmetry reasons. This gives rise to the so-called *selection rules*. $\mathfrak{M}_{ij}$ is a vector, and often only one component, *e.g.* $(\mathfrak{M}_x)_{ij}$, is different from zero. In this case the transition is polarized in the $x$-direction.

### 1.3. Variation Principle and Perturbation Theory

It is generally very simple to formulate the Schrödinger equation for a given system. A closed solution can be given only for the hydrogen atom and a few other one-electron systems. Thus in all practical applications of quantum chemistry one has to rely on numerical (and

[5] In addition to the expectation value, its "mean deviation" is defined: $< \Delta \mathbf{A} >^2 \equiv \int | \mathbf{A} - < \mathbf{A} > |^2 \, d\tau = | < \mathbf{A}^2 > - < \mathbf{A} >^2 |$. For operators that correspond to constants of motion, this deviation is equal to zero, *i.e.* the expectation value is "sharp". In quantum mechanics, a physical quantity $\Omega$ is a constant of motion if the operator $\hat{\Omega}$ assigned to it "commutes" with the Hamiltonian, *i.e.* if $\mathbf{H}\hat{\Omega} = \hat{\Omega}\mathbf{H}$ or $\mathbf{H}(\hat{\Omega}\psi) = \hat{\Omega}\,(\mathbf{H}\psi)$ for any $\psi$. Operators do not in general commute, *i.e.* $\mathbf{x}\mathbf{p}_x \neq \mathbf{p}_x\mathbf{x}$. For atoms the angular momentum is a constant of motion.

[6] $\mathfrak{r}_i$ denotes a vector, *i.e.* it denotes three coordinates $(x_i, y_i, z_i)$. Accordingly, $\hat{\mathfrak{M}}$ and its expectation value $< \hat{\mathfrak{M}} >$ are vectors.

[7] If the bond energy of a large molecule is determined by calculation of the total energy of the molecule and subtraction of the total energies of the isolated atoms (and this is generally the procedure that must be used), the resulting problem, according to *C. A. Coulson* [Rev. mod. Physics *32*, 170 (1960)] is equivalent to finding the weight of the captain of a ship by weighing the ship first with, and then without the captain.

necessarily approximate) methods of solution. The most important ones are those based on the variation principle.

Let the Hamiltonian $\mathbf{H}$ of a system be given and let $\psi_\tau$ be an arbitrary (normalized) function of all the coordinates of the system. It can then be shown [8] that

$$< \mathbf{H} >_\tau = (\psi_\tau, \mathbf{H}\psi_\tau) \geq E_o, \qquad (13)$$

*i.e.* the energy expectation value $< \mathbf{H} >_\tau$ calculated with $\psi_\tau$ is greater than or equal to the energy $E_0$ of the ground state of the system. Moreover the difference $< \mathbf{H} >_\tau - E_0$ is a measure [9] of the goodness of the approximate wave function $\psi_\tau$. In general, the closer the energy $< \mathbf{H} >\tau$ calculated from an approximate function $\psi_\tau$ to the true energy $E_0$, or in accordance with equation (13), the lower $< \mathbf{H} >_\tau$, the better is the approximation. When the variation principle is used, the true energy can only be approached "from above" [10].

In order to apply the variation principle, one formulates the *variation function* $\psi_\tau$ so that it contains certain variable parameters $\lambda_i$ [11]. The expectation value $< \mathbf{H} >_\tau$ will then be a function of these parameters. $<\mathbf{H}>_\tau$ is differentiated with respect to the parameters $\lambda_i$ in order to find its minimum as a function of the $\lambda_i$ and so to obtain the "best" function (in the sense of the variation principle) within the family of (normalized) $\psi_\tau$. In this $\psi_\tau$ the parameters $\lambda_i$ then have their optimum values. If the function is sufficiently flexible, we may come quite close [12] to the true eigenvalue $E_0$ and the true eigenfunction $\psi_0$.

The most important special form of the variation method is the Ritz procedure, in which one starts from a given set of functions $\varphi_1, \varphi_2, \ldots \varphi_n$ of the coordinates of the system and one approximates the variation function as a linear combination of the $\varphi_i$:

$$\psi_\tau = c_1 \varphi_1 + c_2 \varphi_2 + \ldots c_n \varphi_n. \qquad (14)$$

The coefficients $c_j$ are now the variation parameters with respect to which the expectation value $< \mathbf{H} >$ has to be differentiated. If this differentiation is carried out (subject to $\psi_\tau$ being normalized to unity), we obtain a system of linear equations for the determination of the "best" $c_j$:

$$\sum_j [H_{ij} - WS_{ij}]\, c_j = 0 \qquad i = 1, 2 \ldots n \qquad (15)$$

In this equation, the $H_{ij}$ are the *matrix elements* [13] of the Hamiltonian in the chosen basis $(\varphi_1, \varphi_2 \ \ldots \ \varphi_n)$, and the $S_{ij}$ are the *overlap integrals*.

$$H_{ij} = (\varphi_i, \mathbf{H}\varphi_j) = \int \varphi_i^* \mathbf{H}\, \varphi_j \, d\tau$$
$$S_{ij} = (\varphi_i, \varphi_j) = \int \varphi_i^* \varphi_j \, d\tau \qquad (16)$$

It is convenient to use a so-called orthogonal basis, for which the overlap integrals between different functions vanish, *i.e.* $S_{ij} = 0$ for $i \neq j$. If the $\varphi_i$ are also normalized, *i.e.* if $S_{ij} = 1$, the basis is said to be orthonormal. In this case the system of equations (15) reduces to

$$\sum_j H_{ij} c_j = W c_i. \qquad (17)$$

Such systems of equations occur in other fields of physics; they are called secular equations. The system of equations (17) has non-trivial solutions [14] only if

$$| H_{ij} - W\delta_{ij} | = 0 \qquad (18)$$

The vertical lines on both sides indicate that the determinant [15] of the matrix whose elements are $H_{ij} - W\delta_{ij}$ has to be taken ($\delta_{ij} = 1$ when $i = j$ and 0 when $i \neq$ j). This determinant, known as the *secular determinant*, vanishes only for certain values of $W$, the *eigenvalues* of

---

[8] This can be seen as follows: The eigenfunctions $\psi_i$ (with the eigenvalues $E_i$) of the operator $\mathbf{H}$, as for Hermitian operators in general, form a complete orthonormal set, in the sense that any $\psi_\tau$ can be written as a linear combination of the $\psi_i$: $\psi_\tau = \sum_i c_i^\tau \psi_i$.

If we now form the expectation value $< \mathbf{H} >_\tau$ and bear in mind that the $\psi_i$ are eigenfunctions, *i.e.* that $\mathbf{H}\psi_i = E_i \psi_i$, and that the $\psi_i$ are orthogonal, insertion and rearrangement gives:

$$< \mathbf{H} >_\tau = \sum_{ij} c_i^{\tau *} c_j^\tau (\psi_i, \mathbf{H}\psi_j)$$

$$= \sum_i | c_i^\tau |^2 E_i = E_o + \sum_i | c_i^\tau |^2 (E_i - E_o)$$

However, the sum on the right is greater than or equal to zero, since $E_i \geq E_0$ when $E_0$ is the lowest eigenvalue. (Owing to the normalization of $\psi_\tau$ and $\psi_i$, $\sum_i | c_i^\tau |^2 = 1$).

[9] The difference between the calculated energy $(\psi, \mathbf{H}\psi)$ and the true energy $E_0$ is related to the goodness of the approximate solution $\psi$ by the Eckart inequality (*C. Eckart*, Physic. Rev. *36*, 878 (1930), note added in proof):

$$\int | \psi - \psi_0 |^2 \, d\tau \leq \frac{(\psi, \mathbf{H}\psi) - E_0}{E_1 - E_0},$$

where $E_1$ is the energy of the first excited state.

[10] Methods are also possible by which an eigenvalue is approximated *from below*. The distance between upper and lower bounds is then a measure of the accuracy of the calculation – a purely theoretical one, independent of comparison with experiment. The lower limits of *G. Temple* [Proc. Roy. Soc., Ser. A *119*, 276 (1928)] and *D. H. Weinstein* [Proc. nat. Acad. Sci. USA *20*, 529 (1934)], are too far from the true eigenvalues to be of practical use. However, significant progress has been made in recent years, owing mainly to the work of *N. Bazley* and *D. W. Fox* [J. Math. Physics *4*, 1147 (1963); Rev. mod. Physics *35*, 712 (1963)]. It should be mentioned that variation methods to give good approximations for expectation values other than the energy have been suggested [*e.g.*, *H. Preuss*, Z. Naturforsch. *13a*, 439 (1938); *16a*, 598 (1961); *L. M. Delves*, Nuclear Physics *41*, 497 (1963); *45*, 2 (1963)]. The "double perturbation theory" (see [18]) should be mentioned in this context.

[11] The variation parameters, to which optimum values are assigned purely theoretically *via* the variation principle, should not be confused with "semi-empirical" parameters, to which explicit values are given to force agreement with certain empirical data.

[12] "Arbitrarily close" means that the integral $\int | \psi - \psi_0 |^2 \, d\tau$ becomes arbitrarily small ("mean square convergence").

[13] The matrix elements of any operator are generally integrals of the form (16) when $\mathbf{H}$ is replaced by this operator. An overlap integral may be regarded as the matrix element of the "identity operator" (which leaves the function on which it acts unchanged). Diagonal matrix elements, in which the function on the right and on the left of the operator is the same, may of course be regarded as expectation values calculated with this function. The notation using brackets is easier to visualize than the integral notation. Note that the asterisk denoting the complex conjugate is omitted in the former notation.

[14] Let all $c_i = 0$. Obviously this is a solution, but it has no physical significance since it corresponds to zero probability everywhere; such a solution is a *trivial* one.

the matrix ($H_{ij}$). If equation (18) is multiplied out [15], a polynomial of degree $n$ in $W$ is obtained, which in general has $n$ roots which are the $n$ eigenvalues of the matrix. Like most quantum-mechanical operators, $\mathbf{H}$ is *Hermitian, i.e.* $H_{ij} = H_{ji}^*$, and therefore it has only real eigenvalues; some of the $W_i$ may coincide, in which case we say that the corresponding eigenvalue is *degenerate*. The lowest eigenvalue $W_0$ is an approximation to the lowest eigenvalue $E_0$ of the Schrödinger equation, each matrix eigenvalue $W_i$ being an upper bound to one of the true energies $E_i$ of the corresponding state.

Thus the Ritz method reduces the eigenvalue problem of a differential equation, a difficult task, to a matrix eigenvalue problem, which can be solved by routine methods with the aid of electronic computers. Most quantum-chemical problems can be formulated in the language of matrix algebra [16].

More difficult than the solution of the system (17) or (15) is the calculation of the matrix elements $H_{ik}$ (see Section 1.6). The accuracy of the solutions obtained by the Ritz procedure increases in general with the size of the basis set. There exist so-called complete sets of functions. Any wave function referring to a given number of particles can be strictly [17] represented as a linear combination of the functions of this set. If one applies the Ritz procedure with an increasing number of basis functions of this set, then the solution converges to the true solution. For practical purposes the convergence is often so good (consider the analogy to convergent power series, where it often suffices to consider only the first few terms) that even a relatively small basis set may lead to sufficiently accurate solutions.

An alternative to the variation method is *perturbation theory* [18]. It can be applied if the Hamiltonian of the problem can be written as the sum of an operator $\mathbf{H}^{(0)}$ whose eigenfunctions $\varphi_i$ and eigenvalues $\varepsilon_i$ are known, and a perturbation operator $\mathbf{H}'$, which should be small compared to $\mathbf{H}^{(0)}$.

$$\mathbf{H} = \mathbf{H}^{(0)} + \mathbf{H}' \qquad \mathbf{H}\,\psi_i = E_i\,\psi_i$$
$$\mathbf{H}^{(0)}\,\varphi_i = \varepsilon_i\,\varphi_i \tag{19}$$

There are essentially two variants of perturbation theory, that of *Rayleigh* and *Schrödinger* and that of *Brillouin* and *Wigner*; we shall confine ourselves to the former. The eigenfunction $\psi_0$ and the eigenvalue $E_0$ (we are considering the ground state, which is supposed to be nondegenerate [19], *i.e.* there should be only one $\varphi_0$ for $\varepsilon_0$ and only one $\psi_0$ for $E_0$) of the perturbed problem are then expressed in terms of those of the unperturbed problem *plus* a perturbation correction, which is expanded as power series in the perturbation operator. If $\mathbf{H}'$ is very small, the expansion may be confined to first-order and possibly second-order terms, *i.e.* to terms that are linear and quadratic in $\mathbf{H}'$, respectively. The first-order perturbation of the energy is

$$\Delta E^{(1)} = (\varphi_o, \mathbf{H}'\,\varphi_o);$$
$$E^{(1)} = \varepsilon_o + \Delta E^{(1)} = (\varphi_o, \mathbf{H}^{(0)}\,\varphi_o) + (\varphi_o, \mathbf{H}'\,\varphi_o) = (\varphi_o, \mathbf{H}\,\varphi_o) \geqslant E \tag{20}$$

$E^{(1)}$ is the unperturbed energy plus the first-order perturbation energy. In order to calculate the energy to first order, one need only know the *unperturbed* function $\varphi_0$. The calculation of $E^{(1)}$ requires just the calculation of an integral, and does not require the solution of an equation. As can be seen from equation (20), since $E^{(1)}$ is an expectation value of the operator $\mathbf{H}$, it obeys the variation principle, *i.e.* it represents an upper limit for the energy. This is not true of $E^{(2)}$, the energy to second order, which may lie *below* the true energy. The difference between $E^{(2)}$ and the true energy $E$ is therefore not a measure of the goodness of the wave function.

The first-order perturbation correction $\Delta\psi^{(1)}$ of the wave function is conventionally expanded as a linear combination of the eigenfunctions of the unperturbed system. These form a complete set only when the so-called continuum functions are also taken into account. The following expressions are obtained for $\psi^{(1)}$ and $E^{(2)}$:

$$\psi^{(1)} = \varphi_o + \Delta\psi^{(1)} = \varphi_o + \sum_{i>0} c_i\,\varphi_i \tag{21}$$

$$c_i = \frac{(\varphi_o, \mathbf{H}'\,\varphi_i)}{\varepsilon_o - \varepsilon_i} \qquad E^{(2)} = E^{(1)} + \sum_{i>0} \frac{(\varphi_o, \mathbf{H}'\,\varphi_i)\,(\varphi_i, \mathbf{H}'\,\varphi_o)}{\varepsilon_o - \varepsilon_i}$$

The summations over an infinite number of terms containing continuum contributions are extremely inconvenient. One therefore prefers expressions that are equivalent to (21), but easier to evaluate [18].

The second-order perturbation correction to the energy is of interest mainly in those cases where the first-order perturbation vanishes.

A simple example is the Stark effect for the ground state of the hydrogen atom, in which the perturbation operator is simply

---

[15] A (square) matrix $\mathbf{A}$ of dimension $n$ is a square array of $n^2$ numbers $A_{ik}$ arranged in $n$ rows and $n$ columns, *e.g.*, for $n = 2$: $\mathbf{A} = \begin{pmatrix} A_{11} & A_{12} \\ A_{21} & A_{22} \end{pmatrix}$. To each matrix is assigned a determinant $|\mathbf{A}| = \det \mathbf{A}$, which is a single number or a single algebraic expression, and which is calculated from the elements $A_{ij}$ of the matrix as follows:

$$|\mathbf{A}| = \sum_{\mathrm{p}} \varepsilon_{\mathrm{p}}\, A_{1i_1} A_{2i_2} \cdots A_{ni_n}$$

where $i_1, i_2 \ldots i_n$ is any permutation of the numbers $1,2 \ldots n$, the sum being taken over all possible permutations, and $\varepsilon_{\mathrm{p}}$ is the so-called parity of the permutation, *i.e.* $\varepsilon_{\mathrm{p}} = 1$ when $i_1, i_2 \ldots i_n$ can be obtained by an even number of transpositions, and $\varepsilon_{\mathrm{p}} = -1$ when an odd number is required.

Examples: $n = 2; |\mathbf{A}| = \begin{vmatrix} A_{11} & A_{12} \\ A_{21} & A_{22} \end{vmatrix} = A_{11}A_{22} - A_{12}A_{21}$

$$n = 3; |\mathbf{A}| = \begin{vmatrix} A_{11} & A_{12} & A_{13} \\ A_{21} & A_{22} & A_{23} \\ A_{31} & A_{32} & A_{33} \end{vmatrix} = A_{11}A_{22}A_{33} + A_{12}A_{23}A_{31} + A_{13}A_{21}A_{32} - A_{11}A_{23}A_{32} - A_{12}A_{21}A_{33} - A_{13}A_{22}A_{31}$$

[16] Matrix algebra probably is the most important mathematical tool of the theoretical chemist. A suitable introduction to the subject is given in, *e.g.*[22], Appendix V, as well as in the chapters on matrices in *H. Margenau* and *G. M. Murphy*: The Mathematics of Physics and Chemistry. Van Nostrand, Princeton 1943, or in *E. Wigner*: Gruppentheorie. Vieweg, Braunschweig 1931. More detailed treatments are given in *R. Zurmühl*: Matrizen. Springer, Berlin 1958, and *G. G. Hall*: Matrices and Tensors. Pergamon, London 1963.

[17] In the sense that the mean square deviation vanishes (cf. [12]). Complete sets are infinite.

[18] An excellent survey of the present state of perturbation theory in quantum chemistry is given by *J. Hirschfelder, W. Byers-Brown*, and *S. Epstein* in Adv. Quantum Chem. *1*, 256 (1965).

[19] The formalism is somewhat more complicated for degenerate states. Here one has first to find the zeroth-order function adapted to the perturbation, as a linear combination of the eigenfunctions belonging to the same eigenvalue $E_0$.

the potential energy of the electron in the applied external field. $(\varphi_0, \mathbf{H}\varphi_0) = \Delta E^{(1)}$ vanishes in this case, and $\Delta E^{(2)}$ gives approximately the change of the ground state energy due to the field. The interaction energy between two neutral atoms a large distance apart vanishes to first order as well, and the London (or van der Waals) attraction is obtained in the second order. Perturbation corrections of higher than second order are rarely evaluated in practice.

Perturbation theory is based on the assumption that an expansion in powers of the perturbation operator converges. This assumption is not necessarily justified [20]. It is a rule of thumb that perturbation theory fails whenever the difference $E - \varepsilon$ is of the same order as the energy difference between $E_0$ and the first excited state $E_1$.

In time-dependent problems, a stationary system may be regarded as the unperturbed one and the time dependence as the perturbation. "Time-dependent" perturbation theory is used, *e.g.*, in treatment of light absorption.

## 1.4. Energy (or Potential) Hypersurfaces

In the Schrödinger equation (10) with the Hamiltonian operator **H** given by equations (8), (5), and (6), electrons and nuclei are treated in the same way. However, the mass of a proton is about 1800 times that of an electron, and other nuclei are heavier still. If we idealize the nuclei as having infinite mass, then only the electrons move, and only the coordinates of the electrons need to be regarded as variables in the Schrödinger equation. The nuclei are not really infinitely heavy, and they move slightly, but their movement is slow enough for them to be regarded as fixed for a time that is long for the movement of the electrons.

These considerations justify the so-called *adiabatic* or *Born-Oppenheimer approximation* [21], according to which the wave function $\psi$ of a system may be expressed (approximately) as the product of a function $R$ of the nuclei alone and a function $\Phi$ of the electrons (which contains the coordinates of the nuclei as parameters). If within the family of wave functions having the form of such a product $\psi = R\Phi$, we look for the best one in the sense of the variation principle, we obtain a Schrödinger equation $\mathbf{H}_{el}\Phi = E_{el}\Phi$ for the electronic wave function $\Phi$ and a second one, $\mathbf{H}_K R = E_K R$ for the movement of the nuclei, the Hamiltonian operators $\mathbf{H}_{el}$ and $\mathbf{H}_K$ being given approximately by (22) and (23).

$$\mathbf{H}_{el} = \sum_i \mathbf{T}_i - e^2 \sum_i \sum_I \frac{Z_I}{r_{Ii}} + e^2 \sum_{i<j} \frac{1}{r_{ij}} + e^2 \sum_{I<J} \frac{Z_I Z_J}{r_{IJ}} \qquad (22)$$

$\mathbf{H}_{el}$ is the operator of the (kinetic plus potential) energy of the electrons in the field of the "fixed" nuclei.

The summation over $i,j$ refers to the electrons, and that over $I,J$ to the nuclei. $\mathbf{T}_i$ is the kinetic energy operator of the $i$-th electron. The second sum represents the potential energy of the electrons in the field of the nuclei, and the third term the mutual repulsion of the electrons; the last term, representing the repulsion of the nuclei, is constant for fixed nuclei. The Schrödinger equation involving this Hamiltonian operator (22) is now solved to obtain the electronic eigenfunction $\Phi$ and the energy $E_{el}$, both of which depend on the arrangement of the nuclei.

Solution of the equation for all possible nuclear configurations gives $E_{el}$ as a function of nuclear positions. The nuclear configuration is in general characterized by $3N - 6$ *internal coordinates* [22], where $N$ is the number of nuclei. A plot of the electronic energy $E_{el}$ as a function of the internal coordinates gives an *energy hypersurface* [23]. For diatomic molecules, the only internal coordinate is the distance $r$ between the atoms, and the energy hypersurface is a plane curve $E_{el}(r)$ (Fig. 1). In the Born-Oppenheimer approximation, the energy

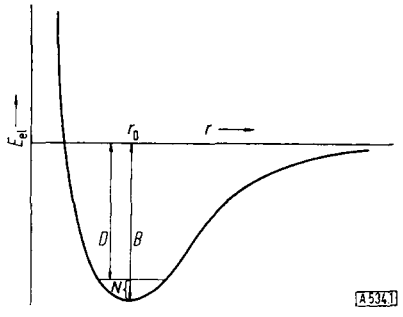

Fig. 1. Potential curve of a diatomic molecule.
$r$: interatomic distance
$r_0$: equilibrium distance
$B$: bond energy
$D$: dissociation energy
$N$: energy of the zero-point vibration

hypersurface plays the part of the potential energy for the movement of the nuclei, and is therefore often called the *potential hypersurface*. The Hamiltonian for the movement of the nuclei is

$$\mathbf{H} = \sum_I \mathbf{T}_I + E_{el}(1,2 \ldots I \ldots). \qquad (23)$$

The potential energy for the movement of the nuclei in a diatomic molecule is represented by the potential curve of Figure 1. For motion with a small total energy, only small displacements from the equilibrium configuration are likely. The potential for small movements near the minimum may be approximated by a parabola:

$$E_{el}(r) = \text{const.} + a(r - r_0)^2 + \ldots \qquad (24)$$

$$a = \frac{1}{2}\left(\frac{\partial^2 E_{el}}{\partial r^2}\right)_{r=r_0}$$

The Schrödinger equation for such a harmonic oscillator can be solved rigorously [22]. If higher powers of $r$ are included in the expansion (24) of the potential, one can account for the anharmonicity of the nuclear vibrations.

[20] The question of the convergence of the perturbation expansion has been studied particularly by *F. Rellich* [Math.-Ann. *173*, 600, 677 (1936); *117*, 336 (1940)] and by *T. Kato* [J. Fac. Sci., Imp. Univ. Tokyo, Sect. I, *6*, 145 (1951); Progr. theoret. Physics (Kyoto) 5, 95 (1950)].

[21] *M. Born* and *R. Oppenheimer*, Ann. Physik *84*, 457 (1927).

[22] The potential energy is invariant with respect to rotation or translation of the molecule, *i.e.* it is independent of the three coordinates corresponding to translation and of the three (or two) coordinates corresponding to rotation. A detailed treatment of the *internal coordinates* and of the quantum theory of molecular vibrations is given in *E. B. Wilson, J. C. Decius,* and *P. C. Cross:* Molecular Vibrations. McGraw-Hill, New York 1955.

[23] A function of $M$ coordinates can be regarded as an $M$-dimensional entity called a *hypersurface* in an $(M+1)$-dimensional space. A hypersurface in two-dimensional space is a curve, and in three-dimensional space a surface. An easily understandable treatment of potential hypersurfaces is given in *H. Preuss*: Quantentheoretische Chemie I. Bibliographisches Institut, Mannheim 1964.

Knowledge of the potential hypersurface for a molecule provides us with some important information.

If the potential hypersurface (or the potential curve) passes through a minimum (at least of the depth of the zero-point vibration) for a finite distance of all nuclei from one another, the molecule is physically stable. If the potential trough is sufficiently deep (larger than $kT$), the molecule can be regarded also as chemically stable [24]. If several minima are present, there are several stable arrangements (*e.g.*, tautomeric forms). If $E_{el}$ is independent of a coordinate corresponding to rotation about a bond, there is free rotation, *etc.* The minimum of the hypersurface gives the equilibrium configuration, *i.e.* the equilibrium distances and angles. The curvature at the potential minimum is a measure of the force constants. The difference between the potential minimum and the energy corresponding to an infinite distance between the atoms is equal to the binding energy (which differs from the experimental dissociation energy by the zero-point energy of the molecular vibrations).

Potential hypersurfaces are also defined for (electronically) excited states. The potential curve for the $He_2$ "molecule" has no minimum in the ground state, but in the first excited state it has. Potential surfaces for different states can intersect (when they belong to different symmetry species or to different spin multiplicities), so that for different nuclear configurations, the electronic ground state may belong to different hypersurfaces. Expectation values of operators can not, of course, be calculated from the hypersurfaces; one needs the wave functions. One should not forget that a potential hypersurface is rigorously defined only when the Born-Oppenheimer approximation is valid. In certain cases this term may have no meaning at all.

Potential hypersurfaces are useful for the discussion of chemical reactions. The nuclei and electrons of the atoms and molecules involved in the reaction are regarded as forming one "super-molecule", and the potential hypersurface of this super-molecule is determined as a function of the arrangement of all the particles. For the reaction A + B = C + D, the potential hypersurface must have at least two minima, one of which corresponds to the isolated (*i.e.* widely separated) molecules A and B, and the other to C and D. Between these two minima there may be peaks, maxima, saddle points, or other minima.

The time-dependent Schrödinger equation should be solved for the movement of the nuclei in this potential. Since it is at present not possible to solve this type of equation, one contents oneself often with a "semiclassical" theory [25] in which the potential hypersurface is calculated quantum-mechanically, while for the movement of the nuclei one uses classical mechanics. This is probably not too rough a simplification, though effects such as the *zero-point vibrations* and the *tunnel effect* [26] (which is presumably non-neglegible only in special cases) are neglected.

In this scheme, the question of whether a chemical reaction takes place depends essentially on the inital conditions, *i.e.* on the relative positions of the molecules A and B at a given instant, and on their kinetic energy, particularly the distribution of the vibrational energy over the vibrational degrees of freedom.

In order to describe a chemical reaction, it is obviously necessary to calculate the movement of the super-molecule for various initial conditions and to take into account their statistical distribution.

Somewhat dubious is the adiabatic postulate, which means that during the reaction the nuclei move on an adiabatic potential hypersurface that belongs to one and the same electronic state. This postulate is probably not justified when potential hypersurfaces intersect or come close to one another. It is better, though more difficult, to treat chemical reactions non-adiabatically. First attempts to do so based on quantum-mechanical scattering theory have not yet attained practical importance.

Since the calculation of the potential hypersurface of a molecule is very laborious, one confines oneself often to calculating some isolated points on this hypersurface, *e.g.*, one that corresponds to the non-interacting starting materials, one to the end-products of the reaction, and another to represent a hypothetical "activated complex" which, however, often has no physical reality.

There are still many unsolved questions in the quantum theory of chemical reactions [27].

For calculations involving a single molecule it is often not necessary to know the whole hypersurface; the equilibrium geometry known from experiment may be used in the calculation when one just wants to know the properties of the molecule in the equilibrium configuration. Most current quantum-chemical studies aim at calculating electronic states of molecules in fixed nuclear configuration.

### 1.5. Treatment of a Separable Many-Body Problem

Let us now confine ourselves to the problem of solving the electronic Schrödinger equation for a fixed arrangement of the nuclei. The number of electrons, and hence the number of coordinates involved in the wave function, is generally so large that in addition to the Born-Oppenheimer approximation other simplifications must be introduced to keep the amount of calculation required within reasonable limits.

---

[24] The stability referred to here is with respect to dissociation or to internal rearrangements. It does not tell us whether the compound is stable in the sense that it can be poured into a bottle and stored (in air or *in vacuo*, at or below room temperature). In order to get information about this kind of stability, one has to consider all possible reactions of the molecule with other molecules of the same kind or with foreign molecules on the basis of the potential hypersurfaces of super-molecules, and to examine both kinetic and thermodynamic aspects.

[25] See, *e.g.*, *H. Eyring*, J. chem. Physics *3*, 107 (1935).

[26] The tunnel effect (passage through a potential barrier that is higher than the kinetic energy of the particle) appears to be of some significance for the movement of a proton in a potential field with two minima, such as occur in hydrogen bonds. No final conclusion appears to have been reached as yet. Cf., *e.g.*, *H. Zimmermann*, Angew. Chem. *76*, 1 (1964); *P. O. Lowdin*, Rev. mod. Physics *35*, 724 (1963).
Somewhat superior to the purely classical treatment of the nuclear motion is the so-called phase-integral or WKB (*Wentzel, Kramers, Brillouin*) method (see textbooks on quantum mechanics), which can be justified on the basis of quantum theory, and by means of which it is possible, *e.g.*, to study the tunnel effect.

[27] An easily understandable, but in many respects outdated, introduction to the theory of chemical reactions is given by *H. Eyring*: Modern Chemical Kinetics. Reinhold, New York 1963. The present state of the (largely classical-mechanical) theory of unimolecular dissociations is described by *N. B. Slater*: Theory of Unimolecular Reactions. Cornell University Press, Ithaca 1959. An example of a quantum-mechanical paper on theoretical reaction kinetics is *L. Hofacker*, Z. Naturforsch. *18a*, 607 (1963). In contrast to the fundamental theory of chemical reactions, the semi-empirical theories of the reactivity of organic molecules have been quite successful; cf. *M. J. S. Dewar*, Adv. chem. Physics *7*, 65 (1965).

If we examine the electronic Hamiltonian operator in equation (22) more closely, we find that it consists of the following terms:

1. [Fourth term in eq. (22)] a constant (*i.e.* independent of the coordinates of the electrons) term for the repulsion of the nuclei, abbreviated to $V_K$.

2. [First and second terms in eq. (22)] a sum of terms, each of which depends only on the coordinates of one electron, and each of which consists of the kinetic energy $\mathbf{T}_i$ and the potential energy of the $i$-th electron in the field of all the nuclei, $e\sum_I Z_I/r_{Ii}$. The two energies are combined to give $\mathbf{h}(i)$:

$$\mathbf{h}(i) = \mathbf{T}_i + e\sum_I Z_I/r_{Ii}$$

3. [Third term in eq. (22)] expressions of the form $e^2/r_{ij}$, each of which are denoted by $\mathbf{g}(i,j)$.

$$\mathbf{g}(i,j) = e^2/r_{ij}$$

Using these abbreviations, the electronic Hamiltonian operator can be written:

$$\mathbf{H}(1,2,\ldots n) = V_K + \sum_{i=1}^{n} \mathbf{h}(i) + \sum_{i<j=1}^{n} \mathbf{g}(i,j) \qquad (25)$$

If the term for the repulsion of the electrons were absent, the Schrödinger equation would be *separable*, *i.e.* the $n$-electron $\psi$-function could be written as a product of functions, each of which depends only on the coordinates of one electron:

$$\psi(1,2,\ldots n) = \varphi_1(1)\,\varphi_2(2)\ldots\varphi_n(n) \qquad (26)$$

The one-electron functions $\varphi_i(i)$ would then be determined as solutions of the single-particle Schrödinger equation

$$\mathbf{h}(i)\,\varphi_i(i) = \varepsilon_i\,\varphi_i(i) \qquad (27)$$

which is a relatively simple numerical problem. The total energy in this case is found to be $E = V_K + \sum_{i=1}^{n}\varepsilon_i$. This can be seen by insertion of (26) and (27) in (25) without the last term.

We must now keep in mind that a wave function must not only be a solution of the Schrödinger equation and satisfy the boundary conditions (to vanish at infinity and to be normalizable), but also be *antisymmetric*[28] with respect to permutation of the coordinates (including spin coordinates) of all the particles. (This is the rigorous formulation of the *Pauli principle*).

The wave function for a (separable) two-electron problem, therefore, must not be of the form $\psi(1,2) = \varphi_1(1)\varphi_2(2)$, but rather

$$\psi = \frac{1}{\sqrt{2}}[\varphi_1(1)\varphi_2(2) - \varphi_2(1)\varphi_1(2)] = \frac{1}{\sqrt{2}}\begin{vmatrix}\varphi_1(1) & \varphi_1(2)\\ \varphi_2(1) & \varphi_2(2)\end{vmatrix} \qquad (28)$$

It is assumed here that $\varphi_1$ and $\varphi_2$ are mutually orthogonal [this is true if they are different solutions of the same differential equation (27)] and are normalized; the factor $1/\sqrt{2}$ guarantees then that $\psi$ is normalized as well.

An antisymmetric $\psi$-function for a separable Hamiltonian can be most conveniently written as a determinant[15], the *Slater determinant*.

$$\psi(1,2,\ldots n) = \frac{1}{\sqrt{n!}}\begin{vmatrix}\varphi_1(1) & \varphi_2(1) & \ldots & \varphi_n(1)\\ \varphi_1(2) & \varphi_2(2) & \ldots & \varphi_n(2)\\ \vdots & & & \\ \varphi_1(n) & \varphi_2(n) & \ldots & \varphi_n(n)\end{vmatrix} \qquad (29)$$

The determinant, when expanded[15], is a sum of $n!$ product functions.

A direct consequence of the antisymmetry principle is that no two electronic functions in the Slater determinant may be identical, since a determinant with two identical columns is equal to zero. For *separable problems*, therefore, the Pauli principle may be simply formulated as the *exclusion principle*: Each one-electron function can be occupied by at most one electron.

Bearing in mind that there are only two single-particle spin functions, denoted by $\alpha$ and $\beta$, and that each single-particle function can be written as the product of a pure position function, a so-called orbital, and a spin function (such a product is called a *spin orbital*), it follows that each orbital can accommodate at most two particles. For a separable problem, the state with minimum energy, *i.e.* the ground state, is obviously obtained when the orbitals having the lowest one-electron energies $\varepsilon$ in accordance with equation (27) are doubly occupied (and in the case of odd numbers of electrons, when the last orbital is singly occupied).

Here, like in many other examples of quantum chemistry, the spin plays a very indirect role and only affects the permutation properties of the wave function, since the Hamiltonian (when spin-orbital interactions *etc.* are ignored) does not involve the spin coordinates. Many attempts have therefore been made to eliminate the (difficult to visualize) spin as far as possible from quantum chemistry and to find some other means of allowing for its role in connection with the antisymmetry principle. However, none of the approaches towards a "spin-free" quantum mechanics[29] is simpler than the conventional formulation. On the other hand, it is always possible to eliminate the spin, whenever it is not directly involved, by using the formalism of reduced "density matrices"[30]. Density matrices play an important role in other domains of present-day quantum chemistry as well. To say more about them would, however, go beyond the scope of the present paper.

For one- and two-electron systems (but not for many-electron systems), the wave function can be expressed as the product of a position function and a spin function. In the two-electron case there are three symmetrical spin functions:

$$^t\Theta_1(1,2) \equiv \alpha(1)\,\alpha(2)$$

$$^t\Theta_{-1}(1,2) \equiv \beta(1)\,\beta(2)$$

$$^t\Theta_0(1,2) \equiv \frac{1}{\sqrt{2}}\{\alpha(1)\,\beta(2) + \beta(1)\,\alpha(2)\}$$

and an antisymmetric spin function:

$$^s\Theta(1,2) \equiv \frac{1}{\sqrt{2}}\{\alpha(1)\,\beta(2) - \alpha(1)\,\beta(2)\}$$

[28] A function is said to be antisymmetric if the transposition of the coordinates of two particles give the same function multiplied by $-1$.

[29] *F. A. Matsen*, Adv. Quantum Chem. *1*, 60 (1965).

[30] See the review by *R. McWeeny*, Rev. mod. Physics *32*, 335 (1960).

The corresponding position functions must be antisymmetric (triply spin-degenerate, triplet state) and symmetric (singlet state), respectively. In spin-free two-electron problems, the spin functions may often be ignored; it is then sufficient to take a symmetric function of the space coordinates for a singlet state and an antisymmetric one for a triplet state.

### 1.6. The Independent Particle Model

The Schrödinger equation for a many-electron problem is not separable, since the Hamiltonian operator contains the electronic interaction $\sum_{i<j}\mathbf{g}(i,j)$.

The (separable) Hamiltonian operator without electronic interaction may be regarded as the "unperturbed" Hamiltonian $\mathbf{H}_0$ and the electronic interaction as the perturbation $\mathbf{H}'$, and the formalism of the perturbation theory may then be used [31]. This procedure has been rather successful for atoms, since the unperturbed problem in this case can be solved in closed form. The solution of the unperturbed system is a Slater determinant built up from "hydrogen-like" functions. This kind of perturbation treatment is less suitable for molecules.

The best-known and most important model used to describe many-electron systems approximately is the independent particle model (IPM) [32], on which nearly all quantitative and qualitative chemical applications are based.

In this model one assumes that the approximate wave function can be written as a single Slater determinant. This can be a rigorous solution only if the electronic interaction vanishes, however, even if there is electron interaction, we can look for the best possible wave function that can be expressed as a single Slater determinant. There are several criteria for defining the best IPM function. Usually one defines it as the best function in the sense of the variation principle, *i.e.* in the family of all functions of the form (29) the one that minimizes the energy expectation value. The condition for this energy minimum leads to a system of *single-electron equations*, which determine the best orbitals.

$$\mathbf{h}_{\text{eff}}\,\varphi_i = \varepsilon_i\,\varphi_i \tag{30}$$

$\mathbf{h}_{\text{eff}}$ is known as the effective one-electron operator, and the system of equations the (unrestricted) *Hartree-Fock equations*. $\mathbf{h}_{\text{eff}}$ consists of the true one-electron operator $\mathbf{h}(i)$ and an effective potential $\mathbf{J}(i)$, which can be interpreted as the potential of the average field produced by the other electrons [33]. Thus the effective potential $\mathbf{J}(i)$, and hence $\mathbf{h}_{\text{eff}}(i)$, depends on the distribution of the electrons, *i.e.* in order to construct it, the solutions $\varphi_i$ should already be known.

In practice, one assumes a starting electron distribution, from which one constructs the initial Hartree-Fock operator; new $\varphi_i$ are obtained as solutions of equation (30), and are used to calculate a new effective potential. This procedure is repeated until the field is *self-consistent*, which is generally the case after a few iterations. The method is therefore known as the self-consistent field (SCF) method.

The solution of the effective one-electron equation, *i.e.* the calculation of the Hartree-Fock orbitals or SCF orbitals, is generally carried out by the Ritz method, *i.e.* the SCF orbitals are approximated as a linear combination of a given set of one-electron functions. The basis in case of atoms may be so-called *Slater functions* of the form

$$\psi_{nlm}(r,\vartheta,\varphi) = N\,r^{n-1}\,\mathrm{e}^{-2\eta r}\,\mathrm{Y}_l^m(\vartheta,\varphi). \tag{31}$$

where $N$ is a normalization factor, $\eta$ is a variable parameter, $n$, $l$, and $m$ are integers satisfying the inequality $m \leqslant l < n$, and $\mathrm{Y}_l^m$ are normalized spherical harmonics [34].

The integrals required for calculating the matrix elements can be evaluated in closed form for atomic calculations, and expansions of *atomic orbitals* in terms of Slater functions converge rather well, so that very accurate analytical SCF orbitals of the atoms are now available. As *Slater* has shown in 1930, one may approximate any orbital by a single Slater function and the optimum values of $\eta$ and $n$ can then be given approximately by very simple rules [35]. Thus according to the *Slater rules*, the approximate atomic orbitals of the carbon atom are

$$\begin{aligned}
&1\mathrm{s}\ :\ \psi_{100} = N\,\mathrm{e}^{-5.7r}\\
&2\mathrm{s}\ :\ \psi_{200} = N'\,r\,\mathrm{e}^{-1.625r}\\
&2\mathrm{p}\sigma\ :\ \psi_{210} = N''\,r\,\mathrm{e}^{-1.625r}\cos\vartheta = N''\,z\,\mathrm{e}^{-1.625r}\\
&2\mathrm{p}\pi\ :\ \psi_{211} = N'''\,r\,\mathrm{e}^{-1.625r}\sin\vartheta\,\mathrm{e}^{\mathrm{i}\varphi} = N'''\,(x+\mathrm{i}y)\mathrm{e}^{-1.625r}\\
&2\mathrm{p}\bar{\pi}\ :\ \psi_{21\bar{1}} = N'''\,r\,\mathrm{e}^{-1.625r}\sin\vartheta\,\mathrm{e}^{-\mathrm{i}\varphi} = N'''\,(x-\mathrm{i}y)\mathrm{e}^{-1.625r}.
\end{aligned}$$

$2\mathrm{p}\pi$ and $2\mathrm{p}\bar{\pi}$ may be replaced by the real functions

$$2\mathrm{p}_x = N''\,x\,\mathrm{e}^{-1.625r} = \frac{1}{\sqrt{2}}\,(2\mathrm{p}\pi + 2\mathrm{p}\bar{\pi})$$

and

$$2\mathrm{p}_y = N''\,y\,\mathrm{e}^{-1.625r} = \frac{-\mathrm{i}}{\sqrt{2}}\,(2\mathrm{p}\pi - 2\mathrm{p}\bar{\pi})$$

The Slater functions resemble somewhat the eigenfunctions of hydrogen-like ions, with one important dif-

[31] The method is due to *Hylleraas* [Z. Physik *65*, 209 (1930)]. An up-to-date survey is given by *D. Layzer et al.*, Ann. Physics *29*, 101 (1964)

[32] The independent particle model is discussed in detail by *W. Kutzelnigg* and *V. H. Smith* (Preprint 130 and 138, Quantum Chemistry Group, Uppsala 1964).

[33] $\mathbf{h}_{\text{eff}}$ also contains the so-called exchange operator, which is difficult to interpret pictorially, and which ensures that electrons having the same spin do not approach one another too closely. A number of good reviews of the Hartree-Fock method have been published, *e.g. D. R. Hartree*: Calculation of Atomic Structures. J. Wiley, New York 1957; *R. K. Nesbet*, Rev. mod. Physics *33*, 28 (1961); *C. C. J. Roothaan*, Rev. mod. Physics *23*, 69 (1951); *32*, 179 (1960).

[34] If the effective field is a central field, *i.e.* if the potential is only a function of the distance from the nucleus, then an atomic orbital can be written as the product of a function $R(r)$ and a spherical harmonic $\mathrm{Y}_l^m$ that depends only on the polar coordinates $\vartheta$ and $\varphi$ (which are similar to geographical latitude and longitude). The possible spherical harmonics are indicated by two indices $l$ and $m$, where $|m| \leqslant l$. The simplest spherical harmonic, $\mathrm{Y}_0^0$, is independent of $\vartheta$ and $\varphi$; $\mathrm{Y}_0^0 \propto \cos\vartheta$; $\mathrm{Y}_1^{-1} \propto \sin\vartheta\mathrm{e}^{-\mathrm{i}\varphi}$; $\mathrm{Y}_1^1 \propto \sin\vartheta\mathrm{e}^{\mathrm{i}\varphi}$ belong to $l=1$. For details see *e.g.* [3]; for the symmetry behavior of the orbitals in general see [32].

[35] *C. Zener*, Physic. Rev. *36*, 51 (1930); *J. C. Slater*, *ibid. 36*, 57 (1930). The best orbitals of this form calculated recently by *E. Clementi* [J. chem. Physics *38*, 2686 (1963); *40*, 1944 (1964)] *via* the variation principle do not differ appreciably from those given by *Slater*'s rules.

ference that the "effective nuclear charge" differs for different orbitals of the same atom. (In the hydrogen-like functions $\eta = Z/n$, where $Z$ is the nuclear charge and $n$ is the principal quantum number.) In this approximation, the influence of the other electrons is taken into account by partial screening of the nuclear charge. It is necessary to distinguish between the Slater functions in the sense of the Slater rules, where each atomic orbital is approximated by a single function of the type (31), and the use of Slater functions as the basis for calculations by the Ritz method. The abbreviation STO (Slater-type orbitals) is commonly used in the second case.

For a single electron in the field of a point charge, the possible orbitals can be characterized by three *quantum numbers* $n$, $l$, and $m$, known respectively as the principal, the angular, and the magnetic quantum number, the orbital energy depending only on the principal quantum number $n$. The inequalities $l < n$; $|m| \leqslant l$ hold; orbitals with $l = 0, 1, 2, 3$, *etc.*, are called s, p, d, f, *etc.*, orbitals, respectively.

For an electron in a central field that is not the field of a point charge, $n$, $l$, and $m$ are still so-called "good quantum numbers", but the energy now depends on $l$ as well as on $n$. This is the case, to a good approximation, for the orbitals in most atoms.

The order of the orbital energies is shown schematically in Figure 2. The structure of the periodic system of

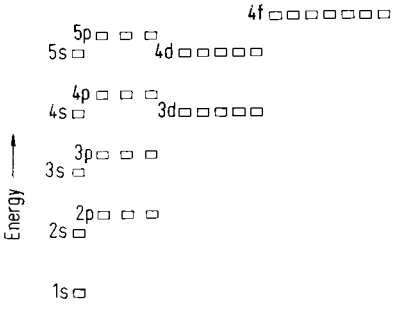

Fig. 2. Energies of the possible orbitals in an atom. Each box can accommodate at most two electrons.

elements is due to the fact that the electrons always occupy the orbitals with the lowest energies. It is easy to see that the K shell ($n = 1$) will be occupied first, then the L shell ($n = 2$), in which the two s electrons ($l = 0$) are followed by the six p electrons ($l = 1$). The lowest 3d level in the potassium atom is slightly higher than 4s, so that the 3d sub-shell is filled (Sc to Zn) only after the 4s shell. The existence of the rare earths can also be explained by this "Aufbau principle" within the framework of the independent particle model. In order to understand the details of the structure of the periodic table and of the spectral terms of the atoms, one must, of course, go beyond this simple model. Even within the IPM the total energy is not the sum of the orbital energies.

In the framework of the independent particle method, electronic transitions, observable in the ultraviolet spectra, are usually described qualitatively as the promotion of an electron from the highest occupied orbital in the ground state to the lowest, or one of the lowest, unoccupied orbitals (Fig. 3).

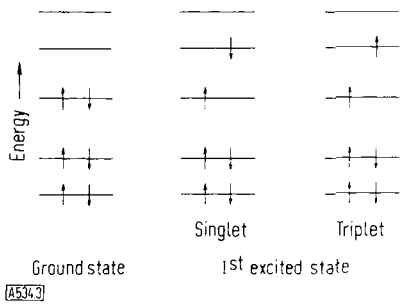

Fig. 3. Schematic representation of an electronic transition in the one-electron scheme. In order to understand the difference between the energies of the singlet and triplet states, it is necessary to take the electronic interaction into account.

More difficult than for atoms is the solution of the Hartree-Fock equations for *molecules, i.e.* the calculation of the best "molecular orbitals" (MO's)[36]. Only for the hydrogen molecule has an accuracy comparable with that of atomic calculations been achieved[37]. However, it has been possible in recent years to come close to the solutions of the Hartree-Fock equations for many diatomic and other small molecules. For this reason, we are now becoming aware of the limitations of the independent particle model (see Section 1.7).

It is sufficient in simple applications to approximate a molecular orbital as a linear combination of the atomic orbitals (or alternatively – what one does in practice – a single Slater orbital for any atomic orbital) of the atoms involved, the optimum values of the expansion coefficients $c_i$ being determined by the variation principle in accordance with equation (14). This is known as the LCAO (linear combination of atomic orbitals) approximation. Better molecular orbitals can in principle be obtained if one uses a basis set of Slater type orbitals the size of which is larger than the number of AO's. Since these STO's are defined for different centers, one has to evaluate many-center integrals, which require very laborious calculations, so that extended LCAO calculations do not at present appear very promising (except for diatomic molecules). In fact, for decades even "minimum basis set" MO-LCAO calculations failed to pass the bottleneck of calculating the necessary matrix elements[38]. The MO-LCAO method

[36] The molecular orbital method ("Methode der Molekülzustände" in the earlier German literature) is the standard scheme of valence theory. It goes back to *F. Hund* [Z. Physik *40*, 741 (1927); *51*, 759 (1928); *52*, 601 (1928); *73*, 1, 565 (1932)] and *R. S. Mulliken* [Physic. Rev. *32*, 186 (1928); *41*, 49 (1932)]. See also *F. Bloch*, Z. Physik *52*, 555 (1928); *G. Herzberg*, Z. Physik *57*, 601 (1929); *J. Lennard-Jones*, Trans. Faraday Soc. *25*, 668 (1929); *E. Hückel*, Z. Physik *70*, 204 (1931); *72*, 310 (1931); *76*, 628 (1932); *83*, 632 (1933).

[38] When Slater type functions are used as the basis, closed mathematical expressions can be obtained only for one-center integrals and for certain two-center integrals. Complicated auxiliary functions defined *e.g.* by infinite power series occur in the calculation of the other integrals. Up to the end of the 1950's, the problem of calculating these integrals was the main obstacle to further development of numerical quantum chemistry. Between 1955 and 1960, several tables of integrals were published,

for molecules is often referred to as the "Roothaan SCF method" [39], whereas the "Pople SCF method" [40] involves further approximations and semi-empirical corrections.

There is a tendency nowadays, rather than use the extended LCAO approximation which involves Slater type functions defined for different centers, to prefer such types of basis functions that are liable to give poorer convergence, but for which the integrals involved are soluble in closed form. These include the one-center expansion method in which the molecular orbitals are expanded as linear combinations of Slater functions all of which are defined for the same center, *e.g.* the centroid of the molecule. This method is well suited for molecules such as $CH_4$. Gaussian functions [41] have also enjoyed great popularity for a number of years. Let $\mathfrak{r}_i = (x_i, y_i, z_i)$ be the center around which $\varphi_i$ is defined. If $\mathfrak{r} = (x, y, z)$ is any point in space, then the Gaussian function $\varphi_i$ (this is a "pure" Gaussian function [42]) is given by

$$\varphi_i(\mathfrak{r}) = N\,\mathrm{e}^{-\alpha|\mathfrak{r}-\mathfrak{r}_i|^2};$$
$$|\mathfrak{r}-\mathfrak{r}_i|^2 = (x-x_i)^2 + (y-y_i)^2 + (z-z_i)^2. \qquad (32)$$

where $\alpha$ is a variable parameter. The origins of the Gaussian functions can be chosen freely, and need not coincide with the positions of the nuclei. A p-function can be very roughly represented by two such Gaussian functions arranged in the form of a dumb-bell about the nucleus in question [42].

from which the desired integrals could be interpolated with some difficulty. Nowadays such tables are rarely used, and one prefers to have the integrals calculated by subroutines within automatic computer programs. A few research groups have excellent integral programs that are not accessible to the general public, so that the same programming work has often been repeated independently. The situation is probably going to improve. The quantum-chemical program exchange (QCPE) (Indiana University, Bloomington, USA) revealed itself as a promising idea.

[39] *C. C. J. Roothaan*, Rev. mod. Physics *23*, 69 (1951); *G. G. Hall*, Proc. Roy. Soc. (London) *205*, 541 (1951).

[40] *J. A. Pople*, Trans. Faraday Soc. *49*, 1375 (1953); *R. Pariser* and *R. G. Parr*, J. chem. Physics *21*, 466, 767 (1953).

[41] The recent literature on the use of Gaussian functions is very extensive. Gaussian functions do not compare too unfavorably with Slater type functions. About three to four times as many functions are needed in a Gaussian basis (compared with an STO basis) to obtain a comparable accuracy, *i.e.* one has to calculate $3^4$ to $4^4$ times as many two-electron integrals, but any of these integrals can be calculated about 100 times as fast, so that the computer time needed is more or less the same. Integrals for Gaussian functions are, however, much easier to program than those for Slater type functions. A general SCF program for molecules using Gaussian functions is now available to anyone through the QCPE (see [38]) under the name POLYATOM. It seems that meanwhile much faster (probably 10 times as fast) programs exist that are not yet publicly available.

Gaussian functions necessarily give a poor approximation to the true wave function close to and at a long distance from the nucleus, but may give rather good approximation at intermediate distances. This shortcoming seems to be unimportant for many applications. Progress has been achieved also in rational programming of Slater type integrals, so that the Slater functions are liable to recover the ground lost to the Gaussian functions. See, *e.g.*, *F. E. Harris* and *H. H. Michels*, J. chem. Physics (1966), in press. It should be mentioned that other sets of functions like Laguerre functions have been used for special atomic probiems, and two-center functions defined in elliptic coordinates for diatomic molecules.

[42] *H. Preuss*, Z. Naturforsch. *11a*, 823 (1956).

The independent particle model is easily visualized; the number of electrons is equal to the number of orbitals (AO's in atoms, MO's in molecules), so that one may regard one electron as being in one orbital. Calculations based on this model usually are not too difficult.

The solutions of the SCF equations are satisfactory only for certain problems; for others the scheme fails completely. The electron density $\varrho$ as a function of position, which is defined by

$$\varrho(1) = n \int \psi^*(1,2,\ldots n)\,\psi\,(1,2,\ldots n)\mathrm{d}\tau_2\mathrm{d}\tau_3\ldots\mathrm{d}\tau_n \qquad (33)$$

is generally obtained with reasonable accuracy. Good results are often also obtained for the expectation values of one-electron operators, *i.e.* operators of the form $\mathbf{A}(1,2,\ldots n) = \mathbf{a}(1) + \mathbf{a}(2) + \ldots \mathbf{a}(n)$. The error in the total energy is about 1% in atomic SCF calculations (and generally somewhat higher for molecules); this would be satisfactory if the total energy were the final purpose of the calculation.

In fact are we interested in *energy differences* (*e.g.*, bond energies or the energies of spectral transitions), which are small compared with total energies. The effects that are ignored when the independent particle model in the form of the Hartree-Fock approximation is used are usually referred to as *electron correlation* [43]. In particular, the difference between the Hartree-Fock energy and the true (non-relativistic) energy is called the *correlation energy*. If the correlation energy for different states of the same atom or molecule were approximately the same (which is not the case) it would cancel in the calculation of the spectral transition energies. Similarly, the change of correlation energy on going from isolated atoms to a molecule is of the same order of magnitude as the change in the SCF energy. Electron correlation must not be ignored in the calculation of bond energies and spectra.

The standard method to take electron correlation at least partly into account is the *configuration interaction* (CI) method. The name originated in atomic spectroscopy, where it referred to states that could not be described by a single electronic configuration even in first approximation. CI is now understood to mean the approximation of the wave function as a linear combination [44] of Slater determinants (rather than as a single Slater determinant like in the SCF method), the optimum coefficients in this linear combination being determined by means of the variation principle. If there is a complete set of spin orbitals $\varphi_i$, then all possible Slater determinants (configurations) that can be constructed from $n$ such $\varphi_i$ are a complete set of $n$-electron functions.

[43] A good survey of the correlation problem is given by *P. O. Löwdin*: The Correlation Problem in Many-electron Quantum Mechanics. Adv. chem. Physics *2*, 207 (1959); see also Physic. Rev. *97*, 1474 (1955).

[44] In some cases, for symmetry reasons, a sum of Slater determinants is used instead of a single Slater determinant; however, the coefficients are then fixed from the outset. It is not customary to call this "configuration interaction".

If we start from a sufficiently large basis of one-electron functions, say $m$ such functions, we can in principle represent the true wave functions as accurately as desired [12] by a CI expansion. One difficulty is that the method does not in general converge very rapidly, and that as the number $n$ of electrons increases, the number of possible configurations increases with $\binom{m}{n}$, so that secular equations (15) occur that are beyond the capacity of even the largest computers.

Any set of one-electron functions may be used as basis set in the CI method, but one usually starts with an SCF calculation and chooses then the SCF orbitals plus some more functions as the basis set. The CI wave function is then a linear combination of the SCF Slater determinant and other Slater determinants. In most CI calculations, only a few additional determinants are taken into account, and normally these are selected on the basis of heuristic considerations, since a systematic CI calculation would be too laborious. The term "complete CI calculation" is generally a euphemism, since it means that one chooses an LCAO basis (for benzene *e.g.* the six $p_z$ orbitals of the 6 C-atoms), constructs all possible $n$-electron Slater determinants from them (benzene has 6 atomic $p_z$ orbitals, *i.e.* 12 spin orbitals, and $\binom{12}{6}$ determinants are possible, neglecting all $\sigma$ electrons), and approximates the desired wave function as a linear combination of these determinants. Often (especially for the calculation of spectra) one chooses the SCF Slater determinant plus some "singly excited configurations", *i.e.* determinants in which one spin orbital of the SCF determinant is replaced by another (so-called virtual) spin orbital. This procedure generally gives better approximations for the excited states than are obtained by simple SCF calculations, but the correlation of the ground state is not accounted for.

There are methods that take the electron correlation into account more successfully than the configuration interaction method, but generally these are applicable only in special cases, such as the Hylleraas expansion [45] for the He atom, which is limited to two-electron systems. A number of recent methods permit the inclusion of electron correlation without becoming unwieldy, *e.g.* the methods of generalized product functions [30], or cluster expansions [46], the direct calculation of "natural" orbitals [47], *etc.*

Figure 4 shows the main types of quantum-mechanical methods, an additional approximation being introduced from one line to the next lower one. The methods given in the first three lines have so far been successfully applied only to one- and two-electron systems. The first non-adiabatic calculation of the $H_2$ molecule (with relativistic corrections) was carried out only in 1963 [48].

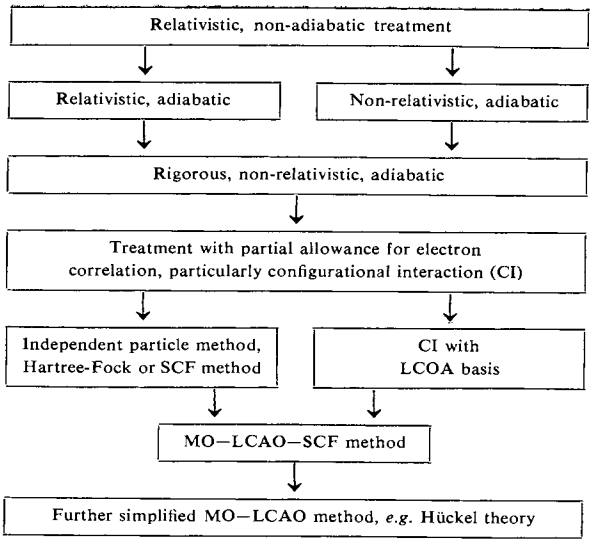

Fig. 4

## 1.8. Conclusion

In quantum-mechanical calculations one generally makes two tacit assumptions. One of them is that all relativistic effects may be neglected, and the second that the Born-Oppenheimer approximation is justified. These two approximations are not critical for most applications. In recent years, however, special interest has been shown in such cases for which at least one of the two approximations is not valid. Nuclear magnetic and electron spin resonance spectra cannot really be explained without recourse to a relativistic theory. On the other hand "vibronic interactions", *i.e.* the interaction between vibrational and electronic states, and the lowering of the symmetry of molecules in the degenerate ground state (Jahn-Teller-theorem) [49] play an important part in the current theory of the electronic spectra of molecules, and in order to explain these phenomena it is necessary to abandon the Born-Oppenheimer approximation.

More critical are approximations such as the independent particle model, the SCF scheme, and the LCAO approximation. Neglect of electron correlation may lead to quantitatively or even qualitatively erroneous results. For example, in the SCF approximation, the $H^-$ ion has a higher energy (−0.485 atomic units [50]) than an H atom plus an isolated electron (−0.500 atomic units); thus the $H^-$ ion should not be stable. However, a more accurate calculation (including correlation) of the energy of $H^-$ gives a value of −0.528 atomic units that shows, in agreement with experiment, that the H atom has a positive electron affinity.

[50] The atomic unit of energy is defined as twice the ionization energy of the H atom, and is equal to 27.2 eV or 628 kcal/mole. The atomic units of mass, electric charge, and length are the mass of the electron, the charge of the electron, and the Bohr radius of the hydrogen atom in the ground state (0.529 Å). In these units $\hbar$, $e$, and $m$ have the numerical value 1, and the quantum-mechanical equations assume a particularly simple form. For this reason, quantum-mechanical calculations are nearly always carried out in atomic units.

The larger a molecule, the more approximations have to be introduced in order to obtain a solution in a finite time. Since the accuracy attainable is rarely satisfactory even for small molecules, calculations on large molecules would be completely in vain unless one tried to compensate the crudeness of the approximations by semi-empirical adjustments. One deals then no longer with quantum-mechanical approximations but rather with *interpolation schemes.*

In this Part I, we looked at the methods of quantum chemistry from the physico-mathematical side. Our next task is to correlate the purely quantum-mechanical ideas with concepts known from experiment, such as valence, valence angle, bond length, electronegativity, inductive effect, *etc.* This brief (and rather simplified) survey of "mathematical" quantum chemistry will be followed by one of "interpretative" quantum chemistry. Neither aspect is independent of the other.

In this article an important tool in quantum chemistry is ignored, namely *group theory*, which allows us to take advantage of the symmetry properties of atoms and molecules [51]. The great value of group theory is that it yields information about the solutions of the Schrödinger equations irrespective of whether they can be calculated. Particularly in the early days of quantum theory, when numerical calculations were much more difficult than they are now, the importance of group-theoretical considerations could hardly be overestimated, *e.g.* for the interpretation of atomic spectra. The ligand field theory of metal complexes is still essentially applied group theory.

The scope of quantum-chemical research is very wide. It extends from the formal theory of the solutions of the Schrödinger equation and other abstract mathematical disciplines to the theory of the magnetic properties of matter, intermolecular interactions, and chemical reactivity, and from rigorous *ab initio* calculations on atoms and small molecules to the semi-empirical theory of biologically interesting macromolecules.

## A New Benzimidazole Cleavage with Subsequent Ring Closure [1]

By Prof. W. Ried and H. Lohwasser

Institut für Organische Chemie
der Universität Frankfurt/Main (Germany)

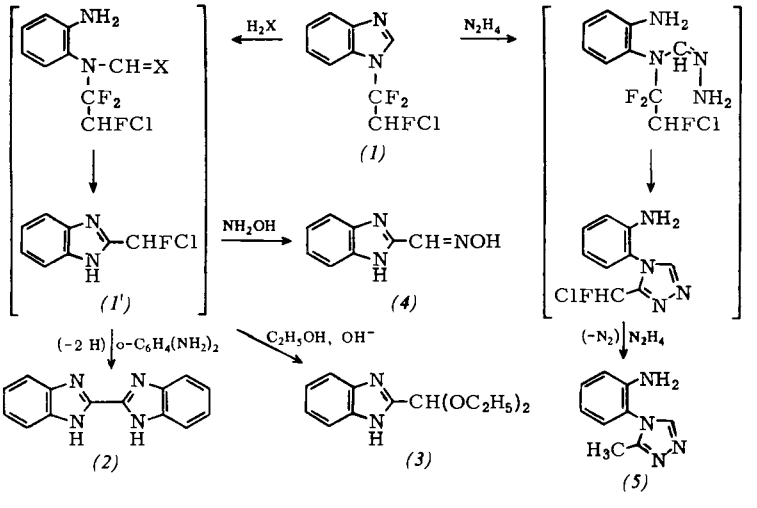
Benzimidazole is alkylated by trifluorochloroethylene in position 1 to give a liquid adduct *(1)*. The halogenoalkyl group is stable to alkaline or acid hydrolysis. Because of the strong electron attraction by the halogenoalkyl group the imidazole ring is attacked at position 2 by nucleophilic reagents $H_2X$ ($o$-$NH_2C_6H_4NH_2$, $C_2H_5OH/OH^-$, $NH_2OH$, or $N_2H_4$), with intermediate formation of *N,N*-disubstituted $o$-phenylenediamines. The active difluoromethylene group of these causes ring closure with the unsubstituted phenyl amino group [yielding a new benzimidazole *(1')*] or, if hydrazine hydrate is used, with the hydrazone amino group (yielding a triazole). Further reaction of the intermediate *(1')* with $o$-phenylenediamine and loss of hydrogen affords compound *(2)*.

Of the reactions with $o$-phenylenediamine to compound *(2)*, with alkoxide to *(3)*, with hydroxylamine to *(4)*, and with hydrazine to *(5)*, only the second and last are preparatively useful. Some analogous reactions have been observed for *N*-trifluorochloroethyl derivatives of 2-methylbenzimidazole, 2,3-naphthimidazole, and perimidine [1].

*N-(1,1,2-Trifluoro-2-chloroethyl)benzimidazole (1)*: 35 g of benzimidazole and 53 g of trifluorochloroethylene in 200 ml of anhydrous THF, when heated for 5 hr in an autoclave at 130–140 °C and distilled, give 61 g (88 %) of compound *(1)* as a colorless oil, b.p. 138 °C/12 mm.

*2,2'-Bibenzimidazolyl (2)*: 5 g of compound *(1)*, 10 g of $o$-phenylenediamine, and 15 g of ethanolamine in 50 ml of ethylene glycol, when boiled for 5 hr and then diluted with water, give 200 mg of compound *(2)* as pale yellow crystals, m.p. > 400 °C (from dilute acetic acid) [3].

*Benzimidazole-2-carbaldehyde diethyl acetal (3)*: 5 g of compound *(1)*, 10 g of potassium hydroxide, and 100 ml of ethanol, when boiled for 3 hr, freed from alcohol, and extracted with ether, afford 1.5 g (32 %) of compound *(3)* as colorless leaflets, m.p. 172 °C (173 °C [2]) (from water).



*Benzimidazole-2-carbaldehyde oxime (4)*: 6 g of compound *(1)* and 8 g of hydroxylamine hydrochloride in 30 ml of pyridine are boiled for 3 hr, then made alkaline with sodium carbonate; unchanged *(1)* is removed in steam, whereafter neutralization gives a small amount of compound *(4)* as colorless crystals, m.p. 302 °C (287 °C [2]) (from methanol/benzene).

*4-(o-Aminophenyl)-3-methyl-1,2,4-triazole (5)*: 30 g of compound *(1)* and 200 ml of 100 % hydrazine hydrate in 200 ml of ethylene glycol, when boiled for 15 hr and then extracted with methylene chloride, afford 15.6 g (73 %) of compound *(5)* (colorless leaflets, m.p. 164 °C, from benzene).

## Hydridopentakis(trifluorophosphine)rhenium [1]

By Prof. Th. Kruck and A. Engelmann

Anorganisch-Chemisches Laboratorium, Technische Hochschule München and Anorganisch-Chemisches Institut, Universität Köln (Germany)

Reduction of an ethereal solution of chloropentakis(trifluorophosphine)rhenium [2] (0.12 mole/l) with an excess of about 1 % potassium amalgam at 20 °C affords potassium pentakis(trifluorophosphine)rhenate, which on treatment with 88 % phosphoric acid forms $HRe(PF_3)_5$, the first hydrido-trifluorophosphine complex of a group VIIA metal. Use of $D_3PO_4$ affords the analogous deuterido compound.

$$ClRe(PF_3)_5 \xrightarrow[(C_2H_5)_2O]{K(Hg)} K[Re(PF_3)_5] \xrightarrow{H^{\oplus}} HRe(PF_3)_5$$

$HRe(PF_3)_5$ is, however, also directly accessible, in 40 % yield, by reduction of $ReCl_5$ with Cu powder (molar ratio *ca.* 1:40) at 300 °C with a $PF_3$ pressure of 250 atm and a $H_2$ pressure of 100 atm. It is purified by sublimation.

Hydridopentakis(trifluorophosphine)rhenium resembles the monohydrido compounds $HM(PF_3)_4$ of cobalt and iridium [3] in its high thermal and chemical stability. The colorless, centimeter-long needles of this hydrophobic compound (m.p. 42 °C, decomp. from 160 °C) sublime at 20 °C/10 mm and are stable for several days in dry air. The covalent nature of the Re–H bond is confirmed by an intense Re–H stretching vibration at 1882 (m) $cm^{-1}$ [4] [$\tilde{\nu}_{Re\text{-}D}$ = 1346 (m) $cm^{-1}$] and the strong chemical shift to high field of its broad $^1H$–NMR signal (no fine structure) [5] ($\delta$ = 8.2 ppm; TMS as internal standard). The P–F vibrations are at 971(w), 918 (vs), 877 (s), 869 (s), and 860 (m–s) $cm^{-1}$.

$K[Re(PF_3)_5]$ is a white, crystalline powder, readily soluble in ether and acetone and immediately hydrolysed by water to the weakly acidic $HRe(PF_3)_5$. In the P–F stretching region its IR spectrum [$\tilde{\nu}_{PF}$ = 942 (w), 930 (m), 912 (w), 863 (vs; broad), and 843 (vs, broad) $cm^{-1}$; in acetone] resembles those of the pentakis(trifluorophosphine) complexes $M(PF_3)_5$ where M = Fe, Ru, and Os, and thus indicates a trigonal-bipyramidal structure for the $[Re(PF_3)_5]^{\ominus}$ anion.

Small amounts of hydridopentakis(trifluorophosphine)manganese were also obtained by the reaction sequence:

$$IMn(CO)_5 \xrightarrow[180\,^{\circ}C]{450\ atm\ PF_3} IMn(PF_3)_3(CO)_2 \xrightarrow[(C_2H_5)_2O]{KHg}$$

$$K[Mn(PF_3)_3(CO)_2] \xrightarrow[H_2O]{450\ atm\ PF_3} HMn(PF_3)_5$$

It is a colorless liquid and was identified by its IR spectrum, which is almost the same as that of the rhenium compound [6]. Both the hydrido-trifluorophosphine compounds are more stable, thermally and against oxidizing agents, than the analogous hydrido-carbonyl complexes.

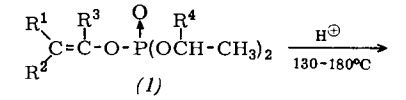
## Proton-Catalysed Cleavage of Enol Phosphates and Phosphonates

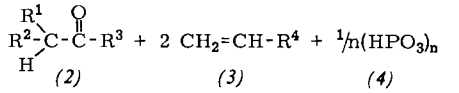
By Dr. K. Pilgram [*] and Dr. H. Ohse [**]

Shell Grundlagenforschung-Gesellschaft, Schloß Birlinghoven-Siegkreis (Germany)

Alkenyl di-sec-alkyl phosphates *(1)* are cleaved at 130 to 180 °C in the presence of catalytic amounts ($\leqslant$ 0.5 %) of concentrated sulfuric acid or *p*-toluenesulfonic acid to ketones *(2)*, alkenes *(3)*, and polymetaphosphoric acid *(4)*.



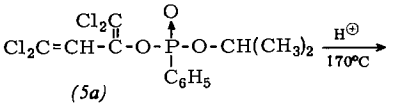
*(1)*



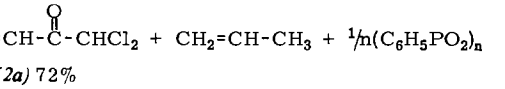
*(2)* *(3)* *(4)*

| $R^1$ | $R^2$ | $R^3$ | $R^4$ | *(2)*, Yield (%) |
|---|---|---|---|---|
| Cl | Cl | $-CH=CCl_2$ | $CH_3$ | 74.5 |
| Cl | Cl | $-CH=CCl_2$ | $C_2H_5$ | 61.2 |
| Cl | Cl | $-CCl=CCl_2$ | $C_2H_5$ | 96.3 |
| Cl | Cl | H | $CH_3$ | 75.0 |
| H | Cl | H | $CH_3$ | 33.3 |
| Cl | $CO-N(CH_3)_2$ | $CH_3$ | $CH_3$ | 73.7 |
| H | Cl | 2,4-Dichlorophenyl | $CH_3$ | 95.3 |
| H | H | 2,4-Dichlorophenyl | $CH_3$ | 36.7 |

Alkenyl sec-alkyl phosphonates, *e.g. (5a)*, react analogously:



*(5a)*



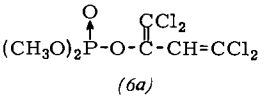
*(2a)* 72%

The rate of this reaction is determined primarily by the nature of the alkyl group and increases along the series:

$$CH_3 \ll C_2H_5 < C_3H_7, C_4H_9, C_5H_{11}, C_6H_{13} \gg \text{iso-}C_3H_7, \text{sec-}C_4H_9$$

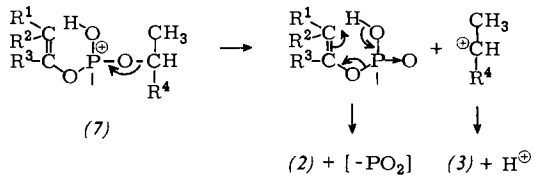
The same order applies to the tendency for olefin formation by dehydration of the corresponding alcohols.

In many cases this method seems to be superior to acid or alkaline hydrolysis of enol phosphates. For instance, none of the ketone *(2a)* is formed from the ester *(6a)* in 57 % sulfuric acid in 3 hr at 80 °C and only a 29 % yield after a further 3 hr at 95 °C. Acid-catalysed cleavage of the isopropyl or sec-butyl ester *(5)* at 170 °C, however, gives a 70 % yield of the ketone within a few minutes.



*(6a)*

It is probable that the phosphonium ion *(7)* formed as intermediate by protonation decomposes by way of an enol phosphoric acid and a carbonium ion into the ketone *(2)*, metaphosphate, olefin *(3)*, and a proton:



(7) → (2) + [-$PO_2$] (3) + $H^{\oplus}$

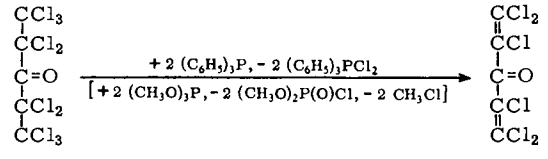
## Dehalogenation of Perchloroketones with Triphenylphosphine or Trialkyl or Triaryl Phosphites

By Dr. K. Pilgram[*] and Dr. H. Ohse[**]

Shell Grundlagenforschung-Gesellschaft,
Schloß Birlinghoven-Siegkreis (Germany)

Perchlorodivinyl ketone *(2)*, b.p. 69 °C/0.3 mm, $n_D^{20} = 1.5661$, $d^{20} = 1.6963$[2], is readily obtained (yield 91.2 %) by treatment of perchloro-3-pentanone *(1)*, b.p. 94–95 °C/0.6 mm, $n_D^{15} = 1.5682$, with triphenylphosphine in ether at 5 to 35 °C. The triphenylphosphine dichloride formed is advantageously converted into triphenylphosphine oxide by addition of water before isolation of the ketone *(2)*. Trimethyl phosphite and *(1)* afford dimethyl phosphorochloridate (yield 100 %) as well as the ketone *(2)* (yield 95.3 %). With both reagents there is a common intermediate whose retention time in gas chromatography lies between those of *(1)* and *(2)*; this compound is most likely perchloro(ethyl vinyl ketone).



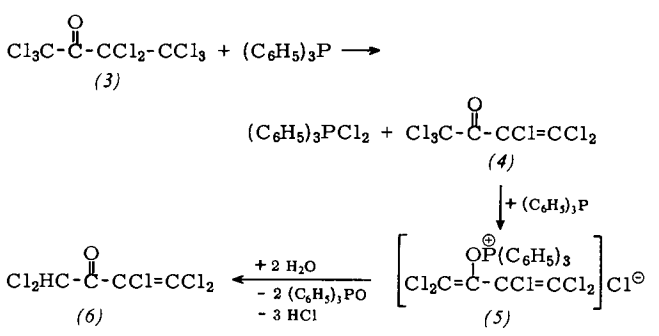
*(1)* → *(2)*

By analogy with the mechanism of dehalogenation[2] of α,β-dibromo compounds with trialkyl phosphites[3,4] and triphenylphosphine[5], we assume that the phosphine (or phosphite) first removes the chlorine atom α to the carbonyl group, this being followed by loss of a β-chlorine atom as an anion.

Perchlorobutanone *(3)* reacts equally smoothly with triphenylphosphine in ethereal solution and, after addition of water, gives 1,1,3,4,4-pentachloro-3-buten-2-one (yield 82.1 %; b.p. 89 °C/9 mm, $n_D^{20} = 1.5440$, $d^{20} = 1.6628$; ref.[6]: b.p. 99–100 °C, $n_D^{20} = 1.5442$). Trichloromethyl trichlorovinyl ketone *(4)* is formed in the first step of this reaction. A second mole of triphenylphosphine then reacts with *(4)* to give an enol phosphonium salt *(5)*, which is extremely sensitive to solvolysis and with water decomposes to 1,1,3,4,4-pentachloro-3-buten-2-one *(6)*, triphenylphosphine oxide, and HCl.

The ketone *(4)* is identical with a sample prepared by a different route[7]. Trialkyl phosphites react with *(3)* by an analogous first step, which leads to *(4)*, alkyl chloride, and dialkyl phosphorochloridate; then a second mole of trialkyl phosphite brings about a Perkow reaction.

Triphenyl phosphite reacts smoothly with *(3)* at room temperature, yielding triphenyl phosphorodichloridate and the ketone *(4)* (yield 96.3 %; b.p. 44 °C/0.2 mm, $n_D^{20} = 1.5319$).



An excess of triphenyl phosphite has no influence, so that the product *(4)* can be distilled continuously when the mixture is heated in an oil bath.

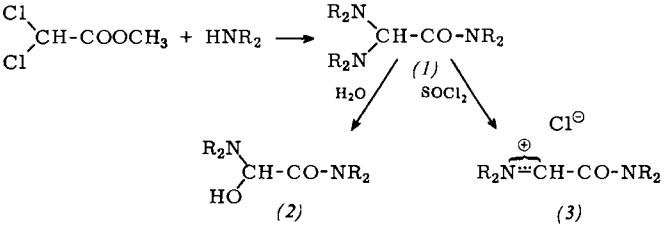
## Preparation of N-Functional Derivatives of Glyoxylic Acid

By Dr. H. Gross and Dr. J. Gloede

Institut für organische Chemie, Deutsche Akademie der Wissenschaften zu Berlin, Berlin-Adlershof (Germany)

Treatment of dichloroacetic ester with piperidine gives 1-(dipiperidinoacetyl)piperidine *(1a)*, m.p. 87–89 °C, yield 90 %. The morpholine derivative *(1b)*, m.p. 120–122 °C, is obtained analogously (yield 70 %). Both compounds are quite stable in closed vessels but, when kept in air or when recrystallized from aqueous solvents (*e.g.* DMF) are converted into the compounds *(2a)*, m.p. 60–61 °C, yield 89 %), and *(2b)*, m.p. 86–87 °C, yield 72 %, respectively, stable compounds that crystallize well. The OH band of *(2a)* occurs at 3366 $cm^{-1}$ (KBr disc; half-width 17.5 $cm^{-1}$) or at 3420 $cm^{-1}$ (in $CCl_4$; half-width 87 $cm^{-1}$)[1].

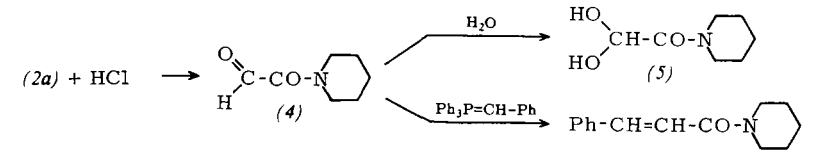


*(a)*, $R_2$ = -$(CH_2)_5$-

*(b)*, $R_2$ = -$(CH_2)_2$-O-$(CH_2)_2$-

Dropping of thionyl chloride into an etheral solution of compound *(1a)* or *(1b)* causes almost quantitative precipitation of the carbenium-imonium salt *(3a)* or *(3b)*, respectively, which can be used for aminomethylations[2].

If compound *(2a)* is treated with 1 mole of ethereal HCl, yields of up to 62 % of 1-glyoxyloylpiperidine *(4)* can be isolated[3] (amide band at 1647 $cm^{-1}$; aldehyde band at 1722 $cm^{-1}$; solvent-free liquid). This product is stable, in contrast to the unstable esters of glyoxylic acid. It forms a stable hydrate *(5)* [m.p. 86–89 °C; amide band at 1653 $cm^{-1}$; OH band at 3362 $cm^{-1}$ (H bonds); KBr disc]. It reacts with benzylidenetriphenylphosphorane, yielding 1-cinnamoylpiperidine (m.p. 119–120 °C; ref.[4] gives 122 °C; no depression with authentic sample).



*1-(2-Piperidinoglycoloyl)piperidine (2a)*:

Methyl dichloroacetate (0.1 mole) and piperidine (0.5 mole) are heated at 110 °C for 2 hr. After cooling, the mixture is extracted with three portions each of 50–60 ml of anhydrous ether, and the ethereal solution is evaporated to dryness. The crude product *(1a)* is dissolved in 50 ml of hot dimethylformamide and treated with 120 ml of water and 0.5 ml of 2 N HCl. Compound *(2a)* separates on cooling. It is recrystallized from dimethylformamide/water; m.p. 60–61 °C.

*1-Glyoxyloylpiperidine (4)*:

Compound *(2a)* (0.1 mole) is dissolved in 100 ml of anhydrous ether, and 24 ml (0.1 mole) of 16 % ethereal HCl is added dropwise at 0 °C. The precipitated piperidinium chloride is removed. The solution is evaporated and then distilled in a high vacuum, affording the product, b.p. 74–76 °C/0.02 mm.

## Poly-4-vinyltriphenylmethyl Polyradicals

By Prof. D. Braun and R. J. Faust

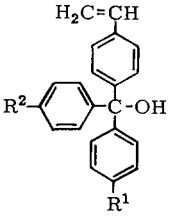
Deutsches Kunststoff-Institut, Darmstadt (Germany)

The following monomers were synthesized (in yields of 50 to 70 %) for the preparation of stable carbon polyradicals[*]:
4-Vinyltriphenylmethanol *(1)*, m.p. 75 °C, by reaction of *p*-vinylphenylmagnesium chloride with benzophenone[1];
4-Phenyl-4′-vinyltriphenylmethanol *(2)*, m.p. 74 °C, by the analogous reaction with 4-phenylbenzophenone;
4,4′-Diphenyl-4″-vinyltriphenylmethanol *(3)*, m.p. 95 °C, by analogous reaction with 4,4′-diphenylbenzophenone.

Compounds *(1)* to *(3)* undergo radical polymerization extremely easily and substantially faster than styrene. The rate of polymerization, and at the same time the tendency (presumably due to chain transfer) to cross-linking during polymerization, increase in the order *(1)*, *(2)*, *(3)*. Radical copolymerization with styrene is also much faster than homopolymerization of styrene under the same conditions; the proportion of cross-linked products decreases with increasing styrene content in the monomer mixture and with decreasing monomer concentration.

The homopolymers of *(1)*, *(2)*, and *(3)*, and the copolymers with styrene, react with acetyl chloride, yielding poly-4-vinyltriphenylmethyl chlorides. However, radical polymerization of 4-vinyltriphenylmethyl chlorides could not be achieved.

*(1)*, $R^1 = R^2 = H$
*(2)*, $R^1 = H$, $R^2 = C_6H_5$
*(3)*, $R^1 = R^2 = C_6H_5$



Treatment of the polymeric triphenylmethyl chlorides in benzene solution with incompletely anhydrous zinc powder gives polycations instead of polyradicals, as shown by the absorption spectra in the visible spectral region. These polyions owe their origin to the formation of a strong Lewis acid from traces of water and the zinc chloride formed. The Lewis acid and the still unchanged triphenylmethyl groups of the polymers form cations and hydrogen chloride, which reacts further with the primarily formed radicals, affording triphenylmethyl and chlorotriphenylmethyl groups. Since radical formation is slow, use of the incompletely dry systems results almost exclusively in the faster formation of polycations. However, if the zinc powder is previously treated with potassium-benzophenone solution in benzene until the solution is no longer decolorized, and if the zinc is then well washed with anhydrous benzene, the product can be used for the preparation of polyradicals. Use of potassium is still more effective: no polyanions are then obtained since anion formation is extremely slow. Use of potassium in benzene and dilute solutions (about 5 g/l of poly-4-vinyltriphenylmethyl chloride) leads to soluble polyradicals, but at higher concentrations (about 30 g/l) insoluble, strongly swollen gels are obtained which contain intermolecular hexaphenylethane groups.

The polyradicals react with oxygen and with iodine similarly to their monomeric analogues.

The polyradicals were detected in benzene solution by their ESR spectra; in contrast to the spectra of monomeric triphenylmethyl radicals, these show practically no fine structure, a phenomenon that must be attributed to the high local concentration of radicals in the individual macromolecular coils and to their mutual interaction. The radical concentrations determined by ESR spectroscopy, and the degrees of polymerization determined osmometrically, indicate that on an average every third to fourth monomer unit is a free radical; each macromolecule contains about 100 unpaired electrons.

Received: July 4th, 1966 [Z 290 IE]
German version: Angew. Chem. *78*, 905 (1966)

[*] We propose this designation, in analogy with di- and triradicals, for macromolecules of which numerous monomer units have unpaired electrons; the designation macroradical should, however, be reserved for macromolecules containing only one (usually terminal) unpaired electron.

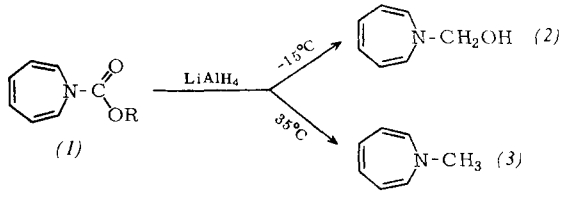
## Dimerization of 1-Methylazepine

By Prof. K. Hafner and J. Mondt[1]

Institut für Organische Chemie, Universität München, and Technische Hochschule Darmstadt (Germany)

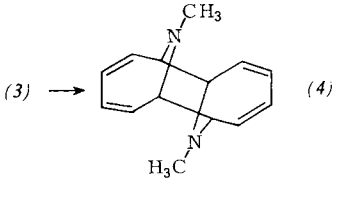
The preparation of alkyl 1-azepinecarboxylates *(1)* by photolysis or thermolysis of azidoformates in benzene or its derivatives has enabled us to study the monocyclic azepine system[2]. On reduction of *(1)*, R = $C_2H_5$, with $LiAlH_4$ in ether at −15 °C we obtained 1-azepinemethanol *(2)*[3] in *ca.* 45 % yield as a thermally unstable, pale yellow oil



*(1)* *(2)* *(3)*

[UV spectrum (in *n*-hexane): $\lambda_{max}$ = 232 mμ, shoulder at 255 mμ], which was isolated as picrate (decomp. > 100 °C)[4]. In boiling ether the same reduction leads to 1-methylazepine *(3)*[3] in 60 % yield as a thermally rather unstable, yellow oil [b.p. 20 °C/$10^{-3}$ mm; structureless UV spectrum, with ε rising towards shorter wavelengths and $\lambda_{max}$ = 236 mμ (ε = 5100) with shoulders at 249 mμ (ε = 4020), 258 (3660), 288 (1950), and 384 (65) (in n-hexane); NMR spectrum (in $CCl_4$), singlet at 7.55 τ ($CH_3$), multiplet at 5.0 to 5.5 τ (6 ring protons)]. Catalytic hydrogenation (Raney Ni; 20 °C) of the azepine *(3)* leads to hexahydro-1-methylazepine[5].

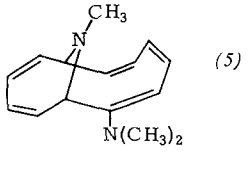
The azepine *(3)* dimerizes rapidly in ether above 0 °C, yielding the colorless 13,14-dimethyl-13,14-diazatricyclo-[6.4.1.$1^{2,7}$]tetradeca-3,5,9,11-tetraene *(4)*, m.p. 171 °C, $\lambda_{max}$ (in n-hexane) = 230 mμ (ε = 15680), 237.5 (16600), and was purified by chromatography with ether on $Al_2O_3$ and recrystallization from methanol[6]. The structure of this dimer follows from the NMR spectrum (in $CDCl_3$), which shows a singlet for the 6 methyl protons at 7.8 τ, a doublet for the 4 bridgehead protons at 6.7 τ, and a multiplet for the 8 olefinic protons centered at 4.1 τ. The dipole moment of the dimer is 0.5 D, which indicates the *trans*-form for *(4)*[7]. The mass spectrum[8] confirms the molecular weight (214); the signal of greatest intensity is at *m/e* 107, which indicates preferential decomposition of *(4)* to the monomer *(3)*; the lower *m/e* values form a pattern characteristic for further decomposition of *(3)*. On catalytic hydrogenation, the dimer *(4)* takes up the amount of $H_2$ calculated for 4 double bonds[8a].



*(3)* → *(4)*

We suggest that dimerization of *(3)* occurs in several stages. 1,3-Dipolar addition of *(3)*, which can be formulated as an azomethine ylide, is improbable in view of the rules of *Woodward* and *Hoffmann*[9].

With hydrogen bromide, the dimer *(4)* gives a dihydrobromide (colorless leaflets, decomp. 240 °C), but with styphnic or picric acid it gives only the monoprotonated product



*(5)*

(styphnate, decomp. 196 °C; picrate, decomp. 195 °C). With methyl iodide in boiling methanol (60 hr) it gives a monomethiodide (decomp. 195 °C), which is converted by Hofmann degradation into the cyclododecapentaene derivative *(5)*, which forms a yellow oil with $\lambda_{max}$ (in n-hexane) = 249.5 mμ; NMR spectrum (in $CCl_4$): two singlets at 7.6 and 7.8 τ (3 $CH_3$), a multiplet centered at 7.15 τ (2 bridgehead protons), and a multiplet centered at 4.15 τ (9 olefinic ring protons).

## Transport Reactions of Silicides and Borides of Transition Metals

By Dr. J. Nickl, M. Duck, and J. Pieritz

Forschungslaboratorium für Festkörperchemie, Institut für anorganische Chemie, Universität München (Germany)

We have grown single crystals of silicides and borides by chemical transport reactions. The transport vessels used were silica ampoules (10 mm in diamter, 100 mm in length) in which the starting material was placed at the hot end. The reagents were the elements in massive form or powdered silicides or borides. Chlorine, bromine, or iodine at a pressure of 5 to 120 mm Hg and 20 °C served as gases for both reaction and transport. Before addition of the halogen the ampoules containing the starting material were heated at $10^{-4}$ to $10^{-5}$ mm; the ampoules were sealed off at a pressure of *ca.* $10^{-5}$ mm in an oxyhydrogen flame. The time for transport was 2 to 22 days. The crystals (volume several $mm^3$) obtained were investigated by stereography and X-ray diffraction and finally their stoichiometry was determined by analysis.

The following compounds were found as well-formed single crystals at the *cool* end of the tubes: $TiS_2$, $VSi_2$, $CrSi_2$, $Cr_3Si$, $NbSi_2$, $TaSi_2$, $TiB_2$, $VB_2$, $CrB_2$, CrB, and $ZrB_2$. However, silicides were not obtained from Zr ($ZrSi_2$ – this and other entries in parentheses are starting materials), W (W + Si, $WSi_2$), U (U + Si), and no boride from Nb (NbB), Hf ($HfB_2$), Ta (TaB), or W (WB); in these cases only well-crystallized silicon was formed at the cool end from silicides, and no transport was observable from borides.

Crystals formed at cool end of transport tube.

| Starting materials | Time (days) | Crystals found: Approx. vol. ($mm^3$) | Structure | Lattice parameters (Å) |
|---|---|---|---|---|
| $TiSi_2$ [a] Ti + Si [b] | 2 | $TiSi_2$ 10 | orthorh. ($D_{2h}^{24}$) | $a = 8.24$ $b = 4.77$ $c = 8.52$ |
| $VSi_2$ | 9 | $VSi_2$ 1 | hexag. ($D_6^4$) | $a = 4.56$ $c = 6.36$ |
| $NbSi_2$ [a] | 10 | $NbSi_2$ 1 | hexag. ($D_6^4$) | $a = 4.78$ $c = 6.58$ |
| $TaSi_2$ [c] | 10 | $TaSi_2$ 1 | hexag. ($D_6^4$) | $a = 4.77$ $c = 6.55$ |
| $CrSi_2$ [c] | 9 | $CrSi_2$ 10 | hexag. ($D_6^4$) | $a = 4.42$ $c = 6.35$ |
| Cr + Si [a] | 10 | $Cr_3Si$ 10 | cubic ($O_h^3$) | $a = 4.55$ |
| $TiB_2$ [c] | 5–22 | $TiB_2$ tiny needles | hexag. ($D_{6h}^1$) | $a = 3.03$ $c = 3.23$ |
| $ZrB_2$ [c] | 22 | $ZrB_2$ tiny crystals | hexag. ($D_{6h}^1$) | $a = 3.17$ $c = 3.53$ |
| $VB_2$ [c] | 5–7 | $VB_2$ tiny prisms | hexag. ($D_{6h}^1$) | $a = 3.00$ $c = 3.06$ |
| $CrB_2$ [a] | 15 | $CrB_2$ | hexag. ($D_{6h}^1$) | $a = 2.97$ $c = 3.07$ |
| CrB [c] | 15 | CrB | orthorh. ($D_{2h}^{17}$) | $a = 2.97$ $b = 7.86$ $c = 2.93$ |

Max. temperature (°C): [a] 1050 ($\Delta T \approx 200$); [b] 900 ($\Delta T \approx 150$); [c] 1100 ($\Delta T \approx 120$–150).

At the *hot* end, powders of $TiSi_2$, $VSi_2$, and $CrSi_2$ were partly converted into well-formed crystals, which were larger than those grown at the cool end. When massive chromium and silicon were used, well-formed $Cr_3Si$ crystals grew from both elements; the same crystals grew at the cool end. No mineralization was observed with boride powders.

Crystals grown at the hot or the cool end have highly reflecting faces of low index. Only with $TiSi_2$ was there a tendency to formation of stepped {111} faces (Hopper effect). Transport of the borides was more than about five times slower than that of silicides.

## Elimination of Hydrogen Sulfide from Ferredoxin and Cysteine Methyl Ester[*]

By Prof. Ernst Bayer and W. Parr

Chemisches Institut, Universität Tübingen (Germany)

After we had shown that hydrogen sulfide is easily eliminated from cysteine esters and cysteinyl-peptides in the presence of iron salts[1], we attributed the "labile sulfur" in ferredoxin – which is regarded by *Rabinowitz et al.*[2] as "inorganic sulfide" – to elimination of $H_2S$ from the cysteine residues in the ferredoxin. *Malkin* and *Rabinowitz*[3] have recently opposed this view because, contrary to our findings, they failed to obtain $H_2S$ from cysteine methyl ester or from glutathione and, moreover, could not detect dehydroalanine in the ferredoxin. – This contradiction is hard to understand, since β-elimination of $H_2S$ from cysteine methyl ester is a very simple experiment and we identified dehydroalanine in ferredoxin after the elimination of $H_2S$ by three independent methods.

Under the following conditions[**] cysteine methyl ester, in the presence of iron salts, eliminates 1 mole of $H_2S$ per mole of iron salt:

For formation of the cysteine methyl ester-iron complex, solutions of 17.1 mg of cysteine methyl ester hydrochloride in 1 ml of oxygen-free distilled water and of 19.6 mg of Mohr's salt in 1 ml of oxygen-free distilled water are mixed in a 25-ml round-bottomed flask. After addition of 5 ml of 0.5 M Tris hydrochloride buffer (pH 7.30), the mixture is boiled for 15 to 20 min under a reflux condenser to which is attached a Péligot tube containing 7 ml of *p*-amino-*N*,*N*-dimethylaniline reagent (0.5 g of the amine hydrochloride in 500 ml of 5.5 N HCl). For determination of the hydrogen sulfide[4], the Péligot tube is removed and the condenser rinsed down with 15 ml of distilled water. The cooled sample (solution and precipitate) is placed in a 500-ml volumetric flask containing 260 ml of 1.3 % zinc acetate solution and 10 ml of 12 % sodium hydroxide solution. Then 50 ml of *p*-amino-*N*,*N*-dimethylanilinium chloride solution containing the reagent solution from the Péligot tube is added, and the flask is stoppered and shaken until the precipitate has dissolved. After about 10 min, 10 ml of a 0.023 M solution of $FeCl_3$ in 1.2 N HCl is added. The mixture is set aside for 15 min and then made up to the mark with distilled water. After a further 30 min the extinction at 670 mμ is determined. In more than 50 experiments, 1.60 ± 0.10 mg of $H_2S$ was found, corresponding to a molar ratio of added iron salt: $H_2S$ = 1:0.94 ± 0.06. This is exactly the ratio of iron to "labile sulfur" found in ferredoxin.

When the reaction was carried out without Mohr's salt, only 0.38 ± 0.05 mg of $H_2S$ was found. This shows that the reaction is catalysed by formation of the iron complex. Since ferredoxin is an iron complex of a cysteine-rich polypeptide, an analogous reaction must be assumed to occur. $H_2S$ is also eliminated if the iron complex of cysteine methyl ester is prepared without boiling, namely by mixing the solutions and setting them aside in a beaker at room temperature for 16 to 24 hr; however, as a result of incomplete formation of the chelate, and also as a result of side reactions, yields are then only about 20 % of those obtained by the procedure given above. Elimination of $H_2S$ from cysteine methyl ester does not require base catalysis and occurs even in a neutral medium.

On elimination of $H_2S$ from ferredoxin a dehydroalanyl-peptide is formed, from which pyruvic acid should be obtained on total hydrolysis. *Malkin* and *Rabinowitz*[3] were unable to detect pyruvic acid after ferredoxin had been heated with 3 N HCl on the water bath for 1 hr. However, if ferredoxin is treated – as is usual in protein hydrolyses – with 6 N HCl under nitrogen for 24 hr at 110 °C, then 1 mg affords 27.5 μg of pyruvic acid, which can be determined enzymatically with lactate dehydrogenase and NADH. In view of the lability of dehydroalanine under the conditions of hydrolysis the yield of about 30 % of pyruvic acid (calculated for 5 moles $H_2S$ eliminated per mole of ferredoxin of molecular weight 6000) is satisfactory, although it permits no quantitative conclusions to be drawn.

A substantially better method for detection of dehydroalanine consists in reduction of the dehydroalanyl-peptide to the alanyl-peptide with sodium borohydride and subsequent amino-acid analysis[5,6]. As the cysteine content decreases, so the alanine content must increase.

If 1 mg of ferredoxin from *Clostridium pasteurianum* is treated with sodium borohydride under the conditions described by *Pigman et al.*[6], then treated with performic acid by *Hirs*'s technique[7], and hydrolysed with 2 ml of 6 N HCl for 24 hr at 110 °C, the following values are obtained for cysteine and alanine:

1 mg of ferredoxin, 5 days at 22 °C in 1 ml of 0.2 N NaOH containing 11.3 mg ($0.3 \times 10^{-3}$ mole) of $NaBH_4$, then oxidation with performic acid and subsequent hydrolysis:
cysteic acid, 0.176 μmole; alanine, 1.410 μmole.

1 mg of ferredoxin, 8 days at 5 °C in 1 ml of 0.1 N NaOH containing 11.3 mg of $NaBH_4$ ($0.3 \times 10^{-3}$ mole), then oxida-

tion with performic acid and subsequent hydrolysis:
cysteic acid, 0.246 μmole; alanine 1.308 μmole.

1 mg of ferredoxin, only treated with performic acid and then hydrolysed:
cysteic acid, 0.772 μmole, alanine 0.974 μmole.

It can be seen that about 0.4 μmole of cysteine is converted into alanine during the elimination of $H_2S$. The other amino acids are unaffected by these processes.

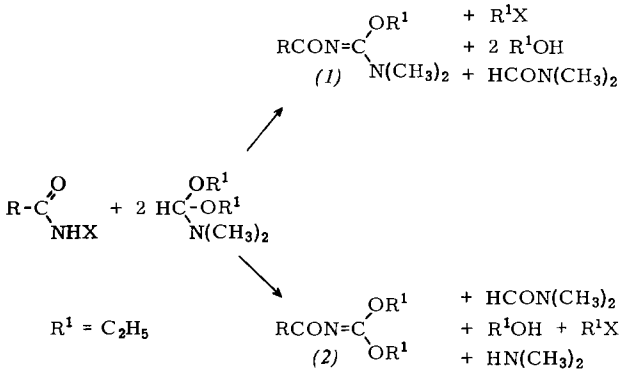
## Preparation of O,N-Acetals of Acyl Isocyanates

By Prof. H. Bredereck, Dr. G. Simchen, and H. Porkert

Institut für Organische Chemie,
Technische Hochschule, Stuttgart (Germany)

Numerous classes of compound that form addition compounds with tertiary amines can substitute dialkylformamide acetals on the formyl-carbon atom[1,2].

We have treated *N*-halogenocarboxamides (as nitrene precursors) with dialkylformamide acetals and have obtained good yields of *O,N*-acetals *(1)* of acyl isocyanates in an exothermic reaction that is, formally, an electrophilic substitution of the formyl-hydrogen atom. For complete reaction one mole of *N*-halogenocarboxamide requires 2 moles of dialkylformamide acetal, of which, however, 1 mole may be replaced by another tertiary amine. Side reactions occasionally afford, alongside *(1)*, *O,O*-acetals *(2)* of the acyl isocyanates.



| R | X | (1) Yield (%) | (1) B.p. (°C/mm) | (2) Yield (%) | (2) B.p. (°C/mm) |
|---|---|---|---|---|---|
| $CH_3$ | Cl | 75 | 52/0.1 | – | – |
| $C_2H_5$ | Cl | 39 | 55–56/0.1 | 15 | 45–48/0.1 |
| n-$C_3H_7$ | Cl | 44 | 72–75/0.1 | 20 | 58–60/0.1 |
| i-$C_3H_7$ | Cl | 41 | 80–85/1.0 | 21 | 56/0.1 |
| $CH_3$ | Br | 67 | 52/0.1 | – | – |
| $C_2H_5$ | Br | 51 | 55–57/0.1 | – | – |
| i-$C_3H_7$ | Br | 53 | 80–84/1.0 | – | – |

Experiments with compounds of type R(R')CHX, which can be considered as carbene precursors, lead analogously to ketene *O,N*-acetals[3].

*Experimental*: 0.1 mole of carboxylic acid *N*-halogenoamide is mixed with 0.2 to 0.3 mole of dimethylformamide *O,O*-diethyl acetal or with 0.1 mole of the latter and 0.1 mole of triethylamine, with exclusion of moisture and with stirring and cooling (10 °C). An insoluble oil first formed soon dissolves while the solution becomes warm. The mixture is then heated for 2 hr at 80 °C and fractionated in vacuum.

## Triazidomethylium Hexachloroantimonate, $[C(N_3)_3]^+[SbCl_6]^-$

By U. Müller and Dr. K. Dehnicke

Laboratorium für Anorganische Chemie,
Technische Hochschule, Stuttgart (Germany)

Because of the energy-rich azide groups, heavy-metal azide halides can undergo various reactions[1]. The compound $[SbCl_4N_3]_2$, which is accessible from $SbCl_5$ and trimethylsilyl azide[2], chlorazide[3], or hydrogen azide[4], reacts when left in boiling $CCl_4$ (1 hr) with formation of the hitherto unknown triazidomethyl cation as hexachloroantimonate in 90 % yield. The salt, pale yellow, slightly hygroscopic needles, insoluble in nonpolar solvents and sensitive to shock or rapid heating, m.p. 145 °C (decomp.), is isolated by filtration.

$$3\ SbCl_4N_3 + CCl_4 \rightarrow [C(N_3)_3]^+[SbCl_6]^- + 2\ SbCl_5$$

The IR spectrum indicates that the cation $[C(N_3)_3]^+$ has $C_{3v}$ symmetry. The three α-N atoms and the carbon atom are coplanar and the azido groups are bent in the same sense at the α-N atoms. The planar arrangement results from $sp^2$ hybridization at the carbon atom, the resonance stabilization corresponding to that of the guanidinium cation. Accordingly, the characteristic IR absorption of the $CN_3$ grouping agrees substantially with that of the guanidinium ion[5].

Characteristic frequencies (in $cm^{-1}$) of the $CN_3$ grouping in $[C(N_3)_3]^+$ and $[C(NH_2)_3]^+$.

| Class | Type | $[C(N_3)_3]^+$ | $[C(NH_2)_3]^+$ |
|---|---|---|---|
| E | $\nu_{as}$ $CN_3$ | 1565 | 1670 |
| $A_1$ | $\nu_s$ $CN_3$ | 1030 | 1010 |
| $A_1$ | $\gamma$ $CN_3$ | 788 | 720 |
| E | $\delta$ $CN_3$ | 529 | 530 |

The four azide stretching vibrations of the ion $[C(N_3)_3]^+$ expected because of its $C_{3v}$ symmetry are 2285 ($\nu_{as}$, $A_1$), 2190 ($\nu_{as}$, E), 1221 ($\nu_s$, $A_1$), and 1050 $cm^{-1}$ ($\nu_s$, E). The IR-active, very characteristic absorption bands[6] of class $F_{1u}$ for the $[SnCl_6]^-$ anion occur at 339 ($\nu_{as}$) and 172 $cm^{-1}$ ($\delta_{as}$). A compound $N{\equiv}C{-}N{=}C(N_3)_2$, which is isoelectronic with $[C(N_3)_3]^+$ and probably has an analogous structure, has been obtained from BrCN and $NaN_3$[7,8].

## Monomeric Boron Imides

By Dr. P. I. Paetzold and W. M. Simson

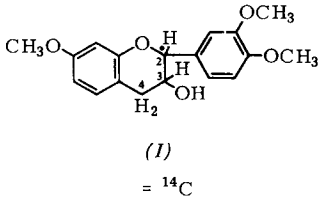
Institut für Anorganische Chemie,
Universität München (Germany)

When dichloro(pentafluorophenyl)borane and an equivalent amount of an aromatic amine are kept in boiling benzene for 2 days, they afford the monomeric boron imides *(1)* and *(2)* in 73 and 83 % yield, respectively, together with the calculated quantities of HCl:

$$C_6F_5BCl_2 + ArNH_2 \rightarrow 2\,HCl + C_6F_5B{=}NAr$$

*(1)*, Ar = *p*-$CH_3O$–$C_6H_4$–

*(2)*, Ar = mesityl



*(1)*

= $^{14}C$

The product *(1)* is accompanied, in 13 % yield, by the dimer $(C_6F_5B{-}N{-}C_6H_4{-}OCH_3)_2$ *(3)*, which is a further representative of the series of 1,3,2,4-diazadiboretidines[1–3], but formation of *(2)* is not accompanied by that of the dimer, presumably for steric reasons. Compounds *(1)*, *(2)*, and *(3)* were characterized by elemental analyses and by cryoscopic and osmometric determinations of molecular weight in benzene.

The Raman spectrum of *(1)* includes an intense band at 1703 $cm^{-1}$ with a subsidiary band at 1710 $cm^{-1}$, which we assign to the $^{11}BN$ and $^{10}BN$ stretching vibrations. From the observation that the BN vibration (but not its overtone at 3400 $cm^{-1}$) is IR-inactive we conclude that the BN bond in compound *(1)* is nonpolar and that the BN vibration is independent of the neighboring polar groups. The nonpolarity of the BN bond is assumed to be caused by the strong electron attraction of the $C_6F_5$ group, which not only draws negative charge from the N atom but also strengthens the two possible BN π-bonds.

With pyridine in benzene, compound *(1)* forms a colorless, crystalline 1:1 adduct. Treatment of compound *(1)* with a solution of HCl in diethyl ether cleaves it to *p*-methoxyanilinium chloride and $C_6F_5BCl_2$; the latter is obtained in only moderate yield. With dimethyl 1,2,4,5-tetrazine-3,6-dicarboxylate in dioxane, compound *(1)* reacts with liberation of nitrogen and formation of a compound of formula $C_{19}H_{13}O_5N_3F_5B$ (colorless crystals from benzene), which seems to be the product of a Diels-Alder-type reaction with *(1)* as a dienophile.

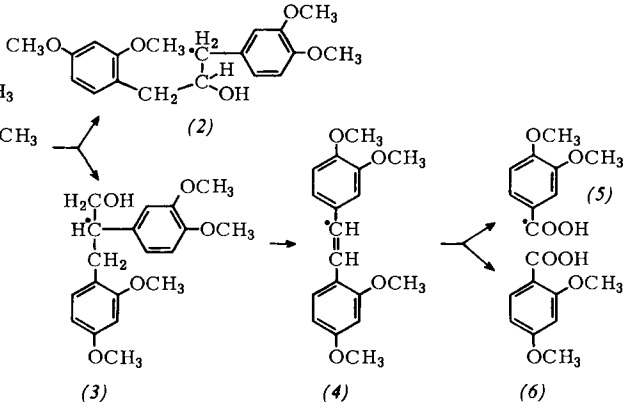
## Mechanism of the Rearrangement of Flavan Derivatives on Reduction with $LiAlH_4/AlCl_3$

By Dr. K. Weinges and F. Nader

Organisch-Chemisches Institut,
Universität Heidelberg (Germany)

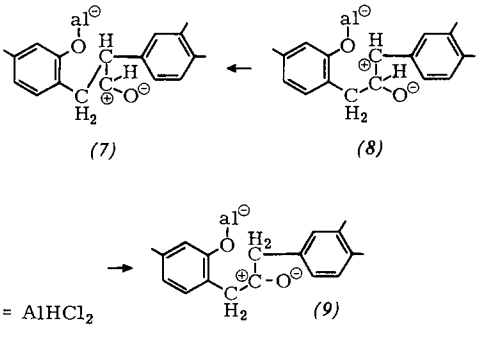
When a flavan containing a 4′-methoxy and a free 3-hydroxy group is reduced with $LiAlH_4/3AlCl_3$, the 1,3-diaryl-2-propanol derivative produced is accompanied by a rearrangement product, namely, the derivative of a 2,3-diaryl-1-propanol[1]. We have studied the course of the rearrangement by means of [2–$^{14}C$]-3′-,4′,7-trimethoxy-3-flavanol *(1)*.

When *(1)* is reduced with $LiAlH_4/3\,AlCl_3$ in tetrahydrofuran and the product is methylated with diazomethane in ether, the compounds *(2)* and *(3)* are formed in the molar ratio 2.3:1 and with a total yield of 61 %. To elucidate the position of the $^{14}C$, the product *(3)* was oxidized to the acid which was then degraded according to the Curtius reaction. The resulting amine gave, on Hofmann elimination, the stilbene *(4)*, oxidation of which afforded veratric acid *(5)* and *O,O*-dimethylresorcylic acid *(6)*. The acids were separated as diphenylmethyl esters. Only the veratric acid *(5)* was radioactive, *i.e.* C-4 of the flavanol must migrate from C-3 to C-2.



*(2)* *(3)* *(4)* *(5)* *(6)*

Probably the hydridodichloroaluminum $AlHCl_2$ formed from $LiAlH_4/3AlCl_3$ attacks the benzyl ether oxygen atom, yielding the carbenium ion *(8)*, which yields the more stable carbenium ions *(7)* and *(9)*. The ion *(7)* arises by migration from C-4, the nucleophilicity of this C atom playing a large part in controlling the yield of *(3)* [the molar ratio *(2)*:*(3)* is 1.2:1 if a further $OCH_3$ group is attached to C-5]. The ion *(9)* arises by hydride shift; that this actually occurs is shown



*(7)* *(8)* *(9)*

al = $AlHCl_2$

by reduction of the flavan *(1)* with $LiAlD_4/3AlCl_3$; it was proved by mass spectrometry and NMR spectrometry that the deuterium in compound *(2)* is then attached to C-2 and C-3 (flavan numbering) in the atomic ratio 3:2.

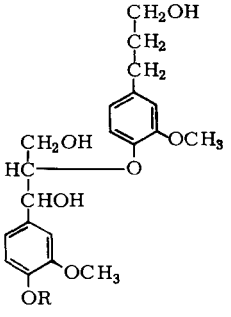
## A New Type of Rearrangement in the Lignin Field

By Dr. H. Nimz

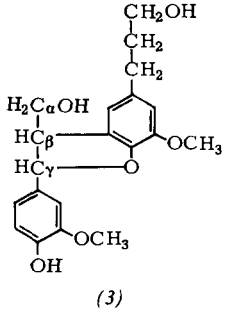
Organisch-Chemisches Institut der Universität und Forschungsinstitut für die Chemie des Holzes und der Polysaccharide, Heidelberg (Germany)

According to present conceptions lignin consists of phenylpropane units linked by C—C and C—O bonds. Glycerol β-aryl ether linkages and phenylcoumaran units are among the most important types of linkage involved.

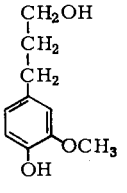
In model experiments on the degradation of lignin we have found a new rearrangement between these two types of linkage. If α-(4-hydroxy-3-methoxyphenyl)glycerol β-dihydroconiferyl ether *(1)* (300 mg) is heated with water (70 ml) under nitrogen for 7 days at 100 °C in a sealed tube, the phenylcoumaran *(3)*[1] (32 %) and dihydroconiferyl alcohol *(4)* (41 %) are formed. Two higher-molecular phenols, whose structures have not yet been determined, can be detected by chromatography as by-products. The ratio of the yields of *(3)* and *(4)* increases with dilution of the starting materials. A corresponding result is obtained if α-(4-hydroxy-3-methoxyphenyl)glycerol β-coniferyl ether [compound *(1)* but with an unsaturated side chain] is heated with water but the methyl ether *(2)* is unchanged under these conditions.



*(1)*, R = H
*(2)*, R = $CH_3$



*(3)*



*(4)*

The rearrangement *(1)* → *(3)* has so far been observed only under the conditions described above. When heated with 2 N NaOH, compound *(1)* gives a styryl ether with loss of water and formaldehyde[2,3]; on using hot, dilute mineral acid (0.2 N HCl in dioxane/water[4]) we obtained from *(1)* neither the compound *(3)* nor products formed therefrom. The course of acetolysis of *(1)* with acetyl bromide is obscure, whereas with acetic anhydride/$BF_3$ nuclear acylation results[5].

## Color of Solutions of Aluminum Bromide in Benzenoid Hydrocarbons

By Prof. H.-H. Perkampus and G. Orth

Abteilung für Molekülspektroskopie, Institut für Organische Chemie, Technische Hochschule Braunschweig (Germany)

In the presence of protons, aromatic compounds and Lewis acids form proton-addition complexes[1] which are responsible for the color of the solutions. However, the π-complexes are supposed to be colored even in absence of protons; *e.g.*, *Brown et al.*[2] state that the complex benzene/$Al_2Br_6$ is pale yellow and the complex mesitylene/$Al_2Br_6$ orange-yellow.

We observed no coloration when such solutions were prepared in a high vacuum with thorough drying of the solvent (over potassium) and of the apparatus. Above 323 mμ the extinction of solutions of $Al_2Br_6$ in benzenoid hydrocarbons is essentially zero.

A criterion for the water content of the benzene used is its conductivity; that of completely anhydrous benzene is $8\times10^{-15}$ $ohm^{-1}$ $cm^{-1}$; on dissolution of $Al_2Br_6$ the conductivity rises to $7.2\times10^{-12}$ $ohm^{-1}$ $cm^{-1}$ at $c = 6.0\times10^{-3}$ M and shows a distinct temperature-dependence.

Similarly, for pure, anhydrous benzene the dielectric constant is 2.2832 at 20 °C; for a benzene solution of $Al_2Br_6$ it is 2.3178 at $c = 6.0\times10^{-3}$ M. Conductivities, dielectric constants, and extinctions were measured on the same solution without breaking the vacuum.

Solutions of $Al_2Br_6$ in intensely dried benzenoid hydrocarbons (benzene, toluene, mesitylene) are therefore colorless. In all experiments during which a color was observed, traces of moisture must thus have been present. Since the extinction coefficient of the proton-addition complexes is 10000 to 30000 l $mole^{-1}$ $cm^{-1}$, mere traces of water suffice for coloration of the solutions.

## Aliphatic Amines from Carbon Monoxide, Steam, and Ammonia

By Prof. H. Kölbel and Dr. J. Trapper

Institut für Technische Chemie, Technische Universität, Berlin (Germany)

Aliphatic amines are formed in the catalytic reaction of CO with $H_2$ and added $NH_3$[1]. We have developed a single-stage amine synthesis in which steam is used instead of hydrogen:

$$3n\ CO + n\ H_2O + NH_3 = C_nH_{2n+1}NH_2 + 2n\ CO_2$$
$$(\Delta H = -52.2n \text{ kcal/mole amine})$$

Similarly to the reaction without added ammonia[2], the synthesis is carried out on a fixed reduced iron catalyst[*] in an electrically heated tube of 15 mm internal diameter and 60 cm length.

In the formation period of the catalyst the temperature is increased from 200 °C to 250 °C in *ca.* 300 h. The synthesis can then be continued for weeks with constant conversions and throughputs (average conditions during a long-time run see Table 1; optimal results: CO conversion 90–95 %, $NH_3$ conversion 70–80 % at a flow rate of 350–370 Sl/h per 1 l of catalyst at 11 atm).

Table 1. Amine synthesis data. (Initial gas composition in vol-%: 53.8 % CO, 20.6 % $H_2O$, 0.9 % $NH_3$, 23.7 % Ar; 11 atm; catalyst: 100 g Fe + 0.2 g Cu + 0.6 g $K_2CO_3$).

| Averaged over (h) | 54 | 56 | 120 |
|---|---|---|---|
| Temperature (°C) | 219–226 | 226–235 | 251 |
| Throughput (Sl/h per 1 l contact) | 48 | 45 | 58 |
| CO conversion (%) | 80 | 80 | 73 |
| $NH_3$ conversion (%) | 31 | 35 | 23 |

The synthesis product consists of primary, unbranched monoamines with exclusively terminal $NH_2$ groups together with saturated and unsaturated, predominantly unbranched hydrocarbons (molar ratio amines : hydrocarbons ≈ 1:5). In side reactions formation of alcohols and carboxylic acids can occur.

Table 2. Amine content of five fractions in operation aimed at production of lower amines.

| Fraction no. | Mean chain length (C atoms) | Proportion of amines (wt.-%) rel. to total product | Proportion (wt.-%) of total amine yield |
|---|---|---|---|
| 1 | 3 | 7.5 | 41.0 |
| 2 | 5 | 2.1 | 11.4 |
| 3 | 9 | 2.3 | 12.7 |
| 4 | 20 | 4.3 | 24.2 |
| 5 | 40 | 2.0 | 10.7 |
| | Total | 18.2 | 100 |

Secondary amines are present at most in traces. The yield of primary, unbranched amines was 10–15 g per $Sm^3$ of CO converted or 4.2 g per g of $NH_3$ converted. The homologues methylamine up to dodecylamine were identified. Increasing potassium carbonate content of the catalyst (from 0.2 % to 0.6 %) results in increased formation of amines (from 18 % to 28 %).

The reaction is of the 0.6th order with respect to ammonia. The preferential formation of primary 1-amines apparently indicates that the first reaction steps follow a mechanism proposed by *Anderson*[3] and that the ammonia chemisorbed on the catalyst (which is similar to the catalysts used in $NH_3$ synthesis) is added with termination of the C-chain and elimination of water.

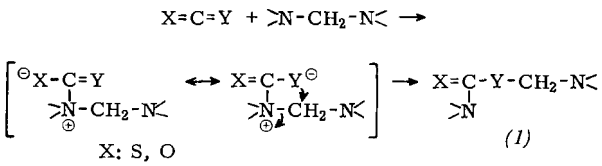
## Reaction of Isocyanates, Isothiocyanates, or Carbon Disulfide with Methylenediamines

By Dr. H. Ulrich and Dr. A. A. R. Sayigh

The Upjohn Company, Carwin Research Laboratories, North Haven, Connecticut (U.S.A.)

The reaction of formaldehyde *O,N*-acetals[1], *O,O*-acetals[2], and mercaptals[2] with isocyanates in the presence of Lewis acids has already been reported. We have now found that formaldehyde *N,N*-acetals (*i.e.* methylenediamines) react with isocyanates, isothiocyanates, or carbon disulfide (molar ratio 1:1 in benzene) already at room temperature in the absence of a catalyst. The 1:1-adducts were obtained in yields of 80–93 %.



*(1)*

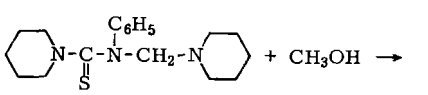
| *(1)* | Amine component in >N–$CH_2$–N< | X=C=Y | Temp. (°C) | F.p. (°C) | $-CH_2-$ signal (ppm) [a] |
|---|---|---|---|---|---|
| *(a)* | Morpholine | Phenyl isocyanate | 25–39 | oil | 4.32 |
| *(b)* | Piperidine | *p*-Toluenesulfonyl isocyanate | 26–45 | oil | 4.14 |
| *(c)* | Morpholine | *p*-Toluenesulfonyl isocyanate | 23–35 | 115–120 | 4.18 |
| *(d)* | *N*-Methyl-aniline | *p*-Toluenesulfonyl isocyanate | 23–39 | oil | 4.78 |
| *(e)* | Piperidine | *p*-Chlorobenzene-sulfonyl isocyanate | 27–42 | oil | 4.12 |
| *(f)* | Piperidine | Phenyl isothio-cyanate | 26–34 | 75–78 | 4.73 |
| *(g)* | Diethylamine | Phenyl isothiocyanate | 27–37 | oil | 4.75 |
| *(h)* | Piperidine | $CS_2$ [b] | 40 | 58–60[3] | 5.2 |
| *(i)* | Morpholine | $CS_2$ [b] | 40 | 121–122 | 5.25 |
| *(j)* | Diethylamine | $CS_2$ [b] | 40 | oil | 5.2 |

[a] Relative to tetramethylsilane (25 % in $CDCl_3$).

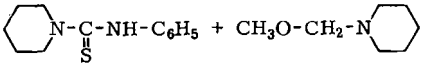
[b] Used as solvent.

The structures of the thermolabile adducts *(1)* (cleavage into the starting materials on heating to *ca.* 100 °C) were proved by elemental analyses and NMR spectra (see table).

The isocyanate and isothiocyanate adducts *(1)* (X = O or S; Y = RN or $RSO_2N$) react with compounds containing active hydrogen, *e.g.* water, alcohols, amines, with cleavage of the newly formed C–N bond. For example, if compound *(1f)* is dissolved in methanol, the thiourea derivative *(2f)*, m.p. 98–99 °C, is formed rapidly and quantitatively.



*(1f)*



*(2f)*

Compound *(2b)* is converted by an additional mole of *p*-toluenesulfonyl isocyanate into the 2:1 adduct, m.p. 85 to 90 °C.

## Preparation of Chlorobis(trifluoromethylthio)-methanesulfenyl Chloride, $(F_3CS)_2CCl-SCl$, and Chlorofluoro(trifluoromethylthio)methanesulfenyl Chloride, $F_3CS-CFCl-SCl$

By Dr. A. Haas and W. Klug

Anorganisch-Chemisches Institut,
Universität Göttingen (Germany)

Carbonyl fluoride, $COF_2$, reacts with alkali fluorides MF (M = K, Rb, or Cs) in acetonitrile at room temperature, giving trifluoromethoxides, $MOCF_3$ [1].

After the analogous reaction of thiocarbonyl fluoride, $CSF_2$, with CsF we could isolate no $CsSCF_3$. Instead, a deep red solution is rapidly obtained, even at −44 °C, with quantitative consumption of the $CSF_2$. On fractional distillation this liquid yields $CH_3CN$, a yellow liquid *(1)*, b.p. 43 °C, and as main product a dark red liquid *(2)*, b.p. 111 °C. The IR spectra, colors, and boiling points show that the yellow liquid *(1)* is the "pseudodimer" $F_3CS-CF=S$ of $CSF_2$, and that the red liquid *(2)* is bis(trifluoromethyl) trithiocarbonate, $(F_3CS)_2CS$ [2]. All the CsF added is recovered.

In absence of solvent, $CSF_2$ and CsF (molar ratio 1:60) in a sealed tube at −78 °C quantitatively give a white powder which changes gradually at room temperature to a yellow to red, transparent mass. When the volatile constituents are removed at room temperature in a high vacuum, a white solid remains which is soluble in chloroform. From the chloroform solution methanol precipitates a viscous, rubber-like product. Quantitative analysis and molecular-weight determination show this to be a polymer of $CSF_2$ [3].

Reaction of $CSF_2$ and CsF without solvent is extremely fast at 0 °C; the ester *(2)* was the sole product found.

$CSF_2$ reacts analogously with KF or $NH_4F$, but the ratio $MF:CSF_2$ may not be varied indefinitely, as it can for CsF. Also, the reactions are appreciably slower and require higher temperatures.

Compounds *(1)* and *(2)* react with chlorine even at −60 °, giving the sulfenyl chlorides *(3)* and *(4)* rapidly and quantitatively:

$F_3CS-CFCl-SCl$ *(3)*

$(F_3CS)_2CCl-SCl$ *(4)*

These materials, yellow liquids with pungent odor, were identified and characterized by elemental analyses, IR spectra, and NMR measurements.

*(3)*: B.p. 113 °C. IR: $\nu_{max}$ = 1165 $cm^{-1}$ (vs, br) [4], 1102 (vs, br), 1039 (vs), 1012 (sh), 792 (vs), 528 (s), 467 (m), 410 (m). The $^{19}F$–NMR spectrum consists of a doublet ($CF_3$) and a quadruplet (CF) with chemical shifts of $\delta_{CF_3}$ = 38.1 ppm, $\delta_{CF}$ = 57.6 ppm [5], and coupling constants $J_{F-F}$ = 22.0 Hz. The starting material *(1)* also gives a doublet and a quadruplet, $\delta_{CF_3}$ = 42.97 ppm, $\delta_{CF}$ = −89.6 ppm, $J_{F-F}$ = 18.0 Hz.

*4*: B.p. 40 °C/0.1 mm. IR: $\nu_{max}$ = 1745 $cm^{-1}$ (m), 1165 (vs, br), 1097 (vs, br), 1011 (sh), 801 (s), 754 (vs), 712 (m), 513 (m), 466 (m), 446 (m). $^{19}F$–NMR: $\delta_{CF_3}$ = 39.1 ppm. Starting material *(2)*: $\delta_{CF_3}$ = 42.0 ppm.

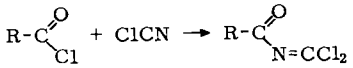
## New Synthesis of *N*-(Dichloromethylene)-carboxamides

By Dr. D. Pawellek

Wissenschaftliches Laboratorium der A-Fabrik,
Farbenfabriken Bayer AG., Leverkusen (Germany)

Reaction of sulfur dichloride with cyanogen chloride gives chlorosulfenyl isocyanide dichloride [1]. We have treated carbonyl chlorides with cyanogen chloride, obtaining *N*-(dichloromethylene)carboxamides *(1)*. The new process has the advantages of easily accessible starting materials compared with the chlorination of isonitriles [2], isothiocyanates [3], and *N*-acyldithiocarbamic esters [4].

The table shows some examples of compounds thus obtained.



*(1)*

| R | B.p. (°C/mm) M.p. (°C) | Yield (%) | IR bands ($cm^{-1}$) $-CO-N\langle$ | $-N=C\langle$ | $=CCl_2$ |
|---|---|---|---|---|---|
| $ClCH_2$[3] | 80/20 | 60–70 | – | – | – |
| $Cl_2CH$[3] | 82/14 | 70–80 | 1750 | 1650 | 925 |
| $Cl_3C$[3] | 85/18 | 70–80 | 1760 | 1650 | 925 |
| $ClCO(CH_2)_2$ | 101–103 | 28 | 1765 | – | 905 |
| $C_6H_5$[3] | 114/20 | 20–30 | 1775 | 1650 | 910 |

For the synthesis of *N*-(dichloromethylene)chloroacetamide, 152 ml of chloroacetyl chloride was placed in an enamelled shaking autoclave (capacity 0.7 l), and 300 ml of cyanogen chloride (molar proportions 1:3) were pressed in. After 2 hours' heating at 50 °C/5 atm the pressure was released and unchanged cyanogen chloride was condensed in cooled receivers. The product was isolated in 64% yield by fractional distillation of the residual reaction mixture. Synthesis of the other products (cf. table) was achieved analogously; further, *N*-(dichloromethylene)methoxymethylamine, b.p. 40 °C/25 mm, was prepared in 10% yield from chloromethyl methyl ether and cyanogen chloride.

These compounds decompose when stored, even in the dark, and faster when heated, into acid chloride and (trimerizing) cyanogen chloride. The temporary appearance of isocyanide dichlorides could be demonstrated by IR spectroscopy in reacting mixtures of cyanogen chloride and acetyl chloride.

Extension of the reaction of chloroacetyl chloride to other nitriles was successful only with 4-cyanomorpholine, then yielding α-chloro-*N*-[chloro(morpholino)methylene]acetamide, b.p. 110–115 °C/15 mm, $-CO-N\langle$ band at 1680 $cm^{-1}$, $-N=C\langle$ band at 1590 $cm^{-1}$ under the above conditions.

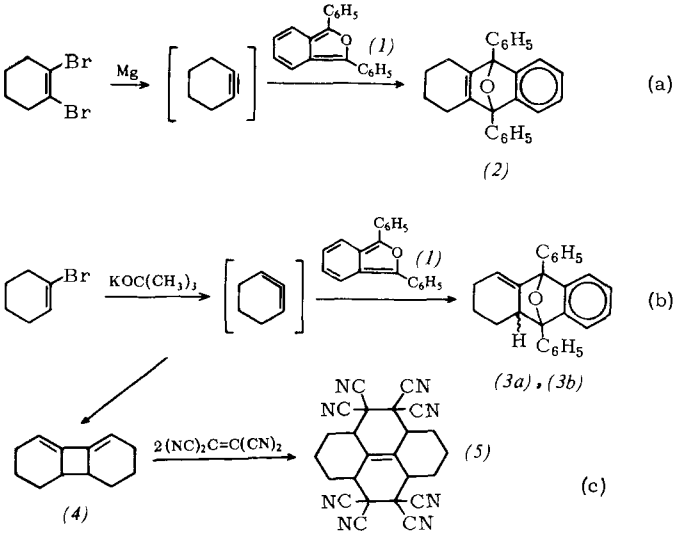
## On the Intermediate Occurrence of 1,2-Cyclohexadiene

By Prof. G. Wittig and Dr. P. Fritze

Institut für Organische Chemie,
Universität Heidelberg (Germany)

1,3-Diphenylbenzo[*c*]furan *(1)* has proved of particular value for the detection of lower-membered cycloalkynes[1]. In order to ascertain that it is cyclohexyne which is trapped, in accordance with equation (a), and not perhaps 1,2-cyclohexadiene, we have generated the cyclic allene by an independent route and allowed it to react with *(1)*.

Sublimed potassium t-butoxide was treated with 1-bromocyclohexene in dimethyl sulfoxide in the presence of *(1)* for several hours at 40 °C. Chromatography on $Al_2O_3$ then gave, among other products, two compounds, *(3a)* (m.p. 137–138 °C) and *(3b)* (m.p. 195–196 °C), in a total yield of 37 %; these are isomers of compound *(2)* (m.p. 170–171 °C) and are clearly differentiated from it by mixed melting point determinations and by IR and NMR spectroscopy. Whereas only aliphatic and aromatic protons can be recognized in the spectrum of *(2)*, the spectra of *(3a)* and *(3b)* both show a multiplet at $\tau = 4.3$, due to an olefinic proton. This indicates that the *exo*- and *endo*-isomers of 1,2-cyclohexadiene adducts have been formed. Control experiments confirmed that the *allene* was trapped: compound *(2)* does not isomerize to *(3a)* or *(3b)* under the conditions used.



Treatment of 1-bromocyclohexene with potassium t-butoxide on dimethyl sulfoxide in the absence of *(1)* affords in 7 % yield a hydrocarbon (m.p. 53–54 °C) whose structure *(4)* was proved by its mass spectrum, elemental analysis, NMR, infrared, and ultraviolet spectra ($\lambda_{max} = 237$ mμ, log ε = 4.176), and a diene reaction with tetracyanoethylene to give *(5)*[2]. In contrast, reaction of 1,2-dibromocyclohexene with lithium amalgam or magnesium gives a trimer, $(C_6H_8)_3$, and a tetramer, $(C_6H_8)_4$, whose structures and probable modes of formation have been determined[3].

Analogous experiments have been carried out on compounds with 7- and 8-membered rings[4].

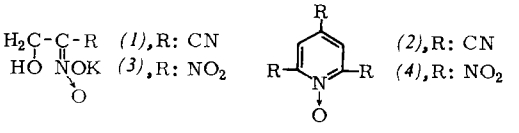
## Synthesis of 2,4,6-Tricyanopyridine 1-Oxide from Nitroacetonitrile

By Prof. K.-D. Gundermann and Dr. H.-U. Alles

Organisch-Chemisches Institut, Bergakademie-Technische Hochschule, Clausthal-Zellerfeld (Germany)

In order to obtain a further protected 2-nitroacrylic acid derivative[1], we treated potassium *aci*-nitroacetonitrile, m.p. 150–155 °C (decomp.), obtained from nitroacetonitrile in anhydrous ether and an equivalent amount of a solution of potassium methoxide in anhydrous methanol, in 40 % aqueous solution with about the two-fold molar amount of formaldehyde solution at room temperature; on vacuum evaporation of the mixture we isolated potassium 3-hydroxy-2-*aci*-nitropropionitrile *(1)*, yield 75 %, m.p. 188–120 °C (decomp.) (from methanol/ether). When kept for 24 hr in the seven-fold volume of 2 N sulfuric acid, this salt evolves nitrogen oxides and gives 2,4,6-tricyanopyridine 1-oxide *(2)*, yield *ca.* 50 %, m.p. 222 °C (from acetone/water). The structure of the oxide *(2)* was ascertained by elemental analysis, molecular-weight determination, NMR spectrum (only a sharp singlet at $\tau = 8.82$ ppm), mass spectrum (peak at $M-16$; characteristic for *N*-oxides[2,*]), and IR spectrum.



Reduction of the oxide *(2)* for 3 hr with iron powder and glacial acetic acid/acetone at 95 °C, extraction of the basic components with sodium hydroxide/ether/acetone, evaporation of the ethereal solution, heating of the residue with HCl in anhydrous methanol, and treatment of the concentrated methanol solution with potassium carbonate gave the known trimethyl 2,4,6-pyridinetricarboxylate in *ca.* 60 % yield.

*Duden* and *Ponndorf*[3] obtained a compound $C_5H_2N_4O_7$ of then unknown structure from potassium 2,2-dinitroethanol *(3)* and dilute sulfuric acid; from its mode of formation and IR and NMR spectra this is also a substituted pyridine 1-oxide, namely, *(4)*. The compounds *(2)* and *(4)* are strong electron acceptors and with, *e.g.*, dimethylaniline give deep red or violet π-complexes.

Studies of the general applicability and mechanism of this new synthesis of substituted pyridine 1-oxides are in progress; reaction presumably occurs by way of Dewar-pyridine derivatives.

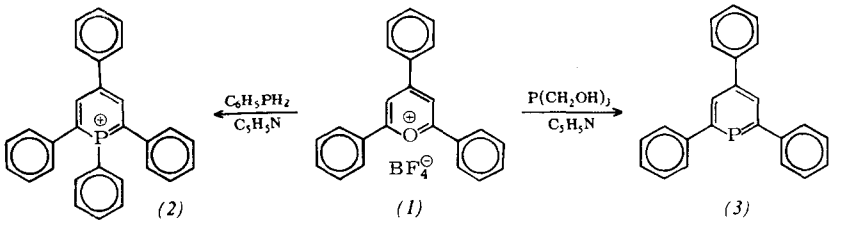
## 2,4,6-Triphenylphosphabenzene

By Dr. G. Märkl

Institut für Organische Chemie,
Universität Würzburg (Germany)

The reaction of phenylphosphine with 2,4,6-triphenylpyrylium tetrafluoroborate *(1)*[1] is to be interpreted as involving the intermediate formation of a cation *(2)* that is unstable under the reaction conditions.

We have synthesized the first derivative of phosphabenzene, namely, 2,4,6-triphenylphosphabenzene *(3)*, from the tetrafluoroborate *(1)* and tris(hydroxymethyl)phosphine[2,3] (molar ratio 1:1.25). When these reactants are heated for 2 hr in boiling pyridine, then cooled and treated with a little water,



*(2)* *(1)* *(3)*

+ 3 $CH_2O$ + $H_2O$ + $HBF_4$

Products

*(3)* crystallizes in 24–30 % yield as pale yellowish needles, m.p. 172–173 °C (from much ethanol or a little chloroform/ethanol). It is not autoxidizable. The molecular weight was found to be 326 in benzene by vapor-pressure osmometry, and 324 by mass spectrometry (MS 9)[2]. $^1H$–NMR spectrum in $CDCl_3$, band complex at $\tau$ = 2.2–3.0 (15 H), doublet at $\tau$ = 1.9 (2 H), $J$ = 6 Hz.

The signal of the $^{31}P$ nuclear magnetic resonance[4], $\delta$ = −178.2 ppm (in pyridine, $\delta H_3PO_4$ = 0) is at unexpectedly low field.

In comparison with the UV spectra of 1,3,5-triphenylbenzene ($\lambda_{max}$ = 254 mμ, $\varepsilon$ = 56000) and 2,4,6-triphenylpyridine ($\lambda_{max}$ = 254, 317 mμ ($\varepsilon$ = 49500, 9390), that of compound *(3)* in methanol ($\lambda_{max}$ = 278 mμ, $\varepsilon$ = 41000) shows a bathochromic shift that agrees qualitatively with observations on phosphacyanines of tervalent phosphorus with coordination number two[5].

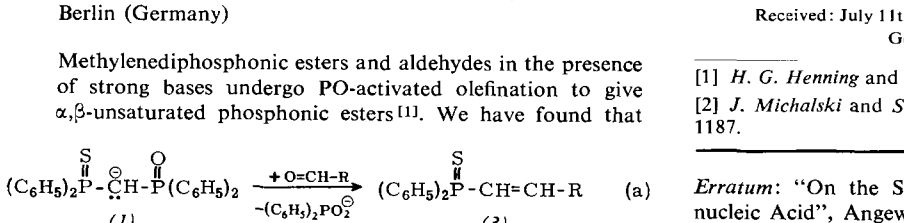
## Preparation of α,β-Unsaturated Phosphines and Phosphine Sulfides

By D. Gloyna and Dr. H. G. Henning

II. Chemisches Institut, Humboldt-Universität, Berlin (Germany)

Methylenediphosphonic esters and aldehydes in the presence of strong bases undergo PO-activated olefination to give α,β-unsaturated phosphonic esters[1]. We have found that this type of reaction can be applied also to unsymmetrical methylenediphosphorus compounds, the carbonyl-oxygen atom of the aldehyde being transferred to the more strongly positive phosphorus atom. Thus by reactions (a) and (b) we obtained diphenylphosphinic acid in average yields of 90 %,



together with unsaturated phosphine sulfides *(3)* or phosphines *(4)*. As shown in eq. (a), no PS-activated olefination[2] occurred.

The phosphines *(4)*, which were isolated in the pure state, could be converted into unsaturated phosphine sulfides *(3)* by warming them with sulfur in benzene or acetone, or into the corresponding phosphine oxides with 5 % hydrogen peroxide in acetone.

*(4)* + S → *(3)* (c)

The influence of the diphenylphosphino group on the smooth reaction (b), and the steric course of reactions (a) and (b), are being investigated.

| R | M.p. (°C) | Compounds *(3)* by eq. (a) yield (%) | Compounds *(3)* by eq. (c) yield (%) | Compounds *(4)* M.p. (°C) | Compounds *(4)* by eq. (b) yield (%) |
|---|---|---|---|---|---|
| Phenyl | 110 | — | 67.2 | 57–58 | 63.5 |
| *o*-Methoxyphenyl | 125–126 | 75.7 | 70.9 | 58–59 | 59.4 |
| Styryl | 139–140 | 63.6 | 58.7 | 90–91 | 64.2 |
| 2-Thienyl | 106–107 | 70.9 | 60.9 | 58–59 | 52.3 |
| 2-Pyridyl | 129–130 | 73.8 | 80.4 | 82–83 | 69.2 |

[*] Under argon in a sealed tube.

α,β-*Unsaturated phosphines (4)*: A solution of 10 mmole of methylenebis(diphenylphosphine) monoxide *(2)* and 20 mmole of potassium t-butoxide in 60 ml of anhydrous benzene was boiled under argon for *ca.* 10 min, then treated with a solution of 10 mmole of pure aldehyde (5 mmole for dialdehydes) in 20–30 ml of anhydrous benzene and set aside for 1 hr. The cooled mixture was shaken with 50 ml of water. On acidification the aqueous phase yielded diphenylphosphinic acid, and the benzene phase on evaporation yielded the phosphines *(4)* which, depending on the radical R, were recrystallized from acetone/$H_2O$, methanol, or DMF/$H_2O$.

Olefinations with compound *(1)* were effected similarly; the phosphine sulfides were recrystallized from ethanol or methanol.

## Chemisorption of Gases on Evaporated Metal Films

*G. Wedler*, Hannover (Germany)

Chemisorption of gases depends not only on the chemical composition of the adsorbing surface, but also to a great extent on its structure and cleanliness. Extremely pure metal surfaces suitable for chemisorption investigations can be obtained by deposition of thin metal films at about $10^{-10}$ mm Hg on degassed glass surfaces.

Electron-microscopic and X-ray studies with numerous 100-Å-thick nickel films that had been condensed at 77 °K and annealed at 60 °C showed that these films consist of crystals of approximately uniform size and oriented preferentially with the {111} face parallel to the underlying surface. X-Ray measurements and also the mean free paths of the conduction electrons (determined from the dependence of resistivity on film thickness) show that these nickel films are in an ordered state. Adsorption phenomena observed on such films are thus characteristic of the compact catalyst material.

Chemisorption of gases was studied by simultaneous measurement of the change of electric resistance and work function of the films, as well as by direct calorimetric measurement of differential heats of adsorption.

For the system nickel/hydrogen, in contrast to the report in the literature that the heat of adsorption is strongly dependent on the coverage of the surface by hydrogen, we observed a heat of adsorption of *ca.* 17.5 kcal/mole independent of the coverage, provided that 100-Å-thick, completely fresh nickel films were used as adsorbent; only when a complete monomolecular layer had been built up did the heat of adsorption decrease with increasing coverage. If the nickel films had previously been covered with oxygen or carbon monoxide up to about a quarter of a monolayer, then the heat of adsorption of hydrogen – which was chemisorbed as atoms – amounted to *ca.* 21 kcal/mole at the beginning of the experiment; the heat of adsorption decreased in this case with increasing coverage, in contrast to the behavior with initially fresh films.

In contrast to the systems nickel/hydrogen and nickel/carbon monoxide[1], with which substantially only chemisorption occurs on the metal surface, we observed marked uptake of hydrogen in the lattice, *i.e.* a volume effect, for the system titanium/hydrogen[2]. With the system nickel/water vapor[3] a reaction clearly occurs between the adsorbent and the adsorbate, with formation of NiOH groups on the surface.

## Preparation and Properties of Substances with *N*- or *S*-Perhalogenomethyl Groups

*E. Klauke*, Leverkusen (Germany)

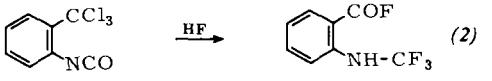
Trichloromethanesulfenyl chloride, $Cl_3C-SCl$ *(1)*, is fluorinated selectively in anhydrous HF to dichlorofluoromethanesulfenyl chloride. Replacement of further chlorine atoms by fluorine requires stronger fluorinating agents, *e.g.* $SbF_3$ or NaF. Whereas 3,6-dichloro-1,4,2,5-dithiadiazine is formed on treatment of *(1)* with $NH_3$[1], dichlorofluoro- and chlorodifluoro-methanesulfenyl chloride and ammonia give the corresponding amides $FCl_2C-SNH_2$, b.p. 54–56 °C/50 mm Hg, and $F_2ClC-SNH_2$, b.p. 89.5 °C/760 mm, respectively.

Perhalogenomethyl arenethiosulfonates can be cleaved to thiols with HCl. However, trichloromethanethiol decomposes to phosgene with loss of HCl. Thiophosgene and other thiocarbonyl dihalides are also obtained by thermolysis of perhalogenomethyl thiosulfonates.

$$Ar-SO_2S-CCl_2F + HCl \rightarrow Ar-SO_2Cl + FCl_2C-SH$$

Reaction products of *(1)* are of practical importance as leaf fungicides. Replacement of the $CCl_3$ by the $CCl_2F$ group leads to preparations with appreciably broader activity spectra[2].

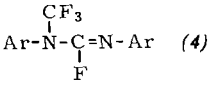
*o*-(Trichloromethyl)phenyl isocyanate undergoes Cl–F exchange in anhydrous HF; isomerization occurs simultaneously and *o*-*N*-(trifluoromethyl)aminobenzoyl fluoride *(2)* can be isolated.



*(2)*

*N*-(Trifluoromethyl)aniline derivatives *(3)* are readily prepared from aromatic isocyanide dichlorides[3].

$$Ar-N=CCl_2 \xrightarrow{HF} Ar-NH-CF_3 \quad (3)$$



*(4)*

In the preparation of *N*-(trifluoromethyl)anilines *(3)*, fluoroformamidines, *e.g. (4)*, are obtained as dimerization products of the intermediate isocyanide difluorides, the amounts varying according to the nature of the substitution and the reaction conditions. *N*-(Trifluoromethyl)anilines *(3)* are smoothly acylated by sulfenyl chlorides, but not by carbonyl chlorides. Chlorocarbonyl isocyanide dichloride and HF give trifluoromethyl isocyanate.

## Types of Bonding of Sulfur in Vulcanization Processes

*W. Scheele*, Hannover (Germany)

In vulcanization processes part of the sulfur is always bound in polysulfide groups ($S_p$-sulfur). The amount of $S_p$-sulfur passes through a maximum during the process; later products contain, *inter alia*, sulfide groups, predominantly as part of five-membered rings either with or without double bonds. The amount of $S_p$-sulfur present in the vulcanizate after a reaction time $t$ can be expressed by the empirical equation (1):

$$[S_p] = at^b e^{-ct} \quad (1)$$

The quantity $b$ is normally a constant of the system, whereas $a$ and $c$ depend on the experimental conditions (*e.g.*, $c$ is related to the rate of uptake of sulfur). The coordinates of the $S_p$ maxima, $[S_p]_{max}$ and $t_{max}$, calculated from eq. (1), are in excellent agreement with experiment.

If the formation and degradation of $S_p$-sulfur are first-order processes, a kinetic expression can be developed, integration of which leads to:

$$[S_p] = \varepsilon \frac{k_1[S_8]_0}{(k_1-k_2)} [e^{-k_1 t} - e^{-k_2 t}] \quad (2)$$

$k_1$ and $k_2$ are the rate constants for decrease in $[S_8]$ and of $[S_p]$, respectively, and $[S_8]_0$ is the initial sulfur concentration. The factor $\varepsilon$ is the quotient of the experimental $[S_p]$ maxima and those calculated on the assumption that all the sulfur contained in a cross-link ($p$ + 2 atoms) reacts further, namely, $[S_p]_{max}/[S_p + 2]_{max}$. The rate constant $k_2$ is obtained by use of $t_{max}$, as in eq. (3):

$$k_1 t_{max} = \ln \omega (\omega - 1)^{-1}, \text{ where } \omega = k_2/k_1 \quad (3)$$

The total rate of formation of all the subsequent products, $\Sigma$ [P], is given by

$$d \Sigma [P]/dt = k_2[S_p] \quad (4)$$

Inserting the expression for $[S_p]$ from eq. (2) and integrating gives

$$\Sigma [P] = \varepsilon [S_8]_0 \left[ \frac{1}{(k_2-k_1)} (k_1 e^{-k_2 t} - k_2 e^{-k_1 t}) + 1 \right] \quad (5)$$

On the other hand, inserting the expression for $[S_p]$ from eq. (4) into eq. (1) gives:

$$\Sigma [P] = (k_2 a/c^2) [1 - e^{-ct} - ce^{-ct}] \quad (6)$$

The kinetics thus developed were tested on vulcanization of natural rubber in the presence of ZnO, zinc benzothiazoyl sulfide, and zinc myristate or stearate in three series of experiments, in which the temperature, the inital concentration of sulfur, or the content of accelerator were varied.

For determination of the $S_p$-sulfur the vulcanizate was degraded with lithium tetrahydridoaluminate; $p$ sulfur atoms were split off as $H_2S$ from the alkenyl alkyl polysulfide bridge bonds each containing ($p$ + 2) sulfur atoms, while in each case two sulfur atoms remain on the polymer chain as thiol groups; it should be noted that that the ZnS formed in the vulcanization must be separately determined and taken into account.

The relation between $S_p$ content of the vulcanizate and reaction time calculated from eq. (2) is in excellent agreement with experiment; calculation of the final concentration ($t = \infty$) of the subsequent products by means of eqs. (5) and (6) gave values also in good agreement with experimental results. These facts can be considered as confirmation of the kinetics developed, since no assumptions were made in deriving eq. (1), on which eq. (6) is based.

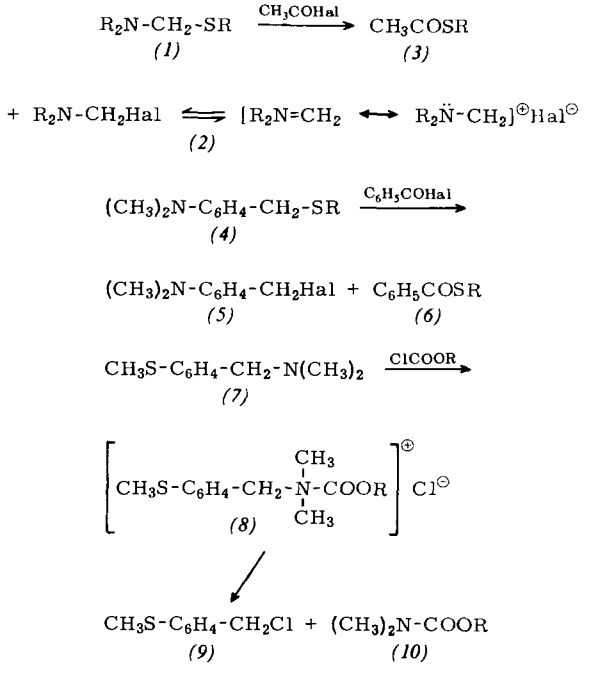
[Lecture at Hannover, May 26th, 1966] [VB 10 IE]
German version: Angew. Chem. 78, 828 (1966)

## Cleavage of Aryl-substituted Tertiary Amines by Acyl Halides

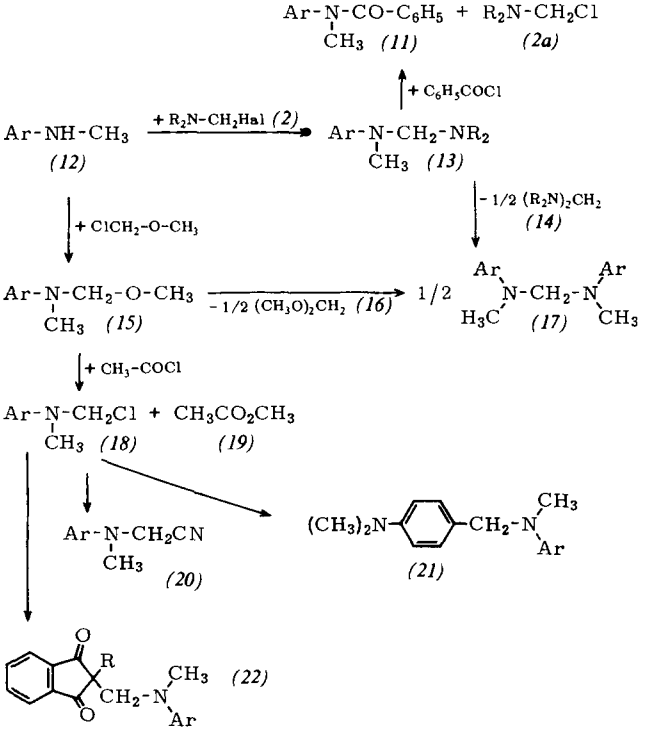
*H. Böhme*, Marburg (Germany)

The reaction of *S,N*-acetals *(1)* with carbonyl halides in indifferent solvents leads to α-halogenated amines *(2)*, together with thiocarboxylic esters *(3)*. By the analogous fission of phenylogous *S,N*-acetals of type *(4)* we have isolated the first of the rather unstable, phenylogous α-halogenated amines *(5)*, which were characterized by reaction with secondary amines to the previously described phenylogous aminals.

Phenylogous *S,N*-acetals of type *(7)* react with carbonyl chlorides and with chloroformic esters at low temperatures (about −60 °C), yielding addition products, *e.g. (8)*, that decompose at room temperature to *p*-(methylthio)benzyl chloride *(9)* and *N,N*-dimethylurethane (R = $C_2H_5$) *(10)*. Other benzylamines behave similarly: the stability of the addition compounds increases as the *para*-substituent is changed in the order $(CH_3)_2N$, $CH_3O$, $CH_3S$, H, $CH_3SO_2$.



Reaction of α-halogenated amines *(2)* and 2,4,6-trichloro- or 2,4,6-trimethyl-*N*-methylanilines *(12)* makes accessible the unsymmetrical aminals *(13)*, which on distillation (80 °C/$10^{-2}$ mm) symmetrize to compounds *(17)* and *(14)* and on cleavage with a carbonyl chloride give *N,N*-dialkylchloromethylamine *(2a)* together with a substituted benzanilide *(11)*. *O,N*-Acetals *(15)* were similarly prepared from chloromethyl methyl ether and the aniline *(12)*, and they also symmetrize



at about 80 °C, yielding compounds *(17)* and *(16)*; on cleavage with acetyl chloride the acetals *(15)* yield *N*-(chloromethyl)aniline derivatives *(18)* and carboxylic esters *(19)*; the compounds *(18)* with hydrogen cyanide afford cyanides *(20)*, with dimethylaniline afford diamines *(21)*, and with monosubstituted indanediones afford compounds of type *(22)*.

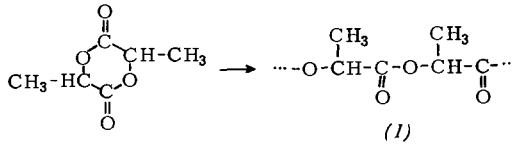
[Lecture at Marl on June 15th, 1966] [VB 13 IE]
German version: Angew. Chem. *78*, 828 (1966)

## Methods and Problems in the Study of Optically Active Polymers

*R. C. Schulz*, Mainz (Germany)

For the preparation of optically active polymers asymmetric monomers were polymerized with radical or ionic initiators [*e.g.*, menthol and borneol acrylate and methacrylate, menthol *N*-vinylurethane, *N*-substituted *N*-(α-methylbenzyl)-acrylamides, *N*-vinylureas derived from α-amino acids], and asymmetric substituents were introduced into optically inactive polymers in polymer-analogous conversions.

High-molecular crystalline polyesters *(1)* with softening points of about 170 °C were obtained by ring-opening polymerization of L-dilactide:

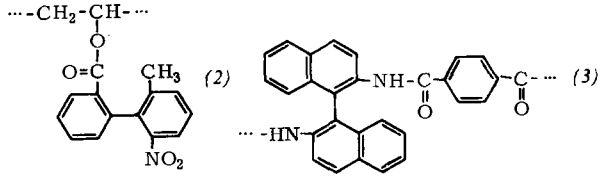


*(1)*

In this reaction the configurations of all the asymmetric C atoms are retained and are the same, so that a completely isotactic polymer results. The optical rotatory dispersion and circular dichroism were measured in several solvents. The Cotton effect, which is observed only for poly-L-lactide, indicates a secondary structure. The rotatory dispersion can be described equally well by the modified two-term Drude equation and by the Moffit-Yang equation; the constants are similar to those for helical proteins and poly-L-amino-acids, but the signs are reversed.

*(2)*

All optically active polymers described previously contain asymmetric C atoms. However, treatment of (+)-2′-methyl-6′-nitrobiphenyl-2-carbonyl chloride with polyvinyl alcohol yields the first polymer *(2)* whose optical activity is due to atropisomerism.



*(2)* *(3)*

This polymer gives the same Cotton effects as monomeric model compounds.

The specific rotation of the polymer corresponds precisely to the analytically determined content of atropisomeric substituents. From the rotatory dispersion and the circular dichroism it can be concluded that there is no mutual optical interaction between the side groups of this polymer, that the polymer structure has no influence on the specific rotation, and that in solution the macromolecules are randomly coiled.

Racemization of atropisomeric model compounds is first order, but the polymer racemizes appreciably more slowly and not according to first-order kinetics.

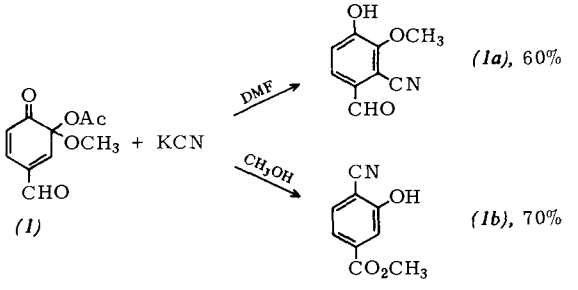
Polymers of type *(3)*, with atropisomeric groups in the main chain, have been obtained by interfacial polycondensation of (+)-1,1′-binaphthyl-2,2′-diamine with terephthaloyl dichloride.

[Lecture at Mainz (Germany), June 23rd, 1966] [VB 16 IE]
German version: Angew. Chem. *78*, 909 (1966)

## Chemistry of *o*-Quinol Acetates

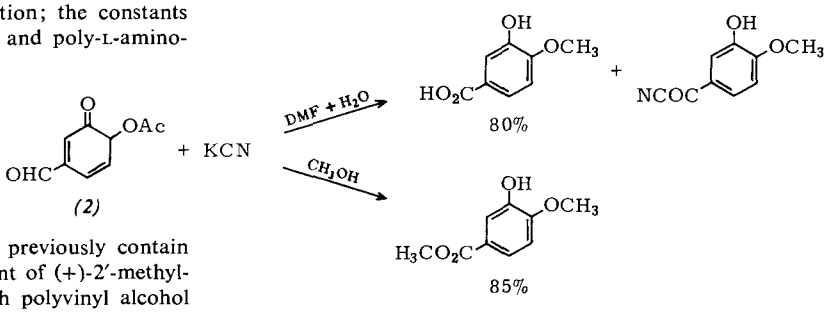
*F. Wessely*, Vienna (Austria)

Whereas, in all cases studied so far, reaction of *o*-quinot acetates with KCN leads to *m*-hydroxybenzonitriles, reaction of compound *(1)* with KCN depends on the solvent. It gives a *m*-hydroxy nitrile *(1a)* only in dimethylformamide, formation of this product being explained by 1,6-addition to the conjugated system of *(1)*. However, in methanol compound *(1b)* is formed, a result for which a complicated rearrangement must be responsible. Both reactions proceed rapidly at room temperature.



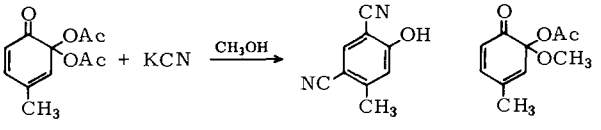
*(1)* *(1a)*, 60% *(1b)*, 70%

On treatment of compound *(2)* with KCN the product is practically independent of the solvent. The reaction leads to conversion of the aldehyde group into a carboxyl group, which can be esterified by the alcohol used as solvent.



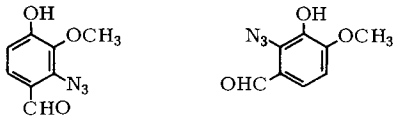
80% 85%

For the mechanism of the reaction leading from *(1)* to *(1b)* it is important that the quinol acetate *(3)* and KCN in methanol give a 55 % yield of compound *(3a)*, whereas only a very small yield of *(3a)* is obtained from the quinol acetate *(4)* under the same conditions. The structure of compound *(3a)* has resemblances to that of compound *(1b)*.



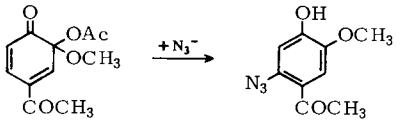
*(3)* *(3a)* *(4)*

Reaction of *(1)* and *(2)* with trimethylsilyl azide in methanol, or with the azide ion, leads to compounds *(1c)* and *(2a)*. Quinol acetates carrying alkyl groups on C-4 or C-5 do not give such products. Thus the azide ion adds to an *o*-quinol acetate only if the latter is activated by a formyl group. The



*(Ic)*, 60%

*(2a)*, 95%



*(5)*

*(5a)*

quinol acetate *(5)* adds the azide ion with formation of compound *(5a)*.

[Lecture at Kiel (Germany), June 30th, 1966] [VB 21 IE]

German version: Angew. Chem. *78*, 910 (1966)

## Chemical Problems in the Pyrometallurgical Reprocessing of Nuclear Fuels

*S. R. Austin*, Clausthal-Zellerfeld (Germany)

The principle of pyrometallurgical reprocessing was explained on the basis of the fuel cycle for the Experimental Breeder Reactor No. II (EBR-II) in Idaho, U.S.A., developed by the Chemical Engineering Division of the Argonne National Laboratory.

The process consists in a melt refining at *ca.* 1400 °C, in which the rare earths and other non-noble fission products are oxidized and further products (*e.g.* Cs, Rb, Cd, I) are volatilized. M tallic uranium is obtained with sufficient purity for operation of EBR-II, which is designed as a fast plutonium breeder. The more noble fission products (Mo, Tc, Ru, *etc.*) are reduced and extracted by molten zinc from a $CaCl_2/MgCl_2/MgF_2$ melt containing the residue from the melt refining process. Uranium which enters into this by-process is recovered by reduction and precipitation with magnesium-zinc alloys.

For development and optimization of this and other pyrometallurgical and pyrochemical processes various chemical matters require clarification, including the following points:

1) Phase relations of the relevant metal and salt systems, in particular solubilities in molten metals and salts.

2) Free energy ($\Delta G$) of the relevant chemical reactions.

3) Activities and partial molar excess thermodynamic functions in molten metals and salts.

In view of the numerous individual problems (interest attaches to, *e.g.*, the properties of U, Pu, Th, and at least 20 elements that occur as fission products, in various molten metals and salts), it is evident why there are still gaps in our knowledge. Our experimental work was confined to a study of the rare earths in molten salts. For instance, the thermodynamic activities in molten $KCl/NdCl_3$ mixtures showed strong negative deviations from ideality,which can probably be explained by appearance of $[NdCl_6]^{3\ominus}$ complexes in the melt. The excess chemical potential $\mu^E$ of $NdCl_3$ is $-1$ kcal/mole at a mole fraction $x = 0.25$, and $-12$ kcal/mole at $x = 0$.

[Chemical colloquium at Clausthal-Zellerfeld (Germany), July 15th, 1966] [VB 9 IE]

German version: Angew. Chem. *78*, 910 (1966)

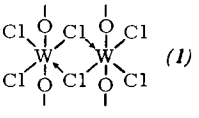
# SELECTED ABSTRACTS

**Ability selectively to dissolve carcinogenic hydrocarbons** has been observed by *M. Wilk* and *E. L. Wynder* for suspensions of isolated mitochondria from mouse liver in an aqueous buffered medium (triethanolamine · HCl / $MgCl_2$ / $KH_2PO_4$ / EDTA; pH 7.2 at 25 °C).

Non-carcinogenic hydrocarbons are not dissolved by mitochondria and have no influence on respiration; however, respiration of the mitochondria is strongly hindered after they have taken up 3,4-benzopyrene or 7,12-dimethylbenz-[*a*]anthracene. Uptake of these substances could be followed by fluorescence spectroscopy. A promotor action by the polycyclic aromatic hydrocarbons is assumed to set in on the mitochondria which are the structural elements for cell respiration. This view is supported by depression of respiration of isolated mitochondria by pure cocarcinogens such as croton oil./Z.Naturforsch.*21b*, 161 (1966) / –De. [Rd 509 IE]

**The oxide fluorides $AsOF_3$, $SbOF_3$, and $SbO_2F$** have been prepared by *K. Dehnicke* and *J. Weidlein*. The fluoride nitrates $AsF_3(ONO_2)_2$, $SbF_3(ONO_2)_2$, and $SbF(ONO_2)_4$ are accessible from the fluoride chlorides $AsF_3Cl_2$, $SbF_3Cl_2$, and $SbFCl_4$ by use of chlorine nitrate and on thermal decomposition afford the hitherto unknown oxide fluorides $AsOF_3$, $SbOF_3$, and $SbO_2F$. $AsOF_3$ is a white, hygroscopic solid, amorphous according to its X-ray diagram, and insoluble in nonpolar solvents; at 240 °C it decomposes without melting; it forms no adduct with pyridine. $SbOF_3$ has similar properties; it is stable up to about 200 °C but, in contrast to $AsOF_3$, forms a 1:1 adduct with pyridine. Decomposition of $SbO_2F$ does not begin until 350 °C; no adduct is formed with pyridine. According to the IR spectra $AsOF_3$ and $SbOF_3$ are associated by means of M–O–M bridges (M = As or Sb) (symmetry $C_{3v}$), but $SbO_2F$ has $C_s$ symmetry. / Z. anorg. allg. Chem. *342*, 225 (1966) / –Sch. [Rd 534 IE]

**Tungsten(V) oxide trichloride** *(1)* has been synthesized by *G. W. A. Fowles* and *J. L. Frost*. Reducing W(VI) oxide tetrachloride with Al powder in a sealed tube at 100 to 140 °C and subsequent removal of the $AlCl_3$ and starting material by sublimation affords the olive-green substance *(1)*, which is only weakly paramagnetic and according to its IR spectrum and X-ray powder diagram has a structure analogous to that of Nb(V) oxide trichloride (tetragonal unit cell: $a = 10.7$ and $c = 3.84$ Å). It forms deeply colored



*(1)*

complexes with pyridine and acetonitrile. In accord with its polymeric structure the product *(1)* is insoluble in solvents such as $C_6H_6$ or $CH_2Cl_2$. / Chem. Commun. *1966*, 252 / –Ma. [Rd 529 IE]

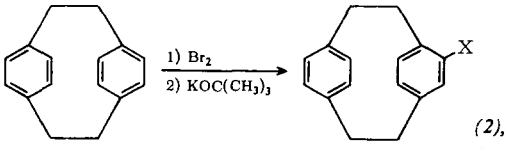
**Electrochemical oxidation of iodide to iodate** at graphite electrodes has been investigated by *R. Landsberg*, *R. Nitzsche*, and *W. Geissler*. Analysis of the potential curves indicated that the reaction leading to iodate is of the first order with respect to iodide; the order with respect to hydroxide ions is 0.23 at pH 6 to 10.6, but zero at higher pH values. The following reaction mechanism is proposed:

$$OH^-_{aq} \rightleftarrows (OH^-)_{ad}$$

$$I^- + (OH^-)_{ad} \rightarrow (IOH^-)_{ad} + e^-$$

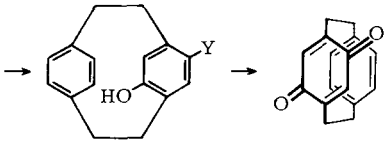
/ Electrochim. Acta *11*, 495 (1966) / –Hz. [Rd 520 IE]

**A paracyclophane with intramolecular electron donor-acceptor action** has been prepared by *D. J. Cram* and *A. C. Day*. Treating [2.2]paracyclophane *(1)* with one equivalent of bromine gives a high yield of the fairly pure monobromo compound *(2)*, which is converted by K t-butoxide in dimethyl sulfoxide through a benzyne intermediate into the phenol *(3)*. This couples with diazotized sulfanilic acid, yielding the azo dye *(4)* which is reduced by sodium hydrogen sulfite to the unstable aminophenol *(5)*. The



*(1)*

*(2)*, X : Br
*(3)*, X : OH



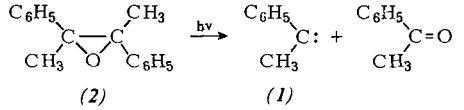
*(4)*, Y : $N{=}N\text{-}C_6H_4\text{-}SO_3H\text{-}p$
*(5)*, Y : $NH_2$

*(6)*

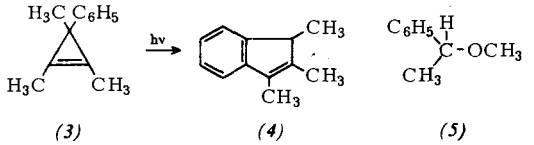
quinone *(6)* is then obtained by oxidation with $Fe_2(SO_4)_3$ in $H_2SO_4$ (total yield *ca.* 10 %); it absorbs at 340 mμ (ε = 600), which is interpreted as a charge-transfer band. / J. org. Chemistry *31*, 1227 (1966) / –Bu. [Rd 511 IE]

**Metastable $K^+$ ions produced by electron impact** have been found in the mass spectrometer by *Florence Fiquet-Fayard*. The first species, which appears above 24.5 ± 2 eV, is interpreted as $K^+$ in the configuration $3s^23p^54s$, whose 4*s* electron has a spin opposite to that of the electron missing from the 3*p* shell, so that this condition is metastable as a result of the selection rule $\Delta S = 0$. The second species, which appears between 33.5 and 36.5 eV, is assigned to the state $3s^23p^5n$, where *n* is a principal quantum number higher than 4; the probability of return of the more highly excited electron is appreciably smaller the greater the value of *n*; the appearance potential of such states is thus close under the second ionization potential, which for potassium is 36.15 V. / J. Chim. physique *63*, 401 (1966) / –Hz. [Rd 518 IE]

**Methylphenylcarbene (α-methylbenzylidene)** *(1)*, hitherto unknown, has been obtained, together with acetophenone, by *H. Kristinsson* by irradiation of *trans*-α,α'-dimethylstilbene oxide (2,3-dimethyl-2,3-diphenyloxirane) *(2)*. This fragmentation is analogous to that occurring on photolysis of stilbene oxide or tetraphenyloxirane which yields phenylcarbene or diphenylcarbene, respectively. Irradiation of the oxide *(2)* (40 hr, 35 °C, low-pressure Hg lamp) in 2-butyne affords 1,2,3-trimethyl-3-phenylcyclopropene *(3)* (10 %),



*(2)* *(1)*



*(3)* *(4)* *(5)*

which is largely rearranged photochemically into 1,2,3-trimethylindene *(4)*. Photolysis of the oxide *(2)* in methanol/benzene leads to methyl α-methylbenzyl ether *(5)* (50 %). / Tetrahedron Letters *1966*, 2343 / –Ma. [Rd 528 IE]

**Fractionation and purification of tRNA** by column chromatography on Sephadex G 25 has been achieved by *K. H. Muench* and *P. Berg*. The procedure leads to 24-fold enrichment and 25 to 40 % purity in one passage (10-l column for 3.5 g of mixed tRNA). The two-phase solvent mixture consists of 6 parts of 1.25 M potassium phosphate buffer (pH 6.88), 2 parts of 2-ethoxyethanol, 1 part of 2-butoxyethanol, 0.01 part of triethylamine, and a little 2-mercaptoethanol. The Sephadex columns are prepared by use of the lower solvent layer and are then equilibrated with the upper layer. After the tRNA mixture has been added, elution is carried out with the upper layer and then with a gradient of the upper layer containing 0.01 to 0.05 part of triethylamine. Between these gradients and the lower layer the distribution coefficient of the tRNA varies from about 0.08 to 0.8. The procedure is also suitable for separation of amino acid-specific tRNA's in pure sub-fractions. / Biochemistry *5*, 970 (1966) / –Hö. [Rd 517 IE]

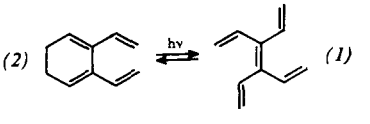
**A new synthesis of (tertiary alkyl)amines** has been described by *P. Kovacic, R. J. Hopper, S. S. Chaudhary, J. A. Levisky*, and *V. A. Liepkalns*. Amination of methylcyclohexane and *p*-cymene by trichloramine in presence of $AlCl_3$ in $CH_2Cl_2$ or ethylene dichloride at 0 to 10 °C affords 1-methylcyclohexylamine *(1)* and 1-methyl-1-*p*-tolylethylamine *(2)*, respectively; for the latter synthesis t-butyl bromide (in amount equimolar with the catalyst) should be added. Molecular proportions for the amination are substrate:trichloramine:$AlCl_3$ = 1:0.1:0.2. No basic product is formed in absence of $AlCl_3$; yields are much reduced in absence of the t-butyl halide. *(1)*: yield 83 %; *(2)*: yield 80 %, b.p. 76–77 °C/5.2 mm. The following reaction sequence is assumed:

$$RH \xrightarrow{-H^{\ominus}} R^{\oplus} \xrightarrow{+NH_2^{\ominus}} RNH_2$$

/ Chem. Commun. *1966*, 232 / –Ma. [Rd 527 IE]

**Cesium fluoride is a donor of particularly active fluoride ions,** as is shown by *D. P. Graham, V. Weinmayr*, and *W. B. McCormack*. Thus anionic polymerization of tetrafluoroethylene has been achieved for the first time by use of CsF, yielding oily fluorocarbons that contain 8 to 14 C atoms. The carbanion complexes formed by addition of CsF to polyfluoroolefins are about as reactive as Grignard compounds. For instance, perfluoro-2-methyl-2-butanol (a water-clear liquid, b.p. 67 °C) was prepared in 86 % yield from tetrafluoroethylene, CsF, and hexafluoroacetone. In this case CsF activates the ketone as well as the olefin. Remarkably, perfluorocarboxylic acids can be obtained by simple carbonylation, *e.g.* perfluoroisobutyric acid in 56 % yield from hexafluoropropene, CsF, and $CO_2$. / J. org. Chemistry *31*, 955, 957, 958 (1966) / –Bu. [Rd 512 IE]

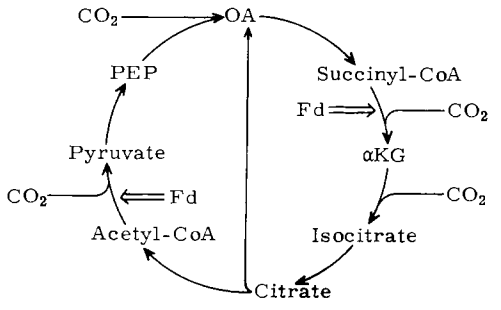
**Tetravinylethylene (3,4-divinyl-1,3,5-hexatriene)** *(1)* was isolated in 6 to 7 % yield by *L. Skattebøl* after irradiation (λ = 2537 Å) of a 10 % solution of 2,3-divinyl-1,3-cyclohexadiene *(2)* in pentane at –78 °C; *ca.* 25 % of polymeric product was also formed. Irradiation of the product *(1)* regenerated *(2)*; in the presence of a sensitizer (benzophenone) none of the open-chain product *(1)* was ob-



*(2)* *(1)*

tained, but formation of the polymer was accelerated. The structure of product *(1)* was deduced from IR, UV, and NMR spectra. After hydrogenation of the crude product, 3,4-diethylhexane was isolated. / Tetrahedron Letters *1966*, 2257 / –Ma. [Rd 530 IE]

**A photosynthetic, reductive carboxylic acid cycle** due to anaerobic microorganisms (*Chlorobium thiosulfatilum*) is contrasted by *M. C. W. Evans*, *B. B. Buchanan*, and *D. I. Arnon* with the Calvin cycle of plants. The total synthesis leads to 1 mole of oxaloacetate (OA) from 4 moles of $CO_2$, as well as regenerating 1 mole of oxaloacetate as starting material for the cycle. The four reactions for fixation of $CO_2$ are: 1) formation of α-ketoglutarate (αKG) from succinyl-coenzyme A, 2) formation of isocitrate from αKG, 3) synthesis of pyruvate from acetyl-coenzyme A, and 4) formation of OA from phosphoenolpyruvate (PEP). Reactions 1) and 3) depend on reduced ferredoxin (Fd), which is regenerated in a light reaction. The cycle makes use of the reversibility of reactions of the citric acid cycle. / Proc. nat. Acad. Sci. U.S.A. *55*, 928 (1966) / –Hö. [Rd 516 IE]



**The recognition of codes by pure tRNA species** from *Escherichia coli B* has been studied by *D. A. Kellog* and his collaborators. They concluded that appearance of several tRNA's specific to one amino acid is not necessarily related to degeneration of the genetic code, but that one pure aminoacyl-tRNA "recognizes" several codons. Thus *E. coli B* contains three (or two) valyl-tRNA, all three (two) of which include a GUU anticodon. Nevertheless there are differences between them: valyl-tRNA I and II are preferentially bound to ribosomes through the ribotrinucleotides GUA, GUG, and GUU; valyl-tRNA III reacts with GUU and GUC. A similar situation exists with alanyl-tRNA, of which I is bound through GCA and GCG and rather worse by GCU, whereas II is bound equally well by GCA, GCG, GCC, and GCU. A pure phenylalanyl-tRNA reads the codons UUU and UUC. As already known, methionyl-tRNA species occupy a special position: I corresponds to UUG, CUG, and AUG, II only to AUG; only I can be formylated and plays a part in starting peptide chains. / Proc. nat. Acad. Sci. U.S.A. *55*, 912 (1966) / –Hö. [Rd 515 IE]

**Isoleucyl-tRNA synthetase** from *Escherichia coli* has been enriched 300 times by *A. N. Baldwin* and *P. Berg*. The enzyme appears homogeneous in ultracentrifugal and chromatographic experiments, has a molecular weight of 112000, and binds one molecule of isoleucyl-AMP per molecule (AMP = adenosine-5′ phosphate). The complex enzyme-isoleucyl-AMP is more stable than the pure enzyme towards denaturation by heat, trypsin, and thiols. The first step (a) in the reaction catalysed by the enzyme occurs with isoleucine ($K_M = 5\times10^{-6}$ mole/l) as well as with valine ($K_M = 4\times10^{-4}$ mole/l), but only isoleucine is transferred to isoleucine-specific tRNA [step (b)]. The complex enzyme-valyl-AMP is,

$$\text{Isoleucine} + \text{ATP} \rightleftarrows \text{Isoleucyl-AMP} + \text{Pyrophosphate} \quad \text{(a)}$$

$$\text{Isoleucyl-AMP} + \text{tRNA}_{\text{Ile}} \rightarrow \text{Isoleucyl-tRNA} + \text{AMP} \quad \text{(b)}$$

on the contrary, decomposed into enzyme, valine, and AMP under catalysis by isoleucine-specific tRNA. This reaction is characteristic of isoleucine-specific tRNS which is inactive after any chemical change investigated (*e.g.* esterification with isoleucine, periodate oxidation of the free 2′- and 3′-hydroxyl groups, removal of the terminal adenosine, or fission near the 5′-end).

The authors suggest that this is a safety mechanism to prevent confusion between the two homologous amino acids isoleucine and valine. / J. biol. Chemistry *241*, 831, 839 (1966) / –Hö. [Rd 514 IE]

**Two conformers of the 3-nitro-1,2,4,5-tetraisopropylbenzene radical anion** have been detected by *T. M. McKinney* and *D. H. Geske* by means of ESR spectroscopy following electrochemical reduction. The two conformers differ in the angular orientation of the nitro group with respect to the ring plane. The free energy of conversion of the form with the greater into that with the lesser angle in acetonitrile was determined as $\Delta G_{298} = (-5 \pm 1)\times10^2$ cal/mole. The radical anion of 2-nitro-1,3,5-triisopropylbenzene does not display conformational isomerism. / J. chem. Physics *44*, 2277 (1966) / –Hz. [Rd 519 IE]

***N*-Unsubstituted hydrazones,** which are otherwise difficultly accessible, have been prepared by *G. R. Newkome* and *D. L. Fishel* from *N,N*-dimethylhydrazones by exchange with anhydrous hydrazine in absolute alcohol. The unsubstituted hydrazones are obtained very pure and in excellent yields. In particular, they are free from azines and can be kept without decomposition in the free state. Some hitherto unknown hydrazones (*e.g.* those of α-tetralone, yield 96 %, m.p. 38–40 °C, and of 1-indanone, yield 79 %, m.p. 77 to 78 °C) have been obtained in this way. The method fails for sterically hindered or aromatic carbonyl compounds that in the *ortho*-position to the carbonyl group have substituents (*e.g.* halogen) that are easily removed by nucleophiles. The last-mentioned compounds afford 1*H*-indazole when treated with hydrazine. / J. org. Chemistry *31*, 677 (1966) / –Bu. [Rd 513 IE]

# BOOK REVIEWS

**Advances in Heterocyclic Chemistry.** Vol. 4. Edited by *A. R. Katritzky* with collaboration by *A. J. Boulton* and *J. M. Lagowski*. Academic Press, New York-London 1965. 1st edit., 462 pp., bound $15.–.

Volume 4 of the series is divided into five chapters, each written by an acknowledged expert. The first three chapters are devoted to sections of heterocyclic chemistry that have not been previously reviewed.

The first chapter treats the addition of water to nitrogen heterocycles that was first observed among pteridines (Qualitative Aspects: *A. Albert* and *W. L. F. Amarego*, 42 pp., Quantitative Aspects: *D. D. Perrin*, 30 pp.). It is followed by one chapter each on isothiazoles whose first simple member was prepared in 1956 (*R. Slack* and *K. R. H. Woolridge*, 13 pp.) and on oxazolones (*R. Filler*, 32 pp.). In a further chapter *H. J. den Hertog* and *H. C. van der Plas* (24 pp.) give an account of the hetarynes, which constitute a new class of energy-rich organic compounds, not isolable in substance.

Hetarynes are of importance chiefly as intermediates in abnormal nucleophilic heteroaromatic substitution reaction. Normal nucleophilic substitution (addition-elimination mechanism) of six-membered aromatic heterocycles (azines) such as pyridine, pyrimidine, *s*-triazine, *etc.*, is the subject of by far the longest contribution (*R. G. Shepherd* and *J. L. Fedrick*, 278 pp.). Since there was an article of nucleophilic heteroaromatic substitution in Vol. 3 of this series, the

question arises whether further treatment after such a short time is justified. In spite of considerable overlap between the two articles the reviewer accepts the duplication: first, because elucidiation of substitution of this type is in very rapid development (90 % of the experimental contributions belong to the last ten years); and, secondly, because of the extraordinary thoroughness of *Shepherd* and *Fedrick*'s article (about 800 references).

The good repute that "Advances in Heterocyclic Chemistry" earned by the first three volumes will certainly not be diminished by Volume 4.

*Th. Kauffmann* [NB 496 IE]

**Agar Gel Electrophoresis.** By *R. J. Wieme*. Elsevier Publishing Company, Amsterdam-London-New York 1965. 1st edit., 425 pp., 116 figs., 25 tables, bound, DM 61.50 (about $15.–).

An explanation of the physical basis of electrophoresis and a review of suitable gels are followed by a description of the methods used in practice for zone electrophoresis on agar gel, *e.g.* fully enclosed gel and agar plates that contain a layer of agar gel or agar sol. Analytical electrophoresis is the kernel of the exposition, which describes in detail the methods used with agar plates. Three types are differentiated: electrophoresis with a voltage drop of 5 V/cm or of 15 V/cm, and electrophoresis in liquid agar sol. The literature is comprehensively and critically surveyed, so that this monograph serves as a handbook of methods. Moreover, analysis of the pherograms is explained in detail: localization of the zones in dried agar film by physical and, particularly, by chemical methods (specific color reactions) and their quantitative evaluation are treated in detail. In addition the interesting methods for localization of substances having enzymatic properties are described, and finally precipitation by antiserum (immuno-electrophoresis). In conclusion an exposition of the application of agar plate methods for the separation of a diversity of substr tes occupies 171 pages, particular attention being naturally p id to proteins and enzymes.

The author's wide experience is eviden in many sections of the book. All who use electrophoresis will benefit from reading this excellent book and it is to be hoped that it will help to show the enquiring research worker the manifest advantages of agar gel electrophoresis. For the next edition, which can be confidently anticipated, the reviewer would like to express a few wishes: The methods used with agar plates (normal voltage, high voltage, and agar sols) are carefully described under these three variants, and it would be very useful if the relative results achieved by them were explained for electrophoresis of one normal serum, with illustrations of the colored pherogram and also of the usual protein diagram.

There is no one ideal method of electrophoresis – each method has its advantages and disadvantages, whose relative importance is determined in part by the problem set. The present book enables the advantages of agar gel electrophoresis to be exploited, and thanks are due to the author for describing his field of work.

*W. Bockemüller* [NB 497 IE]

**Organic Reaction Mechanisms.** By *R. Breslow*. W. A. Benjamin, Inc., New York-Amsterdam 1965. 1st edit. ix + 232 pp., numerous figs., paperback $4.35.–, bound $7.70.

The gap between a textbook and the original literature is great. For a study of organic reaction mechanisms this gap can be bridged by *R. Breslow*'s original and didactically successful contribution. In seven chapters (Bonding in Organic Compounds; Reaction Mechanisms and Reaction Rates; Nucleophilic Aliphatic Substitution; Ionic Elimination and Addition Reactions; Aromatic Substitution; Reactions of Carbonyl Compounds; Reactions Involving Free Radicals) the reader is introduced to nearly all the basic facts and aspects of reaction mechanism. Even difficult subjects, such as MO treatment of conjugated compounds, transition state theory, electronegativity, hybridization, and general acid catalysis are presented simply and clearly. The experiments on which theory is based are always emphasized. The discussions of "special topics" which follow each chapter include the most recent advances and familiarize the reader with such research areas as Hückel's rule, enzyme catalysis, carbonium ion rearrangements, cycloadditions, π-complexes and aromatic substitution, redox reactions, and polar effects in radical reactions.

Production and formulae, with a few exceptions (p. 224), are excellent. As regards content, exception can be taken only to the identification of resonance with valence bond theory on p. 9, for according to *Heilbronner* the former is closer to MO theory.

Students will benefit from this book in their preparation for advanced ex inations, and all others for refreshing their memory, since only textbook knowledge of organic and physical chemistry is required. An attraction, but also a problem, of the book is the brief, concise presentation: this makes reading it a pleasure, but is too demanding for the beginner.

*C. Rüchardt* [NB 500 IE]

**Fortschritte der Arzneimittelforschung** [Advances in Drug Research]. Vol. 8. Edited by *E. Jucker*. Birkhäuser Verlag, Basel-Stuttgart 1965. 1st edit., 530 pp., numerous figs. and tables, bound, DM 115.– (about $29.–).

This volume, like earlier ones, contains comprehensive reviews of problems in drug research.

*G. Woolfe* devotes 42 pages to "The Chemotherapy of Amoebiasis". After a short introduction to the test methods used *in vivo* and *in vitro*, there is a discussion of the chemistry, pharmacology, and clinical use of emetine and the newer effective antibiotics and chemotherapeutic substances (Paromomycin, Biallylamicol, Entobex, Mantomid, Diloxanide, and Mebinol). Although the new substances represent an advance for the physician and the patient, emetine and dehydroemetine are still essential for extraintestinal infections (198 references). – "Biochemical Effects of Drugs Acting on the Central Nervous System" are reviewed by *L. Decsi* in 100 pages. The first part is devoted to metabolism in the central nervous system and chemical transport. There follows a discussion of the biochemical action of substances that excite or depress the central nervous system. The final discussion indicates that there is as yet no satisfactory conclusion in spite of the extremely large number of publications in this field (1841 references).

*H. Uehleke* reviews "Biological Oxidation and Reduction on Nitrogen of Aromatic Amino and Nitro Compounds" in 62 pages. The mechanism and reaction products are discussed first. The second section deals with the toxic action of the products, and in particular with the formation of methemoglobin and with the role the products can play in cancer formation by carcinogenic aromatic amines (473 references).– "Narcotic Antagonists" are reviewed by *S. Ascher* and *L. S. Harris* (58 pages). They report first on the chemistry of antagonists to morphine and substances of similar activity. After a short discription of the methods usually used to determine antagonist action, attention is directed to the relations between chemical structure and activity and to the pharmacology and clinical use. This review (223 references) closes with a criticism of the receptor theory as explanation for the effect. – *M. W. Whitehouse* devotes 106 pages to a comprehensive review of "Some Biochemical and Pharmacological Properties of Anti-Inflammatory Drugs", referring to the often unsolved problems of the pathology and therapy of "rheumatic"diseases. A short introduction on the experimental methods of testing anti-inflammatory or antirheumatic activity is followed by a discussion of presently known effects on the biochemistry of the organism and of relations between chemical constitution and activity. A review of the known changes in the biochemistry of the organism due to rheumatic diseases, and consideration of the conclusions that can be drawn from the results reported, close this contribution (404 references).

The aim of *J. A. Montgomery* in his article "On the Chemotherapy of Cancer" was to discuss the types of substance studied (alkylating agents, antimetabolites, hormones, antibiotics, plant extracts) and to relate their constitution to their activity so far as possible. A section on the therapy and its problems closes the review (68 pages, 496 references). – An extensive subject index, and cumulative indexes of authors and articles in the series, make this volume a useful reference work. The production, with the very numerous structural formulae, is excellent, as in previous volumes.

*O. Schaumann* [NB 493 IE]

**Kunststoff-Handbuch. Aufbau, Verarbeitung, Eigenschaften und Anwendung der synthetischen Werkstoffe** (Handbook of Synthetic Industrial Materials. Structure, Processing, Properties, and Applications). Edited by *R. Vieweg* and 14 co-editors for the single volumes. Carl Hanser Verlag, München. Vol. III: Abgewandelte Naturstoffe (Modified Natural Products). Edited by *R. Vieweg* and *E. Becker*. 1965. xv + 470 pp., 237 figs., 80 tables, linen DM 98.– (about $25.–); on subsctiption to the complete work, DM 79 (about $20.–).

Well-known specialists here report on a field which often is, quite unjustifiably, somewhat neglected in discussions of synthetic industrial materials, namely on materials derived by modification from natural sources such as wood, cellulose, and casein. Although the production of these materials has not increased as rapidly as that of synthetic resins and plastics, their significance (yearly production over 100000 tons in Germany alone) can by no means be overlooked. The greater part of this book is devoted, as expected, to the derivatives of cellulose. Who would want to do without Vulcanized Fiber, cellulose glass, celluloid, acetylcellulose, and other esters and ethers of cellulose? All these are treated by competent specialists who give a clear and easily grasped presentation of their chemical technology, properties, processing, and applications.

The chapter on injection molding compositions of cellulose esters is particularly well written. In the otherwise excellent treatment of cellulose ester films the coverage of the non-German literature is somewhat scanty. As a general principle as much literature should be cited in such compilations as possible, since the documentation of artificial resins and plastics is not yet developed to a satisfactory extent.

The sections on laminated wood and artificial horn, materials produced in smaller amounts smce they can be formed only by cutting, round the book off very well.

Like Volume IV (on polyvinyl chloride) [1], this book also well meets the needs of resea ch and technology. Chemists, physicists; and engineers interested in the scientific aspects, as well as procesing and applications engineers, can gain valuable information from this volume on behavior, uses, and properties of this class of synthetic materials.

# A New Group of Antischistosomal Compounds

BY DR. PAUL SCHMIDT AND DR. MAX WILHELM
RESEARCH LABORATORIES, CIBA AG., BASEL (SWITZERLAND)

*A number of compounds containing the 5-nitro-2-thiazolyl group are suitable for the treatment of schistosomiasis; 1-(5-nitro-2-thiazolyl)-2-imidazolidinone is particularly effective. The compounds are taken up selectively by the schistosomes causing the disease and by their eggs, and destroy both. – A review of earlier attempts to control this tropical disease is also presented in this communication.*

## 1. Schistosomiasis (Bilharziasis)

After malaria, schistosomiasis is the most widespread disease of tropical and subtropical regions. It is caused by trematode parasitic flukes of the genus *Schistosoma* that live in pairs in the blood vessels of man and some other mammals. The male and the female worms are tightly intertwined, the thread-like female virtually enveloped in the ventral fold of the larger male, which effects the attachment and movement of the pair in the lumen of the vascular system by means of its suckers (Fig. 1). Schistosomes derive their nourishment from the blood. They can usually survive 20 years, up to a maximum of 30 years, and reach a length of 0.8–1.2 cm.

Fig. 1. Schistosome pair.

There are three types of schistosome mainly responsible for schistosomiasis in man, each of which gives rise to a typical clinical picture:

*Schistosoma haematobium*, the cause of urogenital schistosomiasis, affects the bladder and anal regions; the symptoms are localized in the urinary tract often involving the kidneys and, in women, the genital tract also.

*Schistosoma mansoni*, the cause of intestinal schistosomiasis, principally affects the mesenteric vessels. Symptoms occur in the intestinal tract, the spleen, and the liver. Dysentery and portal hypertension are frequent consequences.

*Schistosoma japonicum*, the cause of splenohepatic schistosomiasis, inhabits less clearly circumscribed regions than do the other types, but is found mainly in the spleen and liver. *S. japonicum* is responsible for a complex of exclusively splenohepatic symptoms whose development is, however, faster and more spectacular than in *S. mansoni* infections.

The life cycle of the three main types of the parasite involves four stages of development:

1. The female deposits its eggs, principally in the small vessels of the intestine or the urinary organs. The eggs remain lodged there and the blocked sections of the vessels atrophy. Some of the eggs diffuse into the surrounding tissues, where they cause characteristic inflammation. Small granulomas form around eggs or groups of eggs ("pseudo-tuberculomas"). If, however, the eggs reach the lumen of the bladder or intestine they are excreted in the urine or feces. In this way, the disease is transmitted further.

2. Larvae (miracidia) hatching from the eggs when they have found their way into water swim around and eventually bore into the intermediate host, a water-snail.

3. In the water-snail thousands of bifid-tailed cercaria with boring glands develop from each miracidium by asexual reproduction. Several weeks after the infection of the snail, *i.e.* after penetration by the miracidium, the

very numerous cercaria swarm out into the water, where they either swim freely or remain on the surface. On contact with human skin or mucous membrane they enter the organism by means of their acid glandular secretion. By way of the lymph or blood vessels the young parasites reach the liver, where they become sexually mature within a few weeks in the branches of the portal vein.

4. Once paired, the worms migrate to the mesenteric or intestinal veins, where they remain or pass into the plexus of veins of the lesser pelvis. Development is thus complete and the cycle begins again.

## 2. Distribution

According to estimates made by the World Health Organisation, the number of persons suffering from schistosomiasis amounts to 200–300 million. *S. haematobium* is found throughout North Africa from Morocco to the Nile valley, in West Africa from Senegal to Angola, as well as in East and South Africa and Madagascar. Outside Africa, these parasites occur on the Arabian peninsula and in Iraq. *S. Mansoni* occurs particularly in the eastern fringe areas of Africa, from Lower Egypt to South Africa, in Madagascar and in the Yemen, and also in Brazil, Venezuela, and on some of the islands in the West Indies. *S. japonicum* is very widespread in China and is found in certain parts of Japan and the Philippines.

## 3. Antischistosomal Therapy

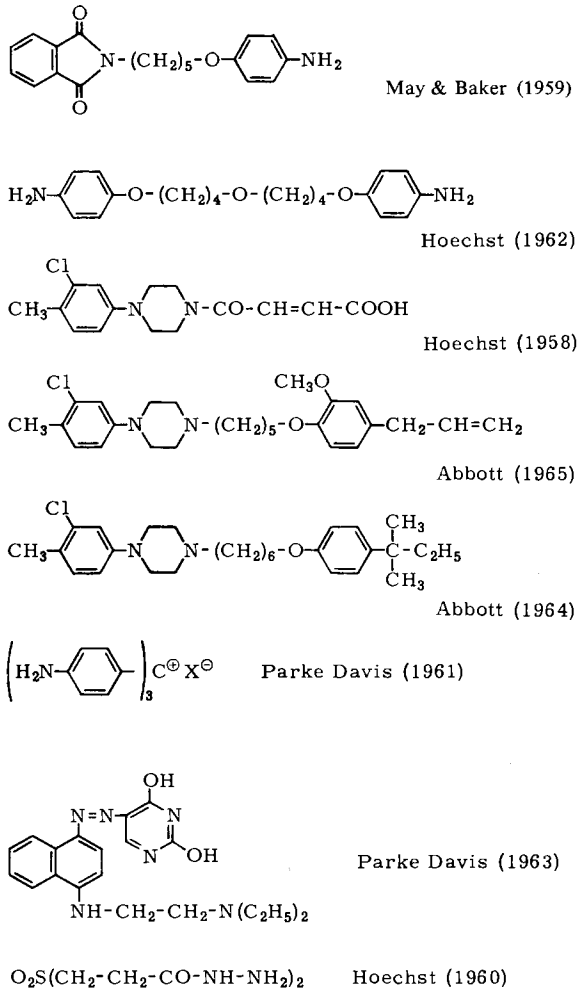
In order to control schistosomiasis successfully the life cycle of the parasites must be interrupted at one or more stages of their development. This could be achieved by eradication of the intermediate host, the water-snail, or by treatment of infected humans with drugs that attack the schistosomes and prevent the production and deposition of eggs.

Each of these courses is beset with considerable difficulties. Eradication of the snails requires a molluscicide that attacks the intermediate host specifically without damaging fish and plants living in the same waters. Much thought and energy have been spent on attempts to find a method of preventing the development of the parasites in the principal host; several substances have shown activity in animal experiments but have so far proved unsuitable for clinical use.

In the past, only two groups of substances have been used, with varying success; these are compounds of tervalent antimony and derivatives of thioxanthone (10*H*-dibenzo[*b*,*c*]thiin-10-one).

The use of tartar emetic in the treatment of bilharziasis was introduced by *Christophersen* [1] as long ago as 1918. Compounds of tervalent antimony are active *in vitro* as well as *in vivo*, regardless of the species of schistosome and of the host. The therapeutic effect is limited only by the fact that relapses occur if the dosage administered is too low; since the substance is highly toxic, however, effective therapeutic doses may not be tolerated.

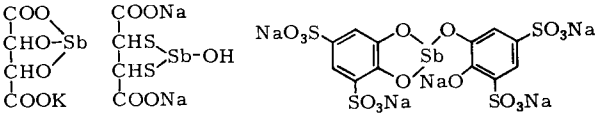
[1] *J. B. Christophersen*, Lancet *195*, 325 (1918).



Scheme 1. Antischistosomal drugs tested.

Attempts to detoxify tartar emetic have always failed because both the antiparasitic effect and the toxicity depend on the amount of antimony administered. Raising the dose improves the action on the parasite but also increases the toxicity, irrespective of the chemical form of the drug. Moreover, antimony compounds must be administered parenterally, which is a further disadvantage.

Scheme 2 shows the antimony compounds customarily used in the treatment of schistosomiasis, namely tartar emetic *(1)*, Astiban® *(2)* (Hoffmann-La Roche), and Fuadin® *(3)* (Winthrop). Astiban is less toxic than tartar emetic and has been well received in various countries [2].

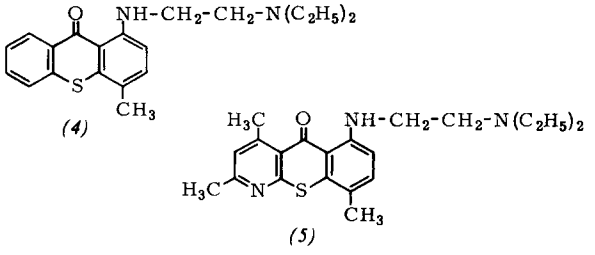


Scheme 2. Antimony-containing antischistomal drugs.

Of the antimony-free schistosomicidal agents, only the thioxanthone derivatives have proved useful in practice. Around 1932, xanthone and thioxanthone derivatives

[2] *E. A. H. Friedheim et al.*, Amer. J. trop. Med. Hyg. *3*, 714 (1954); *P. Cavier*, Biol. medicale *49*, 201 (1960).

containing dialkylaminoalkylamino side-chains were produced as antiprotozoal drugs. These compounds also displayed a therapeutic effect in mice infected with *S. mansoni*[3], but they were not sufficiently active against *S. haematobium* in man. They may be given orally but are relatively toxic. The best-known compound *(4)* in this group is marketed under the names Miracil D® (Bayer) and Nilodin® (Burroughs Wellcome).



Scheme 3. Thioxanthone preparations.

Our preparation CIBA 17,581-Ba *(5)*[4] exhibited good therapeutic action in mice infected with *S. Mansoni*, but clinically had the same disadvantages as Nilodin® and was consequently abandoned. However, we continued to use this compound for some time afterwards as a comparative substance in experiments *in vivo*. Recently, Sterling-Winthrop found that a metabolite of *(4)* in which the methyl group is hydroxylated is equally effective but ten times less toxic[5].

## 4. Experimental Testing

Before any experimental work can be undertaken in the field of schistosomiasis, a suitable model for microbiological testing must be available. The customary *in vitro* test methods such as are used to determine the antibacterial activity of antibiotics have only a limited value in the case of schistosomes, because the damage to the parasites does not become visible until a fairly late stage. During the relatively long period before the drug begins to take effect (at least 2 days), environmental factors may come into play and lead to artefacts in the results. It is thus better to leave the flukes in their natural surroundings, *i.e.* in the blood vessels of the infected host.

In the years 1948/1949, workers in English and German Institutes succeeded in reproducing the natural development cycle of *S. mansoni* in the laboratory. The preferred experimental animal is the white mouse, which usually harbours about 20 paired adult worms in the vessels of the intenstinal tract six weeks after infection with 100 cercaria. As in man, eggs are found in the feces, and also in the liver. With animals uniformly infected in this way it becomes possible to test drugs under reproducible conditions.

## 5. Natural and Synthetic Nitro Compounds

Since 1948 we have been synthesizing and screening nitro compounds, in particular heterocyclic nitro compounds, in the hope of finding effective antibacterial and/or antiparasitic substances. It was about this time that chloramphenicol, an antibiotic with a nitro substituent on an aromatic nucleus, was discovered.

Later it became evident that natural organic nitro compounds are much more common than had previously been supposed. They are consitutents of plant material or metabolites of microorganisms. The nitro group may be bound aliphatically or aromatically. 3-Nitropropionic acid, for instance, occurs fairly frequently in Nature; in the plant it is bound in the form of glycosides, *e.g.* in the roots of the sweet violet (*Viola odorata*). The antibiotic azomycin (2-nitroimidazole) is an example of a naturally-occurring heterocyclic nitro compound; it combines rather low toxicity in warm-blooded animals with potent antibacterial activity.

A large number of nitro compounds has been synthesized in recent years, some of which are suitable for use as insecticides, herbicides, or fungicides. Among the nitroheterocycles, some nitrofuran derivatives, in particular, have proved useful as bactericides and antiprotozoal agents in human and veterinary medicine. Some simple nitrothiazole derivatives are also employed as antiprotozoal agents, especially in veterinary medicine.

We have been concerned particularly with nitro derivatives of the furan, thiophene, imidazole, pyrazole, thiazole, pyridine, and pyrimidine compounds, and with some dinitroheterocycles and anellated nitroheterocycles. Some of these substances possess interesting antibacterial and antiparasitic properties, but none of them meets the demands made nowadays on drugs.

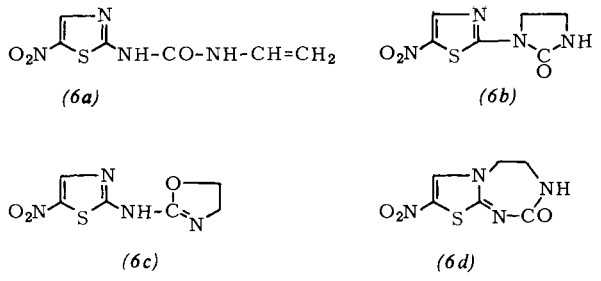
## 6. Nitrothiazoles

### a) Synthesis and Elucidation of the Structure of 1-(5-Nitro-2-thiazolyl)-2-imidazolidinone

Some years ago we began an intensive study of the nitrothiazole series. Condensation of 2-chloroethyl isocyanate with 2-amino-5-nitrothiazole *(7)* led to *N*-(2-chloroethyl)-*N'*-(5-nitro-2-thiazolyl)urea *(8)*, which displayed an interesting activity against protozoa. Under neutral or alkaline conditions hydrogen chloride was split off from this compound *(8)*, and a product with the molecular formula $C_6H_6N_4O_3S$ was formed that distinguished itself by its marked activity against *S. mansoni* in the *in vivo* test described above. After daily doses of 2 mg per mouse for one week no living flukes were found on subsequent autopsy[6].

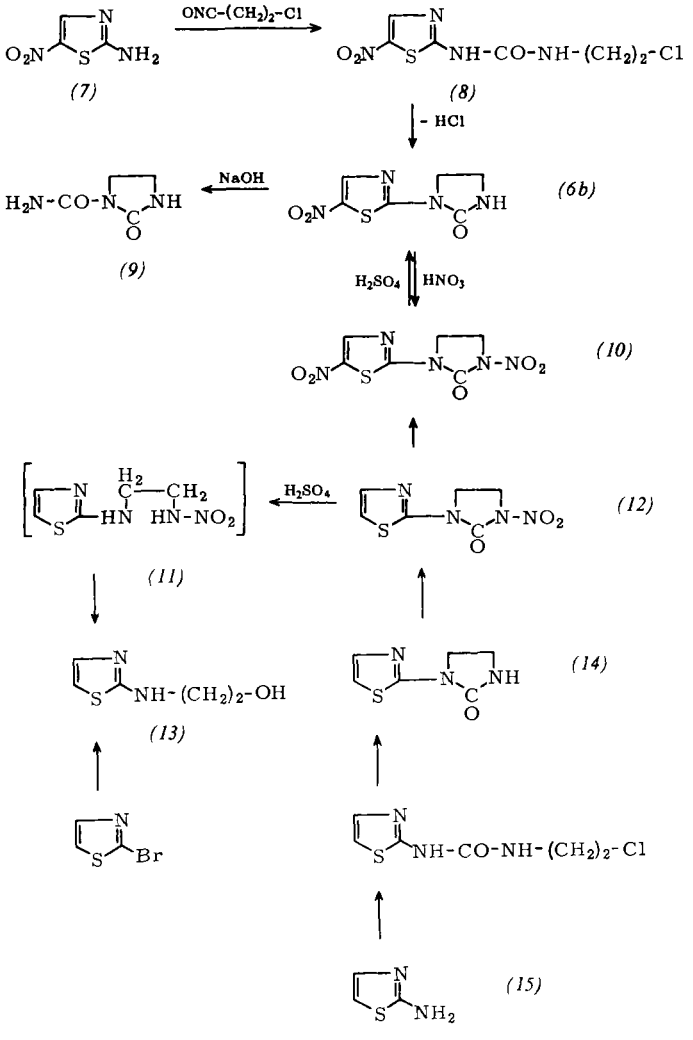
The molecular formula and the nature of the starting materials indicated that the effective compound would have one of the following formulae:

[6] *C. R. Lambert, M. Wilhelm, U. Striebel, F. Kradolfer*, and *P. Schmidt*, Experientia *20*, 452 (1964).



(6a) (6b) (6c) (6d)

In contrast to *N*-ethyl-*N'*-(5-nitrothiazolyl)urea *(27)*, the compound thus obtained is insoluble in cold 1 N sodium hydroxide solution. The characteristic signals of the allyl group are not present in its $^1$H-NMR spectrum. Thus formula *(6a)* is excluded. Degradation reactions (see Scheme 4) indicated that we are dealing with structure *(6b)*, and not structures *(6c)* or *(6d)* [7].



Scheme 4. Degradation of 1-(5-nitro-2-thiazolyl)-2-imidazolidinone.

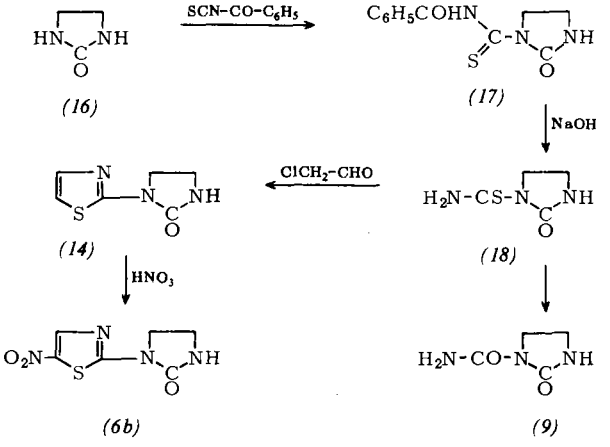
1-(2-Thiazolyl)-2-imidazolidinone *(14)* was obtained by treatment of 2-aminothiazole *(15)* with 2-chloroethyl isocyanate and subsequent cyclization, and on nitration under mild conditions yielded the *N*-nitroimidazolidine *(12)*. The imidazolidinone ring of this substance was cleaved by treatment with dilute acid, 2-(2-thiazolylamino)ethanol *(13)* being formed. This degradation product was also obtained from 2-bromothiazole and ethanolamine. We believe that the degradation proceeds by the way of the *N*-nitroamine *(11)*.

[7] *M. Wilhelm, F. H. Marquardt, Kd. Meier*, and *P. Schmidt*, Helv. chim. Acta, in press.

The *N*-nitroimidazolidinone derivative *(12)* was converted by one mole of nitric acid into the dinitro derivative *(10)*, which was also obtained on nitration of our compound *(6b)*; the dinitroimidazolidinone *(10)* was converted by dilute sulfuric acid into the original mononitroimidazolidinone derivative *(6b)*.

The thiazole ring of our product *(6b)* was opened by sodium hydroxide solution, and 2-oxoimidazolidine-1-carboxamide *(9)* was isolated as fission product; this had already been described by *Jankiewicz-Wasowska* [8] and was synthesized by us by a different route.

These two degradation reactions are strong evidence for the structure *(6b)*. Additional proof was provided by synthesis from 2-imidazolidinone:



Scheme 5. Synthesis of 1-(5-nitro-2-thiazolyl)-2-imidazolidinone *(6b)*.

Condensation of 2-imidazolidinone *(16)* with benzoyl isothiocyanate yielded compound *(17)*, and removal of the benzoyl group with alkali then gave the thiocarboxamide *(18)*, which with chloroacetaldehyde gave 1-(2-thiazolyl)-2-imidazolidinone *(14)*. Subsequent nitration again yielded our compound *(6b)*, which was active against schistosomes.

The structure indicated by the reactions was confirmed by X-ray structure analysis.

### b) Structure and Activity of Similar Thiazole Derivatives

The interesting properties of the nitrothiazole derivative *(6b)* induced us to prepare many similar compounds, but very few of them exerted a good schistosomicidal action [9] (cf. Table 1).

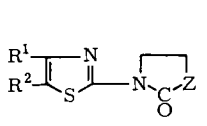
Even a small change in the thiazole ring, such as the introduction of an alkyl or aryl group [compounds *(19)* and *(20)*], gives rise to inactive products. The nitro group in position 5 seems to be essential for activity; if it is omitted, as in *(14)*, or replaced by chlorine, sulfamoyl, or *p*-chlorophenylazo [*(21)*, *(22)*, and *(23)*], the schistosomicidal properties are lost.

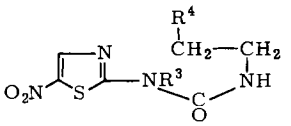
Alkyl substitution in the imididazolidinone ring, as in *(25)*, diminishes the activity; if the ring is enlarged, as in *(24)*, the activity is retained. The open-chain starting material *(8)* is about one-third as active as compound *(6b)*, but the ethylurea derivative *(27)* is inactive. The chloroethyl compound *(8)* probably is partly converted into *(6b)* in the organism.

[8] *J. Jankiewicz-Wasowska*, Roczniki Chem. *34*, 85 (1960).

[9] *M. Wilhelm* and *P. Schmidt*, Acta tropica Suppl. *9*, 3 (1965).

Table 1. Action of thiazole derivatives on *Schistosoma mansoni* in mice (+++ strong, ++ medium, + weak, 0 inactive).



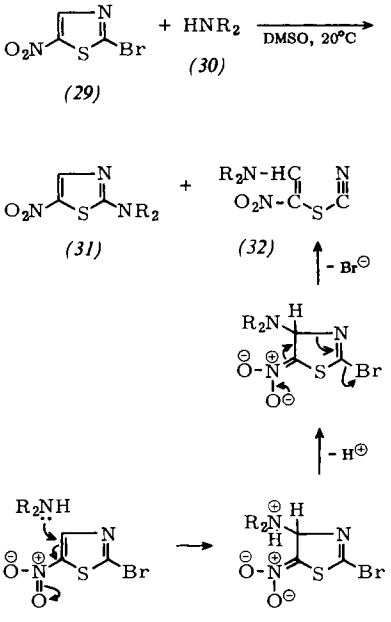


| Compound | $R^1$ | $R^2$ | Z | $R^3$ | $R^4$ | Activity |
|---|---|---|---|---|---|---|
| *(6b)* | H | $NO_2$ | NH | | | +++ |
| *(19)* | Alkyl | $NO_2$ | NH | | | 0 |
| *(20)* | Aryl | $NO_2$ | NH | | | 0 |
| *(14)* | H | H | NH | | | 0 |
| *(21)* | H | Cl | NH | | | 0 |
| *(22)* | H | $SO_2-NH_2$ | NH | | | 0 |
| *(23)* | H | $N=N-C_6H_4$-*p*-Cl | NH | | | 0 |
| *(24)* | H | $NO_2$ | $CH_2$--NH | | | +++ |
| *(25)* | H | $NO_2$ | *N*-Alkyl | | | ++ |
| *(26)* | H | $NO_2$ | $CH_2$ | | | 0 |
| *(8)* | | | | H | Cl | + |
| *(27)* | | | | H | H | 0 |
| *(28)* | | | | $CH_3$ | H | 0 |

We then wondered whether a tertiary nitrogen atom must be present; however, this is apparently insufficient since *N'*-ethyl-*N*-methyl-*N*-(5-nitro-2-thiazolyl)urea *(28)* is inactive.

If the NH group of the imidazolidinone ring is replaced by a methylene group, as in *(26)*, the activity is lost.

The nitrothiazole ring is not particularly stable and is destroyed by warm sodium hydroxide solution. *Ilvespää*[10] isolated fission products by treating 2-bromo-5-nitrothiazole with amines:



Scheme 6. Cleavage of 5-nitrothiazole derivatives.

Condensation of 2-bromo-5-nitrothiazole *(29)* with secondary amines *(30)* often gives two isomeric products *(31)* and *(32)*. The infrared spectrum of *(31)* shows the bands of the expected condensation product, 2-dialkylamino-5-nitrothiazole, whereas a sharp band at 4.63 μ and a very intense band at 6.18 μ in the spectrum of *(32)* indicate a thiocyanate group and a C=C linkage. The presence of the thiocyanate group in compound *(32)* could be shown also by the appearance of a red color upon treatment with iron(III) salts, whereas compound *(31)* displayed no color reaction in this test. The nuclear magnetic resonance spectra of the two compounds are very similar and correspond to what was expected.

The formation of compound *(32)* can be explained by the fact that the secondary amine *(30)* adds to the carbon atom at position 4, which has been rendered positive by the nitro group; the ring then opens, hydrogen bromide being eliminated. Sterically hindered amines give a notably higher yield of compound *(32)* than do simple amines; for instance, dicyclohexylamine yielded virtually only the thiocyanate *(32)*, R = $(CH_2)_6$, whereas only 2-dimethylamino-5-nitrothiazole was obtained when dimethylamine was used. Thus the amine can attack position 2 or 4 of 2-bromo-5-nitrothiazole, substitution at position 2 being more difficult for bases with strong steric hindrance. If the activation energy required to effect substitution at position 2 is high, addition takes place at position 4 and the ring subsequently opens.

As expected, the ring remains intact when primary amines are used.

## 7. Clinical Results

After exhaustive pharmacological, toxicological, and biochemical study, 2-(5-nitro-2-thiazolyl)-2-imidazolidinone *(6b)* (Ambilhar®) was administered for the first time in late 1963 to patients infected with *S. haematobium*. An abrupt decline in the number of viable schistosome ova in the patients' urine was observed, and their general condition improved rapidly, accompanied by an increase in body weight; soon no viable eggs were found in the urine of the patients, indicating that the flukes had been destroyed[11].

Since these first clinical trials, thousands of cases of schistosomiasis have been treated. It soon became apparent that our compound is active against all three types of human schistosome and assures a parasitological cure, provided the treatment is carried out correctly[12]. The effective therapeutic dose is 25 mg/kg administered daily over a period of 5–7 days.

## 8. Mode of Action

1-(5-Nitro-2-thiazolyl)-2-imidazolidinone is particularly active against the mature forms of the parasite, females being clearly more susceptible than males. The first detectable result is the effect on oviposition, which is inhibited already by $^1/_4$ to $^1/_5$ of the schistosomicidal dose[13].

It therefore seemed worthwhile to investigate the absorption of the drug by the host and by the parasite[14]. For this purpose, mice that had been experimentally infected with *S. mansoni* were treated with $^{14}C$-labeled nitrothiazolylimidazolidinone. Autoradiography of the

[12] *C. R. Lambert*, Acta tropica *23*, 1 (1966).

[13] *H. P. Striebel* and *F. Kradolfer*, Acta tropica Suppl. *9*, 54 (1965).

[14] *R. Hess*, *J. W. Faigle*, and *C. R. Lambert*, Nature (London) *210*, 964 (1966).

host tissues and of the parasites showed that the radioactivity was concentrated largely in the mature flukes and in the eggs. Females absorbed more of the radioactive substance than did males. The level of radioactivity was appreciably higher in the deposited eggs than in the surrounding tissues, as is shown in the micro-autoradiogram of a liver section reproduced in Figure 2. There was a high concentration also in the mucous lining of the stomach and in the intestines.

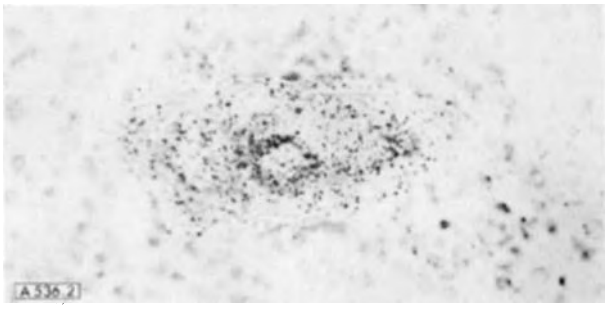

Fig. 2. Micro-autoradiogram (540×) of schistosome ova in the liver of a mouse 24 hours after treatment with 1 g/kg *p.o.* of Ambilhar®.

In the light of our findings, it may be assumed that the mode of action is as follows. Owing to the presence of the imidazolidinone ring [or of the perhydrodiazinone ring in *(24)*], the nitrothiazole derivative is selectively absorbed by the schistosomes and their eggs; the nitro group then exerts its influence on metabolism, perhaps by blocking a redox enzyme. This assumption is all the more plausible in view of the fact that metabolites and synthetic substances without the nitro group displayed no activity.

# Methods for the Synthesis of Uniform Polymers

BY DR. J. H. WINTER

FARBWERKE HOECHST AG., FRANKFURT-HÖCHST (GERMANY)

*The difficulties encountered in the preparation of polymers that are uniform chemically, structurally, and in their molecular weight are due mainly to the wide variety of possible polymers. This article gives a review of attempts to synthesize homogeneous polymers by chain reactions and by stepwise synthesis. Syntheses on templates are extremely important in living cells; methods have recently been found for syntheses of this type that are independent of natural processes. Uniform polymers can also be obtained by reactions on existing polymers. In replicating polymers, this in principle requires the modification of only one polymer molecule.*

## 1. Introduction

### a) The Problem

Polymers are substances formed by the linkage of low molecular weight compounds (monomers) and containing continuous sequences of covalent bonds as in long-chain hydrocarbons (but all the atoms need not be C atoms). The number of monomer units present in a polymer molecule (*i.e.* its degree of polymerization) may be as large as desired. Polymers are characterized by the many possibilities regarding the nature and number of monomer units, the manner in which they are combined, and the side reactions accompanying the synthesis of the polymer.

Owing to this variability, it is very difficult to prepare monodisperse polymers, *i.e.* polymers whose molecules are identical in structure and size. Any side reactions occurring during the preparation of the polymer will affect a much larger proportion by weight of the reaction mixture than in reactions involving only small molecules. Finally, it has been found that the difficulty of isolation and purification increases with the molecular weight of the polymer. For a long time, the chemistry of synthetic polymers was concerned almost exclusively with ill-defined, heterogeneous, amorphous substances. On the other hand, many uniform polymers occur in Nature, some with very high degrees of polymerization, the correct structure of which is essential to the life processes. It was expected that homogeneous synthetic polymers would have better mechanical properties and thermal stability.

This expectation was confirmed when a number of structurally identical, crystallizable polymers had been prepared in the laboratory. Methods have now been developed for the preparation of polymer molecules of uniform length. Even very complex polymers similar to those in Nature and exhibiting biological activity can now be synthesized uniformly with or without the aid of natural substances [1].

### b) The Concept of Uniformity

It is usual to speak of chemical uniformity, structural uniformity, and uniformity of molecular weight. A polymer is chemically uniform if each molecule has the same composition. Homopolymers, by definition, contain only one type of monomer unit (apart from the ends of the chains), so that these polymers satisfy the

[1] Cf. *J. H. Winter*: Die Synthese von einheitlichen Polymeren. Springer, Berlin-Heidelberg-New York, in press.

above condition. However, if a polymer contains more than one type of monomer unit (copolymers), it can be chemically uniform only if the monomer units are present in the same ratio in all molecules and are joined together in a regular manner. (Random distribution of the different monomer units merely presents an illusion of chemical uniformity.) In most polymer syntheses, each monomer unit is linked to *two* other monomer units; the resulting chains should therefore be unbranched. This linearity of the chains is an important criterion of chemical uniformity. Another criterion is the uniformity of the end groups.

In connection with the structure of the polymers, let us consider first their microstructure. The mode of linkage of monomer units of the type $-(A-A')-$ in the polymer chain is important. An arrangement often encountered is

$$-(A-A')-(A-A')-(A-A')-.$$

In polyvinyl compounds and polyolefins, this is known as the head-to-tail arrangement (the substituted C atom being the head). Another factor is the spatial arrangement of the substituents on the C atoms in the chain (*e.g.* the methyl group in polypropylene). These C atoms are asymmetric centers. Following *Natta*, the simplest regular arrangements (with uniform head-to-tail linkage) of the monomer units are known as the isotactic (*d,d,d,d*... or *l,l,l,l*...) and syndiotactic (*d,l,d,l,d,l*...) arrangements of the substituents (Fig. 1)[2].

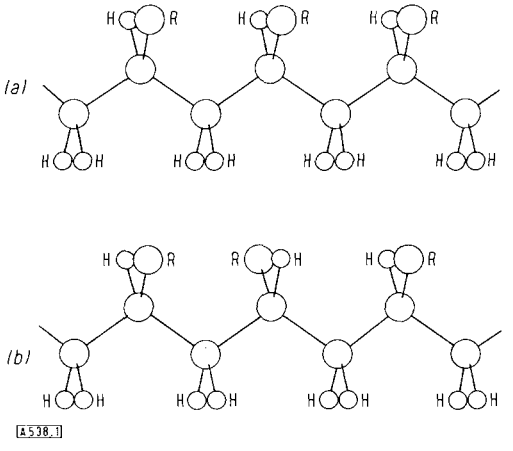

Fig. 1. Model of tactic polymers with head-to-tail monomer units; it is arbitrarily assumed that the chains are extended linearly. (a) isotactic, (b) syndiotactic arrangement of the substituents.

The presence of carbon-carbon double bonds offers the possibility of *cis-trans* isomerism. Configurations of this type in a polymer may again be uniform or nonuniform. The mobility of the chain atoms with respect to one another (*e.g.* "free" rotation about C–C single bonds) enables polymers to assume different conformations, and this is another structural factor. Whereas polymers in solution and in the amorphous state are mainly in the form of random coils, they form certain preferred chain conformations on crystallization. Special mention should be made of the helix structure, which is encountered in many natural macromolecules and in synthetic polymers with regular microstructures.

[2] *G. Natta*, J. Polymer Sci. *16*, 143 (1955).

The measured molecular weight of a polymer generally is an average value. Depending on the method used, the value obtained may be the number-average molecular weight $\overline{M}_n$ or the weight-average $\overline{M}_w$, the latter always being greater. The closer the ratio $\overline{M}_w/\overline{M}_n$ to unity, the more uniform is the molecular weight of the polymer.

## 2. Syntheses Based on Classical Methods

### a) Chain Reactions

The synthesis of a polymer by a chain reaction begins with a reaction (initiation) between an activated substance R* (free radical or ion) as the initiator (sometimes as part of a "catalyst") and a cyclic or unsaturated monomer molecule. As a result, two valences are made available in the monomer by the opening of the double bond or of the ring. The initially activated substance

Free-radical polymerization:

$$R^{\bullet} + n\,CH_2{=}CHCl \xrightarrow[\text{Initiation}]{} R\text{-}CH_2\text{-}C^{\bullet}HCl + (n-1)\,CH_2{=}CHCl$$

$$\xrightarrow[\text{Propagation}]{} R\text{-}(CH_2\text{-}CHCl)_{n-1}\text{-}CH_2\text{-}C^{\bullet}HCl$$

Cationic polymerization:

$$H^{\oplus}\cdots(BF_3OH)^{\ominus} + n\,H_2C\text{-}CH_2 \xrightarrow{\text{Initiation}}$$

$$\left[HO\text{-}CH_2\text{-}CH_2^{\oplus}\cdots(BF_3OH)^{\ominus}\right] + (n-1)\,H_2C\text{-}CH_2$$

$$\rightarrow HO\text{-}CH_2\text{-}CH_2^{\oplus}\cdots(BF_3OH)^{\ominus} + (n-1)\,H_2C\text{-}CH_2$$

$$\xrightarrow[\text{Propagation}]{} H(O\text{-}CH_2\text{-}CH_2)_{n-1}\text{-}O\text{-}CH_2\text{-}CH_2^{\oplus}\cdots(BF_3OH)^{\ominus}$$

Anionic polymerization:

$$R^{\ominus}\cdots Li^{\oplus} + n\,H_2C{=}C(CH_3)(CO{-}OCH_3) \xrightarrow{\text{Initiation}}$$

$$\left[R\text{-}CH_2\text{-}C(CH_3)(CO{-}OCH_3)\cdots Li^{\oplus}\right] + (n-1)\,H_2C{=}C(CH_3)(CO{-}OCH_3)$$

$$\rightarrow R\text{-}CH_2\text{-}C(CH_3)(CO{-}OCH_3)\cdots Li^{\oplus} + (n-1)\,H_2C{=}C(CH_3)(CO{-}OCH_3) \xrightarrow{\text{Propagation}}$$

$$R\text{-}\left[CH_2\text{-}C(CH_3)(CO{-}OCH_3)\right]_{n-1}\text{-}CH_2\text{-}C(CH_3)(CO{-}OCH_3)\cdots Li^{\oplus}$$

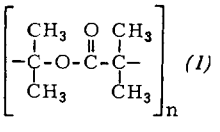
usually becomes linked to the monomer by one of these valences, while the other is used for linkage with another monomer unit, and this process continues (chain growth or propagation).

Whether a chemically uniform polymer can be formed depends on the choice of initiators or catalysts, the monomers, and the other substances present in the reaction mixture. For example, organic peroxides give free radicals that tend to cause side reactions (this tendency is much smaller for azo compounds). Ionic catalysts often react with functional groups in the monomer. As a general rule, the smaller the number of monomer types and of other reacting substances (including impurities) and the higher the activation energies of possible side reactions relative to that of the propagation steps, the easier will be the formation of a chemically homogeneous polymer.

Reactions with high activation energies are relatively unimportant at low temperatures. Reactions of the growing polymers with one another are suppressed by dilution and by polymerization to low conversions. Thus essentially linear homopolymers and copolymers can be obtained by all types of polymerization.

In copolymerization it is not unusual for a monomer unit A at the active end of the polymer to react only with difficulty or not at all with the monomer A, but to react readily with the monomer B, and *vice versa*. The resulting polymer, irrespective of the monomer concentrations, then has an alternating monomer sequence ...A–B–A–B–A–B... An example is the free-radical copolymerization of olefins with sulfur dioxide to form polysulfones [3]. However, the same result can be obtained if only one of the two monomers does not react readily with itself. The concentration of this monomer must then be kept high relative to the other during polymerization.

Thus dimethylketene and acetone, which by itself does not polymerize under these conditions, react alternately at −60 °C in toluene with butyl-lithium as catalyst to give a highly crystalline polyester *(1)* [4].



*(1)*

Dimethylketene and benzaldehyde react similarly [5]. Alternating copolymerization of ethylene with *cis*-2-butene [6] and cyclopentene [7] (and possibly also butadiene [8]) can also be achieved by the use of Ziegler-Natta catalysts. In order to prevent homopolymerization of the ethylene, the other component must always be present in excess.

The activation energy for the incorporation of monomers depends on the mode of addition (*i.e.* head-to-tail, head-to-head). The uniform head-to-tail addition is generally favored on steric grounds, since this is the position in which the substituents present the least hindrance to one another. However, this also means that the monomer unit at the active end of the polymer has a directing influence on the incoming monomer. In polymers in which the substituents on the centers of asymmetry can assume *d* or *l* arrangements, the activation energy for head-to-tail polymerization, for example, in the isotactic position is different from that for the syndiotactic position. In free chain growth, as generally occurs in free-radical polymerization, syndiotactic steps have the lower activation energy. Polymethyl methacrylate prepared by free-radical polymerization contains 75 % of syndiotactically arranged substituents when prepared at room temperature [9], and almost 100 % when prepared at −78 °C.

"Free chain growth" means that the monomer can approach the active polymer ends and can combine directly with the free valences of the terminal monomer units. If the chain growth is not free, the activation energies of the propagation steps change, so that the probabilities of the various steps may change. For example, highly crystalline polyvinyl chloride (crystallinity 80 %) is obtained even at 50 °C by free-radical polymerization in butyraldehyde, whereas the crystallinity is only 10 % in the absence of butyraldehyde [10]. It may be assumed that the butyraldehyde becomes attached to the polymer radical and influences the addition of monomer. Effects of this type are more pronounced in ionic polymerization, where the oppositely charged ion (counterion) can influence the conditions at the active polymer ends. At least two states are possible at the active polymer ends, *i.e.* the state of a dissociated ion pair and that of an undissociated ion pair [11, 12].

In the dissociated state, relatively free, fairly rapid growth occurs at the active chain end. As in free-radical polymerization, this leads to a sterically irregular arrangement of the monomer units, which becomes increasingly syndiotactic as the temperature is lowered. At undissociated ion pairs, on the other hand, the probabilities of the different types of linkage are reversed, so that isotactic addition occurs.

An interesting example is the polymerization of methyl methacrylate with lithium catalysts. At −60 °C in a nonpolar solvent such as hexane, the product is predominantly isotactic [13, 14]. In this system the ion pair at the growing

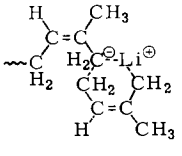
[14] *D. Braun, M. Herner, U. Johnsen*, and *W. Kern*, Makromolekulare Chem. *51*, 15 (1962).

polymer end is undissociated. In polar solvents such as dimethoxyethane, on the other hand, the ion pair is strongly dissociated; the influence of the counter-ion is therefore practically eliminated, free growth can occur, and predominantly syndiotactic polymer is formed.

The tendency towards dissociation of the ion pairs is determined by the polarity of the solvent and the degree of solvation of the ions [15]. The tendency towards solvation increases with decreasing ionic radius and with increasing polarity of the solvent, sometimes also of the monomer.

In growth on the undissociated ion pair, the incoming monomer is probably first coordinately bound [16]. It is therefore oriented with respect to the polymer end, and can add to the chain stereospecifically. A process of this type is particularly likely with monomers containing functional groups that serve merely to enhance the coordination and orientation. This is probably why monomers containing ether, carbonyl, amino, or similar groups or with a second double bond are particularly suitable for stereospecific polymerization. Examples are vinyl alkyl ethers, alkenyl alkyl ethers, alkoxystyrenes, vinylcarbazoles, and β-chlorovinyl ether, which can be polymerized cationically, and butadiene, isoprene, styrene, 2-vinylpyridine, esters of sorbic acid, acrylates, and methacrylates, which can be polymerized anionically to give stereoregular polymers.

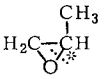
An energetically favored six-membered ring in the *cis*-position may be initially formed with the monomer [17] as the activated coordination complex [*(2)*], (*e.g.* in the ionic polymerization of isoprene).



*(2)*

Even in orientation of the monomer on the ion pair, the terminal monomer unit, and the polymer chain as a whole, still has some directing effect [18]. On the whole, the stereospecificity of a catalyst depends on the interaction of all the substances taking part in the reaction.

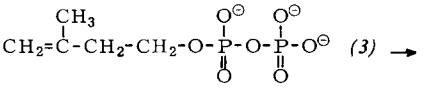
The syntheses of optically active polymers are particularly impressive. For example, propylene oxide generally is a racemic mixture, which gives an inactive product on polymerization with potassium hydroxide as catalyst. However, if diethylzinc that has previously been treated with a little water and (+)-borneol is used as the catalyst, the D-(+)-propylene oxide is polymerized preferentially to give an optically active polymer [19]. The remaining monomer mixture is optically active, since the L-isomer predominates. Owing to the asymmetry in the catalyst (due to the borneol), the activation energies for the incorporation of the two isomers are different (asymmetric induction).



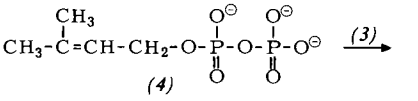
D or L

The first generally convincing stereospecific polymerizations were carried out by *Natta et al.* [20] using Ziegler catalysts. Stereoregular polymers can be prepared with these catalysts even at 100 °C. The mixed catalysts contain a compound of a transition metal in one of its lower oxidation states and an organic compound of a metal from Groups I to III of the periodic system [21]. A typical example is the system $TiCl_3$–$Al(C_2H_5)_2Cl$. The titanium compound forms a crystalline phase of colloidal dimensions, and complexes are formed on the crystal surfaces with the aluminum compound. The active centers from which the polymer grows, generally by an anionic mechanism, are located here. The monomer is again assumed to be coordinately bonded to the active centers [22]. The presence of crystal surfaces undoubtedly contributes to the high stereospecificity of these systems. Important examples are the essentially linear polyethylene and the predominantly isotactic polypropylene obtained by this method at high temperatures [23].

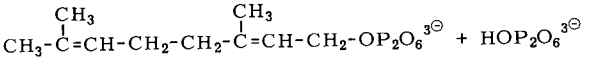
The catalysts with the greatest specificity are produced by Nature in the form of the enzymes. An example of an enzyme-catalysed chain reaction is the synthesis of natural rubber, which was elucidated by *Lynen et al.* [24]. In the chain initiation, the monomer 3-methyl-3-butenyl pyrophosphate *(3)* is isomerized to 3-methyl-2-butenyl (dimethylallyl) pyrophosphate *(4)* by the enzyme isomerase. Another enzyme catalyses the linkage with the next molecule of substrate *(3)*, the pyrophosphate group being eliminated.



*(3)*



*(4)*



Since a new allyl pyrophosphate group is simultaneously introduced, further molecules of the substrate can be introduced in the same manner. The double bond assumes the *cis*-configuration.

Polymers of uniform molecular weight generally are difficult to obtain by chain reactions, since the reactivity of the active polymer end is practically independent of the chain length. Further, chain termination and chain transfer also frequently take place independently of the

molecular weight. In free-radical polymerization, the principal termination reactions are the combination of a polymer radical with an initiator radical or with another polymer radical

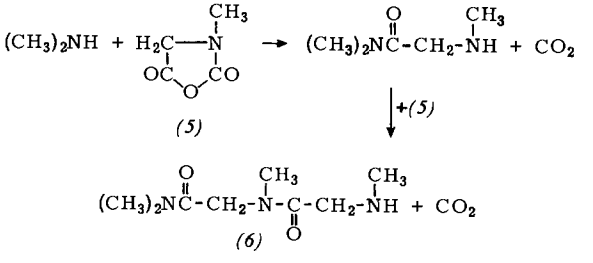
and the disproportionation of polymer radicals

However, the polymer radical may also become saturated by abstraction of an atom or group from another molecule, so that the reaction chain is carried on by the new radical formed (chain transfer):

All these processes occur randomly. In ionic polymerization and in polymerization on Ziegler-Natta catalysts, chain transfer also occurs, mainly to the monomer, as well as catalyst decomposition, side reactions at the active polymer ends, and depolymerization, which also proceed randomly.

Polymers of uniform molecular weight are therefore formed only if none of these reactions take place. Moreover, the growth of all polymer chains must begin as nearly as possible simultaneously and proceed at the same rate. Several cases are now known in which these conditions are approximately satisfied.

For example, in the polymerization of sarcosine *N*-carboxylic anhydride *(5)*, $CO_2$ is eliminated, and a polypeptide *(6)* [25] having a uniform molecular weight is formed. The chain reactions are initiated with protonic substances. Each propagation step leads to the formation of a peptide that is also

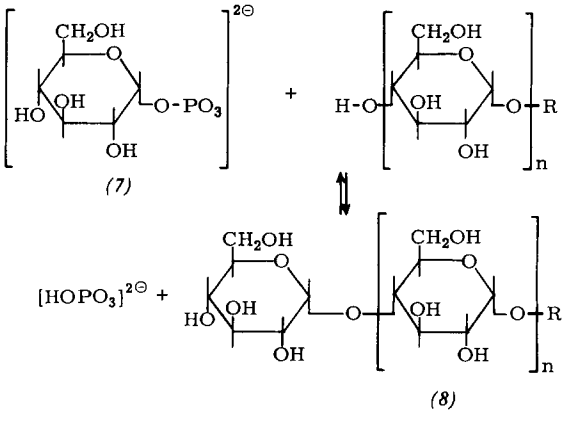


protonic, but very stable in this form in the absence of the monomer. No side reactions occur in acetophenone with secondary amines as initiators. The chains grow at the same rate, so that the molecular weight of the product is fairly uniform [26].

The polymerization of ethylene oxide with protonic substances proceeds similarly, and can also lead to polymers with narrow distributions of molecular weight ($M_n$ = 44000, $M_w/M_n$ = 1.1) [27].

Anionic polymerizations with metal cations are other examples. Many organo-alkali metal compounds, when used as catalysts, give such stable ion pairs that the polymer ends remain active (the polymers remain "living") [28]. However, these processes are very sensitive to impurities. The reaction conditions must be such that either all the polymer anions grow freely or all the ion pairs at the polymer ends are undissociated. For example, in the case of a polystyrene anion with a sodium cation, the dissociation of the ion pairs can be suppressed by the addition of sodium salts that are soluble in the reaction medium [29]. The polymerization then proceeds more slowly, but uniformly. Rapid mixing of the catalyst and the monomers is important, particularly when initiation is slow [30]. In pre-initiation, the whole of the catalyst is first allowed to react with small quantities of monomer [31]. In this way all the chains are initiated, but the degrees of polymerization remain low. The actual polymerization then takes place simultaneously for all polymer molecules as the monomer is added. The "living" polymers must be deactivated by termination when the desired degree of polymerization has been reached; the latter is given by the ratio of the number of monomer molecules to the number of catalyst molecules.

The enzyme-catalysed synthesis of amylose *(8)*, which proceeds *in vitro* in the presence of phosphorylase, can also be carried out in accordance with the above principle [32]. The substrate is glucose-1-phosphate *(7)*, which polymerizes in a chain reaction with elimination of phosphate.



Initiators, such as maltosaccharides containing more than two glucose units, are required. The initiation can be carried out rapidly, and amyloses with very uniform degrees of polymerization (up to 500) can be obtained.

However, polymers of perfectly uniform molecular weight can never be obtained by the above methods. Nevertheless, narrow distributions (Poisson distributions) of the molecular weights are obtained.

### b) Stepwise and Stagewise Synthesis of Polymers

In many polymer syntheses, the two sites of linkage of the monomer react practically independently. Thus

[32] *E. Husemann*, *B. Fritz*, *R. Lippert*, *B. Pfannemüller*, and *E. Schupp*, Makromolekulare Chem. *26*, 181 (1958).

these are not chain reactions in the sense described. A typical example is the polycondensation of a hydroxy acid to a polyester:

$$n\,\mathrm{HO{-}R{-}COOH} \rightarrow \mathrm{H(O{-}R{-}CO)_{n\text{-}1}{-}O{-}R{-}COOH} + (n\text{-}1)\mathrm{H_2O}$$

The process is a mixture of *stepwise* polycondensation (in which one monomer unit is introduced at a time) and *stagewise* polycondensation, in which two polymer fragments combine. This type of monomer will be denoted by a–R–b. Similarly, monomers of the types a–R–a and b–R′–b, each containing two identical functional groups a or b per molecule, combine in an alternating sequence

a–R–ab–R′–ba–R–ab–R′–b.

What has been said about polycondensations is also true when the functional groups combine by addition.

The position of the monomer units of the type a–R–b is fixed by the functional groups. The monomer also determines the centers of asymmetry if these can be introduced unchanged into the polymer, *i.e.* if no racemization or *cis-trans* rearrangement takes place during the synthesis. This can be achieved by the use of mild reaction conditions, in particular low temperatures, by the use of very pure materials, and by catalysis of the linkage reactions.

If it is desired to obtain polymers of this type with uniform molecular weights, the stepwise and stagewise syntheses must not occur randomly, but must proceed in a definite manner. In the case of monomers of the types a–R–a and b–R′–b, one may be used in such a large excess that on grounds of probability only a single linkage step (in both directions in this case) takes place:

$$\mathrm{a{-}R{-}a} + 2\,\mathrm{b{-}R'{-}b} \rightarrow 2\,\mathrm{b{-}R'{-}ba{-}R{-}ab{-}R'{-}b} \qquad (9)$$

or

$$\mathrm{b{-}R'{-}b} + 2\,\mathrm{a{-}R{-}a} \rightarrow \mathrm{a{-}R{-}ab{-}R'{-}ba{-}R{-}a} \qquad (10)$$

If the products *(9)* or *(10)* are now separated from the excess of monomer and then allowed to react with a large excess of the other monomer, the next (double) step also takes place in a controlled manner. Polymer fragments can be joined in accordance with the same principle ("duplication process")[33]:

$$(9) + 2\,(10) \rightarrow (10)\text{–}(9)\text{–}(10)$$

In the cases described, two functional groups can react in each monomer molecule and in each polymer fragment. If only one functional group were present per fragment, it would be easier to obtain uniform polymers, but these would be unable to react further:

$$\mathrm{R{-}a} + \mathrm{b{-}R'} \rightarrow \mathrm{R{-}ab{-}R'}$$

However, it is possible to chemically alter the activities of functional groups, to block them, or to remove them altogether, as well as to introduce new functional groups.

It is therefore also possible to use effectively monofunctional compounds. In the bifunctional monomers a–R–a and b–R′–b, for example, some of the functional groups a may be chemically changed (a′) in such a way that they no longer react with b, and some of the groups b (b′) so that they no longer react with a. The resulting monomers can give only one dimer:

$$\mathrm{a'{-}R{-}a} + \mathrm{b{-}R'{-}b'} \rightarrow \mathrm{a'{-}R{-}ab{-}R'{-}b'} \qquad (11)$$

After conversion of b′ into b or of a′ into a in *(11)*, the process can be continued as follows:

$$\mathrm{a'{-}R{-}ab{-}R'{-}b} + \mathrm{a{-}R{-}a'} \rightarrow \mathrm{a'{-}R{-}ab{-}R'{-}ba{-}R{-}a'} \qquad (12)$$

or

$$\mathrm{a'{-}R{-}ab{-}R'{-}b} + \mathrm{a{-}R{-}ab{-}R'{-}b'} \rightarrow \mathrm{a'{-}R{-}ab{-}R'{-}ba{-}R{-}ab{-}R'{-}b'} \qquad (13)$$

This procedure may be continued as long as the required isolation and purification can still be carried out. It is possible in this way to produce very complex aperiodic polycondensates, *e.g.* polyesters[34], polypeptides, and polynucleotides[35]. The method has very often been used for the synthesis of peptides[36]. The 20 most important naturally occurring amino acids, of which all but glycine are optically active, are used. To prevent racemization, polymerization must be carried out under particularly mild conditions. For example, an amino acid whose amino group is protected by the t-butoxycarbonyl (BOC) group is allowed to react with another amino acid whose amino group is unprotected, but whose carboxyl group is esterified with ethanol. The compounds can be condensed in the presence of dicyclohexylcarbodiimide (DCCI):

$$\mathrm{BOC{-}NH{-}R{-}COOH} + \mathrm{H_2N{-}R'{-}COOC_2H_5} \xrightarrow{\mathrm{DCCI}} \mathrm{BOC{-}HN{-}R{-}COO{-}NH{-}R'{-}COOC_2H_5} + \mathrm{H_2O}$$

After removal of *e.g.* the BOC group, the reaction can be continued. The yields obtained in such syntheses are generally about 80 % per step. Consequently, in a synthesis involving 20 steps, the final yield of uniform material is only about 1 %.

*Merrifield*[37] therefore linked the carboxyl group of the first amino acid of the peptide to an insoluble carrier, *e.g.* a cross-linked polymer

BOC–NH–R–COO-carrier.

All reagents can then be used in excess, so that yields of approximately 100 % per step are obtained. After each reaction, the cross-linked polymer bearing the peptide chains can be filtered off and washed if necessary. When the synthesis is complete, the peptide chains are carefully released from the cross-linked polymer. Other polycondensates can, in principle, also be prepared in this way. The main problem is to find a suitable cross-linked polymer.

A question that arises here is how Nature produces uniform polypeptides and proteins, many of which have

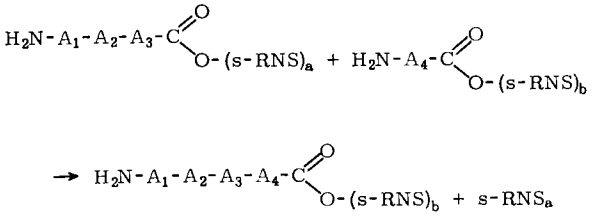
extremely high molecular weights. The syntheses themselves take place in the cell cytoplasm, and exhibit certain similarities to "stepwise" laboratory syntheses. However, one fundamental difference is that the peptide chains are produced in special centers of synthesis, the ribosomes, one chain being synthesized per ribosome. The information concerning the synthesis, *i.e.* the synthesis program, is carried from the cell nuclei to the ribosomes by nucleic acids, the messenger RNA's (m-RNA). Other nucleic acids, the transfer (soluble) RNA's (s-RNA), are linked by their carboxyl groups to the monomeric amino acids. Special s-RNA's correspond to the various amino acids. The synthesis program is fixed in the m-RNA by the sequence of the nucleotide units, a sequence code (the "genetic code") consisting of a combination of three out of four fundamental units ("codons") being assigned to the amino acids [38]. In accordance with this key system, the amino acids are carried to the growing peptide chains by their s-RNA, which becomes attached for a short time to the m-RNA. The linkage itself is brought about by enzymes, and proceeds in accordance with the following scheme:



$A_1$, $A_2$, *etc.*: amino-acid residues.

## 3. Syntheses on Templates

In the syntheses described so far, the contact of a substance with the active polymer ends favors certain reaction steps, and so leads to a more controlled synthesis. Contact of this nature can be extended to include the whole of the polymer molecule being formed. Such processes are known as syntheses on templates.

A t mplate may be described as a polymeric substance or a crystal of a low molecular weight compound, which exerts a contact effect on the polymer being formed; under favorable conditions, the latter assumes the dimensions of the available contact area. The polymer formed may be related or unrelated to the template substance, and in the extreme case the two are interchangeable or even identical, so that replication of polymers becomes possible. The contact effect is exerted by bonding of the entire polymer being formed to the matrix for a limited time; all types of bonds are possible, and they may differ widely in strength. It must be possible for the polymer molecule to be released intact from the template. Thus a template is simply a catalyst, though this does not mean that no other catalysts and (for chain reactions) initiators are required.

[38] See, *e.g.*, *S. Ochoa*, Ber. Bunsenges. physik. Chem. *68*, 707 (1964).

### a) Crystals of Low Molecular Weight Compounds as Templates

Many studies have been carried out in recent years on polymerizations of crystalline monomers. The monomer molecules rearrange in the crystal lattice and form the polymer. The polymer occupies a smaller volume than its monomers. If the contraction on polymerization is not too great, the crystal lattice of the monomer should impose order on the polymer, *i.e.* it should act as a template.

However, only a few examples of this nature are known: Solid methyl methacrylate (mixed with magnesium) undergoes free-radical polymerization at −100 °C to form isotactic polymethyl methacrylate, though it normally gives a syndiotactic polymer at low temperatures [39]. This observation can only be explained by the influence of the solid monomer. Solid trioxane gives a crystalline polymer whose chains are arranged parallel to the trigonal axis of the monomer crystal [40]. Crystalline polymers of high structural uniformity are also formed in the crystalline monomers diketene, β-propiolactone, and 3,3-bis(chloromethyl)oxetane [41].

Whereas the templates in these cases are the crystalline monomers themselves, this function can also be taken over by foreign substances. *Clasen* [42] made use of the fact that crystalline urea and thiourea, when powdered with many low molecular weight compounds (in the presence of a little methanol) and shaken, change their crystal structure. They form tubular tunnels, in which the added compounds are deposited. *Clasen*, and later other authors, prepared tunnel inclusion compounds of polymerizable substances such as 2,3-dimethylbutadiene, 1,3-cyclohexadiene, and vinylidene chloride [43]. These monomers could be converted into polymers of high structural uniformity by heating or by irradiation with electrons, γ rays or X rays. The space available in the tunnels forces the monomers into an arrangement that is reproduced in the polymers (Fig. 2).

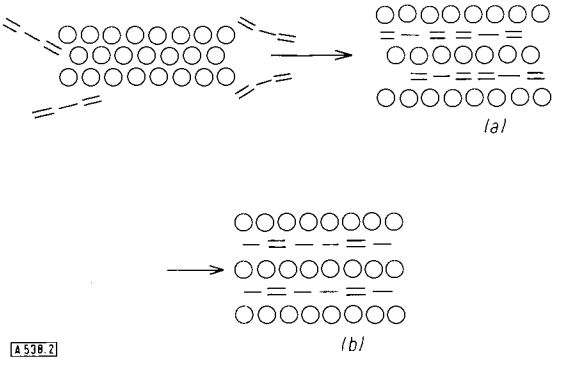


Fig. 2. Channel inclusion (a) and channel polymerization (b), schematic (after [42]).

[39] *V. A. Kargin*, *V. A. Kabanov*, and *V. P. Zubov*, Vysokomolekuljarnye Soedinenija *2*, 303 (1960).

[40] *J. Lando*, *N. Morosoff*, *H. Morawetz*, and *B. Post*, J. Polymer Sci. *60*, S 24 (1962).

[41] *K. Hayashi*, *Y. Kitanishi*, *M. Nishii*, and *S. Okamura*, Makromolekulare Chem. *47*, 237 (1961).

[42] *H. Clasen*, Z. Elektrochem. Ber. Bunsenges. physik. Chem. *60*, 982 (1956).

[43] *J. F. Brown jr.* and *D. M. White*, J. Amer. chem. Soc. *82*, 5671 (1960); *O. L. Glavati* and *L. S. Polak*, Petroleum Chem. 2, 201 (1963).

The template effects of urea and of thiourea can be seen from the fact that only monomers of suitable dimensions can be used in this method. However, the degrees of polymerization are not uniform. To obtain uniformity in size, the lengths of the tunnels would have to be the same and chain-terminating reactions would have to be excluded, and neither of these conditions has so far been achieved. It should also be noted that in all the cases described, the only forces between the templates and the polymers being formed were physical forces.

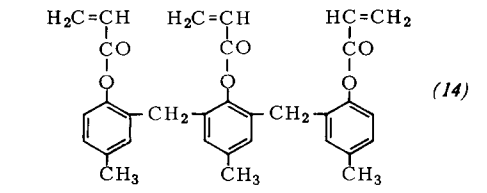
### b) Polymers as Templates

Polymers as templates for the formation of polymers are found in Nature in the replication of deoxyribonucleic acids (DNA), the genetic material of living organisms. The nucleic acids differ only in their bases. There are normally only four bases present, and two of these, a purine and a pyrimidine base, form very strong hydrogen bonds. The result is that two DNA chains of equal length in which the corresponding bases are situated opposite to each other are "complementary" and fit closely together. The double chains are wound into right-handed helices. In replication, the hydrogen bonds are broken, starting at one end. Activated nucleotides can act as the substrate, and are linked with the aid of enzymes and in contact with the individual chains in such a way that they again complete the double chains. Thus the existing polymers have acted as templates for the polymers being formed, which will in turn act as templates in the next replication, and so on. In this way, identical polymer molecules are built up in pairs (ultimately from a single molecule). These processes are not confined to living cells. Artificial polynucleotides have been prepared enzymatically *in vitro*, and these replicated by the same mechanism [44].

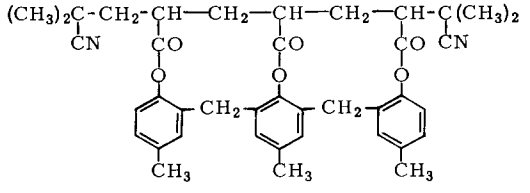
According to *Marx-Figini* and *G. V. Schulz*, another type of template evidently occurs in Nature [45]. These authors found that the secondary-wall cellulose of cotton is uniform, not only in its structure, but also in its degree of polymerization (*ca.* 14000). This degree of polymerization is reached after only a short period of growth, and subsequently remains constant. The templates may be tubular proteins from which the cellulose grows.

The preparation of identical polymer molecules on templates without the aid of enzymes has not yet been accomplished. However, a point of departure for such syntheses is found in the range of low degrees of polymerization.

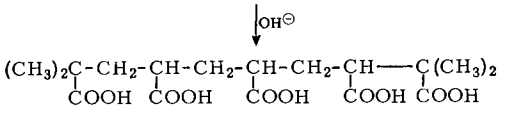
*Kämmerer* and his co-workers started with a monodisperse 4-methylphenol-formaldehyde condensate [4-methyl-2,6-bis-(2-hydroxy-5-methylbenzyl)phenol], obtained by "stepwise" and "stagewise" synthesis [46], and from which they prepared the triacrylate *(14)* [47].



*(14)*



*(15)*



*(16)*

A dilute solution of *(14)* in benzene was polymerized with about four equivalents of azobisisobutyronitrile as a free-radical initiator and chain-terminating agent. Owing to the high dilution and the large quantity of primary radicals present, the oligomers were largely isolated from one another during the reaction, and the dinitrile *(15)* was formed in 70 % yield. Alkaline hydrolysis of *(15)* leads to the pentacarboxylic acid *(16)*, which is uniform in its molecular weight, though it is a mixture of various stereoisomers.

## 4. Other Synthetic Routes

### a) Defined Conversions of Existing Uniform Polymers

It is not always necessary to prepare a desired uniform polymer directly from the monomers. It is sometimes better to convert an existing uniform polymer chemically into the desired polymer. Since polymers generally contain a large number of reactive sites, the reactions may be either complete or incomplete with respect to the individual molecules, but they must take place in the same positions in all the molecules. If the reactions are incomplete with respect to all the molecules of a polymer, it is still possible to isolate the uniformly transformed components.

In practice, one aims at complete reaction without degradation of the polymer. It is necessary to use dissolved or at least solvent-swollen polymers, since the reagents cannot otherwise reach all the reactive sites. The classical example is the hydrolysis of polyvinyl acetate to polyvinyl alcohol [48]. Most of the reactions carried out so far also have taken place on functional

[44] *H. K. Schachman, J. Adler, C. M. Radding, I. R. Lehman,* and *A. Kornberg*, J. biol. Chemistry *235*, 3242 (1960); *C. M. Radding, J. Josse,* and *A. Kornberg, ibid. 237*, 2869 (1962); *C. M. Radding* and *A. Kornberg, ibid. 237*, 2877 (1962).

groups. Since these are generally close together they influence one another, and even their steric position can be of some importance [49], particularly so when the reactions involve *two* adjacent groups (bifunctional reactions). The influence of the chain conformation of a polymer is shown by the difference in the reactivities of proteins before and after denaturation [50]. Specific reactions can be brought about with the aid of enzymes.

### b) Transformation of Replicating Polymers

If replicative polymers are modified in such a way that the power of replication is retained, only one polymer molecule need, in principle, be changed. Identical molecules will then be formed by replication, provided the correct substrate is present. The only replicative polymers known at present are nucleic acids and polynucleotides. Detailed studies have been carried out on changes by mutation in the genetic matter of bacteria, bacteriophages, and viruses. However, these nucleic acids usually suffer lethal lesions during chemical changes. Nevertheless, changes that do not prevent replication occasionally occur in the bases of the nucleotides (premutations). The modified bases are "read" in the same way as a natural, but different base. This leads to the incorporation of these wrongly "read" bases into the resulting polymer, and into the complementary polymer of the latter. Reactions of this type are brought about by X-rays and ultraviolet radiation, as well as by chemical agents (mutagens) such as nitrous acid, mustard gas, nitrogen mustards, diazomethane, ethylene oxide, formaldehyde, and hydroxylamine.

# Syntheses of Carboxylic Acids from 1,1-Dichloroethylene [1]

BY DR. K. BOTT AND PROF. H. HELLMANN

FORSCHUNGSLABORATORIEN DER CHEMISCHE WERKE HÜLS AG., MARL (GERMANY)

*Dedicated to Professor F. Broich on his 60th birthday*

*Many β-alkyl- and β-arylpropionic acids are readily obtainable by the reaction of secondary or tertiary alcohols, esters of these, or olefins with the inexpensive 1,1-dichloroethylene in sulfuric acid. The success of the synthesis depends on the bulk and energy of the carbonium ion intermediate formed from the alcohols or olefins. With carbonium ions having one H atom attached to the carbonium C atom, electrophilic substitution of the 1,1-dichloroethylene takes place to a small extent. Dicarboxylic acids and carboxylic acids with higher molecular weights are sometimes formed as a result of side reactions.*

## 1. Introduction

β-Alkyl- and β-arylpropionic acids generally are prepared by syntheses involving several steps. In the course of attempts to find a convenient route to β,β-dimethylbutyric acid, we discovered a synthesis that can be used for the preparation of a series of carboxylic acids of the above type in a one-stage process using 1,1-dichloroethylene (vinylidene chloride) *(1)*.

Two processes are available for the industrial production of 1,1-dichloroethylene [2, 3].

The action of an equimolar amount of chlorine on vinyl chloride or on 1,2-dichloroethane yields 1,1,2-trichloroethane. Subsequent dehydrochlorination with aqueous sodium hydroxide [4] or calcium hydroxide [5] leads almost exclusively to 1,1-dichloroethylene *(1)*. This dichloroolefin is a colorless liquid boiling at 37 °C; it is stable on storage in the monomeric state only after the addition of polymerization inhibitors such as triethylamine and 4-t-butylcatechol.

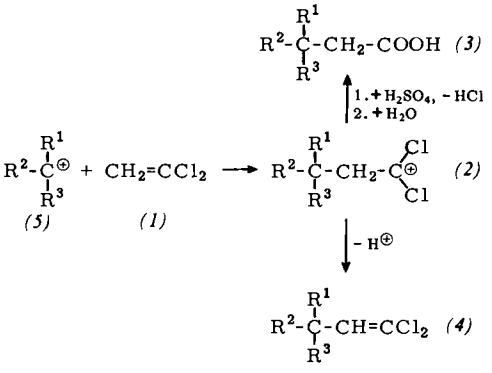
## 2. General Notes on the Course of the Reaction

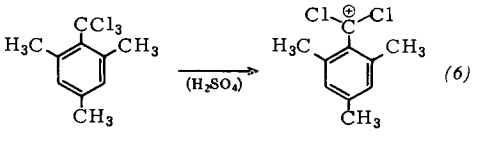
It is well known that trichloromethyl compounds can be hydrolysed to form carboxylic acids; however, the preparation of aliphatic carboxylic acids by hydrolysis of 1,1,1-trichloroalkanes with sulfuric acid requires temperatures between 90 and 100 °C [6]. The rate-determining step may be assumed to be the proton-catalysed removal of a chloride ion, which results in the formation of a dichlorocarbonium ion [*e.g. (2)*].

The principal feature of the new carboxylic acid synthesis is that ions of structure *(2)* can be produced under much milder conditions by the addition of carbonium ions *(5)* to 1,1-dichloroethylene.



Suitable reaction partners for 1,1-dichloroethylene are secondary or tertiary alcohols, esters of these, and olefins, which readily form carbonium ions in 90 to 100% sulfuric acid. The adduct-ion *(2)* cannot be isolated, but reacts very rapidly with the sulfuric acid. Subsequent treatment with water yields the carboxylic acid *(3)*. The rate of reaction at 0 to 15 °C is generally sufficiently high, but it can be considerably increased by the addition of Lewis acids such as boron trifluoride. The low reaction temperature permits also the synthesis of aliphatic carboxylic acids containing aryl groups.

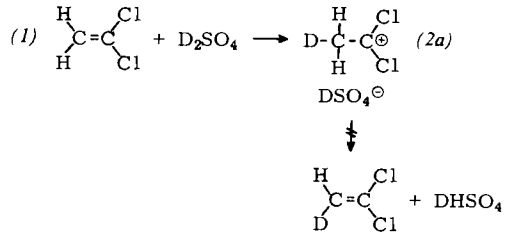
The cation *(6)* resulting from the dissolution of 2,4,6-trimethylbenzotrichloride in sulfuric acid evidently is stabilized by the trimethylphenyl group [7].



The intermediate *(2)* formed by secondary carbonium ions ($R^1$ = H; $R^2$, $R^3$ = alkyl) and dichloroethylene *(1)* can also lose a proton to give substitution products *(4)* of 1,1-dichloroethylene. 1,1-Dichloroolefins having a secondary alkyl group on C-2 are converted into carboxylic acids by sulfuric acid only at temperatures above 60 °C.

If the carbon chain in *(2)* is more highly branched ($R^1$, $R^2$, $R^3$ = alkyl), the elimination of the hydrogen from C-2 is suppressed by steric hindrance.

Instead of the carbonium ion *(5)*, 1,1-dichloroethane itself can take up a proton and forms acetic acid on hydrolysis. This "blank hydrolysis" predominates only when the formation of the carbonium ion *(5)* or the subsequent conversion into *(2)* is not sufficiently fast.



In order to study the formation of acetic acid, dichloroethylene *(1)* was treated with $D_2SO_4$. If the solvolysis is interrupted at an early stage, no deuterium can be detected in the remaining vinylidene chloride by infrared and mass-spectrometric examination. This shows that the protonation of *(1)* is the rate-determining step in the formation of acetic acid.

## 3. Application of the Carboxylic Acid Synthesis

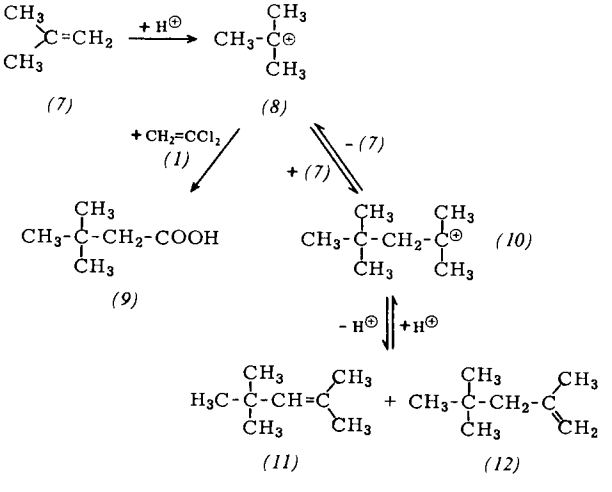
### a) t-Alkylacetic Acids

Several substances (Table 1) can be used as sources of the carbonium ion required for the preparation of β,β-dimethylbutyric acid *(9)*, the simplest t-alkylacetic acid.

Table 1. Starting materials for the synthesis of β,β-dimethylbutyric acid *(9)*.

| $CH_2=CCl_2$ + starting material | Yield (%) |
|---|---|
| $(CH_3)_3COH$ | 80 |
| $(CH_3)_3CCl$ | 79 |
| $CH_3-COOC(CH_3)_3$ | 78 |
| $(CH_3)_2C=CH_2$ *(7)* | 75 |
| *(11)* + *(12)* | 33 |
| $(CH_3)_2CH-CH_2OH$ | 15 |

Isobutene *(7)* first adds a proton to form the t-butyl cation *(8)*, which then reacts with vinylidene chloride *(1)*.



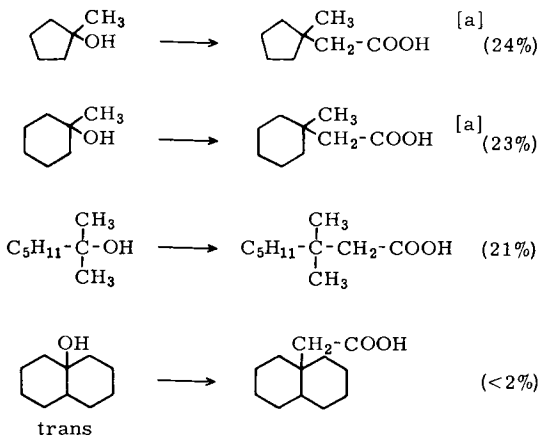
The kinetically preferred addition of *(8)* to isobutene *(7)* to form *(10)* is reversible. Consequently, the formation of t-butylacetic acid from "diisobutylene", a mixture of the olefins *(11)* and *(12)*, is not surprising. The reluctance of the

[6] *R. M. Joyce*, US.-Pat. 2398430 (1942), du Pont; Chem. Abstr. *40*, 3768 (1946).

[7] *R. J. Gillespie* and *E. A. Robinson*, J. Amer. chem. Soc. *86*, 5676 (1964).

cation *(10)* to add to dichloroethylene probably is due to steric hindrance.

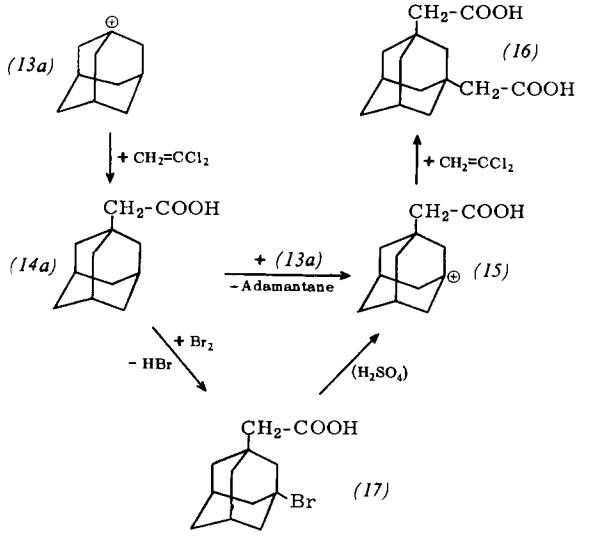
The yields of carboxylic acid decrease rapidly when the number of carbon atoms in the tertiary alcohols increases. This is true both of open-chain and of cyclic alcohols (Scheme 1).



Scheme 1

[a] It was shown by gas-chromatographic analysis of the methyl ester that no isomeric carboxylic acids were present.

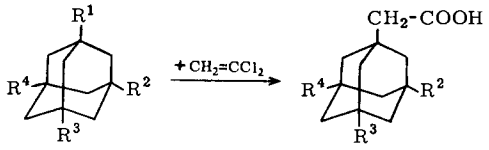
The only exceptions to this rule are carbonium ions of the adamantane series, in which the charge is situated on a bridgehead C atom. The carbon skeleton of the 1-adamantyl cation *(13a)* is so rigid that the steric hindrance is even weaker than in the planar t-butyl cation *(8)*.



The ion *(13a)* is, in addition, stable in concentrated sulfuric acid. Since the conversion of the adamantane system into an olefin and into secondary products of the latter is not possible, the preparation of adamantane-1-acetic acids from adamantane derivatives and vinylidene chloride *(1)* gives particularly high yields (Table 2).

When the reaction of 1-bromoadamantane is carried out at high carbonium ion concentrations, *i.e.* in a small volume of pure sulfuric acid in the presence of boron trifluoride, the resulting adamantaneacetic acid *(14a)* can exchange a hydride ion with the adamantyl cation. The resulting carbonium ion *(15)* undergoes a second synthesis step to form adamantane-1,3-diacetic acid *(16)*. The diacid *(16)* is best prepared from 3-bromoadamantaneacetic acid *(17)*.

Table 2. Preparation of adamantane-1-acetic acid *(14a)* and methylated derivatives.



| R1 | R2 | R3 | R4 | M.p. (°C) | Yield (%) |
|---|---|---|---|---|---|
| Br | H | H | H | | 92 |
| OH | H | H | H | 135–136 | 93 |
| $OCOCH_3$ | H | H | H | | 94 |
| Br | $CH_3$ | H | H | 107–108 | 89 |
| $OCOCH_3$ | $CH_3$ | H | H | | 94 |
| Br | $CH_3$ | $CH_3$ | H | 113–114 | 89 |
| $OCOCH_3$ | $CH_3$ | $CH_3$ | H | 113–114 | 94 |
| $OCOCH_3$ | $CH_3$ | $CH_3$ | $CH_3$ | 139–140 | 80 [a] |

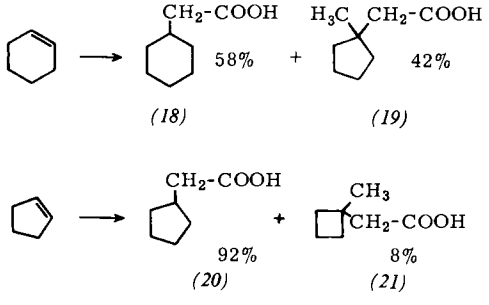
[a] Approximately 15% of the compound used is converted into 1-chloro-3,5,7-trimethyladamantane.

Unlike adamantanecarboxylic acid [8], adamantaneacetic acid *(14a)* and 3-methyladamantaneacetic acid, in which the carboxyl groups are further from the bridgehead C atom, can be brominated as easily as adamantane and its methyl derivatives [9–11].

If the methyl groups in the t-butyl cation are progressively replaced by phenyl groups, the resulting ions no longer add to 1,1-dichloroethylene, owing to their resonance stabilization and their large bulk.

### b) sec-Alkylacetic Acids

The ease of formation of carbonium ions is considerably smaller in secondary alcohols than in tertiary alcohols. The same relationship is found for the olefins on which the alcohols are based. Thus, yields of between 4 and 8% of carboxylic acid are obtained when cyclohexene and cyclopentene are used as the starting materials.



The formation of 1-methylcyclopentylacetic acid *(19)* in addition to cyclohexylacetic acid *(18)* must be regarded as evidence that the cyclohexyl cation has rearranged to form the more stable 1-methylcyclopentyl cation. Further ring contraction is largely suppressed in the cyclopentyl system, owing to the strain of the cyclobutane ring.

The remarkable stability of the norbornyl cation *(22)* in strong acids is due to the rapid establishment of an equilibrium between identical non-classical ions, which change into one another by hydride shifts and Wagner-Meerwein rearrangements [12].

[8] *H. Stetter* and *P. Goebel*, Chem. Ber. *96*, 550 (1963).

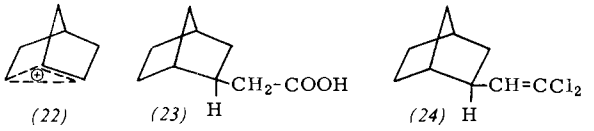
[9] *H. Stetter* and *C. Wulff*, Chem. Ber. *93*, 1366 (1960).

[10] *K. Gerzon, E. V. Krumkalns, R. L. Brindle, F. J. Marshall,* and *M. A. Root*, J. med. Chem. *6*, 760 (1963).

[11] *H. Koch* and *J. Franken*, Chem. Ber. *96*, 213 (1963).

[12] *M. Saunders, P. v. Schleyer,* and *G. A. Olah*, J. Amer. chem. Soc. *86*, 5680 (1964).

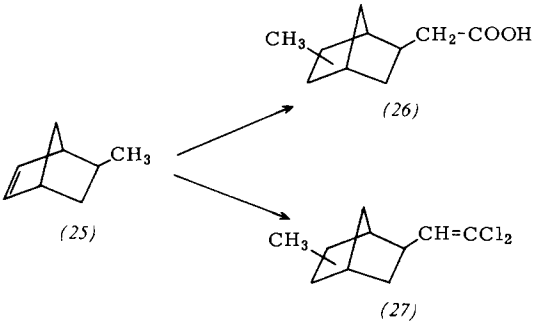
As expected, the reaction of norbornene with vinylidene chloride yields *exo*-2-norbornylacetic acid *(23)* (77% yield), the anilide of which melts at 124–125 °C, *i.e.* 14 °C below *endo*-norbornylacetanilide, which was described by *Alder* and *Windemuth* [13]. The use of *exo*-norborneol or *exo*-norbornyl acetate instead of norbornene results in a lower yield of *exo*-norbornylacetic acid (62 and 46%, respectively).



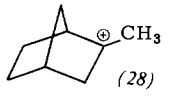
*(22)* *(23)* *(24)*

This shows the smaller ionization tendency of norborneol and its esters as compared with tertiary alcohols. The reaction in 90% sulfuric acid yields not only *(23)*, but also 2-(2-norbornyl)-1,1-dichloroethylene *(24)*, which is formed by electrophilic substitution of dichloroethylene with norbornene. The hydrolysis of *(24)* to *exo*-norbornylacetic acid is possible only above 60 °C. Owing to the presence of the H atom on C-2', *(24)* is readily autoxidized with liberation of hydrogen chloride and small quantities of phosgene.

The alkyl substituent in the norbornyl system has an interesting effect on the course of the reaction. 5-Methylnorbornene *(25)* gives a mixture of methylnorbornylacetic acids *(26)*, the three principal components being present in the proportions 64, 21, and 9%. The position of the methyl group in these compounds is not yet known. It is reasonable to assume that *(26)* consists entirely of *exo*-norbornylacetic acids. The

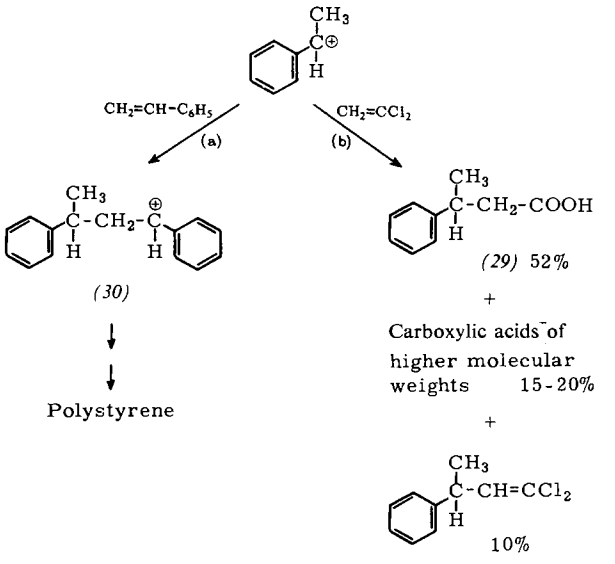


methylnorbornyldichloroethylene *(27)* isolated as a by-product does not contain appreciable quantities of an isomer derived, as suggested by the classical formulation, from the energetically favored 2-methylnorbornyl cation *(28)*. Thus *(27)* is autoxidized and converted into the carboxylic acid at almost the same rate as *(24)* [14].



### c) Hydrocinnamic Acids

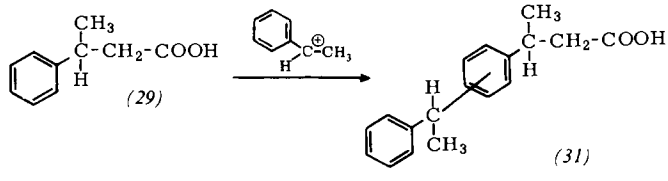
β-Methylhydrocinnamic acid *(29)* is the first aryl-substituted aliphatic carboxylic acid to become readily obtainable through the new synthesis. The recommended starting material is 1-phenylethanol, which is formed by the addition of water to styrene.



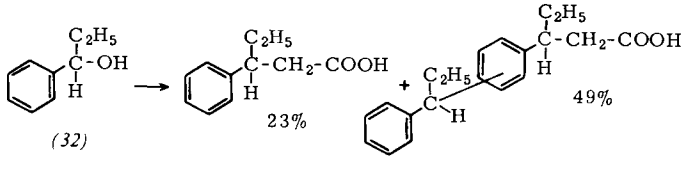
Styrene itself undergoes proton-catalysed polymerization, since step (a) leading to *(30)* is much faster than (b), and is irreversible.

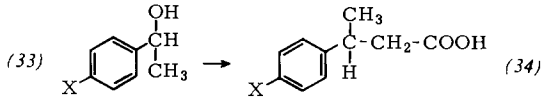
In addition to the acid *(29)* and the dichloroolefin, carboxylic acids with higher molecular weights, *e.g. (31)*, are also formed.

These acids could be formed by the addition of *(30)* to vinylidene chloride or by alkylation of methylhydrocinnamic acid *(29)* in the nucleus to form *(31)*. The following experimental evidence clearly supports the second of these possibilities.



No carboxylic acid is formed by linear distyrene [15], which initially is converted into *(30)* by the action of acids. On the other hand, the reaction of 1-phenylpropanol *(32)*, whose precursor β-methylstyrene exhibits little tendency to polymerize, leads preferentially to carboxylic acids with high molecular weights.





| | Yield |
|---|---|
| *(a)*: X = Cl | 82% |
| *(b)*: X = t-Butyl | 76% |
| *(c)*: X = 1-Methylcyclohexyl | 65% |

The reactions of the *p*-halogeno- and *p*-t-alkylphenylethanols *(33a)–(33c)* are particularly revealing. These reactions lead almost exclusively to the formation of the expected β-methylhydrocinnamic acids *(34a)–(34c)*. The bulky or electro-

[13] *K. Alder* and *E. Windemuth*, Ber. dtsch. chem. Ges. *71*, 1954 (1938).

[14] t-Alkyl derivatives of 1,1-dichloroethylene, on the other hand, are stable towards sulfuric acid up to 90 °C.

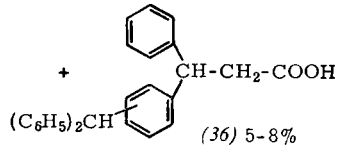
[15] *B. B. Corson, W. J. Heintzelmann, H. Moe*, and *C. R. Rousseau*, J. org. Chemistry *27*, 1636 (1962).

negative substituents in the benzene nucleus prevent the entry of phenylethyl groups into *(34)*, and so increase the yield of the uniform carboxylic acid.

It may seem surprising that the reactivity of the 1-phenylethyl cation is not greater than that of the more stable benzhydryl cation. Benzhydrol, benzhydryl chloride, and benzhydryl acetate all can be used for the preparation of β-phenylhydrocinnamic acid.

$$(C_6H_5)_2CHX \longrightarrow (C_6H_5)_2CH\text{-}CH_2\text{-}COOH$$

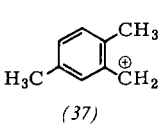
X = OH, Cl, $OCOCH_3$ *(35)* 72-76%



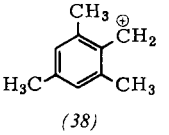
*(36)* 5-8%

Benzhydrylation of *(35)* to *(36)* takes place only to a small extent. The influence of substitution in the nucleus on the composition of the product has so far been studied in only one example. *p,p'*-Dichlorobenzhydryl acetate gives pure 3,3-bis-(*p*-chlorophenyl)propionic acid in 78% yield.

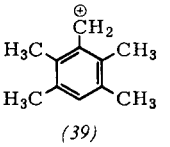
Mention should also be made of the action of primary carbonium ions on 1,1-dichloroethylene. Carbonium ions with a primary carbon atom as the charge carrier are sufficiently stable in strong sulfuric acid only if the positive charge can distribute itself over the molecule by resonance. In our experience the only ions of this type that are suitable for the synthesis of carboxylic acids are the polymethylated benzyl cations *(37)–(39)*.



*(37)*



*(38)*



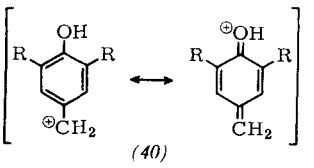
*(39)*

The ions *(37)–(39)* were produced from the products obtained on chloromethylation of *p*-xylene, mesitylene, and durene [16–18].

The reactions of the polymethylbenzyl cations with $CH_2{=}CCl_2$ follow a complex course. The formation of the phenylhydrocinnamic acids is followed by secondary reactions that have already been mentioned. Hydride exchange on the methyl groups leads to dicarboxylic acids; the molecular weight of the carboxylic acids is greatly increased by benzylation in the nucleus.

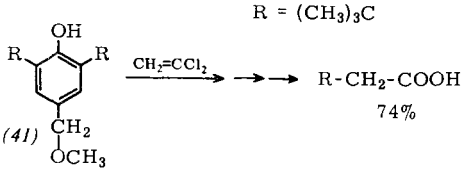
Nevertheless, in the reaction of the 2,3,5,6-tetramethylbenzyl cation *(39)*, pure 2,3,5,6-tetramethylphenylhydrocinnamic acid can be isolated in 5% yield.

A much more stable ion than *(37)–(39)* should be one having the structure *(40)*, the substitution of which with t-butyl groups would prevent any hydride migration in the resulting carboxylic acid. However, 3,5-di-t-butyl-4-hydroxybenzyl methyl ether *(41)*, the precursor of *(40)*, transfers a t-butyl cation *(8)* to the vinylidene chloride, and is itself converted into β,β-dimethylbutyric acid *(9)*.



*(40)*

R = $(CH_3)_3C$



*(41)*

## 4. Procedures

### a) *β,β-Dimethylbutyric acid (9)*

A mixture of 92.5 g (1 mole) of t-butyl chloride and 146 g (1.5 mole) of 1,1-dichloroethylene [19] is added dropwise during 2 hours to 200 ml of 90% sulfuric acid containing 35 g of boron trifluoride, with vigorous stirring at 5 °C. Stirring is continued for a further two hours at 15 °C. The reaction mixture is poured on ice, and the resulting carboxylic acid is taken up in ether and distilled under reduced pressure. Yield 92 g (79% based on the t-butyl chloride); b.p. 80–82 °C/12 mm, m.p. 6–7 °C (lit. [20] 6 °C).

### b) *exo-2-Norbornylacetic acid (23)*

A solution of 188 g (2 moles) of norbornene in 388 g (4 moles) of 1,1-dichloroethylene is added dropwise during 4 hours to 800 ml of 98% sulfuric acid containing 120 g of boron trifluoride at 14 to 16 °C. The mixture is then stirred for 1 hour. On decomposition with ice and dissolution in ether, vacuum distillation yields 237 g of *exo*-2-norbornylacetic acid (77% based on norbornene); b.p. 117–118 °C/1.5 mm, $n_D^{20} = 1.4820$.

### c) *p-Chloro-β-methylhydrocinnamic acid (34a)*

50 g (0.32 mole) of 1-(*p*-chlorophenyl)ethanol and 95 g (0.98 mole) of 1,1-dichloroethylene are allowed to react in 100 ml of 90% sulfuric acid containing 18 g of boron trifluoride, as described in procedure (a). On hydrolysis the crude *p*-chloro-β-methylhydrocinnamic acid separates in crystalline form. This material is further purified by dissolution in sodium hydroxide solution, separation of the neutral product, and precipitation with dilute hydrochloric acid. Yield 53 g (83% based on the alcohol); m.p. 89–92 °C. On recrystallization from cyclohexane, the melting point rises to 92–93 °C.

### d) *3,5-Dimethyladamantaneacetic acid*

A solution of 25 g (0.113 mole) of 1-bromo-3,5-dimethyladamantane and 100 g (1.03 mole) of 1,1-dichloroethylene is added dropwise during 2 hours to 100 ml of 90% sulfuric acid containing 18 g of boron trifluoride at 10 °C. After stirring for a further 2 hours, the solution is decomposed with ice. The crystalline product is purified as in example (c). Yield 20.5 g (90% based on dimethylbromoadamantane); m.p. 110–112 °C. Pure 3,5-dimethyladamantaneacetic acid (from ethanol/water) melts at 113–114 °C.

# Recent Syntheses and Reactions of Cyclic Imidic Esters

BY DR. W. SEELIGER, DR. E. AUFDERHAAR, DR. W. DIEPERS, DR. R. FEINAUER, DR. R. NEHRING, DR. W. THIER, AND PROF. H. HELLMANN

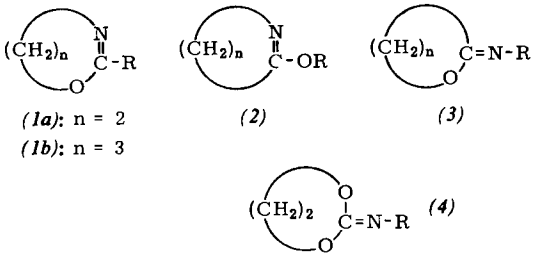
FORSCHUNGSLABORATORIEN DER CHEMISCHE WERKE HÜLS AG., MARL (GERMANY)

*Dedicated to Professor F. Broich on the occasion of his 60th birthday*

*$\Delta^2$-Oxazolines and 4H-5,6-dihydrooxazines are readily obtainable from carboxylic acids and 2- or 3-amino alcohols by gas-phase dehydration, and 4H-dihydrooxazines can also be obtained by condensation of N-(hydroxymethyl)carboxamides with olefins. These cyclic imidic esters undergo reactions in which the ring is cleaved; these reactions include a new type of polymerization. The behavior of alkyl groups in position 2 and the cycloadditions in the 2,3-position also have been studied. Reactions in side chains on position 2 and addition experiments on the sulfur analogues of the cyclic imidic esters are also reported. A table shows the principal infrared bands of substituted $\Delta^2$-oxazolines.*

## 1. Introduction

Since *Pinner*'s pioneering work on the chemistry of imidic esters [1], this class of compounds has excited steadily growing interest [2]. One need only mention the numerous publications dealing with the conversion of these compounds into *N*-substituted amides [2–4]. Cyclic imidic esters generally react like the acyclic derivatives [5] but there are a number of differences, which depend on the constitution. Of the three types of cyclic imidic esters *(1)*–*(3)*, *i.e.* compounds containing the grouping



*(1a)*: n = 2
*(1b)*: n = 3

*(2)*

*(3)*

*(4)*

–O–C=N–, the lactim ethers *(2)* can readily be converted into *N*-substituted lactams [6]. In the iminolactone series *(3)* [7], the rearrangement of the iminocarbonates *(4)* to *N*-substituted 2-oxazolidones has been described [7c,8]. No corresponding rearrangement of the compounds *(1a)* or *(1b)*, which would give *N*-acylaziridines and -azetidines respectively, is known. However, owing to the ring strain in these cyclic imines, the reverse reactions leading to $\Delta^2$-oxazolines [9] and 4*H*-5,6-dihydro-1,3-oxazines [10] can easily be brought about.

## 2. Preparation of Cyclic Imidic Esters

The $\Delta^2$-oxazolines *(1a)* [5,11] and 4*H*-dihydrooxazines *(1b)* [12,13] can be obtained in many ways. From the literature data it can be deduced that the ease of cyclization generally increases with the number of substituents on the heterocycle *(1)* to be formed. Unfortunately the starting materials generally also become more difficult to prepare with increasing substitution.

Particularly suitable derivatives for the study of the reactions of $\Delta^2$-oxazolines *(1a)* and 4*H*-dihydrooxazines *(1b)* are those with substituents only in position 2. An obvious synthesis of these compounds is the reaction of acyclic imidic esters or their hydrochlorides with 2-aminoethanol [5,11a,14] and with 3-aminopropa-

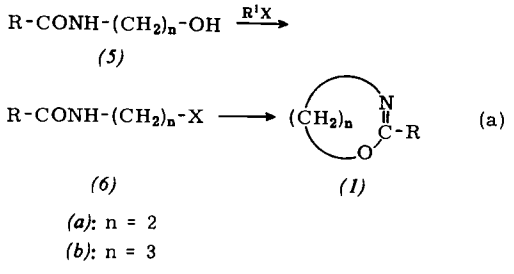
nol [12c, 13]. In our experience these reactions proceed particularly well when equimolar amounts of the imidic ester and the amino alcohol are heated with a catalytic quantity of a strong acid and the resulting heterocycle *(1)* is distilled off.

Most of the syntheses of the compounds *(1)* are based on *N*-2- and *N*-(3-hydroxyalkyl)amides *(5)*, which are readily obtained by treatment of carboxylic acids [15] or their esters [16] with the amino alcohols at 150–200 °C. One molecule of water must formally be eliminated from *(5)*. Usually, however, *(5)* is first treated with reagents such as $SOCl_2$ [5], $RSO_2Cl$ [17], $COCl_2$ [18], or $PO(OR_2)Cl$ [13] in order to replace the hydroxyl group by a group X that can be eliminated more readily.



*(5)*

*(6)* *(1)*

*(a)*: n = 2
*(b)*: n = 3

The cyclization is greatly facilitated if the carbon atom adjacent to either the nitrogen or the substituent X is disubstituted [17, 19].

Particularly ready conversion of *(5)* into *(6)*, X = Cl, is achieved with only slightly more than the equivalent amount of $SOCl_2$ at about 80 °C. The cyclization of *(6)*, X = Cl, containing aromatic groups R proceeds in very good yields in aqueous alkali solutions at 50–70 °C, if necessary in the presence of solubilizing additives such as methanol or dioxane.

### 2.1. Dehydration of *N*-(2-Hydroxyethyl)carboxamides in the Gas Phase

The simplest method of synthesis is obviously the direct dehydration of the *N*-(hydroxyalkyl)amides *(5)*, which can be achieved by heating of the derivative *(5a)* containing the aliphatic group R to 250–300 °C [15, 20]. However, the aliphatically substituted $\Delta^2$-oxazolines are obtained only in modest yields. Aromatic derivatives have not so far been obtained by this reaction [15].

A number of substances have been tested for possible catalysis of the dehydration of *N*-(2-hydroxyethyl)-benzamide. In the presence of granulated alumina, the slow distillation of this compound at 220 °C/25 mm Hg leads to the desired 2-phenyl-$\Delta^2$-oxazoline in a yield of about 50 % (based on a conversion of 70 %). Under similar conditions, the methyl derivative can be prepared in 56 % yield [22a].

From these results one may conclude that the cyclization step is based on an equilibrium

$$(5a) \rightleftharpoons (1a) + H_2O \qquad (b)$$

which normally lies well to the left [21], but which is displaced towards the right at high temperatures, and is established so rapidly on alumina that side reactions cannot interfere. We therefore extended the reaction to the gas phase. However, the thermal stability of the cyclic imidic esters *(1)* was dubious. For example, 2-methyl-$\Delta^2$-oxazoline is completely fragmented in an autoclave at 275 °C/20–120 atm under nitrogen; it was found by mass spectrometry that in addition to ammonia and a tarry residue, the products contained $H_2$, CO, and hydrocarbons.

#### 2.1.1. Apparatus and Method

The gas-phase dehydration is carried out in a contact tube packed with a granulated dehydration catalyst and equipped with a temperature-sensing device [22a]. The pressure in the reaction chamber should be 0.5 to 20 mm Hg. Starting materials *(5a)* which are volatile under these conditions are passed over the catalyst as vapors, while high-boiling or unstable substances are preferably applied in the form of drops. On leaving the contact tube, the dehydration mixture is quenched and condensed in cooled vessels in order to freeze the reverse reaction of equation (b), which takes place slowly already at room temperature [21]. The activity of the catalyst decreases with time, depending on the reaction temperature, contact time, and purity of the starting material; however, the original activity is restored by the usual treatment with steam and air.

#### 2.1.2. Recovery of Products

High-boiling $\Delta^2$-oxazolines that are not very sensitive to hydrolysis can be isolated by direct vacuum fractionation of the reaction mixture. $\Delta^2$-Oxazolines that are sensitive to hydrolysis are separated from the remaining *N*-(2-hydroxyethyl)amide (which has an appreciably higher boiling point), together with the water formed, at the lowest temperature possible (vacuum distillation or thin-film evaporation). The pure $\Delta^2$-oxazolines can be isolated from the distillate by addition of solid KOH and/or extraction with ether, followed by drying with KOH or sodium. Larger quantities are better freed from water by azeotropic distillation [22b]. The residues, which consist of impure *N*-(2-hydroxyethyl)amides, may be mixed with fresh starting material without prior purification, and used again in the dehydration.

### 2.1.3. Results

Table 1 shows that the substituted oxazolines *(1a)* can be obtained in satisfactory purity and in good yields ultimately from carboxylic acids and 2-amino alcohols.

[a] Katalysatorenwerke Houdry-Hüls GmbH.
[b] Based on *(5a)* reacted.
[c] Measured at 30 °C.
[d] Alumina contact HO 417 [a].
[e] Ref. [24]: 66 °C.
[f] Measured on the supercooled melt.

By-products formed, particularly above 400 °C, include small quantities of nitriles, as well as a little diethyl ketone and $CO_2$ in the case of *N*-(2-hydroxyethyl)-propionamide.

The reaction temperatures given in Table 1 are the highest temperatures measured in the contact tube. Because of the endothermic reaction, these are generally reached only in the last quarter of the tube.

Figure 1 shows the relationship between the reaction temperature, conversion, and yield. A surprising feature is the steep rise of the yield curve with rising temperature up to a maximum at about 350 °C.

Interestingly, 2-hydroxyethylammonium benzoate also can be dehydrated to 2-phenyl-$\Delta^2$-oxazoline if its melt is allowed to drop onto the hot contact.

### 2.2. Dehydration of *N*-(3-Hydroxypropyl)amides in the Gas Phase

The gas-phase dehydration of *N*-(3-hydroxypropyl)-carboxamides *(5b)*, including separation of the products, is carried out as described in Section 2.1. The 4*H*-5,6-dihydrooxazines *(1b)* shown in Table 2 have been obtained in this way.

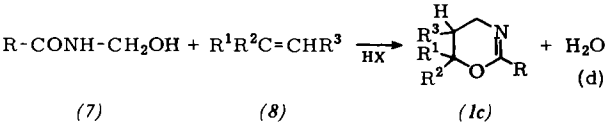
### 2.3. Cyclizing Amidomethylation of Olefins [27]

As shown above, the cyclic imidic esters *(1a)* and *(1b)* are conveniently obtained from 2-aminoethanols and 3-aminopropanols, respectively. However, the substituted 3-aminopropanols required for a similar preparation of substituted 4*H*-5,6-dihydrooxazines *(1c)* generally are accessible only with difficulty. Substituted 4*H*-dihydrooxazines *(1c)* are more simply prepared from olefins *(8)* and *N*-hydroxymethylamides *(7)*, which are readily obtainable from amides and formaldehyde [27].



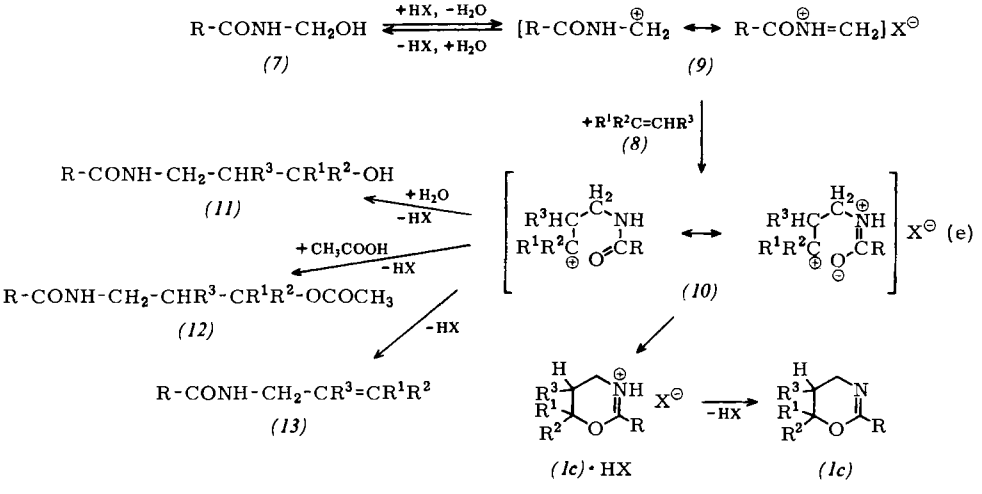
(d)

*(7)* *(8)* *(1c)*

[23] *R. N. Boyd* and *R. C. Rittner*, J. Amer. chem. Soc. *82*, 2032 (1960).
[24] *A. Salomon*, Ber. dtsch. chem. Ges. *26*, 1321 (1893).
[25] *J. F. Arens*, US.-Pat. 2813862 (1957), Organon Inc.; Chem. Abstr. *52*, 8212 (1958).
[26] *J.H.Boyer* and *J.Hamer*, J. Amer. chem. Soc. *77*, 951 (1955).
[27] *W. Seeliger* and *W. Diepers*, Liebigs Ann. Chem., in press.

This reaction, which proceeds in the presence of stoichiometric amounts of a strong acid under otherwise mild conditions, bears a certain resemblance to the amidomethylation [28] and ureidoalkylation [29] of olefins, though these lead to different products. The great versatility of the reaction (d) and the ease with which it can be carried out, together with the ease of hydrolysis of the compounds *(1c)*, permit the convenient preparation of substituted 3-aminopropanols that are otherwise difficult to obtain, or of acyl derivatives of these.

Corresponding to the mechanisms for the amidomethylation proposed by *Hellmann* [30] and the electrophilic addition to olefins, *e.g.* in the Prins reaction [31], reaction (d) may be assumed to proceed in accordance with Scheme (e). The *N*-(hydroxymethyl)amide *(7)* and the acid HX first react to form the resonance-stabilized ion *(9)*, which adds electrophilically to the more nucleophilic carbon atom of the olefin *(8)* to give the intermediate *(10)*. The main reaction under the conditions used is cyclization by intramolecular *O*-alkylation of *(10)* to the HX salt of the 4*H*-dihydrooxazine, while the competing reactions leading to *(11)*, *(12)*, and *(13)* proceed only to a small extent, which varies according to the substituents and reaction conditions.



The salts *(1c)*·HX can be readily converted into the free bases, *e.g.* by treatment with aqueous alkalis.

The reaction (d) is carried out as follows. Roughly equimolar quantities of the olefin *(8)* and the *N*-(hydroxymethyl)amide *(7)* [30] are dissolved in a polar solvent such as glacial acetic acid, and an equimolar quantity of the strong acid (preferably diluted with the same solvent) is gradually added at about 10 °C. Sulfuric acid is particularly suitable. The 4*H*-dihydrooxazinium hydrogen sulfate formed under these conditions can be precipitated by addition of ether and isolated or converted into *(1c)* [27]. The pure 4*H*-dihydrooxazines can be obtained by distillation and characterized as the picrates.

Table 3 shows a number of substituted 4*H*-5,6-dihydrooxazines *(1c)* that have been prepared in this way, most of which were formerly unknown.

## 3. Reactions of Cyclic Imidic Esters Involving Ring Cleavage

The reactions of the cyclic imidic esters *(1a)* and *(1b)* with water [33, 21], halogen acids, acyl chlorides [34a], anhydrides [33], and phenols [34b] proceed with ring cleavage and formation of 2- or 3-substituted *N*-alkylamide derivatives, and less frequently of 2-aminoethyl- or 3-aminopropyl esters of carboxylic acids [22, 33], or compounds derived from these. Sections 3.1 to 3.4 contain further examples of the strong tendency of the cyclic imidic esters to undergo ring cleavage, the driving force of which is probably the formation of the more stable amide structure.

Whereas the hydrohalides of the heterocycles *(1a)* and *(1b)* are converted into the 2- or 3-halogenoalkylamides *(6)*, X = halogen, below 100 °C, and often even at room temperature, their *p*-toluenesulfonates (at 140 °C) and methiodides (1 hour at 180 °C) are thermally very stable and react only very slowly.

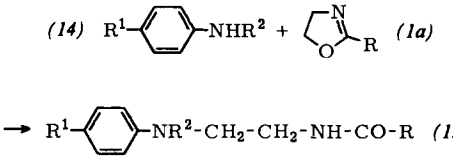
### 3.1. Reaction with Aromatic Amines

Acyclic imidic esters react with ammonia [35] or amines to form amidines [36]. Oxazolines *(1a)* and aromatic amines *(14)* react at high temperatures in the presence of small quantities of strong acids to form *N*-(2-arylaminoethyl)amides *(15)*.



*(14)* $R^1$-C$_6$H$_4$-$NHR^2$ + *(1a)* → $R^1$-C$_6$H$_4$-$NR^2$-$CH_2$-$CH_2$-NH-CO-R *(15)* (f)

The product obtained by *Kormendy et al.* [37a] from 2-phenyl-$\Delta^2$-oxazoline and anilinium chloride at room temperature also has the structure *(15)* (R = $C_6H_5$, $R^1$ = $R^2$ = H), although it was formulated as the product of addition of aniline to the ring double bond.

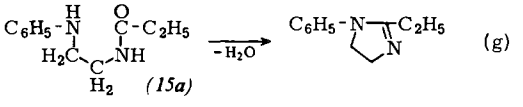
Table 4 shows the success of the reaction (f) with 2-ethyl- and 2-phenyl-$\Delta^2$-oxazoline.

Table 4. *N*-(2-arylaminoethyl)amides *(15)* prepared by the reaction of $\Delta^2$-oxazolines *(1a)* with aromatic amines.

| *(3)* R | $R^1$ | $R^2$ | Yield (%) | B.p. (°C/mm Hg) |
|---|---|---|---|---|
| $C_2H_5$ | H | H | 50 | 185/0.4 |
| $C_2H_5$ | $CH_3$ | H | 84 | 190/0.4 |
| $C_2H_5$ | H | $CH_3$ | 66 | 155–156/0.1 |
| $C_6H_5$ | H | H | 76 | [a] |

[a] M.p. 123–124 °C, Lit. [37a] 123–124 °C, [37b] 127 °C.

The compounds *(15)* can readily be converted into imidazolines.



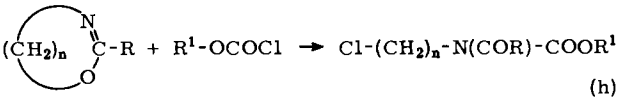
$C_6H_5$-NH-CO-$C_2H_5$ (*15a*) $\xrightarrow{-H_2O}$ $C_6H_5$-N=C($C_2H_5$)-N (g)

#### Procedure

*1-Phenyl-2-ethyl-$\Delta^2$-imidazoline*: 192 g (1.0 mole) of *N*-(2-anilinoethyl)propionamide *(15a)* is mixed in portions with 250 g (1.75 mole) of $P_2O_5$ and heated for 2.5 hr in a bath kept at 150 °C. The solid product is crushed and dissolved in 500 ml of water, and 500 g of KOH in 500 ml of water is added with cooling in ice. After extraction with a total of 600 ml of ether, the ether extract is washed with water, dried over $K_2CO_3$, and fractionated. 1-Phenyl-2-ethyl-$\Delta^2$-imidazoline (133.5 g, 78 %) is obtained as a colorless liquid, b.p. 85–86 °C/0.15 mm Hg.

### 3.2. Reaction with Derivatives of Chloroformic Acid

The addition of aromatic acyl chlorides to oxazolines *(1a)* leads to *N*-2-chloroethyl-*N*-aroylamides [34a]. Acyl chlorides and esters of chloroformic acid react differently with tertiary amines. Whereas the acyl chlorides can form relatively stable salts [38], the esters of chloroformic acid decompose to $CO_2$ and chloroalkanes in the presence of tertiary amines, even under mild conditions [39]. It was therefore of interest to study the behavior of esters of chloroformic acid towards the "tertiary amines" *(1)*. The study showed that in this case the esters of chloroformic acid react in the same manner as acyl chlorides, adding smoothly to oxazolines *(1a)* and 4*H*-dihydrooxazines *(1b)* under mild conditions, sometimes in practically quantitative yields, to give esters *(16)* of *N*-2-chloroethyl- and *N*-3-chloropropyl-*N*-acylcarbamic acids.



*(1a)*: n = 2; *(1b)*: n = 3 + $R^1$-OCOCl → Cl-$(CH_2)_n$-N(COR)-$COOR^1$ (h)

*(16a)*: n = 2; *(16b)*: n = 3

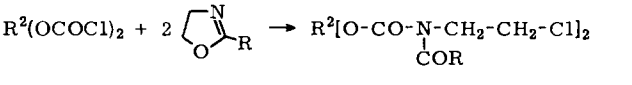
The reaction of esters of chloroformic acid with imidic esters *(1)* in accordance with equation (h) generally is carried out in an inert solvent; after separation the liquid esters *(16)* of *N*-acylcarbamic acids can be purified by distillation, and the crystalline esters by recrystallization. The results are shown in Table 5.

Table 5. Ethyl *N*-ω-chloroalkyl-*N*-acylcarbamates *(16)*, $R^1$ = $C_2H_5$, prepared from $\Delta^2$-oxazolines *(1a)* and 4*H*-5,6-dihydrooxazines *(1b)* with esters of chloroformic acid.

| *(16)* R | n | Temp. (°C) | Yield (%) | B.p. (°C/mm Hg) | $n_D^{20}$ |
|---|---|---|---|---|---|
| $CH_3$ | 2 | 35 [a] | 80 | 115–117/12 | 1.4594 |
| $C_2H_5$ | 2 | 80 [b] | 98 | 120–123/12 | 1.4595 |
| n-$C_3H_7$ | 2 | 80 [b] | 97 | 128–131/10 | 1.4585 |
| n-$C_{11}H_{23}$ | 2 | 80 [b] | 76 | 161–163/0.2 | 1.4622 |
| $C_6H_5$ | 2 | 25 [a] | 84 | 124–126/0.3 | 1.5267 |
| $CH_3$ | 3 | 45 [b] | 42 | 134–135/12 | 1.4618 |
| $C_6H_5$ | 3 | 35 [a] | 77 | 147–150/0.4 | 1.5229 |

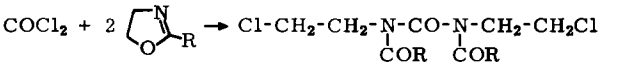
[a] Solvent: ether. [b] Solvent: benzene.

The $\Delta^2$-oxazolines react similarly with diol diesters of chloroformic acid, *e.g.* with the ethylene glycol ester or the cyclohexane-1,4-dimethanol ester; the reaction



$R^2(OCOCl)_2$ + 2 oxazoline → $R^2$[O-CO-N(COR)-$CH_2$-$CH_2$-Cl]$_2$

of $\Delta^2$-oxazolines with phosgene leads to symmetrical bis(2-chloroethyl)diacylureas.



$COCl_2$ + 2 oxazoline → Cl-$CH_2$-$CH_2$-N(COR)-CO-N(COR)-$CH_2$-$CH_2$Cl

### 3.3. Halogenation of 2-Aryl-$\Delta^2$-oxazolines

Chlorine and bromine react with 2-aryl-$\Delta^2$-oxazolines to give different types of products. Tertiary amines such

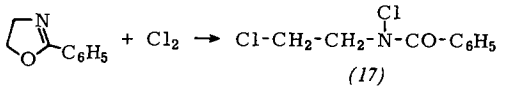
[39] *M. Matzner*, *R. P. Kurkjy*, and *R. J. Cotter*, Chem. Reviews *64*, 645 (1964).

as pyridine or triethylamine form adducts with bromine [40]. In acyclic imidic esters, the hydrogen atom attached to the nitrogen is replaced by bromine [41].

2-Phenyl-$\Delta^2$-oxazoline smoothly adds chlorine, with ring cleavage, to form the *N*-chloroamide *(17)*.



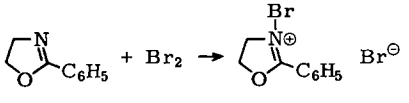
*(17)*

Procedure

*N-chloro-N-2-chloroethylbenzamide (17)*: A mixture of 75.0 g (*ca.* 0.5 mole) of 2-phenyl-$\Delta^2$-oxazoline with 250 ml of $CCl_4$ is saturated with chlorine at 20 °C during $2^1/_2$ hr, and the reaction mixture is then allowed to stand for 60 hr. The excess of chlorine is driven out of the clear solution by a current of nitrogen. The product crystallizes on cooling with ice-water and scratching; it is collected by suction filtration, washed with a little cold $CCl_4$, and dried in air. A second fraction can be obtained from the filtrate by concentration and cooling. A yield of 76.5 g (69 %) of crude, colorless crystals is obtained, and after recrystallization from $CCl_4$ (the temperature not exceeding 30 °C), the product melts at 59–61 °C.

This reaction evidently proceeds *via* an *N*-chlorooxazolinium chloride, which undergoes the ring cleavage characteristic of oxazolinium chlorides.

On the other hand, when bromine is allowed to act on 2-phenyl-$\Delta^2$-oxazoline, the addition stops at the first stage. A crystalline, orange substance is obtained, which analysis and spectra indicate to be *N*-bromo-2-phenyloxazolinium bromide *(18)*.



*(18)*

However, it appears that not all bromine adducts of 2-aryloxazolines have an ionic structure similar to that of *(18)*. The investigations are complicated by the fact that other 2-aryloxazolines often give addition products that do not contain stoichiometric quantities of bromine.

Substitution in the phenyl nucleus can be ruled out, since 2-phenyloxazoline is obtained from *(17)* and *(18)* by treatment with aqueous alkalis. From 2-(4-methoxyphenyl) $\Delta^2$-oxazoline, on the other hand, products brominated also in the phenyl nucleus have been obtained.

Depending on the method of preparation, the bromine adduct *(18)* may be an unstable substance melting at 40 °C and smelling faintly of bromine, even after purification, or a stable substance melting at 85–87 °C and having no smell of bromine, but having the same IR spectrum as the other product [*]. The lower-melting form is obtained by dropwise addition of the calculated quantity of undiluted bromine to the phenyloxazoline (with slight cooling); the higher-melting form is obtained in the presence of a solvent.

Procedure

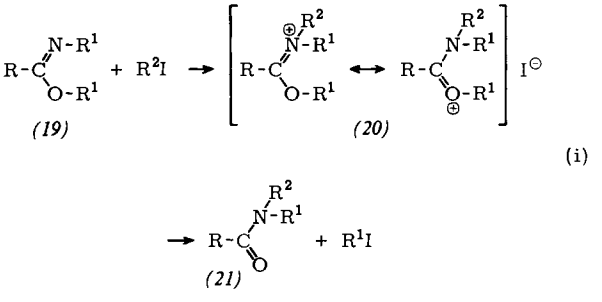
*N-Bromo-2-phenyloxazolinium Bromide (18)*: 32 g (0.2 mole) of bromine is added to a solution of 37 g (0.25 mole) of 2-phenyl-$\Delta^2$-oxazoline in 200 ml of anhydrous ether over 15 min at room temperature. The mixture is stirred for three hr and then refluxed for 1 hr. On standing for 2 days the addition compound, which is sparingly soluble in ether, separates as orange leaflets, m.p. 85–87 °C, yield 60 g (97 %).

To determine the content of "active" bromine, 1.000 g of this adduct is dissolved in 10 ml of acetone and the solution is added to a mixture of 30 ml of 10 % KI solution and 30 ml of acetone. Concentrated HCl (5 ml) is added; this does not lead to any intensification of the iodine color. Solutions of pure samples titrated with 0.1 N thiosulfate solution give the calculated titer of 32.5 ml, corresponding to 26.0 % of "active" bromine.

The compounds *(18)* can be used for the bromination of many substances, *e.g.* olefins, from which dibromo adducts have been obtained.

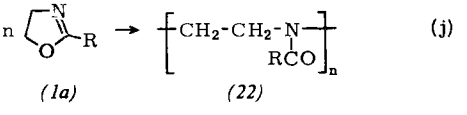
### 3.4. Polymerization of $\Delta^2$-Oxazolines [42]

*N*-Substituted imidic esters *(19)* are converted into *N,N*-disubstituted amides *(21)* by alkylating agents, a compound *(20)* occurring as an intermediate [4].



*(19)* *(20)* *(21)* (i)

The question arose whether this reaction (as described for the cyclic iminolactones *(3)* and cyclic iminocarbonates *(4)* [7c]) can lead to polymerization when the two groups $R^1$ in the imidic ester *(19)* form a ring. The oxazolines *(1a)* can in fact be converted into high polymers *(22)* containing *N*-acylethylenimine units with the aid of cationic catalysts [43].



*(1a)* *(22)* (j)

The preparation of *N*-vinylcarboxamides by dehydrochlorination of *N*-2-chloroethylamides with alkali and the polymerization of these *N*-vinyl compounds with peroxides or Friedel-Crafts catalysts have been described by *Bácskai*

[40] *A. Roedig* in [3], Vol. V/4, p. 34 (1960).

[41] a) *H. L. Wheeler* and *P. T. Walden*, Amer. chem. J. *19*, 129 (1897); b) *J. Stieglitz*, *ibid. 18*, 751 (1896).

[*] This is true of the spectra of the melts; the spectra of the crystalline compounds show slight shifts of individual bands, which can be attributed to differences in crystal structure.

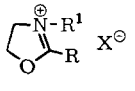
[42] *W. Seeliger* and *W. Thier*, Angew. Chem. *78*, 613 (1966); Angew. Chem. internat. Edit. *5*, 612 (1966).

[43] *W. Seeliger*, German published Pat. appl. 1206585 (1965), Chem. Werke Hüls.

and *Halmos*[44]. It was later found that the dehydrochlorination leads predominantly to 2-alkyl-$\Delta^2$-oxazolines[45], so that one might conclude that these authors had already obtained polyalkyloxazolines *(22)*. However, this cannot be so, since the properties of the polymers and peculiarities of the polymerization reported by *Bácskai* and *Halmos* disagree in essential points with the results obtained in the polymerization of pure 2-alkyl-$\Delta^2$-oxazolines.

### 3.4.1. Catalysts

Compounds of the type *(23)*, where $R^1$ is hydrogen, an alkyl group, or an acyl group and $X^\ominus$ is the weakly nucleophilic anion of a strong acid, generally are suitable as catalysts. These catalysts may be used as such,



*(23)*

or may be generated in the reaction medium by the addition of strong acids or their esters or anhydrides. Complexing agents of the Friedel-Crafts type are also effective. For example, sulfuric acid, dialkyl sulfates, sulfonic acids and their alkyl esters, alkyl iodides, iodine (for 2-alkyloxazolines), the mixed *p*-toluenesulfonic-benzoic anhydride[46a], $BF_3$-ether adduct, *p*-nitrophenyldiazonium fluoroborate, or the crystalline salts *(23)*, R = phenyl, $R^1$ = H, and $X^\ominus$ = *p*-toluenesulfonate or perchlorate[46b], have been found suitable.

Simple carboxylic acids and their anhydrides are not suitable as catalysts for the preparation of polyoxazolines *(22)* of high molecular weight; the corresponding anions are presumably too strongly nucleophilic and become irreversibly attached to the chain ends. Peroxides are also unsuitable.

### 3.4.2. Conditions

In the presence of sufficiently large quantities of catalyst, the reaction (j) proceeds already at room temperature, even though only slowly. The polymerization of the oxazolines *(1a)* (*e.g.* R = ethyl or phenyl) begins rapidly between 120 and 130 °C; the reaction stops when the temperature is reduced to less than 120 °C, and starts again between 120 and 130 °C.

To obtain very high molecular weights, the polymerization should be carried out for several hours in the absence of solvent to as high a conversion as possible.

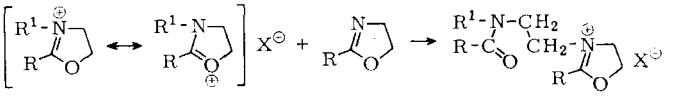
### 3.4.3. Reaction Mechanism

The polymerization of oxazolines may be interpreted analogously to the rearrangement of imidic esters formulated in equation (i):



*(23)* *(1a)* (k)

The initiation, which consists in alkylation of the basic $\Delta^2$-oxazoline by the oxazolinium cation, can be repeated [$R^1$ in *(23)* then denotes the growing polymer chain] as long as monomer molecules are available. Prerequisite for completion of the reaction is that $X^\ominus$ should not be capable of being alkylated or that the alkylation product $R^1$–N(COR)–$CH_2$–$CH_2$–X can again quaternize *(1a)*, as is the case when X = I.

### 3.4.4. Purification of the Monomer

Like most cationic polymerizations, that of oxazolines *(1a)* is very sensitive towards impurities. Though even crude monomers *(1a)* containing water can be polymerized at sufficiently high catalyst concentrations, the viscosities of the resulting products are low. If the reduced viscosities $\eta_{red}$ (measured in 0.5 % chloroform solution at 20 °C) of polymers obtained from samples of 2-phenyloxazoline purified in various ways are plotted against the catalyst concentrations used, viscosity maxima whose positions depend on the pretreatment of the monomer are obtained (Fig. 2). No direct dependence of the viscosity on the purity (up to 99.99 %) as found by gas chromatography could be established. It was therefore necessary to develop suitable purification methods on an empirical basis.

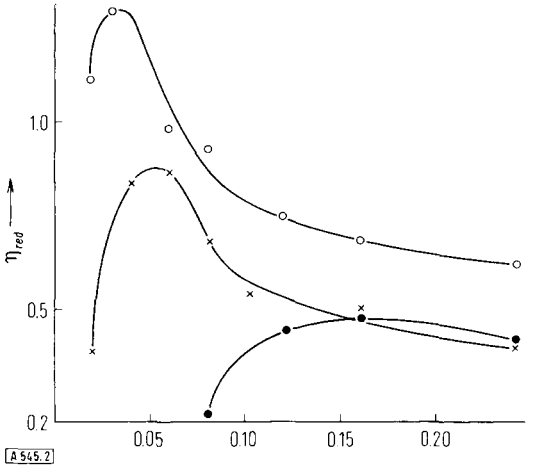


Fig. 2. Polymerization of 2-phenyl-$\Delta^2$-oxazoline; viscosity maxima for monomers purified in various ways; catalyst: 2-phenyl-$\Delta^2$-oxazolinium *p*-toluenesulfonate.

●: monomer distilled once with 1 wt.-% of benzoyl chloride; ×: monomer preteated with powdered KOH (50 °C, 4 hr), filtered and distilled once with 1 wt.-% of benzoyl chloride; ○: monomer rectified after pretreatment with powdered KOH.

Ordinate: Reduced viscosity $\eta_{red} = (\eta_{rel}-1)/c$ (dl/g).

Abscissa: Quantity of catalyst added (mole-%).

The oxazolines can be purified adequately for polymerization purposes by careful fractionation. For laboratory experiments,a two-stage purification is preferable. Most of the interfering impurities are first bound by pretreatment with KOH powder, sodium, small quantities of benzoyl chloride, or diisocyanates, or by polymerization of a small proportion of the monomer. Subsequent column distillation then gives a very pure monomer.

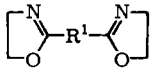
### 3.4.5. Molecular Weights of Polyoxazolines

Theoretically, all the catalyst molecules present should almost simultaneously initiate polymer chains in accordance with equation (k), so that, on statistical grounds, the lengths of all the polymer chains should be approximately the same, and should depend only on the catalyst concentration. The investigation of the polymers obtained at various catalyst concentrations is not yet complete, but it may be concluded from light-scattering measurements that the maxima in Figure 2 correspond to weight-average molecular weights $\overline{M}_w$ of about 300000, 200000, and 100000, respectively. The Zimm diagrams suggest that the polymers *(22)* generally are linear.

### 3.4.6. Copolymerizations

Polyoxazolines *(22)* with different groups R, which may contain halogen, can be prepared by copolymerization of differently substituted oxazolines *(1a)*.

Alkylene- or arylene-bisoxazolines *(24)* give (depending



*(24)*

on the quantity used) viscous, soluble, evidently branched, or even completely cross-linked products. 4*H*-5,6-Dihydrooxazines *(1b)* and *(1c)* also can be polymerized or copolymerized with oxazolines *(1a)* in the same manner the resulting polymers containing (sometimes substituted) poly-*N*-acyltrimethylenimine units.

### 3.4.7. Properties of the Polymers

Polyoxazolines having degrees of polymerization above about 100 are solid and when first obtained more or less yellow. Their properties are strongly dependent on the substituents. Polymers *(22)* in which R is methyl or ethyl dissolve readily in water, in which the derivatives with higher alkyl groups are practically insoluble. All polyoxazolines, however, dissolve very easily in chloroform.

## 4. Reactions at the Alkyl Group of 2-Alkyl-$\Delta^2$-oxazolines

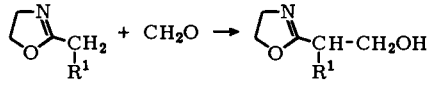
It has already been pointed out that the reactions of $\Delta^2$-oxazolines studied so far are mainly those leading to open-chain amide derivatives. The only known reactions of the alkyl group in position 2 are additions and condensations with aldehydes.

### 4.1. 2-Alkyl-$\Delta^2$-oxazolines and Aldehydes

A reaction that has no parallel in acyclic imidic esters [11a] is the condensation of quaternized 2-alkyl-oxazolines with aromatic aldehydes [47]. Another unusual reaction is the addition of aromatic aldehydes to 2-dichloromethyloxazoline, which proceeds under mild conditions [48]. 4-Disubstituted derivatives of $\Delta^2$-oxazolines *(1a)*, which are much more stable (particularly towards acid hydrolysis) than the unsubstituted compounds, condense with aromatic aldehydes [49] and undergo addition and condensation with any aldehydes [50]. However, the literature [50] does not contain characteristic data or yields for the products obtained from alkyloxazolines substituted only in position 2.

#### 4.1.1. 2-(2-Hydroxyalkyl)-$\Delta^2$-oxazolines

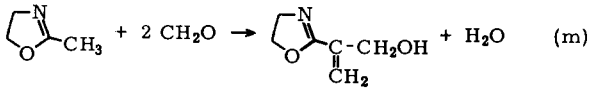
2 Alkyloxazolines *(25)* react with paraformaldehyde in the presence of catalytic amounts of strong bases (*e.g.* triethylamine) to form the compounds *(26)*.



(1)

*(25a)*: $R^1 = H$ *(26a)*: $R^1 = H$
*(25b)*: $R^1 = CH_3$ *(26b)*: $R^1 = CH_3$

The reaction with 2-methyloxazoline *(25a)* proceeds differently when formaldehyde is present in excess: 2-(2-oxazolinyl)-2-propen-1-ol *(27)* is formed in good



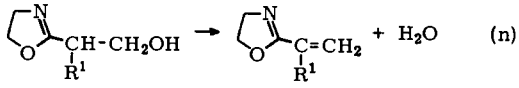
(m)

*(25a)* *(27)*

yield. The reaction of 2-vinyloxazoline *(28a)* with formaldehyde also leads to *(27)*.

#### 4.1.2. 2-Alkenyl-$\Delta^2$-oxazolines

Water can be eliminated readily and in high yield from the hydroxyethyl derivatives *(26)* at elevated temperatures when alkali metal alkoxides or other strongly



(n)

*(26)* *(28a)*: $R^1 = H$
*(28b)*: $R^1 = CH_3$

alkaline substances are used as catalysts. For the compounds *(26)* with no substituents on the ring, the usual

[47] *F. M. Hamer* and *R. J. Rathbone*, Brit. Pat. 541330 (1941), Kodak Ltd.; Chem. Abstr. *36*, 4767 (1942).

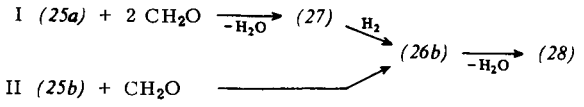
[48] *H. Bretschneider*, *G. Piekarski*, and *K. Biemann*, Mh. Chem. *85*, 882 (1954).

[49] *H. L. Wehrmeister*, J. org. Chemistry *27*, 4418 (1962).

[50] *H. L. Wehrmeister*, French Pat. 1385727 (1965), Commercial Solvents Corp.; Chem. Abstr. *63*, 610c (1965).

acidic calatysts cannot be used owing to the tendency of these compounds to polymerize.

The vinyl derivatives *(28)* can be polymerized by a free-radical mechanism [51]. The interesting 2-isopropenyloxazoline *(28b)* can be prepared by two routes (I and II), in yields of 41 % and 54 % respectively.



Compound *(27)* can be selectively reduced to *(26b)* in a yield of more than 80 % with Raney nickel at normal pressure and room temperature.

Other aldehydes also can be condensed with the oxazolines *(25)*. However, it is recommended that stoichiometric quantities of acidic catalysts should be used with these compounds, since the condensation is otherwise accompanied by polymerization. Condensation of *(25a)* with benzaldehyde by elimination of water in the presence of equimolar quantities of zinc chloride or *p*-toluenesulfonic acid leads to 2-styryl-$\Delta^2$-oxazoline *(28c)* in 44 % yield. When zinc chloride is used, the

*(28c)* 
reaction proceeds *via* a stable, crystalline complex intermediate containing 2 molecules of 2-styryloxazoline per molecule $ZnCl_2$, in which the UV absorption of the former [$\lambda_{max}$ = 280 mμ (ε = 24200)] is retained unchanged, and which is decomposed by alkali solutions.

### 4.1.3. Compounds Prepared

Some of the compounds discussed in Section 4.1 are listed in Table 6.

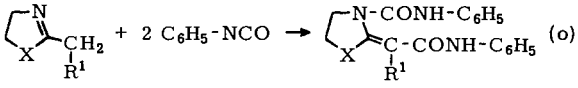
Table 6. 2-Alkenyl- and 2-(2-hydroxyalkyl)-$\Delta^2$-oxazolines.

| Cpd. | Prepn. | Yield (%) | B.p. (°C/mm Hg) (M.p., °C) | $n_D^{20}$ |
|---|---|---|---|---|
| *(28a)* | Eq. (n) | 64.5 | 75/93 | 1.4780 |
| *(28b)* | Eq. (n) | 76.5 | 90/98 | 1.4768 |
| *(27)* | Eq. (m) | 66 | 97—99/1 (44—46) | — |
| *(26a)* | Eq. (l) | 23 | 58/0.1 | 1.4830 |
| *(26b)* | Eq. (l) | 73 | 62/0.1 | 1.4770 |
| *(28c)* | 4.1.2. | 44 | 100—105/0.05 (54) | — |

## 4.2. 2-Alkyl-$\Delta^2$-oxazolines and Isocyanates [52]

### 4.2.1. Results

The 2-alkyloxazolines *(25)* are surprisingly reactive towards phenyl isocyanate. A mixture of 1 mole of *(25a)* and 2 moles of phenyl isocyanate prepared at room temperature yields a crystalline 1:2 adduct, 3-(phenylcarbamoyl)-2-oxazolidinylideneacetanilide *(30a)*, in a strongly exothermic reaction.



*(25a)*: X = O; $R^1$ = H
*(25b)*: X = O; $R^1$ = $CH_3$
*(29)*: X = S; $R^1$ = H

*(30a)*: X = O; $R^1$ = H
*(30b)*: X = O; $R^1$ = $CH_3$
*(30c)*: X = S; $R^1$ = H

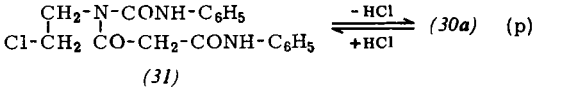
2-Ethyl-, 2-propyl-, and 2-n-undecyl-$\Delta^2$-oxazoline and 2-methyl-$\Delta^2$-thiazoline *(29)* also form adducts of the type *(30)*. 2-Isopropyl- and 2-cyclohexyloxazoline, on the other hand, do not react with phenyl isocyanate. Further, no reaction occurs when isothiocyanates are used in equation (o) instead of phenyl isocyanate.

The structure of the compounds *(30)* was confirmed by an independent synthesis of *(30a)* and by comparison of the IR spectra. The products obtained in accordance with equation (o) are shown in Table 7.

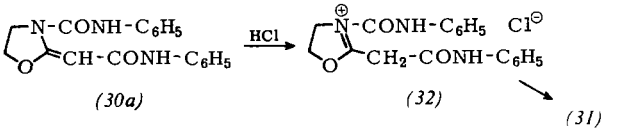
Table 7. Adducts obtained from 2-alkyl-$\Delta^2$-oxazolines and 2-methyl-$\Delta^2$-thiazoline with phenyl isocyanate.

| | *(30)* $R^1$ | X | Yield (%) | M.p. (°C) |
|---|---|---|---|---|
| *(30a)* | H | O | 81 | 153—156 |
| *(30b)* | $CH_3$ | O | 59 | 126—127 |
| | $C_2H_5$ | O | 43 | 100—102 |
| | n-$C_{10}H_{21}$ | O | 42 | 104—105 |
| *(30c)* | H | S | 60 | 169—174 |

The last step in the independent synthesis of *(30a)* is the dehydrochlorination of *(31)* with cyclization, which

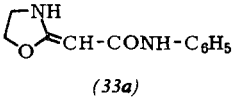


leads to an interesting intramolecular *O*-alkylation of the malonamide derivative *(31)*, though a 5-membered ring would also result from *C*-alkylation. Remarkably, the reaction (p) is reversible, and *(30a)* is smoothly converted into *(31)* with HCl in dioxane at room temperature. The reaction may be assumed to proceed *via* the oxazolinium chloride *(32)*, which rearranges to *(31)*, in analogy to equation (h).

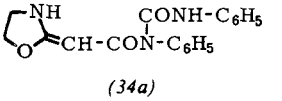


### 4.2.2. Intermediates and Reaction Mechanism

In reaction (o) with 2-methyloxazoline *(25a)*, two intermediates were isolated. On the basis of their spectra these compounds are assigned the structures



*(33a)*



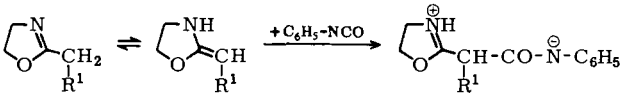
*(34a)*

[51] *L. S. Luskin* and *P. L. De Benneville*, Ger. Pat. 1067437 (1959); Röhm and Haas; Chem. Abstr. *55*, 19960a (1961).

[52] *R. Nehring* and *W. Seeliger*, Liebigs Ann. Chem., in press.

*(33a)* and *(34a)*. Compound *(30a)* is formed from *(34a)* by rearrangement on heating, and from *(33a)* by the uptake of a further molecule of phenyl isocyanate.

On the basis of these observations and of the known [53] reactions of compounds such as cyclopentanone anil, the oxazoline *(25)* [and analogously the thiazoline *(29)*] is assumed to contain a small equilibrium concentration of the "enamine form" *(35)* (possibly induced by phenyl isocyanate), which then adds phenyl isocyanate to form the intermediate *(36)*.



*(25)* *(35)* *(36)*

Compound *(36)* can form the anilide *(33)* by proton shift and the unstable diadduct *(34)* by addition of phenyl isocyanate with proton shift, both *(33)* and *(34)* being converted into the dianilide *(30)* under the conditions of the reaction.

### 4.2.3. Reaction with Diisocyanates

2-Alkyloxazolines *(25)* react with diisocyanates to form polymers; *(25a)* reacts with aromatic diisocyanates vigorously and with considerable evolution of heat when the reactants are undiluted. If the temperature is kept below about 120 °C, the polymers are linear; they can be cross-linked by heating. Since the IR spectra of the linear polymers correspond to those of the compounds *(30a)* and *(30b)*, the structures are assumed to be analogous. 2-Alkyl-4*H*-5,6-dihydrooxazines *(1b)* also form polyadducts with diisocyanates.

## 4.3. Halogenation of 2-Alkyl-$\Delta^2$-oxazolines [54]

In Section 3.3 it was shown that chlorine and bromine can add to 2-aryloxazolines. It was of interest to determine whether the 2-alkyl derivatives *(25)* behave analogously or undergo substitutions similar to those of alkyl groups activated by an adjacent C=N double bond. For example, 2- or 4-methylpyridine derivatives undergo unusually fast halogenation in the methyl group [55], whereas methylaryl compounds generally require free-radical initiators for halogenation of the alkyl group.

The halogenation of 2-alkyloxazolines *(25)* leads mainly to substitution products, *i.e.* *N*-2-halogenoethylamides of carboxylic acids that are partially or completely halogenated in the α position, and $\Delta^2$-oxazolines with halogenoalkyl substituents.

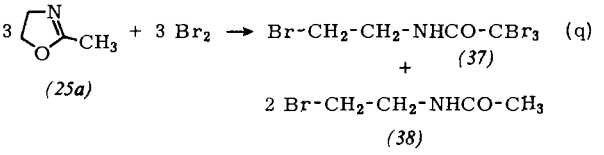
[53] *R. Huisgen, R. Grashey, J. M. Vernon*, and *R. Kunz*, Tetrahedron *21*, 3311 (1965).

[54] *E. Aufderhaar* and *W. Seeliger*, Liebigs Ann. Chem., in press.

[55] a) *B. R. Brown, D. L. Hammick, B. H. Thewlis*, and *D. J. Walbridge*, J. chem. Soc. (London) *1953*, 1369, and literature cited there; b) *W. Koenigs*, Ber. dtsch. chem. Ges. *31*, 2364 (1898).

### 4.3.1. Bromination

When an equimolar amount of bromine is added dropwise to methyloxazoline *(25a)*, a vigorous reaction takes place even in the cold, leading to a mixture of *N*-2-bromoethyltribromoacetamide *(37)* and *N*-2-bromoethylacetamide *(38)*.



*(25a)*

Similarly, other 2-alkyloxazolines give *N*-2-bromoethylamides of α-dibrominated carboxylic acids. No partially α-brominated products could be isolated, even when less than one equivalent of bromine was used. The compounds *(37)* and *(38)* undoubtedly are formed by rearrangement of the corresponding oxazolinium bromides.

Surprisingly, *N*-2-bromoethylamides of α-perbrominated carboxylic acids, which are very sensitive to alkalis, can be cyclized smoothly to 2-(α-perbromoalkyl)oxazolines when the treatment with strong alkali is carried out at room temperature in a heterogeneous mixture, *e.g.* with caustic alkali powder in inert solvents. Thus the interesting 2-tribromomethyloxazoline is formed in 78 % yield in the form of colorless crystals from *(37)*, which can be obtained in 72 % yield in accordance with equation (q).

2- or 4-Methylpyridines (see Section 4.3.) are brominated in glacial acetic acid in the presence of a base, *e.g.* sodium acetate [55]. On the other hand, the 2-alkyl-$\Delta^2$-oxazolines can be halogenated in the undiluted form or in an inert solvent, and it is not even necessary that unchanged oxazoline should be present to act as a base. The same products are obtained in comparable yields even when *e.g.* 2-methyloxazoline is added dropwise to an excess of bromine diluted with ether. In this case an orange salt mixture is first formed, and the IR spectrum shows that this contains bromine adducts of the type *(18)* as well as the hydrobromides of the brominated and the unbrominated oxazolines.

### 4.3.2. Chlorination

In contrast to bromination, chlorination of 2-alkyloxazolines *(25)* leads to partially halogenated products as well. 2-(1-Monochloroalkyl)oxazolines can be prepared directly by the use of an excess of the oxazoline.

2-Ethyloxazoline and an equimolar amount of chlorine give a mixture containing the compounds *(39a)*–*(39c)*, which are difficult to separate; the $^1$H-NMR spectra give values of 1:1:1 to 1.7:1:1.5 for the ratio *(39a)*: *(39b)*: *(39c)*.

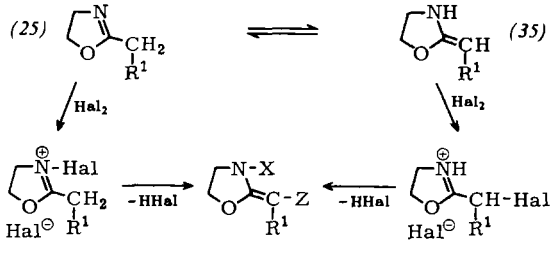
Cl–$CH_2$–$CH_2$–NH–CO–R

*(39a)*: R = $CH_2$–$CH_3$
*(39b)*: R = CHCl–$CH_3$
*(39c)*: R = $CCl_2$–$CH_3$

The chlorination of 2-methyloxazoline leads to a corresponding mixture of chlorinated amides. Conversion

into the mixture of the corresponding oxazolines by treatment with alkali, followed by further chlorination and repetition of this process several times, ultimately leads to pure 2-trichloromethyloxazoline.

On the basis of the existing experimental results, it may be concluded that the halogenation of 2-alkyloxazolines *(25)* proceeds *via* one of the enamine structures *(41)*; *(41a)* could be formed from the oxazoline *(25)* *via* an *N*-halogenooxazolinium halide *(40)*, and *(41b)* from the "enamine form" *(35)* that may exist in equilibrium with *(25)*, *via* the halogen adduct *(42)*.



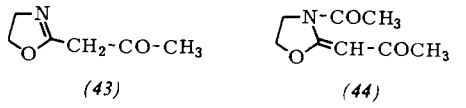
*(40)* *(41a)*: X = Hal; Z = H *(42)*
*(41b)*: X = H; Z = Hal

The data are not sufficient to permit a decision as to whether *(41a)* or *(41b)* occurs as an intermediate. An alkyloxazoline would act as hydrogen halide acceptor in both cases. The difference in degrees of halogenation of the final products obtained with bromine and with chlorine probably is due to the fact that amides *(39)* that under the conditions of the reaction cannot be halogenated further are formed more rapidly with chlorine than with bromine, as was shown in the halogenation of 2-aryl-$\Delta^2$-oxazolines.

### 4.4. 2-Alkyl-$\Delta^2$-oxazolines and Ketene

The reaction of 2-alkyloxazolines *(25)* with ketene is complicated, since the ketene not only enters into addition reactions, but is also polymerized by the base *(25)*.

The principal modes of reaction can be seen in the reaction with 2-methyloxazoline *(25a)*, which can lead to the addition of one or two molecules of ketene, depending on the conditions. The monoaddition product, the *C*-acetyl compound *(43)*, melts at 115–116 °C, can be distilled, and exists as the enol, as expected.



*(43)* *(44)*

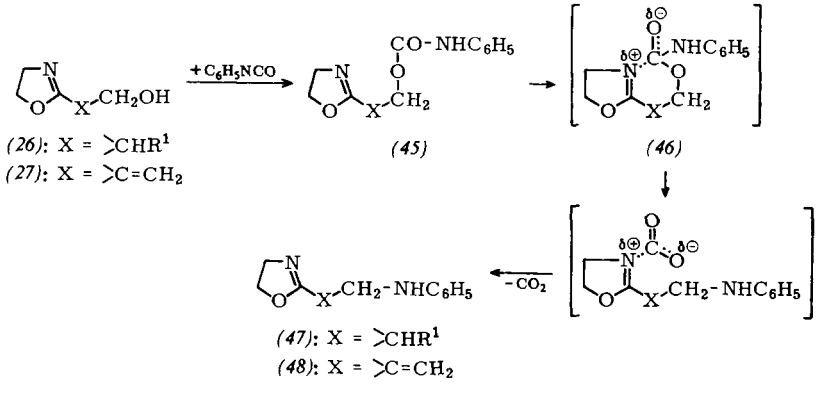
Compound *(43)* is sparingly soluble in cold ether, exhibits the reactions of enols, and forms stable complexes with heavy metal salts.

The structure proposed for the diadduct is that of (3-acetyl-2-oxazolidinylidene)acetone *(44)*.

## 5. Reactions with Other Substituents in Position 2 of $\Delta^2$-Oxazolines

### 5.1. 2-(2-Phenylcarbamoyloxyalkyl)-$\Delta^2$-oxazolines and their Decarboxylation

The ready attack of phenyl isocyanate on 2-alkyloxazolines *(25)* was discussed in Section 4.2. If the hydroxyethyloxazolines *(26)* or *(27)* are used in this reaction, urethanes *(45)* are formed. These can be decarboxylated readily by heating to about 150 °C, giving 2-(2-anilinoethyl)-$\Delta^2$-oxazolines *(47)* or 2-(2-oxazolinyl)-*N*-phenylallylamine *(48)*.



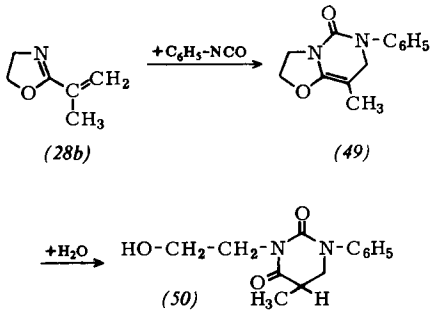
*(26)*: X = $>CHR^1$
*(27)*: X = $>C=CH_2$
*(45)* *(46)*
*(47)*: X = $>CHR^1$
*(48)*: X = $>C=CH_2$

The decarboxylation probably involves the approach of the carbonyl group to the basic ring nitrogen, as shown in *(46)*; this would explain the ease with which this reaction proceeds.

The decarboxylation of 2-(2-phenylcarbamoyloxyethyl)-pyridine leads analogously, though less smoothly, to 2-(2-anilinoethyl)pyridine.

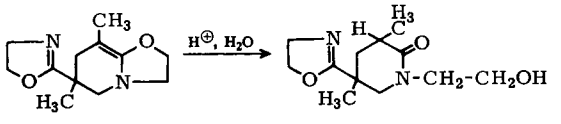
### 5.2. 2-Alkenyl-$\Delta^2$-oxazolines as "Dienes"

The reaction of 2-isopropenyl-$\Delta^2$-oxazoline *(28b)* with phenyl isocyanate leads to an unstable 1:1 adduct which tends to polymerize, and whose characteristic double bond absorption in the IR spectrum at 1760 $cm^{-1}$ is compatible with the structure *(49)*. This compound, which must result from a 1,4-addition to the "diene" system of *(28b)*, very rapidly takes up 1 mole of water in acidic solution to form a hydrolysis product to which structure *(50)* can be assigned.



(28b) (49) (r)

Equation (r) suggests that the possibility of other 1,4-additions should be investigated. Attempts were therefore made to bring about reaction of *(28b)* with dienophiles such as acrylonitrile, maleic anhydride, and hexachlorocyclopentadiene. The only product that could be isolated was a dimer of isopropenyl-$\Delta^2$-oxazoline, to which the structure *(51)* is assigned on the basis of analysis and IR spectra.



*(51)* *(52)*

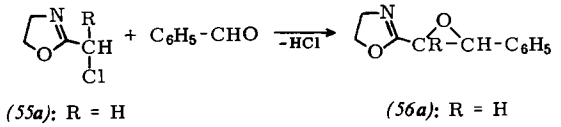
As expected, *(51)* is hydrolysed exothermally in aqueous acid with formation of *(52)*.

### 5.3. 2-(1,2-Epoxyalkyl)-$\Delta^2$-oxazolines

In the preparation of epoxides by the Darzens method (condensation of α-chloro esters with carbonyl compounds in the presence of strongly alkaline substances such as sodamide or potassium t-butoxide), the first step is assumed to be the formation of a carbanion *(53)* [56], to which the carbonyl compound can add. Similarly, *(54)* could be formed as an intermediate from 2-(α-chloroalkyl)oxazolines.

*(53)* *(54)*

It was actually found that α-chloroalkyloxazolines *(55)* can react in the same manner with benzaldehyde in the presence of potassium t-butoxide to give good yields of the 2-(1,2-epoxyalkyl)-$\Delta^2$-oxazolines *(56)*.



*(55a)*: R = H *(56a)*: R = H
*(55b)*: R = $CH_3$ *(56b)*: R = $CH_3$

### Procedure

*2-(2-Phenyl-1,2-epoxyethyl)-$\Delta^2$-oxazoline (56a)*: A solution of 7.8 g (0.2 g-atom) of potassium in 200 ml of anhydrous tert-butyl alcohol is added over a period of 1.5 hr to a mixture of 24 g (0.2 mole) of 2-chloromethyl-$\Delta^2$-oxazoline and 63 g (0.6 mole) of benzaldehyde at 20 °C. The reaction mixture is then stirred for 2 hr at room temperature and refluxed for 3 hr. The mixture is allowed to stand overnight, and the precipitated KCl (15 g, 100 %) is centrifuged off; the solvent is evaporated from the clear dark-red supernatant and the residue is distilled. 23 g (61 %) of the condensation product is obtained in the boiling range 135–138 °C/0.5 mm Hg. The pure compound is a colorless oil, b.p. 102 °C/0.01 mm Hg, which rapidly turns brown in air.

[56] *S. Winstein* and *R. B. Henderson* in [11a], Vol. 1, p. 14 (1950).

## 6. 2,3-Cycloadditions to Cyclic Imidic Esters

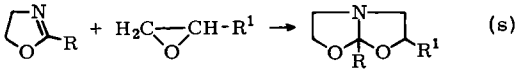
Apart from the additions with ring cleavage described in Section 3, cyclic imidic esters have also been observed to undergo additions with retention of the ring.

By reaction of the imidic ester *(1)* with epoxides, 2,3-cycloadducts [57] can be isolated.

Epoxides undergo a number of additions to C=O or C=N bonds leading to 1,3-dioxolanes [58], 2-oxazolidinones [59], or 1,3-oxazolidines [60]. No reactions with imidic esters are known as yet.

### 6.1. 4,6-Dioxa-1-azabicyclo[3.3.0]octanes

When a $\Delta^2$-oxazoline is heated with equimolar amounts of an epoxide at 120–200 °C in the absence of air and moisture, the epoxide adds to the double bond of the oxazoline to give the 4,6-dioxa-1-azabicyclo[3.3.0]-octane *(57)*.



(s)

*(57)*

Instead of epoxides, substances that yield epoxides under the conditions of the reaction may be used, *e.g.* cyclic carbonates of 1,2-diols [57]. The addition of catalysts such as lithium chloride can accelerate the reaction, but is generally unnecessary; presumably the base *(57)* formed has an autocatalytic effect.

The compounds *(57)* are high-boiling but distillable strong bases, the cyclic structure of which has been shown by molecular-weight determinations and by IR spectra, which contain no absorption in the region of the O–H, N–H, C=O, and C=N vibrations [57], as well as by acid hydrolysis, which leads to the carboxylic acids R–COOH. The position of the substituent $R^1$ in *(57)* was proved in one case by hydrolysis to the known ethanolamine derivative *(58)*.

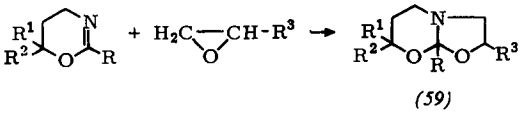
### 6.2. 5,7-Dioxa-1-azabicyclo[4.3.0]nonanes

Like $\Delta^2$-oxazolines, 4*H*-5,6-dihydrooxazines react with epoxides, with formation of the bicyclic ring homologues *(59)* of *(57)*.



*(59)*

The preparation conditions and general properties are similar to those of the compounds *(57)*. Some examples are given in Table 9.

Table 9. 5,7-Dioxa-1-aza[4.3.0]nonanes *(59)* obtained from 4*H*-5,6-dihydrooxazines and epoxides.

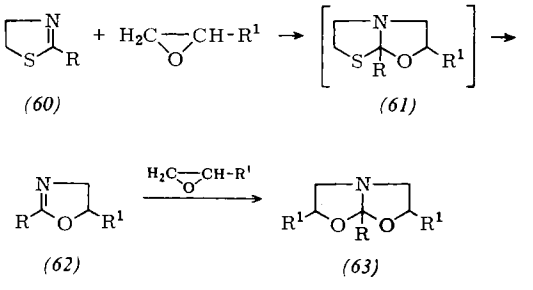
### 6.3. $\Delta^2$-Thiazolines and Epoxides [62]

When the reaction (s) is extended to $\Delta^2$-thiazolines *(60)*, the only pure compounds obtained by distillation are sulfur-free. The principal product is always the oxazoline *(62)*; in one case the 4,6-dioxa-1-azabicyclo[3.3.0]-octane *(63)* (R = $CH_3$, $R^1$ = $CH_2-O-CH=CH_2$) was also isolated. This reaction may be represented by scheme (t) if it is assumed that a bicyclus *(61)*, analogous to *(57)*, is formed as an intermediate, and decomposes with elimination of thiirane (or its polymer) to give the oxazoline *(62)*. This can react further in accordance with equation (s) with the epoxide still present to form the trisubstituted bicyclus *(63)*.



*(60)* *(61)* (t)

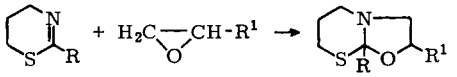
### 6.4. 4*H*-5,6-Dihydro-1,3-thiazines and Epoxides [62]

The experiments described above left unanswered the question of what products are obtained in the reaction of 4*H*-5,6-dihydro-1,3-thiazines *(64)* with epoxides.The 7-oxa-5-thia-1-azabicyclo[4.3.0]nonanes *(65)* obtained by the cycloaddition of epoxides to the 2,3 double bond are sufficiently stable for distillation from the reaction mixture (yields 25–30 %).



*(64)* *(65)*

### 7. IR Spectra of Cyclic Imidic Esters [63]

Table 10 shows the influence of the substituent R on the positions of the IR bands assigned to the $\Delta^2$-oxazoline ring. In this connection, reference should be made to the IR spectra of the simple compounds *(1a)* [64,65,22a].

The IR spectra of the 4*H*-5,6-dihydrooxazines *(1b)* and *(1c)* [66,67,22a,27] contain no surprising differences from those of the oxazolines *(1a)*. In particular, the positions of the C=N double-bond absorptions are practically the same. However, the compounds *(1a)* can be distinguished from *(1b)* and *(1c)* by the position of the skeletal vibrations, which generally give three characteristic bands between 890 and about 1000 $cm^{-1}$ in the case of the 5-membered ring *(1a)*, and between 1070 and 1160 $cm^{-1}$ in the case of the 6-membered rings *(1b)* and *(1c)* [22a,27].

# Syntheses and Derivatives of Squaric Acid

BY DR. G. MAAHS AND DR. P. HEGENBERG

CHEMISCHE WERKE HÜLS AG., MARL (GERMANY)

*Dedicated to Professor F. Broich on his 60th birthday*

*Squaric acid (dihydroxycyclobutenedione), the dianion of which may be regarded as a novel aromatic system, has recently become readily accessible by simple syntheses. The acidic character of squaric acid manifests itself in the formation of salts and of lower alkyl esters, which can be converted into the amides. Squaric acid dichloride shows in its reactions typical acyl chloride behavior. Condensation of squaric acid with pyrrole, phenol, and azulene derivatives yields cyclotrimethine dyes.*

### 1. Introduction

Dihydroxycyclobutenedione *(1)* ("squaric acid") was first synthesized in 1959 by *Cohen, Lacher*, and *Park* [1].

*(1)* *(2)*

*West* suggested that the dianion *(2)* of squaric acid should be regarded as a member of a series of novel aromatic compounds [2]. The formal similarity of the dianion to cyclobutadiene (all the carbon atoms have $sp^2$ hybridization), together with the interest in aromaticity [3] and the increasing study of small rings, have placed squaric acid in a prominent position. As a result of simplified syntheses, it can now be produced in unlimited quantities [*].

### 2. The Structure of Squaric Acid

Squaric acid is a colorless, crystalline compound having a decomposition point of about 293 °C. The infrared spectrum contains a broad absorption band between 3 and 4 μ (maximum at 4.0 μ), indicating strong hydrogen bonding. Two carbonyl bands are present at 5.5 and

[2] *R. West, H. Y. Niu, D. L. Powell*, and *M. V. Evans*, J. Amer. chem. Soc. *82*, 6204 (1960); *R. West* and *D. L. Powell, ibid. 85*, 2577 (1963); *M. Ito* and *R. West, ibid. 85*, 2580 (1963).

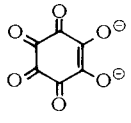
[3] See, *e.g., R. Breslow*, Chem. Engng. News *43*, No. 26, p. 90 (1965).

[*] Suppliers: see "Neues aus Hüls", Series 47, Nov. 1964.

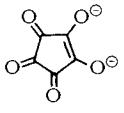
6.0 μ, while the C=C-conjugation band occurs at 6.5 μ. The hydrogen bonding explains the high decomposition point and the very low solubility, which is only about 2 % in water. The acid is insoluble in the usual organic solvents.

Squaric acid is dibasic, $pK_2 = 2.2$, $pK_1 \approx 1$. In the resonance-stabilized dianion *(2)*, all four oxygen atoms can accept the negative charge. The infrared spectrum of the dianion does not contain carbonyl bands at 5.5 μ, but has a broad absorption between 6.5 and 6.75 μ. LCAO calculations of the delocalization energy and the arrangement of the bonds show that the dianion is symmetrical and planar [2].

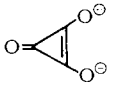
The dianion *(2)* belongs to a new class of compounds having the general formula $(C_nO_n)^{m-}$, the aromatic character of which was predicted and studied by *West et al.* [2]. Of the other members of this series, the dianions of rhodizonic acid *(3)* and of croconic acid *(4)* have been known for some time.



*(3)*



*(4)*

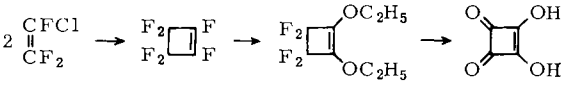


*(5)*

The dihydroxycyclopropenone dianion *(5)* has not yet been prepared [4].

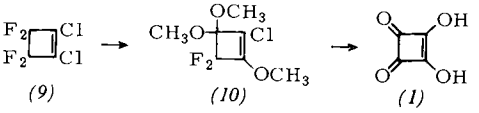
## 3. Syntheses of Squaric Acid

*Cohen et al.* [1] prepared squaric acid from chlorotrifluoroethylene *(6)*, which dimerizes on dechlorination with zinc to perfluorocyclobutene *(7)*. This is then converted into 1,2-diethoxytetrafluorocyclobutene *(8)*, which is finally hydrolysed with strong acid.



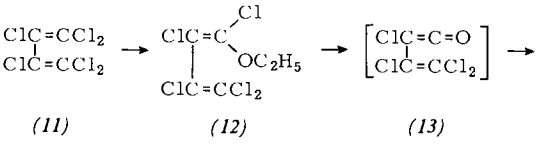
*(6)* *(7)* *(8)* *(1)*

It is more easily prepared [5,6] from the commercially available 1,2-dichlorotetrafluorocyclobutene *(9)*, which reacts with methanol to form 1-chloro-3,3-difluoro-2,4,4-trimethoxycyclobutene *(10)*. Treatment of *(10)* with hydrochloric acid leads to good yields of squaric acid.

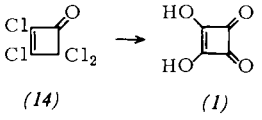


*(9)* *(10)* *(1)*

Other elegant syntheses are based on hexachlorobutadiene *(11)*, which is formed as an undesirable by-product in the manufacture of perchlorinated hydrocarbons or can be prepared by high-temperature chlorination of $C_4$ hydrocarbons [7]. Compound *(11)* generally is inert [8], but nucleophilic substitutions proceed relatively smoothly. Thus *Roedig* and *Bernemann* prepared 1-ethoxypentachloro-1,3-butadiene *(12)* from *(11)* [9]. Compound *(12)* can be thermally and catalytically cyclized, with elimination of ethyl chloride, to perchlorocyclobutenone *(14)*, probably *via* perchlorovinylketene *(13)* [10].



*(11)* *(12)* *(13)*

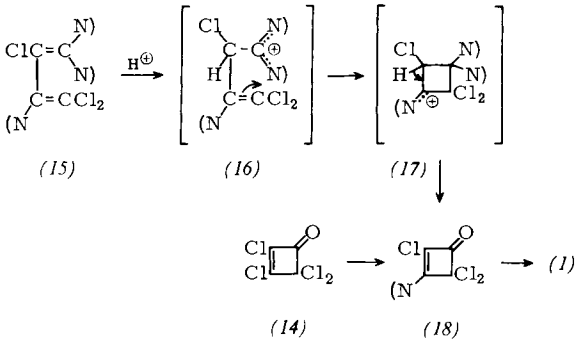


*(14)* *(1)*

Compound *(14)* is hydrolysed in neutral and alkaline media, mainly with simultaneous ring cleavage, whereas high yields of squaric acid can be obtained in acidic media. Compound *(14)* is also used in the preparation of reactive squaric acid derivatives (see Section 5).

Trichlorotrimorpholinobutadiene *(15)*, which can be prepared by the reaction of hexachlorobutadiene with an excess of morpholine [11], also can be used to prepare *(14)*.

When *(15)* is subjected to prolonged treatment with water at pH 5 to 7 at 55 °C, 3-morpholinotrichlorocyclobutenone *(18)* is formed; the structure of *(18)* was proved by the fact that perchlorocyclobutenone *(14)*, as a vinylogous acyl chloride, gives the same product with morpholine. As a vinylogous amide, *(18)* can be readily hydrolysed with acids to form squaric acid *(1)*.



*(15)* *(16)* *(17)* *(14)* *(18)*

N) denotes morpholino

The constitution of the trichlorotrimorpholinobutadiene *(15)* has not been definitely established, but the formation of 3-morpholinotrichloro-1-cyclobutenone *(18)* suggests that the arrangement of the morpholino groups is as shown. It can be seen that a proton can readily become attached to the ketene aminal to form a resonance-stabilized carbenium-imonium ion *(16)*, which can undergo ring closure to form another stabilized ion *(17)* and thence *(18)*.

[7] *L. M. Kogan*, Russ. chem. Reviews (transl. of Usp. Chim.) *33*, 176 (1964); Chem. Zbl. 39-0879, *1965*.

[8] *O. Fruhwirth*, Ber. dtsch. chem. Ges. *74*, 1700 (1941).

[9] *A. Roedig* and *P. Bernemann*, Liebigs Ann. Chem. *600*, 1 (1956).

[10] *G. Maahs*, Liebigs Ann. Chem. *686*, 55 (1965).

[11] *P. Hegenberg* and *G. Maahs*, unpublished.

The preparation of squaric acid from hexachlorobutadiene by the route *(11)* → *(15)* → *(18)* → *(1)* can be carried out in a single step, without isolation of *(15)* and *(18)*; squaric acid is obtained in yields of up to 40 % based on hexachlorobutadiene. This process is therefore of interest for synthesis on the industrial or semi-industrial scale [11].

The tendency of the hexachlorobutadiene derivatives to undergo cyclization is in agreement with the general experience that the formation of four-membered rings is promoted by the introduction of fluorine or chlorine into a conjugated diene [12]. Thus perfluorocyclobutene *(7)* can be prepared in an equilibrium reaction at high temperatures from hexafluorobutadiene [13], the cyclic structure, according to *Haszeldine*, being the thermodynamically more stable one [14].

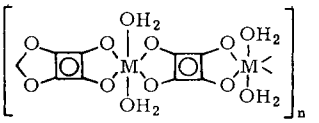
Hexachlorobutadiene itself shows a certain tendency towards ring formation, but in this case the open-chain structure is strongly favored. Hexachlorobutadiene that has been stored is found by IR analysis to contain 1–5 % (depending on the time of storage) of a product that is probably hexachlorocyclobutene *(19)* and which can be concentrated to *ca.* 20 % by vacuum fractionation and low-temperature crystallization. At higher temperatures, *e.g.* on distillation (b.p. 215 °C), *(19)* is reconverted into *(11)*.

*(11)* *(19)*

A fraction of probable structure *(19)* and mass-spectrometric formula $C_4Cl_6$ was isolated by gas chromatography. The infrared spectrum did not contain the characteristic bands at 6.20 and 6.37 μ corresponding to the conjugated double bond of hexachlorobutadiene. On the other hand, it did contain a band at 6.11 μ, suggesting the presence of an isolated double bond. [Other absorption bands of *(19)*: 8.42, 11.1, 12.9, 14.90 μ]. Whereas the ultraviolet spectrum of *(11)* contains a broad absorption due to conjugation, that of *(19)* does not absorb up to 210 mμ [15].

## 4. Reactions of Squaric Acid

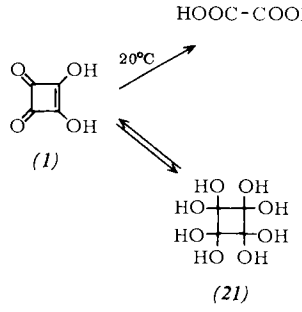
With univalent metals, *e.g.* potassium, squaric acid forms salts which are readily soluble in water, whereas the squarates (cyclobutenedionediolates) of bivalent and tervalent metals are insoluble. The salts of bivalent metals occur as dihydrates, those of tervalent metals as trihydrates. X-ray structure analysis showed that the salts of bivalent Mn, Fe, Co, Ni, Mg, and Zn have the same structure, small differences due to the different radii of the metal ions being observed only in the lattice parameters. *West* postulated a chain structure *(20)* for the salts of the general formula $M^{II}C_4O_4 \cdot 2H_4O$ [16]. The structure of the squarates of tervalent metals, $M^{III}(OH)C_4O_4 \cdot 3H_2O$, has not yet been established.



*(20)*

M = bivalent metal

With oxidizing agents, *e.g.* $HNO_3$ or $Br_2$, at room temperature, squaric acid undergoes oxidative ring cleavage to oxalic acid and carbon dioxide.



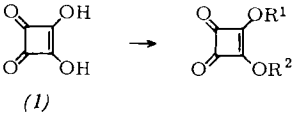
*(1)* *(21)*

Under mild conditions (0 °C, $HNO_3$ or $Br_2$), the four-membered ring remains intact [6], and the product obtained is cyclobutaneoctol *(21)*, the tetrahydrate of cyclobutanetetrone. On reduction with $SO_2$, *(21)* is converted into squaric acid.

Squaric acid reacts with acetic anhydride to form the strongly hygroscopic diacetoxycyclobutenedione *(22)*, which forms colorless crystals on sublimation in high vacuum [17]. This mixed anhydride is immediately decomposed by atmospheric moisture. Alcohols give acetates and free squaric acid, ammonia gives acetamide and diammonium squarate.

## 5. Esters and Amides of Squaric Acid

The diethyl *(23)* [11] and dibutyl *(24)* [10] esters can be prepared easily by the reaction of the acid with an excess of alcohol.



*(1)*

*(22)*, $R^1 = R^2 = COCH_3$
*(23)*, $R^1 = R^2 = C_2H_5$
*(24)*, $R^1 = R^2 = C_4H_9$
*(25)*, $R^1 = R^2 = CH_3$
*(26)*, $R^1 = H$; $R^2 = CH_3$

Dimethyl squarate *(25)* was recently synthesized [18] both by the action of diazomethane on *(1)* and by the reaction of the silver salt with methyl iodide. Transesterification of *(25)* with ethanol yields *(23)*. When squaric acid is heated with excess methanol it forms, not *(25)*, but the half-ester *(26)*, which has also been detected during the hydrolysis of *(25)* [18].

Dibutyl squarate *(24)* can also be prepared from perchlorocyclobutenone *(14)* [10, 19]. Depending on the temperature, the reaction of equimolar amounts of *(14)* and butanol leads either to substitution of a Cl atom and formation of 3-butoxytrichlorocyclobuten-1-one *(27)* or to ring cleavage to butyl

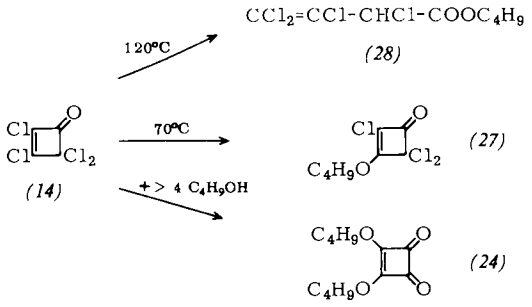
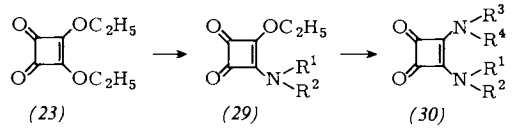
2,3,4,4-tetrachlorovinylacetate *(28)* (or butyl 3,4,4,4-tetrachlorocrotonate). At the boiling point and with a large excess of butanol, dibutyl squarate *(24)* is formed.



Other esters can be synthesized *via* squaryl chloride (see Section 6).

The alkoxy derivatives mentioned exhioit ester properties. They can be hydrolysed with water or alkali to squaric acid.

The diesters react readily with amines to give squaramides [11,18,20]. Equimolar amounts of amine give ester amides of squaric acid, such as *(29)*; excess of amine gives the diamides of squaric acid *(30)*.



Mixed diamides of squaric acid can also be prepared by reaction of the ester amides with other amines. Some examples are listed in Table 1.

Table 1. Examples of ethyl ester amides *(29)* and diamides *(30)* of squaric acid [11,20].

| $R^1$ | $R^2$ | $R^3$ | $R^4$ | *(29)* M.p. (°C) | *(29)* Yield (%) | *(30)* M.p. (°C) | *(30)* Yield (%) |

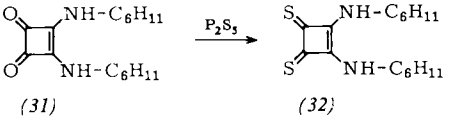
The methyl ester amide and the diamide of squaric acid have recently been described [18].

The ethyl ester amide can be hydrolysed to the monoamide [11].

Thio-analogues of squaramides are obtained by reaction of amides such as *N,N'*-dicyclohexylsquaramide *(31)*

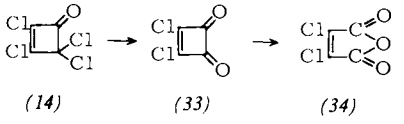


[20] *G. Maahs* and *P. Hegenberg*, German Pat. Appl. C 36340 IVb/120 (July 9th, 1965); Chemische Werke Hüls.

with phosphorus pentasulfide, the product in this case being bis(cyclohexylamino)cyclobutenedithione *(32)* [11].

## 6. Squaryl Dichloride

The dichloride of squaric acid, dichlorocyclobutenedione *(33)*, cannot be prepared from squaric acid. It is formed in the reaction of perchlorocyclobutenone *(14)* with oleum or $SO_3$ ($B_2O_3$ or $SbCl_5$ as catalyst) by the replacement of the geminal chlorine atoms with oxygen [10], a reaction that has already been used for the preparation of other cyclic ketones [21].

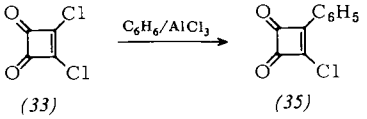


With excess of $SO_3$ at high temperatures *(33)* is oxidized to dichloromaleic anhydride *(34)*.

Compound *(33)* exhibits the typical properties of an acyl chloride. It is readily hydrolysed by water to squaric acid. It reacts with alcohols, *e.g.* with ethanol to give diethyl squarate *(23)*. Di-n-propyl squarate, which cannot be obtained directly from squaric acid, can also be prepared in this way [11].

Under Friedel-Crafts conditions (catalytic amounts of $AlCl_3$) in benzene, *(33)* can be converted into 1-chloro-2-phenylcyclobutenedione *(35)* [11], which also has been prepared from phenylcyclobutenedione [22].

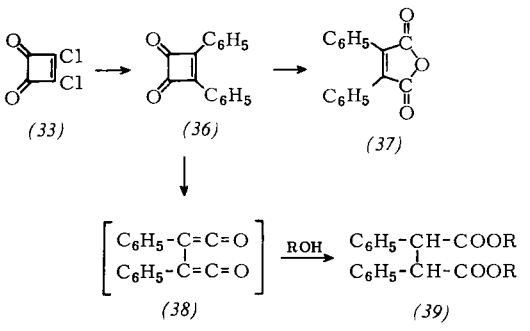
As a vinylogous acyl chloride, *(35)* can be converted into the known compounds 1-hydroxy-, 1-methoxy-, and 1-amino-2-phenylcyclobutenedione, which also exhibit the properties of an acid, an ester, and an amide, respectively [22].



[21] *A. Roedig* and *G. Märkl*, Liebigs Ann. Chem. *636*, 1 (1960).

[22] *E. J. Smutny*, *M. C. Caserio*, and *J. D. Roberts*, J. Amer. chem. Soc. *82*, 1793 (1960).

With stoichiometric amounts of $AlCl_3$ in benzene, *(33)* forms diphenylcyclobutenedione *(36)*[11], which has also been prepared by the hydrolysis of 1,2-diphenyl-3,3,4,4-tetrafluorocyclobutene[23].



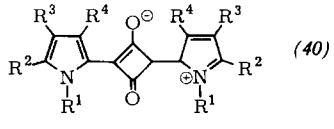
*(33)* *(36)* *(37)* *(38)* *(39)*

Compound *(36)* is very reactive, bright yellow, and crystallizes well. Mild oxidation with $H_2O_2$ yields diphenylmaleic anhydride *(37)*, while degradation to benzoic acid occurs under more vigorous conditions. The reaction of *(36)* with alcohols leads to ring cleavage; it probably proceeds *via* bis(phenylketene) *(38)*, which adds alcohol to form the 2,3-diphenylsuccinate *(39)*[23].

## 7. Condensations

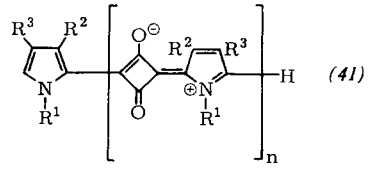
Cyclotrimethine dyes in which the cyclobutene ring is substituted in positions 1 and 3 are obtained from squaric acid itself, while esters of squaric acid in the presence of bases give disubstituted 1,2-cyclobutenediones.

The reaction of activated pyrroles with squaric acid in acetic acid leads to red-violet cyclotrimethine dyes of general formula *(40)*[24]. The pyrrole derivative used



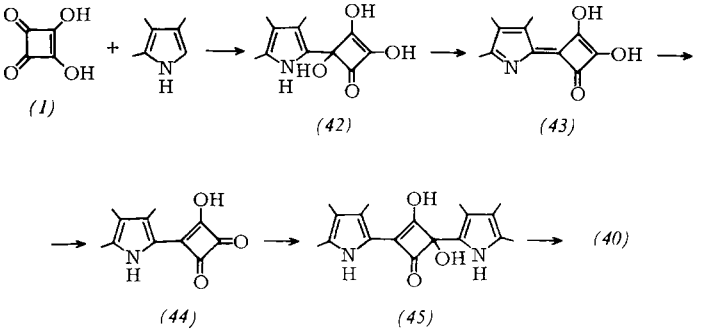
*(40)*

must be unsubstituted in position 2 and substituted in position 5. If positions 2 and 5 are both occupied, *e.g.* by alkyl groups, no reaction occurs. If, on the other hand, both positions are unoccupied, mixtures of readily variable blue to blue-green dyes, to which *Treib* and *Jakob* assign a polymeric structure *(41)*[17], are obtained.



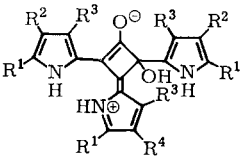
*(41)*

The reaction of pyrroles with squaric acid to form the dye *(40)* is thought to proceed *via* the intermediates *(42)–(45)*.



*(1)* *(42)* *(43)* *(44)* *(45)* *(40)*

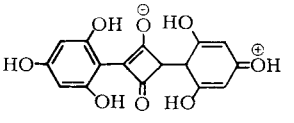
A further pyrrole group may be introduced to form compounds of structure *(46)*.



*(46)*

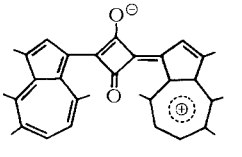
Indole condenses with squaric acid to form indole dyes having the same basic structure as *(40)*, but with the linkage in the indole 3-position.

Phenols have also been used as condensation components, but only the most active of these, *e.g.* phloroglucinol, react with formation of compounds *(47)* which are fundamentally similar to *(40)*.



*(47)*

*Sprenger* and *Ziegenbein* readily obtained condensation products of squaric acid with dialkylaniline. These authors used a butanol/benzene mixture instead of acetic acid as the solvent, and the water formed was removed by azeotropic distillation. The condensation could involve preliminary activation of the squaric acid by the formation of monobutyl squarate. Other interesting condensations have been obtained with azulenes, which give blue to green dyes having the structure *(48)*[25].



*(48)*

In contrast to these condensations, which lead to 1,3-derivatives of cyclobutene, squaric acid esters generally react with compounds containing active methylene groups, *e.g.* *N*-ethyl-2- or -4-methylpyridinium salts or *N*-ethyl-2-methylbenzothiazolium and -benzeneselen-

[23] *A. T. Blomquist* and *E. A. La Lancette*, J. Amer. chem. Soc. *83*, 1387 (1961); *84*, 220 (1962).

## Oxidation of Sulfoxides with Hydroperoxides

By Dr. L. Kuhnen

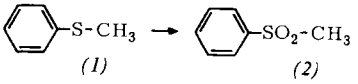
Forschungslaboratorien, Chemische Werke Hüls AG., Marl (Germany)

*Dedicated to Professor F. Broich on his 60th birthday*

Organic hydroperoxides oxidize sulfides to sulfoxides. Addition of excess of oxidizing agent does not lead to the formation of sulfones [1].

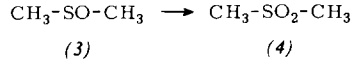
However, sulfides and sulfoxides can be oxidized by equimolar amounts of organic hydroperoxides in the presence of vanadium, molybdenum, or titanium compounds to sulfones in almost quantitative yields. The sulfides and sulfoxides – dissolved if convenient in benzene, ethyl acetate or ethanol – are mixed with the catalyst and heated to 50–70 °C, the organic hydroperoxide being then added slowly. The reaction, which is sometimes strongly exothermic, is complete as soon as only traces of peroxide can be detected with potassium iodide in the reaction mixture. The sulfones are then isolated by crystallization or distillation.

For example, oxidation of thioanisole *(1)* in benzene with t-butyl hydroperoxide in the presence of molybdenyl acetylacetonate produces methyl phenyl sulfone *(2)* in 98 % yield.



*(1)* *(2)*

Oxidation of dimethyl sulfoxide *(3)* with cumyl α-hydroperoxide in the presence of vanadium pentoxide gives dimethyl sulfone *(4)* in 91 % yield.



*(3)* *(4)*

Unsaturated sulfides such as allyl n-butyl sulfide or diallyl sulfide can be oxidized selectively to unsaturated sulfones.

In contrast to conventional oxidation procedures, these reactions proceed without the presence or formation of water or carboxylic acids.

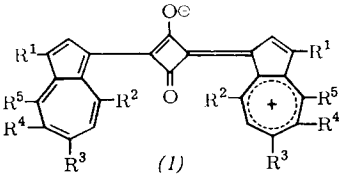
## Condensation Products of Squaric Acid and Azulenic Hydrocarbons

By Dr. W. Ziegenbein and Dr. H.-E. Sprenger

Forschungslaboratorien der Chemische Werke Hüls AG., Marl (Germany)

*Dedicated to Professor F. Broich on his 60th birthday*

On reaction of squaric acid (1,2-dihydroxycyclobutenedione) in, *e.g.*, butanol, with azulene or a homologue thereof [1] there is surprisingly smooth formation of condensation products, to which we assign the limiting structure *(1)* on the basis of elemental analysis and spectroscopic results [2] and in analogy with the products synthesized from squaric acid with pyrroles, resorcinol, and phloroglucinol [3].



*(1)*

*(a)*: $R^1 = R^2 = R^3 = R^4 = R^5 = H$
decomp. >240 °C

*(b)*: $R^1 = R^2 = CH_3$; $R^4 = (CH_3)_2CH$; $R^3 = R^5 = H$
decomp. >245 °C

*(c)*: $R^1 = R^4 = H$; $R^2 = R^3 = R^5 = CH_3$
does not melt below 350 °C

Compounds *(1a)–(1c)* are precipitated as sparingly soluble crystals with a green metallic luster. Their solutions in dimethylformamide are intensely blue to green.

*Preparation of 4-(1-azuleniumylidene)-2-(1-azulenyl)-3-oxo-1-cyclobutenolate (1a)*

A mixture of 1.92 g (0.015 mole) of azulene, 0.86 g (0.007 mole) of squaric acid, 60 ml of butanol, and 40 ml of benzene is refluxed for 5–7 hr with continuous removal of the water formed. After evaporation to one-third of the original volume the crystals that separate are filtered off and washed with methanol and light petroleum. Drying then affords 2.25 g (90 %) of material, which is purified by dissolution in hot benzonitrile and precipitation with ether; $\lambda_{max}$ = 680 mμ (ε = 110000), 460 (3440), 394 (7560), 366 (9500), 311 (17200), 284 (18500) (in chloroform).

Compounds *(1b)* and *(1c)* are obtained analogously. The last-mentioned can be purified by dissolution in warm,

concentrated sulfuric acid and precipitation with ethanol. *(1b)*: $\lambda_{max}$ = 770 mμ (ε = 132000), 440 (10400), 384 (7780), 316 (16400) (chloroform);

*(1c)*: $\lambda_{max}$ = *720*, 465, 405, 380, 316, 262 mμ (chloroform).

## Condensation Products of Squaric Acid and Tertiary Aromatic Amines

By Dr. H.-E. Sprenger and Dr. W. Ziegenbein

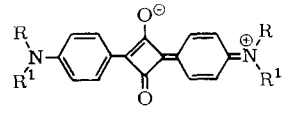
Forschungslaboratorien der Chemische Werke Hüls AG, Marl (Germany)

*Dedicated to Professor F. Broich on his 60th birthday*

Reaction of squaric acid (dihydroxycyclobutenedione) with phenols (resorcinol, phloroglucinol) and reactive pyrroles affords deeply colored condensation products to which respectively a *p*-quinonoid and a betaine structure[1] have been ascribed.

We have found that tertiary aromatic amines also condense smoothly as nucleophilic reagents with squaric acid, intensely blue to green, high-melting products being formed to which we assign the polar structures *(1a)* to *(1d)* on the basis of elemental analysis and spectroscopic findings[2] and in analogy with the condensation products from squaric acid and pyrroles. Structures *(1a)* to *(1d)* are to be regarded as limiting formulae.

The products are very slightly soluble in alcohol or ether, more soluble in dimethylformamide and dimethyl sulfoxide.



| | R | $R^1$ | M.p. [°C] |
|---|---|---|---|
| *(1a)* | $-CH_3$ | $-CH_3$ | 276 |
| *(1b)* | $-(CH_2)_2OH$ | $-(CH_2)_2OH$ | decomp. >230 |
| *(1c)* | $-CH_2-C_6H_5$ | $-CH_2-C_6H_5$ | 274–276 (decomp.) |
| *(1d)* | $-(CH_2)_2-O-(CH_2)_2-$ | | decomp. >250 |

*Preparation of 2-(p-dimethylaminophenyl)-4-(dimethylimonio-2,5-cyclohexadienylidene)-3-oxo-1-cyclobutenolate (1a)*

11.4 g (100 mmoles) of squaric acid and 24.2 g (200 mmoles) of *N,N*-dimethylaniline are heated with 150 ml of 1-butanol and 60 ml of benzene under reflux until a total of 3.6 ml of water has distilled off azeotropically. The mixture becomes deep blue. After cooling to 20 °C the condensation product, which is precipitated as small blue crystals, is filtered off and washed several times with light petroleum (boiling range 35–45 °C); yield 9.2 g (60 %); $\lambda_{max}$ = *628*, 414, 389, 366, 306, *263* mμ (chloroform).

Compounds *(1b)–(1d)* can be prepared analogously. Compound *(1d)* can be recrystallized from ethylene glycol.

*(1b)*, principal absorption band: 640 mμ (methanol)

*(1c)*, $\lambda_{max}$ = *624*, 417, 387, 367, 306, *261* mμ (chloroform)

*(1d)*, principal absorption band: 621 mμ (methanol).

## Addition of Epoxides to 2-Imidazolines

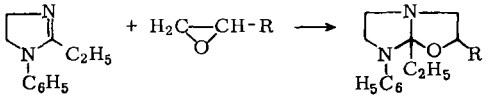
By Dr. R. Feinauer

Forschungslaboratorien, Chemische Werke Hüls AG., Marl (Germany)

*Dedicated to Professor F. Broich on his 60th birthday*

Epoxides react with cyclic imidoic esters with formation of dioxaazabicycloalkanes[1]. Addition of epoxides to cyclic thioimidoyl esters takes place similarly; in the case of 2-thiazolines, however, a subsequent reaction leads to 2,5-disubstituted 2-oxazolines[2].

We have studied the reaction of epoxides with cyclic amidines and have found that 4-oxa-1,6-diazabicyclo[3.3.0]octanes *(2)* are formed smoothly from epoxides and 1-phenyl-2-imidazolines *(1)*.



*(1)* *(2)*

| R | Reaction temp. (°C) | Reaction time (hr) | Yield of *(2)* (%) | B.p. of *(2)* (°C) | B.p. of *(2)* (mm Hg) | $n_D^{20}$ |
|---|---|---|---|---|---|---|
| H | 140 | 7 | 18 | 107–108 | 0.2 | 1.5615 |
| $CH_3$ | 125 | 6 | 79 | 114–115 | 0.4 | 1.5519 |
| $C_6H_5$ | 150 | 5 | 92 | 171–172 | 0.2 | 1.5920 |
| $C_6H_5OCH_2$ | 150 | 6 | 86 | 174–176 | 0.05 | 1.5800 |
| Allyl-$OCH_2$ | 150 | 5 | 85 | 135–136 | 0.05 | 1.5428 |
| Lauryl-$OCH_2$ | 150 | 5 | 66 | 212–213 | 0.1 | 1.5071 |

The components are heated without a solvent to the temperatures given in the table, and the 4-oxa-1,6-diazabicyclo-[3.3.0]octanes formed are isolated by distillation. Cyclic carbonates of 1,2-diols may be used instead of the epoxides, since under the reaction conditions they lose $CO_2$ and are converted into epoxides. The products are viscous, usually yellow oils that are readily hydrolysed by aqueous acids or aqueous alkali. Their structures were proved by elemental analyses, IR spectra, and degradative reactions.

## Synthesis of $\Delta^2$-Oxazolines by Reaction of Epoxides with $\Delta^2$-Thiazolines

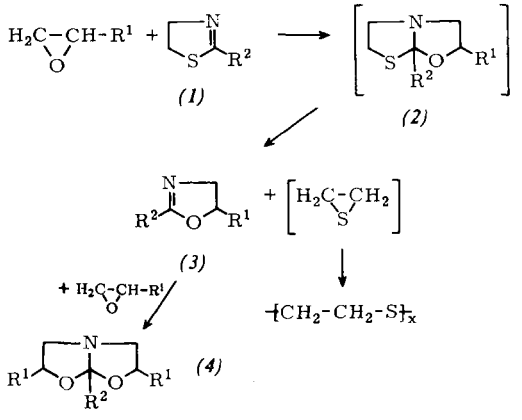
By Dr. R. Feinauer

Forschungslaboratorien der Chemische Werke Hüls AG, Marl (Germany)

*Dedicated to Professor F. Broich on his 60th birthday*

Epoxides add to 2-oxazolines with formation of 4,6-dioxa-1-azabicyclo[3.3.0]octanes *(4)*[1]. However, by reaction of epoxides with 2-thiazolines *(1)* we obtained 2,5-disubsti-

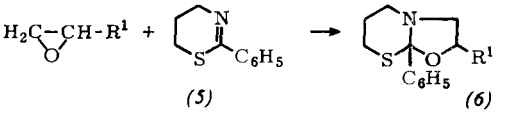
tuted 2-oxazolines *(3)* and products of their reaction with the excess of epoxide. We assume that the 1:1 addition products *(2)* are first formed and that these are then converted into the 2,5-disubstituted 2-oxazolines *(3)* by loss of ethylene sulfide (thiirane) (or its polymers). Depending on the reaction time and the amount of epoxide these products *(3)* may react further to give 4,6-dioxa-1-azabicyclo[3.3.0]octanes *(4)*.



| $R^1$ | $R^2$ | *(3)*, M.p. (°C) B.p. (°C/mm Hg) | $n_D^{20}$ | Yield (%) |
|---|---|---|---|---|
| $CH_2-O-C_6H_5$ | $CH_3$ | 60 | | 26.2 |
| $CH_2-O-C_6H_5$ | $C_2H_5$ | 39–40 | | 29.3 |
| $CH_2-O-C_6H_5$ | $C_3H_7$ | 47–48 | | 27 |
| $CH_2-O-C_6H_5$ | $C_6H_5$ | 75–77 | | 19.8 |
| $CH_2-O-CH_2-CH=CH_2$ | $CH_3$ | 56–58/0.2 | 1.4651 | 21.0 [a] |
| $CH_2-O-CH_2-CH=CH_2$ | $C_3H_7$ | 57–58/0.05 | 1.4663 | 10.4 |
| $CH_2-O-C_{12}H_{25}$ | $CH_3$ | 154–160/0.15 | 1.4539 | 8.8 |
| $C_6H_5$ | $C_2H_5$ | 77–80/0.07 | 1.5364 | 22.9 |

[a] This reaction gave also a 22.3 % yield (calculated on epoxide) of compound *(4)*, b.p. 126–127 °C/0.3 mm Hg, $n_D^{20}$ = 1.4768.

However, reaction of 5,6-dihydro-2-phenyl-4*H*-1,3-thiazine *(5)* with epoxides proceeded no further than the 1:1 adduct *(6)*, as did the reaction of the corresponding 1,3-oxazine[1].



*(6a)*, $R^1$ = $CH_2-O-C_6H_5$, m.p. 133–134 °C, yield 25.4 %

*(6b)*, $R^1$ = $CH_2-O-CH_2-CH=CH_2$, b.p. 133–134 °C/0.02 mm Hg, $n_D^{20}$ = 1.5786, yield 28.8 %

The reactions described above were carried out by heating the components at 140 to 150 °C. The products could be isolated by distillation of the reaction mixture. The structures of the products were proved by elemental analysis, molecular-weight determination, and IR spectra.

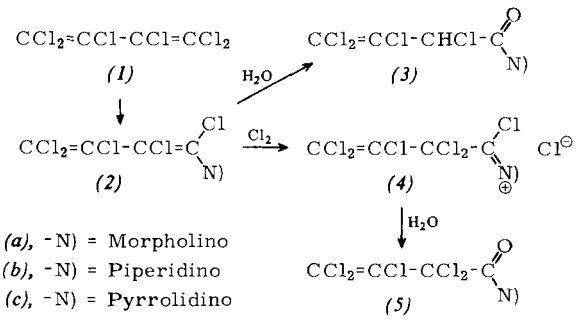
## Synthesis and Reactions of Perchlorodienamines

By Dr. P. Hegenberg and Dr. G. Maahs

Forschungslaboratorien, Chemische Werke Hüls AG., Marl (Germany)

*Dedicated to Professor F. Broich on his 60th birthday*

In the series of perchlorinated enamines only the derivative from perchloroethylene is known[1], and no perhalogenated dienamine has been previously described. Such syntheses have now been achieved by replacement reactions of perchlorobutadiene *(1)* with cyclic secondary amines. The components are mixed in the molar ratio *(1)*: amine = 1:2, without a solvent, and are then distilled. In this way we isolated 4-(pentachloro-1,3-butadienyl)morpholine *(2a)* (66 %), b.p. 110–140 °C/0.7–2 mm (decomp.), $n_D^{20}$ = 1.5727, and 1-(pentachloro-1,3-butadienyl)piperidine *(2b)* (64 %), b.p. 125–129 °C/0.01 mm (decomp.), $n_D^{20}$ = 1.5700.



*(a)*, -N) = Morpholino
*(b)*, -N) = Piperidino
*(c)*, -N) = Pyrrolidino

Compound *(2a)* reacts readily with water, yielding 4-(2,3,4,4-tetrachloro-3-butenoyl)morpholine *(3a)* (97 %, m.p. 91 to 93 °C); however, the analogue *(2b)* is stable to water, although formic acid converts it smoothly into 1-(2,3,4,4-tetrachloro-3-butenoyl)piperidine (90 %, m.p. 94–96 °C).

The perchlorodienamine formed from hexachlorobutadiene and pyrrolidine cannot be isolated by distillation; if the reaction mixture is treated with water it yields 1-(2,3,4,4-tetrachloro-3-butenoyl)pyrrolidine *(3c)* (76 %, m.p. 106 °C). In inert solvents (*e.g.* perchlorinated hydrocarbons, petroleum ether), compound *(2a)* readily adds chlorine, with formation of 4-(hexachloro-3-butenylidene)morpholinium chloride *(4a)* [73 %, m.p. 81–83 ° (decomp.)], which is very sensitive to moisture, being smoothly hydrolysed by water to (4-(pentachloro-3-butenoyl)morpholine *(5a)* (92 %, m.p. 128 to 131 °C)[2]. The product *(4a)* is the first unsaturated perhalogenated amide chloride.

## Alkyl Perchlorobutadienyl Sulfides and their Reactions

By Dr. G. Maahs and Dr. P. Hegenberg

Forschungslaboratorien, Chemische Werke Hüls AG., Marl (Germany)

*Dedicated to Professor F. Broich on his 60th birthday*

Many attempts have been made[2] to find a use for hexachlorobutadiene *(1)*, which is a by-product of the large-scale manufacture of chlorinated hydrocarbons but is relatively inert[1]. Its reactions with alkoxides are rather unsatisfactory[3]. We have now found that it undergoes replacement reactions considerably more smoothly with thiolates. In boiling ethanolic solution equimolar amounts of *(1)*, a thiol, and 50 % NaOH afford high yields of alkyl perchlorobutadienyl sulfides *(2)*, together with disulfides *(3)* whose structures have not been determined unequivocally.

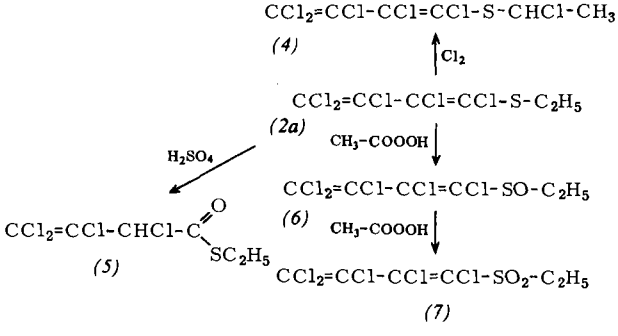
The sulfides *(2a)–(2f)* are much more inert than the corresponding ethers: *e.g.* perchlorocyclobutenethione could not be obtained from compound *(2)* in analogy with the catalytic thermolysis of ethyl pentachloro-1,3-butadienyl ether to perchlorocyclobutenone[4].

$$CCl_2{=}CCl\text{-}CCl{=}CCl_2 \xrightarrow[NaOH]{+\,RSH} CCl_2{=}CCl\text{-}CCl{=}CCl\text{-}SR$$
*(1)* *(2)*

$$+\ C_4Cl_4(SR)_2$$
*(3)*

| R | | Conversion of *(1)* (%) | Yield (%) | B.p. (°C/mm Hg) | $n_D^{20}$ |
|---|---|---|---|---|---|
| $-C_2H_5$ | *(2a)* | 97.5 | 70 | 92–93/0.8 | 1.5835 |
| | *(3a)* | | 18 | 116/0.5 | 1.5941 |
| $-C_4H_9$ | *(2b)* | 74 | 76 | 130/2 | 1.5640 |
| | *(3b)* | | 11 | 155/1 | 1.5645 |
| $-C_6H_5$ | *(2c)* | 70 | 59 | 125–126/0.3 | 1.6296 |
| | *(3c)* | | 11 | 190–200/0.4 | 1.6630 |
| $-CH_2-CHOH-CH_2OH$ | *(2d)* | 78 | 71 | m.p. 87–88 | – |
| | *(3d)* | | 18 | – | – |
| $-CH_2-CH_2OH$ | *(2e)* | 75 | 58 | 155/3 | 1.6004 |
| $-CH_2-COOC_2H_5$ | *(2f)* | 83 | 27 | 135–139/1 | 1.5624 |

Chlorination (at room temperature without solvent) of compound *(2a)* does not, like that of ethyl pentachloro-1,3-butadienyl ether, cause ether fission with formation of an acid chloride[3], but instead leads to α-chloroethyl pentachloro-1,3-butadienyl sulfide *(4)* (84 %, b.p. 119 °C/2.2 mm, $n_D^{20} = 1.5835$).



Reaction of the compound *(2a)* with sulfuric acid [conc. $H_2SO_4$: glacial acetic acid: *(1)* = 3.5:1.5:0.5; 60 °C; 45 hr] occurs with formation of *S*-ethyl 2,3,4,4-tetrachloro-3-butenethioate *(5)* (61 %, b.p. 92 °C/1 mm, $n_D^{20} = 1.5350$).

Oxidation of *(2a)* with 60 % peracetic acid leads to ethyl pentachloro-1,3-butadienyl sulfoxide *(6)* (83 %, m.p. 39 to 41 °C), from which the corresponding sulfone *(7)* (89 %, m.p. 43–45 °C) is obtained on further oxidation with peracetic acid.

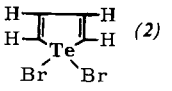
## Synthesis of Tellurophene and its 2,5-Disubstituted Derivatives

By Dr. W. Mack

Consortium für electrochemische Industrie GmbH., München (Germany)

The ring system of tellurophene has so far been encountered only in the form of its tetraphenyl[1] and tetrachloro[2] derivatives. Attempts to prepare the parent compound were unsuccessful[3]. A method of broad scope for the preparation of tellurophene and its 2,5-disubstituted derivatives has now been found in the reaction of sodium telluride and diacetylenes.

$$R\text{-}C{\equiv}C\text{-}C{\equiv}C\text{-}R + Na_2Te \xrightarrow[CH_3OH]{20\,°C}$$



*(1)*, R: -H
*(3)*, R: $-CH_2OH$
*(4)*, R: $-C(CH_3)_2OH$

*(2)*

A solution of sodium telluride in methanol is treated with an equivalent quantity of the diacetylene. The reaction is complete when the violet color of the telluride has disappeared. The majority of the methanol is distilled off and a little water is added to the residue. The tellurophene is then extracted with ether and purified by distillation or recrystallization after evaporation of the ether from the extract.

Tellurophene *(1)* is obtained in this way in 69 % yield as a pale yellow liquid with a faint odor, b.p. 148 °C/714 mm, m.p. *ca.* −36 °C, $n_D^{20} = 1.6856$, $d_4^{22} = 2.13$.

The positions of the NMR multiplets[4] at 7.83 (protons on C-3 and C-4) and 8.94 ppm (protons on C-2 and C-5) indicate that *(1)* must have marked aromaticity. The infrared spectrum of *(1)* shows peaks at 3080 (m), 3030 (m), 1425 (s), 1310 (m), 1240 (s), 1220 (s), 1100 (m), 975 (m), 785 (m), and 665(s) $cm^{-1}$. In cyclohexane, *(1)* has $\lambda_{max}$ at 280 mμ (log ε = 3.62). Its mass spectrum contains the parent peak at m/e = 182 (relative intensity = 0.33) expected for $^{12}C_4{}^1H_4{}^{130}Te$. Other signals of high intensity are due to Te and $C_4$ fragments. Cryoscopic molecular-weight determinations indicate that the compound occurs in the form of its dimer in benzene.

A solution of bromine in methanol reacts with *(1)* to give an orange, insoluble precipitate of *(2)*, m.p. 125 °C (decomp.). Aqueous $HSO_3^-$ reduces *(2)* back to *(1)*.

2,5-Bis(hydroxymethyl)tellurophene *(3)* is obtained analogously in 25 % yield as water-soluble crystals, m.p. 107 °C. Its NMR signals occur at 7.43 (protons on C-3 and C-4), 4.85 (methylene protons), and 2.16 ppm (hydroxyl protons).

2,5-Bis(dimethylhydroxymethyl)tellurophene *(4)* is obtained in almost quantitative yield as colorless crystals, m.p. 94 °C, soluble in hot water. Its NMR signals occur at 7.29 (protons on C-3 and C-4), 1.63 (methyl protons), and 2.74 ppm (hydroxyl protons).

Both *(3)* and *(4)* have the molecular weights of the monomeric forms in benzene.

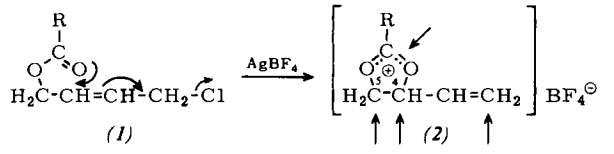
## 4-Vinyl-1,3-dioxolanylium Salts

By Dr. S. Kabuss

Chemisches Laboratorium, Universität Freiburg (Germany)

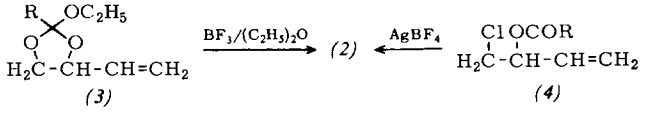
4-Chloro-2-butenyl carboxylates *(1)* react with $AgBF_4$ in nitromethane to yield 4-vinyl-1,3-dioxolanylium salts with allyl rearrangement and participation of the acyloxy group as a vinylogous neighboring group; *cis*- and *trans*-isomers of the esters *(1)* give the same cations *(2)*, as expected[1].

NMR spectra (in nitromethane, TMS as internal standard) of *(2)* include bands at $\tau$ = 3.5–5.0 (unseparated multiplet due to the ring protons at C-4 and C-5 and the vinyl protons), as well as for *(2)*, R = $CH_3$ (obtained as an oil; stable for only a few days) $\tau$ = 7.6 ($CH_3$ protons) and for *(2)*, R = $C_6H_5$ (m.p. 65–72 °C) $\tau$ = 1.5–2.5 (broad multiplet due to phenyl protons).



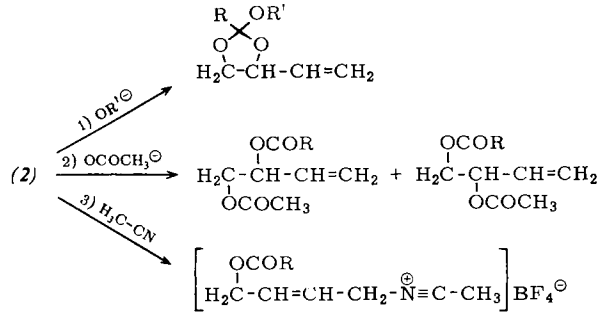
*(1)* *(2)*

The same cations *(2)* are obtained by *Meerwein*'s methods [2], namely, by the action of the $BF_3$-ether adduct on 2-alkoxy-4-vinyldioxolanes *(3)*, or by treatment of 1-(chloromethyl)-allyl esters *(4)* with $AgBF_4$.



*(3)* *(4)*

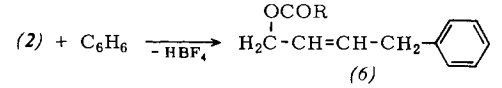
The vinyldioxolanylium ions *(2)* are ambident cations [3] with four different reactive centers [see arrows in formula *(2)*], which react 1) by addition with retention of the ring structure, 2) by alkylation with ring fission, or 3) by alkylation with allylic shift and ring fission, according to the nucleophilicity of the reagent:



*(5)*

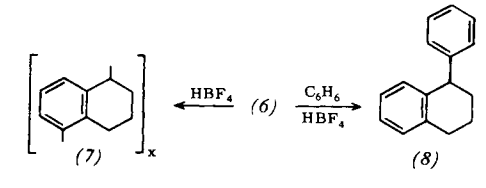
The nitrilium salts *(5)* were identified *via* the amides formed on hydrolysis.

The reactivity of the allylic $>O^{\oplus}-C$ bond results in the vinyldioxolanylium salts being even stronger alkylating agents than dialkoxycarbonium [4] or alkyldioxolanylium salts [5]. They even alkylate aromatic compounds such as benzene, toluene, and anisole at room temperature in *exothermic reactions*. In these reactions, attack is, as with nitriles (see reaction 3), on the terminal C atom of the vinyl group and involves an allyl shift and ring fission [6] (reversal of the reaction forming *(2)*).



*(6)*

The 4-aryl-2-butenyl esters, *e.g.* *(6)*, formed as primary products can be isolated if ethers are added to remove the $HBF_4$ formed. If an ether is not added, polymers of structure



*(7)* *(8)*

*(7)* are formed by alkylation, isomerization, and cyclization. Use of an excess of the aromatic compounds affords 1-aryltetralins, *e.g.* *(8)*.

[6] It is not yet known whether these reactions occur by an $S_N2'$ mechanism or are preceded by a reversible valence isomerization of the dioxolanyl cation to the acyclic allyl cation.

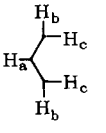
## π-Allylnickel Bromide under the Influence of Phosphines and Phosphites

By Dr. D. Walter and Prof. G. Wilke

Max-Planck-Institut für Kohlenforschung, Mülheim/Ruhr (Germany)

In the presence of Lewis acids π-allylnickel halides catalyse the dimerization of propylene. By the addition of various phosphines to the catalyst, the process can be directed at will so as to yield dimers of various structures [1]. In this connection, the influence of ligands containing phosphorus on π-allylnickel bromide was studied with the aid of the $^1H$–NMR spectra of 1:1 and 1:2 adducts. The crystalline adducts are obtained when π-allylnickel bromide, *e.g.* dissolved in ether, is treated with phosphines or phosphites in stoichiometric proportions.

The table shows the $\tau$ values (TMS as internal standard, Varian A 60, about 30 °C in chlorobenzene [*]) of $H_a$ (*meso*), $H_b$ (*syn*), and $H_c$ (*anti*) protons of the allyl group, as well as the coupling constants and the differences between the $\tau$ values of $H_c$ and $H_b$.



| Compound | $H_a$ | $H_b$ | $H_c$ | $J_{ab}$ | $J_{ac}$ | $H_c-H_b$ |
|---|---|---|---|---|---|---|
| π-$C_3H_5NiBr{\cdot}P(OC_6H_5)_3$ | 5.4 | 6.4 | 7.8 | 7 | 14 | 1.4 |
| π-$C_3H_5NiBr{\cdot}2P(OC_6H_5)_3$ | 5.7 | 6.42 | 7.46 | 7 | 14 | 1.04 |
| π-$C_3H_5NiBr{\cdot}P(C_6H_5)_3$ | 4.9 | 6.62 | 7.55 | 6.5 | 14.5 | 0.93 |
| π-$C_3H_5NiBr{\cdot}2P(C_6H_5)_3$ | 5.1 | 6.62 | 7.04 | 6.5 | 13.5 | 0.42 |
| π-$C_3H_5NiBr{\cdot}P(C_2H_5)_3$ | 5.1 | 6.7 | 7.8 | — | — | 1.1 |
| $C_3H_5NiBr{\cdot}2P(C_2H_5)_3$ | 5.04 | 6.76 | | 10 | | 0.0 |

The $H_a$, $H_b$, and $H_c$ signal intensities are in the ratio 1:2:2. As can be seen from the spectra, the 1:1 and 1:2 adducts of triphenyl phosphite and triphenylphosphine contain a π-allyl group ($H_b$ and $H_c$ are distinguishable). The difference between the $\tau$ values of $H_c$ and $H_b$ is smaller for the 1:2 adducts than for the 1:1 adducts. Whereas the spectrum of π-$C_3H_5NiBr{\cdot}P(C_2H_5)_3$ shows splitting of the $H_b$ and $H_c$ signals, $H_b$ and $H_c$ give only one signal in the spectrum of $C_3H_5NiBr{\cdot}2[P(C_2H_5)_3]$. This is typical of an allyl system in dynamic equilibrium $(CH_2{=}CH{-}CH_2) \rightleftharpoons (CH_2{-}CH{=}CH_2)$ [2]. π-$C_3H_5NiCN$, obtained from $(\pi\text{-}C_3H_5)_2Ni$ and HCN in ether or from π-$C_3H_5NiBr$ and KCN in methanol, behaves analogously. $C_3H_5NiCN{\cdot}2[P(C_2H_5)_3]$ gives the spectrum of the dynamic type ($H_a$: $\tau$ = 5.26; $H_{b/c}$: $\tau$ = 7.36; $J$ = 9.8 Hz, in $C_6D_6$, ratio 1:4).

The transition of the π-allyl system to a dynamic allyl system evidently is brought about by the strong electron donation to the nickel atom by two molecules of triethylphosphine. In π-$C_3H_5PdCl$, the same effect is achieved even with triphenylphosphine[3]. Transitions of this type are produced thermally in $Zr(C_3H_5)_4$ and $Th(C_3H_5)_4$[4].

## Existence of Ternary Compounds of Phosphorus with Sulfur and Hydrogen

By Prof. P. W. Schenk and B. Leutner

Institut für Anorganische und Analytische Chemie, Technische Universität Berlin (Germany)

In this communication we report the first synthesis of volatile ternary compounds of phosphorus, sulfur, and hydrogen.

Equimolar mixtures of gaseous $H_2S$ and $PH_3$, or of $D_2S$ and $PD_3$, or of $CH_3SH$ and $PH_3$, were passed at 0.5 mmole/min and about 0.1 mm Hg through an electrodeless glow discharge (900 V at 90 mA and 27 MHz)[1]. The products were condensed at −196 °C; the conversion was 0.5–1.0 %.

For analysis the gases were passed directly from the glow discharge into a small mass spectrometer[2] or condensed at −180 °C in a low-temperature infrared absorption cell. The following products were indentified:

| Initial mixture | Main product | Subsidiary products |
|---|---|---|
| $H_2S + PH_3$ | $H_2PSH$ | $H_2S_2$, $P_2H_4$ |
| $D_2S + PD_3$ | $D_2PSH$ | $D_2S_2$, $P_2D_4$ |
| $CH_3SH + PH_3$ | $H_2PSCH_3$ | $P_2H_4$, $CH_3SSCH_3$ |

Mass-spectrometric identification of a product of molecular formula $H_3PS$ was complicated by the presence of $H_2S_2$ and $P_2H_4$ with the same nominal molecular weight ($m/e$ = 66). The following evidence is proof for a compound $H_3PS$:

1. The more frequent occurrence of a fragment of nominal mass 63 when a mixture of $H_2S$ and $PH_3$ is subjected to a discharge than with pure $P_2H_4$; this indicates the presence of $PS^+$ together with smaller amounts of $P_2H^+$.

2. The occurrence of the peak at $m/e$ = 63 in the reaction products of $PD_3 + D_2S$, which can be due to $PS^+$ only.

3. The formation of an analogous compound $H_2PSCH_3$ from $CH_3SH + PH_3$, the main peak of which at $m/e$ = 80 is not overlapped by that of any other compound.

A strong, sharp infrared band at 477 $cm^{-1}$, which can be assigned to a P–S single bond[3], of the gas mixture condensed at −180 °C supports the structure $H_2PSH$. It follows from the decrease in intensity of this band that the colorless compound decomposes already above −130 °C to an amorphous, nonvolatile, insoluble[4], yellow residue. The P:S ratio in this residue varies from 2:1 to 6:1 since, depending on the method of preparation, variable amounts of (also unstable) $P_2H_4$ and $H_2S_2$ are present.

$H_2PSCH_3$ is somewhat more stable. At −78 °C it still shows an infrared absorption with a P–S frequency of 480 $cm^{-1}$; at this temperature, however, slow decomposition is noticeable from the spectrum. This compound also leaves a yellow, non-volatile residue.

## Di(cyclooctatetraene)titanium and Tri(cyclooctatetraene)dititanium [1]

By Dr. H. Breil and Prof. G. Wilke

Max-Planck-Institut für Kohlenforschung, Mülheim/Ruhr (Germany)

Di(cyclooctatetraene)titanium, $Ti[COT]_2$ *(1)*, is obtained as deep violet-red crystals in yields of over 80 % when $Ti(OC_4H_9)_4$ is heated at 80 °C in the presence of an excess of cyclooctatetraene (COT) and $Al(C_2H_5)_3$ in the molar ratio 0.2:2:2. The compound is sparingly soluble in aromatic hydrocarbons; the solutions are deep red. It can be recrystallized from hot toluene.

Similarly, tri(cyclooctatetraene)dititanium, $Ti_2[COT]_3$ *(2)*, is obtained as yellow crystals when the reactants are used in a molar ratio of 0.2:0.4:2 (yield 80 %). This complex is also sparingly soluble in aromatic hydrocarbons. Both compounds are extremely sensitive to air. They can be interconverted in accordance with the equation:

$$\underset{(1)}{Ti[COT]_2} \underset{\text{COT; 80 °C; 40 hr, 94 \%}}{\overset{(C_2H_5)_2AlH;\ 60\ °C;\ 40\ hr;\ 95\ \%}{\rightleftharpoons}} \underset{(2)}{Ti_2[COT]_3}$$

Ethanol reacts spontaneously with a suspension of *(2)* in $C_6H_{12}$ giving 1,3,5- and 1,3,6-cyclooctatrienes (88:12), in 90 % yield, together with titanium ethoxide. Under the same conditions, *(1)* gives 1,3,5- and 1,3,6-cyclooctatrienes and cyclooctatetraene (51:37:12) in a total yield of 70 %.

The complexes *(1)* and *(2)* react with formaldehyde or $CO_2$ under pressure (*ca.* 50 atm) to form unsaturated hydroxymethyl or carboxyl derivatives of unsaturated eight-membered rings, which were converted in several steps into methylcyclooctanes. Mono-, di-, and trimethylcyclooctanes were obtained in every case; we also obtained these products analogously from methyl iodide and cyclooctatetraenedisodium. It must be concluded from the formation of mono-, di-, and trisubstituted derivatives of cyclooctane that transmetalation takes place during the reactions of both the titanium complexes and the cyclooctatetraenedisodium, and that the reaction does not occur exclusively in the 1,4-position, as described by *Reppe et al.*[2] for $Na_2[COT]$.

The chemical behavior of the cyclooctatetraene-titanium complexes indicated that the cyclooctatetraene molecules are bonded to the titanium atom at least partly as quasiaromatic, planar 10 π-electron systems, *i.e.* as dianions[3].

The "club sandwich" structure proposed for *(2)* has been confirmed in principle by X-ray analysis[4]. The structure of *(1)* is not yet known.

The presence of dianions is also indicated by the following synthesis:

$$TiCl_4 + 2\ Na_2[COT] \xrightarrow{C_6H_6,\ 70\ °C,\ 72hr,\ 53\ \%} Ti[COT]_2 + 4\ NaCl$$

With this method we prepared the complexes $V[COT]_2$, $Cr_2[COT]_3$, $Mo_2[COT]_3$, $W_2[COT]_3$, Co[COT], and Ni[COT].

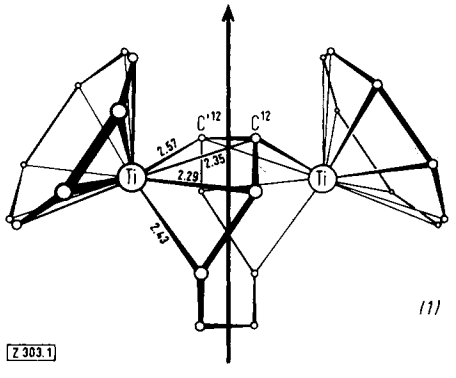
## Crystal Structure of Tri(cyclooctatetraene)dititanium

By Dr. H. Dietrich and Dr. H. Dierks

Fritz-Haber-Institut der Max-Planck-Gesellschaft, Berlin-Dahlem (Germany)

The π-complex tri(cyclooctatetraene)dititanium *(1)* prepared by *Wilke et al.*[1] crystallizes in thin, yellow leaflets, space group Fdd 2 ($C_{2v}^{19}$), $a = 14.41$, $b = 35.99$, $c = 7.25$ Å; $V = 3760$ Å$^3$, X-ray density 1.448 g/cm$^3$, $n = 8$.

The crystals were studied by three-dimensional X-ray diffraction (filtered copper $K_\alpha$ radiation, multifilm technique). The reflection intensities were estimated visually by means of a reference scale and were corrected for absorption.



*(1)*

Z 303.1

The molecules of *(1)* contain two titanium atoms and three cyclooctatetraene rings and have a two-fold axis that passes through the middle ring. The two outer rings are planar (C–C distance 1.39 Å) and are attached symmetrically each to one titanium atom (all Ti–C distances 2.35 Å). The adjacent atoms C-12 and C'-12 of the middle ring are apparently bonded to both titatium atoms although the Ti–1/C-12 and Ti–2/C'-12 distances are very long (2.57 Å).

The anomalous dispersion effect due to the two titanium atoms plays a significant role in the structure refinement presently being carried out, because the two-fold axis of the molecule is also a polar axis of the crystal[2]. The present value $R = 11$ % thus rises to 20 % if the structure factors for inverted structures are used in the calculations.

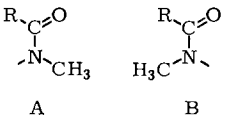
## Magnetic Anisotropy of the Amide Group

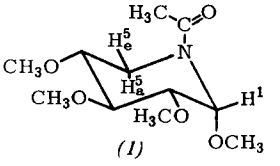
By Dr. H. Paulsen and K. Todt

Chemisches Staatsinstitut, Institut für Organische Chemie, Universität Hamburg (Germany)

Studies of the long-range coupling[1], the intramolecular nuclear Overhauser effect[2], the paramagnetic contact shift[3], as well as by the benzene dilution method[4] showed that in amides in which rotation about the N–CO bond is restricted, protons in the arrangement A (*cis* to the carbonyl group) are shielded more strongly than in arrangement B. The corresponding $CH_3$ NMR signal therefore occurs at higher fields for form A than for form B. We have found that this assignment is valid for freely rotating methyl groups, but has to be differentiated for sterically fixed protons.



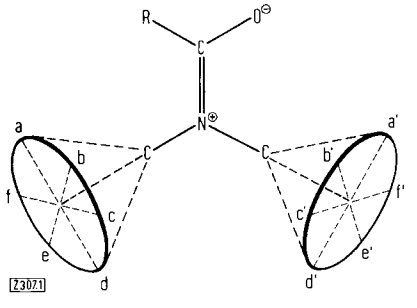
A B



*(1)*

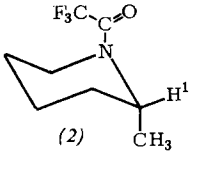
Integration of signal intensities as well as double resonance experiments show that in *(1)*[5] the assignment of the double resonance signals from both $H_a^5$ and $H_e^5$ is reversed. Equatorial protons ($H_e^5$ and $H^1$), which are in the plane of the amide group, give a signal at lower field for form A than for form B. On the other hand, the axial protons (such as $H_a^5$ and the protons of the glycosidic $OCH_3$ group), which are outside the plane of the amide group, give a signal for form B at lower field than that for form A, which corresponds to the assignment for freely rotating methyl groups.

The figure gives a generalized representation of the anisotropic effect of the amide group. The possible proton positions are indicated by letters on the circles. Two regions can be distinguished: the "plane region" in the plane of the amide group with the positions *aa'* (equatorial protons), in which *a* is shielded more strongly than *a'*, and the "out-of-plane region", in which *cc'* (axial protons) are opposed, and position *c'* is shielded more strongly than *c*. The positions *ee'* are equivalent to *cc'*.

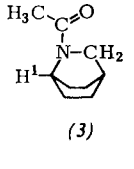


Z 307.1

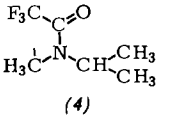
For compound *(2)* we assume a conformation in which the methyl group is axial[5]. $H^1$ lies in the plane region and its assignment is typical of *aa'*. The methyl group, since it lies in the out-of-plane region, shows a typical *cc'* assignment. In the fixed structure *(3)*, $H^1$ lies in the plane region and



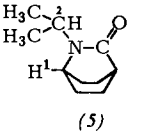
*(2)*



*(3)*



*(4)*



*(5)*

gives two signals with the *aa'* assignment. The protons of the $CH_2$ group in *(3)* have orientations between axial and equatorial, namely the positions *bb'* and *ff'*, respectively. We found only a small degree of splitting for this group. The protons are on the border of the plane and the out-of-plane regions, *i.e.* the shielding between *b* and *b'* is about the same, as is that between *f* and *f'*. Since the influence of *dd'* presumably is small, owing to the larger distance from the carbonyl bond, averaging of the effects of all positions *a–f* and *a'–f'* on the anisotropy shows that freely rotating methyl groups give signals corresponding to the out-of-plane region.

In *(4)* the freely rotating $CH_3^1$ group shows two signals corresponding to the ou-tof-plane region, the CH group signal pair corresponding to the plane region. This shows that in *(4)* a conformation in which the CH proton lies in the plane of the amide group is slightly preferred. Our assignment for the plane region agrees with theoretical calculations[6], which are in contradiction to the assignment for freely rotating methyl groups. Our assignments were made by the benzene dilution method, double resonance, and for *(4)* by F–C–C=N–C–H long-range coupling, to which *cis* > *trans* applies. An independent assignment follows from compound *(5)* with a fixed amide group, for which we found $\tau = 6.4$ for $H^1$ and $\tau = 5.4$ for $H^2$. The isopropyl group in *(5)* has the same orientation as in *(4)*.

Comparison of amides with thioamides in the spectra of *N,N*-dimethylacetamide and *N,N*-dimethylthioacetamide by long-range coupling and the benzene dilution method shows their magnetic anisotropies to be opposite. In thioamides the plane region evidently has a larger cone of influence, so that the assignment of the freely rotating methyl group coincides with that of the plane region.

# CONFERENCE REPORTS

## Surface-active Compounds

The *Deutsche Akademie der Wissenschaften zu Berlin* and the *Chemische Gesellschaft in der DDR* were hosts to the IIIrd International Symposium on Surface-active Compounds in Berlin from the 29th to the 31st March 1966. The following are abstracts of the some of the lectures of particular interest to chemists.

### Reactions Occurring on Hydrogenation of Unsaturated Fatty Acids to Unsaturated Fatty Alcohols

*H. Bertsch, E. König*, and *H. Reinheckel*,
Berlin-Adlershof and Rodleben (Germany)

Mono- and poly-unsaturated carboxylic acids may be converted into unsaturated alcohols by selective, high-pressure hydrogenation. None of the known catalysts acts so selectively as to avoid completely reduction of the C=C double bonds, the amount of such "side reaction" depending on the nature of the acid.

Pure oleic, elaidic, erucic, brassidic, 10-undecenoic, 2-octadecenoic, ricinoleic, linoleic, ricinenic, linolenic, and α- and β-eleostearic acids were hydrogenated under identical conditions (300 °C at 300 atm) in a 250-ml shaking autoclave with a catalyst of copper-cadmium (Cu:Cd = 3:1 to 4:1) that had been precipitated by sodium carbonate solution.

The alcohols were isolated after hydrolysis of the hydrogenation product and were identified by IR-spectroscopy and determination of their iodine and saponification values.

Oleic, elaidic, erucic, and brassidic acids were reduced almost quantitatively to oleyl, elaidyl, erucyl, and brassidyl alcohols, respectively. The selectivity of reduction of the COOH group decreases with increasing number of C=C double bonds. Linoleic acid is thus reduced to a mixture of unsaturated alcohols, with about 20% of the C=C bonds being saturated; little conjugation (*ca.* 4%) occurs in this reaction. The IR spectra indicate that 30% of the alcohols have *trans*-double bonds if only one *trans*-double bond is assumed per molecule.

Linolenic acid gives only 50% of alcohols, 70% of the double bonds being retained. If the reaction time is prolonged, the proportion of *trans*-double bonds increases with saturation. α- and β-Eleostearic acids give a 58% yield of a fatty alcohol mixture in which less than half the original double bonds remain. Under the conditions given above, ricinenic acid cannot be hydrogenated at all.

Migration of C=C double bonds was established by ozonization of the hydrogenation product and gas-chromatographic investigation of the oxidative ozonide fission products. With 9-octadecenoic acids there is migration to the 10,11-, 11,12-, and 8,9-positions; with 13-docosenoic acids there are similar amounts (*ca.* 5:1:2%) of migration to the 14,15-, 15,16-, and 12,13-positions. Analysis is harder for polyenoic acids because the same fragments are formed as a result of structural isomerism as of partial hydrogenation.

### New Synthesis of Surface-active Urethanes of Sucrose

*W. Gerhardt*, Berlin-Adlershof (Germany)

Surface-active derivatives of sucrose have been obtained by a new method. Carbamic esters are prepared by treating reactive alkyl halides with alkali cyanate and a carbohydrate R'OH in an aprotic solvent, particularly dimethylformamide:

$$RX + KNCO \rightarrow R{-}NCO + KX$$
$$RNCO + R'OH \rightarrow R{-}NH{-}COOR'$$

The alkyl isocyanates formed as intermediates can be isolated.

If a long-chain n-alkyl halide is used with sucrose as the alcoholic component, the *N*-n-dodecylurethane of sucrose is obtained; it can also be prepared by reaction of n-dodecyl isocyanate with sucrose in dimethylformamide. The new process does not directly require the alkyl isocyanate, which is often not readily accessible.

The halogen compound used may be an alkyl bromide at *ca.* 95 °C or the chloride at *ca.* 145 °C. If alkali bromide is added to the reaction mixture, alkyl chlorides are transhalogenated to yield alkyl bromides, which then react at *ca.* 95 °C.

Halogenated fatty acids also react with sucrose and potassium cyanate in dimethylformamide, yielding *N*-substituted urethanes of sucrose. Hydrolysis leads to salts of *N*-(carboxyalkyl)urethanes of sucrose, which are characterized by greater solubility in water.

Water-solubility can also be enhanced by oxyethylation of the OH group [conversion of R—OH into R-$(OC_2H_4)_n$—OH]. For this purpose, either oxyethylated sucrose is treated with an alkyl isocyanate, or ethylene oxide is added to an *N*-alkylurethane of sucrose.

A further variation is the use of alkanesulfonyl chlorides as halogen compound; *N*-(alkylsulfonyl)urethanes of sucrose are obtained.

## Formation of Epoxides on Liquid-phase Oxidation of Olefins

*Anneliese Greiner*, Berlin-Adlershof (Germany)

Reactive epoxides are of great interest in the preparation of surface-active compounds. There has hitherto been no simple process for direct oxidation of long-chain olefins to epoxides.

1-Dodecene was therefore investigated with a view to controlled oxidation. Use of pure oxygen leads to formation of considerable amounts of carbonyl compounds and carboxylic acids. An oxygen-nitrogen mixture at 130 °C containing 12 vol-% of oxygen was found to be the most favorable for epoxide formation. Earlier work had shown the striking efficiency of ozone for initiation of oxidation reactions[1]. Addition of ozone influences the primary step in the oxidation, namely, formation of hydroperoxide, which occurs at the carbon atom next to the double bond. Therefore, ozone at a concentration of *ca.* 1 to 3 vol.-% was added to the gas mixture used for our oxidations. In all these experiments there was an increased rate of oxidation and increased formation of epoxides.

A further increase in the yields of epoxide was achieved by addition of 5 % of 1-dodecene ozonide. On the assumption that the increased yield was due not merely to the peroxidic decomposition products from the ozonide, but that the carbonyl compounds formed in this decomposition were also involved, oxidations were carried out with addition of carbonyl compounds (50 % of 1-dodecene, 45 % of liquid paraffin, and 5 % of dodecanal; 130 °C; $N_2$:$O_2$ = 7:1 v/v); these conditions led to yields of 1,2-epoxydodecane amounting to 50 % of the 1-dodecene used.

It was shown by gas chromatography that 1,2-epoxydodecane was formed, but that the epoxide fraction contained also 1-dodecen-3-ol and -3-one. The position of the double bond was unchanged in the unused 1-dodecene.

## Alkylarenesulfonates Derived from Petroleum Hydrocarbons

*P. Hahn*, Rodleben (Germany)

Because "tetrapropylenebenzenesulfonate" ($C_{12}$-substituted benzenesulfonate with mixed alkyl radicals derived by tetramerization of propene) prepared from petrochemicals is not readily biodegradable, alternative starting materials to tetrapropylene have been sought.

As alternatives to 1-alkenes, normal alkanes obtained by the molecular-sieve process are being increasingly used for production of alkylbenzenes. In Table 1 the distribution of chain lengths, content of n- and iso-compounds, and mean chain length $\bar{n}$ of a Fischer-Tropsch paraffin mixture (A, Mepasin I) are compared with those of the paraffins obtained by the Parex[*] process (B, C) from petroleum fractions.

Table 1. Components of paraffin mixtures of various origins.

| Hydrocarbon | Weight-% | | | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|---|
| | $C_8$ | $C_9$ | $C_{10}$ | $C_{11}$ | $C_{12}$ | $C_{13}$ | $C_{14}$ | $C_{15}$ | Total | $\bar{n}$ |
| A Mepasin I | | | | | | | | | | |
| normal | 0.6 | 3.0 | 13.6 | 31.1 | 21.3 | 7.2 | 1.4 | 0.9 | 79.1 | 11.4 |
| iso | | 0.4 | 1.4 | 6.2 | 7.8 | 4.5 | 0.6 | | 20.9 | |
| B n-Paraffin $C_{10}$—$C_{14}$ | | | | | | | | | | |
| normal | | | 3.1 | 44.3 | 43.4 | 5.1 | | | 95.9 | 11.7 |
| iso | | | | 0.1 | 0.7 | 2.3 | 1.0 | | 4.1 | |
| C n-Paraffin $C_{10}$—$C_{13}$ | | | | | | | | | | |
| normal | | 0.4 | 3.2 | 45.5 | 39.5 | 8.7 | 0.2 | | 97.5 | 11.6 |
| iso | | | 0.1 | 0.2 | 1.2 | 1.0 | | | 2.5 | |

The mixture thus contains 96—98 % of normal alkanes of such chain lengths and in such proportions as to make it a suitable starting material for preparation of alkylbenzenes.

The monochloroalkanes required for synthesis of alkylbenzenes were obtained by thermal chlorination of the paraffins. To obtain optimal yields of monochlorides with minimal formation of by-products, the paraffin mixture is chlorinated to 6—8 wt.-% chlorine content (cf. Table 2). The chloroalkanes were then converted with benzene and $AlCl_3$ into n-alkylbenzenes which were fractionated, sulfonated with oleum, and neutralized. Table 3 gives the composition of

Table 2. Products of chlorination of a Mepasin-I fraction of $n$ = 11 to 6 wt.-% chlorine content with $Cl_2$ at 85 °C.

| $C_nH_{2n+2-x}Cl_x$ | Weight-% Cl | | | | |
|---|---|---|---|---|---|
| | Continuous, No. of reactors | | | | Discontinuous |
| $x$ | 1 | 2 | 3 | 4 | |
| 0 | 73.22 | 71.96 | 71.59 | 71.30 | 70.64 |
| 1 | 19.89 | 22.04 | 22.84 | 23.29 | 24.65 |
| 2 | 5.18 | 4.91 | 4.65 | 4.65 | 4.25 |
| 3 | 1.37 | 0.91 | 0.76 | 0.76 | 0.45 |
| 4 | 0.34 | 0.17 | 0.17 | 0.00 | 0.00 |

Table 3. Composition (wt.-%) of sodium alkylbenzenesulfonates (yellowish) derived from various hydrocarbon mixtures.

| Paraffin mixture | Neutral oil | $Na_2SO_4$ | NaCl | $Na_2CO_3$ | ABSNa | I value |
|---|---|---|---|---|---|---|
| Mepasin I | 0.9 | 10.8 | 1.78 | 0.19 | 86.3 | 8 |
| n-Paraffin $C_{10}$—$C_{14}$ | 1.0 | 10.8 | — | 0.28 | 87.9 | 5—10 |
| n-Paraffin $C_{10}$—$C_{13}$ | 0.9 | 9.2 | — | 0.34 | 89.6 | 5 |

the resulting sodium alkylarenesulfonates, as well as the iodine number of the unbleached end product which is a further control of quality.

No difference from the behavior of Mepasin I could be found in relation to the total synthesis of alkylbenzensulfonates. Alkylbenzenesulfonates prepared from normal paraffins are more susceptible to biological oxidation because of their predominantly straight-chain structure.

## Electrochemical Investigation of the Adsorption of Surface-active Materials at the Phase Boundary Mercury/Electrolyte

*H. Jehring*, Berlin-Adlershof (Germany)

We have studied the adsorption of triethyl phosphate and polyethylene oxide ($\bar{M}$ = 1000), separately and in admixture, at the phase boundary mercury/electrolyte by Breyer alter-

[1] *G. Wagner*, J. prakt. Chem. *15*, 327 (1962); *27*, 297 (1965).
[*] VEB Leuna-Werke.

nating-current polarography and tensammetry. The lowering of capacity $\Delta C$ and the height of the tensammetric waves were used as measures of the degree of surface coverage, $\Theta$. The influence of electrode potential $E$, concentration of sorbate, and drop interval $t_m$ were measured. Triethyl phosphate has moderate surface activity. Equilibrium values are obtained that are independent of $t_m$ (rapid diffusion to the surface at the relatively high concentrations, $c_{\Theta=0.5} = 7 \times 10^{-4}$ mole/l). The adsorption isotherm determined from the lowering of capacity is S-shaped. *Frumkin*'s interaction constant $a = 1.57$.

Polyethylene oxide is strongly adsorbed at the interface ($c_{\Theta=0.5} = 1.7 \times 10^{-5}$ mole/l), and the desorption potential is relatively high ($E_- = -1.76$ V). Lower oxide concentrations lead to measurable restriction of diffusion towards the surface. The lowering of capacity is thus proportional to $c$ and $t_m^{1/2}$.

When an electrode surface is completely covered with triethyl phosphate, this can be displaced gradually and finally completely replaced in the boundary layer by polyethylene oxide. The same replacement effect is observed when the drop interval $t_m$ is increased, this leading to increased diffusion of the polyethylene oxide which, although present in lower concentration, is more strongly adsorbed. With the less surface-active triethyl phosphate, which is present in higher concentration in the solution, an equilibrium is almost always set up (rapid diffusion), so that the process is independent of time. If, however, the surface is half-covered with polyethylene oxide, the free part of the surface can become occupied by triethyl phosphate, and at very high concentrations of the phosphate it may displace the oxide from the surface. The alternating-current polarogram shows three characteristic potential regions: in the central area surrounding the origin of the electrocapillary curve there is mixed adsorption of triethyl phosphate and polyethylene oxide; outside this, in both the positive and the negative direction, there are areas of adsorption of polyethylene oxide; and finally two areas with no adsorption.

## The Effect of Chain Length on the Ability of Aliphatic Amines to Render Quartz Hydrophobic

*J. Kloubek*, Prague (Czechoslovakia)

The dependence of their ability to render minerals hydrophobic on the hydrocarbon chain length of aliphatic amines has been studied by many authors in flotation experiments. Their results indicate that the logarithm of the concentration ($c_F$) of amine in solution for a specific flotability is linearly dependent on the number ($n$) of carbon atoms in the chain:

$$n = a_1 \log c_F + b_1 \quad (1)$$

where $a_1$ and $b_1$ are constants of various values according to the results from the literature.

The surface charge on floating quartz depends on the pH of the solution. This charge has an effect on the adsorption of amines similar to that of electrolytes on micelle formation in solution, *i.e.* it increases the formation of hemi-micelles. This follows from the pH-dependence of the slope of the curve of $\log c_F$ *vs.* $n$. Further, this dependence shows that adsorption on the quartz surface at high pH probably occurs by the same mechanism as does separation of amine molecules from solution when the solubility limit is exceeded.

Within certain limits, moreover, the basicity ($pK_a$) and the logarithm of the solubility ($S$) depend linearly on the chain length. Combination of these relations with eq. (1) leads to an expression relating the flotation activity to basicity and solubility of the molecule, namely:

$$\log c_F = a_3(-b_3 pK_a + \log S + c_3) \quad (2)$$

where $a_3$ and $c_3$ depend on the experimental conditions and $b_3$ is the constant determined by the slope d log $S$/ d $pK_a$.

A similar relation between flotation activity, basicity, and solubility was previously found for 5,6,7,8-tetrahydro-1- and -2-naphthylamine and their $N$-methyl derivatives[1].

The ability to effect flotation depends on the formation of hemi-micelles on the surface of the mineral. *Fuerstenau*[2] expressed the concentration ($c_{HM}$) of hemi-micelle formation by:

$$c_{HM} = A' \exp[(W_e' - n\varphi')/kT] \quad (3)$$

where $A'$ is a proportionality constant, $W_e'$ is proportional to the electrostatic adsorption energy, and $\varphi'$ is the free energy of cohesion of a $CH_2$ group.

Eq. (3) permits closer specification of the relation (1). Eq. (3) can be extended if we assume that $W_e'$ is proportional to $pK_a$ and the surface charge ($M$) on the quartz also in the case of $c_F$, and that adsorption is influenced by hydrophobic forces related to the chain length of the adsorbed amine and to the pH of the solution. These assumptions seem to be experimentally substantiated; they are partly confirmed by eq. (2). Relation (4) follows as a measure of floatability:

$$c_F = A' \exp[(-a_5 pK_a M - n\varphi' - nb_5 pH)/kT] \quad (4)$$

where $A'$ is proportionality constant, $Wc'$ is proportional reproduces the experimental results up to pH 10. The sudden drop in floatability at higher pH values is probably caused by a change in the quartz surface and its increased solubility.

## Preparation of Hydrogen Sulfate Esters by Reaction of Higher Aliphatic Alcohols with Sulfamic Acid

*S. M. Loktew* and *E. L. Wulach*, Moscow (USSR)

We have used cetyl alcohol and the $C_{12}$–$C_{18}$ alcohol fraction to study the common features of their esterification including the influence of reaction conditions (temperature, duration of reaction, relative quantities, *etc.*) and the nature and amount of the catalyst.

Esterification in the presence of urea leads to 96–98% conversion of cetyl alcohol and 87% conversion of the $C_{12}$–$C_{18}$ fraction. For cetyl alcohol and the $C_{12}$–$C_{18}$ fraction the relative molar quantities acid:alcohol:urea were 115–120:100:10–20 or 110–130:100:10–20, respectively, the temperature 105 and 110 °C, respectively, and the reaction time 6–8 and 2 hr, respectively. Optimization by a statistical method of the esterification of the $C_{12}$–$C_{18}$ alcohol fraction in the presence of urea and poly(ethoxyalkyl)phenol as catalysts led to elucidation of conditions that gave 89% (*p*-toluidine method) and 96% (hydrolysis method) of esterification. These conditions were a molar ratio acid:alcohol:urea:poly(ethoxyalkyl)phenol = 115:100:12:5.5. The surface properties of ammonium salts of the hydrogen sulfates of the $C_{12}$–$C_{18}$ alcohols are comparable with those of sodium lauryl sulfate. The results indicate the following reaction mechanism:

$$H_3\overset{\oplus}{N}\text{–}S\overset{\ominus}{O}_3 + :B \rightleftarrows H_3N + B:SO_3 \text{ (slow)}$$

$$ROH + B:SO_3 \rightarrow ROSO_3H + :B \text{ (fast)}$$

The catalytic activities of more than 50 Lewis bases (:B) (amides, amines, ethers, *etc.*) have been studied. Decrease in activity parallels decrease in electron-donor properties. The catalysts studied can be divided into two types: *1.* substances whose nucleophilic center arises by mesomeric $\pi$-electron shift (dimethyl sulfoxide, pyridine *N*-oxide, *N,N*-dimethylacetamide, dimethylformamide, tetrahydrothiophene dioxide, thiourea, urea, butyl butyrate, acetonitrile, nitrobenzene). *2.* Substances whose nucleophilic center is a localized lone electron pair (pyridine, quinoline, 2-pyridinecarboxylic acid,

[1] *J. Kloubek*, Collect. czechoslov. chem. Commun. *31*, 3526 (1966).

[2] *D. W. Fuerstenau, T. W. Healy*, and *P. Somasundaran*, Trans. Soc. Mining Engr. *229*, 321 (1964).

2-bromopyridine, 2-fluoropyridine, dioxane, hexyl methyl ether). The intermediate reaction of catalysts of the first group with sulfamic acid occurs through π-bonds. These catalysts have high polarity and low basicity; there is a correlation between catalytic activity and basicity. The intermediate reaction of catalysts of the second group with sulfamic acid occurs through σ-bonds. Catalysts of this group have lower polarity than those of the first group; catalytic activity is observed at sufficiently high basicity. Within this group also there is correlation between catalytic activity and basicity.

## Reaction of Sulfonyl Chlorides with Alkylaluminum Compounds

*H. Reinheckel* and *D. Jahnke*, Berlin-Adlershof (Germany)

Triethylaluminum and ethylaluminum sesquichloride react with aliphatic and aromatic sulfonyl chlorides in the molar ratio 1:1 in non-aromatic solvents such as methylene chloride, giving better than 95% yields of the corresponding aliphatic and aromatic sulfinic acids and ethyl chloride. It is assumed that electrophilic attack of the aluminum compound on the sulfonyl chloride is followed by a synchronous process in which the chlorine is removed cationically from the sulfur and combines with the ethyl group (which has become negative) of the organoaluminum compound, yielding ethyl chloride. Hydrolysis of the aluminum sulfinate formed at the same time gives the corresponding sulfinic acid.

When twice the molar amount of organoaluminum compound is used, there is a characteristic difference between the modes of reaction of aliphatic and aromatic sulfonyl chlorides. Either of the ethylaluminum compounds with aromatic sulfonyl chlorides in the molar ratio 2:1 gives, besides ethyl chloride, more than 75% of the corresponding ethyl sulfoxide and small amounts of ethyl sulfide. A second mole of organoaluminum compound has no influence on the reaction of aliphatic sulfonyl chlorides; the corresponding alkanesulfinic acid is always formed.

The electron density at the sulfur atom is considered responsible for these differring modes of reaction. The aluminum sulfinate resulting from the first reaction step permits alkylation of the sulfur if the electron density on the latter is sufficiently reduced by an electron-attracting substituent for attack by the negative ethyl group to be succesful. The same results attend the use of alkylaluminum compounds containing longer alkyl chains. Thus reaction of tri-n-hexylaluminum with benzenesulfonyl chloride (2:1) gives 70% of n-hexyl phenyl sulfoxide.

The economy of this one-stage process can be considerably improved by carrying out the reaction in two independent steps. In the first step a cheap alkylaluminum compound is used for preparation of the aluminum sulfinate, *e.g.* ethylaluminum dichloride or ethylaluminum sesquichloride; then in the second step the desired sulfoxide is prepared by using an alkylaluminum with a longer alkyl radical. Thus dichloroaluminum benzenesulfinate, obtained from ethylaluminum dichloride and benzenesulfonyl chloride (1:1) in a first step, reacts with di-n-hexylaluminum chloride to give n-hexyl phenyl sulfoxide in 61% yield. Tri-, di-, and mono-alkylaluminum compounds can all be used for these reactions; monoalkylaluminum compounds are preferred because of the greater utilization of the alkyl groups.

## Concentration of Hemoglobin Solutions by Flotation

*J. Spurný* and *B. Jakoubek*, Prague (Czechoslovakia)

Dilute solutions of hemoglobin can be concentrated by foaming. We have studied pure hemoglobin solutions as well as solutions to which a quaternary ammonium base has been added (*e.g.* ethoxycarbonylpentadecyltrimethylammonium chloride). The flotation time was not limited, so that the simple relations

$$M_P = M_R + M_K$$

and $$c_P V_P = c_R V_R + c_K V_K$$

hold, where $M_P$, $M_R$, and $M_K$ are the total amounts of protein dissolved in the original solution, in the residual solution, and in the concentrate, respectively, $c_P$, $c_R$, and $c_K$ are the corresponding concentrations, and $V_P$, $V_R$, and $V_K$ are the corresponding volumes.

We were interested particularly in the dilution of the initial solution and in the concentration range the method can be used, to what extent the protein content of the concentrate can be raised above that of the original solution, and what yields can be obtained. We consider that the quaternary ammonium bases form complexes with proteins.

| | Concn. range (g/ml) | Degree of concn. $Q = (c_K - c_P)/c_P$ | Yield [%] | pH |
|---|---|---|---|---|
| Without quat. base | $0.06 \times 10^{-3}$—$0.3 \times 10^{-3}$ | 0.10— 4.86 | 39—97 | 8.4 |
| With quat. base ($c = 10^{-4}$ g/ml) | $5 \times 10^{-7}$—$1.0 \times 10^{-4}$ | 0.96—10.3 | 79—98 | 8.6 |

For the concentration of pure hemoglobin solutions (without addition of quaternary salt) the following relations between volume of concentrate and concentration of the original solution hold:

$$V_K = k'(c_K - k)$$

and $$V_K = V_P(c_P - c_K)/(c_K - c_R)$$

where $k'$ and $k$ are constants with the values $15.67 \times 10^4$ ml²/g and $3.3 \times 10^{-5}$ g/ml, respectively.

[VB 3 IE]

## Kinetics of Non-Isothermal Decompositions

By H. Jüntgen[*], Essen (Germany)

Non-isothermal reactions in nature and in industry are influenced by the variation of temperature with time. For simplicity, investigations are confined to reactions at constant rates of heating. Some general equations have been derived for this case. In particular, for the rate of gas evolution per unit temperature change, $dV/dT$ ($V$ = volume of gas formed up to temperature $T$) in thermal decompositions as a function of the temperature $T$, we find, for a reaction order $n = 1$:

$$\frac{dV}{dT} = \frac{k_0 V_0}{m} \exp\left(-\frac{E}{RT} - \frac{k_0 RT^2}{mE} e^{-E/RT}\right)$$

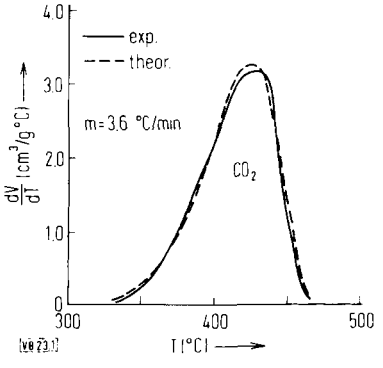
and for $n \neq 1$:

$$\frac{dV}{dT} = \frac{k_0}{m} e^{-E/RT}\left[V_0^{-(n-1)} + (n-1)\frac{k_0 RT^2}{Em} e^{-E/RT}\right]^{-n/(n-1)}$$

The shapes and positions of the maxima of these functions depend on the rate of heating $m = dT/dt$, the order $n$ of the reaction, the activation energy $E$, and the frequency factor $k_0$; the quantity $V_0$ (volume of gas evolved at $t = \infty$), being a proportionality factor, simply produces a parallel displacement of the curves. If $n$ is known, the quantities $E$ and $k_0$ can be determined from the observed gas formation at a given rate of heating $m$ by regression analysis with the aid of an electronic computer. Whether or not $n$ has been chosen correctly can be judged from the correlation coefficient and residual scatter.

The method was illustrated with the aid of three experimental examples, in which finely divided samples with helium passing through them were decomposed in an accurately adjustable oven at a constant rate of heating. The rate of gas formation was determined from the measured constant flow rate of the flushing gas and by continuous mass-spectrometric concentration measurements.

The reproducibility of the method was checked in the decomposition of basic magnesium carbonate. The figure shows that the calculated rate of decomposition agrees closely with that observed. The activation energy is 42.6 ± 1.4 kcal/mole, and the frequency factor is $(3.7 \pm 0.5) \times 10^{12}$ min$^{-1}$, assuming $n = 1$. The technically significant influence of the rate of heating can be shown very clearly in the case of 4 $MgCO_3 \cdot Mg(OH)_2 \cdot 5H_2O$: at low rates of heating ($m < 10$ °C/min), the basic carbonate liberates $CO_2$ directly between 400 and 450 °C, whereas at high rates of heating ($m < 100$ °C/min), it is first converted into magnesite, and decomposes only above 600 °C to give MgO.



The pseudo-unimolecular reduction of sulfuric acid to $SO_2$ on activated coke, which is important in new flue-gas desulfurization processes, can also be represented as a first-order reaction. An activation energy of 17 kcal/mole and a frequency factor of $5 \times 10^5$ min$^{-1}$ are obtained. For the first-order decarboxylation of ferulic acid, which was studied at a heating rate of 5.6 °C/min, an activation energy of 27.7 kcal/mole and a frequency factor of $3.6 \times 10^{-11}$ min$^{-1}$ are found.

## Reactions of Strongly Electropositive Metals with Graphite and with Metal Dichalcogenides

*W. Rüdorff,* Tübingen (Germany)

Graphite reacts with solutions of alkali and alkaline-earth metals in liquid ammonia, forming metal ammine-graphite compounds. According to the concentration of the metal, europium or ytterbium gives compounds $([C_{16-18}]M(NH_3)_3)_n$ (2nd stage) and $([C_8]M(NH_3)_2)_n$ (1st stage) [1]. With graphite the blue ammoniacal solutions of Be, Mg, Al, Ba, Ce, and Sm prepared electrolytically with an anode of the appropriate metal give metal - graphite compounds such as $([C_{30}]Mg(NH_3)_{2-3})_n$ (4th stage) and $([C_{18}]Sm(NH_3)_3)_n$ (2nd stage). Further, compounds can be prepared having two metals in an ordered layer structure, *e.g.* a 1st stage $([C_{30}]MgK_2(NH_3))_n$ from a 4th stage magnesium-graphite and potassium, or a 1st stage $([C_{10}]BeK_{0.62}(NH_3))_n$ with $I_c = 31$ Å [2] from a 5th stage beryllium-graphite. Electrolysis with a uranium anode in the presence of KI leads to a graphite containing uranium and potassium $([C_{18}]UK_{0.18}(NH_3)_3)_n$.

Magnetic measurements show that $M^{2+}$ and $M^{3+}$ ions are present in ytterbium- and samarium-graphite, the proportion of $M^{3+}$ ions increasing with rising temperature, whereas europium-graphite contains only $Eu^{2+}$ ions. Europium-graphite (1st stage), like the metal, shows strong dependence of susceptibility on the field strength at low temperatures.

Sulfides such as $MoS_2$, $WS_2$, $ReS_2$, and $TiS_2$ that crystallize with layer lattices, as well as the corresponding selenides, react with metals dissolved in liquid ammonia. Compounds such as $K_{0.5}WS_2$, $K_{0.8}TiS_2$, and $NaTiSe_2$ are formed, in which metal layers are intercalated between the $MX_2$ layers. The properties of these compounds (pyrophoric nature, reaction with water with evolution of $H_2$, magnetic behavior) indicate that they are essentially intermetallic compounds. The transition to ionic thiometalates can be followed in the isostructural series $Na_{0.8}TiS_2$–$NaVS_2$–$NaCrS_2$. ($NaVS_2$, prepared from $Na_2S$ and $V_2S_3$, has the following properties: black; slowly decomposed by water without evolution of $H_2$; $I_a = 3.57$ Å, $I_c = 19.68$ Å; $\mu_{eff} = 2.1$ BM at 293 °C; $\varkappa = 5.9$ ohm$^{-1}$ cm$^{-1}$.

[Lecture at Hannover (Germany), June 23rd, 1966] [VB 15 IE]

German version: Angew. Chem. *78*, 948 (1966)

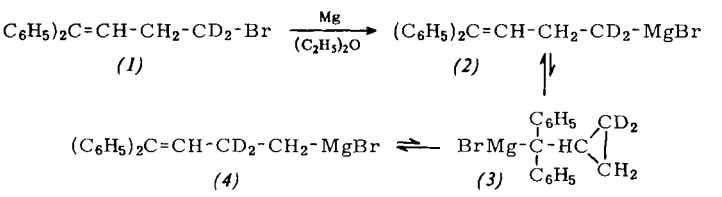
[1] In the first stage the metallic reactant forms a layer between *each* pair of graphite layers parallel to the basal plane of the lattice, in the second stage between each second pair of such layers, and so on.

[2] $I_c$ denotes the lattice parameter in the c-direction.

# SELECTED ABSTRACTS

**Photochemical formation of bicyclo[3.1.0]hex-2-ene and 3-vinylcyclobutene** was observed by *J. Meinwald* and *P. H. Mazzocchi* on irradiation of ether solutions of 1,3-cyclohexadiene. The products were identified by mass, NMR, and IR spectroscopy. It had previously been assumed that 1,3-cyclohexadiene gives only polymers and 1,3,5-hexatriene. / J. Amer. chem. Soc. *88*, 2850 (1966) / –Kr. [Rd 540 IE]

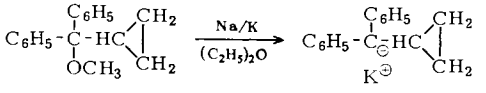
**The allylmethyl-cyclopropylmethyl rearrangement** of the Grignard reagent from [1,1-$D_2$]-1-bromo-4,4-diphenyl-3-butene *(1)* has been studied by *M.E.H.Howden, A. Maercker, J. Burdon,* and *J. D. Roberts.* The solution of this organometallic compound (ether, 20 °C) shows a $^1$H–NMR spectrum corresponding to an equilibrium mixture of equal parts of compounds *(2)* and *(4)*; the assumed intermediate *(3)* cannot be present in the equilibrium mixture to an extent greater than 0.3 %. With $CO_2$ or $HgBr_2$ the non-deuterated system *(2)* ⇄ *(3)* ⇄ *(4)* gives only open-chain products; use of $D_2O$ affords [4-D]-1,1-diphenyl-1-butene as sole deuterated hydrocarbon (97 % yield). Equilibration is much



faster ($\tau^1/_2 = 30$ hr at 27 °C) than when the phenyl substituents are not present ($\tau^1/_2 = 30$ hr at 27 °C). / J. Amer. chem. Soc. *88*, 1732 (1966) / –Eb. [Rd 532 IE]

**Reactive copolymers of styrene as carriers for proteins and enzymes** have been prepared by *G. Manecke* and *H.-J. Förster*. Copolymerization of 4- or 3-fluorostyrene with methacrylic acid and divinylbenzene, followed by nitration, led to hydrophilic, insoluble copolymers which contained dinitrofluorophenol groups and swelled readily in methanol. At room temperature the copolymers absorb up to 54% of the available 4-aminobenzoic acid from a 0.4% solution of 4-aminobenzoic acid in 0.1 N $NaHCO_3$; high molecular weight proteins, on the other hand, are absorbed only to a small extent or not at all. The copolymers react with a 2% diastase solution in 0.1 N $NaHCO_3$. The enzyme activities obtained were determined by iodometric study of the degradation of starch. The enzyme-charged resins retain their activity for long periods on storage under phosphate buffer at 4 °C. Makromolekulare Chem. *91*, 136 (1966) / –Hl. [Rd 554 IE]

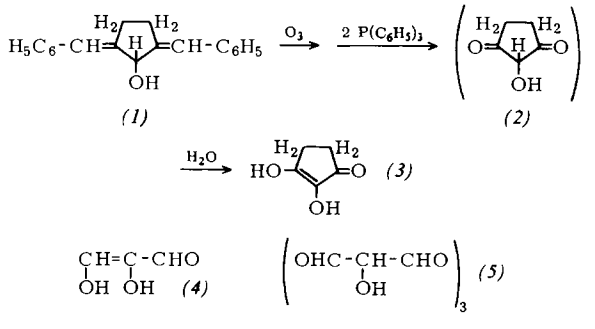
**Cyclopropyldiphenylmethylpotassium (α-cyclopropylbenzhydrylpotassium)** *(1)* was obtained by *A. Maercker* and *J. D. Roberts* from the ether *(2)* by use of sodium/potassium alloy. The NMR spectrum of its THF solution in the region for aromatic protons agrees substantially with that of triphenylmethyl-lithium. The salt *(1)* affords cyclopropyldiphenylmethane almost quantitatively on hydrolysis. Although, when M = MgBr, > 99.7% of the form $(C_6H_5)_2C{=}CH{-}CH_2{-}CH_2{}^{\ominus}M^{\oplus}$ is present in the equilibrium mixture, no indication of this form could be found when M = K.



*(2)* *(1)*

The deep-red color of the potassium compound indicates delocalization of the negative charge into the phenyl rings. With the less electropositive magnesium the effect of the phenyl groups does not suffice to overcome the strain in the three-membered ring. Li is intermediate between K and Mg in this respect. If the red ethereal suspension of salt *(1)* is treated with LiBr, decolorization occurs and carboxylation then leads to a carboxylic acid (72% yield) which gives no $^1$H–NMR signal in the cyclopropane region. Addition of THF to the ethereal solution of *(1)* and LiBr regenerates the color of the cyclopropyldiphenylmethyl anion and carboxylation then gives a mixture of carboxylic acids in which the cyclopropane derivative preponderates. This is the first case of allylmethyl-cyclopropylmethyl rearrangement produced by change of the solvent. / J. Amer. chem. Soc. *88*, 1742 (1966) / –Eb. [Rd 531 IE]

**A new route to reductones** consists, according to *G. Hesse*, *E. Bayer*, and *P. Thieme*, in fission of doubly α,β-unsaturated alcohols such as *(1)* by ozone in $CH_2Cl_2$ or $CH_2Cl_2$/ether at –78 °C. Alcohols of type *(1)* are readily accessible by reduction of α,α′-dibenzylidene ketones with tetrahydroborates. Triphenylphosphine at low temperature is a good reagent for reduction of the ozonide, proceeding by way of

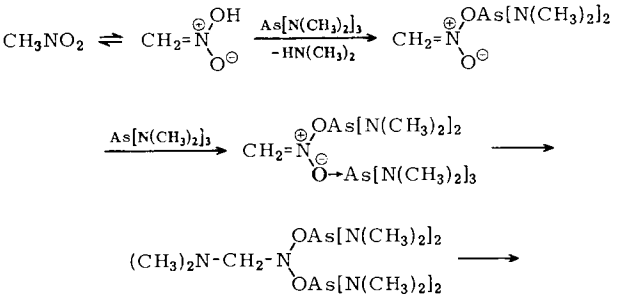


*(1)* *(2)* *(3)*

*(4)* *(5)*

2-hydroxy-1,3-cyclopentanedione *(2)*, which rearranges to the reductone *(3)*. Triose reductone *(4)*, reductic acid *(3)*, and 4,5-dihydropyrogallol are prepared in 41%, 36%, and 29% yield, respectively. In the synthesis of compound *(3)* by ozonization in methanol and subsequent catalytic hydrogenation the hemiacetal of tartronaldehyde is formed and trimeric tartronaldehyde *(5)* can be isolated on cautions concentration of the solution. / Chem. Ber. *99*, 1810 (1966) / –Ma. [Rd 524 IE]

**Amination-dehydration of nitromethane by tris(dimethylamino)arsine** has been observed by *H. Weingarten*. This arsine reacts with nitromethane exothermally, developing large amounts of dimethylamine and dimethylcyanamide *(1)* (80% yield). A possible reaction mechanism is:

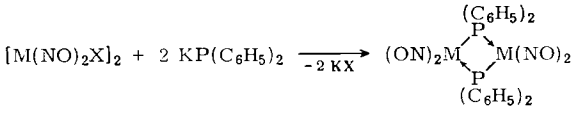


$$(CH_3)_2N{-}C{\equiv}N + 2\ OAs[N(CH_3)_2] + 2\ HN(CH_3)_2$$

*(1)*

/ Chem. Commun. *1966*, 293 / –Ma. [Rd 523 IE]

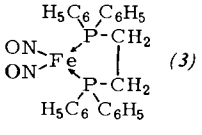
**Nitrosyl compounds of metals of the iron group with bivalent phosphino groups as bridging ligands** have been described by *W. Hieber* and *G. Neumair*. For example, dinitrosyliron bromide and dinitrosylcobalt chloride with $(C_6H_5)_2PK$ in



M : Fe, Co — *(1)*, M : Fe

X : Cl, Br — *(2)*, M : Co

tetrahydrofuran afford the tetranitrosyldi-μ-phosphinodimetal complexes *(1)* and *(2)*, respectively. These products are very stable thermally and chemically; the cobalt compound *(2)* melts at 180 °C (decomp.), the iron compound *(1)* at 310 °C. Reduction of dinitrosyliron iodide with sodium amalgam in THF in presence of an excess of ethylenebis(diphenylphosphine) gives the pale yellow, crystalline ethylenebis(diphenylphosphino)dinitrosyliron, for which structure *(3)* is proposed; the monomeric structure



*(3)*

was supported by osmometric determinations of molecular weight in benzene. Reaction of dinitrosylcobalt chloride with an equimolar amount of ethylenebis(diphenylphosphine) leads to a binuclear complex *(4)* containing phosphino bridges:

$$[Co(NO)_2Cl]_2 + C_2H_4[P(C_6H_5)_2]_2 \rightarrow [Cl(ON)_2Co{\leftarrow}P(C_6H_5)_2{-}CH_2]_2$$

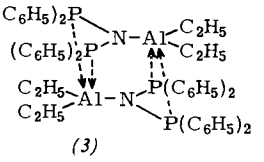
*(4)*

Use of an excess of the phosphine and simultaneous reduction with sodium amalgan gives the reddish-brown, halogen-free, binuclear compound $Co_2(NO)_2[C_2H_4(P(C_6H_5)_2)_2]_3$. The IR spectra of all the compounds are discussed. / Z. anorg. allg. Chem. *342*, 93 (1966) / –Sch. [Rd 533 IE]

**Phosphorus-aluminum compounds with pentacoordinated aluminum** have been described by *D. F. Clemens, H. H. Sisler,* and *W. S. Brey jr.* Triethylaluminum with, for instance, tetraphenyldiphosphine or bis(diphenylphosphino)methylamine gives the complexes *(1)* (m.p. 99–101 °C, yield 60 %) and *(2)* (m.p. 130–132 °C, yield 80 %), respectively. The authors conclude from IR and NMR measurements that the products contain pentacoordinated aluminum.

$(C_6H_5)_2P\text{-}P(C_6H_5)_2 \cdot Al(C_2H_5)_3$ *(1)*

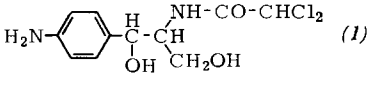
$H_3C\text{-}N[P(C_6H_5)_2]_2 \cdot Al(C_2H_5)_3$ *(2)*



*(3)*

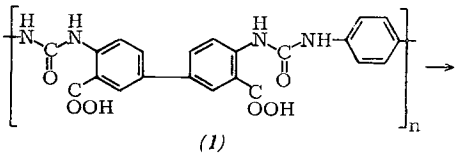
On interaction of bis(diphenylphosphino)amine and triethylaluminum, ethane is evolved and a dimeric compound is formed for which structure *(3)* with pentacoordinated aluminum is proposed. Reaction of tetramethyldiphosphine with triethylaluminum, however, affords a 1:2 adduct $(CH_3)_2P-P(CH_3)_2 \cdot 2Al(C_2H_5)_3$ (b. p. 102 °C / 0.1 mm) containing the usual tetracoordinated aluminum. This difference is ascribed to the higher basicity of tetramethyldiphosphine than of tetraphenyldiphosphine. / Inorg. Chem. *5*, 527 (1966) / –Sch. [Rd 537 IE]

**Chloramphenicol-specific antibodies** have been observed by *R. N. Hamburger* in immunized rabbits. The formation of the antibody was demonstrated by precipitin- and complement-fixation reactions with "reduced chloramphenicol", namely, D-*threo*-1-*p*-aminophenyl-2-dichloroacetamido-1,3-propanediol *(1)* that has been coupled to rabbit-serum albumin. Immunization of the rabbits was effected with *(1)* that had been coupled by diazotization to ox γ-globulin. Reduced chloramphenicol couples also with human serum albumin and affords an antigen for determination of chloramphenicol antibodies. $10^{-5}$ g (= $4\times10^{-4}$ mole) of chloramphenicol suffices for detection by quantitative complement fixation. / Science (Washington) *152*, 203 (1966) / –De. [Rd 538 IE]

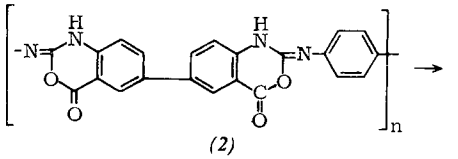


*(1)*

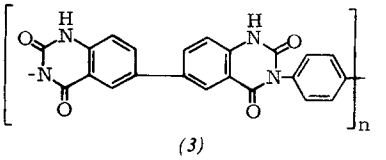
**New thermostable aromatic polyquinazolinediones** have been synthesized by *N. Yoda, R. Nakanishi,* and *M. Kurihara.* Condensation of aromatic diisocyanates (*e.g. p*-phenylene diisocyanate) with 4,4′-diamino-3,3′-biphenyldicarboxylic acid in the melt or in solution at temperatures of up to 180 °C yields a polyurea *(1)*, which, when heated in vacuum at 230 to 320 °C, undergoes cyclodehydration to a polymer *(2)* containing 2-imino-6*H*-2,3-dihydro[1,3]benzoxazine-6-one groups. Further heating leads to intramolecular rearrangement to the thermodynamically more stable polyquinazolinedione *(3)*. When heated in air up to 650 °C at 6 °C/min the polymer *(3)*, the structure of which has been confirmed by IR



*(1)*



*(2)*



*(3)*

analysis, exhibits a weight loss of only 20 %. Under nitrogen this weight loss occurs only at 860 °C. These polymers are also highly resistant to heat. The polyquinazolinediones are stable to strong acids and alkalis, and insoluble in most organic solvents, but soluble in fuming nitric acid and cold concentrated sulfuric acid. / J. Polymer Sci. B, Polymer Letters *4*, 11 (1966) / –Hl. [Rd 555 IE]

# BOOK REVIEWS

**Die Antibiotica** (The antibiotics). Edited by *R. Brunner* and *G. Machek*. Vol. II. Die Mittleren Antibiotica (The medial antibiotics). Verlag Hans Carl, Nuremberg 1965. 1st ed., xvi, 992 pp., bound DM 145.– (*ca.* $36).

This ambitious book on antibiotics, which was written by a group of Austrian scientists, deals with the chemistry, biochemistry, and clinical use of these compounds, and is the first comprehensive German-language work on this important class of substances. The present second volume of the three-volume handbook contains detailed chapters on macrolides, amino acids and oligopeptides, polypeptides, peptolids, antibiotics containing sugars, and polyenes. Special antibiotics containing nitrogen heterocycles and antibiotics with special structures are also discussed. Other chapters deal with the use of antibiotics in animal nutrition, in the conservation of foods, and in the protection of plants. Recent studies on resistance and on semi-synthetic penicillins are discussed in an appendix.

In the individual chapters, experts describe the chemistry, fermentation and biosynthesis, methods of determination, resorption, distribution and elimination, action spectra, action mechanisms, and toxicities of the compounds; their use in human and veterinary medicine is described in particular detail.

More emphasis on stereochemistry would have been desirable in many places, *e.g.* in the discussion of the macrolides. A hydroxyl group has been omitted from the open-chain formula of oleandrose on page 56. While the text is otherwise very lucid, the description of attempts to elucidate the configuration of cycloheximide (p. 630) is rather confusing. The formula given on this page is that of *cis*-(–)-2,4-dimethylcyclohexanone. Contrary to the statement on page 891, the repressor is nowadays regarded as an allosteric protein or as a compound of such a protein with RNA.

The book is outstanding in its layout and contents, and should prove a mine of information for anyone concerned

with any problem in the antibiotics field, particularly since publications that are difficult to obtain are also considered. The literature is covered in part up to 1964, including many patent references. The printing and presentation of the book are very good. However, it would have been better to reproduce the formulae from drawings rather than by typesetting. The volume contains a detailed author and subject index.

*H. Grisebach* [NB 520 IE]

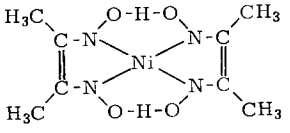
**Advances in Inorganic Chemistry and Radiochemistry.** Vol. 7. Edited by *H. Emeléus* and *A. Sharpe*. Academic Press, New York-London 1965. 1st ed., 449 pp., several illustrations, $15.50.

The present volume[*] reflects a general unrest in current inorganic chemical research, which is overlapping to an increasing extent with the marginal fields of organic chemistry. Thus only two of the six contributions are devoted to pure inorganic chemistry, the "Halides of Phosphorus, Arsenic, Antimony, and Bismuth" by *L. Kolditz*, and the "Hydride Complexes of the Transition Metals" by *M. L. H. Green* and *D. J. Jones*. The organic component makes an appearance in "Phthalocyanines" by *A. B. P. Lever* (despite the fact that this contribution deals with metal-nitrogen bonds), becomes more prominent in "Organoaluminum Compounds" by *R. Köster* and *P. Binger* and in "Carbosilanes" by *G. Fritz*, *J. Grobe*, and *D. Kummer*, and finally becomes dominant in the "Reactions of Chelated Organic Ligands" by *Qu. Fernando*.

The presentation and layout of this volume, as of the earlier ones, is impeccable. Special mention should be made of the editors' constant efforts to include contributions by specialists from all over the world.

The first five contributions named above are consistent with the high regard in which the "Advances" are held. However, the article on "Reactions of Chelated Organic Ligands" leaves one with the impression of having been carried back a century. The ignorance and indifference shown in this article regarding the complicated and versatile bonding, valence, and nomenclature rules for the 10 "inorganic" elements could scarcely be surpassed.

Thus *every* bond, whether ionic or covalent, coordinate, dative back-donation, or hydrogen bond, is indicated by a valence line. Lone electron pairs are not shown, so that the reader is left to deduce the origin of the bonding electrons for himself. This is possible with some loss of time except where the author, from a desire to surround each carbon atom with four valence lines and each nitrogen atom with three, presents completely new structural formulae, as on p. 206 for bis(diacetyldioximato)nickel(II) ("Ni dimethylglyoxime"). Here the diacetyldioxime has become an ethylene derivative, and if one lone electron pair is assigned to each N atom to avoid an electron sextet, the Ni atom must supply at least four electrons for the bonds to the N atoms. According to the author, this complex forms a chlorine adduct with hydrogen chloride:

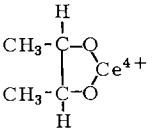


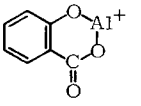
$$(C_4H_7O_2N_2)_2Ni + 2\ HCl \rightarrow (C_4H_8O_2N_2)_2Ni{\cdot}Cl_2$$

Similarly, the reaction of manganese(III) ion with oxalate ion is reported (p. 240) to proceed, *via* a chelate, by regrouping of bonds, and *via* free-radical states, according to the overall equation:

$$C_2O_4^{2-} + Mn^{3+} \rightarrow 2\ CO_2 + Mn^{2+}$$

whereas even first-year chemistry students are taught that electrons cannot disappear in redox reactions. Oxidation numbers and (formal) ionic charges also are mixed up indiscriminately, as in the examples:





Of the five equations in the scheme (LXXXIII) on p. 243, four do not balance; careful perusal of the article reveals an abundance of other errors and absurdities.

To protect the reputation of the "Advances", the editors should in future have the courage to reject such contributions, or at least take the patience to edit them carefully.

*U. Wannagat* [NB 504 IE]

**The Ring Index – A List of Ring Systems Used in Organic Chemistry.** Supplement III (1962–1963) to the 2nd edition. Rings 11525–14265. American Chemical Society, Washington 1965. 1st ed., vi, 546 pp., numerous illustrations, $10.00.

The third supplement to the second edition of the Ring Index has now been published[*]. It contains all the new ring systems described in the literature and referred to in Chemical Abstracts between January 1, 1962 and December 31, 1963. This amounts to a total of 2741 compounds, whereas the corresponding figures for 1960/1961 and 1957–1959 were about 1800 and 2000, respectively. This again reflects the accelerated growth of knowledge in the natural sciences. The ring index now includes 14 265 cyclic systems.

An appendix to the third supplement contains addenda and corrections to the earlier volumes. The addenda consist mainly of names and references for new hydro or dehydro derivatives or for ring systems formerly known only as components of compounds. The corrections also include references to better numbering and alternative nomenclature.

The Ring Index needs no special recommendation. It is so useful that any volume that carries on the good work must be regarded as welcome.

*H. Grünewald* [NB 511 IE]

**CRC Handbook of Chemistry and Physics.** Edited by *R. C. Weast*, *S. M. Selby*, and *C. D. Hodgman*. The Chemical Rubber Co., Cleveland, Ohio 1965. 46th ed., about 1700 pp., numerous illustrations, $16.00.

The 46th edition of the "Handbook of Chemistry and Physics" contains 200 more pages of tables and other information than the 45th edition, so that the book now contains more than 1700 pages and almost 450 tables.

New features include tables on superconductivity, physical constants of organometallic compounds, the thermal conductivity of gases, the surface tension of liquid elements, and trade names of dyestuff intermediates. Other tables have been revised, *e.g.* the table on buffer solution, but in the reviewer's opinion this section is still too brief. For example, a survey of the buffer solutions commonly used in biochemistry is missing.

Several mathematical tables have been rearranged, so that they are now vertical instead of horizontal, and there is no doubt that a new table (23 pages containing every imaginable conversion factor will be particularly welcome.

Special care should be given in future editions to the clear definition of the data listed in the tables. For example, it is not very significant to give values for the toxicity of gases and vapors (in ppm or mg/l) without explaining what has been taken as the measure of toxicity. It is also unfortunate that

[*] Vol. 5 is reviewed in Angew. Chem. *77*, 63 (1965); Angew. Chem. internat. Edit. *4*, 102 (1965), Vol. 6 in Angew. Chem. *78*, 500 (1966); Angew. Chem. internat. Edit. *5*, 530 (1966).

[*] Cf. Angew. Chem. *77*, 688 (1965); Angew. Chem. internat. Edit. *4*, 725 (1965).

the only information offered regarding a table containing values of heats of formation, free energies of formation, the logarithms of the equilibrium constants of the formation reactions, and the entropies of compounds is that "all values are expressed as kilo-cals". The Handbook contains such a wealth of information that it would be regrettable if its value were to be diminished by inaccuracies of this nature.

*H. Grünewald* [NB 512 IE]

**The Organic Chemistry of Titanium.** By *R. Feld* and *P. L. Cowe*. Butterworths, London 1965. 1st ed., viii, 213 pp., 6 illustrations, several tables, bound £2/12/6.

The chemistry of organic titanium compounds has been developing rapidly for more than ten years. Research in this field has received impetus from the discovery of Ziegler catalysts. The scientific and patent literature has become so extensive that a survey of the entire field in the form of this monograph is very welcome. The material has been concisely and lucidly arranged in 12 chapters, and the numerous compounds discussed are summarized in tables together with their properties. Extensive lists of references, also covering the patent literature, are given at the end of each chapter. The following classes of compounds are discussed: organometallic compounds of titanium, titanate esters and ester chlorides, chelates, products of the reaction of titanium compounds with polyalcohols, carboxylic acid derivatives (titanium acylates), compounds of titanium with organic derivatives of other metals, compounds containing the group Ti–O–Si, addition compounds of titanium halides, and derivatives of bi- and trivalent titanium.

The chapters on the organometallic compounds of titanium and their use as polymerization catalysts will find particular interest among specialists, but the selection of the references leaves something to be desired. A welcome feature of this book is the fact that the many applications are illustrated on the basis of an extensive patent literature.

On the whole, this handy book provides an excellent survey of the organic compounds of titanium.

*H. Bestian* [NB 522 IE]

**Valence Theory.** By *J. N. Murrell, S. F. A. Kettle*, and *J. M. Tedder*. John Wiley & Sons Ltd., London 1965. 1st edit., xiii + 401 pp., numerous figs., bound £2.10.– (about $7.–).

In recent years theoretical chemistry has become of ever increasing importance in the training of chemists. So it is understandable why the number of new books, and in particular of introductory textbooks, in this field is very great. According to the preface, *Murrell, Kettle* and *Tedder*'s "Valence Theory" is intended for first year chemistry students and for graduates who have not specialized in theoretical chemistry. It is divided into two parts: The first five chapters give a descriptive account of the atomic theory and the foundations of the theory of chemical bonding; it is intended for the beginner. The second and by much the larger part of the book demands a knowledge of the fundamentals of differential, integral, and vector calculus; it offers a more mathematical description of the quantum-mechanical methods of theoretical chemistry. In 13 chapters it treats atomic theory, MO and VB theory, ligand-field theory, π-electron systems, and chemical reactivity. Individual sections are concerned also with electron-deficient compounds, the inductive and the resonance effect, donor-acceptor complexes, and the hydrogen bond. In this way the theoretical methods of organic and inorganic chemistry are clearly presented and explained with examples. Particular mention should be made of the chapter on symmetry and ligand-field theory, which introduces the concepts of group theory extremely briefly but in easily intelligible form and includes detailed examples of its use.

The authors state their aim as closing the gap between the more qualitative description in *Coulson*'s "Valence" and the formal-mathematical treatment in *Eyring, Walter*, and *Kimball*'s "Quantum Chemistry". In this they have been completely successful, not least by means of the numerous problems at the end of each chapter; indeed the mathematically less advanced chemist obtains a complete understanding of the methods of quantum chemistry only by personal intensive participation. There is, therefore, value in the idea of giving indications for solution of the problems in a first appendix and complete solutions in a second.

*Murrell, Kettle*, and *Tedder*'s "Valence Theory" is a book which, it is to be hoped, as many chemists as possible will work through. It is very warmly recommended to all.

*M. Klessinger* [NB 490 IE]

**pH and potentiometrische Titrierungen** (pH and Potentiometric Titrations). By *F. L. Hahn* and *R. E. Fresenius*. Methoden der Analyse in der Chemie (Methods of Chemical Analysis), Vol. 3, Akademische Verlagsgesellschaft, Frankfurt a.M. 1964, 1st ed., x, 110 pp., DM 18.– (*ca.* $4.50).

The first part of this book deals with the calculation of the pH value of aqueous solutions of acids and bases. In keeping with the limited size of this section (12 pages), which is evidently intended as a sort of introduction, the discussion of pH and the calculation or estimation of pH values stops at a rather elementary stage. At the same time a new terminology for acid-base systems ("basacid systems") is suggested, which at first seems rather unfamiliar and unconventional, but which on closer examination convinces by its consistence. The remainder of the book is mainly devoted to the determination of the end-point in potentiometric titrations, and it is repeatedly emphasized that the end-point of a potentiometric titration does not always coincide with the maximum of the recorded curve. Around this central theme are grouped a number of further discussions on various sources of error and on the determination of end-points by interpolation and extrapolation. Unfortunately, the advances in equipment in the last 25 years are completely ignored, apart from a passing reference to the glass electrode and automatic recording titration instruments; moreover, no mention is made of titrations in non-aqueous systems. This is undoubtedly a good book, but it has unfortunately been published 25 years too late. However, the theoretical discussions in the book are still valid; they are consistently thought out and clearly formulated. However, in present-day determinations requiring extreme accuracy, dropwise titrations with a tap buret are no longer used, but are replaced by instrumental methods.

# Relation of Microbes to Blood-Group Active Substances [*]

BY PROF. G. F. SPRINGER

IMMUNOCHEMISTRY DEPARTMENT [**], EVANSTON HOSPITAL AND DEPARTMENT OF MICROBIOLOGY, NORTHWESTERN UNIVERSITY, EVANSTON, ILLINOIS (U.S.A.)

*Substances with blood-group ABH(0) specificity are not confined to human red blood cells. Rather, such substances are ubiquitous antigenic surface structures which Nature has preserved throughout the phylogenetic development from microbes to man. – It could be shown experimentally that so-called "pre-existing natural" antibodies can result from inapparent immunization by these widely distributed antigens. – The blood-group specific structures of bacteria are chemically closely related to the determinant structures of the human blood-group ABH(0) glycoproteins. The situation is more complicated for the blood-group active substances from higher plants; these give extraordinary immunochemical reactions and two of their blood-group specific monosaccharides precipitate antibodies. – Recently the nature of the M and N blood-group antigens of erythrocyte surfaces has been elucidated. They are the main antigens of the second of at least 14 human blood-group systems. These substances, which are glycoproteins, are also excellent myxovirus receptors and inhibitors. The NN antigen is the first reported physically homogeneous, chemically defined and highly blood-group active cell surface structure of human origin. As surface structures, blood-group active substances appear to be frequently endowed with receptor properties in addition to those for blood-group antibodies.*

## 1. Introduction

The title of this article speaks deliberately of blood-group active substances rather than of blood-group substances, since the latter term nowadays generally denotes blood-group ABH(0) and $Le^a$ specific glycoproteins occuring in the epithelial secretions of man and higher animals [1–5]. The term "blood-group substances" is justifiable only on the basis of historical development, *i.e.* the discovery of these substances on the surface of human erythrocytes [1]; their isolation from epithelial fluids shows the dubious nature of this term.

Blood-group active substances, on the other hand, are ubiquitous surface structures possessing receptor properties, which in addition to their function as receptors of antibodies may have other physiologically more important tasks [6]. These surface structures appear to represent the realization of a structural principle which has been retained from the lowest to the highest forms of life through all stages of phylogenetic development [7, 8]. The blood-group active substances, which are by no means confined either to the blood or to man, are receptors in the sense defined by *Paul Ehrlich* [9, 10].

The function of the blood-group substances (at present 14 blood-group systems are known in man, including more than 60 factors) is only partially understood. We shall not discuss

their role in blood transfusion [11,12], in mother-fetus incompatibility [13–15], as bifidus factor [16,17], or their relation to the intrinsic factor [18].

## 2. The Origin of "Pre-existent Natural" Blood-Group Antibodies

Antigens are discovered, determined, and characterized by their ability to react with antibodies, and the discovery of the first blood-group system, ABH(0) [1], was based on the surprising pre-existence of the blood group anti-A and anti-B antibodies. Every individual over 6 months old possesses those blood-group antibodies of the ABH(0) system that are not directed against its own blood-group antigens. Their origin is a long-standing mystery of immunobiology, since it is not necessary that the individual in question should ever have been in contact with erythrocytes containing the corresponding antigens. The prevalent theory of the last 40 years was that these antibodies were hereditary [5,19,20]. It was assumed therefore that the gene controlling the formation of blood group A was linked with a gene controlling the formation of anti-B antibodies. The same was postulated for antigen B and anti-A antibodies. However, antibodies are, by definition, serum globulins formed or modified in response to an antigenic stimulus.

*Madeleine Dupont* [21] proposed that the human anti-blood group A and B isoagglutinins result from exogenous stimuli and represent cross-reacting antibodies. Although this view was discarded even by *Landsteiner* [21a], it was supported by others [5,19–24].

This argument appeared to be amenable to experimentation in at least two ways, particularly after it had become known that blood-group A, B, and H(0) activities are widespread in Nature [24–25a]. First, one could raise animals capable of forming such antibodies under germfree conditions. If the antibodies in question are gene products, they ought to be present to the same degree both in the germfree and in the normal animal; if, on the other hand, they are caused by environmental factors they could be absent from germfree animals. Secondly, it should be possible to increase isoagglutinins of normally low titer by immunization in the "normal" way, *i.e.* by inhalation or swallowing of widespread antigens.

It has been known for a long time that chickens of many races regularly form human anti-B blood-group antibodies when they reach the age of about 20 days [26,27]; these antibodies, too, have been regarded as gene products. We therefore tested the correctness of this assumption in germfree chickens as well as chickens reared under ordinary conditions from the same hatch. It was found [28] (Figure 1) that germfree White Leghorn chickens possessed no anti blood-group B specific antibodies 45 days after hatching, whereas chickens raised under ordinary conditions showed about the same titer as normal humans. Feeding of blood-group B active

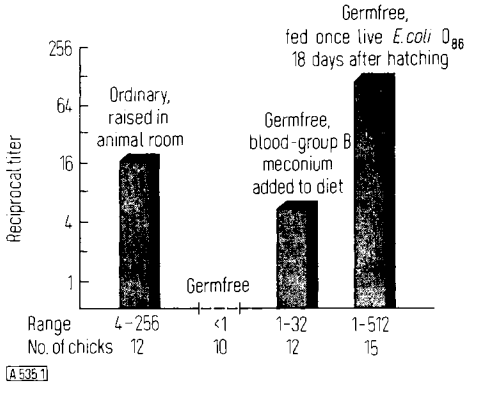

Fig. 1. Anti-human blood-group B isoagglutinins in 45-day-old White Leghorn chicks (average weight of normal chicks 489 g, of germfree chicks 545 g) [28].

meconium extracts or spraying them into the germfree tanks led to a moderate anti-B titer. A single feeding of live blood-group B active *Escherichia coli* $0_{86}$ produced an extremely high anti-B titer in germfree chickens. Feeding of bacteria having no blood-group activity did not lead to the formation of blood-group antibodies.

We also carried out feeding experiments in man [29], although the conditions were not as "ideal" as those described above. The results (Table 1) show that isoagglutinins can result from immunogenic stimuli both in children and in adults. Feeding of *Escherichia coli* $0_{86}$ killed by desiccation to infants suffering from severe diarrhea at an age when they begin to form isoagglutinins led, within one week, to a highly significant 32-fold increase in the titer of anti-B antibodies. The titer began to decrease slightly only after several months. This shows that the ingestion of even dead *E. coli* stimulates *de novo* isoagglutinin formation in infants or increases pre-existing levels in adults suffering from severe intestinal disorders. Such diseased individuals

were chosen since their intestines have an increased permeability towards macromolecules. In order not to upset the intestinal flora, we did not feed living bacteria in large quantities.

These investigations show that "normal" hemagglutinins can develop due to immunogenic stimuli. The findings are important for aspects of blood transfusion and can probably be generalized. Only the antibody-producing apparatus is inherited, but not the specific antibodies themselves [29–31].

## 3. Blood-Group Specific Substances in Bacteria

*E. coli* $O_{86}$ with which the experiments mentioned in Section 2 were carried out has an unusually high blood-group activity, but blood-group specificity is not rare among gram-negative bacteria, which constitute the bulk of the human intestinal flora (Table 2). Of 282 bacterial strains, 137 showed A, B, or 0 specificity or a combination thereof [32]. Only a random selection of these bacteria is shown in the table; also the activities were frequently low.

Table 2. Distribution of blood-group activity among gram-negative bacteria [32].

| Genus | Strains tested | $A_1$ | B | H(0) | $A_1BH(0)$ | $A_1B$ | $A_1H(0)$ | BH(0) | Inactive |

The immunological simulation of human blood-group ABH(0) substances by toxic bacterial lipopolysaccharides can go so far that they become adsorbed onto human erythrocytes and thus change the genetically determined blood-group specificity of the red cells [33, 34]. This has to be taken into account in blood transfusions. Further, the ability of the erythrocytes with their enormous surface area to bind toxic substances of this type suggests a transport and detoxifying function of red blood cells that has so far been largely neglected [33–35]. These functions and the possibility of therapeutic application of soluble erythrocyte membrane components to block toxins are being investigated in our laboratory [34].

We shall now discuss the chemical and immunological relations between bacterial B specific substances isolated from *E. coli* $O_{86}$ and the glycoprotein from human ovarian cysts. Table 3 shows that the isolated lipopolysaccharide is at least as active as highly purified human glycoprotein from ovarian cysts. We have further shown that *E. coli* $O_{86}$ not only specifically inhibits hemagglutination and stimulates the formation of anti-B antibodies, but also absorbs anti-blood-group B antibodies [24, 32, 33]. Hyperimmune anti-B sera retard the growth of *E. coli* $O_{86}$ in the absence of complement [24], and kill this bacterium if complement is present [36]. This is the first demonstration of a pathophysiological role of blood-group antibodies outside the field of the blood groups proper.

The blood-group active complex was extracted from *E. coli* $O_{86}$ B:7 with pyridine/water [37] or phenol/water [38], fractionally precipitated with ethanol [33], and ultracentrifuged until two-dimensional agar-gel diffusion showed only one line with human anti-blood-group B serum. The sugar components of this lipopolysaccharide and of the human glycoprotein obtained from ovarian cysts are shown in Table 4. All blood-group active bacteria studied contained at least three of the

four sugars which are characteristic of the human blood-group ABH(0) specific glycoprotein. In each case the sugar mainly responsible for the specificity of a human blood-group substance was also present in the corresponding bacterial substance [32].

The blood-group specificity of human glycoproteins is based on recurring oligosaccharide chains spread over the surface of the macromolecule [39,40]. We therefore investigated whether similar structures are responsible for the B specificity of bacterial antigens [41, 34]. Mild acid hydrolysis of the purified lipopolysaccharide with a water-soluble ion-exchange resin [41] produced dialysable blood-group B specific oligosaccharide fractions, which could be obtained by preparative paper chromatography in a yield of about 5% by weight [34, 8, 41]. The most active of these preparations is about 10 times as active as α-D-galactopyranosyl-(1→3)-D-galactose, the active disaccharide of the human B blood-group substance [42, 40, 39]. Quantitative analysis of the products of total hydrolysis of the bacterial oligosaccharides (12 hours, 2 N HCl, 100 °C) indicated them to be penta- to octasaccharides [34,41].

Although the composition of these oligosaccharides is similar to that of the human blood-group B specific structures obtained by mild acid hydrolysis, they differ in important aspects. The oligosaccharides isolated from bacteria are more active; this may be explained by the fucose present in each case (1 molecule per oligosaccharide) [34,41], which is absent from the blood-group B specific oligosaccharides of human origin obtained by acid hydrolysis [39,40,42]. A further difference is the presence of galactosamine in the bacterial oligosaccharides [34,41], as opposed to the presence of glucosamine in the human oligosaccharides [39,42,40]. All B active *E. coli* $O_{86}$ oligosaccharides contained glucose, which is absent from human B glycoprotein [4,5], and which is not involved in B specificity [6].

D-Galactose must be linked to *E. coli* $O_{86}$ terminally by an α-glycopyranosidic linkage, since coffee-bean α-galactosidase destroys the blood-group B activity of the macromolecule as well as of the oligosaccharides isolated from it with liberation of galactose; concomitantly, blood-group H(0) activity occurs *de novo* [43]. These findings correspond to those obtained with oligosaccharides from ovarian cyst glycoproteins [44,45]. The coffee-bean α-galactosidase uncovers non-reducing fucose structures which become accessible to eel anti-H(0) antibodies.

After exposure to α-galactosidase, an increase in the cross-reactivity of the macromolecule with antipneumococcus type XIV horse serum could be observed [34], suggesting that non-reducing β-galactosyl units (probably linked to *N*-acetylhexosamine) are present on the surface of the molecule [45a]. This is consistent with our observation that *E. coli* β-galactosidase [46] liberates galactose [34] after the α-glycosidically linked galactose has been split off. β-*N*-Acetylhexosaminidase [47] liberates 1 mole of *N*-acetylgalactosamine from oligosaccharides pretreated with both galactosidases.

On the basis of the chemical, serological and enzymatic investigations described above and in analogy to the findings of other authors on blood-group B specific structures in man [39,40], it seems possible that the oligosaccharide structure shown in Fig. 2 occurs in *E. coli* $O_{86}$ and is responsible for its blood-group B specificity.

*O*-α-D-Gal-(1→3)-*O*-β-D-Gal-(1→3 or 1→4)-GalNAc-R
|
α-L-Fuc

Fig. 2. Tentative formula of the blood-group B active structure occurring in *E. coli* $O_{86}$. R contains glucose and may also contain galactose and galactosamine [34,43].

Rigorous chemical proof of this structure, however, is still lacking. Serological results support the view that the fucopyranosyl residue is linked to the subterminal β-galactosyl by an α-glycosidic linkage, since H(0) specificity developed *de novo* as a result of treatment with α-galactosidase of the lipopolysaccharide (after dialysis) and of B active oligosaccharides obtained from it [43, 34]. The linkage of a fucosyl residue to a β-galactosyl structure does not prevent the hydrolytic removal of the β-galactosyl group (5 days' incubation, enzyme:substrate, 1:3 by weight) [47a]. A related structure differing in that it contained *N*-acetylglucosamine instead of *N*-acetylgalactosamine and fucose linked to

it has recently been observed in *Salmonella* group U [48]; this salmonella group carries the 0 antigen 43, the blood-group B specificity of which has been described earlier [32].

It is apparent that the chemical findings on the blood-group active oligosaccharides of gram-negative bacteria are consistent with the earlier, purely immunological observations [24, 25, 25a, 28, 32, 33, 49] of the close relation of structures of *E. coli* $0_{86}$ and of other bacteria to the human blood groups ABH(0).

## 4. Blood-Group Specific Substances in Higher Plants

We found blood-group specific substances not only in bacteria, but also in higher plants and viruses. These blood-group active antigens are not to be confused with plant agglutinins [50]. For the active substances isolated from the yew tree *(Taxus cuspidata* and *baccata)* as well as from the sassafras tree *(Sassafras albidum)*, the chemical situation differs from that observed for blood-group active substances in bacteria [51–54]. We were able to isolate physico-chemically homogeneous polysaccharides from the twigs of these plants by extraction with water and fractionation with organic and inorganic solvents. As an example, Table 5 shows data for the sassafras polysaccharide.

Table 5. Physical data for the highly purified blood-group H(0) active sassafras polysaccharide [54].

The blood-group H(0) activity of these preparations, measured with eel antiserum, is as high as that of the most active preparations of human origin (Table 6). In contrast to the human blood-group glycoproteins, these plant polysaccharides inhibit human, rabbit, or plant anti-H(0) agglutinins only weakly or not at all, but they are antigenic, though only in a minority of the immunized chickens and rabbits [24, 54].

Table 6. Carbohydrate components of blood-group H(0) active macromolecules [32, 51, 52, 54].

| | Human glycoprotein | *Sassafras albidum* polysaccharide | *Taxus cuspidata* polysaccharide | *E. coli* $O_{128}$ lipo-polysaccharide |

| | | Rhamnose | Glucose | Heptose(s) |
| | D-Galactose | Galacturonic acid | | |

Not only hemagglutination inhibition, but also agar-gel diffusion and strictly quantitative precipitin tests (Fig. 3) have shown that blood-group H(0) substances of man and from yew (not shown in Fig. 3) and sassafras are immunologically equivalent when measured with eel serum, although the three substances differ considerably

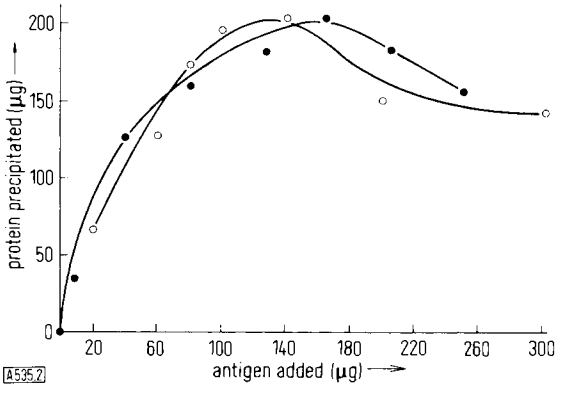

Fig. 3. Precipitation of human H(0) active glycoprotein (○) (Morgan human ovarian cysts 277/PI/WS PR XXXIII) and H(0) active polysaccharide from Sassafras (●) (Sassafras C-70 PR XXIV) with eel anti-H(0) serum [54].

in their chemical properties. Although the molecules are of approximately the same size [4, 52, 54], the blood-group H(0) active substances from plants, unlike those of human origin, contain neither nitrogen nor fucose, although the L-form of this sugar in α-glycopyranosidic linkage has been considered to be predominantly responsible for the blood-group H(0) specificity of human H(0) substances [55, 56]. Rather, 2-*O*-methyl-L-fucose

was found to be the blood-group active sugar in the yew [51,52], a sugar up to that time not known to occur in Nature. The blood-group specificity in the sassafras polysaccharide is based on the very rare 3-*O*-methyl-D-galactose [54]. Table 6 shows the composition of some blood-group H(0) active antigens. Galactose is the only sugar that sassafras polysaccharide and human ovarian cyst glycoprotein have in common. This sugar, however, does not play a primary role in the blood-group H(0) activity, and is H(0) inactive [55–58]. Among the other monosaccharides of the sassafras polysaccharide, only arabinose could be expected to be blood-group H(0) active [55,57]; however, it proved to be the D-enantiomer [54], whereas only the L-form is active. Remarkably, the sassafras polysaccharide molecule contains 355 3-*O*-methyl-D-galactose residues (based on a molecular weight of $2.5 \times 10^5$) [54]; one molecule of H(0) cyst substance contains about the same number of blood-group active sugar residues in the form of L-fucose [59]. The composition of the sassafras polysaccharide is shown in Table 7.

Table 7. Components of the blood-group active sassafras polysaccharide [54].

| Structural units | % | Moles per mole sassafras polysaccharide |
|---|---|---|
| 3-*O*-Methyl-D-galactose | 25.0 | 355 |
| Rhamnose | 26.0 | 445 |
| Xylose | 9 | 171 |
| Galactose | 8 | 124 |
| Galacturonic acid | 5.6 | 78 |
| L-Arabinose | 5 | 95 |
| Glucose | 2 | 31 |
| Acetyl | 11.33 | 660 |

The close immunological relation between the blood-group H(0) specific macromolecules of man and of higher plants as shown by four different methods, *i.e.* hemagglutination inhibition, quantitative immunoprecipitation, two-dimensional agar-gel diffusion, and immunization is surprising, as the blood-group substances in man, in *Taxus*, and in *Sassafras* are chemically completely different. These findings point to the limitations of immunological methods, particularly when heterologous reagents such as most blood-group antibodies are used (see [54]). However, the unreliability of immunochemical reactions may be apparent rather than real as will now be shown [54,60,68].

## 5. On the Specificity of Heterologous Immunochemical Reactions

We studied the problem of the identical blood-group specificities of different sugars by means of synthetic model substances [57,53], and by investigating natural products containing methyl sugars [58]. Some cardiac glycosides and antibiotics have the same serological specificity when measured with certain reagents as the human blood-group substance H(0), although they are quite different chemically [58]. This is illustrated by the structure of the active odoroside H which arises from inactive odorotrioside G monoacetate by removal of two molecules of glucose or one of gentiobiose (as well as one acetyl group) [61] (Fig. 4). A similar situation

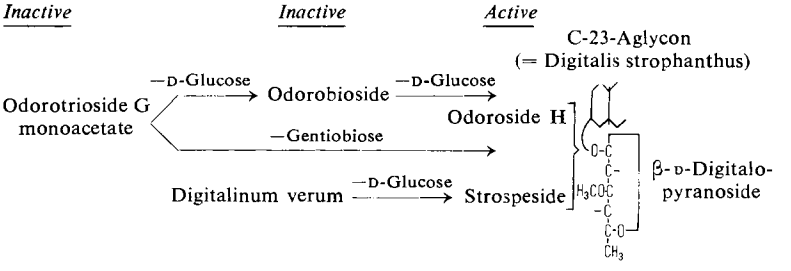

Fig. 4. Transformation of blood-group H(0) inactive into H(0) active cardiac glycosides

pertains to the transformation of inactive Digitalinum verum to active strospeside (Fig. 4). If an unusual sugar such as digitalose (3-*O*-methyl-D-fucose) is a constituent of a cardiac glycoside, it is always directly linked to the aglycon [62]. Only digitalose-containing substances having this sugar in terminal position are active [58].

It will be seen from the immunochemical reactions described so far that antibodies,if their specificity is known, may serve as reagents in the elucidation of chemical structures provided interpretations are advanced with caution. Thus, linkage and nature of uronic acid were correctly predicted in a polysaccharide where it occurred only once per approximately 40 sugar units [63]. We successfully used eel serum and the related *Lotus tetragonolobus* reagent [58] to predict the position of the second *O*-methyl group in the D-fucose of the cardiac glycoside strebloside [64], as well as the position and ring form of the blood-group active sugar 3-*O*-methyl-D-fucose in the disaccharide part of the antibiotic chartreusin [65,66].

All substances found to be blood-group H(0) active by means of eel serum or lotus reagent had a hapten with at least one methyl group. We therefore investigated systematically the methyl ethers of L- and D-fucose and of D-galactose and their methyl glycosides. A number of these compounds were synthesized and crystallized for the first time [57,53]. Table 8 shows some striking

L-fucose (for a complete list of active as well as inactive fucose and galactose methyl ethers and their methyl glycosides see [53,54,57]. These observations did not at first seem to fit in with the classical view of the specificity and especially stereospecificity of serological and biological reactions in general; a plausible explanation was advanced by *Kabat*, however [67].

Not only enantiomorphs, but also quite different sugars such as L-fucose and 3-*O*-methyl-D-galactose can possess equal activities. These results were first obtained with semiquantitative hemagglutination inhibition assays. Strictly quantitative precipitin inhibition tests led to the same result [57,53]. Our experiments and conformation studies on models have shown [53,54,60] that the minimal complementary structure for the eel antibody is smaller than a single sugar and hence can be present in several otherwise unrelated monosaccharides [53,54,57,60]. Such a small complementary structure has so far never been considered for either anti-carbohydrate or anti-protein antibodies. This minimum complementary structure appears to consist of a methyl substituent attached equatorially to a pyranose ring; adjoining is an ether oxygen. On a contiguous C atom is an axial oxygen-carrying substituent in *cis* position to the methyl group. The situation is similar for the anti-H(0) reagent of *Lotus tetragonolobus*.

Another phenomenon difficult to reconcile with the concepts of classical immunochemistry was observed in our studies on fucose and galactose methyl ethers: the anti-H(0) antibodies of most, but not all, eel anti-H(0) sera could be precipitated with 3-*O*-methyl-D-fucose and 3-*O*-methyl-D-galactose [54,60] (Fig. 5). The precipitate consists of the anti-H(0) specific protein of the eel serum, which in the ultracentrifuge behaves as a single component with the properties of a 7 S γ-globulin [68,54,60]. The antibody can be recovered quantitatively from the precipitate, and shows unchanged activity in the hemagglutination and precipitin tests [60,68]. The two precipitating sugars probably are the smallest uncharged haptens yet described that are capable of precipitating antibodies [54]. The precipitation can be specifically inhibited with haptens such as α-methyl-L-fucopyranoside and 2-*O*-methyl-L-fucose.

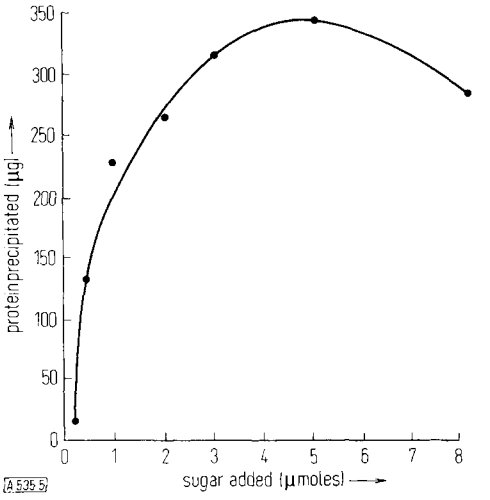

Fig. 5. Precipitin curve obtained with eel anti-H(0) serum and 3-*O*-methyl-D-fucose [60,68]. (Antiserum, 0.5 ml eel M', total test vol. 1.5 ml.)

The mechanism of this precipitation is difficult to explain on the basis of the lattice theory, since these low molecular weight haptens have no characteristic recurrent groups, such as would be required to create a three-dimensional network between hapten and eel antibody units. Vapor-pressure osmometry and cryoscopy gave no indication of aggregation of the sugar molecules in solution [68]. However, both haptens carry at least one lipophilic group, which can enter into "hydrophobic bonding". *Karush* [69] assumes that each non-polar group in an antigenic determinant [*] has a decisive influence on the stability of an antigen-antibody complex. The situation in our case, however, is complex since certain modifications such as reduction on C-2 or 2-*O*-methylation and/or methylglycosidation of the two 3-*O*-methyl sugars abolish their precipitating ability and convert them into potent neutralizing haptens (Table 9) [60,68].

We also found substances in higher plants which neutralize specifically and in low concentration the

effect of antibodies of the rhesus system (Rh) [70]. Table 10 shows the results obtained with extracts of lilac and forsythia branches. As can be seen, lilac extracts inhibited all antibodies of the Rh system. The extracts were even more active than rhesus-active preparations from human erythrocytes [71]. The plant material, however, had physical and chemical features quite different from those of the human material. Lignin components kindly given us by Prof. *K. Freudenberg* [72] were also found to be active. Dr. *Ph. Levine* informed us that lilac extracts precipitate in agar with anti-Rh sera. Caution must be exercised in interpretation of these surprising observations in spite of their specificity. It remains to be shown that the inhibitors react with the combining site of the antibody directly and not in a way akin to an allosteric effect.

## 6. Blood-Group Specific Substances in Viruses

Myxoviruses were studied as representatives of the viruses. The last two aspects of this review will be discussed using them as an example. One is a problem of their surface structure and the other one of the substrate of their action. Influenza viruses type A and B as well as fowl-pest virus were investigated with regard to their blood-group activity [73–75].

All viruses were cultivated in chicken eggs. All virus preparations and vaccines, including chromatographically purified preparations, showed significant A blood-group and Forssman antigen specificity in their non-dialysable residue, which retained its antigenicity. This activity could not be separated from the intact virus and increased with increasing purification (see Table 11). The A-like substances of the influenza and fowl-pest virus probably are components from the cytoplasm of the host [76–80]. Chicken embryos are known to contain A blood-group antigen and Forssman antigen [81–83]. Treatment of myxoviruses with ether led to the enrichment of the A activity mainly in the ether phase; some also seemed to be associated with the hemagglutinins [75]. Subcutaneous injection of the macromolecular part of commercial influenza virus vaccine and of highly purified influenza viruses into human volunteers led to the formation of considerable quantities of anti-A isoagglutinin and isohemolysin [74, 75, 84] (Table 12).

Table 11. Blood-group activity of influenza virus preparations (macromolecular part after heating at 95 °C) [74].

| Preparation | C.C.A. [a] | Smallest amount (mg/ml) [b] which completely inhibits 4 agglutinating doses of the following antisera: | |
|---|---|---|---|
| | | $A_1$ | $A_2$ |

The extremely close relationship between the A blood-group and the Forssman antigens has also been proved chemically[85]. Our experiments were carried out with relatively large amounts (3-5 protective doses of influenza virus vaccine) of chicken-egg grown influenza virus preparations. The possible deleterious effects of vaccination with such substances for mother-fetus relationships (*e.g.* mother blood group 0, fetus blood group A) especially for abortions and the high degree of cytotoxicity of the Forssman antibody have been discussed elsewhere[74,85,85a]. The problem of immunizing the mother with substances which share antigenic components with the embryo but not with the mother is of general importance because of the possible ensuing damage to the fetus. According to our investigations, the A-like antigen seems to be a component of the host cytoplasm, which is incorporated almost unchanged and may be enriched by the myxoviruses. It therefore seems probable that influenza viruses in persons infected with it incorporate the host's own blood-group active substances which are not normally antigenic for the host. Thus an increase in isoagglutinin titer as a result of ordinary influenza virus infection seems unlikely[74] and has not been observed in more recent epidemological studies[86].

## 7. The Blood-Group Substances of the MN System

This report began with human blood-group substances and at its conclusion we return to them. We and somewhat later a group of Finnish workers have discovered a second relation between influenza viruses and blood-group substances[87,88]: Influenza viruses specifically destroy the main antigens of the second human blood-group system[89,90], the MN system (Table 13). After publication of these results, other workers contributed to the elucidation of the chemical nature of the MN

Table 13. Action of influenza viruses and "Receptor Destroying Enzyme" on human red-cell antigens [87]. The blood-group antigens $A_1$, B, H(0), Le$^a$, Le$^b$, S, s, P, Jk$^a$, K, k, Fy$^a$, Rh$_o$, rh', rh'', hr', and hr'' are not inactivated.

blood groups[91–93]. We succeeded in isolating highly active, immunogenic MM, MN, and NN substances from erythrocytes. These are glycoproteins[6,8,94–96]. More recently, we obtained an N-like glycoprotein in satisfactory yield from human meconium[6,8,95,96].

The method of isolation of these antigens consisted in gentle extraction of either erythrocyte stroma or crude meconium in the presence of electrolytes, differential centrifugation and fractionation on agar gel as well as Sephadex columns with preceding and subsequent precipitation by organic and inorganic solvents followed by renewed differential centrifugation and final electrodialysis[96]. Heating damaged the erythrocyte substances biologically and chemically. We obtained the N and N-like antigens in physico-chemically homogenous form[95] and characterized them biologically and chemically[6,8,94–96].

Table 14 contains physical data for the NN antigen and the antigen isolated from meconium (Me–Vg). The NN antigen has a somewhat higher molecular weight and a somewhat higher diffusion coefficient, but a lower viscosity than the meconium substance[95]. The high $f/f_0$ values point to a marked asymmetry of the two preparations. Both antigens are levorotatory, and absorb between 255 and 282 mμ. The strongly negative charge of the glycoproteins was shown by their migration, as a single band, to the anode between pH 4.5 and 9.2. The NN antigen behaved on Whatman No. 1 paper like human serum albumin, and the Me–Vg antigen like α-globulin. The mobility of both antigens was somewhat lower on cellulose acetate.

Table 14. Physical data on highly purified blood-group N active human antigens [95].

| | Erythrocyte Antigen (NN) Ca 825 | Meconium Antigen (Me–Vg) Ca 851 |
|---|---|---|
| $S_{20,w}$ (S) | 12.8 ($c$ = 0) | 10.8 ($c$ = 0) |
| $10^7$ $D_{20,w}$ (cm$^2$ sec$^{-1}$) | 1.67 [a] | 1.41 ($c$ = 0) |
| $\bar{V}$ (ml/g) | 0.68 | 0.63 |
| $M_w$ | 595000 | 520000 |
| $f/f_0$ | 2.34 | 2.96 |
| $[\alpha]_D^{29}$ ($H_2O$, 1 dm) | −27.0° ($c$ = 0.1) | −32.4° ($c$ = 0.5) |
| $\eta_{rel}$ (0.85% NaCl, 37.5 °C) | 1.052 [b]; 1.099 [c] | 1.707 [b]; 2.408 [c] |
| $A$ 1%/274 mμ | 10.90 | 4.49 |

[a] Average of values at 8.9 and 4.4 mg/ml; not concentration dependent.
[b] $c$ = 0.5%. [c] $c$ = 1.0%.

A striking feature is the apparent ability of the NN antigen to dissociate into subunits. Thus one preparation obtained by us earlier by only slightly harsher means had a molecular weight of 150000, *i.e.* a quarter of

that given in Table 14. The existence of aggregation-disaggregation phenomena in the red-cell antigens is further supported by the following observations: the asymmetry of the boundaries of our preparation in the ultracentrifuge [95], as well as the extraction from erythrocytes with hot alkaline phenol solution [97], of a glycoprotein having similar chemical and biological properties to those of the substance described here [6,8,96] but with a molecular weight of only about 30000. Moreover, an inhomogeneous NN antigen preparation dissociated into subunits of molecular weight of 30000 after addition of alkyl sulfate detergents [98]. It must be emphasized that the NN antigen with the highest molecular weight also showed by far the highest activities (based on equal weights). The isolated antigens are nearly lipid-free [96].

macromolecule. Table 15 (columns 3 and 4) clearly shows that different human anti-N sera possess different specificity. But all human sera differ in their affinity from those produced in rabbits. Yet human *and* rabbit antisera react with parts of the same receptor surface, those of rabbits apparently with a larger area [96]. The agglutinin from *Vicia graminea*, on the other hand, reacts with a surface structure of the NN macromolecule different from that responsible for N specificity. Our results [100a,96] indicate that the *Vicia* reagent, contrary to widely held belief, does not react with part of the NN specific receptor but either with a genetic precursor of both, the NN and MM antigens, or that the *Vicia* specificity is heterophile and accompanies these antigens only accidentally.

Table 15. NN and Me–Vg antigens: activity *in vitro* and enzymatic inactivation [96].

| Antigen | Treatment | Smallest amount (mg/ml) inhibiting agglutination of human erythrocytes by 4 agglutinating doses | | | | |
|---|---|---|---|---|---|---|
| | | Anti-N | | | | |
| | | Man (Armst.) | Man (Kon. SN-6, Stur 25543) | Rabbit [55–57] | *Vicia graminea* | Influenza virus PR 8 |
| NN [a] | None | 0.01–0.02 | 0.6–2.0 | 0.1 | 0.003–0.005 | 0.003 |
| Ca 825 | R.D.E. [b] | N.A. [c] | N.A. | N.A. | 0.003 | 0.425 |
| | Trypsin | N.A. | N.A. | 2.5 | N.A. | 0.135 |
| Me–Vg [a] | None | N.A. | N.A. | N.A. | 0.1 | 0.03 |
| Ca 851 | R.D.E. | N.A. | N.A. | N.A. | 0.1 | > 1 |
| | Trypsin | N.A. | N.A. | N.A. | 0.1 | 0.03 |

[a] Inactive with 3 human and 4 rabbit anti-M sera.
[b] Receptor Destroying Enzyme.
[c] N.A. = no inhibition of agglutination with 10 mg/ml or less.

Biological data for the two antigens are given in Table 15. The antigens are not only blood-group substances of high activity, but also, as can be seen from the last column, extremely potent myxovirus inhibitors. The meconium antigen was less active when tested with influenza virus of type A (PR 8 and Melbourne) but it was 4 times as active as the NN antigen against the B strain of type Maryland 1/59 [96].

NN and MM substances are good antigens; they are useful for production of blood-group specific antisera [6, 8,96]. The meconium (Me–Vg) antigen possesses the serological specificity measured with the *Vicia* reagent. N specificity is not demonstrable either with human or animal antisera. Its immunogenicity in the production of anti-N sera is poor. Only 1 of 17 rabbits formed anti-N specific antibodies after immunization with Me–Vg antigen [96].

The NN antigen is an excellent example of the mosaic structure of blood-group antigens in general [100,96]. Investigations of its serological properties showed that antibodies of different origin with the same overall specificity are nevertheless adapted to react preferentially with not absolutely identical structures on the same

The isolated NN antigen showed signs of damage to its biological activity towards some human anti-N antibodies in spite of the relatively mild extraction and purification procedures (Table 15, column 4) [96].

Influenza viruses and "receptor destroying enzyme" (R.D.E.) of *Vibrio cholerae* and *Clostridium perfringens* as well as proteolytic enzymes destroy blood group N activity and also the antiviral properties of the NN antigen. Treatment of the NN antigen and the desialized NN antigen with galactose oxidase or *D.pneumoniae* β-galactosidase destroyed *Vicia* specificity. It is remarkable that galactose oxidase destroyed in addition N specificity measured with human anti-N serum (Armstrong) and, to a lesser extent, that measured with rabbit serum [96]. Neither of the two latter enzymes affected the antiviral activity. The receptor properties of the NN antigen determined with the plant extract from *Vicia graminea* were also inactivated by proteases but not by sialidases. Analogous results were obtained with all these enzymes on the MM antigen [6,8,96]. α-Galactosidase, *E. coli* β-galactosidase, β-hexosaminidase, and lysozyme had no influence on the blood-group and virus receptors of the NN and MM antigens. None of these enzymes inactivated the *Vicia* receptor of the Me–Vg antigen [96].

Enzymatic hydrolyses first showed the importance of sialic acid for blood-group N and M specificity [87,88,91, 93,96] as did mild acid hydrolysis [100a,96]. Our most recent findings with galactose oxidase and the analysis of

[97] *R. H. Kathan, R. J. Winzler,* and *C. A. Johnson,* J. exp. Medicine *113*, 37 (1961).

[98] *A. Morawiecki,* Biochim. biophysica Acta *83*, 339 (1964).

[100] *A. S. Wiener, J. Moor-Jankowski,* and *E. B. Gordon,* J. Immunology *92*, 391 (1964).

[100a] *Y. Nagai* and *G. F. Springer,* Federat. Proc. *21*, 67d (1962).

dialysable degradation products of the NN antigen indicate that galactose probably is necessary for full N activity of the macromolecule or haptens isolated from it. This galactose is present either in subterminal position or less likely as a branch adjoining sialic acid. This interpretation is based not only on the effect of galactose oxidase on the N activity but also on the composition of the blood-group N specific haptens obtained by mild acid and pronase hydrolysis. These haptens possessed as carbohydrate components 1–2 *N*-acetylneuraminic acid residues per 1–2 galactose residues. The presence of hexosamine may not be essential for activity [96, 101]. Dialysable hexosamine- and sialic acid-containing structures have also been isolated which either have no activity [96] or which were not examined for activity [102]. *Vicia*-receptor specificity of the NN and MM antigens appears to depend on galactose [99, 96] in β-glycosidic linkage [96]. Therefore sialyl, sialyl-galactopyranosyl and β-galactopyranosyl groups appear to determine virus and blood-group specificity.

NN and Me–Vg antigens are glycoproteins. Galactose is the predominating carbohydrate (molar basis) in both antigen preparations discussed here. However, in some earlier NN preparations sialic acid was the most abundant carbohydrate by a small margin [8]. Both antigens contain large amounts of *N*-acetylneuraminic acid, galactosamine, glucosamine, and mannose and the Me–Vg antigen also a large quantity of fucose. The ratio glucosamine:galactosamine is *ca.* 0.75, an extraordinarily low figure for a glycoprotein. Both antigens, but especially the Me–Vg substance, possess components with chromatographic properties of *N,O*-diacetylneuraminic acid; these substances have hitherto not been found in man [8, 96].

Table 16. Carbohydrate components of highly purified NN and Me–Vg antigens [96].

| Structural units | NN-antigen Ca 825 | | Me–Vg-antigen Ca 851 | |
|---|---|---|---|---|
| | (wt-%) | Moles per mole antigen | (wt-%) | Moles per mole antigen |
| Acetylneuraminic acid | 16.2 | 312 | 10.4 | 175 |
| Galactosamine | 4.32 | 144 | 7.50 | 217 |
| Glucosamine | 3.1 | 103 | 15.03 | 436 |
| Galactose | 11.1 | 367 | 20.3 | 586 |
| Mannose | 5.4 | 179 | 7.5 | 216 |
| Glucose | 0.3 | 10 | 1.7 | 49 |
| Methylpentose | 0.7 | 25 | 8.4 | 266 |

Tables 16 and 17 show the composition of both antigens. The values add up to approximately 100% since the NN antigen contains approximately 10% of water and 2.5% of ash; these figures are 14 and 0.7% for the Me–Vg antigen. The molar ratio sialic acid:total hexosamine:galactose is close to 1:1:1 in the NN antigen and almost 1:4:5 in the Me–Vg antigen.

Table 17. Amino acid analysis of the NN and Me–Vg antigens [96].

| Amino acid | NN-antigen (wt-%) | [a] | [b] | Me–Vg-antigen (wt-%) | [a] | [b] |
|---|---|---|---|---|---|---|
| Aspartic acid | 2.93 | 131 | 6.3 | 0.92 | 36 | 6.3 |
| Threonine | 4.26 | 213 | 10.3 | 2.99 | 131 | 22.8 |
| Serine | 3.58 | 203 | 9.8 | 1.34 | 66 | 11.5 |
| Glutamic acid | 4.21 | 170 | 8.2 | 1.04 | 37 | 6.4 |
| Proline | 2.93 | 151 | 7.3 | 1.85 | 83 | 14.4 |
| Glycine | 1.46 | 116 | 5.6 | 0.55 | 38 | 6.6 |
| Alanine | 2.21 | 148 | 7.2 | 0.72 | 42 | 7.3 |
| Valine | 3.07 | 156 | 7.5 | 0.57 | 25 | 4.3 |
| Isoleucine | 2.52 | 114 | 5.5 | 0.37 | 15 | 2.6 |
| Leucine | 4.07 | 185 | 8.9 | 0.72 | 29 | 5.0 |
| Tyrosine | 1.78 | 58 | 2.8 | 0.15 | 4 | 0.7 |
| Phenylalanine | 1.85 | 67 | 3.3 | 0.33 | 10 | 1.7 |
| Lysine | 2.31 | 94 | 4.5 | 0.35 | 13 | 2.3 |
| Histidine | 2.08 | 80 | 3.9 | 0.25 | 8 | 1.4 |
| Arginine | 2.54 | 87 | 4.2 | 0.35 | 10 | 1.7 |
| Methionine | 2.46 | 98 | 4.7 | 0.92 [c] | 28 [c] | 4.9 [c] |
| Sum | 44.26 | 2071 | | 13.42 | 575 | |
| Tryptophan | 0.00 | | | 0.01 | | |
| $NH_4^+$ | 0.77 | 255 | | 0.77 | 222 | |
| Methionine sulfoxide | | | | 0.06 | | |

[a] Moles of amino acid/mole of antigen (nearest whole number).
[b] Moles amino acid/moles total amino acid.
[c] Including methionine sulfoxide.

Threonine, serine, leucine, and glutamic acid are the predominant amino acids in the NN substance, whereas proline ranges before serine, and alanine is fourth in the meconium antigen. The sum of acidic amino acids amounts to approximately three quarters and that of the basic ones to two thirds of the hydroxyamino acids in the NN antigen; the corresponding figures for the Me–Vg antigen are one third and one sixth. Both antigens are characterized by their low content of aromatic amino acids (except proline); tryptophan and cystine are absent. The amino acid composition of both antigens resembles that of the ABH(0) blood-group substances from ovarian cysts [103, 104].

It was attempted to elucidate the nature of the carbohydrate-peptide linkage in both antigens by alkali degradation following the procedures of *Anderson, Hoffman,* and *Meyer* [105] and *Kabat* and associates [106]. The results are given in Table 18. Galactosamine and galactose as carbohydrates, and threonine and serine as amino acids are the constituents involved in this linkage in both antigens since they are destroyed by β-elimination [96]. In addition, 30% glucosamine is destroyed in

Table 18. Components of NN and Me–Vg antigens, destroyed by 0.5 N NaOH at 23 °C (63 hours) [96]. (Other structural units were not destroyed).

| Component | % Destruction NN Antigen Ca 825 | Me–Vg Antigen Ca 851 |
|---|---|---|
| Hexosamine, total | 48 | 43 |
| Galactosamine | 80–90 | 61 |
| Glucosamine | 0 | 30 |
| Galactose | 66 | *ca.* 30 |
| Threonine | 48 | 46 |
| Serine | 39 | 34 |
| Tyrosine | 56 | 0 |

the Me–Vg antigen. The results further indicate for both antigens destruction of part of the carbohydrates by an additional "peeling reaction" since approximately twice as many sugar residues as amino acid residues are destroyed in the NN antigen; the proportion is even 5:1 for the Me–Vg antigen [96].

It can be concluded from the sum of the chemical and biological results that the sugar chains have a length of only 4–6 monosaccharides in the NN antigen but that they must be considerably larger in the meconium antigen. The immunological specificity is probably determined by small oligosaccharide groupings on these chains: multiple units of not more than 2 sugars for *Vicia* specificity and not more than 4 for human N specificity (measured with the Armstrong anti-N serum). The total number of chains with N specificity as determined with human anti-N serum is at most approximately 300 per molecule of antigen Ca 825 [96].

The MM and NN antigens possess more than one biological function. Therefore they can serve as models not only in blood-group serology, biochemical genetics of man and in virology but in a number of other fields. The NN antigen is the first physically homogeneous, chemically defined cell membrane component of a mammal which possesses blood-group activity of the same order as that of the best ABH(0) glycoproteins, determined with their corresponding antibodies, but isolated from body secretions.

# Isotope Effects in Organic Chemistry and Biochemistry

BY PROF. H. SIMON AND DR. D. PALM

CHEMISCHES INSTITUT DER FAKULTÄT FÜR LANDWIRTSCHAFT UND GARTENBAU, WEIHENSTEPHAN, AND ORGANISCH-CHEMISCHES INSTITUT DER TECHNISCHEN HOCHSCHULE MÜNCHEN (GERMANY)

*The present article shows the extent to which isotope effects are likely to be encountered in the use of isotope techniques and what problems are studied with primary and secondary isotope effects. By way of example, the results of studies on E2 reactions, particularly in the Hofmann degradation, are discussed, followed by a discussion of some "analytical isotope effects". Finally, the problems encountered and the information that can be obtained from isotope effect studies on enzyme reactions, and the advantages and disadvantages of competitive and non-competitive techniques are described. In addition to a survey of isotope effects in dehydrogenase reactions, new isotope effects encountered in the dehydrogenation of T-labeled alcohols are reported.*

## I. Introduction

When stable or radioactive isotopes are used as tracers in organic chemistry and biochemistry, it is usually assumed that the various nuclides of an element behave in the same way, *i.e.*, that there is no discrimination between labeled and unlabeled molecules in chemical or physical operations. However, quantitative investigation shows that some such discrimination does exist. These isotope effects [1–9a] are due mainly to differences in the masses of the nuclides and the resulting differences in the zero-point energies of the bonds (cf. Fig. 1). Some (very small) isotope effects are due to other properties of the nuclei, such as the quadrupole moment and the magnetic moment.

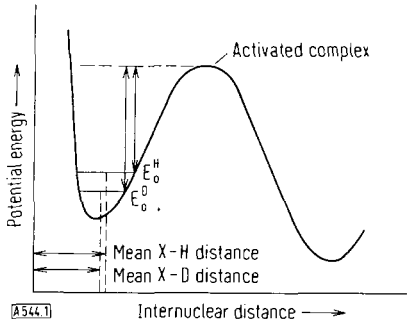

Fig. 1 Potential energy of a molecule HX and of the transition state. The asymmetry of the potential energy curve (exaggerated for clarity) results in a slightly shorter equilibrium internuclear distance in DX than in HX. The different zero-point energies $E_0^H$ and $E_0^D$ lead to different activation energies for reactions of HX and DX (arrows) and are the principal cause of the kinetic isotope effect.

The smaller the relative difference between the masses of two nuclides, the less pronounced are the isotope effects. Thus already in the carbon isotopes the isotope

effects generally are not very important. On the other hand, isotope effects must always be taken into account in the use of the hydrogen isotopes, since often experimental results can be interpreted only in this way, particularly in a reaction in which bonds formed by the hydrogen isotope itself or adjacent bonds are broken.

The main reasons for the publication of more than 100 original papers and several reviews[5–8] on isotope effects alone in 1964 are:

1. The so-called *kinetic isotope effect* can be used in the study of reaction mechanisms.

According to the theory of absolute reaction rates[9a,b], the kinetic isotope effect is equal to the quotient of the equilibrium constants for the formation of the transition states in the unlabeled and labeled compounds, respectively (cf. the discussion of equilibrium isotope effects under 2 below). The calculation is therefore possible when the vibrational frequencies of the ground state and of the transition state of the reactants are known[3,4,9,9a,10]. The frequencies in the transition state are unknown; the frequencies in the ground state and the isotope effect, however, can be measured. One can therefore obtain information about the transition state in this way. *Wolfsberg* and *Stern*[10] and *Willi*[11–13] calculated theoretical isotope effects for concrete transition states on the basis of the ideas developed by *Bigeleisen* and others [1–4]. Computer programs have been developed for the calculation of the influence of various parameters on the isotope effects[10,10a].

The problems most frequently studied in current experimental work are that of the rate-determining step of a sequence of reactions and that of the extent to which a bond has already been broken or formed in the transition state.

2. The *equilibrium isotope effects* observed in exchange equilibria are of industrial importance in isotope separation. For example for the exchange reaction used for the production of heavy water[14],

$$H_2O + HDS \underset{k_2}{\overset{k_1}{\rightleftharpoons}} HDO + H_2S$$

the equilibrium constant at 25 °C is $k_1/k_2 = K = 2.2$ (this is an extreme value, most values being nearer to 1).

The knowledge or estimation of equilibrium isotope effects also is of interest in the preparation of compounds labeled with hydrogen isotopes and in biochemical studies. In biochemical reaction sequences, *e.g.* glycolysis, proceeding in tritiated water it is found that for reversible reaction steps resulting in equilibration, the hydrogen isotope content of a given position in the intermediates differs from the isotope content of the water only because of an equilibrium isotope effect. However, if reversibility is incomplete, the isotope contents are smaller, since the splitting of a water molecule always involves an intramolecular isotope effect, which frequently amounts to about 3.5–4 in the case of HOD and about 7 in the case of HOT (cf. Section V.4).

The equilibrium constant for the distribution of an isotope between two molecules A and B in the reaction A + B′ ⇌ A′ + B is given by

$$K = \frac{Q_{A'}\,Q_B}{Q_A\,Q_{B'}} \prod^{3n-6} \frac{e^{-1/2u_{A'}}}{e^{-1/2u_A}} \prod^{3n-6} \frac{e^{-1/2u_B}}{e^{-1/2u_{B'}}}$$

where

$n$ = number of degrees of freedom
$Q_i$ = partition function of $i$-th molecule in the ground state
$u = h\nu/kT$
$h$ = Planck's constant
$\nu$ = frequencies of the normal modes
$k$ = Boltzmann's constant
$T$ = absolute temperature.

At the temperatures normally encountered in organic chemistry and biochemistry, the equation

$$K = \frac{e^{-\Sigma h\nu/2kT_{(A')}}\;\; e^{-\Sigma h\nu/2kT_{(B)}}}{e^{-\Sigma h\nu/2kT_{(A)}}\;\; e^{-\Sigma h\nu/2kT_{(B')}}}$$

holds approximately. For the complete calculation of examples see[9a,14a].

There is a close relation between equilibrium isotope effects and reaction mechanisms. Thus the change in rate constants when $D_2O$ is used instead of $H_2O$ as solvent for acid- or base-catalysed reactions is often used to distinguish between different mechanisms[15–20a]. However, definite conclusions can be drawn only if the order of magnitude of the isotope effect for a certain mechanism can be calculated theoretically. Equilibrium isotope effects are important in geology also[21,22].

3. As will be shown in Section V, isotope effects are very important in biochemistry, and will contribute further to a deeper insight into biochemical mechanisms.

4. So-called "analytical isotope effects" are observed in analytical tracer studies. Labeled compounds generally can be used only if they can be purified to constant specific radioactivity by recrystallization, distillation, or a continuous distribution method. Owing to isotope effects, this is sometimes impossible because of incomplete establishment of exchange equilibria and kinetic effects.

## II. Primary and Secondary Kinetic Isotope Effects

### 1. Primary Isotope Effects

According to the theory of absolute reaction rates [9a,9b], the maximum kinetic isotope effect at a given temperature is obtained when the bond is completely broken in the transition state. However, in the removal of a proton from a carbon atom by a base, for example, the proton becomes bonded to the base B as it is removed from the carbon. The maximum isotope effect therefore occurs at the point of "half-separation" C···H···B. If, on the other hand, the proton in the transition state is more strongly bonded to the C atom (C··H····B), or to the base (C····H··B), the isotope effects are smaller.

The mathematical treatment of this effect is given by *Westheimer* [23] and by *Bigeleisen* [9]. On the basis of theoretical considerations and calculations, however, *Willi* and *Wolfsberg* [23a] concluded that a pronounced maximum of the isotope effect as a function of the breaking and formation of bonds in the transition state depends on the form of the potential barrier separating the reactants from the products. No experiments confirming this view appear to have been published.

In reactions involving several stages, isotope effects can naturally be observed only if the bond to the isotope is broken in the rate-determining step (primary isotope effect). The maximum isotope effect in the rupture of carbon-hydrogen bonds is generally $k_H/k_D$ [*] = 8.3 at 0 °C, $k_H/k_D$ = 6.9 at 25 °C, *etc.* [4]. However, this is true only if the proton transfer takes place without tunnelling [24a].

In the 2,6-lutidine-catalysed iodination of [2-D]-2-nitropropane for example, it was found that $k_H/k_D$ = 24 at 25 °C, whereas in the same reaction with pyridine as catalyst $k_H/k_D$ = 9.8 [24]. It was concluded that sterically hindered slow proton transfers can in general exhibit extremely large isotope effects. The electrophilic aromatic substitution of D or T generally exhibits only slight kinetic isotope effects or none at all [6]. However, larger values can occur under certain steric conditions. In the bromination of 1,3,5-tri-t-butyl[2-D]benzene in the presence of silver ions it was found that $k_H/k_D \geqslant 3.6$ [26d], and a value of 4.75 was obtained in the bromination of deuterated 2,4-dibromo-1,3,5-trimethoxybenzene [26e]. In oxidations [27–32], on the other hand, the hydrogen isotope effects are usually close to the maximum value.

Isotope effects for tritium are often calculated from those for deuterium with the aid of the equation [25]

$$(k_H/k_D)^{1.44} = k_H/k_T$$

(but cf. also [26]).

In addition to the relatively large isotope effects of the hydrogen isotopes, many effects with the nuclides $^{13}C$, $^{14}C$, $^{15}N$ $^{18}O$, and $^{34}S$ or $^{35}S$ have been measured [4].

Values of up to 1.086 at 11 °C [26a] have been reported for $k_{12C}/k_{13C}$ in $S_N2$ reactions; in $S_N1$ reactions, on the other hand, the isotope effects are much smaller, and sometimes even inverted [26b]. The effects for $^{12}C/^{14}C$ may be assumed to be twice as large. In the decarboxylation of [*carboxy*-$^{14}$C]benzoic acid and its derivatives, isotope effects of 1.068 to 1.18 have been observed at 210 and 238 °C [26c], whereas the maximum value expected was 1.057 [3]. Most of the values found for $k_{14N}/k_{15N}$ are less than 1.03.

Other types of reactions in which primary isotope effects have been measured for the nuclides D,T, $^{13}C$, $^{14}C$, $^{15}N$, and $^{34}S$ are solvolysis, decarboxylation, elimination, fragmentation, and isomerization [4]. A review has also been published [32a] on isotope effects in the unimolecular decomposition of simple alkanes and alkyl radicals. An example of isotope effects in metal-catalysed reactions is the decomposition of deuterated formic acids [32b].

### 2. Secondary Isotope Effects

Detailed and critical treatments and reviews of the secondary isotope effect have been published by *Halevi* [8] and others [33]. In the secondary isotope effect, no bond to the nuclide in question is broken in the rate-determining step. Here also equilibrium and kinetic isotope effects can be distinguished.

The difference in the dissociation constants of $C_6H_5-CH_2-COOH$ and $C_6H_5-CD_2-COOH$ ($K_H/K_D$ = 1.12) is a secondary equilibrium isotope effect. Similarly, $C_6H_5-CD_2-NH_2$ is a stronger base than

$C_6H_5-CH_2-NH_2$ ($K_a^H/K_a^D = 1.13$)[34]. These values appear to be uncertain, and isotope effects of 1.06[34] to 1.03[34a] have been reported for $CH_3COOH$ and $CD_3COOH$. On the other hand, the differences in the rates of the Hofmann degradation of

$$(CH_3)_3N^{\oplus}C^{\alpha}HT-C^{\beta}H_2-C^{\gamma}H_3\ OH^{\ominus} \qquad (1)$$

$$(CH_3)_3N^{\oplus}-C^{\alpha}H_2-C^{\beta}HT-C^{\gamma}H_3\ OH^{\ominus} \qquad (2)$$

(if HOH, and not HOT, is eliminated), and

$$(CH_3)_3N^{\oplus}-C^{\alpha}H_2-C^{\beta}H_2-C^{\gamma}H_2T\ OH^{\ominus} \qquad (3)$$

in relation to the unlabeled compound are secondary isotope effects. In the case of *(1)*, a so-called α-isotope effect occurs in the breaking of the C–N bond, and a β-isotope effect in the breaking of the $C^{\beta}$–H bond; *etc.*

Following *Streitwieser*[34b], *Halevi*[8] distinguishes between secondary isotope effects of the first and second kind. The criterion for this distinction is whether or not the bond to the isotope changes its steric orientation as a result of the reaction. For example, the transition of a deuterated C atom from $sp^3$ to $sp^2$ hybridization is an effect of the first kind, as is the Hofmann degradation of *(1)* and *(2)*; the degradation of *(3)*, on the other hand, is an effect of the second kind.

Since a methyl group, for example, often is completely deuterated, the isotope effects are generally referred to 1 D (*e.g.*, $\Delta\Delta F = (RT/n)\ln(k_H/k_D)$, where $n$ is the number of D atoms per molecule).

*Collins*[35] also found an example of a secondary $^{14}C$ isotope effect in the reaction of $C_6H_5-{}^{14}CO-CH_3$ with 2,4-dinitrophenylhydrazine ($k_{12C}/k_{14C} = 1.0085 \pm 0.0004$). However, it is doubtful whether any conclusions can be drawn on the basis of such small effects.

The theories on the secondary isotope effect are involved and in part contradictory[8, 33]. Therefore we shall give only a few physical facts that are closely related to the chemical reactivity, and frequently confirmed rules on the direction and magnitude of the effects in various types of reactions.

There are fundamentally two views:

1. Secondary isotope effects may be regarded as substituent effects, a C–D bond having a stronger +I effect than a C–H bond[8, 10, 13, 33, 34, 36, 37] and a $CD_3$ group exhibiting weaker hyperconjugation than a $CH_3$ group[53].

2. Secondary hydrogen isotope effects can be explained by the smaller bulk of deuterium[33a], *i.e.* by the smaller amplitude of vibration of D as compared with H[41].

Hydrogen isotope substitution affects dipole moments, nuclear quadrupole coupling constants, and optical activity. From the slight anharmonicity of the molecular energy function (Morse function)[9b], it is possible (cf. Fig. 1) to derive a small difference in electron distribution between C–H and C–D bonds, resulting in slight bond shortening and slightly stronger electron donation by a C–D bond than by a C–H bond[8].

The dipole moments of $ND_3$, $CD_3ND_2$, DCNO, and $(CH_3)_3CD$ are 0.01 to 0.04 Debye larger than those of the corresponding hydrogen compounds[38–38b]. It can therefore be stated that a C–D bond exerts a stronger inductive effect than a C–H bond. Thus $C_6H_5-CD_2-COOH$ and $C_6H_5-CD_2-\overset{\oplus}{N}H_3$ are less dissociated than the undeuterated compounds. The influence of deuterium becomes particularly clear in a comparison of the nuclear quadrupole coupling constants of $CH_3X$ and $CD_3X$ (X = halogen). The C–X bonds are more strongly ionic in the deuterated compounds.

The same conclusion is reached by a study of the effect of deuteration on the chemical shifts of nuclear magnetic resonance signals. The $^1H$ signals of $-CH_2D$ are displaced by 0.015 ppm relative to those of $-CH_3$[39], and the $^{19}F$ signals of $-CF_2D$ by 0.60 ± 0.05 ppm relative to those of $-CF_2H$[40]. However, in a recent comparison of *m*-fluorotoluene and [*methyl*-$D_3$]-*m*-fluorotoluene, the expected shift of the $^{19}F$ signal was not observed[40a]. Electron spin resonance measurements on deuterated benzene, naphthalene, and cyclooctatetraene also failed to show any stronger electron-donating action of deuterium[40d].

The C–D bond is less polarizable than the C–H bond; this property results in optical asymmetry in compounds of the type $R^1R^2CHD$. A theory developed to explain the optical activity due to isotope effects is based on the interaction of light with the various atoms and isotopes[40c]. *Streitwieser*[36] refers to the similarity of the optical rotatory dispersion curves of $CH_3-CH_2-CH_2-CHD(OH)$, $CH_3-CHD(OH)$, and $CH_3(CH_2)_5CH(OH)-CH_3$[40b].

It is concluded from these facts that this "electronic isotope effect"[8] may be treated as a true substituent effect. The effect of replacement of a hydrogen atom in a C–H bond by D is qualitatively similar to that of replacement by a $CH_3$ group. The replacement of a $CH_3$ by a $CD_3$ group has a similar effect to that of replacement by $C_2H_5$ or even by $(CH_3)_3C$.

The "transmission" of isotope effects *via* multiple bonds and benzene nuclei has been discussed by *Shiner* and *Kriz* [53].

The effects observed on replacement of H by D or T can be explained in another way: *Bartell* [41] believes that both the α- and the β-deuterium isotope effects are due to the greater amplitude of vibration of C–H bonds as compared with C–D or C–T bonds. The repulsive forces between H atoms are consequently greater than those between H atoms and deuterium or tritium, or between deuterium atoms or tritium atoms. Moreover, the repulsion between non-bonded atoms fixed to an $sp^3$ carbon atom is greater than that between atoms attached to C atoms in the $sp^2$ state. Consequently, the energy gain resulting from the decrease in repulsive forces in going from $sp^3$ to $sp^2$ hybridization is greater in protium compounds than in deuterium or tritium compounds. It may be deduced from this that in a transition from the $sp^3$ to the $sp^2$ state, H compounds will react faster than D or T compounds; this is a well established rule [36,42–46]. The reverse is true in transitions from the $sp^2$ to the $sp^3$ state [8,46,47].

This has also been confirmed for a free-radical reaction. In the polymerization of styrene, [α-D]-, [β,β-$D_2$]-, [α-T]-, and α,β-*trans*-$T_2$-styrene react faster than unlabeled styrene [47a].

The smaller bulk of $CD_3$ groups as compared with $CH_3$ groups has been clearly shown by *H. C. Brown* [33a]. The quaternization of 2-trideuteriomethylpyridine exhibits an inverse secondary isotope effect of 0.97 with methyl iodide, 0.96 with ethyl iodide, and 0.935 with isopropyl iodide. The value found for 2,6-bis(trideuteriomethyl)pyridine was 0.92. Since 3-trideuteriomethylpyridine and 4-trideuteriomethylpyridine exhibit only insignificant isotope effects, *Brown* considers any explanation of secondary isotope effects other than by steric effects as unacceptable.

The same conclusion is suggested by the fact that only 2,6-bis(trideuteriomethyl)pyridine has a greater heat of reaction (by 0.23 kcal/mole) with $BF_3$, than the undeuterated compound, and not the 3- and 4-methyl compounds.

*Streitwieser et al.* [48] first demonstrated the influence of D in the α-position in $S_N1$ solvolyses (transition state with $sp^2$ character), and interpreted it as being due to the higher energy gain of the H compound on transition from the $sp^3$ to the $sp^2$ state in the activated complex. They described an approximation with which $k_H/k_D$ can be determined from the (generally known) vibration frequencies of the unlabeled starting material and of the product. Values of 1.12 to 1.15 are found for $k_H/k_D$ of many acyclic compounds, and somewhat higher values for cyclic compounds [8,33].

Very small or even inverse isotope effects are observed in $S_N2$ reactions. Thus we found [49] $k_H/k_T = 0.96$ for the quaternization of pyridine with [T]methyl iodide (see also [8]). The solvolysis of halides and tosylates has been intensively studied [50,51]; inverse isotope effects were observed throughout this work. (Cf. also calculations by *Willi* [13]).

The possibility of using secondary isotope effects to obtain a better insight into the course of solvolysis reactions has been discussed by *Lee* and *Wong* [52]. In the solvolysis of [1,1-$D_2$]-2-cyclopentylethyl, [1,1-$D_2$]-2-(2-cyclopentenyl)ethyl, and [1,1-$D_2$]-2-(3-cyclopentenyl)-ethyl *p*-nitrobenzenesulfonates, an appreciable isotope effect is observed only for the third compound, for which $k_H/k_D = 1.07$ per D. It was concluded from this result that the transition state has partial $S_N2$ character, and in agreement with *Streitwieser* [34], that neighboring group effects are involved.

In the formation of methyl radicals from 1-trideuteriomethyl-2-phenylethyl hypochlorite an α-deuterium isotope effect of 1.15 per D was observed, in good agreement with the results obtained in $S_N1$ reactions and unimolecular thermal cleavages [46].

That the secondary isotope effect of $k_H/k_D = 1.09$ in the hydrolysis of [1,1,1-$D_3$]-4-chloro-4-methyl-2-pentyne [53] depends very little on the solvent is strong evidence that the hyperconjugation of a $CD_3$ group is weaker than that of a $CH_3$ group, since steric effects cannot be involved in this case [53].

In addition to the much-studied $S_N1$ and $S_N2$ reactions [54], secondary isotope effects have been used to investigate Diels-Alder reactions [55]. The results suggest a four-center reaction with a transition state situated largely on the reactant side.

Other steric isotope effects due to deuteration have been observed in the racemization of 9,10-dihydro-4,5-dimethylphenanthrene [56]. Samples deuterated in the methyl or methylene groups racemize more rapidly. A distinct isotope effect was also observed in the racemization of 2,2′-dibromobiphenyl-4,4′-dicarboxylic acid [57].

## III. Isotope Effects in E2 Reactions such as the Hofmann Degradation

The study of isotope effects in E2 reactions is interesting in that *two* bonds in the transition state are broken "simultaneously". One may therefore ask, *e.g.* in the Hofmann degradation of quaternary cations of the type $(CH_3)_3N^{\oplus}-C^{\alpha}H_2-C^{\beta}H_2-R'$, how this "simultaneous" rupture depends on R, *i.e.* isotope effects can be used in an attempt to establish whether the rupture of the C–N bond or that of the $C^{\beta}$–H bond is faster. We therefore determined the $^{14}C$ and T isotope effects in the Hofmann degradation of the quaternary ammonium cations listed in Table 1 [42–44].

Table 1. Summary of the primary $^{14}C$ and T isotope effects ($IE_{exp}$) found by us [43–45], and comparison with some D isotope effects found by various authors (recalculated for T) in the Hofmann degradation of quaternary ammonium cations $(CH_3)_3N^{\oplus}R$.

| R | $IE_{exp.}$ converted to 40 °C [a] | R | $IE_{exp.}$ converted to 60 °C [a] | Ref. |
|---|---|---|---|---|
| $^{14}CH_2-CH_3$ | 1.05 [b] | $CH_2-CH_2T$ | 3.0 [a, b] | [43–45] |
| $^{14}CH_2-CH_3$ | 1.06 [b] | $CH_2-CH_2T$ | 2.8 [a, b] | [43–45] |
| $^{14}CH_2-C_2H_5$ | $1.07_3$ | $CH_2-CHT-CH_3$ | $2.8_6$ [a] | [43–45] |
| $^{14}CH_2-CH_2-C_6H_4-NO_2$-*p* | $1.03_4$ | $CH_2-CHT-C_6H_5$ | 4.2 [a] | [45] |
| $^{14}C(CH_3)_3$ | $1.06_4$ | $CH_2-CHT-C_6H_4-NO_2$-*p* | 8 ± 1.6 [a] | [45] |
| $CH_2-^{14}CH_2-CH_3$ | $1.03_8$ | | 12 ± 4 | [66] |
| | | $CH_2-CD_3$ | 14 | [60] |
| | | $CH_2-CD_2-C_6H_5$ | 3.9 | [59] |

[a] For experimental details, conversion of the values found at various temperatures to 40 or 60 °C, discussion of error, *etc.*, see [43–45].

[b] Various conditions.

Though isotope effects were already known for the breaking of $C^{\beta}$–H bonds [58–60], the only value known for the rupture of the C–Y bond (Y = N,S) was $k_{32S}/k_{34S} = 1.0015$ for the elimination of dimethyl sulfide from β-phenethyldimethylsulfonium bromide [61]. Later this value was revised to 1.0065 [61a].

*Arey et al.* found [62] a $^{15}N$ isotope effect of 1.017 for $(CH_3)_3N^{\oplus}-CH_2-CH_3$ at 60 °C and 1.009 for $(CH_3)_3N^{\oplus}-CH_2-CH_2-C_6H_5$. The electron-attracting phenyl group therefore decreases the isotope effect in the rupture of the C–N bond. Our $^{14}C$ isotope effects (Table 1) are in good agreement with this conclusion and showed even more clearly that the isotope effect is increased by electron donors such as methyl groups (cf. R = $C_3H_7$ with R = $C_2H_5$), and greatly decreased by electron-attracting groups such as *p*-$NO_2-C_6H_4$.

The determination of the isotope effect of $(CH_3)_3N^{\oplus}C(CH_3)_3$ was of interest, since the t-butyl group exhibits particularly small isotope effects in $S_N1$ reactions, presumably because of the strengthening of the bonds between the tertiary carbon and the methyl groups in the carbonium ion [63]. As can be seen, the tertiary butyl group exhibits no peculiarities in the Hofmann degradation.

$k_{32S}/k_{34S}$ for $(CH_3)_2S^{\oplus}-C(CH_3)_3$ is 1.007 [64]. The $^{15}N$ isotope effect in the degradation of $(CH_3)_3N^{\oplus}-CH_2-CH_2-C_6H_4-X$-*p*, where X = H, $CH_3O$, and Cl, does not vary with X [65].

Whereas the isotope effects found for the rupture of the C–N bond were mutually compatible and reasonable, this was not so for the cleavage of the $C^{\beta}$–H bond when all known values were taken into account. The tritium isotope effects found by us and the isotope effects from the literature are listed in Table 1. For ease of comparison, all values are converted to 60 °C and the deuterium values were converted to tritium values [45].

It can be seen that the tritium isotope effect with substituents in the β-position increases in the order $CH_3 \leqslant H < C_6H_5 < C_6H_4-NO_2-p$ [*].

As can be seen, a large hydrogen isotope effect in the Hofmann degradation is accompanied by a small carbon isotope effect, and *vice versa*. What does this tell us about the transition state? For electron-attracting groups, such as phenyl and *p*-nitrophenyl, the hydrogen isotope effects are large, showing that the release of the proton must have reached approximately the half-way stage in the transition state ("half-release", cf. Section II.1). The question then arises of whether the release of the proton in the presence of alkyl groups has progressed beyond or has not yet reached the "half-released" state, since smaller isotope effects are observed in this case.

[*] *E. M. Hodnett* and *J. J. Sparapany*, Pure appl. Chem. *8*, 385 (1964), reported a much smaller value; however, this was not determined directly as in the earlier measurements by *Hodnett* [66] and by us [45], but was found indirectly from the kinetic and secondary isotope effects. This procedure seems unsuitable in view of the polymerization of *p*-nitrostyrene.

The value for $(CH_3)_3N^{\oplus}-CH_2-CD_3$ [60] deviates strongly from this sequence. Since the primary object of these studies [60] was not the determination of the isotope effects, a relatively large error is possible: *V. J. Shiner* and *M. L. Smith*, personal communication.

A group R that facilitates the removal of a proton (relative shift of the E2 elimination to a transition state with carbanion character) may be assumed to hinder the release of a leaving group that takes the electron pair with it, and *vice versa*. It may also be assumed that a negative charge on $C^{\beta}$ cannot be stabilized by an alkyl group, and that under the influence of the positive charge on the nitrogen, the irreversible displacement of electrons to form the products consequently occurs already on slight loosening of the $C^{\beta}$–H bond in the transition state. In the case of aryl groups, the negative charge formed can be better stabilized, so that the proton can move farther away before the irreversible electron transfer takes place.

These assumptions are supported by the secondary isotope effects. If the transition state in the Hofmann degradation were similar in structure to the final products, relatively large secondary isotope effects should occur. However, as we have found for the quaternary ammonium cations with R = $CH_2$–CHT–$CH_3$, $CH_2$–$CH_2$–$CH_2T$, and CHT–$C_2H_5$, this is not so; we obtained values of 1.33, 1.10, and 1.10 respectively [43].

These conclusions are in disagreement with the assumption [67,68] that in the Hofmann degradation of quaternary ammonium cations the rupture of the $C^{\beta}$–H bond is already relatively far advanced in the transition state. Since the isotope effect of the ethyl compound [60] (R = $CH_2$–$CD_3$) is much greater than that of the phenethyl compound (R = $CH_2$–$CH_2$–$C_6H_5$), *Ayrey et al.* [62] also assumed that the $C^{\beta}$–H bond has reached the "half-release" stage in the ethyl compound, and has progressed beyond this stage in the phenethyl compound. However, since our extensive measurements showed that the ethyl and propyl compounds (R = $CH_2$–$CH_2T$, $CH_2$–CHT–$CH_3$) have a much smaller isotope effect than the phenethyl and nitrophenyl compounds(R = $CH_2$–$CH_2$–$C_6H_5$, $CH_2$–CHT–$C_6H_4$–$NO_2$-*p*), the conclusions of *Ayrey et al.* [62] agree with ours only in that the rupture of the $C^{\beta}$–H bond is further advanced for compounds with electron-attracting groups than for compounds with alkyl groups.

In our opinion, the Hofmann degradation shows clearly what is involved in the determination of isotope effects and what conclusions can be drawn. Particularly for hydrogen isotope effects, a definite conclusion can be drawn only from a large value (cf. however [23a]). It is advantageous to label all points of a molecule at which bonds are broken of formed, and to determine whether or not isotope effects occur. Generally it is also useful to study a reaction as a function of the substituents at the reacting centers.

Systematic studies of this type were carried out [69] for the Dieckmann condensation, the Wolff rearrangement, the hydrolysis of benzyl chloride and *para*-substituted benzyl chlorides, and the substitution of 3-chloro-1-butene by diethylamine. In this last case the $^{14}C$ isotope effects for [1-$^{14}C$]-, [2-$^{14}C$]-, and [3-$^{14}C$]-3-chloro-1-butene were found to be 1.057 ± 0.007, 1.074 ± 0.003, and 1.079 ± 0.003. The chlorine isotope effect $k_{35Cl}/k_{37Cl}$ was found to be 1.0112 ± 0.0006. This is a particularly good example, since it shows that in the reaction

$$(C_2H_5)_2NH + CH_2{=}CH{-}\underset{\displaystyle CH_3}{\underset{|}{C}}H{-}Cl \rightarrow (C_2H_5)_2N^{\oplus}CH_2{-}CH{=}CH{-}CH_3 + Cl^{\ominus}$$

all the bonds of 3-chlorobutene-1 are influenced in the transition state.

## IV. "Analytical" Isotope Effects

If hydrogen-labeled compounds are subjected to simple separations, *e.g.* recrystallization or distillation, which are less efficient methods than multi-stage distribution, surprisingly large isotope effects can nevertheless occur when such a separation is associated with a chemical reaction.

In the recrystallization of [1-T]mannose phenylhydrazone from 60% aqueous methanol, for example, we found that the labeled molecules crystallize more slowly [70,71]; $k_H/k_T = 1.12$. Owing to the importance of recrystallization in the purification of labeled compounds, this observation was checked by the National Bureau of Standards, Washington, who confirmed our results [71]. This large isotope effect probably is due to the fact that the mutarotation of one or more forms of mannose phenylhydrazone is rate-determining for the crystallization.

A second example is the distillation of aqueous solutions of [T]formaldehyde [42]. The reaction involved probably is the hydration and dehydration of the formaldehyde. As mentioned in the discussion of secondary isotope effects, D- and T-labeled molecules react more slowly than unlabeled molecules in $sp^3 \rightarrow sp^2$ transitions, and correspondingly faster in $sp^2 \rightarrow sp^3$ transitions. In T-labeled formaldehyde, therefore, for the equilibria

$$CH_2O + H_2O \underset{k_{H(-H_2O)}}{\overset{k_{H(+H_2O)}}{\rightleftharpoons}} CH_2(OH)_2 \quad \text{and}$$

$$CHTO + H_2O \underset{k_{T(-H_2O)}}{\overset{k_{T(+H_2O)}}{\rightleftharpoons}} CHT(OH)_2$$

$$k_{H(+H_2O)} < k_{T(+H_2O)} \text{ and } k_{H(-H_2O)} > k_{T(-H_2O)}.$$

Thus in T-labeled formaldehyde the equilibrium is displaced further towards the hydrated form than in the unlabeled compound, so that [T]formaldehyde is less volatile. Equilibria with the dimer, methylene glycol, or with oligomeric oxymethylene hydrates may also play some part.

[71] *F. Weygand*, *H. Simon*, *K. D. Keil*, *H. S. Isbell*, and *L. T. Sniegoski*, Analytic. Chem. *34*, 1753 (1962).

Remarkable isotope effects occur in the paper and column chromatography of T-labeled aldosterones [72]. The change in the ratio T/$^{14}$C in intermolecularly doubly labeled samples was followed. In the paper chromatography of aldosterone diacetate, for example, the ratio T/$^{14}$C for 4 segments of the spot, which were cut out across the flow direction, were 11.2, 8.5, 6.3, and 5.6. Similar fractionations were observed in chromatographic cloumns. It was shown that the fractionation takes place, not on the basis of the $^{14}$C labeling, but only on the basis of the tritium labeling [*].

It is not surprising, therefore, that small molecules with different hydrogen isotope contents, *e.g.* methanes [74], and ethanes [75], can be completely or largely separated by normal chromatographic methods. The effects depend not only on the number of hydrogen isotopes, but also on their position. Thus *Lee* and *Rowland* [76] separated position-isomeric T-labeled olefins such as propylene ($CH_2T-CH=CH_2$ from $CH_3-CT=CH_2$ and $CH_3-CH=CHT$), *cis*-butene ($CH_2T-CH=CH-CH_3$ from $CH_3-CT=CH-CH_3$), as well as 1-butene ($CH_3-CHT-CH=CH_2$ from $CH_3-CH_2-CH=CHT$ and/or $CH_3-CH_2-CT=CH_2$). Traces of tritium in hydrogen gas can be accumulated on an alumina-iron oxide column at −183 °C [77]. Examples of isotope effects occurring in column- or gas-chromatographic separations are listed in Table 2.

Table 2. Isotope effects in chromatographic separations [a].

| Chromatography method | Compound | Isotope effect (in retention vol-% [b]) | Ref. |
|---|---|---|---|
| Ion exchange | [$^{14}$C] Amino acids | −0.123 to 0.338 | [77a] [77b] |
| | [T]-2-Aminopurine | −2.4 | [77c] |
| | [$^{14}$C]Formic acid | 0.62 at 6 °C<br>0.32 at 35.4 °C | [77d] |
| Paper | [6,7-$T_2$]Estradiol | 0.75 | [77e] |
| | [1, 2-T]-Aldosterone diacetate | 0.2 | [77f] |
| Column | [T]Formic acid | 2.4 | [77g] |
| | [*methyl*-T]Methoxy-acetic acid | 1.01 | [77g] |
| | [T]Linoleic acid | 0.41 | [73] |
| | [T]Cholesterol acetate | up to 0.49 | [72] |
| | [1, 2-T]Aldo-sterone diacetate | up to 0.73 | [77f] |
| | [1, 2-T] Aldosterone | up to 1.63 | [77h] |
| Gas | [T]Steroids | up to −1.15 | [77i] |
| | [D]Trimethylsilylated carbohydrates | up to 2.62 | [77j] |

[a] We are grateful to Dr. *P. D. Klein* for making a manuscript available to us before publication.

[b] Retention volume per cent is the percentage difference between the retention volume at which 50% of the unlabeled and 50% of the labeled compound are eluted. Negative values indicate that the labeled compound flows more rapidly.

## V. Isotope Effects in Biochemistry

In addition to the equilibrium, kinetic, and solvent isotope effects defined above other isotope effects can be observed in biological systems, *e.g.* changes in permeability, morphologic and genetic changes, changes in growth rates, and even inability of the cells to survive [78]. The strongest effects are again produced by hydrogen isotopes. However, if the steps involved in the process are known, the overall effects can be traced to primary and secondary isotope effects of labeled substrates in enzyme reactions and the influence of $D_2O$ on substrates and enzymes [79–82].

Generally the labeled and the unlabeled compounds are present together and the enzyme-kinetic measurements are competitive. The proportion of the labeled compound is characterized by atom weight percentage or by the specific radioactivity. With deuterium, 100% isotopic substitution can be obtained; in such instances kinetic measurements can be carried out on each substrate individually. This case, which is designated as *non-competitive* or *independent* [4], will be discussed first.

## 1. Isotope Effect and Enzyme Mechanism

### a) Non-competitive Measurements

Isotope effects of enzymatic reactions with a single substrate can be expressed by the isotope effects of the maximum rate $V$ and of the Michaelis constant $K_m$. For the reaction of an enzyme E with a substrate S or a labeled substrate S', we have, in the simplest case[83]:

$$\begin{aligned} &E + S \underset{k_{-1}}{\overset{k_{+1}}{\rightleftharpoons}} ES \xrightarrow{k_{+2}} E + P \\ &E + S' \underset{k'_{-1}}{\overset{k'_{+1}}{\rightleftharpoons}} ES' \xrightarrow{k'_{+2}} E + P' \end{aligned} \quad (1)$$

From equation (1) we obtain the equations for the initial rate, $v_i$:

$$v_i = \frac{V}{1 + K_m/[S]}; \quad v'_i = \frac{V'}{1 + K'_m/[S']} \quad (2)$$

For substrate saturation, we have:

$$V = k_{+2}\,[E_0] \quad (3)$$

where $[E_0] = [E] + [ES]$.

By definition, $K_m$ is equal to the substrate concentration at which $v_i = V/2$. Moreover, it follows from equation (1) that:

$$K_m = \frac{k_{+2} + k_{-1}}{k_{+1}} \quad (4)$$

If equilibrium between the enzyme, the substrate, and the complex ES has been established ($k_{+2} \ll k_{-1}$), $K_m$ is practically equal to the dissociation constant $K_s$ of the complex ES:

$$K_m \approx \frac{k_{-1}}{k_{+1}} = K_s \quad (5)$$

Equation (2) is used to find the constants $V$, $V'$, $K_m$, and $K'_m$, and from these the isotope effects $V/V'$ and $K_m/K'_m$ are calculated.

In a single-substrate reaction, an isotope effect of $V$ indicates that an isotope-substituted bond is broken or formed in the rate-determining step. An isotope effect of $K_m$ can, if condition (5) is satisfied, serve as a measure of the relative affinity of the substrates being compared. For $K_m/K'_m > 1$, the isotope-substituted substrate is more firmly bound than the unlabeled substrate.

From equation (2), the isotope effect of the initial rate $v_i$, which is the quantity that can be measured directly, is:

$$\frac{v_i}{v'_i} = \frac{V[S]\,(K'_m + [S'])}{V'[S']\,(K_m + [S])} \quad (6)$$

For equal substrate concentrations ($[S] = [S']$), there follow equation (7) at substrate saturation and equation (8) at low substrate concentrations.

$$\frac{v_i}{v'_i} = \frac{V}{V'} = \frac{k_{+2}}{k'_{+2}} \quad (7)$$

$$\frac{v_i}{v'_i} = \frac{V}{V'} \cdot \frac{K'_m}{K_m} \quad (8)$$

Further, it follows from equation (6) that in a given enzyme reaction the isotope effect of $v_i$ is a function of the substrate concentration, and may be greater or less than 1.

For two-substrate reactions [including those of the NAD-dependent dehydrogenases (see Table 3), which are particularly interesting in connection with D and T isotope effects], most of the possible mechanisms lead to the same rate law, which is given by the Dalziel equation (9)[84]; this replaces equation (2).

$$\frac{E_0}{v_i} = \Phi_0 + \frac{\Phi_1}{[S_a]} + \frac{\Phi_2}{[S_b]} + \frac{\Phi_{1,2}}{[S_a]\,[S_b]} \quad (9)$$

$[S_a]$ and $[S_b]$ are the concentrations of the substrates or coenzymes. The $\Phi_i$ are the products of the rate constants of the individual steps; their connection with the mechanism is given by *Dalziel*[84], and their determination is also described in[83]. From the $\Phi$ of an overall reaction (forward and reverse reactions), it is possible, with the aid of the Haldane equation[85], the Dalziel equations[84], and equations for product inhibition[86,87], to derive quantities that characterize a mechanism. The enzyme mechanism can be derived in a similar and complementary manner from the isotope effects found for the quantities $\Phi$.

To illustrate the information obtainable from isotope effects, consider the liver alcohol dehydrogenase reaction (which was originally assumed to proceed by a simple Theorell-Chance mechanism[88]):

$$E + CoH \underset{k_{-1}}{\overset{k_{+1}}{\rightleftharpoons}} ECoH \underset{+SH;\ k_{-2}}{\overset{+S;\ k_{+2}}{\rightleftharpoons}} ECo \underset{k_{-3}}{\overset{k_{+3}}{\rightleftharpoons}} E + Co$$

(Co, CoH, S, and SH represent the coenzyme and the substrate and their reduced forms)

The parameters of the forward and the reverse reactions are

$$\Phi_0 = 1/k_{+3};\ \Phi_1 = 1/k_{+1};\ \Phi_2 = 1/k_{+2};\ \Phi_{1,2} = k_{-1}/k_2 k_{+1}$$

(forward reaction)

$$\Phi_{0r} = 1/k_{-1};\ \Phi_{1r} = 1/k_{-3};\ \Phi_{2r} = 1/k_{-2};\ \Phi_{1,2r} = k_{+3}/k_{-2}k_{-3}$$

(reverse reaction)

For the isotope effects $\Phi/\Phi' = \varphi$ we obtain the following conditions:

$$\varphi_{1r} = 1; \quad \varphi_0 = 1; \quad \varphi_{2r} = \varphi_{1,2r}; \quad \varphi_1\,\varphi_2/\varphi_{1,2} = \varphi_{0r}$$

[87] *W. W. Cleland*, Biochem. biophysica Acta *67*, 104, 173, 188 (1963).

[88] *H. Theorell* and *B. Chance*, Acta chem. scand. *5*, 1127 (1951).

In *Baker*'s investigations [89] the second and fourth conditions were not satisfied, so that a simple Theorell-Chance mechanism probably is not involved. Other applications of the Dalziel equation are given in [50, 89–94].

### b) Competitive Measurements

#### α) [S] and [S'] are comparable

The overall rate $v_t$ for the transformation of an isotopic substrate mixture [94a] is

$$v_t = v_s + v'_s = \frac{V\,[S]}{[S] + K_m\,(1 + [S']/K'_m)} + \frac{V'\,[S']}{[S'] + K'_m\,(1 + [S]/K_m)} \quad (10)$$

where $v_s$ and $v'_s$ are the partial reaction rates of the labeled and non-labeled substrates, respectively. Since $K_m/K'_m$ may be greater or smaller than 1, each partial rate may also be greater or smaller than that at the corresponding substrate concentration in the absence of isotope effects. The rate equation (10) corresponds formally to that of a competitive inhibition, but it cannot be concluded that a labeled substrate acts as a competitive inhibitor.

Equation (10) shows that the ratio of the partial rates in the competitive experiment is always proportional to the ratio of the substrate concentrations [95].

$$\frac{v_s}{v'_s} = \frac{V}{V'} \cdot \frac{K'_m}{K_m} \cdot \frac{[S]}{[S']} \quad (11)$$

$V/V'$ and $K_m/K'_m$ can be determined by two methods in competitive experiments: by determination of $v_t$ and the ratio of the partial rates, or by determination of the dependence of $v_t$ on the ratio of the substrate concentrations [96].

#### β) [S] is much greater than [S'] (radioactive tracer)

In nearly all experiments with radioactively labeled substrates, $[S'] \ll [S]$ and $[S'] \ll K'_m$. The information obtainable from equation (10) is considerably restricted. $v_t$ practically corresponds to the partial rate $v_s$, so that the partial rate $v_s$ cannot be determined independently [*]. Thus equation (11) gives an isotope effect only for the ratio $VK'_m/V'K_m$.

If the specific activity of the substrate is $[S']/[S] = N_0$ and that of the product is $N_p$, the isotope effect at low conversion $f$ [3] is

$$\left(\frac{N_0}{N_p}\right)_{f\to 0} = \frac{k}{k'} = \frac{v_i}{v'_i} \cdot \frac{[S']}{[S]}.$$

Substitution in equation (11) gives (see also [97])

$$\left(\frac{N_0}{N_p}\right)_{f\to 0} = \frac{V}{V'} \cdot \frac{K'_m}{K_m} \quad (12)$$

### c) Comparison of Non-competitive and Competitive Experiments

The advantage of the use of highly or completely labeled substrates is that $K_m$, $V$, $K'_m$, and $V'$, as well as the kinetic quantities $\Phi$ and $\varphi$ (cf. Section V, 1a) can be determined directly in multi-substrate reactions [50, 89–94]. However, even if the reaction conditions are closely controlled, the errors in the individual measurements lead to large errors in the isotope effect [5]. This is shown by a comparison of the results obtained for alcohol dehydrogenase [50, 92] and the dependence of the isotope effect of the urease reaction on various enzyme preparations [97].

The competitive procedure has the following advantages: There are no errors due to the comparison of two sets of measurements, such as are necessary in non-competitive experiments. In the competitive method, the isotope effect can be determined with small errors by radioactive or mass-spectrometric analysis of the products. Labeling of the required substrates in trace amounts is generally easier than the preparation of isotopically pure substrates; *e.g.* also the preparation of stereospecifically labeled substrates is unnecessary (cf. notes to Table 4). The procedure is better suited to *in vivo* investigations. One disadvantage is the fact that tracer labeling generally gives only $VK'_m/V'K_m$ (cf. Section V, 1b).

## 2. Interpretation of the Isotope Effect in Biochemistry

Most publications on enzymatic isotope effects deal with deuterium isotope effects, and particularly with the study of hydrogen transfer by oxidoreductases and isomerases. Examples are given in Section V.3 and in Table 3. Although far less enzyme reactions than organic reactions have been studied with the aid of isotope effects, some general data on the magnitude of isotope effects in enzyme reactions and their interpretation can be given.

[*] This is most easily seen from the fact that for $[S'] \ll K'_m$, equation (2) simplifies to $v'_i = V'[S']/K'_m$. Consequently, only the ratio $V'/K'_m$ can be determined, and not the individual quantities.

[a] Isotope effects of the Michaelis constant or of equilibrium constants of the listed substrates in E3. $K_m/K'_m > 1$ indicates firmer bonding of the deuterated substrate [cf. eq. (5)].

[b] Isotope effects for the rate constants of the bonding of coenzymes.

[c] Activation energies ($E_A$) for rupture of the C—H and C—D bonds.

[d] Secondary isotope effects.

The deuterium isotope effects of $v_i$ and $V$ in enzyme reactions are comparable with those of ordinary organic reactions. Though a value of 6 to 7 is expected for a normal deuterium isotope effect between 20 and 35 °C[16], the observed effects of, on average 1.5 to 3 still fit into the same scheme if the transition state is similar to the reactants or to the products. The remarks in Section II.1 on the magnitude of the isotope effect as a function of the loosening of the bond along the reaction coordinate then apply. Moreover, there is often some compensation and hence reduction of the measurable isotope effect because, in the absence of substrate saturation, the ratio $v_i/v'_i$ depends on $VK'_m/V'K_m$ [eqs. (6), (8), and (11)]. Even when the rate-determining step is preceded by equilibration, effects of this type must be expected in the overall isotope effect[4]. Consequently, deuterium isotope effects of 6 or more are seldom attained (see Table 3 and [99, 100]).

The isotope effect of $K_m$ is often higher than that expected for equilibrium constants, even when it is known that $K_m$ actually does have the significance of a dissociation constant $K_s$. For this case *Mahler*[92] and *Shiner*[50] believe that there must be interaction between

[99] *J. F. Thomson* and *F. J. Klipfel*, Biochem. biophysica Acta *44*, 72 (1960).

[100] *P. Strittmatter*, J. biol. Chemistry *237*, 3250 (1962).

the enzyme and the isotope-substituted bond already during binding of the substrate to the enzyme. This interaction also explains the large isotope effects of $K_m$ found when the substrate contains an isotope-substituted bond that does not take part in the overall reaction, *e.g.* the 4-B position of NADH for A-specific enzymes [50,93,94, *].

An interaction between the substrate and the enzyme during the binding of the substrate is also indicated by the hydrogen exchange brought about in dihydroxyacetone phosphate by aldolase even in the absence of an acceptor [94b].

There are several examples of greater affinity of the deuterated substrate for the enzyme ($K_m/K'_m > 1$) (see Table 3). Lower affinity of the deuterated substrate has also been confirmed by stronger inhibition of the deuterated substrate by a competitive inhibitor [95].

While the isotope effect of $K_m$ can provide information about the binding of the substrate, and hence about the active site of the enzyme, the isotope effect *per se* can be used as evidence of changes in the active site. A good example is found in native and carboxypeptidase-treated aldolase [101]. While the native enzyme showed no isotope effect in the synthesis with labeled triose phosphates, a deuterium isotope effect of 6 and a tritium isotope effect of 20 were found for the treated enzyme [101].

## 3. Specific Examples

The examples described here are arranged in accordance with the enzyme list [98]. The importance of the isotope effect for the elucidation of enzyme mechanisms can be shown *inter alia* for the participation of an enzyme in a coupled system, stereospecificity of a Caabd molecule, intramolecular proton shift, and cleavage of a molecule into identical fragments.

### a) Hydrogen Isotope Effect

Measurements of the isotope effect in the alcohol dehydrogenase (yeast) reaction with [4-D]-NADH (chemically and enzymatically reduced) and [1,1-$D_2$]-ethanol have been reported [50,91,92,102]. The authors assume that the rate-determining step is the transformation of the ternary complex

$$ECoSH \underset{k_-}{\overset{k_+}{\rightleftharpoons}} ECoHS$$

the isotope effect of which is $k_+/k'_+ = k_-/k'_- = 1.75$ (Table 3).

This small isotope effect can be explained by only a partial rupture of the hydrogen bond in the transition state of the complex. Such loosening is in agreement with the unexpectedly high isotope effect of the substrate dissociation constants, which is explained by an interaction between the enzyme and the C—H bond involved in the hydrogen transfer. According to *Silverstein* and *Boyer* [103], the cleavage of the NAD or NADH product is the rate-determining step. In this case the above assignment of the isotope effect to the kinetic constants would be invalid. *Müller-Hill* and *Wallenfels* [104] concluded from the temperature dependence of the reaction that the first of these mechanisms applies below 20 °C, and the second above 20 °C.

We have studied the temperature dependence of the isotope effect of [1-T]ethanol and [A-4-T]NADH as substrates of alcohol dehydrogenase (from yeast) [105, 105a]. The increase in the isotope effect with rising temperature (Table 4) can be explained by a change in the rate-determining step.

Since alcohol dehydrogenase of yeast also catalyses the oxidation of the homologues of ethanol at comparable rates, we were able to use this enzyme to study the influence of various substrates on the isotope effect in an enzyme reaction [105] (see Table 4). The increase in the isotope effect from ethanol to propanol is much greater than the accompanying change in the reaction rate, which is only 34% [106].

Table 4. Comparison of the isotope effects ($k_H/k_T$) in the reaction of some alcohols with alcohol dehydrogenase (yeast) under various conditions [105].

| Conditions | [1-T]Ethanol [a] | [1-T]Propanol [a] | [1-T]Butanol [a] |
|---|---|---|---|
| pH 7.6<br>15 °C | 3.3 ± 0.1 | 6.4 ± 0.05 | 6.8 ± 0.2 |
| pH 7.6<br>25 °C | 4.1 ± 0.05 | 6.7 ± 0.2 | 6.8 ± 0.2 |

[a] Mixture of the two stereoisomers. With tracer amounts of the tritiated substance, there is no appreciable double labeling, so that there is no need to use stereospecifically labeled substrates when the isotope effect is measured on the [A-4-T]-NADH formed.

For the alcohol dehydrogenase of liver [91], an iterative method was used to find the 13 kinetic constants from the 12 independent equations obtained for the forward and reverse reactions. Isotope effects could then be calculated for each step of a complex mechanism. In addition to the values in Table 3, $k_H/k_D = 2.28$ was obtained for the hydrogen transfer from $CH_3CH_2OH$ to $NAD^+$, and $k_H/k_D = 3.11$ for the transfer from [A-4-D]NADH to $CH_3CHO$.

In the determination of the isotope effect of [A-4-T]-NADH in the alcohol dehydrogenase reaction with acetaldehyde, propionaldehyde, or butyraldehyde, a substrate dependence is observed with the enzyme from yeast [105a], but not with that from liver [105b]. This confirms that the rate-determining step in the reaction of the liver enzyme depends on the dissociation of the enzyme.

[*] $NAD^+$ ($NADP^+$) = nicotinamide adenine nucleotide (phosphate); NAD (NADPH) = reduced forms of $NAD^+$ and $NADP^+$; [A-4-D]NADH: in the nicotinamide portion of NADH, the 4-position facing forward when the atoms are numbered 1 to 6 in the anticlockwise direction is now labeled, *i.e.* [4*R*-4-D]-NADH [100a]. Similarly, [B-4-D]NADH is [4*S*-4-D]NADH. Depending on the stereospecificity of the hydrogen transfer, enzymes that transfer hydrogen to the A position of NADH are known as A-enzymes, and substrates of the type CHHbd are divided into A- and B-substrates.

[106] *J. van Eys* and *N. O. Kaplan*, J. Amer. chem. Soc. *79*, 2782 (1957).

*Thomson* [92,93a] studied isotope effects of [A-4-D]NADH and [B-4-D]NADH in the lactate dehydrogenase reaction. [B-4-D]NADH gives an inverse isotope effect in relation to the normal isotope effect of V due to [A-4-D]NADH (Table 3); this points at least to the interaction of both hydrogens in position 4 of the NADH with the enzyme in the course of the reaction.

From the isotope effect of the NADP-dependent glucose 6-phosphate dehydrogenase, it was possible to determine the rate-determining step for the formation of $CO_2$ from glucose in whole cells. This is a C–H cleavage, either during the H transfer from glucose to NADP or during the reoxidation of the NADP. The same was found for tumor cells [107].

Whereas various substrates have been studied with the one enzyme alcohol dehydrogenase, *Aebi* [108] has carried out comparative measurements with one substrate (formate) and various enzymes (Table 3).

The succinate dehydrogenase reaction on deuterated succinic acid is a classic example of enzymatic isotope effects [109]. With perdeuterated substrates, it was later found that $V/V' = 5.9$ [99]. However, secondary isotope effects must also be taken into account in the case of the [$D_4$]succinate. As a substrate of the respiratory chain, [$D_4$]succinate has no retarding effect on the oxidative phosphorylation.

The elucidation of a stereospecific reaction was achieved by *Belleau* [110] for the enzymatic decarboxylation of amino acids to amines and the dehydrogenation of the latter. The two enantiomeric [1-D]tyramines were prepared, and their isotope effects in the monoamine-oxidase reaction with the decarboxylation product obtained from tyrosine in $D_2O$ were compared.

An isotope effect was expected in the dehydration of malate (fumarase reaction), but none was found [111]. Since the rupture of the stereospecifically labeled carbon-hydrogen bond is not rate-determining, one must postulate a mechanism involving a malate-X complex that is as yet unknown.

$$\text{malate} + \text{E} \overset{\text{slow}}{\rightleftharpoons} \text{malate-E} \rightleftharpoons \text{malate-X} \rightleftharpoons \text{E–fumarate} \rightleftharpoons \text{E} + \text{fumarate}$$

In the racemization of [2-D]lactate by an extract from *Clostridium butylicum*, an isotope effect of ${}_{\text{H}}k/k_{\text{D}} = 2.14$ was observed for both enantiomers. The fact that no deuterium was lost as a result of the racemization was shown by the fact that the rate of dehydrogenation by the lactate dehydrogenase both for the D- and for the L-form corresponded exactly to that of the deuterated lactic acids [111a].

Measurement of the deuterium isotope effect in the hexose isomerase reaction of [1-$^{14}$C-2-D]glucose 6-phosphate showed the occurrence of an intramolecular proton transfer [112]. In the substrate-enzyme complex, about 50% of the hydrogen is transferred as protons from C-2 into position 1 of the substrate (and *vice versa*) without exchange with the solvent.

An isotope effect of 2 was found for deuterium (about 3.2 for tritium) in both directions in the isomerase reaction. A similar isotope effect was found [113] for the triose phosphate isomerase. [3-D]1,3-Dihydroxyacetone-1-phosphate reacts 2.2 times more slowly than the unsubstituted substrate.

In the epimerization of uridine diphosphate galactose and glucose by an enzyme from yeast, an inverse isotope effect of $k_{\text{H}}/k_{\text{T}} = 0.66$ to 0.33 was found for the [4-T]labeled hexoses [113a]. The direction and magnitude of this isotope effect are in agreement with a mechanism in which the first step is a reversible hydrogen transfer from C-4 to the enzyme. Inverse isotope effects also have been found for an equilibrium of this type in the case of alcohol dehydrogenase (Table 3). This indicates a rearrangement of the enzyme complex, the hydrogen taking up the appropriate position for transfer to the epimeric position of the hexose. From the magnitude of the equilibrium isotope effect it is concluded that C, N, or O atoms are involved in the hydrogen transfer, and the participation of S can be excluded.

An interesting application of deuterium and tritium isotope effects was demonstrated [114,115] in the elucidation of various steps in the ribulose diphosphate carb-

oxylase reaction (carboxydismutase). The object was to find whether the $CO_2$ is attached to C-2 or C-4 of the ribulose diphosphate *(4)* before cleavage into two molecules of 3-phosphoglyceric acid *(5)*. An intramolecularly doubly labeled [2-$^{14}$C-2-D]phosphoglyceric acid *(5a)* can be formed as well as the unlabeled acid only if the $CO_2$ is attached to C-2. Since the [$^{14}$C]glycolic acid obtained from the phosphoglyceric acid exhibited an isotope effect of 2.5 on oxidation with glycolic acid oxidase, this glycolic acid must have contained D as well as $^{14}$C, *i.e.* the $CO_2$ is attached to C-2 in *(4)*. 3-Tritiated *(4)* reacts four to six times more slowly than the H compound in the carboxylation at pH 8.1 and 25 °C. The release of the proton appears to be the limiting step of the overall reaction [115].

In the irreversible formation of a C–H bond by proton abstraction from a solvent in which the hydrogen is partially labeled, a much smaller content of the higher hydrogen isotopes is usually found in the product than in the solvent. This is a result of the isotope effect in the cleavage of an X–H bond, where X may be O, S, N, *etc.* A typical example, which has been studied both experimentally and theoretically, is the hydration of isobutylene in acidic media [121]. When this reaction is carried out in $H_2O/D_2O$ mixtures, the concentration of D in the t-butyl alcohol formed is 3.9 times lower than that in the water; the ratio for T is 7.1, and that for T in $D_2O$ is 1.9.

Corresponding biochemical examples are: In the enzymatic cleavage of citrate in HOT, T is incorporated into acetyl CoA. Hydrogen is incorporated preferentially, in the ratio $k_H/k_T = 6.7$ [122]. In the cleavage of *threo*-$D_S$-isocitrate to succinate and glyoxylate, an isotope effect of $k_H/k_T = 6.5$ to 13.9 is found, depending on the isocitrate concentration ($2\times10^{-3}$ to $4\times10^{-3}$ M), when the reaction is carried out in a buffer solution containing tritium [123]. In the cleavage of phosphoenol pyruvate by pyruvate kinase in HOT, T is incorporated with an isotope effect $k_H/k_T$ of 6.4 [124].

### b) Isotope Effects of Carbon

*Lynn* and *Yankwich* [97] studied the isotope effect of the urease reaction (with urea having the natural $^{12}$C/$^{13}$C ratio) as a function of conversion, concentration, buffer, temperature, pH, and aging of the enzyme, and found a maximum value of 2.3%. The differences of the isotope effects found for various enzyme preparations were in some cases larger than the differences found for the above variables. The isotope effect of 5 to 10% found by other authors could not be confirmed.

A $^{14}$C isotope effect of an unusual magnitude was found [119] for the enzymatic oxidation of [$^{14}$C]formate by formic acid dehydrogenase. The value of 1.27 at 37 °C was independent of the substrate activity, which varied between 0.8 and 100 μCi/mmole.

The decarboxylation of oxalacetate to pyruvate by an enzyme from *Micrococcus lysodeikticus* shows no isotope effect with the $^{13}$C-labeled substrate. The Mn(II)-catalysed, non-enzymatic decarboxylation, on the other hand, gives an isotope effect of 1.06; solvent isotope effects in $D_2O$ indicate that the limiting step is not the actual decarboxylation [120].

# Progress in the Chemistry of Allene

BY DR. K. GRIESBAUM

CENTRAL BASIC RESEARCH LABORATORY, ESSO RESEARCH AND ENGINEERING COMPANY, LINDEN, NEW JERSEY (U.S.A.)

*Considerable progress has been made in the past decade in the preparation and chemistry of allene. The present article is a critical review of this progress, and shows that owing to the particular structure of allene (two double bonds situated in mutually perpendicular planes), the chemistry of this compound is unique in many respects.*

## I. Introduction

The chemistry of acetylene and of butadiene, *i.e.* the smallest hydrocarbons containing a triple bond and two conjugated double bonds respectively, has been well known for a number of years, and both compounds are used as raw materials for huge industries [1]. On the other hand allene, *i.e.* the parent compound of the cumulenes, has found hardly any industrial use, and its chemistry, unlike that of acetylene and of butadiene, remained underdeveloped for a long time. Thus even a few years ago, little was known about such fundamental

[1] See, *e.g.*, *W. Reppe*: Neue Entwicklungen auf dem Gebiet der Chemie des Acetylens und Kohlenoxids. Springer, Heidelberg 1949; *Y. Mayor*, Ind. Petrole *32*, 62 (1964); *I. Kirshenbaum* and *R. P. Cahn* in: Encyclopedia of Chemical Technology. Interscience, New York 1964, Vol. III, p. 784.

aspects as the behavior of allene in free-radical reactions, the course of ionic additions, or the chemistry of organometallic compounds of allene.

This lack of interest is explained by the fact that for a long time no practically useful synthesis of allene was known, and the compound was regarded as a laboratory curiosity. However, modern petroleum chemistry has led to the development of economical processes for the synthesis of allene from petroleum fractions [2]. This, in turn, appears to have resulted in a growing interest in the chemistry of allene.

It was accepted for a long time that since the double bonds in allene are situated in mutually perpendicular planes, they react independently of each other, *i.e.* that allene may be regarded as a diene with isolated double bonds. However, the data available today show that this picture is oversimplified. Allene, which consists of two $sp^2$-hybridized carbon atoms and one sp-hybridized carbon atom, exhibits a combination of olefinic and acetylenic character. Thus a number of reactions of allene, such as its ease of hydration or its electrophilically induced cyclodimerization, are reminiscent of the behavior of acetylenes.

However, allene also differs from its own higher homologues. A typical example is the free-radical addition of thiols, which in the case of allene *(1)* proceeds predominantly by attack on one of the terminal carbon atoms, whereas in the case of 1,1-dimethylallene *(2)*, attack takes place preferentially at the central carbon atom [3,4].

$$H_2C{=}C{=}CH_2 + RSH \rightarrow RS\text{-}CH_2\text{-}CH{=}CH_2$$

*(1)*

$$\begin{matrix} H_3C \\ \diagdown \\ \quad C{=}C{=}CH_2 \\ \diagup \\ H_3C \end{matrix} + RSH \rightarrow \begin{matrix} H_3C \quad SR \\ \diagdown \quad | \\ \quad CH\text{-}C{=}CH_2 \\ \diagup \\ H_3C \end{matrix}$$

*(2)*

It follows that reactions observed with allene cannot be arbitrarily transposed to its homologues and that the validity of such generalizations must therefore always be checked experimentally. The present review is therefore confined to the chemistry of allene itself, in contrast to earlier reports on allenic hydrocarbons, which did not make such a clear distinction between the parent compound and its homologues [5].

## II. Synthesis and Occurrence of Allene

Most of the syntheses described below lead to mixtures of allene and its isomer, methylacetylene. These compounds exist in equilibrium with each other. At 300 °C in the gas phase, the equilibrium mixture consists of about 20% of allene and about 80% of methylacetylene [6].

$$H_2C{=}C{=}CH_2 \rightleftharpoons H_3C\text{-}C{\equiv}CH$$

However, this isomerization takes place only in the presence of catalysts. In the absence of catalysts allene is stable up to 400 °C [6]. Active charcoal is the most effective and most selective catalyst [7], whereas other substances, such as $Al_2O_3$ or $SiO_2$, lead to undesirable side reactions [6]. The use of active charcoal in combination with distillation at a low temperature or above atmospheric pressure is suitable for the quantitative conversion of allene into methylacetylene, and *vice versa* [7].

### A. Formation of Allene in Cracking Processes

Allene and methylacetylene are formed in a number of cracking processes, particularly in steam cracking, and are present to the extent of 1 to 1.5% in propylene obtained by the cracking of hydrocarbons [8]. The high consumption of propylene presents the possibility of the production of considerable quantities of allene. At present, however, the two isomers are usually removed from propylene by hydrogenation [8], and it is not clear whether this is due to lack of interest in allene or to lack of a separation process. Considerably better yields of allene are obtained in the cracking of pure hydrocarbons, *e.g.* propylene or isobutylene.

#### 1. Cracking of Propylene

The course of the pyrolysis of propylene is strongly dependent on the temperature and pressure. At high temperatures (above 750 °C) and reduced pressure, the reaction leads mainly to allene and methylacetylene, whereas at low temperatures and higher pressures, polymers are the main products [9]. These and similar earlier observations [10–13] were recently explained by the intermediate formation of allyl radicals *(3)*, which, depending on the reaction conditions, either lose hydrogen to form allene or add to the double bond of propylene to form oligomers and polymers [9].

$$H_3C\text{-}CH{=}CH_2 \xrightarrow{\Delta} \cdot CH_2\text{-}CH{=}CH_2 \quad (3) \quad \begin{cases} \rightarrow H_2C{=}C{=}CH_2 + H\cdot \\ \xrightarrow{+H_3C\text{-}CH{=}CH_2} \text{Polymers} \end{cases}$$

[2] Stabilized gas mixtures containing up to 60% of allene and methylacetylene (MAPP-Gas®) are marketed in the USA by the Dow Chemical Co. as a cutting and welding gas. See: *J. D. Hembree, R. W. Belfit, H. A. Reeves*, and *J. P. Baughman*, Welding Journal, *42*, 395 (1963); Iron Steel Eng. *41*, (5), 153 (1964).

[3] *T. L. Jacobs* and *G. E. Illingworth Jr.*, J. org. Chemistry *28*, 2692 (1963).

[4] A similar reversal of orientation has been observed in the ionic addition of HCl to allene and 1,1-dimethylallene (see [81]) and in the hydroboration of allene [125, 126] and 2,3-nonadiene [129].

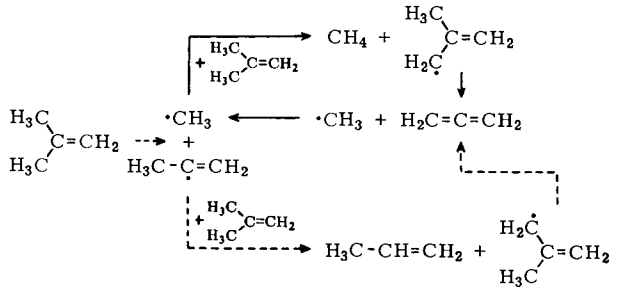
## 2. Cracking of Isobutylene

The preparation of allene by the pyrolysis of isobutylene has been known for some years [14], and several variants, such as steam cracking [15], cracking in the presence of inert diluent gases [16], or catalytic cracking [17], have been described. The course of the reaction again depends on pressure, temperature, and contact time. However, it can be directed to yield up to 60% of an allene/methylacetylene mixture [18]. The formation of methane and propylene as the principal by-products is understandable on the basis of Scheme 1.

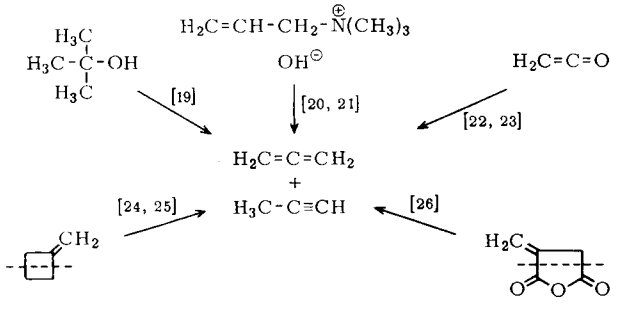


Scheme 1. Reaction steps in the pyrolysis of isobutylene.

Under conditions favoring long free-radical chains (full arrows), the reaction proceeds *via* methyl and methallyl radicals and yields methane as principal by-product. If the free-radical chain is shorter (broken arrows), the reaction *via* the 2-propenyl radical predominates. Since, in this case, half of the isobutylene is converted into propylene the conditions must be chosen such as to suppress the reaction by this second route.

## 3. Other Cracking Reactions

Allene and methylacetylene are formed also in other cracking reactions. Some typical examples are shown in Scheme 2.



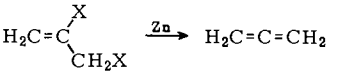
Scheme 2. Formation of allene and methylacetylene in cracking processes.

In most cases the starting material already contains the $C_3$ skeleton of allene, and the reactions are self-explanatory. An exception is the formation of allene in the pyrolysis of ketene, which contains only two carbon atoms.

### B. Formation of Allene from $C_3$ Halides

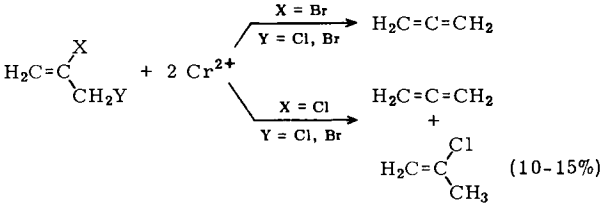
## 1. Dehalogenation of Vicinal $C_3$ Dihalides

Allene was first prepared by the debromination of 2,3-dibromopropene [27], and later by the dechlorination of 2,3-dichloropropene [28] with zinc dust in alcohol:



Both these methods have the disadvantage that the corresponding 2-halopropenes are also formed, and cannot be completely separated. This difficulty is avoided if the reaction is carried out in butyl or isoamyl acetate [29].

It was reported recently that chromium(II) sulfate is a suitable agent for the conversion of 2,3-dihalopropenes into allene [30]. To obtain optimum yields, it is necessary to use a starting material that contains a bromine (not chlorine) atom in the 2 position, and care must be taken to ensure that the allene formed is not reduced to propylene by excess of chromium(II) sulfate.



## 2. Reduction of Monohalides

The reduction of propargyl *(4)* or allenyl bromides *(5)* with zinc/copper leads to a 2:1 mixture of allene and methylacetylene [31].

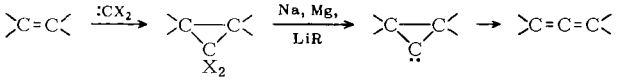
*(4)* *(5)*

The reduction of propargyl bromide *(4)* with magnesium *via* an intermediate Grignard compound also can be used for the synthesis of allene in the laboratory [32].

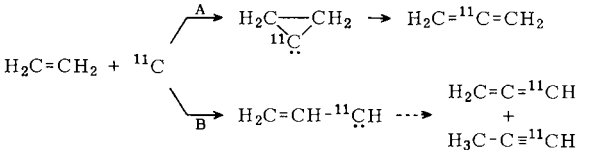
### C. Formation of Allene Via Intermediates Containing Bivalent Carbon (Cyclopropylidene)

After the discovery that halocarbenes can add to olefins to form geminal dihalocyclopropanes *(6)* [33], several substituted allenes were prepared by this reaction [34–37].

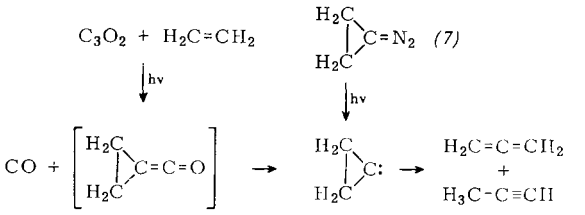


*(6)*

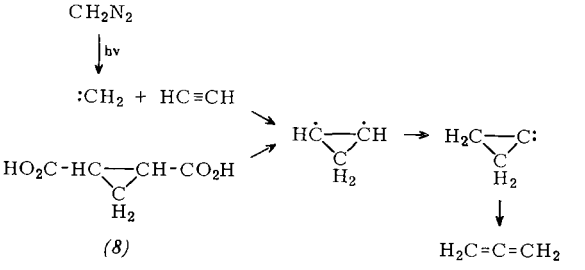
While this reaction has never been used for the synthesis of allene itself, the underlying principle of the insertion of carbon into a double bond has been utilized in a number of other reactions leading to allene. The direct routes, *i.e.* the insertion of atomic carbon into ethylene, has recently been studied thoroughly [38–42]. It was found with the aid of $^{11}C$ that this reaction proceeds mainly by insertion of a carbon atom into the $\pi$ bond (route A), and that insertion into a C–H bond (route B) occurs only to a minor extent.



Probably the same type of reaction is responsible for the formation of allene during photolysis of carbon suboxide, $C_3O_2$, in the presence of ethylene [43,44] and during that of diazocyclopropane *(7)* [45].



Allene (instead of cyclopropene) is obtained also in the reaction of methylene with acetylene, irrespective of whether the reaction is carried out in the gas phase [46] or in a solid argon matrix [47]. The mechanism proposed for this reaction could also explain the earlier observation that allene is formed in the Kolbe electrolysis of *cis*-cyclopropane-1,2-dicarboxylic acid *(8)* [48].



*(8)*

Allene is formed in many other reactions. However, since these do not represent a general synthetic principle (with the possible exception of the hydrolysis of carbides such as magnesium carbide [49] or calcium carbide [50]), they will not be discussed further.

### D. Deuterated Allenes

All the possible deuterated forms of allene, *i.e.* [D]-, [1,1-$D_2$]-, [1,3-$D_2$]-, [$D_3$]-, and [$D_4$]allene, have recently been synthesized and characterized [51]. They were all prepared by the dehalogenation of suitable halides with zinc.

## III. Physical Properties of Allene

Allene can be dangerous in the gaseous state (b.p. −34.5 °C), since its vapor can decompose exothermically and propagate a flame even in the absence of oxygen [52].

The classical physical data for allene are given elsewhere [5,53], and the present review will deal only with

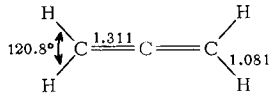
more recent, mainly spectroscopic studies. Several papers have been concerned with the NMR spectrum of allene [54–56]. The IR spectra of gaseous and liquid allene and of a single crystal of allene have been recorded, and all the absorption bands have been assigned [57,58]. The Raman spectrum has also been studied in detail [58b,59]. Electron diffraction studies of gaseous allene gave the following parameters [60]:



The melting curve of allene between 0 and 9 kbar has recently been determined [61].

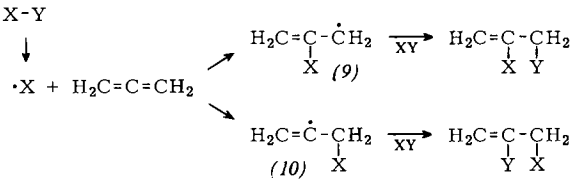
## IV. Reactions of Allene

### A. Additions to Allene

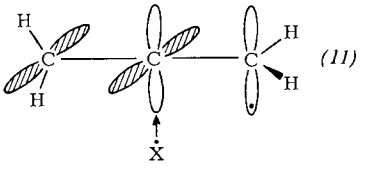
Addition reactions to allene were reported at the time of its first preparation [62] and soon afterwards [63], but only recently have such reactions been studied systematically. It was not until 1954 that the first definitely free-radical addition was described [64], and a number of entirely new aspects of electrophilic additions were discovered only two years ago [65].

#### 1. Free-Radical Additions

According to the classical views on free-radical additions, the mechanism of such a reaction of allene should depend on the point of attack of the chain-initiating radical. In the case of unsymmetrically substituted olefins, the preferred route is generally that involving the more stable of the possible free-radical intermediates [66]. It was therefore expected that free-radical attack on the center carbon atom of the allene molecule would be favored, since a resonance-stabilized allyl radical *(9)* can then be formulated as the intermediate, whereas terminal attack leads to a vinyl radical *(10)*.



In view of the special geometry of the allene molecule, however, these considerations are undoubtedly oversimplified. The radical *(11)* formed by attack on the center carbon atom resembles a radical on a primary carbon rather than an allyl radical, since the orbital of the odd electron does not overlap with the π-orbitals of the remaining double bond. This complication could increase the activation energy for an attack on the center carbon atom, and thus indirectly favor terminal attack. In other words, the course of such reactions cannot be predicted *a priori*.



*(11)*

During the past ten years, several free-radical additions to allene have been studied. The selectivities observed range from 100% terminal attack to 100% attack on the center carbon atom, depending on the nature of the compound added (Table 1) and on the reaction conditions.

Table 1. Selectivities of free-radical additions to allene.

| Reagent | Attacking radical | Attack on terminal C atom (%) | Attack on central C atom (%) | Ref. |
|---|---|---|---|---|
| $CF_3I$ | $CF_3$· | 100 | 0 | [64] |
| $H_2S$ | HS· | >95 | <5 | [67] |
| RSH | RS· | 80–95 [a] | 5–20 [a] | [3, 68] |
| $(CH_3)_3SnH$ | $(CH_3)_3Sn$· | 55 | 45 | [69] |
| HBr | Br· | 0–48 [b] | 52–100 [b] | [70–72] |

[a] Depends on the nature of R.

[b] Depends on the reaction temperature; low temperatures favor attack on the terminal C atom.

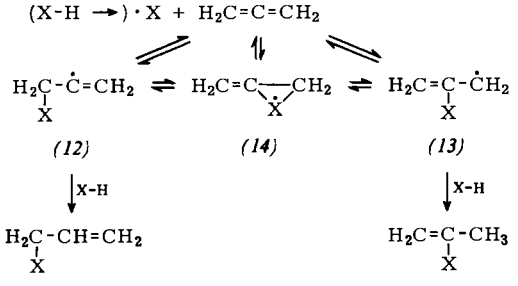
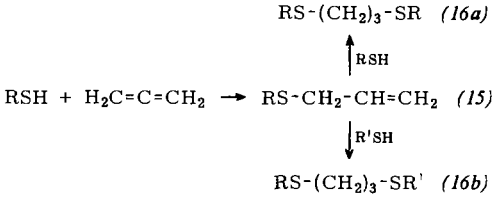
Numerous attempts have been made to explain the difference in the behavior of the various attacking reagents. It has been suggested that the point of attack may depend on the polarity of the attacking radical [73]. It was assumed that electrophilic radicals such as $\cdot CF_3$ would attack preferentially on the terminal carbon atom, while nucleophilic radicals such as $\cdot CH_3$ would tend to attack the center carbon atom. However, it can be seen from Table 1 that this assumption is not generally valid, since the nucleophilic trimethyltin radical yields only 45% of the center adduct, whereas the strongly electrophilic bromine atom gives 100% of the center adduct. It appears, therefore, that several factors are involved, *e.g.* the reversibility of the initial attack, the rate of the chain transfer, and the migratory aptitude and the steric requirements of the attacking radical. It is even possible [71], and this appears to be confirmed by more recent results [72], that the final product need not always reflect the site of the initial attack, since the radical formed first may rearrange [*e.g. (12)→(13)* or *vice versa*] before the chain transfer occurs, or it may be a bridged radical *(14)*, in which case any discussion of the point of initial attack would be meaningless.



However, whereas the orientation of free-radical additions to allene, and possibly also the cause of the orientation, may vary from one reagent to another, all these reactions appear to have certain features in common. Thus it has been repeatedly stated that allene is stable under the conditions of free-radical reactions, and does not isomerize to methylacetylene. Moreover, the reaction could generally be stopped at the monoadduct stage, provided that the monoadduct is stable under the conditions of the reaction and that allene is used in excess. Lower reaction temperatures have generally been found to give increased terminal attack and a decrease in the yield of the monoadduct, the diadduct being favored instead [68, 71].

The most thoroughly studied and most widely used of these reactions is the free-radical addition of thiol compounds, in the widest sense, to allene [3, 67, 68, 74, 75]. At temperatures up to 30 °C, these reactions exhibit high selectivity (at least 80%) for terminal attack, and apart from the addition of $H_2S$ [76], they can be directed to give either the monoadducts *(15)* or the diadducts *(16)*.



The formation of diadducts has been used for the synthesis of many symmetrical [75] (Table 2) and some unsymmetrical derivatives of propane-1,3-dithiol [77], which are not so readily obtained by other methods.

Table 2. Symmetrical thiol-allene diadducts.

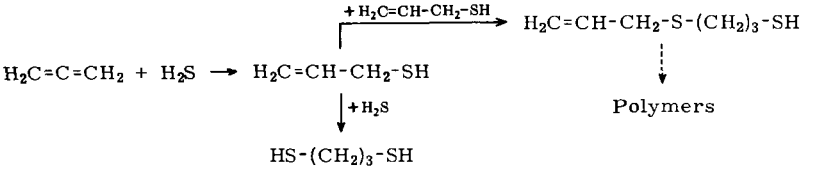
| Thiol | Diadduct | Selectivity (%) |
|---|---|---|
| $H_2S$ | $HS-(CH_2)_3-SH$ | 73 |
| $C_2H_5SH$ | $C_2H_5S-(CH_2)_3-SC_2H_5$ | 77 |
| $(CH_3)_3CSH$ | $(CH_3)_3CS-(CH_2)_3-SC(CH_3)_3$ | 80 |
| $C_6H_5CH_2SH$ | $C_6H_5CH_2S-(CH_2)_3-SCH_2C_6H_5$ | 90 |
| $C_6H_5SH$ | $C_6H_5S-(CH_2)_3-SC_6H_5$ | 57 |
| $CH_3COSH$ | $CH_3COS-(CH_2)_3-SCOCH_3$ | 90 |
| $(CH_3O)_2P(S)SH$ | $(CH_3O)_2P(S)S-(CH_2)_3-S(S)P(OCH_3)_2$ | 76 |
| $CH_3OCOCH_2SH$ | $CH_3OCOCH_2S-(CH_2)_3-SCH_2COCOCH_3$ | 95 |
| $HOCH_2CH_2SH$ | $HOCH_2CH_2S-(CH_2)_3-SCH_2CH_2OH$ | 84 |

[73] *A. P. Stefani, L. Herk,* and *M. Szwarc,* J. Amer. chem. Soc. *83*, 4732 (1961).

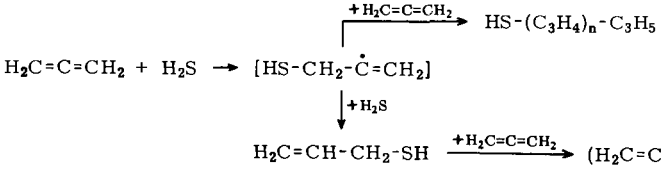
[74] *H. J. Van der Ploeg, J. Knotnerus,* and *A. F. Bickel,* Recueil Trav. chim. Pays-Bas *81*, 775 (1962).

[75] *A. A. Oswald, K. Griesbaum, D. N. Hall,* and *W. Naegele,* Preprints of Papers presented before the Division of Petroleum Chemistry, American Chemical Society Meeting, Chicago 1964, p. 29.

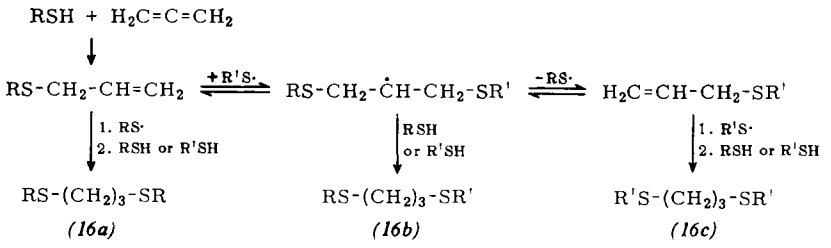
[76] The addition of $H_2S$ involves essentially two complications:
a) If $H_2S$ and allene are used in equimolar quantities, the principal side reactions are the dimerization of the initially-formed allylthiol and the further addition of $H_2S$:



b) If allene is used in excess it oligomerizes, and diallyl sulfide is also obtained:



[77] *D. N. Hall, A. A. Oswald,* and *K. Griesbaum,* J. org. Chemistry *30*, 3829 (1965).



However, while the formation of symmetrical diadducts *(16a)* normally proceeds without difficulties, the two-step addition of two different thiols is complicated sometimes by a reversal of the second addition step, in which the thiol added first is eliminated [77]. This effect leads then to three diadducts *(16a)–(16c)* instead of only the desired one *(16b)*. This difficulty can be avoided by suppression of the reversal of the second addition step (by use of the better hydrogen-releasing thiol in the second step instead of the first, or use of excess thiol, or both [77]). The success of such measures is shown in Table 3.

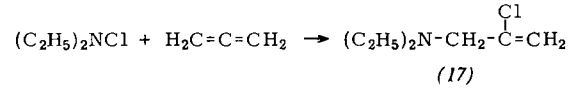
Table 3. Unsymmetrical thiol-allene diadducts.

| Starting materials | | Selectivity of formation of $RS-(CH_2)_3-SR'$ (mole-%) |
|---|---|---|
| $RS-CH_2-CH=CH_2$ R = | R'SH R' = | |
| $C_6H_5$ | $C_2H_5$ | 6 |
| $C_2H_5$ | $C_6H_5$ | 93 |
| $C_2H_5$ | $C_6H_5$ [a] | 100 |

[a] Fivefold excess.

The free-radical addition of hydrogen bromide to allene has been the subject of three recent studies [70–72]. In each case it was found that at ambient or higher temperatures, the product resulting from attack on the center carbon atom, *i.e.* 2-bromopropene, is formed with high selectivity. At lower temperatures the orientation of the addition changes, and at −80 °C the ratio of the products of center attack and terminal attack is almost 1:1 [71].

The free-radical addition of *N*-chlorodiethylamine to allene is reported to give the product *(17)* resulting from terminal attack [78]. However, the yields obtained



in this reaction were rather low, and the paper does not indicate whether it was ascertained that the center-attack product is not formed. The preferred course of the free-radical addition of $CCl_4$, $CCl_3Br$ [74], and $PH_3$ [79] also remains uncertain, since the yields were again very low. Although the products of terminal attack were detected in all three cases, they were evidently not the only compounds formed.

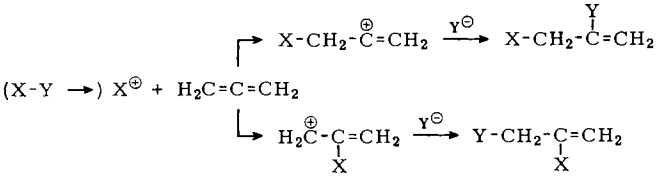
## 2. Electrophilic Additions

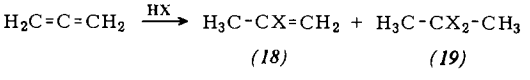
Electrophilic additions to allene can proceed in two ways (Scheme 3).



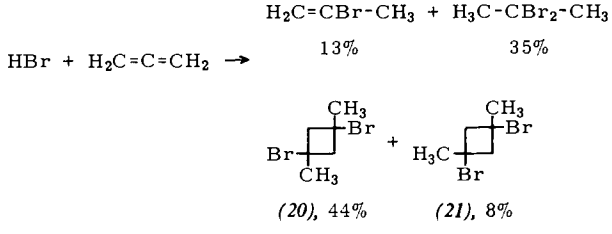
Scheme 3. Electrophilic additions to allene.

Both modes of reaction have been reported, and as in free-radical additions, the route followed appears to depend mainly on the nature of the compound being added.

Compounds of the form HX add in accordance with the Markovnikov rule. For a long time it was thought that 2-substituted propenes *(18)* and/or 2,2-disubstituted propanes *(19)* were the only products [80,81].



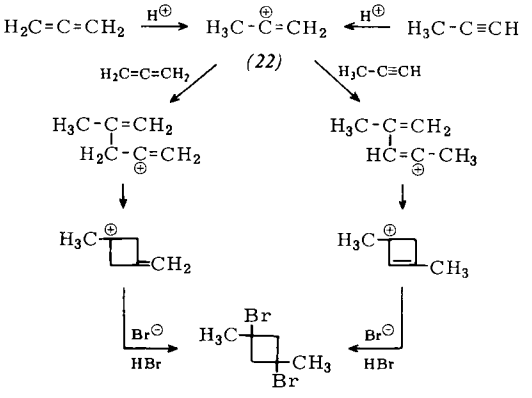
However, it was recently recognized that such reactions may be more complex. Thus in the electrophilic addition of hydrogen bromide to allene, it was found that considerable quantities of 1,3-dibromo-1,3-dimethylcyclobutane [two isomers, *(20)* and *(21)*] were formed as well as products of the type *(18)* and *(19)* [65].



Model experiments showed that these cyclic products do not result from a simple head-to-tail dimerization of 2-bromopropene. A mechanism was therefore proposed [82] for this novel electrophilically induced cyclodimerization, in which the cyclization is assumed to be

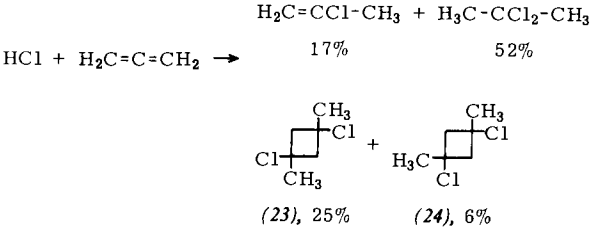
[80] *P. R. Austin*, U.S.-Pat. 2585529 (1952); Chem. Abstr. *46*, 3799 (1952).
[81] *T. L. Jacobs* and *R. N. Johnson*, J. Amer. chem. Soc. *82*, 6397 (1960).
[82] *K. Griesbaum*, Angew. Chem. *76*, 782 (1964); Angew. Chem. internat. Edit. *3*, 697 (1964).

brought about by a vinyl carbonium ion *(22)*. However, since the reaction of methylacetylene with HBr also leads to cyclodimerization [82], and since the rearrangement of allene to methylacetylene in the presence of HBr cannot be ruled out, it is not immediately possible to distinguish between the two routes given in Scheme 4.



Scheme 4. Cyclodimerization of allene and methylacetylene on addition of HBr.

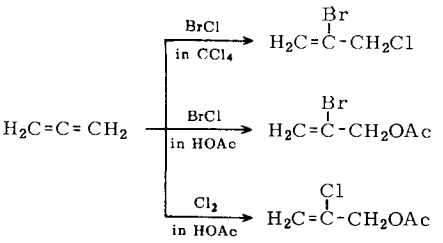
Preliminary studies of the scope of this cyclodimerization have shown that, contrary to previous results [81], considerable quantities of the cyclodimerization products *(23)* and *(24)* are also obtained in the hydrochlorination of allene [83].



No such cyclodimerization products were observed in the ionic addition of hydrogen fluoride [80], hydrogen iodide [83], phenol [84], and water [62] to allene. These reactions are all reported to lead to the conventional Markovnikov adducts. Apart from the addition of hydrogen iodide, however, all these reactions were studied before the occurrence of cyclodimerization was recognized, so that further studies will be necessary before a final conclusion can be reached. Nevertheless, all these reactions, irrespective of whether they give cyclic or linear products, evidently begin with the protonation of a terminal carbon atom.

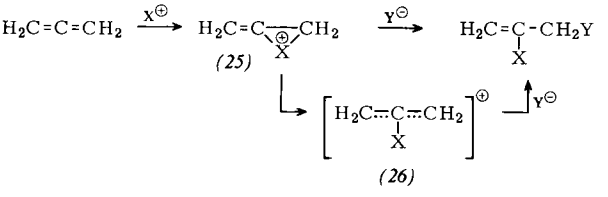
In the addition of halogens and interhalogen compounds [85], on the other hand, the opposite orientation was observed (Scheme 5).

In analogy to the bromonium complex formed in the addition of bromine to olefins [86], the first intermediate



Scheme 5. Addition of halogens and interhalogen compounds to allene.

in these reactions may be a π-complex *(25)*, which rearranges to form the resonance-stabilized allyl carbonium ion *(26)*.



However, the observed orientation could also be explained by a direct attack of the nucleophile $Y^{\ominus}$ on *(25)*; in this case, the reaction on the terminal $sp^3$ carbon atom should be preferred to that on the center $sp^2$ carbon atom. It would then be unnecessary to assume the formation of the allyl carbonium ion *(26)*. In any case, the difference in orientation in the addition of HX compounds on the one hand and of $X_2$ and XY compounds on the other is understandable in view of the fact that protons cannot form bridged π-complexes with olefins [86]. The addition of HX compounds is probably influenced by the polarization of the allene molecule [5]:

All reported additions of compounds of the types $X_2$ and XY can be selectively directed so as to give the monoadduct. Sometimes, however, the nature of the adduct is strongly dependent on the solvent. For example, if the reaction is carried out in acetic acid with the chloride ion as the nucleophile, *i.e.* in the addition of $Cl_2$ or BrCl, the principal product is the haloacetate *(27)*, *i.e.* the acetate ion successfully competes with the chloride ion. This difficulty does not arise when the bromide ion is used as the nucleophile. Thus the addition of bromine to allene yields 2,3-dibromopropene *(28)*, no matter whether the reaction is carried out in acetic acid or in an inert solvent such as $CCl_4$ or $CH_2Cl_2$. The addition of BrCl in an inert solvent leads to the expected adduct *(29)*, whereas the addition of chlorine, also in an inert solvent, yields not only the adduct *(30)*, but also an equimolar quantity of the adduct *(31)*.

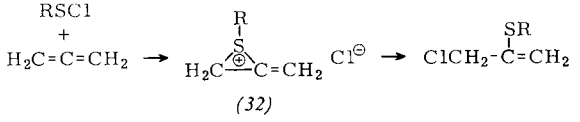
[86] *N. C. Deno* in: Progress in Physical Organic Chemistry. Interscience, New York 1964, p. 145.

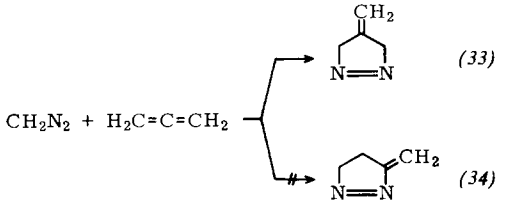
A predominantly anti-Markovnikov orientation was also observed in the addition of 2,4-dinitrophenylsulfenyl chloride [81] and in the reaction of dimethyl- [87] and diethylphosphorylsulfenyl chloride [88] with allene. Since these reactions also proceed *via* a bridged ion *(32)*, the orientation probably depends on the same factors as were indicated for the addition of halogens [89].



*(32)*

### 3. 1,3-Dipolar Additions

The only known example of this type of reaction with allene is the addition of diazomethane [90–92]; of the two possible products *(33)* and *(34)*, only the isomer *(33)* is obtained, *i.e.* the orientation is the same as in the addition of compounds of the type HX.



*(33)* *(34)*

### 4. Selective Reduction of Allene

The term "selective reduction" or "selective hydrogenation" of allene is used in the literature both for the reduction of allene to propylene and for the reductive removal of allene from mixtures of olefins without hydrogenation of the double bonds of these olefins [8,93]. Selective reduction of allene to propylene can be achieved either with chromium(II) sulfate or by catalytic hydrogenation [94]. Metals of group VIII, as well as noble metals, have been used as catalysts at relatively low hydrogen pressures and at temperatures between 20 and 120 °C. Some of these reactions are 100% selective [94].

## B. Cyclization and Condensation Reactions of Allene

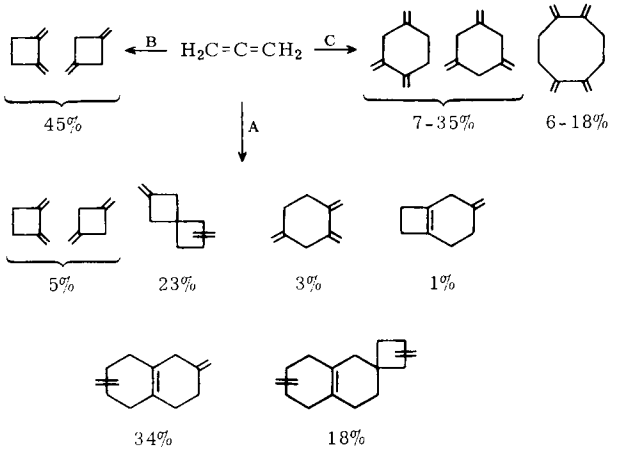
### 1. Homocyclization of Allene

The homocyclization or oligomerization of allene can be achieved by three methods: prolonged heating of liquid allene in a sealed tube at 110 to 160 °C, heating of gaseous allene at 400 to 600 °C for a short time in a flow apparatus, and cyclization in the presence of catalysts.

The oligomerization of liquid allene has been known for more than 50 years [95]. Though the impression has arisen over the years that this reaction is a convenient process for the synthesis of the allene dimer 1,2-dimethylenecyclobutane, more recent studies [96–99] have confirmed the original observation [95] that several compounds are formed and that the above dimer constitutes only a small part (about 5%) of the mixture of products. Other products are shown in Scheme 6 [97–99]

The pyrolysis of gaseous allene at 400 to 600 °C in a flow apparatus yields less of the higher oligomers [96–100], a mixture of 1,2- and 1,3-dimethylenecyclobutanes in a ratio of 3:1 to 4:1 being obtained in a yield of up to 45% [101,102].

Catalytic oligomerization with phosphorus-modified nickel carbonyl catalysts, on the other hand, leads to two trimers and a tetramer, whereas no dimer is formed (Scheme 6) [103–105].



Scheme 6. Products of the oligomerization of allene.

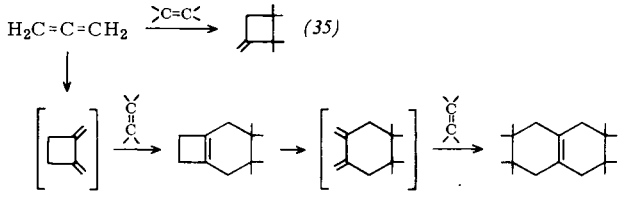
[105] This ratio can be varied by the proper choice of catalyst.

## 2. Co-cyclization and Condensation of Allene with other Unsaturated Compounds

Allene can be co-cyclized with monoolefins containing an activated double bond, with conjugated diolefins, and with acetylene.

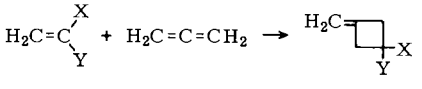
The thermal condensation of allene with activated monoolefins may proceed by one of the routes shown in Scheme 7. The product formed depends largely on the nature of the olefin, and sometimes also on the reaction conditions, particularly the ratio of the reactants.



Scheme 7. Reactions of allene with olefins containing an activated double bond.

Tetrafluoroethylene [106] and some monosubstituted and unsymmetrically disubstituted ethylenes [107] react with preferential formation of derivatives of methylenecyclobutane *(35)* (Table 4), and this provides a particularly elegant one-step synthesis of 3-substituted methylenecyclobutanes [108].

Table 4. Examples of the one-step synthesis of 3-substituted methylenecyclobutanes [107].



| X | Y | Yield (%) |
|---|---|---|
| H | CN | 60 |
| $CH_3$ | CN | 62 |
| H | COOH | 21 |
| H | $COOCH_3$ | 25 |
| $CH_3$ | $COOCH_3$ | 25 |
| $CH_3$ | CH=O | 6.7 |
| H | $C_6H_5$ | 22 |
| $CH_3$ | $C_6H_5$ | 20 |

The photochemical reaction of cyclopentenone with allene leads to good yields of the two isomeric methylenecyclobutane adducts *(36)* and *(37)*, compound *(36)* being the major product [109].

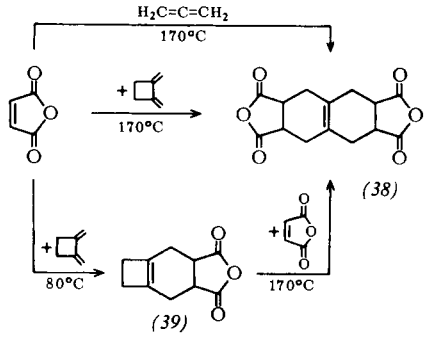
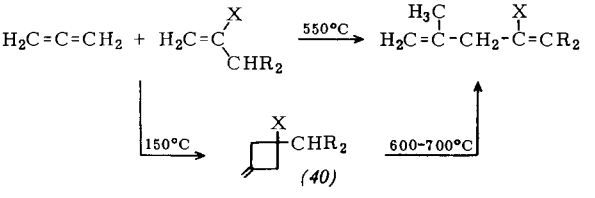
[109] *P. E. Eaton,* Tetrahedron Letters *1964,* 3695.

Heating with maleic anhydride, on the other hand, leads preferentially, but not exclusively [110], to the $\Delta^{4a,8a}$-octahydronaphthalene derivative *(38)* [96, 110, 111]. Model experiments with 1,2-dimethylenecyclobutane and maleic anhydride at different temperatures gave the strong indication that this reaction proceeds *via* 1,2-dimethylenecyclobutane and its subsequent Diels-Alder adduct *(39)* [96].



A reaction that does not at first sight appear to fit into either of these two categories is the condensation of allene with certain 2-substituted α-olefins to form open-chain 1,4-dienes [112]. However, when this reaction was carried out in steps at relatively low temperatures, it was found that it proceeds *via* a methylenecyclobutane intermediate *(40)*.



X: -CN, $-CO_2CH_3$, $-CH_3$, $-C_6H_5$

The co-cyclization of allene with conjugated dienes (Diels-Alder reaction) has been repeatedly described. Reliable data are available for the reactions of allene with cyclopentadiene and with hexachlorocyclopentadiene [113–115]. Both these reactions lead to the expected Diels-Alder adducts *(41)* having a methylenenorbornene structure.

[110] Small quantities of the compounds *(37a)* and *(37b)* were also formed: *K. Alder* and *O. Ackermann,* Chem. Ber. *90,* 1697 (1957).

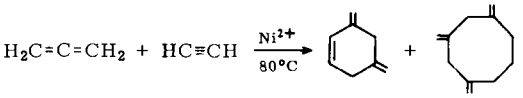
*(41b)*, 76% *(41a)*, 48%

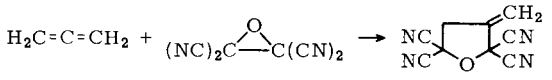
The reaction of allene with acetylene in the presence of nickel salts leads to a mixture of the 2:1 and 3:1 adducts *(42)* and *(43)*, but not to the acetylene tetramer, cyclooctatetraene, provided that allene is used in excess with respect to acetylene [116]. Similar results were obtained with substituted acetylenes [116].



*(42)*, 45% *(43)*, 5%

### 3. Addition of Allene to Saturated Systems

The reaction of allene with tetracyanoethylene oxide [117] yields the crystalline adduct *(44)* in a yield of more than 70%.

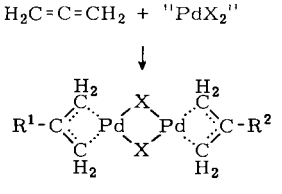


*(44)*

## C. Organometallic Chemistry of Allene [118]

Apart from a description of an $HgCl_2$ and an Na adduct [62] of doubtful structure, the organometallic chemistry of allene was virtually non-existent up to about 10 years ago. It is only recently that definite metal compounds of allene, the palladium $\pi$-allyl complexes, were prepared [119,120]. When gaseous allene is introduced into a solution of $(C_6H_5CN)_2PdCl_2$ in benzene or into a methanolic solution of $Na_2PdCl_4$ or $K_2PdBr_4$, complexes of the type *(45)* are formed in good yields.

On the other hand, when solid $(C_6H_5CN)_2PdCl$ is added to a solution of allene in benzene, the main product is the complex *(46)*. The reaction of allene with the same palladium reagent in benzonitrile yields the complex *(47)*, and in methanol the complexes *(47)* and *(48)* are formed in a ratio of almost 1:1.



*(45)*, $R^1 = R^2 = X = Cl, Br$

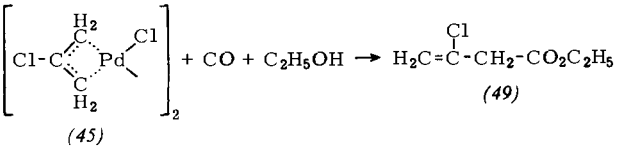
*(46)*, $R^1 = X = Cl$; $R^2 = -C(=CH_2)-CH_2Cl$

*(47)*, $R^1 = R^2 = -C(=CH_2)-CH_2Cl$; $X = Cl$

*(48)*, $R^1 = R^2 = -C(=CH_2)-CH_2OCH_3$; $X = Cl$

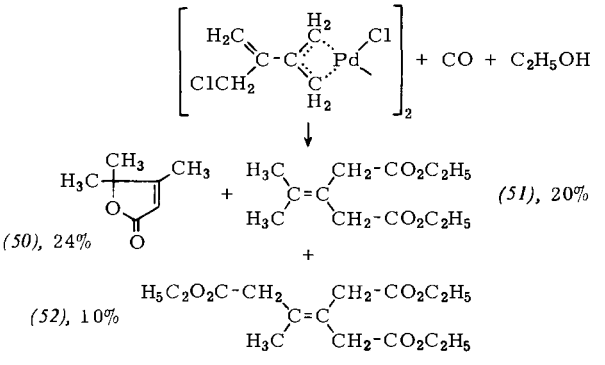
Preliminary studies showed that the bridging chlorine atoms in these compounds can be replaced by bromine, iodine, or thiocyanate, that the bridges can be cleaved by amines, and that the reaction with acetylacetone yields mononuclear complexes [120].

In analogy to the carbonylation of other Pd-allyl complexes [121], the carbonylation of the $PdCl_2$ complex *(45)* in ethanol leads to the ester *(49)* [122].

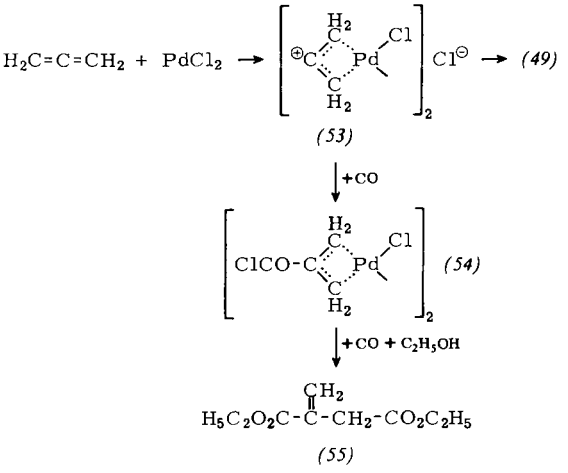


*(45)* *(49)*

The carbonylation of the $PdCl_2$ complex *(47)*, on the other hand, takes a more complicated course, and gives at least three products *(50)–(52)* in moderate yields [122].



Yet another route is followed by the direct carbonylation of allene in the presence of $PdCl_2$ [122]. Instead of a chlorination of the center carbon atom, such as occurs in the carbonylation of the $PdCl_2$ complex *(45)*, the $\pi$-complex *(53)* is chloroformylated to the intermediate complex *(54)*, which then yields the ester *(55)* in a normal carbonylation.



[116] *R. E. Benson* and *R. V. Lindsey jr.*, J. Amer. chem. Soc. *81*, 4250 (1959).

[117] *W. J. Linn* and *R. E. Benson*, J. Amer. chem. Soc. *87*, 3657 (1965).

[118] This section deals with reactions that could equally well be discussed as "Addition reactions".

[119] *R. G. Schultz*, Tetrahedron Letters *1964*, 301; Tetrahedron *20*, 2809 (1964).

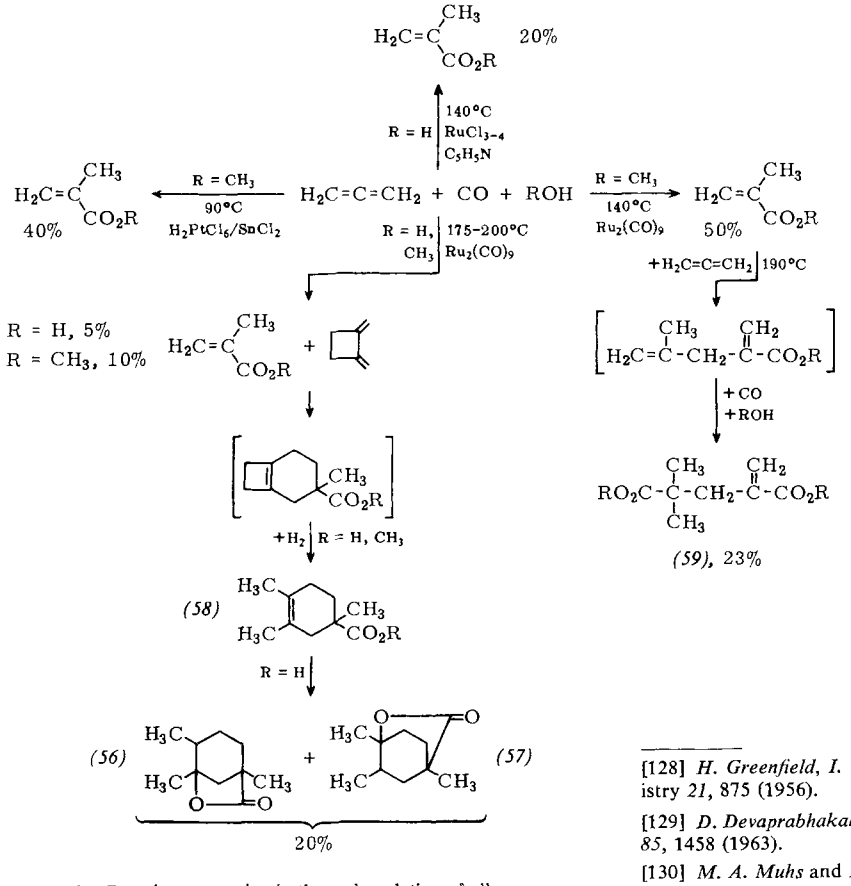
[120] *H. S. Lupin* and *B. L. Shaw*, Tetrahedron Letters *1964*, 883.

[121] *T. Tsuji, J. Kiji, S. Imamura*, and *M. Morikawa*, J. Amer. chem. Soc. *86*, 4350 (1964).

[122] *J. Tsuji* and *T. Susuki*, Tetrahedron Letters *1965*, 3027.

Interesting results were obtained also in the carbonylation of allene with $H_2PtCl_6/SnCl_2$ and particularly with $Ru_2(CO)_9$ as catalyst [123,124]. The reaction with $Ru_2(CO)_9$ between 90 and 140 °C leads to methacrylic acid when water is used as the solvent, and to methyl methacrylate when methanol is used. At 175 to 200 °C, on the other hand, only traces of these compounds are formed, and the main products isolated are the lactones *(56)* and *(57)* or the cyclic methyl ester *(58)*, depending on whether water or methanol is used as solvent. Finally, if the reaction is carried out in steps, first at 140 °C and then at 190 °C in methanol, dimethyl α,α-dimethyl-α'-methyleneglutarate *(59)* is formed together with methyl methacrylate. These results, which appear remarkable at first sight, are explained by Scheme 8 [124], from which it can be seen that some of the reactions resemble those discussed in the last section.

The hydroboration of allene is reported to yield a waxy organoborine polymer, from which 1,3-propanediol is obtained on treatment with hydrogen peroxide and base [125,126]. It was concluded, therefore, that the polymer has a 1,3-structure, *i.e.* that the electrophilic diborane [127] adds to the terminal carbon of allene.



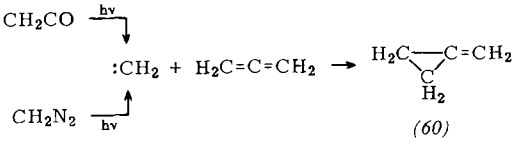
Scheme 8. Reactions occurring in the carbonylation of allene.

The reaction of allene with octacarbonyldicobalt leads to an ill-defined organocobalt compound, which catalyses the polymerization of allene [128]. A mercury(II) chloride adduct [129] and a silver nitrate complex [130] of allene have recently been described; however, no details were reported.

## D. Carbene Chemistry of Allene

### 1. Addition of Carbenes to Allene

The photolysis of ketene and of diazomethane in the presence of allene gives good yields of the expected methylenecyclopropane *(60)*, provided that the conditions are such that the initially highly excited adduct can be stabilized [131,132].



[123] *E. L. Jenner* and *R. V. Lindsey jr.*, U.S.-Pat. 2875254 (1959); Chem. Abstr. *53*, 14000 (1959).

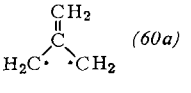
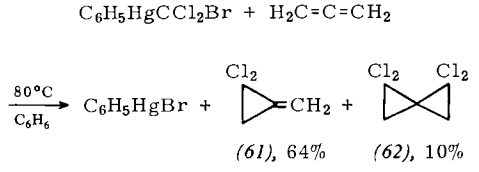
[130] *M. A. Muhs* and *F. T. Weiss*, J. Amer. Chem. Soc. *84*, 4697 (1962).

[131] *H. M. Frey*, Trans. Faraday Soc. *57*, 951 (1961).

[132] The pyrolysis of the diazomethane adduct *(33)* also yields methylenecyclopropane *(60)*; however, this reaction proceeds not *via* a carbene, but *via* trimethylenemethane *(60a)* [92]. Since trimethylenemethane is also formed in the photolysis of *(33)* at low temperatures, the formulation of this photolysis as a carbene reaction [131] became doubtful.



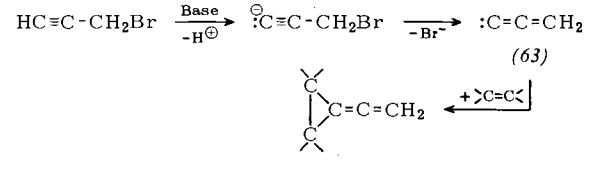
No additions of dihalocarbenes to allene were known until recently, probably because most syntheses of dihalocarbenes require strongly basic conditions, which lead to isomerization of allene. However, after introduction of the thermal preparation of dihalocarbenes from phenyltrihalomethylmercury compounds in the absence of bases, addition of dichlorocarbene to allene was recently achieved [133]. The product is a mixture of the adducts *(61)* and *(62)*.



*(61)*, 64% *(62)*, 10%

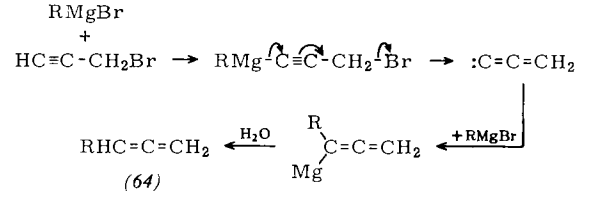
## 2. Allenyl Mono- and Dicarbenes

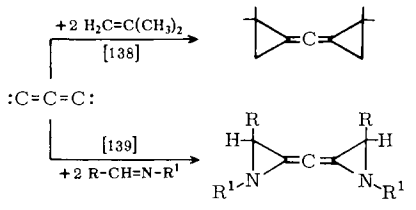
Whereas the existence of substituted alkenylidenes has been conclusively demonstrated [134], the evidence for the existence of allenylidene *(63)* was for a long time rather meager. The reaction of propargyl bromide with potassium t-butoxide in the presence of *cis*-2-butene leads to a mixture of hydrocarbons, whose infrared spectrum shows the presence of both allenic and acetylenic unsaturation. It was concluded that this reaction proceeds at least partly with the intermediate formation of allenylidene [135].



More convincing evidence has recently been discovered: The reaction of propargyl bromide with alkylmagnesium bromide in ether below 0 °C yields a substituted allene *(64)* as main product, and the following mechanism was proposed for this reaction [136]:

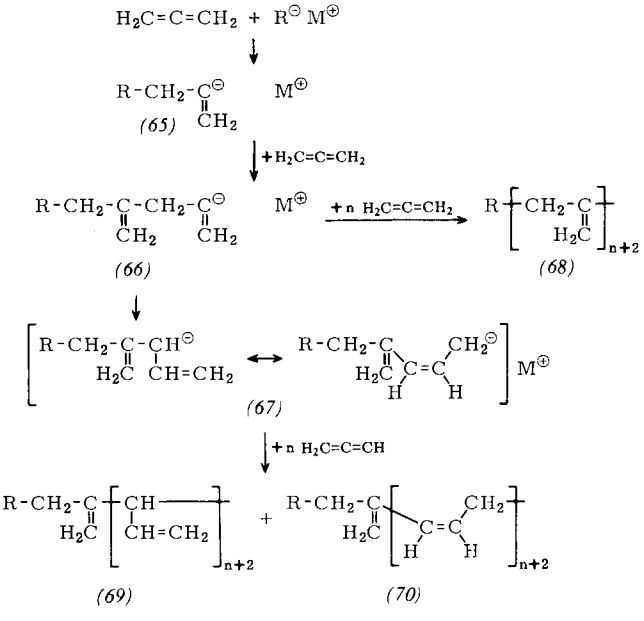
Allene dicarbene, which was first discovered in the atmosphere of a comet [137], was recently also detected on Earth. The dicarbene occurs in carbon vapor produced *in vacuo* from elementary carbon.





### E. Polymerization of Allene

Though a radon-initiated [140] and a photochemical [141] polymerization of allene had been reported earlier, no authentic high polymer of allene had been described up to 1963. The polymerization of allene by various transition-metal salts reduced with triisobutylaluminum (Ziegler catalysts) yields a linear polyallene of high molecular weight. The polymer is amorphous or crystalline (m.p. 122±3 °C), depending on the reaction conditions [142, 143]. Its structure is not uniform, but consists of blocks of vinylidene *(68)*, vinyl *(69)*, and *cis*-olefin structures *(70)*. This non-uniformity is thought to be due to the anionic reaction sequence in Scheme 9 [142], leading by a selective terminal attack on allene to the intermediates *(65)*–*(67)*, from which the observed structures *(68)*–*(70)* are derived.



Scheme 9. Polymerization of allene.

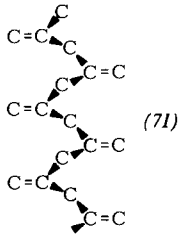
[143] *I. M. Robinson,* U.S.-Pat. 3151104 (1964); Chem. Abstr. *62*, 1760 (1965).

A largely uniform high molecular weight polyallene ($\overline{M}_n \approx 10^5$; m.p. 60 to 61 °C) with a vinylidene structure is obtained when π-complexes of nickel are used as catalysts. On the basis of X-ray analysis and because of the occurrence of dichroism in the IR spectrum, this polymer was assigned the helix structure *(71)* [144, 145].



*(71)*

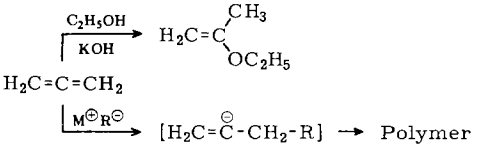
Experiments with other catalysts have so far had little success. For example, the polymerization of allene with octacarbonyldicobalt [124, 144], tri-(π-allyl)cobalt, or nickel(II) acetonylacetate reduced with triethylaluminum yielded only insoluble polymers, while nickel(II) complexes, pentacarbonyliron, and other iron complexes gave no polymer at all [144].

The copolymerization of allene with other olefins has been repeatedly described but no data have been given regarding the structures of the copolymers [146, 147]. The copolymerization of allene and ethylene in the presence of transition-metal salts reduced with aluminum alkyls is reported to yield a copolymer containing the allene in the form of vinyl, vinylidene, and *cis*-olefin structures [148], as in the products obtained by the homopolymerization of allene with Ziegler catalysts [142].

## V. Conclusion

This brief survey has shown that considerable progress has been made in the past ten years [149] in the preparation and in the chemistry of allene. However, it should not be assumed that the chemistry of allene is now known and understood in all its details. On the contrary, it is probable that allene will attract even more interest in the future for several reasons.

First, there are many questions mentioned in this report that still remain to be answered. Thus there is no general concept that permits an adequate description of the manner in which the course of ionic or free-radical additions depends on the nature of the addend. The explanations advanced so far are at best only working hypotheses. Further, there are a number of typical olefin reactions that have never been systematically investigated for allene. For example, only one publication describes a true anionic addition to allene [150], and the course of this reaction is opposite to that of the polymerization of allene, though the latter has also been described as an anionic reaction [142].



Secondly, any progress in the separation of allene, *i.e.*, in the direction of a more economical synthesis, could lead to industrial interest in the chemistry of this compound, *e.g.* in the use of some of the selective free-radical additions leading to 1,3-difunctional products, or in the use of organometallic reactions of allene. On the other hand, the discovery of reactions that utilize allene selectively, or give the same products from a mixture of allene and methylacetylene [151], would also be of interest.

Thirdly, the results of studies on the chemistry of allene may prove useful in other fields of chemistry. Thus the study of free-radical additions has thrown light on the relative availability of vinyl radicals in comparison with primary, secondary, and tertiary alkyl radicals, and the preferred addition of HX compounds to allene *via* a vinyl carbonium ion (propenylium ion) casts doubt on the reported instability of vinyl carbonium ions.

# Reactions of the Carbonyl Group in Fluorinated Ketones

BY DR. N. P. GAMBARYAN, E. M. ROKHLIN, YU. V. ZEIFMAN, CHEN CHING-YUN, AND PROF. I. L. KNUNYANTS

INSTITUTE FOR ORGANO-ELEMENTAL COMPOUNDS, ACADEMY OF SCIENCES OF THE USSR, MOSCOW (USSR)

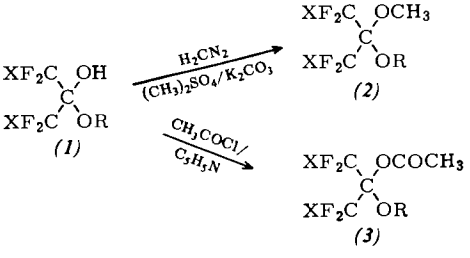
*The chemistry of polyfluorinated ketones has recently received a great deal of attention* [1,2] [a]. *The carbonyl and imino groups of the fluorinated ketones and their imines react in many different ways. In particular, the electron-attracting perfluoroalkyl groups intensify the electrophilic properties and weaken the nucleophilic properties of the carbonyl group. The perfluoroalkyl group also hinders the heterolytic removal of the hydroxyl group from adducts*  *by reducing the stability of the carbonium ion*  *. The increased electrophilicity of the carbonyl group and the increased stability of the addition products leads not only to a change in reactivity in the characteristic ketone reactions, but also to numerous new reactions which are not observed with non-fluorinated ketones. Thus it is possible to synthesize a wide variety of fluoroorganic compounds from perfluorinated ketones* [b].

## I. Reactions of Fluorinated Ketones with Nucleophiles

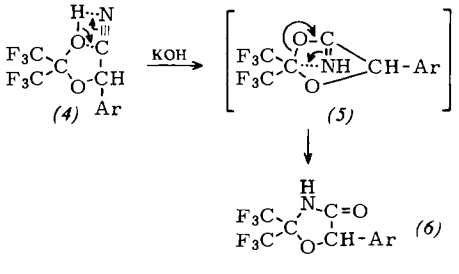
### 1. Alcohols and Amines

Hexafluoroacetone reacts vigorously with water [c] or alcohols, giving the "hydrate" or 2-alkoxyhexafluoropropan-2-ols *(1)*, with X = F, which decompose on heating to the starting materials [5,6] [d]. Alkylation of the compounds *(1)*, X = F, Cl, leads to fairly stable acetals *(2)* [5,6,8]; acylation yields *O*-acyl derivatives *(3)* [9].

Hexafluoroacetone and *gem*-hydroxynitriles (cyanohydrins) give unstable 2-(cyanoalkoxy)hexafluoro-2-propanols, *e.g. (4)*, which react with an excess of alkali



to form 5-substituted 4-oxo-2,2-bis(trifluoromethyl)-1,3-oxazolidines such as *(6)*, probably *via* unstable 4-imino-1,3-dioxolanes *(5)* [10,11].



Reactions with amines, amides, hydroxylamine, or semicarbazide lead to geminal amino alcohols *(7)* or to

[2] *H. P. Braendlin* and *E. T. McBee* in: Advances in Fluorine Chemistry. Butterworths, London 1963, Vol. 3, p. 1.

[a] The review by *Braendlin* and *McBee* [2] does not deal only with perfluorinated ketones; moreover, though published in 1963, it is already outdated. The papers discussed in [1,2] will not be reviewed in the present article.

[b] We have been concerned mainly with hexafluoroacetone, since in addition to being the most readily available and simplest perfluorinated ketone, this is also a typical representative of this class of compounds.

[c] Similarly, geminal mercapto alcohols are formed from fluorinated ketones with $H_2S$ [3,4].

[6] *I. L. Knunyants, Chen Ching-yun*, and *N. P. Gambaryan*, Izvest. Akad. Nauk SSSR, Otdel. chim. Nauk *1960*, 686.

[d] 2-Alkoxynitropentafluoro-2-propanols, prepared from perfluoronitroacetone, are more stable [7].

[7] *I. L. Knunyants, A. V. Fokin*, and *V. A. Komarov*, Izvest. Akad. Nauk SSSR, Ser. chim. *1966*, 466.

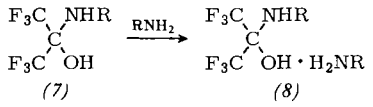
[8] *H. E. Simmons* and *D. W. Wiley*, J. Amer. chem. Soc. *82*, 2288 (1960).

[9] *P. E. Newallis* and *P. Lombardo*, J. org. Chemistry *30*, 3834 (1965).

[10] *Yu. V. Zeifman* and *N. P. Gambaryan*, Izvest. Akad. Nauk SSSR, Ser. chim. *1964*, 1687.

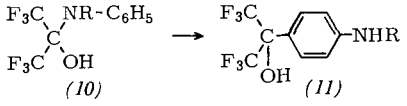
[11] *Yu. V. Zeifman* and *N. P. Gambaryan*, Izvest. Akad. Nauk SSSR, Ser. chim. *1964*, 1622.

the adducts *(8)* [12–18] [e]. A compound previously [2] thought to be the semicarbazone of hexafluoroacetone was identified by us as *(7)*, R = $NHCONH_2$ [14].



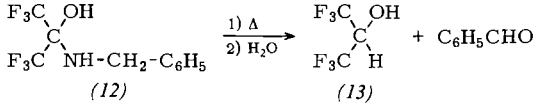
*(7)* *(8)*

The further reaction of geminal amino alcohols depends on the reaction partner RR'NH, and can lead to products of rearrangement, redox reactions, or cleavage. Geminal amino alcohols containing an *N*-aryl group, *e.g. (10)*, rearrange to carbinols such as *(11)* [18, 23, 24] [f].



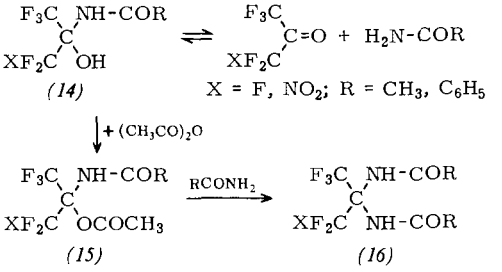
*(10)* *(11)*

Geminal amino alcohols containing an *N*-benzyl group, *e.g. (12)*, undergo a redox reaction on heating to give benzaldehyde derivatives and a fluorinated alcohol [26] (cf. Section I.6).



*(12)* *(13)*

When heated with acetic anhydride, geminal amino alcohols containing an *N*-acyl group, *e.g. (14)*, are converted into *O*-acetyl compounds *(15)* or 2,2-bis-(acylamino)pentafluoropropanes *(16)* [17, 27] [g].

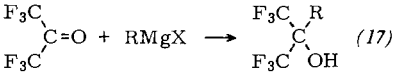


*(14)* X = F, $NO_2$; R = $CH_3$, $C_6H_5$

*(15)* *(16)*

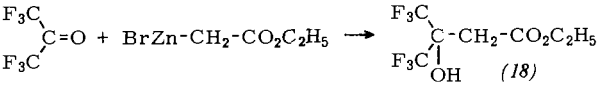
## 2. Organometallic Compounds

Like all ketones, hexafluoroacetone reacts with organometallic compounds, *i.e.* Grignard, Iozič [h], and Reformatsky compounds, to give derivatives of the types *(17)* and *(18)* [6, 18] [i].



*(17)*

R = $CH_3$, $C_2H_5$, $C_6H_5$, $HC{\equiv}C$, $C_6H_5{-}C{\equiv}C$, $CH_2{=}CH{-}C{\equiv}C$, $(CH_3)_2C(OH){-}C{\equiv}C$, $(CF_3)_2C(OH){-}C{\equiv}C$



*(18)*

The reaction with organometallic compounds is well suited to the experimental confirmation of the stronger electrophilic activity of fluorinated as compared with non-fluorinated ketones, owing to its irreversibility and the stability of the products. Thus a mixture of acetone, hexafluoroacetone, and phenylmagnesium bromide gives only bis(trifluoromethyl)phenylmethanol, *(17)* with R = $C_6H_5$, the yield being unaffected by the amount of acetone present [18].

## 3. Aliphatic Diazo Compounds

In reactions with diazoacetic ester, non-fluorinated ketones are generally nucleophilic, since they react with the electrophilic ethoxycarbonylcarbene to form enol ethers [28]. Unlike non-fluorinated ketones, hexafluoroacetone reacts with the weakly nucleophilic diazoacetic ester *(19)* to form ethyl 2,3-epoxy-4,4,4-trifluoro-3-

[26] *N. P. Gambaryan* and *I. L. Knunyants*, Izvest. Akad. Nauk SSSR, Ser. chim. *1965*, 722.

[27] *I. L. Knunyants, Yu. V. Zeifman*, and *N. P. Gambaryan*, Izvest. Akad. Nauk SSSR, Ser. chim. *1966*, 1108.

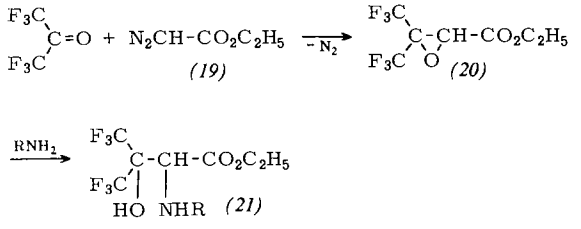
[g] Geminal amino alcohols, *(7)* with R = alkyl or aryl, are decomposed to hexafluoroacetone and *N*-alkyl- (or aryl)acetamide by acetic anhydride [13].

[h] Iozič compounds are alkynylmagnesium bromides.

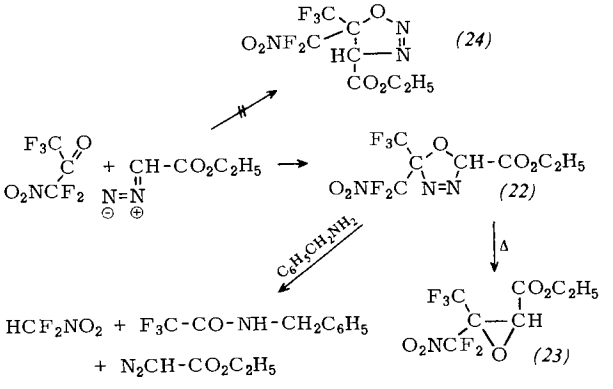
[i] Isopropylmagnesium bromide gives only hexafluoroisopropanol (80% yield) [18].

[28] *I. L. Knunyants, N. P. Gambaryan*, and *E. M. Rokhlin*, Usp. Chim. *27*, 1361 (1958).

trifluoromethylbutyrate *(20)* [29] [k]. As can be seen by comparison with the non-fluorinated analogue, cleavage of the oxirane ring in *(20)* by nucleophiles proceeds more readily and in another direction. Thus, with amines racemic ethyl 2-alkylamino-4,4,4-trifluoro-3-hydroxy-3-trifluoromethylbutyrates *(21)* are formed [30].



Pentafluoronitroacetone, which is even more electrophilic than hexafluoroacetone, reacts very vigorously with diazoacetic ester, even at −40 °C, to give a stable adduct *(22)*, which liberates nitrogen only on prolonged heating at 165 °C to give ethyl 2,3-epoxy-4,4-difluoro-4-nitro-3-trifluoromethylbutyrate *(23)* [29]. The fragments formed by the reaction of the primary adduct with benzylamine are compatible only with structure *(22)*; the isomer *(24)* may be ruled out.

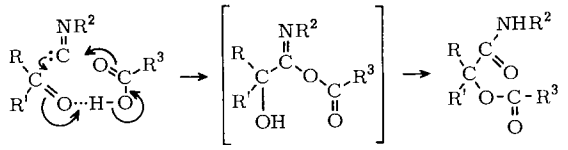


It is of interest to establish the direction of addition of the diazoacetic ester to polar multiple bonds. Since the carbonyl double bond in perfluoroketones is polarized (see Section I.4), the direction of addition is determined by the electronic structure of the diazoacetic ester. Our results, which indicate a nucleophilic attack by the terminal nitrogen atom on the carbonyl carbon, show that a considerable contribution is made by canonical structures such as

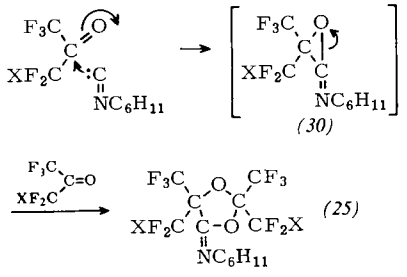
$\overset{\ominus}{N}{=}\overset{\oplus}{N}\text{–}CH\text{–}CO_2R$ and $\overset{\ominus}{N}{=}N\text{–}\overset{\oplus}{C}H\text{–}CO_2R$.

### 4. Isocyanides and Trialkyl Phosphites

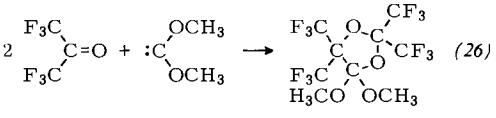
Isocyanides generally are regarded as weak nucleophiles, or to some extent as nucleophilic carbenes. However, the nucleophilicity of isocyanides is insufficient for reaction with ordinary carbonyl compounds in the absence of a third component. Non-fluorinated ketones react with isocyanides only in the presence of acids, which increase the positive charge on the carbonyl carbon (Passerini and Ugi reactions) [31, 32].



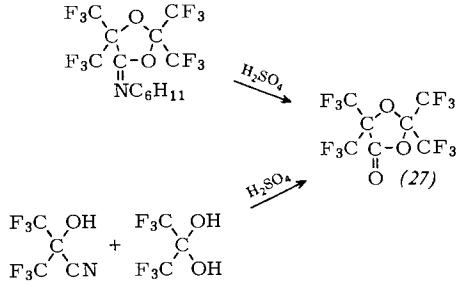
The electrophilicity of fluorinated ketones, on the other hand, is so high that they react vigorously with cyclohexyl isocyanide without a catalyst, to form cyclohexyl-



iminodioxolanes *(25)*, X = F or $NO_2$ [33]. A similar reaction of fluorinated ketones with dialkoxycarbenes, which leads to dialkoxydioxolanes such as *(26)*, has recently been described [34, 35] [l].



The iminodioxolane *(25)*, X = F does not decompose at 200 °C, and is hydrolysed only slowly by concentrated sulfuric acid at 100 °C to the dioxolanone *(27)*, the structure of which is confirmed by its chemical properties and by independent synthesis [33, 36].



[29] *N. P. Gambaryan, L. A. Simonyan,* and *I. L. Knunyants,* Doklady Akad. Nauk SSSR *155*, 833 (1964).

[k] In a similar reaction, diphenyldiazomethane gives 1,1-bis(trifluoromethyl)-2,2-diphenylethylene oxide [18].

[30] *N. P. Gambaryan* and *L. A. Simonyan,* Izvest. Akad. Nauk SSSR, Ser. chim. *1964*, 1529.

[31] *M. Passerini,* Gazz. chim. ital. *61*, 964 (1931).

[32] *I. Ugi,* Angew. Chem. *74*, 9 (1962); Angew. Chem. internat. Edit. *1*, 8 (1962).

[33] *N. P. Gambaryan, E. M. Rokhlin, Yu. V. Zeifman, L. A. Simonyan,* and *I. L. Knunyants,* Doklady Akad. Nauk SSSR *166*, 864 (1966).

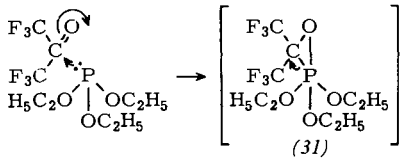
[34] *R. A. Braun,* J. Amer. chem. Soc. *87*, 5516 (1965).

[35] *R. A. Braun,* J. org. Chemistry *31*, 1147 (1966).

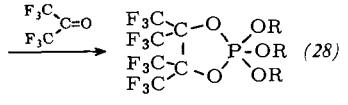
[l] A similar cyclic adduct (2:1) is formed with dimethylsilene $(CH_3)_2Si$ [34].

[36] *I. L. Knunyants, E. M. Rokhlin, N. P. Gambaryan, Yu. A. Cheburkov,* and *Chen Ching-yun,* Chim. Nauka i Prom. *4*, 802 (1959).

The characteristic ability of isocyanides to undergo α-additions is due to the fact that the "carbene" carbon has a lone pair of electrons as well as an empty orbital. Tervalent phosphorus, whose compounds are also characterized by α-additions, has a similar dual character. Thus hexafluoroacetone reacts with triethyl phosphite under mild conditions to form an adduct of two molecules of hexafluoroacetone and one of triethyl phosphite. The properties of this adduct indicate a cyclic phosphorane structure *(28)*, R = $C_2H_5$. In contrast to the reaction with isocyanides, two fluoroketones are attached *via* C–C bridges in this case [37].

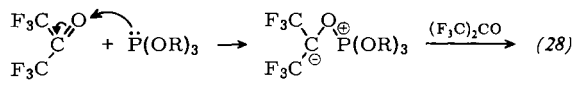


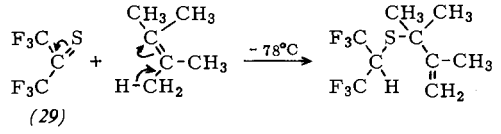
*(31)*



*(28)*

It is possible to explain the formation of the cyclic phosphorane *(28)*, R = $C_2H_5$, by an "inverse" polarization of the carbonyl group in hexafluoroacetone, similar to that of the thiocarbonyl group in perfluorothioacetone *(29)* [38]. Many authors believe that the Perkov reaction starts with an attack on the oxygen of the carbonyl group [39]. *Ramirez* [40]



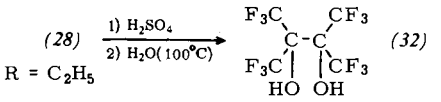


*(29)*

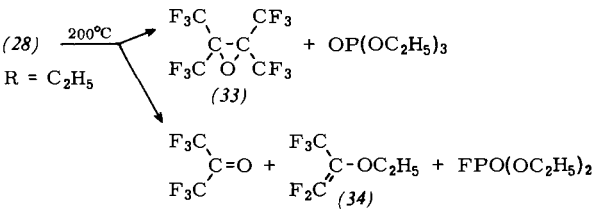
postulated a similar mechanism for the reaction of trialkyl phosphites with 1,2-dicarbonyl compounds. The first step in the reactions is assumed to be the attack of the nucleophilic trialkyl phosphite on the carbonyl oxygen. However, since the electronegativity of carbon is so much smaller than that of oxygen, "inverse" polarization of the carbonyl group is unlikely.

It may be assumed that the reaction of perfluoroketones both with isocyanides and with trialkyl phosphites begins with a nucleophilic attack on the carbonyl carbon and formation of a particularly reactive 1:1 adduct *(30)* or *(31)* containing a strained three-membered ring. The structure of the final product, *i.e.* the 2:1 adduct, will then depend on where the ring of the original 1:1 adduct opens. The iminooxirane *(30)* reacts by cleavage of a C–O bond, and not of a C–C bond as in most reactions of oxiranes. The phosphorane *(31)*, on the other hand, adds the second molecule of hexafluoroacetone by cleavage not of the P–O bond of the three-membered ring, but of the P–C bond, just as in the decomposition of the phosphorane containing a four-membered ring, which is formed as an intermediate in the Wittig reaction of carbonyl compounds with phosphorylides.

Hydrolysis of *(28)* yields perfluoro-2,3-dimethylbutane-2,3-diol (dodecafluoropinacol) *(32)* [37,41]. Thermal decomposition of *(28)* leads to perfluoro-2,3-dimethyl-2-butene oxide *(33)* [m] and 2-ethoxyperfluoropropene



*(32)*



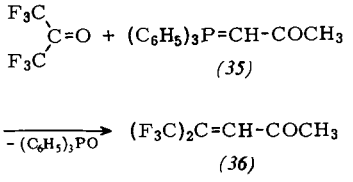
*(33)*

*(34)*

*(34)* [41]. Thus *(34)* is not a direct product of the reaction of hexafluoroacetone with triethyl phosphite, as was assumed by *Wiley* and *Simmons* [43], but is the result of further transformation of the stable adduct *(28)*.

## 5. Wittig-Staudinger Reactions

Unlike non-fluorinated ketones, hexafluoroacetone reacts even with very inactive "phosphorylides"; thus the reaction with acetylmethylenetriphenylphosphorane *(35)* leads to perfluoro(isopropylidene)acetone *(36)* [44,n].



*(35)*

*(36)*

Tetraphenyl(phosphine imide) *(37)* also reacts readily with carbonyl compounds of the type *(38)* [13,18] [o]. However, hexafluoro-*N*-phenylpropane-2-imine *(39)*, R =

[37] *N. P. Gambaryan, Yu. A. Cheburkov*, and *I. L. Knunyants*, Izvest. Akad. Nauk SSSR, Ser. chim. *1964*, 1526.

[m] The structure of *(33)* has been confirmed by independent syntheses from dodecafluoropinacol *(32)* with $P_2O_5$ and from bis(trifluoromethyl)diazirine with hexafluoroacetone [41,42].

[42] *R. B. Minasyan, E. M. Rokhlin, N. P. Gambaryan, Yu. V. Zeifman*, and *I. L. Knunyants*, Izvest. Akad. Nauk SSSR, Ser. chim. *1965*, 761.

[43] *D. W. Wiley* and *H. E. Simmons*, J. org. Chemistry *29*, 1876 (1964).

[44] *V. F. Plakhova* and *N. P. Gambaryan*, Izvest. Akad. Nauk SSSR, Otdel. chim. Nauk *1962*, 681.

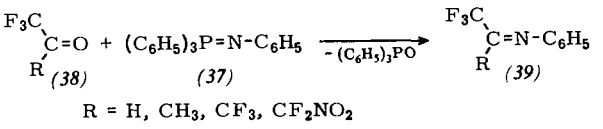
[n] Acetone does not react with *(35)* or with ethoxycarbonylmethylenetriphenylphosphorane *(35a)* even under severe conditions [44,45]. Monofluoroacetone, on the other hand, reacts with *(35a)* at 90 °C [45].

[45] *H. Machleidt, V. Hartmann*, and *H. Bünger*, Liebigs Ann. Chem. *667*, 35 (1963).

[o] *P,P,P*-triphenylphosphine imine reacts with hexafluoroacetone in the same way to give hexafluoropropan-2-imine [46].

[46] *Yu. V. Zeifman, N. P. Gambaryan*, and *I. L. Knunyants*, Doklady Akad. Nauk SSSR *153*, 1334 (1963).

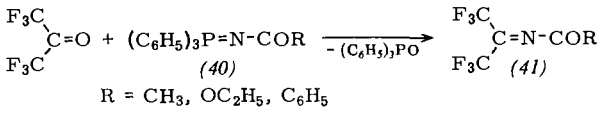
$CF_3$, is more conveniently prepared by heating hexafluoroacetone with phenyl isocyanate and a catalytic



*(38)* *(37)* *(39)*

R = H, $CH_3$, $CF_3$, $CF_2NO_2$

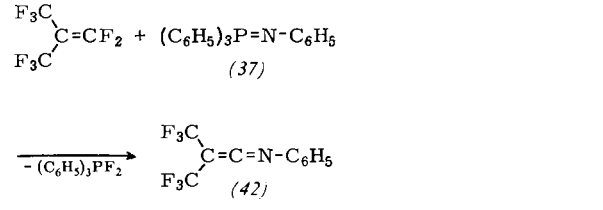
amount of triphenylphosphine oxide[46]; evidently *(37)* is an intermediate in this reaction[47]. Hexafluoroacetone reacts readily even with *N*-acyltriphenyl(phosphine imides) *(40)* to form *N*-acylimines *(41)*[17].



*(40)* *(41)*

R = $CH_3$, $OC_2H_5$, $C_6H_5$

Interestingly, tetraphenyl(phosphine imide) also reacts readily with perfluoroisobutene to give difluorotriphenylphosphorane and the anil *(42)* of bis(trifluoromethyl)ketene[48].

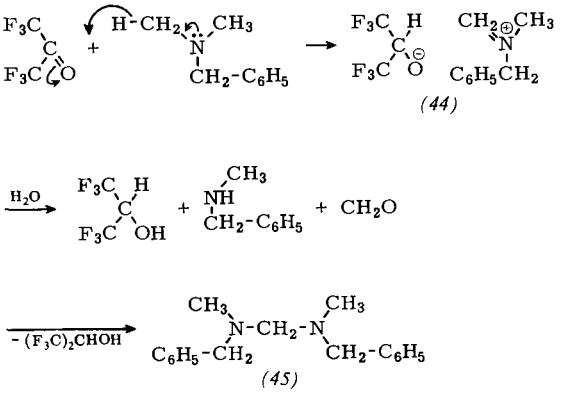


*(37)* *(42)*

### 6. Hydride Transfer

Hexafluoroacetone is readily reduced to 1,1,1,3,3,3-hexafluoro-2-propanol by $H^{\ominus}$ donors such as $Na[BH_4]$, $Li[AlH_4]$[49,50], or isopropylmagnesium bromide[18] (see also[51])[p].

However, the ease with which hexafluoroacetone abstracts protons from amines is unexpected. Hexafluoroacetone reacts exothermically with *N*-benzyldimethylamine to form an iminium salt *(44)*[26]. Surprisingly, the hydride ion is not removed from the methylene, but from the methyl group, evidently because of steric factors. The structure of *(44)* is inferred from the NMR spectrum and the chemical properties. Hydrolysis of *(44)* yields 1,1,1,3,3,3-hexafluoro-2-propanol and *N,N'*-dibenzyl-*N,N'*-dimethylmethylenediamine *(45)*, the latter being formed by condensation of formaldehyde and *N*-benzylmethylamine[26].



*(44)*

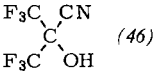
*(45)*

The fluorinated isopropyl alcohol is also obtained from hexafluoroacetone with benzylamine, triethylamine, and *N*-isopropyldimethylamine[26]. *N*-Benzyldiethyl- and tribenzylamines, on the other hand, do not react even when heated.

## II. Acid- and Base-Catalysed Reactions of Fluorinated Ketones

Many reactions of carbonyl compounds proceed only in the presence of acids or bases, and fluorinated ketones are fundamentally no exception in this respect. Basic catalysts liberate the conjugate base, *i.e.* the anion, from weak acids such as HCN or ethyl malonate, and this can then add on to carbonyl compound[54].

Like non-fluorinated carbonyl compounds, hexafluoroacetone reacts with HCN[q] only in the presence of a catalyst (*e.g.* a little piperidine) to form the *gem*-hydroxycyanide *(46)*, which can be converted readily into perfluoro-α-hydroxyisobutyric acid or its derivatives[36].



*(46)*

Perfluoronitroacetone reacts with HCN at 100 °C in the absence of catalysts[7]. Fluorinated ketones react also with KCN or NaCN to form the corresponding "cyanohydrin" salts[56].

Hexafluoroacetone in pyridine reacts readily with compounds such as *(47)* or *(48)* containing reactive methyl-

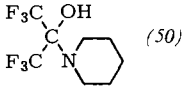
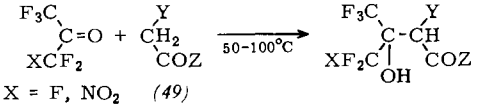
ene [5,6,10,18,57,58] [r]. For reaction with non-fluorinated carbonyl compounds, the methylene groups must be activated with the stronger base piperidine [60]. In the reaction of hexafluoroacetone with malonic acid, more than two equivalents of piperidine even interfere due to formation of the adduct *(50)*, which cannot form the compound corresponding to *(51)* with malonic acid by the Knoevenagel mechanism [5].



*(50)*

In some cases the condensation of fluorinated ketones with compounds containing active methylene groups *(49)* proceeds at 50–100 °C *without* catalysts [61,61a].[1]



X = F, $NO_2$ *(49)*

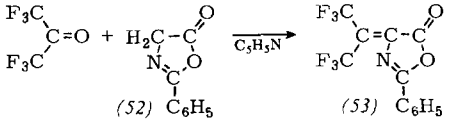
|---|---|---|---|
| Z | $CH_3$ | $C_6H_5$ | OR |

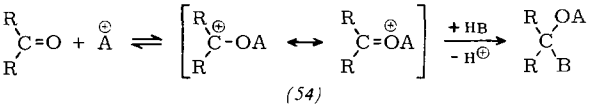
The behavior of hexafluoroacetone confirms the general rule that *the hydroxy compounds obtained from fluorinated ketones and compounds containing active methylene groups can be converted only with difficulty into the corresponding unsaturated compounds* [2].



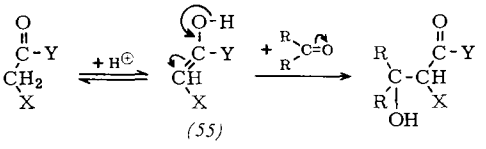
*(52)* *(53)*

An exception to this rule is the conjugated unsaturated derivative *(53)* obtained from hexafluoroacetone and 2-phenyl-$\Delta^2$-1,3-oxazolidin-5-one *(52)* in pyridine at room temperature [62] (but cf. [63]) [s].

An acid used as catalyst in reactions of carbonyl compounds can play a dual role: it activates the carbonyl compound, *i.e.* converts it into a carboxonium ion *(54)*, which is sufficiently electrophilic to interact with the weak nucleophile HB; in reactions with pseudo-acids, the catalyst favors the conversion of the pseudo-acid, which has no nucleophilic properties, into a sufficiently nucleophilic enol *(55)* [54].

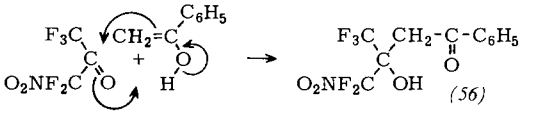


*(54)*



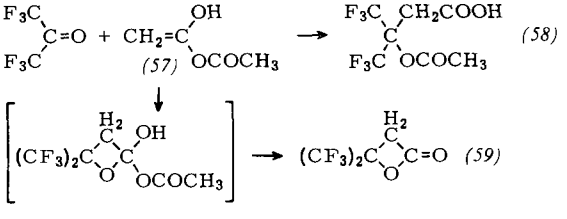
*(55)*

The second type of activation apparently occurs in the reaction of perfluoronitroacetone with acetophenone in the presence of a catalytic quantity of $H_2SO_4$, which leads at about 20 °C to the hydroxy ketone *(56)* [65].



*(56)*

The participation of the enol form of the compounds with active CH groups has been confirmed in the reaction of hexafluoroacetone with acetic anhydride in the presence of a catalytic amount of $H_2SO_4$ [66]. Thus the enol form *(57)* of acetic anhydride reacts in two ways, giving both an acetoxy acid *(58)* and a β-lactone *(59)*.



*(57)* *(58)* *(59)*

In this second type of activation, the fluorinated ketones react more readily than their non-fluorinated analogues. However, in reactions in which the catalytic action of the

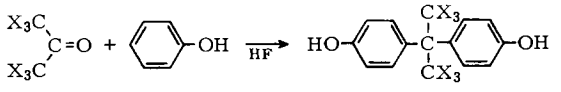
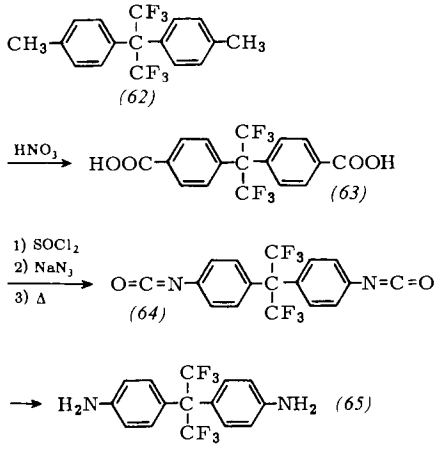
acid is based simply on activation of the carbonyl group, the reaction of the fluorinated ketones becomes more difficult owing to the lower basicity of the oxygen atom[t]. Thus acetone reacts with phenol in anhydrous hydrogen fluoride at room temperature to form 2,2-bis-(*p*-hydroxyphenyl)propane *(60)*[23], whereas hexafluoroacetone reacts only at about 100 °C to form the analogous compound *(61)*[u][6,23].



X = H : 20°C — *(60)*, X = H
X = F : 100°C — *(61)*, X = F

Toluene reacts with hexafluoroacetone in the presence of HF in the same way as phenols, but under somewhat more vigorous conditions[v]. The reaction yields hexafluoro-2,2-bis(*p*-tolyl)propane *(62)*, which is used for the synthesis of the dicarboxylic acid *(63)*, the diisocyanate *(64)*, and the diamine *(65)*[73–76].



*(62)*

*(63)*

*(64)*

*(65)*

[t] Accordingly, non-fluorinated ketones dissolve in concentrated $H_2SO_4$, whereas fluorinated ketones do not [67]. Hexafluoroacetone reacts with $PCl_5$ only at 275–300 °C, giving 2,2-dichlorohexafluoropropane [68]. Concerning the reaction of perfluorocyclobutanone with boron chlorides, see [21].

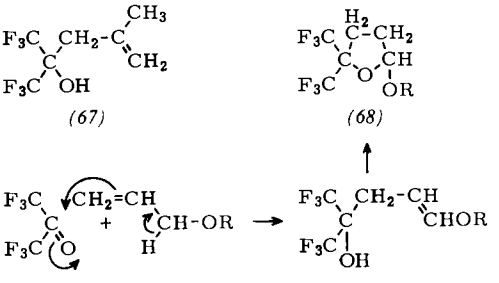
The condensation of fluorinated ketones with aromatic compounds and with compounds containing active methylene groups is also catalysed by Lewis acids[6,73,77–81].

The electrophilicity of fluorinated ketones is so high that they can react sometimes without prior activation of the carbonyl group, even with very weak nucleophiles which react with non-fluorinated ketones only in the presence of catalysts. For example, hexafluoroacetone reacts with isobutene at room temperature[82]; with less nucleophilic olefins, it reacts only on heating or in the presence of $AlCl_3$[82,83]. Perfluoronitroacetone[82] and perfluorocyclobutanone[78], which is further activated as a result of the ring strain, react even more readily with olefins.

Fluorinated ketones react with olefins containing allylic hydrogen by a six-membered cyclic transfer, *i.e.* with allyl rearrangement[w], resulting in the formation of unsaturated alcohols such as *(67)* or of products such as *(68)*[78,82].



*(67)*

*(68)*

With olefins containing no allylic hydrogen (*e.g.* styrene or vinyl ethers)[61a,65,85] and with 1,3-dienes[78,86,87], fluorinated ketones react under very mild conditions to

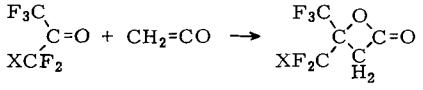
give four-membered *(69)* [x] or six-membered cycloadducts *(70)* [y].

*(69)* *(70)*

X = F, $NO_2$; Y = $C_6H_5$, OAlk

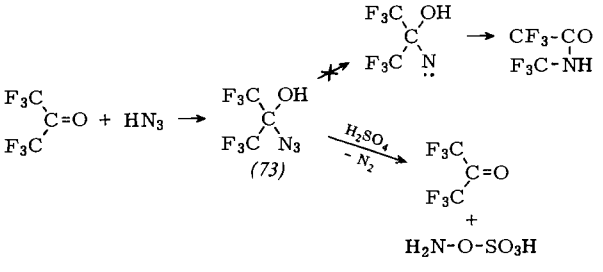
Hexafluoroacetone [90] and perfluoronitroacetone [7] react still more readily, and in the absence of catalysts, with ketene to form the β-lactone *(72)*, whereas a Lewis acid, *e.g.* $BF_3$, is required to activate acetone [91]. It is worth noting that the reaction of trifluoroacetone with



X = F, $NO_2$ *(72)*

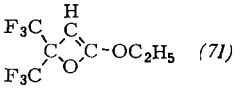
ketene proceeds only in the presence of a catalyst and under more vigorous conditions than are required for acetone. The electrophilicity of trifluoroacetone, which hinders catalytic activation, is apparently not high enough to enable this ketone to react without additives [92].

Perfluoroketones are also electrophiles in relation to hydrazoic acid, whereas non-fluorinated ketones behave as nucleophiles. With non-fluorinated ketones, the reaction begins with an attack by the acid catalyst on the carbonyl oxygen atom; the *gem*-hydroxyazide formed as an intermediate, which normally cannot be isolated, loses $N_2$ and undergoes a Schmidt rearrangement [93]. Hexafluoroacetone reacts with $HN_3$ without catalysts to form 2-azido-1,1,1,3,3,3-hexafluoro-2-propanol



*(73)*

[x] Hexafluoroacetone reacts with ethoxyacetylene to give the adduct *(71)* [88].



*(71)*

[88] *W. J. Middleton*, J. org. Chemistry *30*, 1307 (1965).

[y] Non-fluorinated ketones do not enter into this diene synthesis. Even the reactive ethyl mesoxalate reacts only at 100 to 135 °C; only carbonyl dicyanide reacts at 20 °C to give a 5,6-dihydro-2*H*-pyran [89].

[89] *O. Achmatowicz* and *A. Zamojski*, Bull. Akad. Sci. polon. Cl. III *5*, 927 (1957).

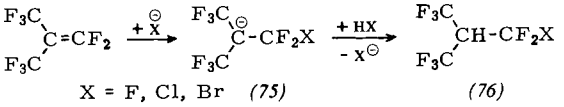
[93] *H. Wolf*, Org. Reactions *3*, 307 (1946).

*(73)* [z]. Conversion into *N*-trifluoromethyltrifluoroacetamide could not be achieved; instead of the Schmidt rearrangement, the *gem*-hydroxyazide decomposed and hexafluoroacetone was liberated [18].

Perfluoronitroacetone [7] and perfluorocyclobutanone [94,95] give stable adducts even with hydrogen halides, FNO, and $FNO_2$ (probably as with nucleophilic reagents). Although hexafluoroacetone forms a fairly stable adduct with FNO [95], it does not react with hydrogen halides; with KF in diglyme, however, it gives potassium heptafluoro-2-propanolate [96] [A].

A change in reaction mechanism is observed also in the hydrohalogenation of perfluoroisobutene to *(76)*, which unlike that of non-fluorinated olefins, proceeds readily only in the presence of catalytic quantities of halogen anions [98,99] [B].



X = F, Cl, Br *(75)* *(76)*

Thus in reactions of fluorinated ketones (as well as of other compounds containing π-bonds of low electron density) with weak nucleophiles, a peculiar "reversal" of the reaction mechanism is observed in some cases:

*Electrophilic addition in non-fluorinated ketones becomes nucleophilic addition in fluorinated ketones.*

[z] A *gem*-hydroxyazide of this type was also obtained [78] from perfluorocyclobutanone and $HN_3$.

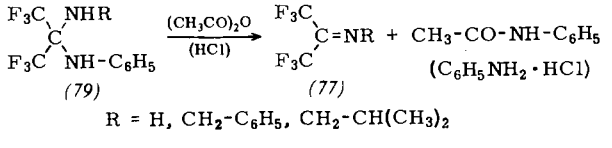
## III. Peculiarities in the Formation and Chemical Properties of Fluorinated Imines

A characteristic feature of perfluoroketones is that reactions with ammonia, amines, hydrazine, hydroxylamine, and other compounds containing amino groups do not lead to substitution of the carbonyl oxygen and formation of a C=N grouping. They lead instead to geminal amino alcohols[C], which do not lose water spontaneously, and which usually cannot be dehydrated even with reagents such as acetic anhydride[13].

When the carbonyl group carries only *one* perfluoroalkyl substituent, the usual derivatives of carbonyl compounds are still obtained. Thus benzyl trifluoromethyl ketone[108] and 1,1,1-trifluoroacetone[109,110] give oximes and hydrazones in the usual manner.

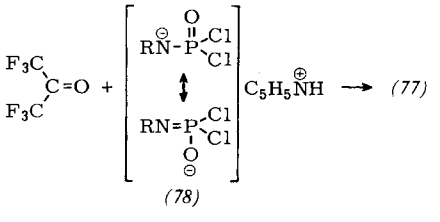
We have also obtained the anil 1,1,1-trifluoro-*N*-phenylpropane-2-imine directly from 1,1,1-trifluoroacetone and aniline[13], whereas hexafluoropropane-2-imines *(77)* could only be obtained by special methods (see also Section I.5). For example, the reaction of hexafluoroacetone with $NH_3$ followed by treatment with $POCl_3$ in pyridine yields imines *(77)*, R = H or $CH_3$[111] [D].

The most remarkable imine synthesis is based on the decomposition of *N*-alkyl-*N'*-phenylhexafluoropropane-2,2-diamines *(79)* in the presence of electrophilic reagents[13,46]. The route of decomposition of the diamine *(79)* depends on the relative basicities of the two amine residues: If the difference in the basicities of the amine residues (and hence the stability of the cations *(80)* resulting from the cleavage) is very large (several powers of ten), the route of decomposition is determined by the stability of the cation *(80)* and the less basic amine is split off (route A); if the difference in basicity is not large (not more than one power of ten), as in the diamine *(81)*, the predominant point of attack for the electrophile is the deciding factor, with the result that the more basic amine is split off (route B)[112].

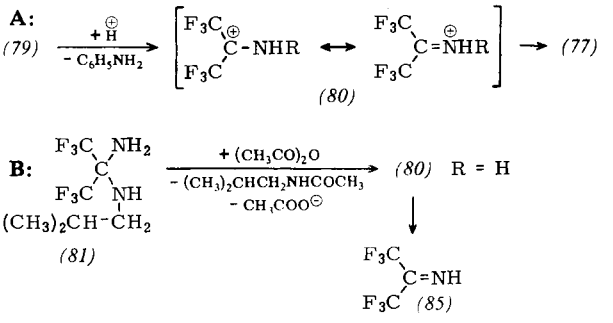


*(79)* *(77)*

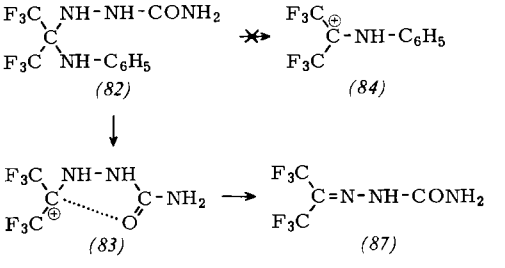
R = H, $CH_2$-$C_6H_5$, $CH_2$-$CH(CH_3)_2$



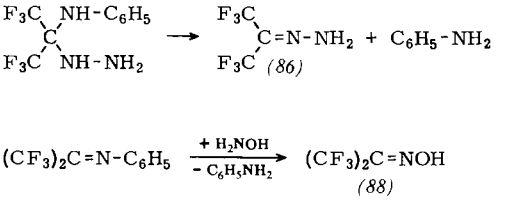
*(78)*



In the HCl-catalysed decomposition of 1-(1-anilino-2,2,2-trifluoro-1-trifluoromethylethyl)semicarbazide *(82)*[14], the elimination of aniline is due to the greater basicity of the latter as well as to the greater stability of the carbonium ion *(83)* in comparison with the carbonium ion *(84)*.



The unsubstituted hexafluoropropane-2-imine *(85)* [= *(77)*, R = H] is most easily obtained by thermal elimination of aniline (180 °C) from hexafluoro-*N*-phenylpropane-2,2-diamine *(79)*, R = H[46]. Thermal decomposition has also been used for the preparation of the hydrazone *(86)*, the semicarbazone *(87)*, and the oxime *(88)*[E] of hexafluoroacetone[13,14]; the oxime *(88)* can be prepared by other methods as well[113–115].



[C] Perfluoro-4-heptanone [107] and perfluoronitroacetone [7, 13] undergo haloform cleavage on reaction with amines.

[107] *M. Hauptstein* and *R. A. Braun*, J. Amer. chem. Soc. *77*, 4930 (1955).

[108] *W. R. Nes* and *A. Burger*, J. Amer. chem. Soc. *72*, 5412 (1950).

[109] *F. Swarts*, Bull. Akad. roy. Belg. *13*, 175 (1927).

[110] *A. L. Henne, M. S. Newman, L. L. Quill*, and *R. A. Staniforth*, J. Amer. chem. Soc. *69*, 1819 (1947).

[111] *W. J. Middleton* and *C. G. Krespan*, J. org. Chemistry *30*, 1398 (1965).

[D] This probably involves not a dehydration of a geminal amino alcohol, but a reaction of the Wittig-Staudinger type between hexafluoroacetone and the pyridinium salt *(78)*, R = H or $CH_3$ [112].

[112] *N. P. Gambaryan*, Dissertation, Institute for Organo-Elemental Compounds, Moscow 1965.

[E] The oxime of hexafluoroacetone and hexafluoro-2-(hydroxylamino)-2-propanol does not undergo the Beckmann rearrangement; sulfuric acid regenerates hexafluoroacetone [13,18].

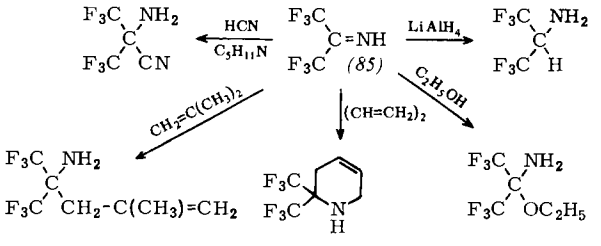
[113] *I. L. Knunyants, B. L. Dyatkin, L. S. German, I. N. Rozhkov*, and *V. A. Komarov*, Ž. vses. chim. Obšč. im. D. I. Mendeleeva *8*, 709 (1963).

[114] *B. L. Dyatkin, E. P. Mochalina, L. T. Lanceva*, and *I. L. Knunyants*, Ž. vses. chim. Obšč. im. D. I. Mendeleeva *10*, 469 (1965).

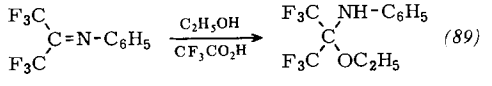
[115] *I. L. Knunyants, L. S. German, I. N. Rozhkov*, and *B. L. Dyatkin*, Izvest. Akad. Nauk SSSR, Ser. chim. *1966*, 250.

The trifluoromethyl groups considerably increase the electrophilicity of the azomethine bond in hexafluoropropane-2-imine *(85)*. This is shown particularly by the ease of reaction with ammonia and with amines [F]. In contrast to the non-fluorinated azomethines [116], adducts can be isolated in this case [13,46]; thus hexafluoropropane-2,2-diamine can be distilled at 91–92 °C/760 mm without decomposition [46].

Unlike the other known aliphatic imines [117], hexafluoropropane-2-imine *(85)* is stable up to 250 °C. It gives many of the characteristic reactions of azomethines, such as reduction with lithium tetrahydridoaluminate or addition of HCN [G]. Unlike azomethines, *(85)* reacts smoothly with ethanol at 100 °C [46]. The diene synthesis and the reaction of hexafluoropropane-2-imine *(85)* with isobutene [86] are also novel.

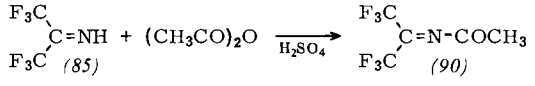


Hexafluoro-*N*-phenylpropane-2-imine is less reactive than *(85)*. However, the geminal ethoxy amine *(89)* can be obtained with ethanol and a little trifluoroacetic acid [46].

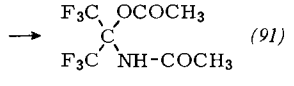


*(89)*

This reaction shows that catalysis by electrophiles is more important with hexafluoropropane-2-imines than with hexafluoroacetone itself, since the imine nitrogen is more nucleophilic than the carbonyl oxygen. Thus the imine *(85)* is acylated by ketene only in the presence of $BF_3$, the product being the *N*-acetyl derivative *(90)* [111]. Compound *(85)* does not react with acetic anhydride in the absence of catalysts, even at 100 °C, but in the presence of $H_2SO_4$ at 0 °C it gives the adduct *(91)*, probably *via (90)* [27].

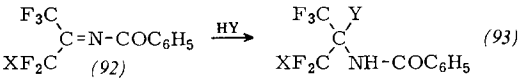


*(85)* *(90)*



*(91)*

The azomethine linkage in imines of fluorinated ketones can be activated not only by acids, but also by replacement of the hydrogen in the imino group by electron-attracting substituents. Thus *N*-acylimines of fluorinated ketones, *e.g. (92)*, react readily with water, alcohols, amines, amides, phenylacetylene, and acetophenone to give the corresponding adducts *(93)* [17,118].

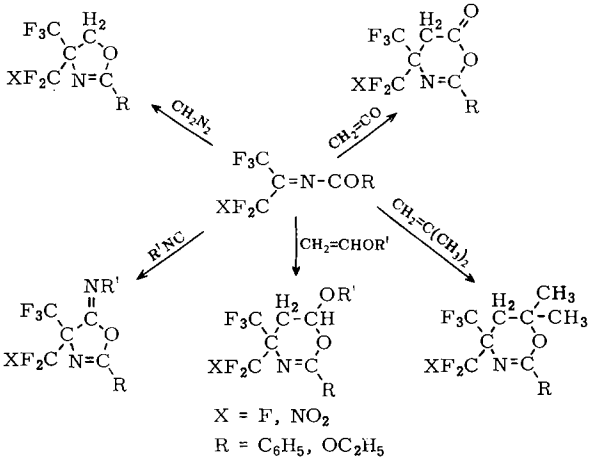


*(92)* *(93)*

X = F, $NO_2$

Y = OH, OR, NHR, $C{\equiv}C\text{-}C_6H_5$, $NH\text{-}COC_6H_5$, $CH_2\text{-}COC_6H_5$

*N*-Acylimines of hexafluoroacetone and pentafluoronitroacetone also enter into 1,4-additions with diazomethane, isonitriles, ketene [H], vinyl ethers, and olefins, which had previously been unknown for acylimines [33,



X = F, $NO_2$

R = $C_6H_5$, $OC_2H_5$

118,121]. Nevertheless, the activities of the *N*-acylimines of perfluorinated ketones are lower than those of hexafluoroacetone and perfluoronitroacetone. This is due to the lower polarity of the C=N bond as compared with the C=O bond.

Institut für Chemie, Heidelberg (Germany)

From lobster shells a blue chromoprotein (crustacyanin) can be isolated [1], whose prosthetic group is astaxanthin (3,3'-dihydroxy-4,4'-dioxo-β-carotene [2]). We used Calgon® to decalcify the shells, from which the chromoprotein could then be extracted readily with a phosphate buffer (pH 7). Purification was effected by salting out with ammonium sulfate and by preparative ultracentrifugation.

α-Crustacyanin, the native chromoprotein ($\lambda_{max}$ = 632 mμ in water), is stable for months in 0.2 M phosphate buffer (pH 7). It behaves as a single substance in the analytical ultracentrifuge, on fractional salting out with ammonium sulfate, and on electrophoresis. Extinction coefficients of 1% aqueous solutions (1 cm path) are: $E_{278\ m\mu} = 19.4 \pm 0.4$ and $E_{632\ m\mu} = 65 \pm 2$. One mole of astaxanthin is present in 19000 ± 1000 g of chromoprotein. α-Crustacyanin contains 15.7% of N (Dumas method) and the following amino acids [3] (g of anhydro amino acid per 100 g of chromoprotein): Lys 6.86; His 1.99; Arg 4.37; Asp 12.95; Thr 5.71; Ser 5.58; Glu 8.41; Pro 4.69; Gly 2.61; Ala 5.58; Val 6.64; Ileu 3.82; Leu 4.20; Phe 8.67; Tyr 9.76; Cys 1.39; Try 2.5.

α-Crustacyanin has a molecular weight of *ca.* 310000; it contains 16 molecules of bound astaxanthin. The intrinsic viscosity at 20 °C is $[\eta] \approx 0.09$ dl/g, corresponding to an axial ratio of about 10:1 if an ellipsoid of revolution [4] is assumed.

Subunits of molecular weight *ca.* 38000 (= β-crustacyanin, $\lambda_{max}$ = 585 mμ in water) are formed from α-crustacyanin in neutral phosphate buffers of low ionic strength; β-crustacyanin contains two molecules of bound astaxanthin per protein molecule.

In acidic solution (pH 3.7 to 3.0) and in neutral 0.15% sodium dodecyl sulfate solution α- and β-crustacyanin dissociate to subunits of molecular weight *ca.* 20000; the absorption maximum is shifted to 440 mμ (acidic solution) or 482 mμ (dodecyl sulfate solution). These subunits contain one molecule of bound astaxanthin each.

α- and β-Crustacyanin can be further dissociated by the action of alkali (pH ≥ 11) or urea (≥ 4 M), yielding smaller, colorless subunits, which sediment at only 1.2 S, and a colored component which sediments faster ($\lambda_{max}$ of the whole solution = 400 mμ).

Like α-crustacyanin, β-crustacyanin and the fragments of molecular weight *ca.* 20000 also behave homogeneously in the ultracentrifuge.

The changes in quaternary structure of α- and β-crustacyanin under the influence of acids, bases, or urea are reversible: neutralization or dialysis against phosphate buffer regenerates α-crustacyanin from the solutions of the subunits, and this product cannot be differentiated from native α-crustacyanin in the ultracentrifuge. Treatment of β-crustacyanin with acids, bases, urea, or detergents yields subunits having the same $\lambda_{max}$ values and molecular weights as those from α-crustacyanin. Neutralization or dialysis of solutions of these subunits, however, regenerates only β-crustacyanin and no α-crustacyanin, whence it follows that the formation of β-crustacyanin from α-crustacyanin is not reversible.

| Substance | $\lambda_{max}$ [mμ] | Mol. wt. at 20 °C | Method |
|---|---|---|---|
| α-Crustacyanin | 632 | 320000 | Ultracentrifuge |
| | | 307000 | Light scattering [5] |
| β-Crustacyanin | 585 | 36000 | Ultracentrifuge |
| | | 39500 | Osmometry [6] |
| α- or β-Crust. after treatment with 0.15% Na dodecyl sulfate | 482 | 19600 | Ultracentrifuge |
| α- or β-Crust. at pH 3.5 | 440 | 19800 | Ultracentrifuge |
| α- or β-Crust. at pH 13 | 400 | ≤10000 | Ultracentrifuge |
| α- or β-Crust. in 8 M urea soln. | 400 | ≤10000 | Ultracentrifuge |
| Equiv. wt. of α- and β-crust. (calc. per mole of astaxanthin) | | 19000 | Photometry, dry wt. |

## Synthesis of the Central Octacyclic Structure of the Principal Calebash Curare Alkaloid, C-Curarine-I [1]

By Prof. H. Fritz and R. Oehl

Institut für Organische Chemie, Universität Frankfurt/Main (Germany)

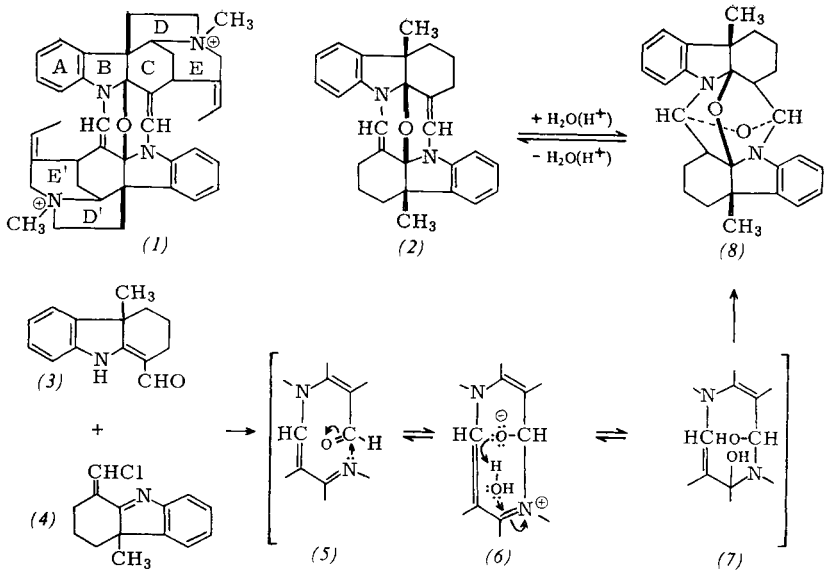
If from C-curarine-I [2] *(1)* one formally eliminates the rings D,E,D', and E' fused around the periphery, one obtains an octacyclic ring system *(2)* which constitutes the chromophore of the alkaloid. We have succeeded in synthesizing this long sought chromophore [3], whose structural peculiarity is the central diazacyclooctadiene system bridged by an oxygen atom.

If an equimolar mixture of the compounds *(3)* [4] and *(4)* [5] in moist ether is kept for about 18 hr at 20 °C, the racemate (m.p. 216 °C) of the indoline derivative *(8)* is first formed, in about 20% yield, in a stereospecific reaction [5].

The structure *(8)* is proved by elemental analysis, UV spectrum (indoline absorption), IR spectrum (ether band at 8.38 μ; no OH or NH band), and mass spectrum ($M^+ = 426$). In particular, the NMR spectrum (in $CDCl_3$) shows the presence of two equivalent *C*-methyl groups (6H singlet at $\tau = 8.93$; TMS as internal standard) and two equivalent amino-acetal protons (2H singlet [6] at $\tau = 4.63$). The $C_2$ symmetry required for formula *(8)* follows from the equivalence of these groups. The central tricyclic system of structure *(8)* — which is almost strain-free in the model — is isosteric with that of adamantane, and in fact is that of 2,6-dioxa-4,8-diazaadamantane. The "indoline base VII" of unknown constitution [7] obtained from C-curarine-I is very probably identical with compound *(8)* in its central nonacyclic structure.

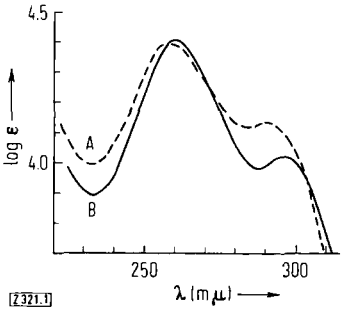
Formation of compound *(8)* from *(3)* and *(4)* and one molecule of water presumably proceeds by way of *(5)*, *(6)*, and *(7)*.

Acid catalysed dehydration (methanolic 1 N HCl; 20 °C; 24 hr) leads to equilibration of *(8)* with *(2)* (m.p. 205 °C), which is also formed in a sterically pure form. An approxi-



mately equimolar mixture of *(8)* and *(2)* results, independently of which of them is the starting material. These substances can be easily separated by preparative chromatography on silica gel G with benzene; they crystallize readily.

The structure *(2)* is in agreement with elemental analyses, the molecular weight (408) determined by mass spectrometry, and the IR spectrum (no OH or NH band). The NMR spectrum shows that like *(8)*, compound *(2)* has $C_2$ symmetry, since the six protons of the two *C*-methyl groups give a sharp singlet at $\tau = 8.87$ (in $CDCl_3$; TMS as internal standard). The two protons attached to enamine C atoms give a signal at $\tau = 3.30$ slightly split by allylic coupling, *i.e.* at the same position as that of the corresponding protons of nor-C-curarine-I [2b]. This result definitely excludes one alternative structure to *(2)* for our synthesis product (O bridge between the two CH groups and correspondingly different positions of the double bonds) because in that case the two protons in question would be attached to amino-acetal C atoms and their resonance signals would appear at appreciably higher field.



UV spectra.

A: Synthetic C-curarine derivative *(2)*, 0.390 mg in 25 ml of methanol.

B: C-curarine-I dichloride *(1)* + $2Cl^{\ominus}$, 0.507 mg in 25 ml of methanol.

Finally, the UV spectrum of compound *(2)* (see Figure) agrees as well with that of C-curarine-I *(1)* as is possible in view of the simplified structure of the former. The higher alkyl substitution of the alkaloid *(1)* than of compound *(2)* is weakly discernable in that the spectrum of the former has the short-wavelength and the long-wavelength maxima shifted bathochromically by 2 and 7 mμ, respectively, in comparison with that of the latter.

Our synthetic C-curarine-I derivative *(2)* also gives the intense blue color with ceric sulfate/sulfuric acid [8] that is typical of C-curarine-I, the shades and the intensities being identical.

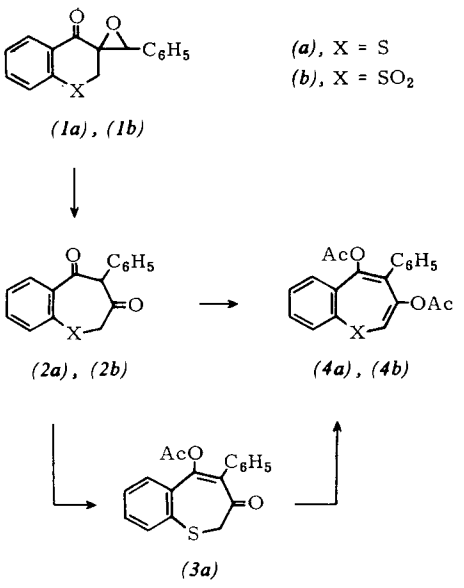
## Synthesis of Derivatives of Benzo[*b*]thiepin and Benzo[*b*]thiepin 1,1-Dioxide [1]

By Dr. Hans Hofmann and H. Westernacher

Institut für Organische Chemie
der Universität Erlangen-Nürnberg (Germany)

Treatment of spiro[1-thio-4-chromanone-3,2′-(3′-phenyloxirane)] *(1a)* or spiro[(1-thio-4-chromanone 1,1-dioxide)-3,2′-(3′-phenyloxirane)] *(1b)* [2] with concentrated sulfuric acid or boron trifluoride-ether affords 2,3,4,5-tetrahydro-4-phenylbenzo[*b*]thiepin-3,5-dione *(2a)*, m.p. 93 to 94 °C, yield 70 %, or its dioxide *(2b)*, m.p. 162–163 °C, yield 90 %. The compounds *(2a)* and *(2b)* were isolated in the same way as the analogous benzo[*b*]oxepins [3].

The IR spectrum (in KBr; C=O stretching vibrations at 1732 and 1673 $cm^{-1}$) and the $^1$H-NMR spectrum [in $CDCl_3$; $\tau = 6.5$ (2 H), $\tau = 3.65$ (1 H)] show that compound *(2a)* exists exclusively as diketone in the solid state and in slightly polar solvents. However, the IR spectrum (in KBr, OH stretching vibration at 3550 $cm^{-1}$, C=O stretching vibrations at 1735, 1698, and 1636 $cm^{-1}$, S=O stretching vibrations at 1321 and 1160 $cm^{-1}$) of compound *(2b)* indicates an enolized molecule.



*(1a), (1b)* *(a)*, X = S; *(b)*, X = $SO_2$

*(2a), (2b)* *(4a), (4b)* *(3a)*

Treatment of compound *(2a)* with acetic anhydride in pyridine for 45 min at room temperature gives 5-acetoxy-2,3-dihydro-4-phenylbenzo[*b*]thiepin-3-one *(3a)*, m.p. 124 to 125 °C, in 65 % yield, but after 15 hr at room temperature only 3,5-diacetoxy-4-phenylbenzo[*b*]thiepin *(4a)*, m.p. 86 to 87 °C, was obtained (yield 98 %). To the best of our knowledge this is the first compound containing a benzo[*b*]thiepin skeleton.

The compound *(2b)* with acetic anhydride in pyridine (10 min, room temperature) affords directly 3,5-diacetoxy-4-phenylbenzo[*b*]thiepin 1,1-dioxide *(4b)*, m.p. 140–141 °C (yield 98 %).

The structures of compounds *(4a)* and *(4b)* follow from the IR and NMR spectra:

*(4a)*: IR (in KBr): enol acetate C=O at 1768 $cm^{-1}$.
NMR (in $CDCl_3$): non-aromatic protons at $\tau$ = 8.35 and 8.15 (each 3 H of the two acetate groups) and at $\tau$ = 4.0 (1 H).

*(4b)*: IR (in KBr): enol acetate C=O at 1775 $cm^{-1}$; S=O stretching vibration at 1324 $cm^{-1}$ (the asymmetric S=O stretching vibration is overlapped by the C–O vibration).
NMR (in $CDCl_3$): non-aromatic protons at $\tau$ = 8.28 and 8.20 (each 3 H of the two acetate groups) and at $\tau$ = 3.25 (1 H).

## 3,4-Diazanorcaradiene [1]

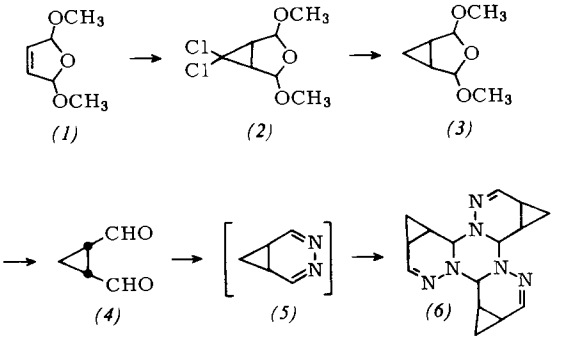
By Dr. G. Maier and T. Sayrac

Institut für Organische Chemie,
Technische Hochschule Karlsruhe (Germany)

The valence-tautomeric equilibrium between diphenyldiazanorcaradiene and diphenyldiazacycloheptatriene lies entirely on the side of the norcaradiene form [2]. It was hoped that synthesis of the unsubstituted diazanorcaradiene would provide information whether, and to what degree, the nitrogen atoms or the phenyl substituents are responsible for the greater stability of the bicyclic tautomer.

When treated with ethyl trichloroacetate/$CH_3ONa$, the *cis-trans* mixture of 2,5-dihydro-2,5-dimethoxyfurans *(1)* obtained from furan on treatment with $Br_2$ in $CH_3OH$ gives *(2)*, m.p. 40 °C; yield 11 %. Probably only the *cis*-isomer takes part in this reaction since the product *(2)* is homogeneous on gas chromatography and its NMR spectrum ($CCl_4$) shows only three sharp singlets at $\tau$ = 4.94, 6.57, and 7.42 in the ratio 1:3:1. Reduction of compound *(2)* with Li/t-butyl alcohol affords a product *(3)*, b.p. 65–67 °C/14 mm, $n_D^{20}$ = 1.4352; yield 67 %, whose NMR spectrum (without a solvent) shows an $AMX_2$ system (three ring protons: $\tau_A$ = 10.04, $\tau_M$ = 9.44, $\tau_X$ = 8.32; $J_{gem.}$ = 4.7, $J_{cis}$ = 8.0, $J_{trans}$ = 4.0 Hz) and two singlets at $\tau$ = 6.69 and 5.22 in the ratio 1:1:2:6:2. In contrast to *(2)*, the product *(3)* gives an immediate precipitate with dinitrophenylhydrazine solution.

When heated with 0.1 N sulfuric acid (13 min at 100 °C) the ether *(3)* gives *cis*-1,2-cyclopropanedicarbaldehyde *(4)*, which can be extracted from the aqueous solution with chloroform and purified, though with great loss, by gas chromatography. The dialdehyde is stable in chloroform at −78 °C; its IR spectrum ($CCl_4$) contains the bands expected for an aldehyde (1710, 2730, and 2830 $cm^{-1}$), and its NMR spectrum ($CDCl_3$) shows aldehyde protons at $\tau$ = 0.5 as well as the cyclopropane protons (multiplet at $\tau$ = 7.4 to 8.5). Oxidation with $KMnO_4$ gives *cis*-1,2-cyclopropanedicarboxylic acid.



*(1)* *(2)* *(3)* *(4)* *(5)* *(6)*

Condensation of the dialdehyde *(4)* with hydrazine affords three substances which, according to their elemental composition and molecular weights, must be trimers of *(5)*. These three components can be separated chromatographically ($Al_2O_3$, ether). Each of them yields the original mixture of three components when treated with acid. Presumably these isomers are compounds of type *(6)*. This structure is supported by the IR spectrum (KBr; C=N bands at 1615 $cm^{-1}$), the UV spectrum [$CH_3OH$; *(6a)*, m.p. 211 °C, $\lambda_{max}$ = 252.5 mμ (ε = 11500); *(6b)*, m.p. 184 °C, $\lambda_{max}$ = 256 mμ (10600); *(6c)*, decomp. 232 °C, λmax = 262.5 mμ (8300)], and the NMR spectra [$CDCl_3$; 12 cyclopropane protons as a multiplet at $\tau$ = 7 to 9.5; 3 protons as a multiplet centered at $\tau$ = 2.88; *(6a)*, 1 proton each as singlet at $\tau$ = 5,82. 6.33, and 6.62; *(6b)*, analogously at $\tau$ = 5.65, 5.87, and 6.27; *(6c)*, 3 protons as singlet at $\tau$ = 5.43]. Oxidation of the mixture of isomers with $KMnO_4$ in 2 N hydrochloric acid again affords *cis*-cyclopropanedicarboxylic acid.

The formation of compound *(6)* from *(4)* and hydrazine indicates that the bicyclic diazanorcaradiene *(5)* which can be assumed to be an intermediate also is more stable than its monocyclic valence tautomer.

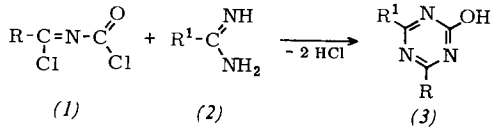
## Ring Closure Reactions of *N*-(α-Chloroalkylidene)carbamoyl Chlorides

By Dr. E. Degener, Dr. H.-G. Schmelzer, and Dr. H. Holtschmidt

Wissenschaftliches Hauptlaboratorium, Farbenfabriken Bayer AG., Leverkusen (Germany)

IR spectra of aliphatic isocyanates that are perchlorinated in the α-position indicate that in many cases these compounds exist partly or wholly as *N*-(α-chloroalkylidene)carbamoyl chlorides *(1)* [1]. With compounds of amidine structure *(2)* they react under the conditions of the Schotten-Baumann reaction to give almost quantitatively 2-hydroxy-*s*-triazines *(3)* [2]. 2-Hydroxy-*s*-triazines with two different hydrocarbon radicals in the 4- and the 6-position can also be prepared in this way.



*(1)* *(2)* *(3)*

## Ring Closure Reactions of Polychloroazaalkenes

By Dr. H.-G. Schmelzer, Dr. E. Degener, and Dr. H. Holtschmidt

Wissenschaftliches Hauptlaboratorium, Farbenfabriken Bayer AG., Leverkusen (Germany)

Polychloroazaalkenes *(1)* containing the structural unit of 1,1,3-trichloro-2-azapropene can be obtained by high-temperature chlorination of amines [1]. They afford *s*-triazines *(3)* on reaction with amidines *(2)* or their salts [2, 3]. In particular, trichloromethyl isocyanide dichloride gives 2,4-dichloro-*s*-triazines. Methylthio-*s*-triazines *(5)* are obtained when *S*-methylisothioureas *(4)* are used as amidine component. Use of guanidines *(6)* leads to amino-*s*-triazines *(7)*.

The ring closures can be effected under the conditions of the Schotten-Baumann reaction. A two-phase system, *e.g.* methylene chloride/water, is used as reaction medium in the preparation of 2,4-dichloro-*s*-triazines. The ring closure provides the first one-stage preparation of *s*-triazines with three different hydrocarbon substituents [3] and of 2-chloro-*s*-triazines with two different hydrocarbon substituents in the 4- and the 6-position [2].

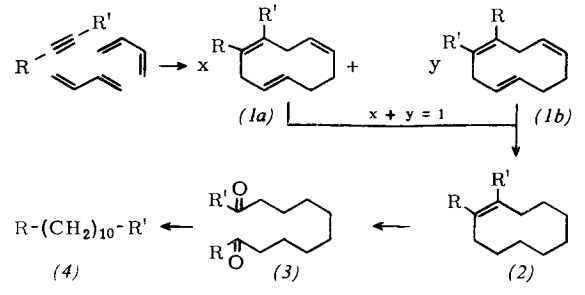
## Reactions of 4,5-Dimethyl-*cis*-1,*cis*-4,*trans*-7-cyclodecatriene

By Dr. P. Heimbach [*]

Max-Planck-Institut für Kohlenforschung, Mülheim/Ruhr (Germany)

4- or 5-Mono- or 4,5-disubstituted *cis*-1, *cis*-4, *trans*-7-cyclodecatrienes can be prepared in good yield from butadiene and mono- or di-substituted acetylenes by means of catalysts containing zerovalent nickel [1]. These products can serve as starting material for syntheses illustrated below for 4,5-dimethyl-*cis*-1,*cis*-4,*trans*-7-cyclodecatriene *(1)*, R = R′ = $CH_3$.

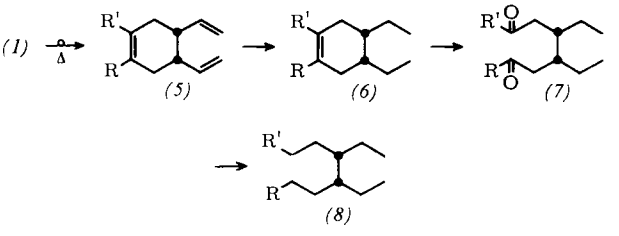


| | $n_D^{20}$ | | Yield (%) |
|---|---|---|---|
| *(1a)* + *(1b)* | 1.5141 | B.p. 30–35 °C/$10^{-4}$ mm | 95 [a] |
| *(2)* | 1.4940 | B.p. 112 °C/20 mm | 94 |
| *(3)* | | M.p. 67–67.5 °C [3] | 68 |

[a] Calculated on converted 2-butyne; 75% of the 2-butyne was consumed; 80% of the butadiene converted gave cyclooctadiene. Catalyst: Ni(0) + tri-(2-biphenyiyl) phosphite in the molar ratio 1:1. Temperature: 40 °C.

1,2-Dimethyl-*cis*-cyclodecene *(2)* can be prepared in 94% yield by partial hydrogenation of the triene *(1)* over Raney nickel under pressure (30 atm, 20 °C). Ozonization of compound *(2)* in methanol at −40 to −80 °C and subsequent hydrogenation of the hydroperoxy hemiketal formed [2] over $Pd/CaCO_3$ at 1 atm and 20 °C leads to 2,11-dodecanedione *(3)*, which is converted by Wolff-Kishner reduction into n-dodecane *(4)* in 85% yield. This reaction sequence makes possible the junction of R and R′ by ten methylene groups with the intermediacy of a disubstituted acetylene.

The stereospecific valence isomerization [4] of compound *(1)* to 1,2-dimethyl-*cis*-4,5-divinylcyclohexene *(5)*, R = R′ = $CH_3$, is about 25 times faster than the Cope rearrangement of *cis*-1, *trans*-5-cyclodecadiene to *cis*-divinylcyclohexane. The compound *(5)* can be hydrogenated over Raney nickel in hexane at 20 °C and atmospheric pressure to *cis*-4,5-diethyl-1,2-dimethylcyclohexene *(6)* in almost 100% yield. Oxidative fission of this product *(6)* by the method used for *(2)* gives good yields of *meso*-4,5-diethyl-2,7-octanedione *(7)*, Wolff-Kishner reduction of which affords *meso*-4,5-diethyloctane *(8)*.



| | $n_D^{20}$ | B.p. (°C/mm) | Yield (%) |
|---|---|---|---|
| *(5)* | 1.4869 | 92/20 | 100 |
| *(6)* | 1.4639 | 96/20 | 99 |
| *meso-(7)* [a] | 1.4505 | 133–134/10 | 72 |
| *meso-(8)* | 1.4276 | 73/10 | 70 |

[a] Purity 96%.

In the Wurtz synthesis of 4,5-diethyloctane from 3-bromohexane both the *meso*- and the racemic form are obtained; these can be separated by gas chromatography (50-m $V_2A$ capillary column, squalane, 100 °C, 0.7 atm of argon; retention time for the *meso*-form 24.6 min and for the racemic form 25.0 min).

The reaction sequence *(1)* → *(4)* is a general route for the preparation of 1-mono- or 1,2-di-substituted cyclodecenes *(2)*, 1,10-diketones *(3)*, and 1,10-substituted decanes *(4)*. The reaction *(7)* → *(8)* gives the *meso*-form when R = R′, but the pairs of diastereoisomers of *(7)* and *(8)* when R ≠ R′.

nickel to give 4,5-oligomethylene-*cis*-1,*cis*-4,*trans*-7-cyclodecatrienes such as *(1)* in high yields. Reactions analogous to those described for 4,5-dimethyl-*cis*-1,*cis*-4,*trans*-7-cyclodecatriene[3] lead in good yields from *(1)* and related compounds to products containing large rings. Of the compounds *(1)* to *(8)*, only *(4)* was previously known.

After reaction of the cyclotetradecadiyne *(9)* with butadiene, a bicyclic hydrocarbon *(12)* and the tricyclic hydrocarbons *(10a)* and *(10b)* were isolated.

## Chloro(dicyclopentadienyl)ethylzirconium and its Reaction with Triethylaluminum

By Prof. H. Sinn and G. Oppermann

Lehrstuhl für Angewandte Chemie, Institut für Anorganische Chemie, Universität Hamburg (Germany)

Dichloro(dicyclopentadienyl)zirconium reacts with triethylaluminum or with ethylaluminum chlorides with removal of ethane, but, unlike the corresponding titanium compound (which is of interest as a catalyst for the low-pressure polymerization of ethylene), without formation of a compound containing zirconium in a lower oxidation state[1].

We have now prepared chloro(dicyclopentadienyl)ethylzirconium(IV), analogous to the titanium compound[2], by a Grignard reaction of $Cp_2ZrCl_2$ in $CH_2Cl_2$ at 0 °C. The bright yellow compound is extracted from the reaction

mixture with heptane, from which it is crystallized at −80 °C. The yield was 27 % calculated on the total amount of starting material, and 54 % on the amount consumed.

$C_2H_5Cp_2ZrCl$ is a crystalline, intensely yellow, diamagnetic compound [$\chi_g = -(0.44 \pm 0.04) \times 10^{-6}$ E.M.U./g], which is decomposed by light, air, or water. It is stable under nitrogen at 0 °C.

$C_2H_5Cp_2ZrCl$ (1.4 mmole) was treated with $Al(C_2H_5)_3$ (14.7 mmole) at 20 °C and atmospheric pressure. The chloride dissolved rapidly and a yellow-red color developed. After a short time, gas evolution began and the color deepened. Only ethane was evolved, whereas in the corresponding reaction of the titanium compound ethane *and* ethylene were formed. After 19 min, 1 mole of $C_2H_6$ had been liberated per gram-atom of zirconium. The time-yield curve for the evolution of the first mole of $C_2H_6$ indicates a reaction of the second order with respect to zirconium. Two moles of ethane are evolved per gram atom of zirconium within 24 hours.

When gas evolution had ceased the mixture had a susceptibility $\chi_g$ of $-(0.69 \pm 0.02) \times 10^{-6}$, *i.e.* the compound formed by loss of ethane is diamagnetic.

## Iron(III) Sulfide

By Prof. H. P. Boehm and E. Flaig

Anorganisch-Chemisches Institut, Universität Heidelberg (Germany)

The existence of an iron(III) sulfide, $Fe_2S_3$, has been repeatedly asserted [1] and at least as often disputed [2]. Most of the studies were carried out in connection with the purification of coal gas with iron(III) oxide hydroxides; the products were rarely characterized by X-ray diffraction but only by elemental analysis and by their behavior on dissolution in HCl. $Fe_2S_3$ cannot be prepared from the elements since in the system Fe–S only $Fe_{0.88-1.00}S$ and $FeS_2$ (pyrites) are stable, at least at higher temperatures [3].

On addition of $SH^-$ ions to ammoniacal $Fe^{3+}$ solutions stabilized by complex formation with tartrates, we obtained an ammonia-containing, pyrophoric iron(III) sulfide which lost $NH_3$ and $H_2S$ on drying; after the material had been degassed in a vacuum at 100–130 °C its composition corresponded to $Fe_2S_3 \cdot ca.\ 0.03(NH_4)_2S$. The reflections in the X-ray powder diagram were diffuse. In the presence of alkali, alkali-metal thioferrates(III) were always formed, *e.g.* the well known $KFeS_2$.

The same X-ray diagram, but much less diffuse, was given by iron(III) sulfide that we obtained by passing pure $H_2O$ into a solution of iron(III) methoxide or ethoxide [4] in a mixture (2:1 v/v) of anhydrous alcohol and benzene. After the mixture had been kept for 3 to 4 days in an atmosphere of $H_2S$, the precipitate was centrifuged off and dried in a high vacuum at 100–120 °C. Such preparations always tenaciously retained alcohol and $H_2S$ (0.06–0.28 mole of $CH_3OH$ and 0.16–0.20 mole of $H_2S$ per $Fe_2S_3$ unit). We studied a sulfide of composition Fe 50.7 wt.-%, S. 45.9 %, active H 0.32 %, $OCH_3$ 4.09 %; it was not pyrophoric but was oxidized in air within a few days.

Iron(III) sulfide dissolved in acids such as dilute HCl to give the Fe(II) salt, a corresponding amount of sulfur remaining.

The Mössbauer spectrum also accorded with the presence of $Fe^{3+}$ ions [5]. The 28 reflections[*] in the Debye diffraction pattern (Co–$K_\alpha$ radiation) can be indexed in the tetragonal system with $a_o = 11.30$ Å and $c_o = 13.05$ Å. The extinctions accord with the $D_4^4$ or $D_4^8$ space group. The interferences can be equally well indexed on the basis of a monoclinic unit cell of half the size: $a_o = 7.11$ Å, $b_o = 11.30$ Å, $c_o = 11.30$ Å, $\beta = 113.4°$, possible space group $C_{2h}^6$. On the basis of the density $d = 3.25$ g cm$^{-3}$ found pyknometrically, the unit cell contains 16 or 8 formula units, respectively. A final decision about the crystal system is not possible because of lack of larger crystals. Approximately square, small platelets with sides of maximally *ca.* 0.3 μ can be seen in the electron microscope.

When heated in a vacuum, iron(III) sulfide loses sulfur at *ca.* 150 °C and gives ferromagnetic $Fe_3S_4$, which dissolves only very slowly in dilute HCl. The X-ray diagram of $Fe_3S_4$, which crystallizes in the cubic system, corresponds to that of magnetite; we found the lattice constants to be 9.810 ± 0.006 Å. This iron thiospinel has been mentioned earlier [6] and was recently found as the mineral greigite [7]. On treating an aqueous suspension of amorphous or crystalline (α- or γ-)-iron(III) oxide hydroxides with $H_2S$ we obtained mainly $FeS_2$ and $Fe_3S_4$.

## A Convenient Preparation of Isothiocyanates [1]

By Dr. R. Gottfried

Institut für Pflanzenchemie der Technischen Universität Dresden (Germany)

Like other disulfides, trichloromethyl disulfides are cleaved by bases [2, 3] to a sulfenyl compound and a thiol. Trichloromethanethiol *(2)*, which is indicated as intermediate by the kinetics of the aminolysis, gives thiophosgene *(4)* by elimination of HCl [2]. Trichloromethyl disulfides, which are easy to handle, can thus be used for the same reactions as the toxic thiophosgene. For instance, with thiols in alkaline solution they yield trithiocarbonates [4, 5]. With not less than 6 moles of amine per mole of trichloromethyl disulfide in ether or benzene solution one obtains *N,N'*-disubstituted thioureas [2]; with at most 5 moles of amine, isothiocyanates are formed.

Bis(trichloromethyl) pentathiodiperoxycarbonate *(1)*, from which thiophosgene also can be obtained directly (by thermal decomposition) is an inexpensive, reactive compound particularly suited to replace thiophosgene. When pure, the ester *(1)* is a stable, slightly volatile, and only slightly toxic red liquid. It is obtained [2, 6, 7] from trichloromethanesulfenyl chloride and sodium trithiocarbonate.

Like thiophosgene, the ester *(1)* also reacts in aqueous suspension with amines, giving isothiocyanates *(5a)–(5d)*; only 3 moles of amine per mole of ester are needed since the *N,N'*-disubstituted trithiodiperoxycarbondiamides *(3)* (which have been identified[2]) also yield isothiocyanates on reaction with thiophosgene *(4)*.

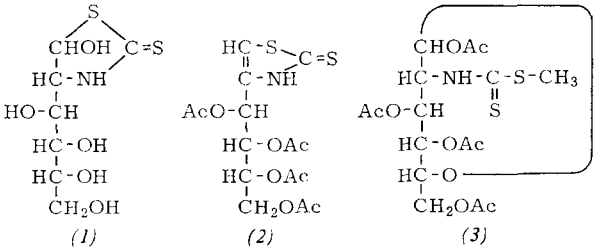
## Reaction of D-Glucosamine with Carbon Disulfide

By Dr. J. C. Jochims

Max-Planck-Institut für Medizinische Forschung, Institut für Chemie, Heidelberg (Germany)

D-Glucosamine and $CS_2$ in methanol give 5-hydroxy-4-(D-*arabino*-1,2,3,4-tetrahydroxybutyl)thiazolidine-2-thione *(1)* in 80% yield.



*(1)* *(2)* *(3)*

5-Hydroxythiazolidines appear not to have been described previously. The product *(1)* is precipitated as a mixture of about 80% of the α-form and 20% of the β-form. The mixture has $[\alpha]_D^{20} = 108°$ ($c = 1$; in dimethylformamide) and decomposes from 146 °C. With the calculated amount of acetic anhydride in pyridine at 0 °C it gives the penta-*O*-acetyl derivative which can be separated into its anomers by fractional crystallization from ethyl acetate:

α-5-Acetoxy-4-(D-*arabino*-1,2,3,4-tetraacetoxybutyl)thiazolidine-2-thione, $[\alpha]_D^{20} = +238°$ ($c = 1$; in dimethylformamide), m.p. 137–138 °C.

β-5-Acetoxy-4-(D-*arabino*-1,2,3,4-tetraacetoxybutyl)thiazolidine-2-thione, $[\alpha]_D^{20} = -218°$ ($c = 1$; in dimethylformamide), m.p. 165–168 °C.

When boiled for 16 hr in anhydrous pyridine, both these compounds afford D-*arabino*-1,2,3,4-tetraacetoxybutyl-$\Delta^4$-thiazoline-2-thione *(2)*, $[\alpha]_D^{20} = -37°$ ($c = 1$; in dimethylformamide), m.p. 169–170 °C[1].

The thiazolidinethione ring in compound *(1)* can be easily opened. Use of methyl iodide + triethylamine in pyridine leads to an α,β-mixture of 2-deoxy-2-[methylthio(thiocarbonyl)amino]-D-glucopyranoses, isolated as the crystalline 1,3,4,6-tetra-*O*-acetyl derivative *(3)*, m.p. 143–145 °C (decomp.), $[\alpha]_D^{20} = +100°$ ($c = 1$; in dimethylformamide). Compound *(1)* can be titrated as an acid with alkali; salts of 2-deoxy-2-[methylthio(thiocarbonyl)amino]-D-glucopyranose are thus obtained, form which *(1)* is regenerated on acidification. The yellow Cu(II) salt of *(1)* is practically insoluble in all solvents. Compound *(1)* is stable in glacial acetic acid, but in boiling 2 N hydrochloric acid it affords glucosamine hydrochloride quantitatively. The structures of all the products are proved by, *inter alia*, elemental analyses, molecular-weight determinations, and IR and NMR spectra.

Formation of 5-hydroxythiazolidine-2-thiones appears to be a general reaction of α-amino carbonyl compounds with $CS_2$.

## Cyclododecasulfur, $S_{12}$

By Prof. Max Schmidt and Dr. E. Wilhelm

Institut für Anorganische Chemie, Universität Würzburg (Germany)

In sulfur melts innumerable forms of sulfur, $S_x$, with $x = 8$ to about $10^6$, coexist in hitherto unelucidated equilibria. Nevertheless, only two definite structures have so far been isolated, namely cyclooctasulfur, $S_8$ (crystallizing as $S_\alpha$, $S_\beta$, and $S_\gamma$), and cyclohexasulfur, $S_6$ ($S_\rho$)[1]. Recently[2] we developed a process for the planned synthesis of rings or chains of identical atoms and used it to obtain the unstable molecules $S_6$ and $S_{10}$, of which the latter, being extremely, unstable, was insufficiently characterized. We have now prepared a new, surprisingly stable modification of sulfur, *viz.* cyclododecasulfur, $S_{12}$:

$$H_2S_x + Cl_2S_y \rightarrow 2\,HCl + S_{12}$$
$$(x + y = 12)$$

$S_{12}$ is formed, together with polymeric sulfur, from sulfanes and chlorosulfanes ($x + y = 12$) in $CS_2$-ether mixtures by use of the dilution principle. It forms small, pale yellowish rectangular prisms from benzene, which melt at 148 °C (with decomposition), *i.e.* appreciably higher than all previously known forms of sulfur; the resolidified melt consists of $S_8$, m.p. 119 °C, which is formed by way of polymeric sulfur. The solubility of $S_{12}$ in benzene, about 0.4 g/l, is too low for vapor-pressure osmometric or ebullioscopic determination of the molecular weight. On concentration of its solutions in carbon disulfide, $S_{12}$ separates as colorless plates with a circular indentation in the centers of the large faces and containing solvent which they rapidly lose with disintegration, but the solubility in carbon disulfide is also remarkably low (*ca.* 2 g/l), so that vapor-pressure osmometric determination of the molecular weight gives values between 377 and 390 (theory 384).

$S_{12}$ cannot be volatilized without decomposition in a vacuum (above 148 °C it is converted into $S_8$ *via* polymeric forms), but it can be identified mass-spectrometrically by bringing it into an ion source preheated to 90 to 120 °C (the spectrum, with $S_{12}$ as its highest mass, shows all fragments from $S_{10}$ to $S_2$; intensity ratio $S_8:S_{12} = 100:0.3$; the isotope fine structure of the $S_{12}^+$ ion corresponds with expectation) [3].

$S_{12}$ is intermediate between $S_8$ and $S_6$ in its activity as Lewis acid, *e.g.* towards $(C_6H_5)_3P$ [4].

Contrary to *Pauling*'s prediction [5], $S_{12}$ is much more stable than $S_{10}$ or $S_6$. His prediction was based on the assumption that sulfur chains or rings with a bond angle of about 105° would be the more stable the nearer the torsion angle approached the ideal value of *ca.* 100° (deviation from the ideal value for $S_8$ is *ca.* 1°, and for $S_6$ *ca.* 25°). With the atoms arranged in two planes, as postulated for $S_{12}$, deviation of the torsion angle from the ideal value would amount to *ca.* 30°. Structure determination [6] has, however, shown that in twelve-membered rings the sulfur atoms lie not in two planes, but in three, with a resulting torsion angle of *ca.* 107°. This relatively small deviation from the ideal value explains the great stability of the new sulfur modification: it remains unchanged at room temperature in air and is not destroyed even by long exposure to light or X-rays.

*Preparation of $S_{12}$ (Example)*

Solutions of 5 g of $S_4Cl_2$ and 6.5 g of $H_2S_8$, each in 150 ml of $CS_2$, were added simultaneously and at equal rates to a well-stirred mixture of 900 ml of ether (dried over Na–K alloy) and 300 ml of very pure $CS_2$ at room temperature. The addition was made, during 25 hours, from dropping funnels fitted with glass taps controlled by finely threaded screws. Twelve hr after addition was complete the liquid phase was decanted from the precipitate, which was then washed repeatedly with 500 ml portions of pure $CS_2$ preheated to about 40 °C. Cautious concentration of the extract in vacuum gave 1.5 to 2 g (15 to 20 %) of $S_{12}$, which was recrystallized from much anhydrous benzene.

## Crystal Structure of Cyclododecasulfur, $S_{12}$

By Dr. A. Kutoglu and Prof. E. Hellner

Mineralogisches Institut, Universität Marburg (Germany)

The $S_{12}$ modification [1] of sulfur crystallizes in the orthorhombic system with lattice constants $a_0 = 4.730$ Å, $b_0 = 9.104$ Å, and $c_0 = 14.574$ Å. The pyknometric density is 2.04, the X-ray density 2.02 g cm$^{-3}$. The extinction rules lead to the space group Pnnm-$D_{2h}^{12}$.

For the structure investigation 634 X-ray intensities were estimated from Weissenberg equiinclination photographs. All the parameters of the sulfur atoms could be obtained from a three-dimensional Patterson synthesis.

The parameters were refined by the method of least squares. After five iterations with the four atoms in the asymmetric unit and individual isotropic temperature factors the *R* value was reduced from 0.27 to 0.11.

The unit cell of cyclododecasulfur contains 24 atoms (Fig. 1). The two zigzag rings of twelve atoms each, one around the origin, the other around the point $\frac{1}{2}\,\frac{1}{2}\,\frac{1}{2}$, are nearly parallel to the plane {100}. The average of the shortest S–S distances in a ring is 2.055 Å; and the average S–S–S angle is 106°30′. The shortest distance between two rings is 3.60 Å. Thus the distances and angles in this modification are the same as those found previously for other S modifications ($S_8$ and $S_6$ rings).

Distances (error ± 0.01 Å) and angles (error ± 0.5°) within a ring:

| | | |
|---|---|---|
| $S_1$–$S_2$ 2.05 Å | $S_2$–$S_3$ 2.06 Å | $S_1$–$S_2$–$S_3$ 107.8° |
| $S_1$–$S_3$ 3.32 Å | $S_2$–$S_4$ 3.28 Å | $S_2$–$S_3$–$S_4$ 105.9° |
| $S_1$–$S_4$ 4.27 Å | $S_3$–$S_4$ 2.05 Å | $S_3$–$S_4$–$S_5$ 107.2° |
| | | $S_{12}$–$S_1$–$S_2$ 105.0° |

Distances between two rings:

| | | |
|---|---|---|
| $S_1$–$S_1'$ 5.17 Å | $S_2$–$S_2'$ 4.55 Å | $S_3$–$S_3'$ 4.79 Å |
| $S_1$–$S_2'$ 4.09 Å | $S_2$–$S_3'$ 3.60 Å | $S_3$–$S_4'$ 6.03 Å |
| $S_1$–$S_3'$ 3.68 Å | $S_2$–$S_4'$ 5.26 Å | $S_4$–$S_4'$ 7.78 Å |
| $S_1$–$S_4'$ 4.34 Å | | |

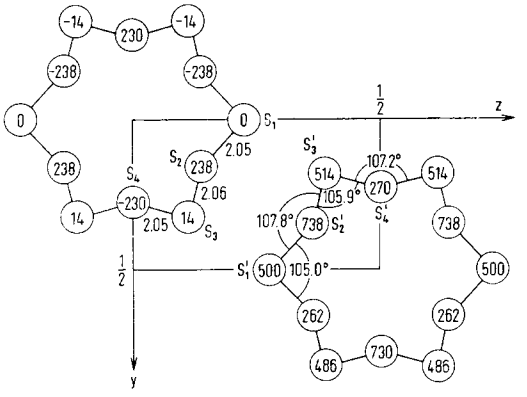

Fig. 1. Projection of the $S_{12}$ modification on the {100} plane. The numbers in the circles show the $x$ values ($10^3x$) of the S atoms. The distance values (in Å) are given in the ring around the origin; the angles are shown in that around $\frac{1}{2}\,\frac{1}{2}\,\frac{1}{2}$.

## Investigation of Cyclododecasulfur, $S_{12}$, by Mass Spectrometry

By Dr. J. Buchler

Institut für Organische Chemie,
Technische Hochschule Braunschweig (Germany)

In a mass spectrometer the modifications of elemental sulfur previously known do not yield ions heavier than $S_8^+$ (*m/e* 256 and isotope satellites); $S_9^+$ has been recorded (0.4 %, relative to $S_8^+ = 100$ %) in one case only [1].

When cyclododecasulfur, which has been recently synthesized [2], is introduced into the ion source of a mass spectrometer at 90 °C and then heated to 120 °C the mass spectrum of cyclododecasulfur appears alongside a typical mass spectrum of $S_8$ (Fig. 1). The intensity of this $S_{12}$ spectrum is about three orders of magnitude smaller than that of the $S_8$ spectrum.

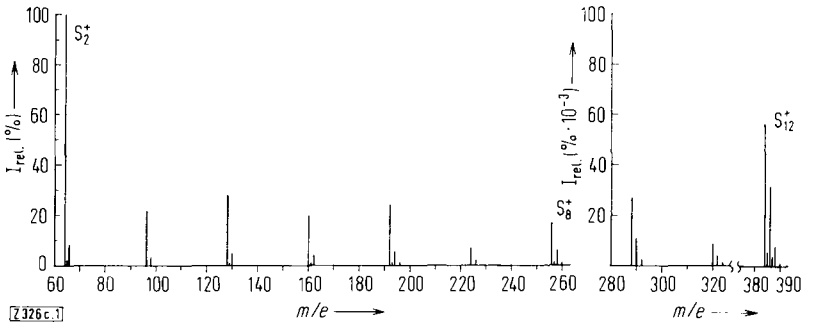

Fig. 1. Mass spectrum of cyclododecasulfur.

During the change of $S_{12}$ to $S_8$ that occurs at the temperature of measurement [3] and gives rise to the intense $S_8$ spectrum, enough $S_{12}$ is vaporized to allow the $S_{12}^+$ ion (*m/e* 384) to be identified and the isotope pattern to be measured (Table 1).

Table 1. Isotope pattern of the $S_{12}^+$ ion.

| *m/e* | Formula | Relative intensity (%) | |
|---|---|---|---|
| | | calc. [4] | found [5] |
| 384 | $^{32}S_{12}$ | 100 | 100 |
| 385 | $^{32}S_{11}{}^{33}S$ | 9.6 | 9.4 ± 0.5 |
| 386 | $^{32}S_{11}{}^{34}S$ | 53.6 | 54.0 ± 0.6 |
| 387 | $^{32}S_{10}{}^{33}S^{34}S$ | 4.7 | 5.2 ± 0.6 |
| 388 | $^{32}S_{10}{}^{34}S_2$ | 13.0 | 13.3 ± 1.1 |
| 390 | $^{32}S_9{}^{34}S_3$ | 1.9 | 2.1 ± 0.2 |

The mass of the $^{32}S_{12}^+$ ion was found[4] by peak matching to be 383.660 ± 0.010 (calc. 383.665).

## Synthesis and Reactions of Lithium Chloromethyldimethylsilanolate

By Dr. M. Wieber and Dr. C. D. Frohning

Institut für Anorganische Chemie,
Universität Würzburg (Germany)

Alkali trimethylsilanolates can be prepared by the action of alkali metals on trimethylsilanol. This reaction cannot, however, be applied to the organofunctional chloromethyldimethylsilanol *(1)* [1], because the hydrogen evolved removes the halogen atom. This side reaction is prevented if a stoichiometric amount of methyl-lithium (in ether, ice-cooling) is titatively as a precipitate which is sparingly soluble in ether.

$$(CH_3)_2(CH_2Cl)SiOH + M^0 \rightarrow (CH_3)_2(CH_2Cl)SiOM + {}^1/_2\ H_2$$
*(1)*

used instead of lithium; methane is evolved and lithium chloromethyldimethylsilanolate *(2)* is obtained almost quan-

$$(1) + LiCH_3 \rightarrow (CH_3)_2(CH_2Cl)SiOLi + CH_4$$
*(2)*

Compound *(2)* is a colorless powder, m.p. 208–210 °C (decomp.), that can be sublimed at 200 °C/$10^{-3}$ mm (with partial decomposition). Its structure was determined by elemental analysis, determination of the acid equivalent, and IR and $^1$H–NMR spectra (Varian A60, 5 % solution in $CHCl_3$, tetramethylsilane as internal standard). As expected, the $^1$H–NMR spectrum contains two signals, at $\tau$ = 7.22 and $\tau$ = 9.93 ppm, with area ratio 1:3.

Compound *(2)* serves as starting material for syntheses of new organofunctional heterosiloxanes, three examples of which are shown in Table 1.

Table 1. Organofunctional heterosiloxanes obtained from lithium chloromethyldimethylsilanolate.

| Reaction [a] of *(2)* with | Mol. propns. | Product | Yield (%) | B.p. (°C/12 mm) | $^1$H–NMR ($\tau$ in ppm) Si–$CH_3$ / Ge–$CH_3$ | $-CH_2$ / $-CH_2$ |
|---|---|---|---|---|---|---|
| $(CH_3)_3GeCl$ | 1:1 | $(CH_2Cl)(CH_3)_2Si-O-Ge(CH_3)_3$ | 80 | 62 | 9.87<br>9.6 | 7.4<br>– |
| $(CH_2Cl)(CH_3)_2GeCl$ | 1:1 | $(CH_2Cl)(CH_3)_2Si-O-Ge(CH_2Cl)(CH_3)_2$ | 74 | 96 | 9.85<br>9.5 | 7.4<br>7.0 |

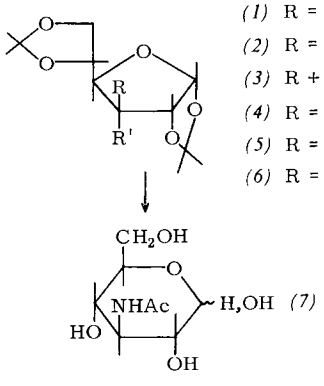
## A Simple Synthesis of 3-Amino-3-deoxy-D-glucose (Kanosamine)

By Dr. W. Meyer zu Reckendorf

Institut für Pharmazeutische Chemie,
Universität Münster (Germany)

Nucleophilic displacement of the sulfonyl ester group in compounds *(1)*[1] by α-attack is sterically hindered by the 1,2-*O*-isopropylidene group. The methanesulfonate *(5)* with the opposite configuration at C-3 should be more reactive since attack from the β-side is not hindered. This is the case, as is shown by the following experiments.

Compound *(3)* is obtained in 30% yield from the readily accessible substance *(2)* by dehydrogenation[2] with dimethyl sulfoxide/$P_2O_5$. It is stereospecifically reduced by $NaBH_4$ in methanol to the alcohol *(4)*, which on mesylation with methanesulfonyl chloride and pyridine affords the ester *(5)*, m.p. 129–130 °C, $[\alpha]_D^{20} = +80.0°$ ($c$ = 1.0 in $CHCl_3$). It was not necessary to isolate the difficultly crystallizing intermediates *(3)* and *(4)*.



*(1)* R = OMs; OTs; R' = H
*(2)* R = OH; R' = H
*(3)* R + R' = O
*(4)* R = H; R' = OH
*(5)* R = H; R' = OMs
*(6)* R = $N_3$; R' = H

*(7)*

Heating the product *(5)* with sodium azide in dimethylformamide (16 hr, reflux) gave the azide *(6)* as a chromatographically pure oil (yield 90%), which on catalytic hydrogenation (Pd/C), acetylation, and hydrolysis with Lewatit S 100 ion-exchange resin ($H^+$ form) afforded *N*-acetylkanosamine *(7)*[3,4] in 80% yield; m.p. and mixed m.p. with authentic material[4,5] 203–204 °C; $[\alpha]_D^{20} = +20.5° \rightarrow +53.0°$ ($c$ = 1.0 in water; lit.[4] +18.6° → +52.7°).

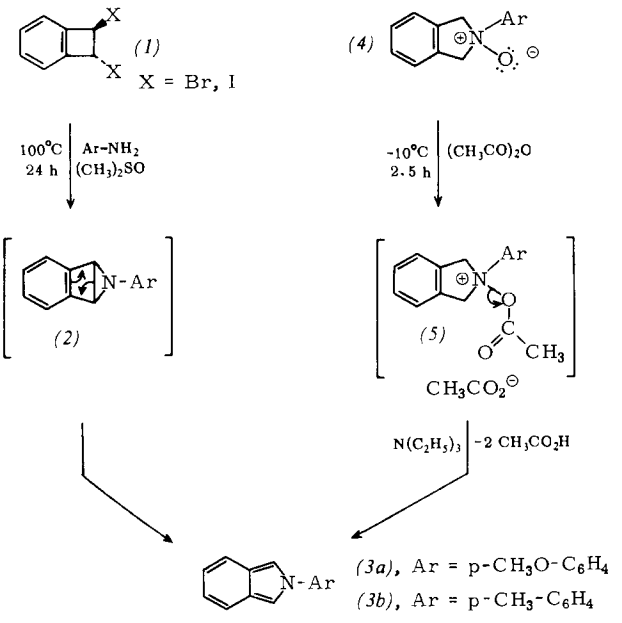
## 2-Arylisoindoles[1]

By Dr. R. Kreher and J. Seubert

Institut für Organische Chemie,
Technische Hochschule Darmstadt (Germany)

2-(*p*-Methoxyphenyl)isoindole *(3a)*, m.p. 175–176 °C (from 2-propanol), and 2-(*p*-tolyl)isoindole *(3b)*, m.p. 173–174 °C (from 2-propanol) have been prepared by two new methods, as follows:



7,8-Dihalogenobicyclo[4.2.0]octa-1,3,5-trienes *(1)*, which are relatively simply accessible from α,α,α',α'-tetrabromo-*o*-xylene[2], are treated with the appropriate primary aromatic amine in dimethyl sulfoxide, with $N[CH_2CHOHCH_3]_3$ as halide acceptor; products *(3a)* and *(3b)* are thus obtained in yields of up to 40%. Because of the relatively high reaction temperature this process can be used only for the 2-arylisoindoles which are particularly stable to heat. Presumably formation of these products *(3)* depends on whether the *trans*-form of the dihalides *(1)* is rearranged to the *cis*-form in the polar solvent dimethyl sulfoxide[2a], the latter being able to react with the primary amine to give the ethylene imine derivatives *(2)*. The strained ring system *(2)* can, by cyclic electron shift, give structures *(3)* that are favored by resonance stabilization. In a comparable reaction, *cis*-3,4-dichloro-1,2,3,4-tetramethylcyclobutene and primary amines yield pyrrole derivatives[3].

2-Arylisoindoline *N*-oxides *(4)* are converted by acetic anhydride/triethylamine, even at −10 °C, directly into isoindoles *(3)* in yields of up to 70%. The sensitive *N*-oxides *(4)* were obtained from the readily accessible 2-arylisoindolines by means of 30% $H_2O_2$/formic acid and were converted into the products *(3)* without isolation. We have previously used this process for the synthesis of 2-alkylisoindoles[4]. We believe that formation of the *N*-acetoxyammonium salts *(5)* as intermediate is indicated by formation of 2-(2-acetoxy-4-methoxyphenyl)isoindoline (m.p. 112–114 °C; $^1H$–NMR spectrum containing 3H singlets at $\tau$ = 7.6 and $\tau$ = 6.15, a 4H singlet at $\tau$ = 5.25, and a 7H multiplet at $\tau$ = 2.4–3.2), which arises, together with *(3a)*, on acetolysis of *(4a)*, evidently by rearrangement of[5] *(5a)*, Ar = *p*-$CH_3O$–$C_6H_4$.

The isoindole structure is indicated by the $^1H$–NMR spectra: the multiplet from the 5- and 6-ring protons appears between $\tau$ = 2.0 and 3.2; the protons of the methoxy group and of the methyl group give singlets at $\tau$ = 6.13 and $\tau$ = 7.56, respectively.

The UV spectra of products *(3a)* and *(3b)* are very similar to those of the 1-arylisoindoles first prepared by *Lwowski*[6]:

*(3a)* in methanol: $\lambda_{max}$ = 245 mμ (log ε = 4.45); 287.5 (4.02); 298 mμ (log ε = 4.03); 337 (3.66).

*(3b)* in methanol: $\lambda_{max}$ = 242.5 mμ (log ε = 4.50); 288 (3.94); 298 mμ (log ε = 3.94); 337 (3.62).

Structure *(3)* is further supported by conversion of 2-arylisoindoles by *N*-phenylmaleimide at room temperature into Diels-Alder adducts, namely *N*-phenyl-1,4-(arylepimino)-

1,2,3,4-tetrahydronaphthalene-2,3-dicarboximides, *e.g.* Aryl = *p*-tolyl, of which the *endo*-form has m.p. 136–137 °C and in the $^1$H–NMR spectrum has a 3H singlet at $\tau = 7.7$ and 2H quartets at $\tau = 6.0$–$6.1$ and $\tau = 4.3$–$4.4$, while the *exo*-form has m.p. 226–227 °C and in the $^1$H–NMR spectrum a 3H singlet at $\tau = 7.8$ and 2H singlets at $\tau = 6.8$ and $\tau = 4.5$.

## Bis(2,2′-biphenylylene)phosphorane and the Bis(2,2′-biphenylylene)phosphoranyl Radical

By Dr. D. Hellwinkel

Organisch-Chemisches Institut, Universität Heidelberg (Germany)

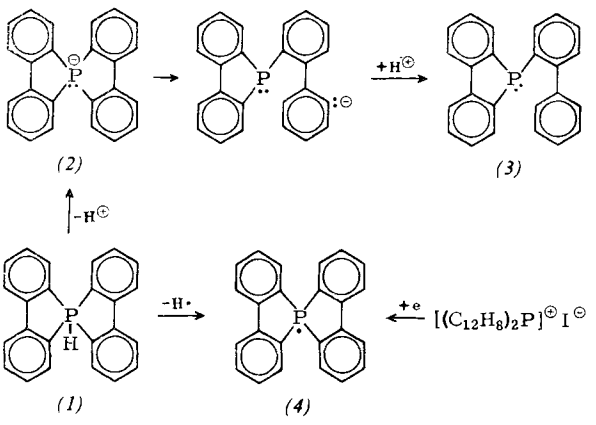
Whereas earlier attempts to prepare hydrido derivatives of quinquevalent phosphorus, arsenic, and antimony were unsuccessful[1–3], we have now succeeded in synthesizing a stable derivative of the hypothetical phosphorane, $PH_5$.

Bis(2,2′-biphenylylene)phosphonium iodide[4] is treated with a small excess of $LiAlH_4$ in ether under nitrogen in a double Schlenk tube with ice cooling. After filtration and cooling to −70 °C bis(2,2′-biphenylylene)phosphorane *(1)* crystallizes. Several recrystallizations from ether afford the pure product in 45% yield; the compound is stable indefinitely under nitrogen in the dark and can be kept for some days in air, but decomposes with discoloration between 95 and 100 °C, depending on the rate of heating.

The product *(1)* was identified by elemental analysis (C, H, P), by its $^1$H–NMR spectrum ($\delta_{H-P} = 9.33$ ppm; $J_{H-P} = 482$ Hz; in benzene, TMS as internal standard), and by its IR spectrum ($\tilde{\nu}_{P-H} = 2097$ cm$^{-1}$). Further evidence of structure is provided by evolution of hydrogen on treatment with ethanolic HCl or ethanolic iodine solution, which regenerate the bis(2,2′-biphenylylene)phosphonium cation in good yield:

$$[(C_{12}H_8)_2P]^{\oplus}I^{\ominus} \underset{LiAlH_4}{\overset{HCl/KI}{\rightleftarrows}} (1) \xrightarrow[-H_2]{I_2} [(C_{12}H_8)_2P]^{\oplus}I_3^{\ominus}$$

The phosphorane *(1)* reacts with methyl- or butyl-lithium in ether with evolution of methane or butane, respectively, giving a dark violet solution which is almost completely decolorized within an hour. An excess of $LiAlH_4$ reacts with *(1)* only after addition of tetrahydrofuran, $H_2$ being evolved and an intensely blue-green solution formed which is also decolorized within an hour. On ethanolysis, 2-biphenylyl-2′,2″-biphenylylenephosphine *(3)* can be isolated from both these reaction mixtures in about 75% yield. With strong bases *(1)* evidently forms the corresponding base, the bis(2,2′-biphenylylene)phosphoranyl anion *(2)*[5], which is violet in ether and blue-green in THF and rearranges with fission of a P–C bond to a colorless carbanion which is finally protonated to the phosphine *(3)*.



Organic phosphorus radicals usually are unstable, and therefore few ESR-spectroscopic studies of them have been reported[6–9]. If a *ca.* 0.5 M solution of the phosphorane *(1)* in benzene is prepared at 20 °C with stringent exclusion of oxygen and moisture, a pale violet coloration is observed which becomes very intense in the course of several hours (even if the solution is exposed only to diffuse daylight). Half an hour after preparation of the solution the ESR spectrum shows a well-formed doublet with a coupling constant of 18 gauss; the intensity of the signal increases during about 7 hr to a constant value while the doublet is gradually transformed into a singlet owing to the increasing radical concentration (in less concentrated solutions the doublet remains). Simultaneously the $^1$H–NMR spectrum is observed to lose the original strong doublet ($J = 482$ Hz) due to the hydrogen bound to phosphorus. These results indicate quantitative conversion of *(1)* into the bis(2,2′-biphenylylene)phosphoranyl radical *(4)*.

The radical *(4)*, characterized by its ESR doublet, also arises when bis(2,2′-biphenylylene)phosphonium iodide[4] is treated with Na/K alloy in benzene, the solution being filtered immediately on appearance of a red-violet color in order to prevent further reaction to the anion.

## Nucleophilic Ligand Exchange by Phosphoranes [*]

By Dr. M. Schlosser, T. Kadibelban, and Dr. G. Steinhoff

Organisch-Chemisches Institut,
Universität Heidelberg (Germany)

The organic groups of phosphorus ylides[1], phosphines[2], phosphine oxides[3], or phosphine sulfides[4] undergo nucleophilic exchange with organolithium reagents. We have now observed similar replacements also with pentaorganylphosphorus compounds.

If an ethereal solution ($c \approx 0.01$ M) of pentaphenylphosphorus is treated at room temperature with, for instance,

5 equivalents of *p*-tolyl-lithium, the tetraarylphosphonium salt obtained by subsequent action of acids shows the IR bands of a tolyl group. Phenyl-lithium (7 %) is liberated and can be converted into bromobenzene by 1,2-dibromoethane. Whether this exchange occurs by way of a sexicovalent ate complex *(1)* [5] is being studied by kinetic and NMR methods.

$$Li^{\oplus}\ [(C_6H_5)_5P{-}C_6H_4{-}CH_3{-}p]^{\ominus} \qquad (1)$$

When primary or secondary alkyl-lithium compounds in petroleum ether are allowed to act on pentaphenylphosphorus, phosphorus ylides (and resins) are obtained. n-Butyl-lithium affords triphenylphosphine n-butylide as the LiCl adduct *(2)*, which was characterized as n-butyltriphenylphosphonium bromide (yield 12–24 %), m.p. 233–236 °C, and 1-phenyl-1-pentene (yield 8 %; formed by reaction with benzaldehyde). With an excess of butyl-lithium some of the product *(2)* is metalated further, giving *(3)* (yield up to 14 % calculated on pentaphenylphosphorane) [6]; *(3)* was trapped as ([1,1-$D_2$]-butyl)triphenylphosphonium bromide, m.p. 232–234 °C, with DBr.

$$(C_6H_5)_5P \xrightarrow[(+\ LiCl)]{C_4H_9{-}Li} (C_6H_5)_3\overset{\oplus}{P}{-}\overset{C_3H_7}{\underset{H}{C}}{}^{\ominus}\cdots LiCl \qquad (2)$$

$$(2) \xrightarrow[(+\ LiCl)]{C_4H_9{-}Li} (C_6H_5)_3\overset{\oplus}{P}{-}\overset{C_3H_7}{\underset{Li}{C}}{}^{\ominus}\cdots LiCl \qquad (3)$$

Only the singly bound ligand R of the phosphoranes *(4)* and *(5)* could be removed (in ether or tetrahydrofuran) (cf. the following communication).

## Ligand Exchange with Compounds of Quinquevalent Arsenic [*]

By Dr. D. Hellwinkel and Dr. G. Kilthau

Organisch-Chemisches Institut,
Universität Heidelberg (Germany)

Aryl- and alkyl-bis-2,2'-biphenylylenearsenic *(1)*, which can be prepared from bis-2,2'-biphenylylenearsonium iodide and lithium aryls [1], alkyls [2], or Grignard compounds [3], undergo ligand exchange [4] on reaction with suitable organolithium reagents in ether ($c \approx 0.05$ M) (cf. table).

| R' | R = $CH_3$ | | R = $C_6H_5$ | | R = $C_4H_9$ | | R = *p*-$CH_3$–$C_6H_4$ | | R = *p*-Cl–$C_6H_4$ | | R = *p*-$(CH_3)_2N$–$C_6H_4$ | |

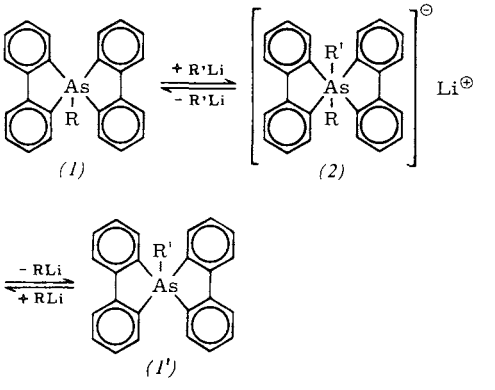
The structures of the phosphoranes *(4)*–*(8)* were proved by elemental analysis, NMR and IR spectra, or comparison with authentic material. Compounds *(4)* [7] and *(5)* [8] were known; compounds *(6)*, m.p. 185–186 °C, *(7)*, m.p. 198.5 to 200 °C, and *(8)*, m.p. 177.5–178 °C, were synthesized analogously.

Received: July 18th and September 15th, 1966 [Z 329a IE]
German version: Angew. Chem. *78*, 1018 (1966)

All the mixtures indicated in the table were stirred for 10 hr and then hydrolysed. The exchange products were identified by mixed melting points and by comparison of IR spectra.



The table shows that the strength of bonding of the ligands R decreases in the order:

$$C_4H_9 \gg p\text{-}(CH_3)_2N{-}C_6H_4 \approx CH_3 \approx p\text{-}CH_3{-}C_6H_4 \approx p\text{-}Cl{-}C_6H_4 > C_6H_5.$$

Formulation of these exchange reactions *via* intermediate hexaarylarsenate(v) complexes *(2)* is supported by the fact

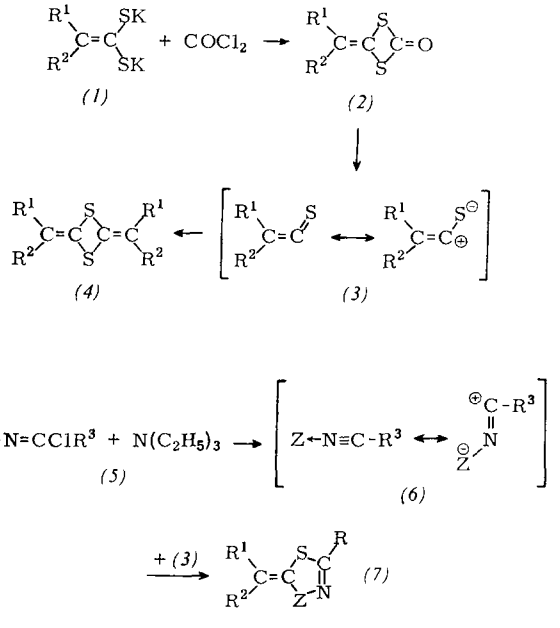
## Formation of 1,3,4-Thiadiazoles and 1,4,2-Oxathiazoles from Thioketenes

By Dr. K. Dickoré and Dr. R. Wegler

Wissenschaftliches Hauptlaboratorium,
Farbenfabriken Bayer AG., Leverkusen (Germany)

Little is known about monomeric thioketenes because of their great tendency to polymerize. They can be obtained by pyrolysis of ethynyl sulfides, but polymerization begins already at −80 °C [1].

We have found that reaction of phosgene with alkali salts *(1)* of 2,2-disubstituted ethylene-1,1-dithiols [2,3] in suspension in methylene chloride gives 1,3-dithietanes *(2)*. These yellow to brown substances give a characteristic strong IR band at 1790–1810 $cm^{-1}$ (stretching vibration for carbonyl in a four-membered ring); they decompose to thioketenes *(3)* and COS under catalysis by Lewis bases, surface-active compounds, or polar solvents or even when heated. In the absence of a suitable reactant these thioketenes dimerize generally to 2,4-dialkylidene-1,3-dithietanes *(4)* [*] [2,4,5]. In the presence of nitrile oxides or nitrile imines *(6)*, obtained *in situ* from oximes or hydrazones *(5)*, Z = O or $NC_6H_5$, with triethylamine, the thioketenes *(3)* undergo 1,3-dipolar cycloaddition [6] to give heterocyclic products *(7)* [*].



Other strongly polar addends such as chloral [7] and compounds of the type $RN{=}C(SR')_2$ [8], which have proved useful for trapping ketenes generated *in situ*, do not add to thioketenes, even when used in great excess.

| *(2)* | $R^1$ | $R^2$ | Yield (%) | M.p. (°C) |

| *(e)* | CN | $COOCH_3$ | $NC_6H_5$ | $C_6H_5$ | 61 [a] | 216–217 [b] |

[a] Yield of mixture of geometrical isomers.
[b] M.p. of less soluble isomer (from acetone).

*Experimental*: 92 g of phosgene is introduced into a suspension of 194 g of compound *(1)*, $R^1 = R^2 = CN$, in 1.2 l of $CH_2Cl_2$ at 10 to 15 °C. The mixture is stirred for 1/2 hr at 20 °C, precipitated salts are removed by filtration, and the solvent is removed in vacuum at not more than 30 °C. This procedure yields 117 g of compound *(2a)*. A sample recrystallized from cyclohexane forms pale yellow leaflets melting at 103–105 °C (decomp.).

A solution of 33.6 g of compound *(2a)* and 40.2 g of *p*-chlorobenzohydroxamoyl chloride in 550 ml of $CH_2Cl_2$ is treated dropwise with 21.2 g of triethylamine at 0 to 10 °C. The mixture is stirred for 2 hr at 20 °C and the solid product is filtered off and washed with a little methylene chloride, acetone, and much water, yielding 39.8 g of compound *(7b)*, which forms pale yellow leaflets, m.p. 210 °C (decomp.), from acetone.

## Arylammonium Polyphosphates from *O,O,S*-Trialkyl Thiophosphates and Arylamines

By Prof. G. Hilgetag, Dr. H. Teichmann, and Dr. M. Krüger

Institut für Organische Chemie der Deutschen Akademie der Wissenschaften zu Berlin, Berlin-Adlershof (Germany)

Trialkyl phosphates alkylate primary aliphatic amines, giving up one alkyl group, but they alkylate the more weakly basic primary aromatic amines with all three alkyl groups [1]. Dialkyl phosphorochloridates, phosphoramidates, and phosphorazidates also can transfer both alkyl groups to arylamines; this reaction has been suggested for the preparation of *N*-arylphosphoramidic acids *(1)*, which are reported to be thus formed [2].

In analogous reactions of *O,O,S*-trialkyl thiophosphates with arylamines (molar ratio 1:3 to 1:4.5, temperature 130 to 160 °C) we have obtained, alongside *N*-alkylarylamines and

alkanethiols, high yields of products that are identical with the supposed *N*-arylphosphoramidic acids *(1)* previously described.

$$(RO)_2PO(SR') + 3\ ArNH_2 \rightarrow 2\ ArNHR + R'SH + [ArNHPO(OH)_2]$$
*(1)*

R = $CH_3$, $C_2H_5$, or n-$C_4H_9$;

R' = $CH_3$ or $C_2H_5$;

Ar = $C_6H_5$, *p*-Cl–$C_6H_4$, *m*-$CH_3$–$C_6H_4$, *o*-$CH_3$–$C_6H_4$, *p*-$CH_3$–$C_6H_4$, *p*-$CH_3O$–$C_6H_4$, or 2-naphthyl

These products have precisely the composition of the appropriate *N*-arylphosphoramidic acids. Yet they have remarkably high and unsharp melting points (in the range 230 to 300 °C), are almost insoluble in the usual solvents, and cannot be converted into the known derivatives of *N*-arylphosphoramidic acids (salts, esters, dichlorides). The IR spectra give no indication of a P–N bond, but very definite P–O–P bands at 890 to 940 $cm^{-1}$. Like Kurrol's potassium salt $(KPO_3)_n$, which also is insoluble[3], most of these products dissolve readily in saturated NaCl solution; on paper chromatography of such solutions the substances remain behind those oligophosphates that are separable (up to $n = 9$).

Thus we are not dealing with *N*-arylphosphoramidic acids *(1)*, but with the isomeric arylammonium polyphosphates *(2)*. The same is true for preparations obtained by other methods[4]. The conversion of compounds *(1)* into *(2)* corresponds to the behavior of the parent substance $H_2NPO_3H_2$ when heated to 100 °C[5]. On addition of a suitable alcohol the metaphosphate intermediate can be trapped, *e.g.* as the ester *(3)*.

$$ArNHPO(OH)_2 \rightleftharpoons Ar\overset{\oplus}{N}H_2PO(OH)O^{\ominus}$$
*(1)*

$$\rightarrow [HPO_3] + ArNH_2$$

$$\xrightarrow{c\text{-}C_6H_{11}OH} c\text{-}C_6H_{11}OPO(OH)_2 \quad {}^1/_n\ [Ar\overset{\oplus}{N}H_3\ PO_3^{\ominus}]_n$$
*(3)* *(2)*

*O,O*-Dibutyl *S*-ethyl thiophosphate and aniline (molar ratio 1:4.4; 3.5 hr; 160 °C) afford 81 % of the pure salt *(2)* (Ar = $C_6H_5$), but *O*-butyl *S*-ethyl hydrogen thiophosphate gives only 18 % of impure product under the same conditions; however, reactions of dialkyl *N*-phenylphosphoramidates with aniline yield the salts *(2)* smoothly; *O,S*-dimethyl *O*-phenyl thiophosphate and aniline give phenyl hydrogen *N*-phenylphosphoramidate. It thus follows that the first step in the reaction is phosphorylation of the amine to a diester of the *N*-arylphosphoramidic acid, which is then dealkylated to give the (unstable) acid *(1)*.

## A New Synthesis of Tetrakis(dimethylamino)ethylene

By Prof. H. Bredereck, Dr. F. Effenberger, and H. J. Bredereck

Institut für Organische Chemie, Technische Hochschule Stuttgart (Germany)

Tris(dimethylamino)methane *(1)* has been prepared previously by treatment of tetramethylformamidinium salts with alkali dimethylamides[1]. We have now found that compound *(1)* readily loses dimethylamine on being heated under nitrogen, leading to tetrakis(dimethylamino)ethylene *(2)*, which is purified by distillation; yield 80 % after 2 hr under reflux.

$$H\text{-}C[N(CH_3)_2]_3 \xrightarrow{\Delta} (CH_3)_2N\text{-}C(N(CH_3)_2)=C(N(CH_3)_2)\text{-}N(CH_3)_2 + 2\ HN(CH_3)_2$$
*(1)* *(2)*

The compound *(2)* was first synthesized[2] from chlorotrifluoroethylene and dimethylamine in 54 % yield. It is also obtained on thermal decomposition of aminal esters[3], but only in low yields.

## (Dimethylsulfonio)(phenylsulfonyl)-(vinylsulfonyl)methanide

By H. Diefenbach and Dr. H. Ringsdorf

Institut für Polymere, Universität Marburg (Germany)

In attempts to substitute the protons of the $-SO_2-CH_2-SO_2-$ group of *S*-vinylmethylene disulfones[1] while retaining the vinyl group, we have prepared the first unsaturated, polymerizable sulfur ylide, namely (dimethylsulfonio)(phenylsulfonyl)(vinylsulfonyl)methanide *(2)*. The method of preparation was equivalent to that used for condensation of sulfoxides with sulfonamides[2] or active methylene compounds[3].

$$CH_2{=}CH\text{-}SO_2\text{-}CH_2\text{-}SO_2\text{-}C_6H_5 + S(=O)(CH_3)_2 \xrightarrow{Ac_2O} CH_2{=}CH\text{-}SO_2\text{-}\overset{\ominus}{C}(\overset{\oplus}{S}(CH_3)_2)\text{-}SO_2\text{-}C_6H_5$$
*(1)* *(2)*

An exothermic reaction occurs at 120 °C when 5 g of methylene *S*-phenyl *S'*-vinyl disulfone *(1)* and 15 g of dimethyl sulfoxide are heated together in 20 g of acetic anhydride. After the mixture had cooled, the volatile components were removed in a vacuum (60 °C/2 mm). The ylide solidified after a few days and was recrystallized from water. Yield, 1.5 g (24.2 %); m.p. 133.5–134.5 °C.

Elemental analysis, and the fragments as well as the highest peak (306) in the mass spectrum[4], prove the composition and molecular weight of the product *(2)*. Preponderance of the ylide structure shown over a possible ylene structure (>C=S<) is confirmed by the UV spectrum (in 95 % ethanol). The fine structure ($\lambda_{max}$ = 261 mμ, log $\varepsilon_{max}$ = 2.93; $\lambda_{max}$ = 267 mμ, log $\varepsilon_{max}$ = 3.09; $\lambda_{max}$ = 274 mμ, log $\varepsilon_{max}$ = 3.02) due to the aromatic system in the starting material *(1)* is absent from the spectrum of the product *(2)*,

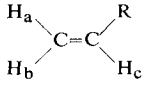
which gives a broad and more intense band at $\lambda_{max} = 248$ mμ (log $\varepsilon_{max} = 3.93$) comparable with that due to the methylene *S,S'*-diphenyl disulfone anion, $C_6H_5-SO_2-{}^{\ominus}CH-SO_2-C_6H_5$ ($\lambda_{max} = 267$ mμ, log $\varepsilon_{max} = 3.85$) [5].

Characteristic differences in the IR and NMR spectrum of compounds *(1)* and *(2)* are collected in Tables 1 and 2.

Table 1. Positions of the IR bands ($cm^{-1}$) due to the $SO_2$ stretching vibrations of compounds *(1)* and *(2)*.

| | *(1)* | *(2)* |
|---|---|---|
| ν ($SO_2$) | 1317/1305 | 1300/1285 |
| ν ($SO_2$) | 1160/1150 | 1135/1120 |

Table 2. Chemical shifts (τ) and coupling constants (*J*) of compounds *(1)* and *(2)* [measured in $(D_3C)_2SO$, TMS as internal standard, at 20 °C and 60 MHz].



| | $\tau_a$ | $\tau_b$ | $\tau_c$ | $J_{ac}$ | $J_{bc}$ | $\tau C_6H_5$ | $\tau CH_3$ | α [a] |
|---|---|---|---|---|---|---|---|---|
| *(1)* | 3.64 | 3.68 | 2.91 | 9.5 | 17.0 | 2.1 | – | 0.37 |
| *(2)* | 4.23 | 4.03 | 3.07 | 9.8 | 16.3 | 2.3 | 7.07 | 0.28 |

[a] $\alpha = J_{bc}/(\nu_b - \nu_c)$; cf. [6].

The higher electron density of the vinyl group in the ylide *(2)* than in *(1)* is reflected in the chemical shifts of the vinyl protons and in the α values [6].

## Reduction of Phthalocyanine to Tri- and Tetra-lithium Phthalocyanine

By Dr. R. Taube and P. Meyer

Institut für Anorganische Chemie,
Universität Greifswald (Germany)

We have found earlier [1] that transition-metal derivatives of phthalocyanine (MPc) can be reduced in tetrahydrofuran, in a series of steps, by lithium, sodium, or radical anions of aromatic compounds:

$$[MPc] \xrightarrow{+n\ominus} [MPc]^{n-}$$

The anionic phthalocyanine complexes formed can be isolated as well-crystalline lithium salts that contain tetrahydrofuran [2]. In order to elucidate the structure of these new electron-rich complexes it was necessary to find whether the ligand $Pc^{2-}$ is itself reducible [3].

If dilithium phthalocyanine ($Li_2Pc$) [4], in which only reduction of the phthalocyanine system is theoretically possible [5], is treated in tetrahydrofuran with dilithiobenzophenone ($Li_2Bzph$), then trilithium phthalocyanine *(1)* is obtained.

$$Li_2Pc + {}^1/_2\ Li_2Bzph \xrightarrow{THF} {}^1/_2\ Bzph + Li_3Pc{\cdot}6THF \quad (1)$$

This product forms shiny, violet-brown needles, dissolves in THF or acetonitrile to intensely blue solutions, can be recrystallized from THF, and in THF consumes one atom of iodine. At 293 °K, $\chi_g = +(1.15 \pm 0.01)\times10^{-6}$ cm³/g, whence it follows that $\mu_{eff} = 2.09 \pm 0.01$ B.M.

Use of an excess of $Li_2Bzph$ leads to tetralithium phthalocyanine *(2)*. This compound forms olive-green crystals with a yellow surface sheen, is only sparingly soluble in THF or

$$Li_3Pc{\cdot}6THF + Li_2Bzph \xrightarrow{THF} LiBzph + Li_4Pc{\cdot}8\ THF \quad (2)$$

acetonitrile, giving intensely violet solutions, consumes two iodine atoms in THF, and at 293 °K has $\chi_g = -(0.05 \pm 0.02)\times10^{-6}$ cm³/g, corresponding to $\mu_{eff} = 1.36 \pm 0.02$ B.M.

Compounds *(1)* and *(2)* are both sensitive to oxygen and moisture, lose the THF quantitatively in vacuum at 150 °C, and, like $Li_2Pc$, are electrolytes, as was shown by transport experiments in acetonitrile. Their structures are represented by the formulae $Li_2[LiPc]{\cdot}6THF$ and $Li_3[LiPc]{\cdot}8THF$, respectively.

Simple LCAO–MO theory requires that the electrons taken up go into the lowest unoccupied orbital in the complex. For $D_{4h}$ symmetry this is the two-fold degenerate, weakly antibonding π-orbital $6e_g$ of phthalocyanine [5]. Accordingly compound *(2)* must have $(6e_g)^2$ occupied and therefore, by Hund's rule, a triplet ground state. The observed magnetic moment, however, indicates a singlet state. For a multielectron scheme this should result from consideration of configuration interaction [6], but it could also be caused by lowering of symmetry by geometrical instability of the complex [7] which would remove the degeneracy of the $6e_g$ orbital.

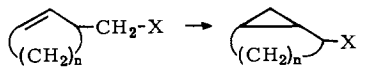
## Rearrangement of Unsaturated Compounds to Cyclopropane and Cyclobutane Derivatives

*M. Hanack*, Tübingen (Germany)

In carbonium-ion reactions homoallylic compounds readily rearrange to cyclopropylmethyl and cyclobutyl derivatives. This reaction has been studied for cyclic compounds of various structures in relation to ring size.

Compounds of formula *(1)*, X = OTs or $NH_2$, rearrange to bicyclic derivatives *(2)*, X = OH, if n > 2.



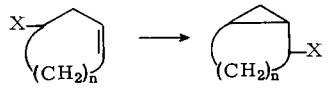
*(1)* *(2)*

However, 2-cyclobutenylmethyl derivatives *(1)*, n = 1, X = OTs, do not cyclize during solvolysis. Moreover, no participation of the double bond in carbonium-ion reactions could be detected by kinetic measurements.

Cyclopropylmethyl derivatives *(4)*, X = OH, are formed also from systems of structure *(3)*, X = OTs or $NH_2$, if n > 2.

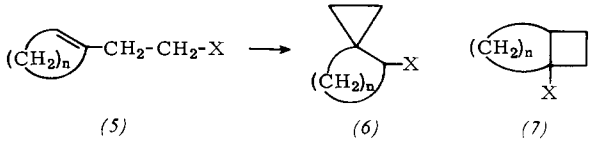
3-Cyclopentenyl derivatives *(3)*, n = 1, X = Br or OTs, however, do not react to give bicyclic compounds.

Compounds of structure *(5)*, n = > 3, rearrange to give spiro compounds *(6)*, X = OH, and condensed cyclobutane derivatives *(7)*, X = OH, which thus become easily accessible.



*(3)* *(4)*

Acetylenes of structure *(8)*, R = alkyl, X = *m*-$NO_2$-$C_6H_4$-$SO_3$, can be cyclized to cyclobutanones *(9)*, R = alkyl. When trifluoroacetic acid is used as the ionizing solvent, the cyclobutanones *(9)* are obtained almost quantitatively and thus become readily available for the first time.



*(5)* *(6)* *(7)*

Reaction of 4-phenyl-3-butynyl derivatives gives preponderatingly phenyl cyclopropyl ketones; solvolysis of the ethoxy derivative *(8)*, R = $OC_2H_5$, X = *m*-$NO_2$–$C_6H_4$–$SO_3$, affords ethyl cyclopropanecarboxylate.

## Reactions of Nucleophiles with Pyridinium Ions

*R. E. Lyle*, Durham, New Hampshire (U.S.A.)

The extreme electrophilicity of the pyridinium ion makes it a convenient substrate for the study of reactions of aromatic systems with nucleophiles. A pyridinium ion having an electron-withdrawing substituent in the 3-position may form a 1,2-, 1,4-, or 1,6-dihydropyridine. The factors which determine the site of reaction with the nucleophile, and thus the structure(s) of the product(s), are not well defined. The results of a study of the reactions of cyanide ion with 5-bromo-3-ethoxycarbonyl-1-methylpyridinium iodide, 1-benzyl-3-cyanopyridinium bromide, and 3-benzoyl-1-methylpyridinium iodide showed that the product of "kinetic control" was a 6-cyano-1,6-dihydropyridine, but in solution in ethanol or chloroform this derivative was converted into the 4-cyano-1,4-dihydropyridine. Evidence was presented that these reactions are reversible, showing that the 1,4-dihydropyridine is formed by "thermodynamic control".

The importance of steric interference to approach of the nucleophile to the position adjacent to the quaternary nitrogen in a "kinetically controlled" process was illustrated with results from sodium borohydride reductions.

The generalization of these results suggests that irreversible reactions of pyridinium ions with nucleophiles (kinetic control) occur at the positions adjacent to the quaternary nitrogen if steric interference of the nucleophile with the nitrogen substituent is not too large.

Reactions with nucleophiles which produce dihydropyridines capable of dissociation under the reaction conditions lead to 1,4-dihydropyridines, the isomers of apparently greater stability under equilibrium conditions.

The reversibility or irreversibility of the reaction of a nucleophile with a pyridinium ion provides a basis for correlating many of the known reactions of pyridinium ions.

## Preparation of High-Melting Substances by Pyrolysis

*E. Fitzer*, Karlsruhe (Germany)

High-melting substances can be prepared by thermal decomposition of compounds containing their components. If the pyrolysis is carried out on the boundary between a fluid and a heated solid surface the pyrolysis products are obtained as growth layers. In such growth reactions the kinetics of pyrolysis, transport processes, nucleation, or crystallization may have a decisive effect on the chemical composition and habit of the deposited material.

These interdependent processes can be demonstrated for the growth reaction of SiC produced by decomposition of chloro(methyl)silanes. Monochloro(trimethyl)silane can be pyrolysed to yield SiC from 1100 °C. Between 1150 and 1350 °C polycrystalline SiC of vitreous appearance can be produced with a rate of growth of the layer of 0.2 to 0.5 mm/hr. In spite of the superstoichiometric presence of carbon the formation of SiC always precedes the separation of free carbon. Depending on the conditions, heterogeneous SiC/C laminates can be obtained, which have layers parallel to the surface of the substrate and are of industrial interest. This type of deposition is indicated by an oscillating surface reaction.

The course of reactions in a fluidized-bed reactor and of growth reactions leading to $B_4C$ and TiC were compared. In formation of $B_4C$, separation of carbon precedes carbide formation. During the pyrolysis of methane at 1 atm and 1200–1500 °C under stationary reaction conditions to pyrocarbon we observed spiral and whisker growth.

Pyrolysis of cross-linked polymers, *e.g.* furan resins, leads to impermeable carbons with He densities of 1.55 g/cm³. Small-angle scattering showed the presence of uniform pores of 20–30 Å diameter.

Cellulose can be thermally degraded to flexible graphite fibers and it was shown by wide- and small-angle X-ray diffraction that the fibrillar structure of the cellulose is retained in the carbon residue. If flexible products are to be obtained it is necessary to avoid formation of tarry by-products by instant removal of pyrolysis gases.

## Aliphatic Semidiones; Application of Electron Spin Resonance to Problems of Conformation

*G. A. Russell*, Iowa State University (U.S.A.)

Aliphatic semidiones, $RC(O\cdot)=C(O^-)R$, can be readily prepared by the base-catalysed oxidation of cyclic [1], acyclic [2], and bicyclic ketones [3,4]. There is an appreciable conformational preference for the simple alkyl groups (other than methyl) in the symmetrical acyclic semidiones. The acyclic semidiones with R = methyl or ethyl exists as *cis* and *trans* structures. For R = methyl the *cis/trans* ratio (quaternary ammonium cation) is 5/95 at 25 ° and 12/88 at 90 ° in dimethyl sulfoxide solution [5]. Use of lithium as the cation gives only the *cis* structure which shows hyperfine splitting by a single lithium ion. With potassium as cation the *trans* structure is greatly preferred in dimethyl sulfoxide solution but the *cis* structure is the only detectable species in dimethoxyethane solution.

The formation of semidiones from substituted cyclohexanones and decalones can yield information in regard to the conformation of the resulting cyclic semidiones (a cyclohexene or octalin derivative). In addition, by comparison of the percent attack at C-2 and C-4 for 3-keto steroids and decalones it is possible to empirically assign the conformational preference of the starting ketone. We find that both *cis*-9-methyl-2-decalinone and *cis*-10-methyl-2-decalinone prefer the "non-steroidal" conformation, that is, the methyl group occupies an axial position of the ring containing the carbonyl group.

Oxidation of 4-substituted cyclohexanones yields the 4-substituted cyclohexane-1,2-semidiones as a pair of unequally populated but rapidly time averaged half-chair conformers at 25 ° [6]. The equilibrium constant for the 4-methylcyclohexane-1,2-semidione has a value of about 5 (in favor of the equatorial substituent) at 25 °.

The rate of conformational interconversion of 3,3,5,5-tetramethylcyclohexane-1,2-semidione has been investigated by line broadening analysis from −50 to +80 °. The data yield $E_a = 3.3 \pm 0.5$ kcal/mole, $\Delta S^{\neq} = 5.9 \pm 3$ e.u.

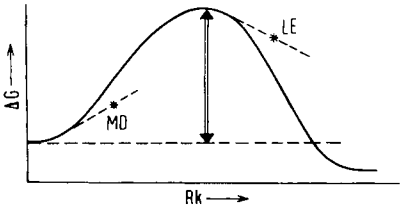
## Quantum-Theoretical Estimates of Chemical Reactivities

*O. E. Polansky*, Vienna (Austria)

Chemical reactivities can be discussed by the simple HMO theory on the basis of molecular diagrams (MD), or of localization energies (LE). In the first case the model for the transition state is a state between the initial system and the activated complex, in the second a state between the activated complex and the reaction product (see Figure). Since both these states are fictitious and not equivalent to the transition state, both methods give some unrealistic results [1].



Provided that the activated complex involved in individual reactions of a given type is always in the same, not too broad region of reaction coordinates (Rk), and further that the substituents at the reaction centers exert no steric effect, relative free activation energies can be estimated by simple HMO calculations. To this end the π-electron contribution $(\Delta H_i^{\neq})_\pi$ to the activation enthalpy $\Delta H_i^{\neq}$ is separated as follows:

$$\Delta H_i^{\neq} = (\Delta H_i^{\neq})_\pi + (\Delta H_i^{\neq})_{\text{residual}}$$

Defining the residual amount of the free energy of activation as

$$(\Delta G_i^{\neq})_{\text{residual}} = (\Delta H_i^{\neq})_{\text{residual}} - T\Delta S_i^{\neq},$$

which is approximately constant under the above conditions for constant temperature and solvation, then expression (1) is obtained for the free energy of activation of a reaction i.

$$\Delta G_i^{\neq} = (\Delta H_i^{\neq})_\pi + (G_i^{\neq})_{\text{residual}} \quad (1)$$

Expression (2) then follows for the relative free activation energy of two reactions i and j.

$$[\Delta G_i^{\neq} - \Delta G_j^{\neq}] = [(\Delta H_i^{\neq}) - (\Delta H_j^{\neq})_\pi] + G_{i,j}^{\neq} \quad (2)$$

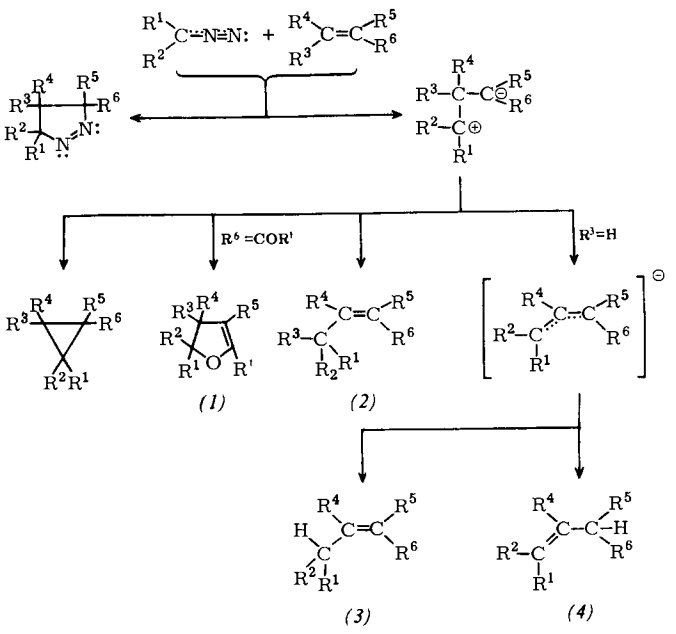
Whereas $(\Delta H^{\neq})_\pi$ is estimated by HMO calculations, $G_{i,j}^{\neq} = [(\Delta G_i^{\neq})_{\text{residual}} - (\Delta G_i^{\neq})_{\text{residual}}]$ is a constant determined empirically.

Further, since $[\Delta G_i^{\neq} - \Delta G_j^{\neq}] = -RT \ln (k_i/k_j)$, this method can be used to calculate relative yields in competitive reactions following the same rate law. The combination with eq. (2) leads to

$$-RT \ln (k_i/k_j) = [(\Delta H_i^{\neq})_\pi - (\Delta H_j^{\neq})_\pi] + G_{i,j}^{\neq}$$

which allows empirical determination of $G_{i,j}^{\neq}$ if the competitive reactions of the same rate law lead to equal amounts of products formed; in that case $\ln(k_i/k_j) = 0$ and therefore $G_{i,j}^{\neq} = -[(\Delta H_i^{\neq})_\pi - (\Delta H_j^{\neq})_\pi]$. If unequal yields are obtained, the comparison of calculations and experimental results of several reactions of the type discussed leads to a rather sharp restriction of $G_{i,j}^{\neq}$.

Application of this method to the reactions of diazoalkanes with olefins according to a mechanism involving seven types



of products[2] shows surprisingly good agreement between calculated and experimental results[3].

[Lecture at Berlin (Germany), June 24th, 1966] [VB 20 IE]

German version: Angew. Chem. 78, 1024 (1966)

[2] Compounds *(1)–(4)* may react with a further molecule of the diazoalkane.

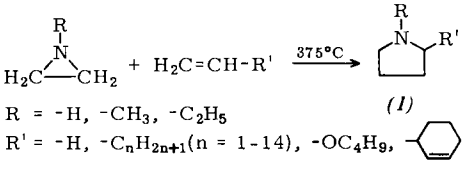
[3] Messrs. *P. Schuster* and *A. Eitel* (Farbenfabriken Bayer, Leverkusen) collaborated in setting up the mathematical model and the mechanism. See also: *A. Eitel*, Dissertation (University of Vienna, 1964) and *P. Schuster*, Dissertation (University of Vienna 1966).

## Cycloaddition on Thermal Cleavage of Aziridines in the Presence of Olefins[1]

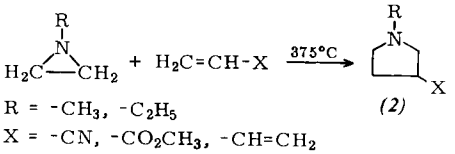
*M. Fremery*, Hamburg (Germany)

Aziridines add to olefins above 300 °C with formation of pyrrolidines *(1)*. This one-stage reaction can be carried out either in the liquid phase under autogenous pressure in autoclaves or in the gas phase in a flow reactor. Depending on the nature of the olefin the additions occur with 35 to 98 % yield. The olefin must be present in 10- to 20-fold excess.

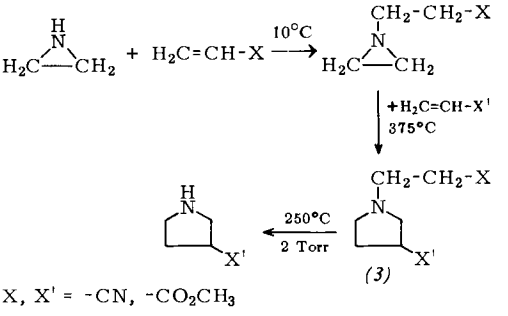
Alkenes with terminal double bonds are appreciably better acceptors than are cycloalkenes or olefins with non-terminal double bonds. NMR studies have shown that the alkyl group of olefins with terminal double bonds are found exclusively at position 2 of the pyrrolidines.



Olefins activated by electronegative substituents react with aziridines to give pyrrolidines *(2)* with the substituents on C-3.



However, only *N*-substituted aziridines can be used for this reaction, since those without such substituents undergo side reactions. Nevertheless, pyrrolidines with functional groups on C-3 but no substituent on the nitrogen are obtained if the ethylene imine used as starting material has on the nitrogen a group which can be exchanged for hydrogen after addition. Favorable for this purpose was the reaction of ethylene imine with olefins activated by electronegative groups [principle of the Michael reaction].



The *N*-substituent of the resulting pyrrolidines *(3)* could then be removed by a thermal retro-Michael reaction.

Above 300° C acetylene also react with aziridines, yielding pyrrolines and pyrroles by 1,3-cycloaddition.

In the above reactions the aziridine is cleaved at a C–N bond. It is not yet known whether the cycloaddition involves a radical or an ionic reaction. Either mechanism suffices to explain the stereoselectivity of the reactions leading to compounds *(1)* and *(2)*.

[Lecture at Mülheim (Germany), July 14th, 1966] [VB 22 IE]

German version: Angew. Chem. 78, 1024 (1966)

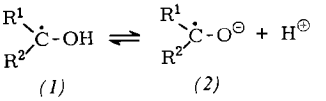
[1] This work was carried out at the Shell Development Co., Emeryville, Cal. (U.S.A.).

## Study of Fast Chemical Reactions of Electrons and Radicals by Pulse Radiolysis

*A. Henglein*, Berlin (Germany)

When an aqueous solution is irradiated with a short pulse (1–10 μsec) of energetic electrons, OH radicals and hydrated electrons are formed. The reactions of these intermediate products of radiolysis can be followed by recording the decay of their optical absorption after the radiation pulse, or the rise in absorption of the resulting products, as a function of time.

The OH radical reacts with primary or secondary alcohols $R^1R^2CHOH$ by abstraction of H and formation of an α-alcohol-radical. In alkaline solution the OH radical and the alcohol yield a species *(2)* which absorbs strongly in the ultraviolet and is in equilibrium with the α-alcohol-radical.



These forms *(1)* and *(2)* also arise when the hydrated electron adds to a dissolved aldehyde or ketone. The pK value of an alcohol-radical is greater the greater is the Taft σ* value for the inductive effect of the organic groups attached to the α–C atom. Equilibrium is established with participation of the $OH^-$ ion:

The anionic form of the alcohol-radical transfers an electron to nitrobenzene with $k = 3\times10^9$ mole$^{-1}$ l sec$^{-1}$, independently of the structure of the alcohol. The acidic form *(1)* can also transfer an electron, but the reaction is then about 10 times slower and depends on the structure: the electron is in this case transferred more easily the greater is the Taft $\sigma^*$ value.

A hydrated electron adds to nitrobenzene, giving the anion $C_6H_5NO_2^-$ ($\varepsilon_{max}$ at 2850 Å; $k = 1.4\times10^4$ mole$^{-1}$ l cm$^{-1}$). In acidic solution mainly $C_6H_5NO_2H$ is present. The pK of the equilibrium

$$C_6H_5NO_2H \rightleftarrows C_6H_5NO_2^{\ominus} + H^{\oplus}$$

is 3.2. The ion $C_6H_5NO_2^{\ominus}$ is very stable. Two $C_6H_5NO_2H$ particles disproportionate to $C_6H_4N(OH)_2$ and $C_6H_5NO_2$ with $k = 6\times10^8$ mole$^{-1}$ l sec$^{-1}$. $C_6H_5N(OH)_2$ then decomposes with loss of water to nitrosobenzene. The rate constant of this unimolecular decomposition depends on the $H^{\oplus}$ concentration. $C_6H_5NO_2^{\ominus}$ can transfer an electron to nitrosobenzene with $k = 4.1\times10^7$ mole$^{-1}$ l sec$^{-1}$. The free H atom does not attack the $NO_2$ group of nitrobenzene, but adds to the aromatic nucleus, giving the nitrocyclohexadienyl radical. An OH radical reacts similarly, giving a hydroxynitrocyclohexadienyl radical.

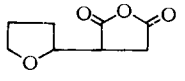
# SELECTED ABSTRACTS

**An adduct of maleic anhydride and tetrahydrofuran** is produced on irradiation with ultraviolet light, according to *L. Ledwith* and *M. Sambhi*. Primarily a donoracceptor complex absorbing at 270 mμ is formed, which yields the 2-tetrahydrofurylsuccinic



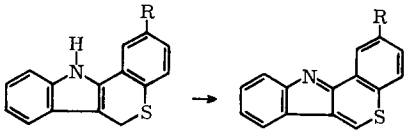
*(1)*

anhydride *(1)*. This highly hygroscopic compound can be easily hydrolysed to the corresponding substituted succinic acid, m.p. 136 to 137 °. / J. chem. Soc. (London) B *1966*, 670 / –Bu. [Rd 547 IE]

**A simple method for the determination of $D_2O$ in water** is based on the different solubility of anhydrous $CuSO_4$ in $D_2O$ and $H_2O$. Differential photometry is used by *J. Cabican* and *F. Einhorn* to compare the extinctions of saturated $CuSO_4$ solutions in $H_2O$ and in the water sample containing an unknown amount of $D_2O$. At 650 mμ the difference in extinction between the saturated $H_2O$ and $D_2O$ solutions reaches a maximum of $\Delta E = 0.7$. Since there is an almost linear relationship between $\Delta E$ and the $D_2O$ content, the determination can be carried out with an accuracy of better than 0.5% in the whole concentration range. / Z. Naturforsch. *21a*, 504 (1966) / –Bu. [Rd 541 IE]

**An enzyme that catalyses thiol-disulfide interactions in proteins** has been concentrated by a factor of 960 from ox-liver microsomes by *F. de Lorenzo et al.* The enzyme catalyses either the renaturation of a protein the disulfide bridges of which have been reductively broken, or the re-establishment of the original arrangement of the disulfide bridges in a randomly bridged protein. Ribonuclease and the trypsin inhibitor from soybeans were used as test substrates. Electrophoresis in starch and polyacrylamide gels gave two enzymatically active bands, which unite on reduction and alkylation. The molecular weight was found to be 42000; the molecule contains three cysteine residues. / J. biol. Chemistry *241*, 1562 (1966) / –Hö. [Rd 553 IE]

**[1]Benzothiopyrano[4,3-*b*]indoles, a new group of pseudoazulenes** (heterocyclic iso-π-electronic analogues of azulenes), have been synthesized by *N. P. Buu-Hoï, A. Croisy, A. Ricci, P. Jacquignon*, and *F. Perin*. Dehydrogenation of compounds of type *(2)* by picric acid in boiling alcohol affords readily the [1]benzothiopyrano[4,3-*b*]indoles *(1)*. The parent *(1a)* is an iso-π-electron analogue of dibenz[*b,f*]azulene. The constitutions of the new products are proved by NMR spectra.

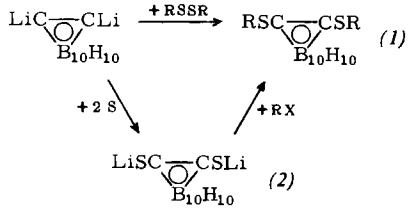


*(2a)*, R = H
*(2b)*, R = $CH_3$
*(2c)*, R = Cl

*(1a)*, R = H
*(1b)*, R = $CH_3$
*(1c)*, R = Cl

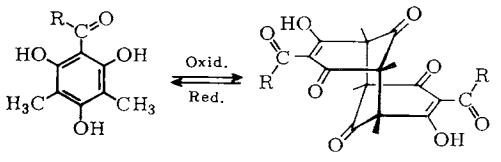
Also, compounds *(1)* are structural analogues of the carcinogenic benz[*c*]acridines. / Chem. Commun. *1966*, 269 / –Ma. [Rd 526 IE]

**Carborane bis(thioethers) *(1)*, the first compounds containing carborane-sulfur bonds,** have been synthesized by *H. D. Smith Jr., C. O. Obenland*, and *S. Papetti* from dilithio-*o*- or -*m*-carborane and organic disulfides, or from the same carborane derivative and sulfur *via* the intermediate *(2)*, which with halogenoalkanes gives the thioethers *(1)*.

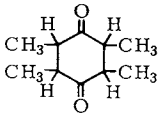


Hydrolysis of *(2)* leads to the dithiol. Boron-substituted mono-, di-, and tribromocarboranes may also be used. Examples: *o*-carborane 1,2-bis(methyl thioether), m.p. 101–102 °C; 1,2-bis(mercapto)-*o*-carborane, m.p. 265–267 °C; *m*-carborane 1,7-bis(ethyl thioether), b.p. 114 °C/0.1 mm Hg. In contrast to the ready metalation of dialkyl or aryl alkyl sulfides, the reaction of *o*-carborane 1,2-bis(methyl thioether) with butyl-lithium leads to cleavage of the carborane-S bond to give dilithiocarborane and butyl methyl sulfide. The thioethers do not form adducts with chlorine or bromine. / Inorg. Chem. *5*, 1013 (1966) / –Kr. [Rd 539 IE]

**A new type of phenol dehydrogenation** has been observed by *H. Davies, H. Erdtman*, and *M. Nilsson*. 2,4,6-Trihydroxy-3,5-dimethylacetophenone *(1a)* is oxidized by $FeCl_3$ in alcohol to a dimeric product *(2a)*, m.p. 270–273 °C, in 85% yield. This product regenerates the starting material on catalytic hydrogenation or on reduction with Zn/acetic acid; on oxidation with $H_2O_2$ it affords 2,3,5,6-tetramethyl-1,4-cyclohexanedione *(3)* in 18% yield. Oxidation of 2,4,6-trihydroxy-3,5-dimethylbenzaldehyde with $FeCl_3$ leads to the dimeric product *(2b)*, m.p. 278–282 °C, which regenerates the aldehyde *(1b)* on treatment with Zn/acetic acid.



*(1a)*, R : $CH_3$ *(2a)*, R : $CH_3$
*(1b)*, R : H *(2b)*, R : H



*(3)*

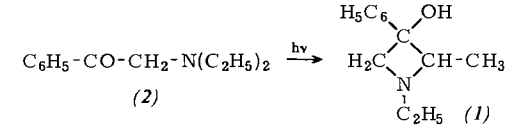
The spectra of compounds *(2a)* and *(2b)* indicate that they are dimers of enolized β-tricarbonyl compounds. / Tetrahedron Letters *1966*, 2491 / –Ma. [Rd 525 IE]

**Resolution of ethyl *p*-tolyl sulfoxide into optical antipodes** has been reported by *A. C. Cope* and *E. A. Caress*. Reaction of (+)- or (–)-*trans*-ethylene(α-methylbenzylamine)platinum(II) dichloride with ethyl *p*-tolyl sulfoxide in $CH_2Cl_2$ gives two diastereoisomeric *trans*-(ethyl *p*-tolyl sulfoxide) (α-methylbenzylamine)platinum(II) dichlorides in each case. The complexes are fractionally precipitated. Then decomposition

$$PtCl_2(C_2H_4)\ (^*RNH_2) + R^1SOR^2 \rightarrow PtCl_2(R^1SOR^2)\ (^*RNH_2) + H_2C{=}CH_2$$

with aqueous NaCN affords (–)-ethyl *p*-tolyl sulfoxide, $[\alpha]_D^{25} = 203.6°$, and the (+)-enantiomer, $[\alpha]_D^{25} = +203.2°$. / J. Amer. chem. Soc. *88*, 1711 (1966) / –Ma. [Rd 521 IE]

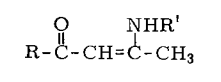
**The synthesis of 3-azetidinols** has been described by *R. A. Clasen* and *S. Searles jr.* 3-Azetidinols *(1)* are readily obtained by UV-irradiation of β-dialkylamino ketones. Thus photocyclization of *N,N*-diethylphenacylamine *(2)* affords 1-ethyl-2-methyl-3-phenyl-3-azetidinol, b.p. 72–73 °C/0.05 mm. Analogously, *N,N*-dimethyl- and *N,N*-diisopropylphenacylamine give 1-methyl-3-phenyl-3-azetidinol and 1-isopropyl-2,2-dimethyl-3-phenyl-3-azetidinol, respectively



*(2)* *(1)*

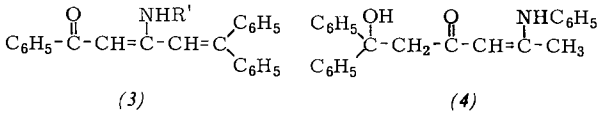
(yields in the three cases are 2 %, 9 %, and 22 %, respectively). In all cases acetophenone and the trimeric imine expected are formed as by-products. The reaction is the first synthesis of an azetidine by C–C ring closure. / Chem. Commun. *1966*, 289 / –Ma. [Rd 522 IE]

**Condensations with β-oxo enamines** can be achieved in compounds *(1)* and *(2)* with aromatic substituents R′ on the nitrogen, according to *S. Boatman* and *C. R. Hauser*, by



*(1)*: R = $C_6H_5$
*(2)*: R = $CH_3$

preparation of the dialkali salts with alkali amide in liquid ammonia. Condensation of *(1)* with benzophenone followed by dehydration with $H_2SO_4$ or polyphosphoric acid leads to the unsaturated β-oxoenamine *(3)* in a yield of about 80%; *(2)* forms only the dianion on the γ-C atom, which reacts with benzophenone to give *(4)*, m.p. 144–145 °C, in 45% yield.



*(3)* *(4)*

The dialkali salts also can be condensed with esters or alkylated. For example, the dialkali salt of *(1)* (with R = R′ = $C_6H_5$) reacts with methyl benzoate to give 3-anilino-1,5-diphenyl-2-pentene-1,5-dione, m.p. 120–122 °C in 50% yield; with benzoyl chloride it gives 3-anilino-1,5-diphenyl-2-penten-1-one, m.p. 64–65 °C, in 62% yield. / J. org. Chemistry, *31*, 1785 (1966) / –Bu. [Rd 549 IE]

**3-Alkyl- and 3,3-dialkyl-1-bromoallenes,** which are useful in the preparation of allene derivatives, can be prepared in good yields at room temperature from secondary and tertiary alkynols and hydrogen bromide, according to *S. R. Landor, A. N. Patel, P. F. Whiter*, and *P. M. Greaves*. The reaction is considerably accelerated by equimolar amounts of CuBr and $NH_4Br$. The IR spectra of 1-bromoallenes contain unusually intense allene bonds at 1950 $cm^{-1}$; strong bands at 1165 and 725 $cm^{-1}$ are due to the hydrogen on C-1, as could be shown by labeling with deuterium. Examples: 3-isopropyl-4-methyl-1-pentyne-3-ol → 82% of 1-bromo-3-isopropyl-4-methylpenta-1,2-diene, b.p. 49–50 °C/6 mm; 3-methyl-1-pentyne-3-ol → 73 % of 1-bromo-3-methylpenta-1,2-diene, b.p. 51–52 °C/24 mm Hg. / J. chem. Soc. (London) C *1966*, 1223 / –Bu. [Rd 550 IE]

**Iodotetrakis(trifluorophosphine)cobalt(I)** *(1)* has been described by *Th. Kruck* and *W. Lang*. Under quite low $PF_3$ pressures a mixture of anhydrous cobalt(II) iodide and copper powder gives the crystalline, brown iodotetrakis-(trifluorophosphine)cobalt(I), which can also be obtained from hydridotetrakis(trifluorophosphine)cobalt(I) and iodoform.

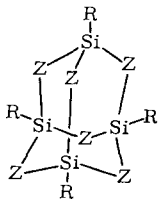
$$CoI_2/Cu \xrightarrow{PF_3\,(50\ atm)} ICo(PF_3)_4 \xleftarrow{I_3CH} HCo(PF_3)_4$$

*(1)*

Compound *(1)* is very volatile and is sensitive to air; it is a non-electrolyte which dissolves without decomposition only in non-polar solvents; from 70 °C it decomposes with total loss of $PF_3$ into an unstable, pale brown substance, amorphous according to its X-ray diagram, and apparently being the hitherto unknown cobalt(I) iodide.

Compound *(1)* is important as starting material for preparation of other trifluorophosphine complexes of cobalt. With triphenylphosphine it gives the disubstitution product $ICo(PF_3)_2[P(C_6H_5)_3]_2$, which is very much more stable thermally and chemically and dissolves without decomposition in aromatic hydrocarbons and in ether; its reduction with potassium amalgam leads to the salt $KCo(PF_3)_4$, which is stable in air, and from which the volatile hydride $HCo(PF_3)_4$ is liberated by acids. This hydride is stable in air and dissolves in polar and non-polar solvents; it has m.p. 174–175 °C; from 193 °C discoloration and decomposition set in; substitution by triphenylphosphine becomes possible only at 135 °C. / Z. anorg. allg. Chem. *343*, 181 (1966) / –Sch. [Rd 535 IE]

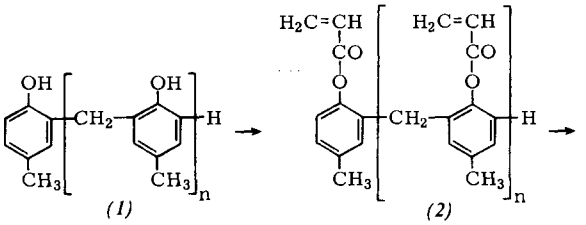
**Tetraalkyltetrasilicon hexachalcogenides with the adamantane structure** *(1)*, which form a new class of compounds, have been prepared by *J. A. Forstner* and *E. L. Muetterties*. Methylsilane with $H_2S$ at 200 °C or $H_2Se$ at 400 °C gives $(CH_3Si)_4S_6$ or $(CH_3Si)_4Se_6$, respectively. $(CH_3Si)_4S_6$ is readily soluble in pentane, chloroform, or benzene, moderately soluble in acetonitrile or alcohol, melts at 272 °C, and gives only one signal in the proton resonance spectrum ($CDCl_3$). $(CH_3Si)_4Se_6$ can be purified by sublimation; it melts at 283 °C and also gives only one signal in the $^1H$–NMR spectrum.



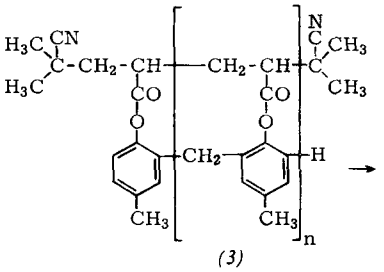
*(1)*, Z = S, Se

The corresponding ethyl derivatives cannot be prepared from ethylsilane, but only from trichloro(ethyl)silane, which reacts with thiols and selenols in the presence of metallic aluminum. All the products are very sensitive to moisture. / Inorg. Chem. *5*, 552 (1966) / –Sch. [Rd 536 IE]

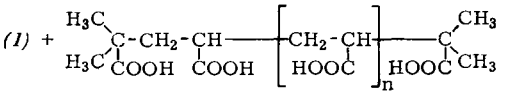
**A new preparation of oligomers** from acrylic and vinyl compounds, as a model of a template reaction, was described by *H. Kämmerer* and *S. Ozaki*. Well-defined oligomeric phenol-formaldehyde resins of the type *(1)* ($n$ = 1 or 2) are converted into polymerizable esters with acrylic acid, and these esters



*(1)* *(2)*



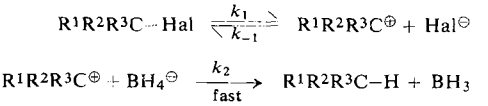
*(3)*



*(4)*

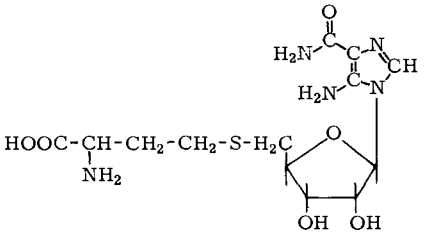
are then polymerized further at high dilution in the presence of azoisobutyronitrile. The polymers *(3)* can be hydrolysed to the original phenols *(1)* and the oligomeric polyacrylic acids *(4)*. The polyphenolic resin template *(1)* can then be used again. / Makromolekulare Chem. *91*, 1 (1966) / –Hl. [Rd 556 IE]

**Reduction of secondary and tertiary halogen compounds under $S_N1$ conditions** can be achieved with $NaBH_4$ in ionizing media, according to *H. M. Bell* and *H. C. Brown*. While the reduction of halogen compounds with $LiAlH_4$ in ether proceeds by an $S_N2$ mechanism (second-order reaction, inversion), and secondary and tertiary halides consequently often react slowly and in poor yields (extensive elimination to form the olefin), excellent yields of hydrocarbons are sometimes obtained under $S_N1$ conditions. A suitable ionizing medium is diethylene glycol dimethyl ether (diglyme)/water; the only reducing agent that can be considered is $NaBH_4$, which is fairly stable in water. The first-order rate constant ($2.1 \times 10^{-4}$ $sec^{-1}$ at 45 °C, 80% diglyme) for the reduction of diphenylchloromethane is of the same order of magnitude as that for the solvolysis of the substrate under the same conditions, but without $NaBH_4$. This shows that a carbonium-ion intermediate is formed in accordance with the general scheme



The 50% increase in the rate of reduction as compared with solvolysis may be interpreted as a salt effect due to the $NaBH_4$. The high yields of hydrocarbon obtained in 65% diglyme/4.0 M $NaBH_4$/1.0 M NaOH (reduction of diphenylchloromethane, 99%; triphenylchloromethane, 96%; 2-chloro-2-phenylpropane, 81%; 1-phenyl-1-chloroethane, 75%) show that the $BH_4$ ion can compete successfully with water (formation of an alcohol) for the carbonium ion. Apart from alcohols, olefins also are formed as by-products. / J. Amer. chem. Soc. *88*, 1473 (1966) / –Eb. [Rd 557 IE]

**(5-Amino-4-carbamoylimidazolyl)-5-S-homocysteinylriboside *(1)*, a new S-amino acid derivative,** is present in the urine of persons suffering from homocystinuria, a hereditory disturbance of the methionine metabolism. *Th. L. Perry*, *S. Hansen*, *H.-P. Bar*, and *L. MacDougall* found the new amino acid in the two-dimensional thin-layer chromatogram, and isolated it by ion-exchange and paper chromatography. The structure was confirmed by degradation and comparison with known cleavage products.

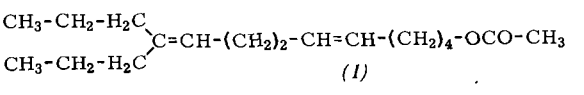


*(1)*

The daily elimination of *(1)* in children with homocystinuria is 0.3 mmole *(1)* per gram of creatinine. Nothing is known as yet about the metabolism of *(1)*. / Science (Washington) *152*, 776 (1966) / –De. [Rd 558 IE]

***N*-Acetyl-L-histidine, the first acetylated basic amino acid, found in nature,** was isolated from frogs' hearts by *Y. Kuroda* and *T. Ikoma*. These authors purified the compound by chromatography on Dowex-50-X8 with pyridine/acetate buffer (pH 3.1) and preparative paper chromatography. 30 mg of a crystalline substance was obtained from 300 bullfrog (*Rana catesbeiana*) hearts and identified by chromatography and spectrography, and by comparison with authentic material, as *N*-acetyl-L-histidine. This is the third known naturally occurring *N*-acetylated amino acid. / Science (Washington) *152*, 1241 (1966) / –De. [Rd 559 IE]

**10-Propyl-*trans*-5,9-tridecadienyl acetate, the sexual attractant** of *Pectinophora gossypiella* (Saunders) has been isolated in the pure form by *W. A. Jones*, *M. Jacobson*, and *D. F. Martin*, who also elucidated its structure. A sample of 1.6mg was obtained from 850000 female animals, and the structure *(1)* was assigned on the basis of mass, NMR, IR, and UV spectra. The authors obtained *(1)* in an overall yield of 0.2% by an 11-step synthesis starting with 4-heptanone.



*(1)*

The attractant of *Pectinophora gossypiella*, which is one of the most dangerous cotton pests, is the first known natural product containing a di-n-propylalkyl group. / Science (Washington) *152*, 1516 (1966) / –De. [Rd 560 IE]

**Organosilicon Compounds.** By *V. Bažant, V. Chvalovský,* and *J. Rathouský*; translated from Czech into English by *Arnošt Kotyk* and *Jiří Saláč*. Publishing House of the Czechoslovak Academy of Sciences, Prague. Academic Press. New York-London 1965. 1st edit., Vol. 1: Chemistry of Organosilicon Compounds. 616 pp., bound $25.–; Vol. 2: Register of Organosilicon Compounds. Part 1: 699 pp., bound $25.–; Part 2: 544 pp., bound, $25.–.

In view of the very rapid development of the chemistry of organosilicon compounds, particularly in the last decade, the appearance of such a work as this is to be warmly welcomed. Volume 1 begins with an explanation of how the characteristics of organosilicon chemistry are related to the lower electronegativity of silicon than of carbon and to the ability of silicon to use 3d orbitals for bond formation. After an account of the physical properties of organosilicon compounds (chapter 2) the character and formation of silicon-halogen and -pseudohalogen bonds are explained. Chapters 4 and 5 treat the preparation and properties of compounds of silicon with elements of the 6th and 5th group of the Periodic System, in particular the Si–N bond. Chapter 6 is devoted to compounds in which silicon is bound to an element of groups 1 to 4 (except Si and C). Chapters 7, 8, and 9 are concerned with the S–H, Si–Si, and particularly the Si–C linkage. "Carbon-functional" organosilicon compounds take up a large amount of space (122 pages).

The individual chapters treat their material very carefully and are clearly subdivided. Clarity is aided by numerous tables. There are exhaustive subject, patent, and author indexes, and a list of references, equally well prepared, which contrary to the usual custom are arranged according to journals. The "register" volumes 2/1 and 2/2 contain the compounds listed in order of molecular formula. For each compound there follow the name, structural formula, physical data, method of preparation, reactions, calculated values of the elemental analysis, and molecular weight. When necessary, derivatives and salts are also listed. The data on preparation give not only the reference but also the yields and, notably, the synthetic process used. For rapidity in use each reaction procedure is given a number. Thus an entry "Prep. 7. 23 %" denotes that the compound was obtained by a reaction of type 7 in 23 % yield.

Register volume 2/1 contains silicon compounds up to $Si_1C_{19}H_{42}O_4$, and volume 2/2 $Si_1C_{20}H_3F_{15}$ to $Si_{26}C_{68}H_{170}O_{31}$. These volumes are a kind of "Beilstein" of organosilicon-compounds.

The books are a mine of information for those active in this field. Unfortunately they contain the literature only up to 1961, or in isolated cases up to 1962 so that publication of a new edition, or at least a supplement to the register volumes, is very desirable. The production of the books and particularly the formulae are very good.

These books can be read with great profit and are warmly recommended to all who are concerned with the chemistry of organosilicon compounds or who wish to enter the field.

*L. Birkofer* [NB 495 IE]

**The Amino Sugars. The Chemistry and Biology of Compounds Containing Amino Sugars.** Vol. IIA: Distribution and Biological Role. Edited by *E. A. Balazs* and *R. W. Jeanloz*. Academic Press. New York-London 1965. 1st edit., 591 pp., numerous tables, bound $22.–.

The present volume contains 20 chapters on the occurrence and biological importance of amino sugars and polymers containing amino sugars in the animal and the vegetable kingdom. Individual chapters deal with amino sugars in plants, microorganisms, and invertebrates (*N.Sharon*), amino sugars and amino sugar-containing polymers in liver and kidney (*R. G. Spiro*), in urine (*N. F. Boas*), in mucus and mucous membranes (*Z. Dische*), in saliva, salivary glands, and sputum (*I. Werner* and *L. Odin*), in skin (*R. H. Pearce*), in tumors (*B. Sylvén*), in pathological effusions (*I. Werner* and *L. Odin*), in mast cells and mast cell tumors (*N. R. Ringertz*), in the umbilical cord (*J. A. Szirmai*), in synovial fluid (*L. Sundblat*), in the connecting tissue of electrical organs (*J. A. Szirmai*), in cartilage, tendons, and spinal discs (*M. Schubert* and *D. Hamerman*), in bones and teeth (*E. A. Balazs* and *H. J. Rogers*), in cell walls (*H. Muir*), in plasma and other body fluids (*R. J. Winzler*), in blood cells and hemopoetic organs (*S. Hakomori*), in the nervous system (*L. Svennerholm*), and in the eye and ear (*E. A. Balazs*).

The literature is considered up to 1963, but most of the chapters contain an appendix giving important papers of 1964. The book provides an excellent survey of the state of our knowledge in this heterogeneous field, in both the chemical and the biological aspects. Each chapter treats in detail the problems of isolating, purifying, and characterizing the polymers containing amino sugars; the practising chemist will be particularly interested in the meticulous description and critical discussion of the analytical methods and their advantages and disadvantages and possible disturbing factors (*e.g.* in *Sundblad*'s article the method of determination of hyaluronic acid in synovial fluid).

Much space is occupied by a biological-medical discussion of the content and nature of amino sugar-containing polymers in the individual tissues. The articles by *Balazs* and *Rogers* on the development of teeth and of *Balazs* on changes in the glycoproteins and glycosaminoglucans during development of the eye are of great importance for biochemical consideration of morphogenetic processes. Almost all the authors report changes in the amount and metabolism of glycosaminoglucans in pathological processes (arthritis, Tay-Sachs disease, detachment of the retina, *etc.*). Discussions of causal relations in such fields are, however, often speculative.

In review compilations where several authors collaborate there is a danger of overlap between individual chapters. In the present book, for instance, the ascites fluid is discussed twice. The article, only two pages long, on pathological effusions would have been better incorporated into the larger article on plasma and other body fluids. The chapter on microorganisms should have contained at least one table listing the bacterial enzymes active in amino sugar-metabolism, which it would have been of interest to compare with *Spiro*'s tables for liver and kidney, inasmuch as there is no detailed discussion of enzyme processes.

A consistent nomenclature for amino sugar-containing substances is given at the beginning of the book, and the editors' initiative is to be warmly welcomed; it avoids the confusion of terms such as mucopeptides, mucolipids, *etc.*

*H.-J. Risse* [NB 503 IE]

**Fluorine Chemistry.** Vol. IV. By *J. H. Simons*. Academic Press, New York - London 1965. 1st ed., xvii, 786 pp. $28.00.

Interest in inorganic and organic compounds of fluorine has increased steadily over the past two decades. The unusual properties of plastics and pharmaceuticals containing fluorine have led to an intensification of industrial studies in fluorine chemistry. Consequently, damage by fluorine to plants and animals in the neighborhood of fluorine-processing factories has steadily gained in importance. The use of inorganic fluorine compounds for the prevention of tooth decay has also become more widespread.

In the fourth volume of the series "Fluorine Chemistry" [*], *H. C. Hodge* and *F. A. Smith* deal exclusively with the biological properties of inorganic fluorides (Chapter 1, 363 pp.) and effects of fluorides on bones and teeth (Chapter 2, 306 pp.).

The acute and chronic toxic properties of fluorine towards man and animals, the biological properties (reactions with enzymes), and the metabolism of inorganic fluoride are described in the first chapter. Doses and effects of fluorides are summarized in 58 tables.

The second chapter describes the role of fluorine in the human and animal organism, and places special emphasis on the problem of the prevention of tooth decay.

Twenty tables deal with the fluoride content of bones and teeth, the elimination of fluoride, histological changes in bones and teeth, and clinical investigations with inorganic fluorides.

The book is richly illustrated with diagrams, and contains 84 pages with 3780 references. The fourth volume of "Fluorine Chemistry" should be particularly important as a reference work. *H. Machleidt* [NB 509 IE]

**Computer Programming for Chemists.** By *K. B. Wiberg*. Frontiers in Chemistry. W. A. Benjamin, Inc., New York-Amsterdam 1965. 1st ed., viii, 269 pp., 13 tables, bound $12.50.

The development of the program languages FORTRAN (FORmula TRANslation) and ALGOL (ALGOrithmic Language) has greatly simplified the programming of electronic computers. These program languages permit the formulation of a problem without reference to the type of computer to be used. This presupposes, naturally, that the computer in question is equipped with a FORTRAN or ALGOL translation program.

This book is an introduction to programming in FORTRAN. One chapter also deals with the symbolic internal program language FAP (Fortran Assembly Program). An introduction to the input and output of data is followed by an explanation of arithmetical expressions, functions, and subprograms. The various "statements" are mostly illustrated by examples, so that their general significance at first remains rather in the background; however the most important statements are again summarized in a special chapter and their operation explained. Nearly every chapter contains exercises for practice, the solutions of which are given in the appendix. Many programs, some of them very comprehensive, from the fields of kinetics, NMR spectroscopy, and quantum chemistry are given in a special chapter These add greatly to the value of the book, since, as photoreproductions of tested programs they are free from errors and offer the reader the opportunity to analyse and understand the programs of others. The author sees this as "the best method of becoming familiar with computer programming", and the reviewer must agree with this view. In order to understand definitions of FORTRAN statements and FAP instructions that lie beyond the scope of the book, many readers will still refer to the existing literature, but *K. B. Wiberg*'s book will prove a great help to both the beginner and the initiate in the construction of serviceable programs.

*G. Ege* [NB 527 IE]

**Melting and Crystal Structure.** By *A. R. Ubbelohde* Clarendon Press. Oxford 1965. 1st ed., xi, 320 pp., several illustrations and tables, paper £3.3.0.

Despite many experimental and theoretical studies on the liquid and crystalline states of matter, the process of melting still presents a host of problems in connection with both the equilibrium and the kinetics of the process. For this reason even the specialist will welcome the publication of *Ubbelohde*'s book, which contains an excellent discussion of melting from the viewpoints of thermodynamics and of atomic structure.

Starting with the phenomenological observations on melting, with special reference to modern findings on behavior under high pressures, a short description of the more traditional ideas of *Lindemann* and others is followed by a systematic discussion of the influence of special structural properties and of cooperative phenomena up to the *Lennard-Jones* and *Devonshire* theory of melting for simple crystals, and its modification for the superposition of several melting mechanisms in more complicated cases. Individual chapters deal with pure crystal lattice transitions (which are related to melting) and the melting of glasses, liquid crystals, and polymeric materials; premelting and precrystallization in the liquid phase and the rates of melting and of nucleation are discussed in detail. These discussions are based on extensive experimental material, which is presented to the reader in the form of numerous tables showing the influence of the various parameters.

A book on a subject that is very much a center of interest is naturally stamped with the author's personal views, so that one or other idea or special theory receives little or no attention (this is true *e.g.* of the *Kirkwood-Monroe* theory); in every case, however, the reader finds a detailed discussion of fundamentally similar ideas, the author probably having given preference to points that demand less theoretical knowledge on the part of the reader, and this should gain the book a wide circle of users. *K. Schäfer* [NB 529 IE]

**Nonexistent Compounds – Compounds of Low Stability.** By *W. E. Dasent*. Marcel Dekker, Inc., New York 1965. 1st ed., ix, 192 pp., several illustrations, bound, $ 8.50.

At a time when new types of compounds whose existence formerly was deemed impossible are being discovered with ever-increasing frequency, the title "Nonexistent Compounds" is as attractive as it is daring. For good reason the author himself adds the neutralizing subtitle "Compounds of Low Stability".

There is scarcely a preparative chemist who has not had the experience of finding that one or other of the compounds he wishes to prepare is unobtainable in spite of all his efforts. Moreover, lecturers at universities are only too familiar with the penetrating questions of students regarding the "gaps" in the otherwise rigid taxonomy of chemistry. For these reasons *Dasent*'s book, which was preceded a few years earlier by an article by the same author [Journal of Chemical Education *40*, 130 (1963)], can expect a good reception.

However, this small volume can, of necessity, only partly satisfy our expectations, although the author discusses a number of interesting examples in such a way that similar problems can also be worked out on this basis. A list of 407 references is particularly valuable in this respect. In view of the examples chosen, this book may be recommended in particular to the inorganic chemist.

*H. Schmidbaur* [NB 516 IE]

**Treatise on Analytical Chemistry.** Edited by *I. M. Kolthoff* and *Ph. J. Elving*. John Wiley & Sons Ltd., London 1965.
Part I, Vol. 6: **Theory and Practice.** xxiii, 899 pp., several illustrations, bound £8.15.0.
Part II. **Analytical Chemistry of Inorganic and Organic Compounds.** Vol. 11: 573 pp., several illustrations, bound £7.10.0. Vol. 12: xvi, 383 pp., several illustrations, bound £5.13.0.

The importance of the entire work to any analytical laboratory has already been stressed [1], though certain reservations should be mentioned concerning the over-emphasis of the

[*] Cf. Angew. Chem. *77*, 599 (1965); Angew. Chem. internat. Edit. *4*, 613 (1965).

theoretical principles and the rather minor place given to the combination of several methods in tackling analytical problems. The various sections in Part I are arranged according to methods and Part II according to elements, and all sections were written by specialists.

The sixth volume of Part I continues the discussion of optical methods in analysis; it contains a section on emission spectrography by *B. F. Scribner* and *M. Margoshes* and a section on flame photometry by *B. L. Vallee* and *R. E. Thiers*. Both sections present good surveys; the section on emission spectrography does not stress sufficiently the importance of this method for the automated analysis of metals. In the chapter on flame photometry, the reader searches in vain for the more recent developments, particularly atomic absorption and the possibilities of the flame fluorescence technique. Indications towards the end of the section, as well as the list of references, suggest that this section, like several others, does not correspond to the latest stage of development.

*A. L. Smith* contributes more than 200 pages on infrared spectroscopy. A closer reference to practice would have been preferable in many places, and in particular a list of the characteristic bands of inorganic and organic compounds might have been included. The next section, in which *E. J. Rosenbaum* deals with Raman spectroscopy, can only be described as poor. Though the importance of Raman spectroscopy as a molecular-spectroscopic method is smaller than that of infrared spectroscopy, advances in both apparatus and methods have been made in recent years which might have been mentioned in this section. Considerably more detailed, the next two sections by *J. H. Reisner* and *G. W. Leddicotte* deal with electron diffraction and scattering and with neutron absorption and scattering. The section on neutron scattering scarcely mentions the possibilities of this method in the structural analysis of organic compounds. *S. Z. Lewin* and *W. S. Struck* then discuss the measurement of refraction, and *E. C. Olson* describes the measurement of optical rotation. Both of these are good surveys. The use of circular dichroism for the structural analysis of organic compounds receives too little attention. The literature (and hence also recent findings) is evidently covered up to 1959 at latest. The last two sections of the book are both good reviews, dealing with optical (*W. C. McCrone* and *L. B. McCrone*) and electron microscopy (*G. G. Cocks*).

The first ten volumes of Part II of Kolthoff-Elving are systematically arranged according to chemical elements, and deal mainly with the analysis of inorganic compounds. Volume 11 begins Section B of the second part, which deals with organic analysis. The present two volumes give a well-rounded impression, and in addition to an introduction on nomenclature (*L. T. Capell* and *K. L. Leoning*), the stability of organic compounds (*H. Eyring* and *F. W. Cagle*), and reaction kinetics (*G. S. Hammond*), they deal with the elementary analysis of organic compounds. The description of the methods for the determination of carbon and hydrogen (*G. Ingram* and *M. Lonsdale*) and of nitrogen and phosphorus (*G. M. Gustin*, *C. L. Ogg*, and *E. Q. Laws*) in Vol. 11 is preceded by general considerations on this field by *E. W. D. Huffman* and a review of ultramicro methods by *M. Williams*. Vol. 12 deals with the determination of oxygen (*A. Steyermark*), sulfur (*J. F. Alicino*, *A. I. Cohen*, and *M. E. Everhard*), fluorine (*T. S. Ma*), boron (*R. D. Strahm*), and silicon (*H. J. Horner*). *T. T. Gorsuch* concludes this volume with a review of the methods for the determination of metallic elements in organic compounds. A special section in Vol. 11 finally deals with biological and biochemical methods of analysis.

Apart from the reservations mentioned above, the three volumes are worthy successors, both in content and in presentation, to those published earlier.

*H. Kienitz* [NB 536 IE]

[1] Angew. Chem. *77*, 927 (1965); Angew. Chem. internat. Edit. *4*, 381 (1965).

**Chemistry of the Rare-Earth Elements.** By *N. E. Topp*. Monograph Series: Topics in Inorganic and General Chemistry. Edited by *P. L. Robinson*. Elsevier Publishing Company, Amsterdam-London-New York 1965. 1st edit., xi + 164 pp., bound. Dutch fl. 27.50 ($7.50).

The author reports the chemistry of the rare earths in an easily intelligible manner. Twelve chapters introduce the occurrence, treatment, and use of the rare earths. Various chapters describe in detail the history of their discovery, their most important minerals, and methods of processing. Methods of separation, *e.g.* by ion exchange and countercurrent extraction, are also treated. Analysis, preparation of rare-earth metals, and the most important technical uses are reported. The book includes the preparation of pyrophoric alloys ("flints"), manufacture of east iron by means of nodular iron, purification of high-melting metals, use of compounds of the rare-earth metals as polishing materials, inclusion of rare earths in ultraviolet- absorbing glass, coloration of glass. and preparation of glass with a high refractive index. In addition, the use of cerium fluoride to increase the light yield from carbon arcs and of sulfides for preparation of materials stable at high temperatures is reported briefly. The isotopes of the rare earths, with their physical properties, are tabulated in an appendix.

*E. Ruf* [NB 501 IE]

**Diels-Alder Reactions. Organic Background, Physico-chemical Aspects.** By *A. Wassermann*. Elsevier Publishing Company, Amsterdam-London-New York 1965. 1st ed., viii, 114 pp., numerous illustrations and tables, paper, Dutch fl. 15.00.

The author, himself a pioneer in this field, presents a concise monograph on Diels-Alder reactions, which is intended mainly for the chemist interested in the relationships between structure and mechanism.

A twenty-page section on preparative aspects of the reaction is followed by 15 pages on its stereochemistry, 9 pages on equilibrium phenomena, 26 pages on kinetic results, and a 25-page discussion of the mechanism. In view of the importance of Diels-Alder additions and the current interest in their mechanism, a much more comprehensive treatment of this subject would have been desirable.

The important aspects of cycloadditions with formation of six-membered rings are presented systematically, but often briefly and without detailed discussion; many readers will probably find it necessary to refer to the original literature. Useful data are presented in tabulated form in chapters 2 to 5.

The references are mainly confined to the years up to 1962, and only a few references bring us up to 1963/1964; consequently, a number of results are out of date or should be supplemented (*e.g.* reactions of benzene, hexamethylradialene, Woodward-Hofmann rule). The book does not contain an alphabetic author index. The print and most of the formulae are clear, with only very few confusing printer's errors. *J. Sauer* [NB 507 IE]

**Atmospheric Oxidation and Antioxidants.** By *G. Scott*. Elsevier Publishing Company, Amsterdam-London-New York 1965. x, 528 pp., numerous illustrations, bound, Dutch fl. 72.50.

In recent years, autoxidative processes and their inhibition have been the subject of growing practical interest, particularly in connection with the development of petroleum, rubber, and plastics technology. The author presents an interim report on this fast-growing subject, ranging from the general reaction mechanisms of the autoxidation of organic compounds and the action of antioxidants, through the measuring techniques employed, to the description of special autoxidation reactions in industrial materials and their prevention by stabilizing additives.

The first chapter deals with the historical development of antioxidants, the second and third with the mechanisms and the energetic and kinetic fundamentals of autoxidation reactions, and the fourth and fifth with the general aspects of the action of antioxidants, both by free-radical chain termination and by prevention of chain initiation. The sixth chapter is devoted to the measurement of oxidation reactions and oxidative effects. The seventh chapter deals with the oxidative degradation of saturated organic materials, *i.e.* lubricating oils and plastics, and its inhibition by antioxidants, and in the eighth chapter the same treatment is given to unsaturated materials such as olefins, edible fats and oils, drying oils and their films, and raw rubber; the ninth chapter is concerned with the ageing of vulcanized rubber and its prevention, and the tenth with the ageing phenomena (ozone ageing and fatigue-cracking) produced by mechanical stresses and their prevention.

The main emphasis of the treatment which, owing to the volume of material discussed is highly concentrated although interspersed with numerous diagrams and tables, is laid on the reaction mechanism. Antioxidants are regarded mainly from the point of view of their structure-dependent modes of reaction and chemical effectiveness, and to a smaller extent from the point of view of their behavior under practical conditions and their technical importance. Thus the book is aimed predominantly at those who are interested in the scientific principles. It presents an exhaustively compiled and classified literature survey, supplemented by many of the author's own results. However, the literature is fully covered only up to and including 1960; a few publications from 1961 are also referred to. Consequently, a number of recent fundamental theoretical ideas (*e.g.* the critical antioxidant concentration in polymers) as well as some technically important additives (particularly light stabilizers) are not included in this edition.

The discussion of the stabilization of PVC touches on a field that is rather outside the scope of this book, and the description is therefore biased a little too much towards the inhibition of oxidation (organic phosphites are considered only as agents for the decomposition of peroxides), while no mention is made of the oxidative removal of chromophoric structures as a stabilizing factor. It should be stressed, however, that these are minor details which in no way detract from the value of the book.

*G. Scott*'s book is the first self-contained and uniformly presented monograph on autoxidation and antioxidants, and there is no doubt about its importance as a standard work.

# Coupling Principles in Organic Dyes[1]

BY DR. S. DÄHNE AND DR. D. LEUPOLD

INSTITUT FÜR OPTIK UND SPEKTROSKOPIE DER DEUTSCHEN AKADEMIE DER WISSENSCHAFTEN ZU BERLIN (GERMANY)

*Dye molecules containing two or more polymethine structural units, or at least one polymethine and one polyene structural unit, generally exhibit coupling effects that determine the spectroscopic behavior and other physicochemical properties of the substance. The coupling concept can be used inter alia to fit the quinone dyestuffs, the indigoids, and the indanthrenes into a general polymethine color system and to predict new dye structures.*

## 1. Introduction

The hundred years of aromatic chemistry following *Kékulé's* proposal of the structure of benzene have also been a century of intensive research on the relation between color and structure in organic compounds [3]. As early as 1876, *Witt* [4] put forward his fundamental theory of chromophoric and auxochromic groups, which was extended by *Wizinger* in 1927 to include antiauxochromic groups [5], and which in this extended form still permits the description of the color properties of aromatic compounds [6].

It is mainly due to *König* that the polymethine structure was recognized in 1926 as the true cause of color. Organic compounds are always deeply colored [7] when they contain a polymethine structural unit *(1)* [2,8].

$$\cdots(p \pm 1)\pi\cdots$$
$$X\text{—}(CR)_n\text{—}X' \qquad (1)$$

$n = p - 2 = 1,3,5\ldots$

X,X′ = atoms from groups IV, V, or VI

R = any substituents

$(CR)_n$ = grouping that can be replaced by atoms of groups V or VI

A polymethine chain containing an odd number of carbon atoms, which may carry almost any substituents, and which has two atoms of elements from groups IV, V, or VI at its extremities [9], contains one $\pi$ electron more or, as has only recently been recognized, one $\pi$ electron less than the number of atoms in the chain (including the atoms at the ends of the chain). This particular electronic structure leads not only to the intense long-wavelength light absorption of the polymethines, but also to an alternating $\pi$-electron distribution with simultaneous equalization of the bond lengths in the polymethine chain. For a given chain length, the wavelength of the light absorption increases with decreasing electronegativity of the substituents at the ends of the chain and with increasing symmetry of the distribution of the $\pi$-electron system over the chain. To a first approximation, it is independent of the state of charge of the polymethines. Depending on the position of the terminal atoms in the periodic system and on the number of substituents, the polymethines may be electrically neutral or charged [2a].

The alternating $\pi$-electron density distribution associated with deep colors is equivalent to the alternating charge distribution in the polymethine chain proposed by *König*. This alternation follows from quantum-mechanical calculations, *e.g.* by the free electron (FE) method [10] or the LCAO–MO method [2b,11], and has been experimentally verified by proton magnetic resonance measurements [12,13]. The alternation of charge, *i.e.* of

π-electron density, occurs irrespective of whether or not the molecule as a whole is charged [*].

The definition of the polymethines essentially includes the color theories known so far. Thus in order to obtain $(p+1)$ or $(p-1)$ π electrons over a total of $p$ chain atoms, the chain ends X and X′ must, according to *König*, have the properties of an "aci-perichrome" and an "onium-perichrome", respectively. These terms coincide with the definitions of "auxochromic" and "antiauxochromic" substituents, or in more modern terminology with those of electron donors and acceptors. The definition also includes the idea proposed by *von Baeyer* [14] and *Willstätter* [15] that the color of meroquinoid [**] compounds is due to oscillation of valences between groups linked to one another [2a].

In addition to the polymethine dyes, there are many deeply colored organic radicals, which could not at first be rationalized by existing theories. On the basis of arguments advanced by *Weitz* [16], this difficulty could be overcome by an extension of the polymethine concept [2a, 17]. Free radicals are particularly deeply colored when they contain a polymethine structural unit having the formula *(1)* in which the number of chain atoms is even ($n = 0, 2, 4 \ldots$). Such radicals are therefore known as polymethine radicals.

Two other groups of organic compounds containing π electrons can with equal right stand alongside the polymethines; these are the aromatic compounds and the polyenes [2b]. Compounds of both groups can be colored if the molecule is sufficiently large. Aromatic compounds and polyenes always absorb at lower wavelengths than polymethines containing the same number of $sp^2$-hybridized atoms. Aromatic compounds contain $(4n+2)$ π electrons distributed over $4n+2$ atoms, *i.e.* in general, $p$ π electrons over a total of $p$ atoms. The polyenes *(2)* have the same electron distribution, but differ from the aromatic compounds in that the bond lengths alternate. In analogy to the polymethine radicals, polyene radicals *(3)* with an odd number, $p$, of π electrons on $p$ chain atoms are also known.

$X=(CH-CH=)_mX'$ *(2)* $m = 0, 1, 2 \ldots$

$\dot{X}-(\dot{C}H)_n-\dot{X}'$ *(3)* $n = 1, 3, 5 \ldots$

X,X′ = atoms of groups IV, V, or VI.

In the ideal state, the polyenes and aromatic compounds differ from the polymethines in that the π-electron densities do not alternate in compounds of the first two classes. The possibilities of transitions between the three types of compound are practically unlimited [2a,b]. A polymethine *(1)* becomes more polyene-like as the symmetry of the distribution of the π electrons over the chain decreases, *i.e.* as it approaches one of the possible limiting structures *(4a)* or *(4b)* as a result of differences in the donor and acceptor actions of the substituents X and X′ [18]; polymethines change directly to polyenes on uptake or loss of one electron, or to aromatic compounds on formation of rings containing 6 π electrons, and *vice versa* [*].

$X=(CH-CH=)_mCH-\ddot{X}'$ *(4a)*

$\cdots\cdots (2m+4)\,\pi \cdots\cdots$

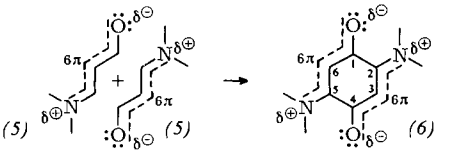
$X-(CH-CH-)_mCH-X'$

$\ddot{X}-(CH=CH-)_mCH=X'$ *(4b)* $m = 0, 1, 2 \ldots$

### 1.1. The Coupling Principle

For a general color system, it is found necessary to extend the term "polymethines" to include compounds that contain more than one polymethine structural unit having the general formula *(1)*. If these structural units can interact with one another across π bonds, this interaction leads to coupling effects, which determine the color and other physicochemical properties of the molecules. Compounds of this type are known as coupled polymethines. A special form of this coupling is the combination of two dipolar meropolymethine structural units *(1)* in which X = X′ and $n = 1,3,5 \ldots$. This necessarily gives rise to compounds having quadrupole character, which we have named quadrupole meropolymethines, the compounds obtained from *(1)* with X = $NR_2$ and X′ = O being quadrupole merocyanines [19].

For example, the physicochemical behavior of the 2,5-diamino-*p*-benzoquinones *(6)* can be fully understood only if the molecule is assumed to consist of two trimethine-merocyanine structural units *(5)*, which can couple *via* the $C^1-C^2$ and $C^4-C^5$ bonds.



[*] For this reason the expression "charge mesomerism" for the distribution of the charge of a dye ion over the chromophore system should be avoided, or should be used to denote an alternation of charge. For example, the electrically neutral meropolymethines and the non-alternant hydrocarbons (azulene, *etc.*) have a very pronounced charge alternation, though they are not ions themselves [2b].

[14] *A. v. Baeyer*, Liebigs Ann. Chem. *354*, 152 (1907).

[15] *R. Willstätter* and *J. Piccard*, Ber. dtsch. chem. Ges. *41*, 1467 (1908).

[**] "Meroquinones" are compounds, particularly di- and triphenylmethane dyes, that according to the conventional structure notation contain a quinoid and a hydroquinoid benzene ring.

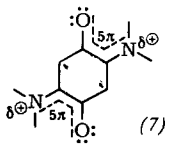
[16] *E. Weitz*, Z. Elektrochem. angew. physik. Chem. *34*, 538 (1928); Angew. Chem. *66*, 658 (1954).

[17] *S. Hünig* and *H. Quast*, Lecture at the 2nd International Color Symposium, Schloß Elmau (Germany), April 1964. Verlag Chemie, Weinheim/Bergstr. 1966.

[18] *L. G. S. Brooker*, Rev. mod. Physics *14*, 289 (1942) and in *C. E. K. Mees*: The Theory of the Photographic Process. MacMillan, 2nd Edit. New York 1954, p. 371–429.

[*] For example, the higher condensed aromatic compounds give polymethine-like, deeply colored radical-anions or -cations on uptake or loss of one electron. The aromatic *p*-phenylenediamines give the Wurster polymethine radical on uptake of one electron; on uptake of two electrons they give polyene-like quinonediimonium dications. Polymethine dyestuffs give less deeply colored polyene radicals *(3)* on gain or loss of one electron [2a].

The nature of the coupling can generally be seen from the structural formula [*(1)*, $n = 1, 3, 5 \ldots$]. In principle, however, coupling of two dimethine radicals in accordance with formula *(7)* would also be feasible in 2,5-diamino-*p*-benzoquinone. Nevertheless, experience has



*(7)*

shown that where there is a possibility of coupling either between two polymethine dyes [*(1)*, *n* odd] or between two polymethine radicals [*(1)*, *n* even], resonance within the odd chains, *i.e.* in the conventional terminology, within the "conjugated" carbonyl and amino groups, always predominates.

The coupling concept was first confirmed on the basis of spectroscopic data [19] (cf. Section 2.1.2). It also follows directly from quantum-mechanical calculations by the LCAO–MO method [19d]. If the calculation for the molecules is carried out in the usual manner [20] with equal values of the resonance integral $\beta$ for all the bonds involved, the wavelength found for the ligth absorption is too high, and a remarkably low $\pi$-bond order is found for the bonds that according to the structural formula effect the coupling of the polymethine structural units.

For the best approximation it is necessary to take into account this decrease in the $\pi$-bond orders in a second calculation step by reduction of the resonance integrals to about 0.5 $\beta$.

Conversely, if the coupling principle is known, the energy-level diagrams of the uncoupled parts of the molecule can be calculated first, and these parts of the molecule can then be brought together in steps, *i.e.* by gradually increasing the resonance integral for the coupling bonds to 0.5 $\beta$, to give the energy-level diagram of the coupled polymethine. In this way the changes in the energy levels of the individual systems on coupling can be followed directly. There is necessarily some resonance splitting of the levels, which may be regarded as the true cause of the long-wavelength absorption of the coupled polymethines [19d].

From the coupling concept, the bond lengths within the polymethine chains should be largely equalized, and the coupling bonds should be lengthened. The predicted interatomic distances [19d] in 2,5-diamino-*p*-benzoquinone have in fact been largely confirmed [19e].

On the basis of these experimental and theoretical results, some typical examples of dyes containing two or more polymethine structural units linked by $\pi$ bonds, so that coupling effects are to be expected, are described below.

The theoretical values given were calculated by an extended LCAO–MO method [11, 19d] using heteroatom Coulomb integrals ($\alpha_X$) and resonance integrals ($\beta$) also of non-adjacent atoms [*]. In a first calculation step, equal values were used, as usual [20], for the resonance integrals of all $\pi$ bonds. When the calculated and experimental wavelengths of the light absorption did not agree, a second calculation was carried out in which the resonance integrals of the bonds for which particularly low $\pi$-bond orders had been obtained in the first calculation were reduced to about 0.5 $\beta$. The substituent effects of the *N*-alkyl groups [21] were disregarded.

It is found that for many dyes, the light absorption and the $\pi$-bond orders [**] and electron densities [†] estimated from experimental results can be satisfactorily described even by this extended LCAO–MO method. The approximation can be further refined if instead of the overall reduction in the resonance integrals, the relations between calculated bond orders, bond lengths, and resonance integrals [22, 23] are used to find the optimum values of the integrals by an iteration method.

Since relatively high delocalization energies are found for the polymethines [2b, 19d], the preferred formulation of polymethine structural units in the molecule appears to be justified from the point of view of energy. However, it should not be expected that the polymethine structures will always be unambiguously defined as described above. The tendency to form polymethine systems, particularly in more extensive chromophore systems, is more or less strongly opposed by a tendency towards aromatization and the possibility of the formation of polyene structures. More detailed molecular-physical studies are therefore essential for a more accurate determination of the electronic structure of a dye. Even without molecular data, however, the coupling concept has shown itself to be a useful heuristic principle. Many dyes that formerly defied logical classification, such as the amino- and hydroxyquinone dyes, the indigoids, and the indanthrenes, can be readily fitted into a general system of polymethines, and the existence of new dyes can be predicted.

The coupling principle is not restricted to compounds with two polymethine structural units in the molecule. Similar coupling effects occur between a polymethine structural unit and a polyene-like structural unit (cf. Section 3), and even polyene-polyene coupling is conceivable.

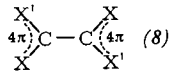
## 2. Coupled Polymethines

### 2.1. Coupling of Polymethines over One Bond Length

#### 2.1.1. Coupled Monomethines

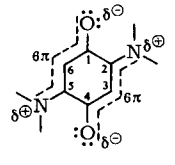
Coupling of two monomethinecyanines can be formulated in the dication *(8)*, X + X′ = $N\diagup$ + $\overset{\oplus}{N}\diagdown$ [25,26], that of two oxonols in the oxalate dianion *(8)*, X = X′ = O + $O^{\ominus}$, and that of two merocyanines in the electrically neutral oxamide derivative *(8)*, X = $N\diagup$, X′ = O. The tetracyanoethylene dianion *(8)*, X + X′ = C=N + C=$N^{\ominus}$ [27] may possibly also be regarded as a coupling product of two dicyanomonomethines [2a].



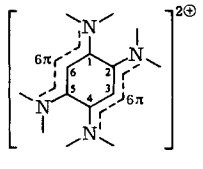
*(8)*

#### 2.1.2. Coupled Trimethines

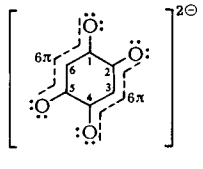
The coupling of two trimethinemerocyanines across two principal valences to give a quadrupole merocyanine *(6)* was described in Section 1. Similarly, two trimethinecyanines are coupled in *(9)* and two trimethinoxonols in *(10)*. Other isologously substituted compounds are known, *inter alia*, in the form of the 2,5-diaminodithio-*p*-benzoquinones. For a satisfactory LCAO–MO description of their absorption, π-bond orders, and π-electron densities, the resonance integrals for the coupling bonds $C^1$–$C^2$ and $C^4$–$C^5$ must be reduced to approximately 0.5 β.



*(6)*
$\lambda_{max}$(exp) = 336, 488 nm
(–$NH_2$, in $(CH_3)_2SO$) [28])
$\lambda_{max}$(theor) = 362, 485 nm
(resonance loss = 0.5 β)
[19d]



*(9)*
$\lambda_{max}$(theor) = 290, 501 nm
(resonance loss = 0.5 β)



*(10)*
$\lambda_{max}$(exp) = 315, 496 nm
(in 0.1 N NaOH)
$\lambda_{max}$(theor) = 319, 455 nm
(resonance loss = 0.5 β)

Figure 1, for example, shows the splitting of the energy levels for oxonol coupling, and Figure 2 shows the corresponding molecular diagram in the ground state. As mentioned earlier, the bond lengths calculated in this way have been confirmed by X-ray structure analysis of a 2,5-diamino-*p*-benzoquinone [19e].

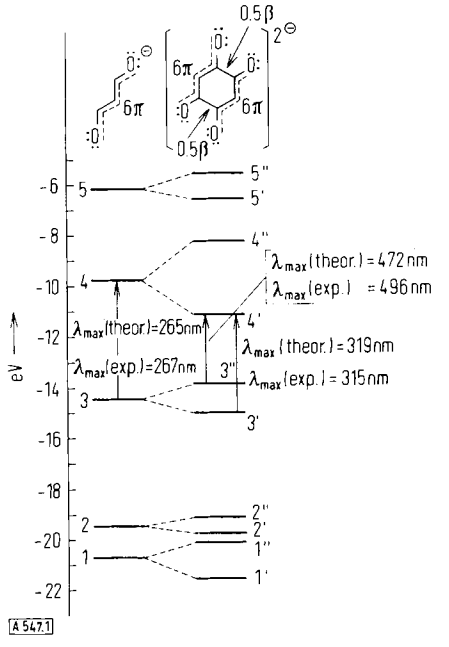


Fig. 1. LCAO–MO energy-level diagram of trimethinoxonol and of the 2,5-dihydroxy-1,4-benzoquinone dianion (term splitting on coupling). [Note: For the dianion *(10)* read $\lambda_{max}$(theor.) = 455 nm instead of 472 nm].

According to the calculations, the absorption band in the visible region of the spectra of *p*-benzoquinones with electron-donating substituents in positions 2 and 5 corresponds to a π→π* transition. Since the intensity of this band is low, it was formerly assigned to an n→π* transition of the quinone displaced to longer wavelengths. This contradiction could be resolved by symmetry considerations in the course of the LCAO–MO calculations, according to which the lowest energy transition of the coupled polymethines *(6)*, *(9)*, and *(10)* is forbidden [19d]; its occurrence as a band of low intensity is evidently due to a relaxation of the restriction on the transition as a result of mixing of the closely spaced highest occupied energy levels (levels 3′ and 3″ in Fig. 1) by participation of nuclear vibrations. This so-called Herzberg-Teller effect can in fact be detected experimentally in the 2,5-diamino-*p*-benzoquinones *(6)* [28]: as a result of *N,N′*-substituent effects the two bands of longest wavelength approach each other. The mixing then becomes stronger, and the intensity of the forbidden longest-wavelength transition

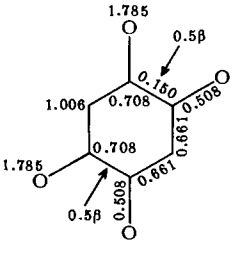

Fig. 2. 2,5-Dihydroxy-1,4-benzoquinone dianion *(10)*. Molecular diagram in the ground state (π-bond orders and π-electron densities).

[24] *Th. Förster*, Pure appl. Chem. *4*, 121 (1962).

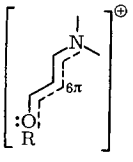
[26] *H. Wanzlick* and *F. Eßer*, Angew. Chem. *76*, 614 (1964).
[27] *O. W. Webster*, *W. Mahler*, and *R. E. Benson*, J. Amer. chem. Soc. *84*, 3678 (1962).
[28] *S. Dähne* and *D. Leupold*, Z. Naturforsch. *20b*, 76 (1965); *D. Leupold* and *S. Dähne*, J. molecular Spectroscopy *17*, 325 (1965).

consequently increases at the expense of the intensity of the next highest allowed transition. In agreement with its assignment as a forbidden $\pi \rightarrow \pi^*$ transition, the longest-wavelength band exhibits positive solvatochromism in many solvents. However, an $n \rightarrow \pi^*$ transition appears to be subjacent to it.

Corresponding to the behavior of the simple polymethine chains, the charge state of the coupled polymethines is of minor importance for the absorption. The distribution of the $\pi$ electrons over the individual polymethine chains must again be as symmetrical as possible. For example, 2,5-diamino-*p*-benzoquinones with NHR substituents dissolve in dilute alkali to form dianions, which differ only slightly in color from the undissociated quadrupole merocyanines *(6)* [29].

The existence of analogous dioxonium cations is to be expected, particularly in view of the recent preparation of the uncoupled cationic trimethinemerocyanines *(11)* [30]. Cou-

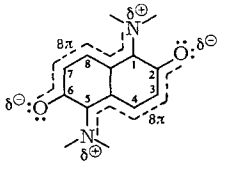


*(11)*

pling of electrically neutral cyanines may similarly be assumed in the diaminoquinonediimides [*(9)*−2H$^{\oplus}$] and coupling of electrically neutral oxonols in the dihydroxyquinones [*(10)*+2H$^{\oplus}$]. The absorption of these compounds is hypsochromically displaced relative to that of the doubly charged ions; for example, the longest-wavelength absorption band of [*(10)*+2H$^{\oplus}$] is displaced by 102 nm relative to *(10)* [*]. This is evidently due to the increase in the polyene character of the coupling structural units as a result of the less symmetrical $\pi$-electron distribution.

### 2.1.3. Coupled Penta- and Heptamethines

Coupling of two pentamethinemerocyanines occurs in 1,5-diamino-2,6-naphthoquinone *(12)*, prepared by *Paul* and *Zimmer* [30a]. This is a deep blue dye which, in agreement with spectroscopic measurements (solvatochromism, infrared, and $^1$H-NMR spectra), is to be



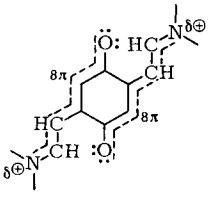
*(12)*

$\lambda_{max}$(exp) = 321, 581 nm
(−$NH_2$ in $(CH_3)_2SO$) [19b]

$\lambda_{max}$(theor) = 303, 572 nm
(resonance loss = 0.5 $\beta$) [19d]

formulated as a quadrupole merocyanine [19a, 19b]. To obtain a sufficiently accurate LCAO–MO approximation, the resonance integrals for the coupling bonds must again be reduced to 0.5 $\beta$. The transition of lowest energy is not forbidden by symmetry in this case, and the absorption band of longest wavelength is consequently several orders of magnitude more intense than that of the 2,5-diamino-*p*-benzoquinones [19b, 19d].

A similar coupling may be formulated for the blue dyes *(13)* prepared by *Henbest* [31]. Since the absorption may be affected by *cis-trans* isomerization, torsion in the



*(13)*

$\lambda_{max}$(exp) = 537, 645 nm

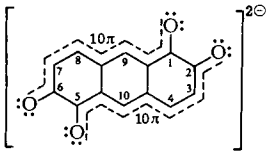
$\lambda_{max}$(theor) = 591 nm
(resonance loss = 0.5 $\beta$)

vinylene groups, and by the substituent effect of the ethyl groups the assignment of the calculated value to the two absorption bands observed is not yet certain.

Similarly coupled oxonols are also known. *Horner* [32] recently prepared the deep blue dianion of 1,5-dihydroxy-2,6-naphthoquinone, which may be formulated as a coupled pentamethinoxonol similar to *(12)*. *Boldt* [33] described the dark green di(?)anion of 2,6-dihydroxy-1,5-anthraquinone *(14)* in which, according to our



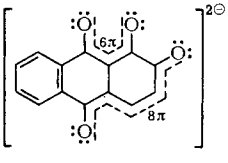
*(14)*

$\lambda_{max}$(exp) = 442, 700, (850) nm
(in NaOH/$CH_3OH$) [33]

notation, two heptamethinoxonols are coupled. The corresponding coupled cyanines have not yet been studied.

### 2.1.4. Coupling of Polymethines of Different Chain Lengths

In many polyhydroxy- and polyaminoquinone dyes it is possible to formulate two or more polymethine structural units of different chain lengths. Well known examples are alizarin and indanthrene blue. In alizarin, a trimethinoxonol apparently is coupled with a pentamethinoxonol, the well known electrically neutral form [*] again being less strongly colored, while the dianion *(15)* is deeply colored. Mention may be made of the naphthoquinone, anthraquinone, and phenanthrenequinone dyes, which can be formulated in a similar



*(15)*

$\lambda_{max}$(exp) = 245, 303, 520[**] nm

manner. Earlier infrared measurements [34] showed that the carbonyl frequencies are greatly reduced in such dyes; on the basis of the polymethine concept, this is no longer surprising.

Indanthrene Blue *(16)* may be hypothetically represented as a combination either of two pentamethinemerocyanine or two trimethinemerocyanine structural units. However, information about the contribution of these units to the coupling will only be obtainable from quantum-mechanical calculations and more detailed experimental studies.

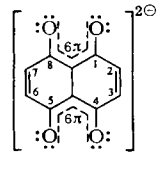
etc.

## 2.2. Coupling of Polymethine Dyes via Vinylene Groups

In some dyes the polymethine structural units are not linked by simple C–C bonds. According to the structural formula, coupling should take place across one or more vinylene groups. It is found that in such compounds it is not necessary, to a first approximation, to reduce the resonance integrals for the coupling bonds.

From the conceivable and known possibilities, it is again possible to select only a few interesting examples. In naphthazarin *(17)* and in quinizarin, coupling of two trimethinoxonols appears to take place across a central C–C bond and two outer vinylene groups. Similar couplings are known between two trimethinemerocyanines.



*(17)*

$\lambda_{max}$(exp) = 585, 614 nm (in 0.1 N NaOH) [35]

$\lambda_{max}$(theor) = 550, 653 nm (without resonance loss)

Since equal values of the resonance integral can be used for all the bonds in these substances in a rough LCAO–MO approximation, the preferred formulation of the trimethine structures and vinylene groups in *(17)* at first appears arbitrary. However, if the molecular diagram (Fig. 3) is considered in relation to the physicochemical properties of naphthazarin and similar compounds, it becomes clear that an approximately correct description of the molecule is given by the structural formula based on the coupling concept. Summation of the calculated π-electron densities within the polymethine

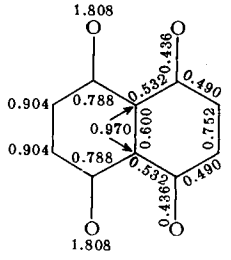


Fig. 3. 5,8-Dihydroxy-1,4-naphthoquinone dianion *(17)*. Molecular diagram in the ground state (π-bond orders and π-electron densities).

chains gives the characteristic polymethine like π-electronic structure with approximately six π electrons to a total of five atoms. The π-bond orders within the polymethine chains, including the C=O groups, are also found to be largely equalized. The double bonds of the vinylene groups are clearly distinguished by a remarkably high π-bond order and π-electron densities close to 1. In agreement with this, the frequency of the carbonyl stretching vibrations is greatly reduced, and such systems can be very readily hydrogenated on the $C^2=C^3$ bond, but not on the carbonyl oxygen [36].

The hypsochromic shift of the absorption of the electrically neutral dihydroxyquinone [*(17)* + $2H^{\oplus}$], which amounts to about 45 nm [35], is also understandable in view of the asymmetry of the π-electron distribution. This unsymmetrical bonding is confirmed by X-ray structure analysis in the case of the electrically neutral naphthazarin [37].

Coupling of two trimethine structural units *via* a vinylene bridge, as in *(18a)*, may also be assumed in the case of the indigoids, for which several isologous substitutions are known [19d]. Two intersecting trimethines having a common pair of π electrons, as in *(18b)* [38], may be considered as a second mesomeric structure; this will be discussed more fully in Section 2.3. The indigo structure can therefore be considered as a resonance hybrid of a total of four polymethine structures.

A more or less pronounced inclination towards polyene-like bonding is expected, depending on the donor strength of the X,X′ substituents. In the calculation for indigo [*(18)*, X = X′ = NH], the unreduced values are again required, to a first approximation, for the resonance integrals of the coupling bonds [19d].

Despite the simplicity of the quantum mechanical approximation used, the positions of the absorption bands

[34] *M. S. C. Flett*, J. chem. Soc. (London) *1948*, 1441; *M.-L. Josien, N. Fuson, J.-M. Lebas*, and *Th. M. Gregory*, J. chem. Physics *21*, 331 (1953).

[35] *R. A. Morton* and *W. T. Earlam*, J. chem. Soc. (London) *1941*, 159.

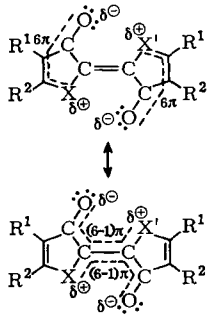
[36] *S. Bloom* and *R. Hutton*, Tetrahedron Letters *1963*, 1993.

[37] *C. Pascard-Billy*, Acta crystallogr. *15*, 519 (1962).

[38] Owing to the common pair of electrons, each of the polymethine structural units has one π-electron less. To demonstrate the polymethine-like electronic structure of the individual systems (6 π electrons to 5 chain atoms), this is indicated in *(18b)* by the expression (6 − 1) π. Structure *(18b)* corresponds to the resonance [19d] involving the non-polar structure and the two polar structures suggested by *F. Arndt* and *B. Eistert* [39].

[39] *B. Eistert*: Tautomerie und Mesomerie. G. Enke, Stuttgart 1938, p. 173.

of longest wavelength and the hypsochromic shifts both on *cis* isomerization and on vinylogous extension of the coupling –C=C– bridge are satisfactorily reproduced [19d]. The calculated π-bond order of the vinylene bridge is lower than in *(17)*, indicating increased resonance. The calculations confirm the quadrupole formulation of indigo, proposed by *Kuhn* as early as 1932 [19d,40].

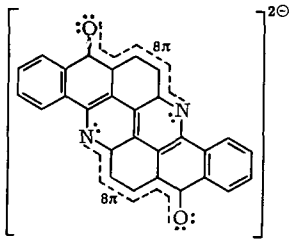


*(18a)*

*(18b)*

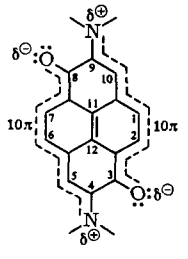
X = or ≠ X′ = NR, O, S, Se
$\lambda_{max}$(exp) = 350, 610 nm
(X = X′ = NH, $R_1 + R_2$ = annellated benzene ring [*] in ethanol [41])
$\lambda_{max}$(theor) = 368, 554 nm
(without resonance loss)
$R_{1,2}$ = H [19d]
Concerning the π electron numbers cf. [38].

Coupling of two pentamethinemerocyanines *via* several vinylene groups may be assumed in the deep blue vat of flavanthrene *(19)*.



*(19)*
$\lambda_{max}$(exp) = 630 nm
(in 2N NaOH)

Similarly, coupling of two heptamethinemerocyanines can be expected in 4,9-diamino-3,8-pyrenoquinone *(20)*.



*(20)*
$\lambda_{max}$(theor) = 481, 770 nm
(without resonance loss)

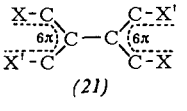
If in the calculations on this as yet unknown molecule the unreduced resonance integrals are used the two allowed longest-wavelength transitions should occur at 481 and 770 nm. The dye should therefore appear green and, as a quadrupole, should be sparingly soluble in non-polar solvents. Reduction of the resonance integrals for the $C^3$–$C^4$ and $C^{2a}$–$C^{12}$ bonds gives a hypsochromic shift for both transitions. However, the maintenance of maximum resonance is suggested by the possibility of coupling *via* the central vinylene group and the relatively high π-bond orders obtained for all the bonds involved from the first calculation step.

Another important property of the types of dyestuffs described here can be deduced directly from the concept of coupling: On gain or loss of one electron, the simple polymethines *(1)* are converted into substances of the polyene or aromatic types [2]. Accordingly, the gain or loss of two electrons in coupled polymethines should yield less strongly colored substances with aromatic or polyene-like behavior. An example is again indigo, the reduction and oxidation products of which (leuco- and dehydroindigo) have been studied in detail [41].

### 2.3. H-Chromophores

The term H-chromophore (linkage of conjugated systems in the form of an H) was proposed by *Klessinger* and *Lüttke* in connection with the indigo problem [42]. These chromophores merit special interest, since the coupling principle of two polymethine dyes is not always applicable to them in the form described above.

Coupled monomethines with an H-shaped structure have already been encountered in Section 2.1.1. H-shaped chromophores of the type *(21)* can be obtained by linkage of two trimethines *via* one principal valence [43]. The wavelength of the absorption of *(21)*, $X + X' = N\diagup + \overset{\oplus}{N}\diagdown$, calculated on the assumption of



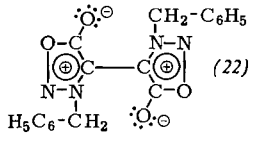
*(21)*

$\lambda_{max}$(exp) = 318 nm [44]
$X + X' = -N(CH_3)_2 + -N^{\oplus}(CH_3)_2$

$\lambda_{max}$(theor) = 404 nm
$X + X' = N\diagup + N\diagup^{\oplus}$
(resonance loss = 0.5 β)

partial coupling (0.5 β) is 100 nm lower in relation to the trimethinecyanines coupled *via* two principal valences *(9)*, and 90 nm too high in relation to the uncoupled trimethines. The experimental value essentially agrees with that of the uncoupled trimethinecyanines [*] [44].

One may mention here the striking red shift on linkage of two sydnones in 3,3′-dibenzyl-4,4′-bisydnonyl *(22)*, which



*(22)*

Sydnones: $\lambda_{max}$(exp) = 294 nm (in $C_2H_5OH$ [45])
Bisydnonyl: $\lambda_{max}$(exp) = 350 nm (in $CHCl_3$ [45])

[40] *R. Kuhn*, Naturwissenschaften *20*, 618 (1932).

[*] The removal of the two benzene rings in the transition from thioindigo (*(18)*, X = X′ = S; $R_1 + R_2$ = fused benzene rings; $\lambda_{max}$(exp) = 543 nm in ethanol) to bis-thiophenеindigo (*(18)*, X = X′ = S, $R_{1,2}$ = H) leads to a blue shift of the longest-wavelength absorption band by about 40 nm [41].

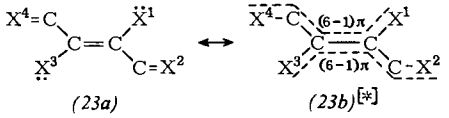
was not to be expected by analogy with biphenyl[45]. The obvious interpretation of the bathochromism is as a coupling effect.

A stepwise reduction of the size of the indigo chromophore gives the H-shaped chromophore *(23)*. According to *Klessinger* and *Lüttke*[42,46] this still possesses indigoid properties, but smaller structural units do not. The chromophore lacks the isolated polymethine structural units required for coupling if one ignores the formal representation as two coupled dimethine radicals [*(23a)*, ($X^1$–C–C–$X^2$) and ($X^3$–C–C–$X^4$), each having 5 $\pi$ electrons to 4 atoms].

The relatively long-wavelength absorption of the H chromophore *(23)* and its vinylogues, as well as their other physicochemical properties (*e.g.* low C=O bond order for $X^2 = X^4 = O$[46]), can in our opinion be interpreted, in analogy with the indigoid mesomeric structural formula *(18b)*, by the assumption of two crossing polymethine units *(1)* with *n* odd, and in particular two trimethines in *(23b)*. On the basis of this interpretation,



*(23a)* *(23b)*[*]

$\lambda_{max}$(exp) = 450 nm for $X^1{=}X^3 = S$; $X^2{=}X^4 = O$ (*trans-s-cis-s-cis*, in cyclohexane) [46]

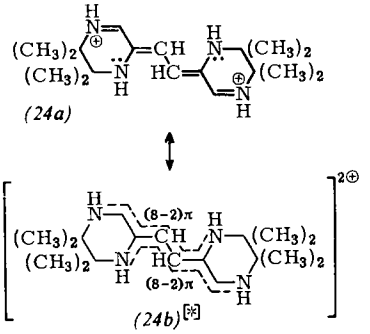
$\lambda_{max}$(theor) = 914 nm for $X^1{=}X^3 = N$; $X^2{=}X^4 = O$ (*trans-s-cis-s-cis*, no resonance loss)

$\lambda_{max}$(theor) = 743 nm for $X^1{=}X^3 = N$; $X^2{=}X^4 = N^{\oplus}$ (*trans-s-trans-s-trans*, no resonance loss)

$\lambda_{max}$(theor) = 473 nm (the same with alternation of resonance integral values)

if the X substituents at the ends of the individual systems are not the same ($X^1 \neq X^4$ and $X^2 \neq X^3$), the systems can again form a quadrupole structure, a possibility that cannot be reproduced with the aid of a single Kekulé structure[19d]. As with the simple polymethines, a transition to a bonding state similar to the polyene type is to be expected, together with a hypsochromic absorption shift, as the distribution of the $\pi$ electrons over the two individual polymethine chains becomes more unsymmetrical. Structure *(23a)* correponds to the pure polyene limiting structure with $X^1$ and $X^3$ as substituents.

Experimental values have been reported for the absorption of a number of H-chromophores with sulfur substituents [*(23)*, $X^1 = X^3 = S$, $X^2 = X^4 = O$][46]. A vinylogue of *(23)* (with $X^1 = X^3 = N$; $X^2 = X^4 = N^{\oplus}$) has been synthesized in the form of the deep red compound *(24)*[47]. The system may again be regarded as consisting of two crossing pentamethinecyanines having two common pairs of $\pi$ electrons[*], which more or less approximate to the polyene structure.



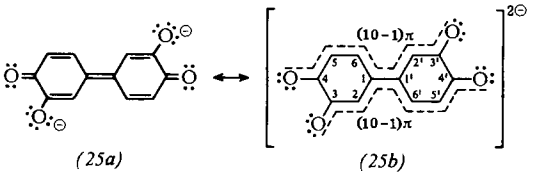
*(24a)* *(24b)*[**]

$\lambda_{max}$(exp) = 550 nm (in buffer solution, pH = 1 [47]

$\lambda_{max}$(theor) = 900 nm (no resonance loss)

$\lambda_{max}$(theor) = 491 nm (with alternation of resonance integral values)

3,3′-Dihydroxy-4,4′-diphenoquinone *(25)*, the dianion of which is deep green[48], may be formulated as an H-chromophore with further vinylogous extension. The limiting structures of a substituted polyene *(25a)* and of crossed polymethines, in this case crossed heptamethinoxonols *(25b)*, with one common pair of $\pi$ electrons[*], must again be taken into account. A $\pi$–$\pi$ interaction *via* the $C^3$–$C^4$ and $C^{3'}$–$C^{4'}$ bonds must also be expected in these compounds, so that it is not possible to distinguish between pure crossing and pure coupling of two heptamethines by means of the structural formula.



*(25a)* *(25b)*

Without additional assumptions, our quantum-mechanical approximation does not give good agreement with experiment for such systems of crossed polymethines. A better approximation can be obtained if the systems are assumed to have a structure of the polyene type. Thus with an alternating modification of the resonance integrals as described by *Coulson* and *Golebiewski*[22][**] the calculation for *(23)* and *(24)* gives much lower wavelengths for the absorptions, which are in better agreement with experiment. On the basis of this result, it should be expected that the polyene structures *(23a)* and *(24a)* are slightly favored in the H-chromophores. This tendency towards a polyene-like bonding state is also qualitatively understandable. Owing to the crossing of the polymethine chains, the polymethine-like alternating $\pi$-electron density distribution is interrupted over the common members of the two chains.

*Lüttke* and *Klessinger* obtained satisfactory agreement with experiment on calculation of the absorption of the H-chromophore *(23)* and of its *cis-trans*-isomeric derivatives with the aid of the Pariser-Parr-Pople approximation[42,46]. Since the H-shaped systems *(23)* absorb at relatively long wavelengths and are also similar to the indigoids in their

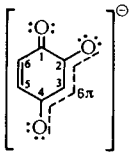
[**] About 0.8 $\beta$ for bonds with more single bond character and about 1.2 $\beta$ for bonds with more double bond character.

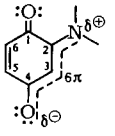
ease of reduction and of *cis*-isomerization, the authors believe that the formulation of indigoids as a mesomeric structure of coupled polymethines as in *(18a)* is disproved [46]. However, this discussion is not yet closed. For detailed molecular-theoretical considerations it is necessary to determine other physical properties, particularly the crystal structure of the systems under discussion.

## 3. Polyene-Polymethine Coupling

On the assumption that the coupling principle is of general validity as the cause of the color of complex dyes, it seemed impossible at first to understand the color of the monosubstituted quinone dyes, *e.g.* monohydroxy- and monoamino-*p*-benzoquinones *(26)* and *(27)*, which contain only one polymethine structural



*(26)*



*(27)*

$\lambda_{max}$(exp) = 258, 497 nm ($-N(CH_3)C_6H_5$, in $(CH_3)_2SO$)

$\lambda_{max}$(theor) = 280, 530 nm (resonance loss = 0.5 β [19d])

unit *(1)* (*n* odd) in the molecule. As can be seen from the formulae, this structural unit is linked, *via* the $C^1-C^2$ and $C^4-C^5$ bonds, to the polyene structural unit $-C=CH-C=O$, which is characterized by alternation of bond lengths and equal π-electron densities on all the atoms. It can again be shown by the LCAO–MO method that when these two structural units are brought together in steps, the individual energy levels change into those of the composite molecule. This conversion is shown in Figure 4 for *(27)* with coupling resonance integrals of 0.1, 0.3, and 0.5 β. Each coupling term receives components of both individual systems, as is indicated by the dotted levels. The optimum approximation is again obtained with a coupling resonance integral of about 0.5 β, *i.e.* the same as that required for polymethine-polymethine coupling *via* single bonds.

If, on the other hand, the calculation for the molecule *(27)* is carried out without application of the coupling concept, *i.e.* with equal values of the resonance integral for all bonds, the wavelength of the lowest-energy electron transition is found to be 500 nm too high, and particularly low π-bond orders are obtained for the bonds that form the coupling between the polyene and polymethine structural units ($C^1-C^2$ and $C^4-C^5$) and for the bond in the polyene having more single-bond character ($C^1-C^6$) [19d]. The lowering must then be taken into account in a second calculation by overall [19d] or iterative [23] modification of the resonance integrals. Thus the polyene-polymethine coupling principle also follows from the LCAO–MO calculations. The validity of this procedure is confirmed not only by the satisfactory description of the visible absorption, but also by infrared and proton magnetic resonance

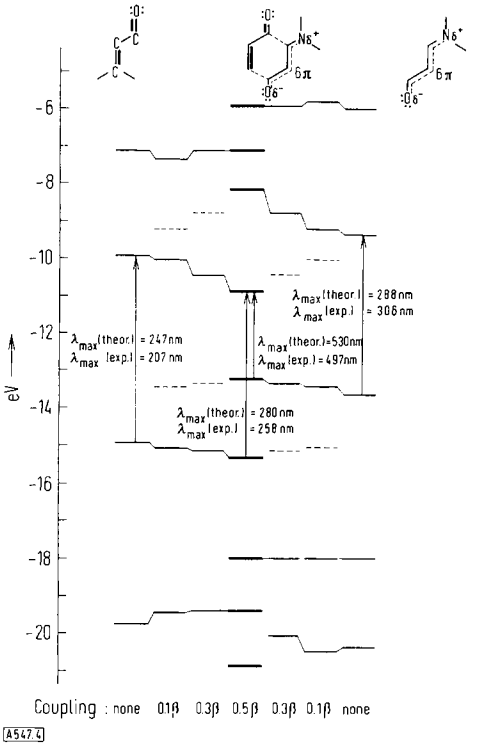


Fig. 4. LCAO–MO energy-level diagrams for the polyene-polymethine coupling in 2-amino-1,4-benzoquinone.

Polyene (acrolein): calculation to a rough approximation by the use of alternating resonance integrals: 1.0 β for $C^1-O$ and $C^2-C^3$; 0.5 β for $C^1-C^2$, Coulomb integrals [19d], experimental value in ethanol [49].

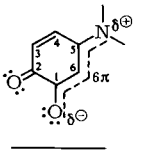
spectroscopy. The C=O stretching absorption of the polyene side is situated at higher frequencies than that of the polymethine side. The chemical shifts of the protons, after correction for the ring current, agree with those of the uncoupled polyene and of the uncoupled polymethine [50].

The bathochromism on coupling of the polyene with the trimethine in *(26)* and *(27)* is comparable to that arising on coupling of two trimethines in *(10)* and *(6)*. However, the fact that owing to asymmetry, the transition is not forbidden in the polyene-polymethine coupling provides a simple explanation for the remarkable observation that the *mono*substituted *p*-benzoquinones absorb much more intensely in the visible region than the 2,5-*di*substituted derivatives.

Similar coupling should occur in the 4-amino-*o*-benzoquinones *(28)*, in which the polyene structural unit is linked in the opposite direction with the trimethine structural unit. In fact, calculation to a simple approximation (reduction of the resonance integrals to 0.5 β



*(28)*

$\lambda_{max}$(exp) = 266, 314, 503 nm ($-N(CH_3)C_6H_5$ in $(CH_3)_2SO$)

$\lambda_{max}$(theor) = 309, 510 nm (resonance loss = 0.5 β)

[49] *W. F. Forbes* and *R. Shilton*, J. Amer. chem. Soc. *81*, 786 (1959).

[50] *S. Dähne, D. Leupold, H. Paul*, and *J. Ranft*, Angew. Chem. *77*, 1017 (1965); Angew. Chem. internat. Edit. *4*, 970 (1965).

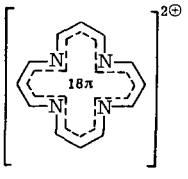
for the bonds $C^1-C^2$, $C^2-C^3$, and $C^4-C^5$) gives a similar long-wavelength absorption, which agrees closely with the experimental value.

Many other colored systems with polyene-polymethine coupling are to be found among the monosubstituted naphthoquinones, anthraquinones, and higher condensed quinones.

For consistent application of the polymethine system one should also mention here the dye radicals formed from coupled polymethines by the uptake of *one* electron. In this case only *one* polymethine structural unit should formally be converted into a polyene unit, and the actual coupling state probably will exhibit pronounced resonance equalization. The relatively long wavelength absorption of the indigo and 5,8-diamino-1,4-naphthoquinone radicals[51] appears to substantiate this procedure.

## 4. Other Possibilities of Coupling

The intense long-wavelength absorption of the porphyrins, whose essential chromophore *(29)* contains 18 $\pi$ electrons to 16 chain atoms, can be formally explained by *cyclic* linkage of pairs of polymethine structural units that merge into one another.

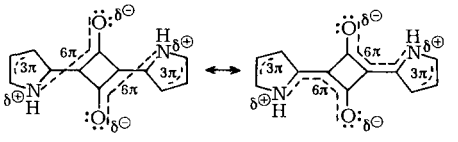


*(29)*

A similar polymethine-like $\pi$-electron distribution, with $2(n+1)$ $\pi$ electrons to $2n$ atoms is evidently also to be found in the interesting colored polyhydroxyquinone dianions of general formula $C_nO_n^{2\ominus}$ ($n = 4,5,6$)[17].

In general, the branching of a polymethine system leads to splitting of the absorption bands of longest wavelength. The only exceptions are higly symmetrical molecules. "Classic" examples of substances exhibiting this splitting of the band are the triphenylmethane dyes. However, similar effects are known with the neocyanine, flavone, and anthocyanin dyes, which can also be interpreted as branched polymethines (with more or less strong polyene or aromatic character)[2a]. It seems obvious to interpret the spectra of these dyes on the basis of coupling effects.

The formulation is problematic when this apparently leads to biradicals, *e.g.* in *(30)*. Owing to intramolecular spin



*(30)*

$\lambda_{max}$(exp) = 550 nm (in $CHCl_3$ [52])

saturation, the compound is diamagnetic. There is a possibility of a decrease in stability, expressed in the biradical notation.

It must also be checked whether it is justifiable to speak of polyene-polyene coupling as well as of polymethine-polymethine and polyene-polymethine couplings. As we have seen, the polymethine structural unit becomes increasingly polyene-like as the $\pi$-electron distribution becomes more unsymmetrical, *e.g.* in the electrically neutral hydroxyquinone and quinone imide dyes. Pure polyene-polyene coupling is to be expected in *p*-benzoquinone and in its derivatives with electron-accepting substituents in positions 2 and 5. Further studies will be necessary in this connection.

This discussions should, however, give some idea of the large number of possible polymethines. The possible coupling variations have by no means been exhausted. The synthesis of coupled polymethines with isologous chain substituents opens a large new field for investigation.

# Polymers Containing Lactone Groups

BY DR. R. PALM [*], DR. H. OHSE [**], AND DR. H. CHERDRON [***]

SHELL GRUNDLAGENFORSCHUNG-GESELLSCHAFT,
SCHLOSS BIRLINGHOVEN/SIEGKREIS (GERMANY)

*Polymers containing intact lactone groups are a new class of macromolecules with reactive groups, which are relatively easy to obtain by polymerization, polycondensation and polyaddition, as well as by reactions on existing macromolecules. Polymers with β-lactone groups in particular can enter into numerous addition reactions, which can be used, for example, to obtain macromolecules containing hydroxy acid or amino acid groupings. The reactions proceed under mild conditions, and can even be carried out in aqueous media, frequently giving water-soluble polymers. The polymers can be cross-linked at low temperatures, even from the aqueous phase, by the addition of bifunctional or oligofunctional reagents. Polymers containing β-lactone groups can also be used as a basis for graft copolymers; polyester or polyether branches can be grafted on, depending on whether monomeric lactones or monomeric epoxides are used.*

Macromolecules containing reactive groups have been intensively studied in recent years [1], but little is known about polymers containing intact lactone groups. Though a few studies have been carried out on the introduction of γ-lactone groups into existing polymers (see Section I.2.c), the only method reported so far for the preparation of macromolecules having high contents of β-lactone groups is exposure of liquid diketene to high-energy radiation at high temperatures [2]. Polymers of this type are of interest in view of the special readiness of the β-lactone group to undergo additions. The following sections describe the synthesis of suitable monomers, the preparation of polymers containing β- or γ-lactone groups, and the reactions of these polymers.

## I. Preparation of Polymers Containing Lactone Groups

The principal methods for the preparation of macromolecules containing intact lactone groups are:

1. polymerization of lactones containing another polymerizable group, *e.g.* a double bond or an epoxy group;

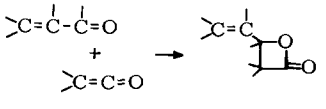
2. polycondensation or polyaddition of lactones containing functional groups, *e.g.* dihydroxylactones; and

3. reactions on suitable macromolecules, *e.g.* intramolecular lactonization or addition of dihydropyran β-lactones to polymeric hydroxy compounds.

### 1. Polymers Containing β-Lactone Groups

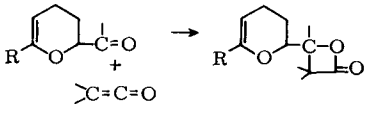
#### a) Polymerization of β-Lactones Containing a C=C Double Bond

β-Lactones *(1)* with a vinyl group in the β-position are obtained by the addition of ketene or dimethylketene to acrolein or α-methylacrolein [3]. Though such β-lactones can be selectively polymerized across the



*(1)*

lactone ring to give unsaturated polyesters [4], satisfactory polymerization across the C=C double bond, with retention of the lactone ring, has not yet been achieved. However, the addition of ketene or dimethylketene to dimeric acrolein or dimeric methacrolein by conventional methods [3] yields β-(2,3-dihydropyran-2-yl)-β-lactones *(2)*, which contain a lactone group and a cyclic vinyl ether group.



*(2)*, R = H, $CH_3$

The β-(2,3-dihydropyran-2-yl)-β-lactones *(2)* can be selectively polymerized across the vinyl ether double bond [*], for example by Lewis acids or alkylaluminum

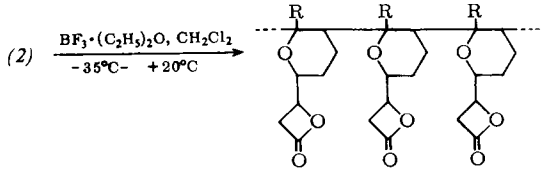
[4] *H. Ohse* and *H. Cherdron*, Makromolekulare Chem. *95*, 283 (1966).

[*] Selective polymerization across the lactone ring to obtain polyesters with intact vinyl ether groups is also possible [4].

halides, without attack on the lactone ring [5], as can be shown *e.g.* by IR spectroscopy (the β-lactone absorption at 1820 $cm^{-1}$ is retained, the absorption of the C=C double bond at 1675 $cm^{-1}$ disappears, and no open-chain ester absorption appears at 1720 $cm^{-1}$) or by gas-chromatographic determination of the $CO_2$ liberated on heating (see Section II.1).



*(3)*, R = H, $CH_3$

Owing to a transfer reaction to the monomer, the molecular weights obtained under these conditions do not exceed 10000. The resulting polymers *(3)* are solid, high-melting substances [poly-β-(2,3-dihydropyran-2-yl)-β-lactone melts at 180–200 °C with decomposition], which dissolve in chlorinated hydrocarbons and in tetrahydrofuran, and can be precipitated with ether or petroleum ether.

Copolymerization across the vinyl ether group with other vinyl monomers, *e.g.* styrene [5], is also possible, and in this way the number of intact lactone groups per macromolecule can be controlled.

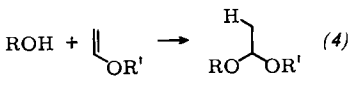
The polymers *(3)* change on storage in the solid state in the presence of catalytic quantities of protonic acids or Lewis acids. Even at room temperature, the spectrum shows the following changes after a few days: the absorption of the β-lactone band at 1820 $cm^{-1}$ becomes weaker, while a γ-lactone band occurs first at 1765 $cm^{-1}$, followed by an open-chain ester absorption at 1720 $cm^{-1}$. The formation of open-chain esters is probably due to an intermolecular reaction (cross-linking); such a reaction also explains the fact that the polymers become insoluble and infusible. This rearrangement of the polymers *(3)*, which probably involves both the β-lactone ring and the pyran ring, can be suppressed by the addition of amines (*e.g.* 0.1–1 % of β-naphthylamine).

Macromolecules containing intact lactone groups are also obtained by selective polymerization of monomers that contain an epoxy group as well as a lactone group, *e.g.* β-oxiranyl-β-propiolactone, which can be prepared by addition of ketene to glycidaldehyde *(3a)* [6].

*(3a)*

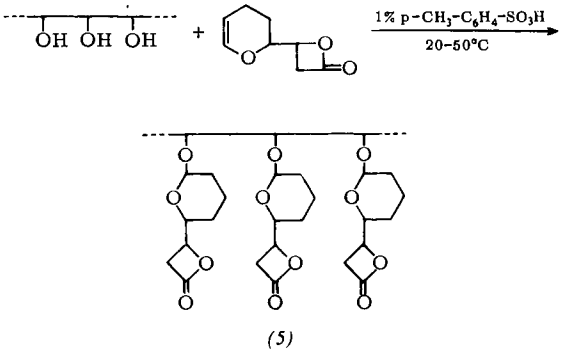
### b) Addition of β-(2,3-Dihydropyran-2-yl)-β-lactones to Polymers Containing Free Hydroxyl Groups

Alcohols add to vinyl ethers in the presence of acidic catalysts to give acetals *(4)*. It has been found that β-(2,3-dihydropyran-2-yl)-β-lactones can be added in



*(4)*

the same manner to polymers containing free hydroxyl groups. The lactone ring is not cleaved during this reaction, though lactones can normally be readily transesterified under these conditions; instead, the



*(5)*

reaction leads to polymers of the type *(5)*. This route to polymers containing intact lactone groups is very versatile, since the starting material may be any of a wide variety of polyhydroxy compounds (*e.g.* polyalkylene glycols, polyvinyl alcohol, alkyd resins, and natural polymers such as starch and cellulose); it is particularly suitable for the preparation of water-soluble polymers, which can subsequently be cross-linked in two ways. The lactone group of a water-insoluble adduct (*e.g.* starch containing more than 20 mole-% of lactone groups) may be treated with *e.g.* a monoamine until the adduct becomes water-soluble; the adduct can then be cross-linked from the aqueous phase *via* the remaining lactone groups, *e.g.* by treatment with a diamine. Alternatively, just enough β-(2,3-dihydropyran-2-yl)-β-propiolactone may be added to a water-soluble polymer containing hydroxyl groups to retain solubility in water; the polymer is then cross-linked *via* the lactone groups introduced, by treatment with bifunctional reagents. Thus the latter method can be used for the additive cross-linking of polymers containing hydroxyl groups under mild conditions similar to those used for cross-linking with diisocyanates; this cross-linking can even be carried out in aqueous media.

The reaction of ketene with polymers containing intact carbonyl groups, which should also lead to macromolecules containing β-lactone groups, has not yet been tried as far as we know.

## 2. Polymers Containing γ-Lactone Groups

### a) Polymerization of Unsaturated γ-Lactones

The first attempts to polymerize unsaturated γ-lactones were made by *Marvel* and *Levesque* [7]. From the lactone of γ-hydroxyangelic acid with $BF_3$·ether as the initiator, these authors obtained a dark red, tacky mass having

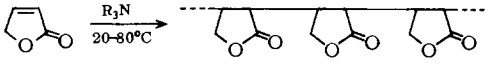
[5] *H. Cherdron* and *H. Ohse*, unpublished.

[6] *P. H. Williams, G. B. Payne, W. J. Sullivan*, and *P. R. van Ess*, J. Amer. chem. Soc. *82*, 4883 (1960).

[7] *C. S. Marvel* and *C. L. Levesque*, J. Amer. chem. Soc. *61*, 1682 (1939).

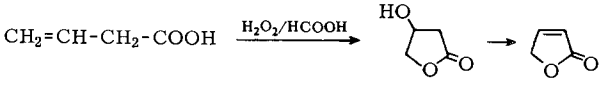
a molecular weight of 800–900 (ebullioscopic). In addition to γ-lactone groups, this polymer still contained about 25 % of its hydroxyl and carboxyl groups.

The only data available on the lactone *(6)* of γ-hydroxycrotonic acid, which is the simplest unsaturated γ-lactone, deal with its free-radical induced copolymerization with styrene [8]; according to this report, the free-radical polymerization of this monomer proceeds only with great difficulty. On the other hand, with a number of tertiary amines (*e.g.* triethylamine) as initiators, we readily obtained solid polymers (softening points about 150 °C), which are soluble only in strongly polar solvents (dimethylformamide or formic acid). On the basis of the IR spectrum (the γ-lactone absorption at 1765 $cm^{-1}$ is retained and the absorption of the C=C double bond at 1675 $cm^{-1}$ disappears) and of the titration with aqueous NaOH and HCl, these polymers must be



*(6)* *(7)*

assigned the structure *(7)*. They depolymerize quantitatively at 250 °C to the monomer. The lactone of γ-hydroxycrotonic acid can be conveniently prepared as follows:



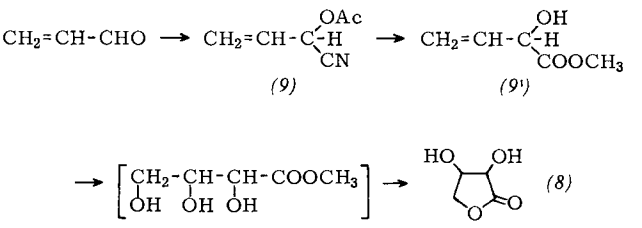
*(6')* *(6)*

*Lactone of γ-Hydroxycrotonic Acid (6)*: 470 g of 30 % (or 140 g of 100 %) hydrogen peroxide is added dropwise to a mixture of 344 g (4 mole) of vinylacetic acid and 840 ml of formic acid at 40–45 °C. This temperature is maintained until all the $H_2O_2$ has been consumed, catalytic quantities of platinum (*e.g.* platinum black) are added to decompose any remaining performic acid, and the formic acid is distilled off under vacuum. Concentrated HCl (20 ml) and water (600 ml) are added to the residue, and the mixture is refluxed for 2 hours. The hydrochloric acid and the water are then evaporated off under vacuum, and the crude product is dried by azeotropic distillation with chloroform. Fractional distillation of the residual solution yields 357 g (88 %) of pure β-hydroxy-γ-butyrolactone *(6')* (b.p. 133 °C/0.35 mm Hg; $n_D^{20}$ = 1.4652). After addition of two drops of polyphosphoric acid, this product is heated to 160 °C/13 mm Hg. A mixture of water and the lactone *(6)* distils, and most of the water is removed from the mixture as described above. Fractional distillation yields 288 g (98 %) of the pure lactone of γ-hydroxycrotonic acid (b.p. 90–92 °C/13 mm Hg; $n_D^{20}$ = 1.4682).

### b) Polycondensation and Polyaddition of Dihydroxy-γ-lactones

An example of a suitable diol component for the synthesis of polymers containing γ-lactone groups by polycondensation or polyaddition is α,β-dihydroxy-γ-butyrolactone *(8)*, which can be readily prepared from acrolein *via* 1-cyano-2-propenyl acetate *(9)*.

[8] *J. M. Judge* and *C. C. Price*, J. Polymer Sci. *41*, 435 (1959).



*(9)* *(9')* *(8)*

*1-Cyano-2-propenyl Acetate (9)*: 79 g (0.77 mole) of acetic anhydride is quickly added dropwise to a mixture of 150 ml of benzene and 43.3 g (0.77 mole) of acrolein cooled to −10 °C, and a solution of 55 g (1.12 mole) of sodium cyanide in 280 ml of water is then added. The mixture is stirred for 2 hours at −10 °C, then warmed to 0 °C, and the benzene layer is removed. The aqueous layer is extracted with benzene, and the organic phases are combined and washed first with a little acetic acid, then with $NaHCO_3$, and finally with water. The solution is dried over $MgSO_4$, the benzene is evaporated off, and the residue is fractionated under vacuum. Yield: 84 g (87 %); b.p. 63–65 °C/10 mm Hg; $n_D^{20}$ = 1.4240.

*Methyl 2-Hydroxy-3-butenoate (9')*: A mixture of 250 g (2 moles) of 1-cyanoprop-2-enyl acetate and 215 ml of anhydrous methanol is heated until it boils gently. The heating bath is then removed, and a mixture of 215 ml of methanol saturated with HCl and 55 ml of concentrated hydrochloric acid (36.4 %) is gradually added at such a rate that the reaction mixture just continues to boil. When the exothermic reaction has stopped, the mixture is refluxed for a further 2 hours and then allowed to cool, and the ammonium chloride is filtered off. The methanol solution is then concentrated, diluted with ether, washed with $NaHCO_3$ and then with water, and dried over $MgSO_4$. When the ether has been evaporated off, the residue is fractionated under vacuum. Yield: 174 g (75 %); b.p. 60 °C/13 mm Hg; $n_D^{20}$ = 1.4392.

*α,β-Dihydroxy-γ-butyrolactone (8)*: 59 g (0.517 mole) of 30 % hydrogen peroxide is added dropwise over a period of 3 hours to a solution of 58 g (0.5 mole) of *(9)* in 105 ml of 98–100 % formic acid at 40–45 °C. This temperature is maintained until performic acid can no longer be detected iodometrically, then any traces still remaining are decomposed with catalytic quantities of platinum, and the mixture is filtered. The formic acid and water are distilled off, and the residue is refluxed for 2 hours with a mixture of 75 ml of water and 0.5 ml of concentrated hydrochloric acid. The water is distilled off and the residue is diluted with 50 ml of dioxane, dried over $MgSO_4$, and distilled. Yield: 32.7 g (55.5 %); b.p. 164–166 °C/0.03 mm Hg; $n_D^{20}$ = 1.4900.

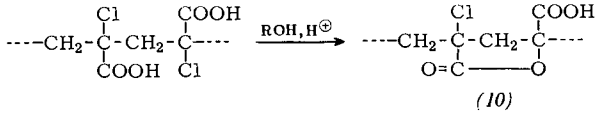
The polycondensation of α,β-dihydroxy-γ-lactones such as *(8)* with dicarboxylic acids or their derivatives, *e.g.* dichlorides of dicarboxylic acids, in the melt or in solution, leads only to low molecular weight products, since the lactone ring is partially cleaved under the reaction conditions. On the other hand, with diisocyanates (polyaddition in the melt or in toluene) such as toluene diisocyanate (mixture of 2- and 4-methyl-1,3-phenylenediisocyanate (1:4); "Desmodur T" produced by Farbenfabriken Bayer), high molecular weight polyurethanes with intact γ-lactone groups are obtained. These polyurethanes dissolve in polar solvents.

### c) Introduction of γ-Lactone Groups by Reactions on Macromolecules

By refluxing poly-α-chloroacrylic acid with water, *Marvel* [9] obtained polymers containing γ-lactone groups, but these polymers were cross-linked as a result of

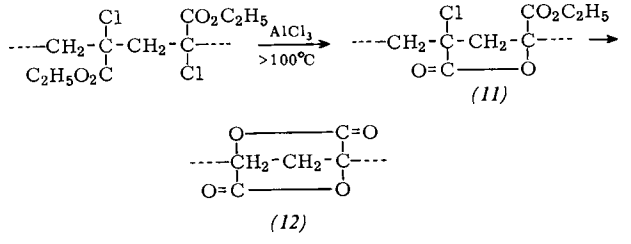
[9] *C. S. Marvel, J. Dec, H. G. Cooke*, and *J. C. Cowan*, J. Amer. chem. Soc. *62*, 3495 (1940).

simultaneous intermolecular esterification. On the other hand, when poly-α-chloroacrylic acid is boiled in alcohol,soluble polymers of the type *(10)* are formed [10].



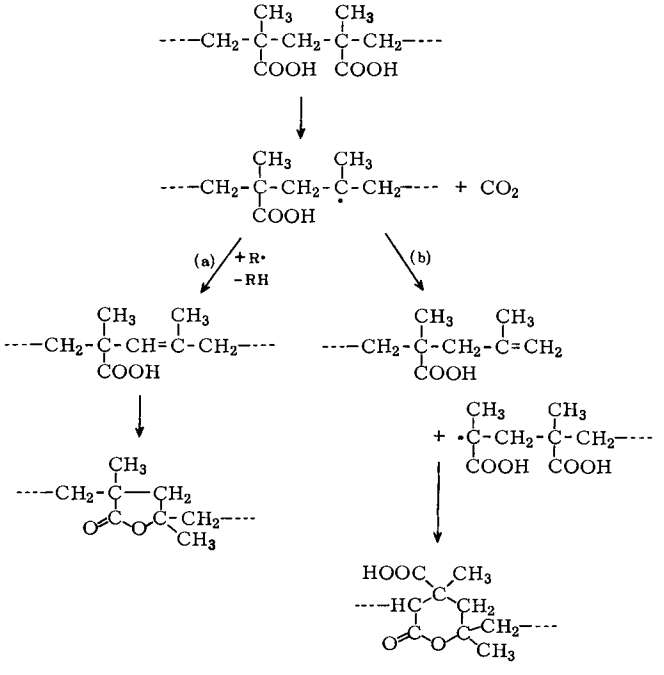
*(10)*

Polymers containing γ-lactone groups can also be obtained from esters of poly-α-chloroacrylic acid by rearrangement with Friedel-Crafts catalysts [11]. In this reaction, up to 80 % of the ester groups may be in the monolactone *(11)* or dilactone form *(12)*.

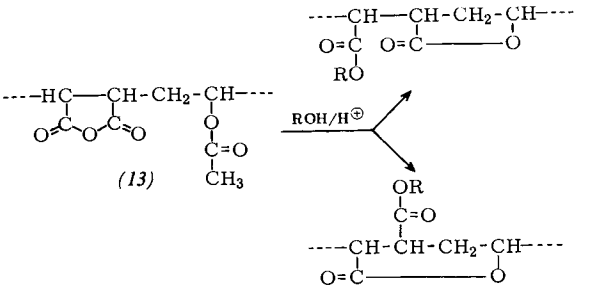


*(11)* *(12)*

Lactonization was observed by *Smets* [12] during electrolysis of polymethacrylic acid. Macroradicals are first formed by decarboxylation; double bonds are then introduced into the macromolecules by disproportionation (a) or degradation (b), and these can react with the remaining carboxyl groups with cyclization to form γ-lactones or δ-lactones. Depending on the electrolysis, the content of lactone groups can amount to 35–40 %.

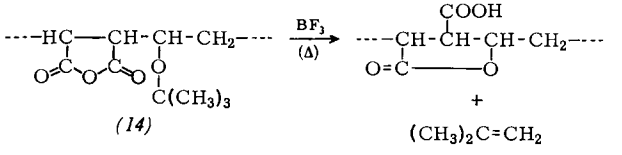


Maleic anhydride-vinyl acetate copolymers *(13)* can also be converted into polymers containing intact lactone groups [13]; polymers containing both γ- and δ-lactone rings are obtained.



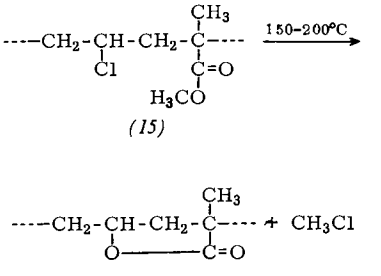
*(13)*

Copolymers *(14)* of t-butyl vinyl ether and maleic or citraconic anhydride react in the presence of $BF_3$ to form polymers containing δ- and β-lactone groups as well as γ-lactone groups [14]; the same rearrangement takes place on heating.



*(14)*

Finally, polymers containing intact γ-lactone groups can be obtained by thermal elimination of methyl chloride from 1:1-copolymers *(15)* of methyl methacrylate and vinyl chloride [15].



*(15)*

## II. Reactions of Polymers Containing Lactone Groups

Reactions of polymers containing intact lactone groups are distinguished above all by the following characteristics:

1. With few exceptions, they are addition reactions, most of which (particularly in the case of polymers containing β-lactone groups) proceed under very mild conditions.
2. The reactions can often be carried out in aqueous media, and they then give water-soluble polymers.

As in low molecular weight compounds, β-lactone groups react more readily than γ-lactone groups.

### 1. Reactions of Polymers Containing β-Lactone Groups

These reactions were carried out with poly-β-(2,3-dihydropyran-2-yl)-β-propiolactone as a model substance;

[10] *L. M. Minsk* and *W. O. Kenyon*, J. Amer. chem. Soc. *72*, 2650 (1950).

[11] *G. Smets* and *P. Flore*, J. Polymer Sci. *35*, 519 (1959).

[12] *G. Smets*, *X. van der Borght*, and *G. van Haeren*, J. Polymer Sci. A *2*, 5187 (1964).

[13] *L. M. Minsk*, *G. P. Waugh*, and *W. O. Kenyon*, J. Amer. chem. Soc. *72*, 2646 (1950).

[14] *R. J. Kern*, Makromolekulare Chem. *79*, 122 (1964).

[15] *N. L. Zutty* and *F. J. Welch*, J. Polymer Sci. A *1*, 2289 (1963).

however, it has been found that they can also be applied directly to other polymers containing intact β-lactone groups.

Reactions of compounds containing β-lactone groups can be conveniently followed by IR spectroscopy (β-lactone absorption at 1820 $cm^{-1}$). Titration with base can be used for quantitative analysis in only a few cases.

The gas-chromatographic determination (by the ampoule technique) of the carbon dioxide liberated on heating (see Scheme 1, a) is very accurate and free from perturbing influences[16]: 5 mg of polymer is decomposed in a glass ampoule during 2 hours at 250 °C; the $CO_2$ is then quantitatively determined at 50 °C and 0.3 atm on a 2 m di-n-decyl phthalate column.

### a) Thermal Elimination of Carbon Dioxide

Polymers containing β-lactone groups quantitatively lose $CO_2$ at high temperatures; in the case of poly-β-(2,3-dihydropyran-2-yl)-β-propiolactone *(3)*, this occurs above 180 °C with formation of a polymeric 2-vinyl-dihydropyran (see Scheme 1,a). If this reaction is allowed to proceed above the softening point of the polymer, porous foams are obtained.

### b) Reaction with Acids

According to *Gresham*[17], the reaction of β-lactones with hydrohalic acids leads to β-halogenopropionic acids. This reaction does not occur with poly-β-(2,3-dihydropyran-2-yl)-β-propiolactone *(3)*, which instead is cross-linked by Brönsted or Lewis acids, even at room temperature, *via* the lactone groups. Carboxylic acids open the lactone ring at high temperatures to form the esters of the (substituted) β-hydroxypropionic acid, the alkali metal salts of which are water-soluble (see Scheme 1,$b_2$).

### c) Reaction with Alcohols

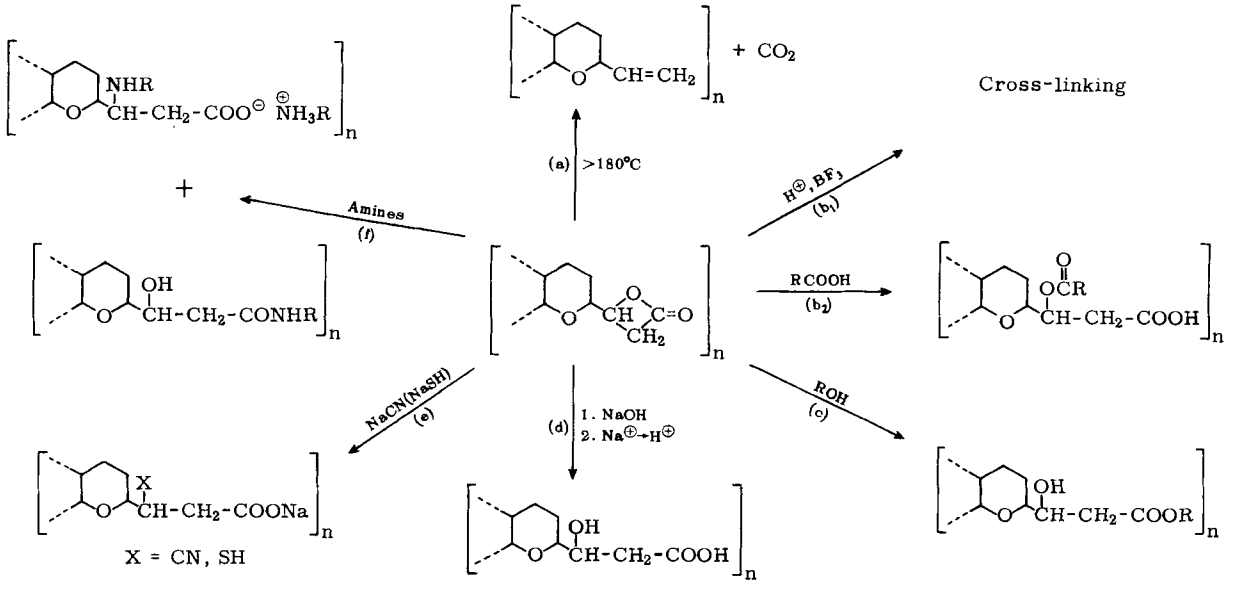
The acid-catalysed reaction of poly-β-(2,3-dihydropyran-2-yl)-β-propiolactone *(3)* *e.g.* with ethanol leads to the polymeric (substituted) β-hydroxypropionate (see Scheme 1,c). A suspension of the polymer in an excess of methanol is heated, the product gradually going into solution. Attempts to catalyse this reaction with alkali have been unsuccessful.

### d) Reaction with Alkali Metal Hydroxides

Poly-β-(2,3-dihydropyran-2-yl)-β-propiolactone *(3)* dissolves in 1N NaOH, even in the cold, to give a clear solution which contains sodium poly-β-(2,3-dihydropyran-2-yl)-β-hydroxypropionate, which can be converted into the free acid with cation exchange resins or by acidification and extraction of the concentrated residue with ethanol (see Scheme 1,d).

### e) Reaction with Salts

Whereas the reaction corresponding to that of β-propiolactone with sodium chloride to give sodium β-chloropropionate[17] does not take place, poly-β-(2,3-dihydropyran-2-yl)-β-propiolactone reacts with salts of weak acids, such as NaCN and NaSH, in aqueous media at 20 to 50 °C. The reaction leads to water-soluble polymeric Na salts of (substituted) β-cyano- and β-mercaptopropionic acids (see Scheme 1,e). Hydrolysis of β-lactone groups takes place at the same time, so that in addition to the desired groups, the polymeric products contain also β-hydroxypropionic acid groups.



Scheme 1. Reactions of poly-β-(2,3-dihydropyran-2-yl)-β-propiolactone.

### f) Reactions with Amines

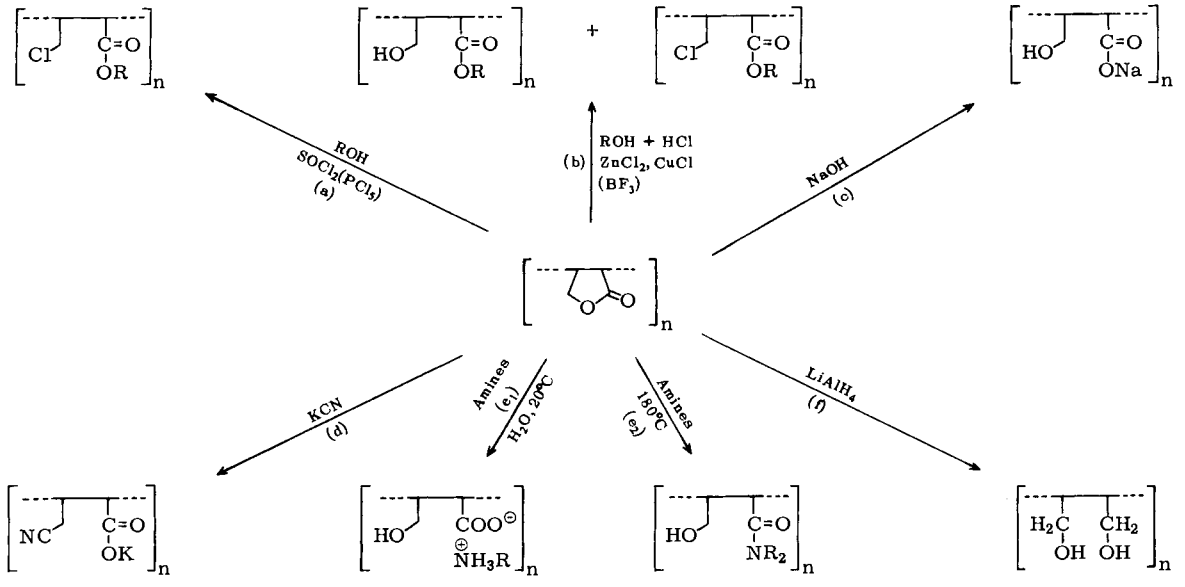
Amines react with β-propiolactone[18] to give either the β-hydroxypropionamide or the β-aminopropionic acid, depending on the reaction conditions. The reaction of

[16] *H. Cherdron, L. Höhr,* and *W. Kern,* Angew. Chem. *73*, 215 (1961).

[17] *T. L. Gresham,* J. Amer. chem. Soc. *70*, 999 (1948); *74*, 1223 (1952); *76*, 486 (1954).

[18] *T. L. Gresham,* J. Amer. chem. Soc. *73*, 3, 168 (1951).

poly-β-(2,3-dihydropyran-2-yl)-β-propiolactone with ammonia or primary or secondary amines in water at 20 to 50 °C leads to water-soluble products containing both β-hydroxypropionamide and β-aminopropionic acid groups, or possibly their ammonium salts (Scheme 1,f). To obtain water-soluble polymers, only some of the β-lactone groups in the insoluble polymer need react with a monoamine; cross-linking from the aqueous solution can then be achieved by reaction of the remaining β-lactone groups with diamines or polyamines at 20 to 50 °C. In organic solvents, *e.g.* in an excess of the reagent, the reactions of poly-β-(2,3-dihydropyran-2-yl)-β-propiolactone *(3)* with amines are much slower.



Scheme 2. Reactions of poly-γ-hydroxycrotonolactone.

### g) Preparation of Graft Copolymers

The intact lactone groups *e.g.* in poly-β-(2,3-dihydropyran-2-yl)-β-propiolactone can also be used for the preparation of graft copolymers. Thus polyester branches can be grafted on by dissolution of *(3)* in monomeric lactones, such as β-propiolactone, and addition of an initiator. Polyether branches can also be grafted on, since lactones copolymerize with epoxides [19]. This graft copolymerization can be initiated by cationic or anionic initiators under conditions similar to those used in the homopolymerization of lactones [20]. Ethylene oxide and propylene oxide have been used as epoxide components.

## 2. Reactions of Polymers Containing γ-Lactone Groups

The model substance used for reactions of polymers containing γ-lactone groups was polymeric γ-(hydroxycrotono)lactone. All the reactions of γ-lactone groups, except the alkaline hydrolysis and the reaction with amines in water, require higher temperatures than those of β-lactone groups, so that considerable chain degradation occurs in many cases. The reactions can be followed quantitatively by IR spectroscopy (γ-lactone absorption at 1770 $cm^{-1}$).

### a) Reaction with Inorganic Acid Halides

Inorganic acid halides (*e.g.* $PCl_5$ or $SOCl_2$) react with poly-γ-(hydroxycrotono)lactone to give polymeric γ-halogenoacyl halides, from which the esters of the γ-halogeno acids can be directly obtained by treatment with alcohol (see Scheme 2,a).

### b) Reaction with Alcohols

When gaseous hydrogen chloride is led into an ethanolic suspension of poly-γ-hydroxycrotonolactone in the presence of $ZnCl_2$, the polymer dissolves, but is precipitated unchanged on addition of ether. However, if the solution is heated for several hours under reflux, the polymeric ester of the γ-hydroxycarboxylic acid and a little of the ester of the γ-chlorocarboxylic acid are formed (see Scheme 2,b).

### c) Reaction with Alkali Metal Hydroxides

Polymeric γ-hydroxycrotonolactone dissolves in aqueous sodium hydroxide solution on gentle heating to give the Na salt of the corresponding polymeric γ-hydroxy acid (see Scheme 2,c). The original polymer is recovered quantitatively on acidification.

### d) Reaction with Salts

When a suspension of poly-γ-hydroxycrotonolactone in aqueous potassium cyanide solution is heated, the polymer dissolves within two hours; the only product is the salt of the γ-hydroxycarboxylic acid, from which the original polymer can be recovered by acidification. However, the salt of the γ-cyanocarboxylic acid can be

[19] *H. Cherdron* and *H. Ohse*, Makromolekulare Chem. *92*, 213 (1966).

[20] *H. Cherdron*, *H. Ohse*, and *F. Korte*, Makromolekulare Chem. *56*, 179, 187 (1962).

obtained in anhydrous dimethylformamide at 150 °C (Scheme 2,d).

e) Reaction with Amines

Poly-γ-hydroxycrotonolactone reacts with amines in aqueous media at 20 to 50 °C to give the ammonium salt of the polymeric γ-hydroxy acid (see Scheme 2,$e_1$). In organic solvents, *e.g.* in an excess of the amine, higher reaction temperatures are required, and the polymeric γ-hydroxy carboxamide is then formed (Scheme 2,$e_2$).

f) Reduction with Lithium Tetrahydridoaluminate

Polymeric crotonolactone can be smoothly reduced with $LiAlH_4$ in tetrahydrofuran to give a water-soluble polymer of 2-butene-1,4-diol (Scheme 2,f).

*We are grateful to Professor Korte for his interest in this work.*

# Conformational Aspects of Many-Membered Rings[*]

BY PROF. J. DALE

UNION CARBIDE EUROPEAN RESEARCH ASSOCIATES, BRUSSELS (BELGIUM) [**]

*The stereochemistry of the various chemical groupings which constitute the structural units of ring systems is first reviewed. It is then shown that the strain-free possibilities even of large rings are restricted, and that the ring conformations theoretically derived generally correspond to those found by physical methods. Variations of physical properties and of cyclization yield in homologous series are explained on a conformational basis.*

## Introduction

Although the conformational analysis of aliphatic six-membered rings has had a remarkable development [2,3] over the twenty years following *Hassel*'s demonstration [1] by electron diffraction that the chair is the normal stable form and that axial and equatorial substituents can be distinguished, the development has been much slower in other ring systems. In larger rings the understanding of conformational details was virtually lacking until *Dunitz*'s recent demonstration [4] by X-ray diffraction of a unique conformation of the ten-membered ring skeleton in a variety of cyclodecane derivatives. It is true that synthetic difficulties, certain anomalies in physical properties, and abnormal transannular reactions of medium (eight- to eleven-membered) rings had been rationalized vaguely as being due to compression in the interior of the ring and to the proximity of atoms across the ring, but the conformational details remained obscure.

The nature of the unique Dunitz conformation of cyclodecane (see below) is such that, as in the cyclohexane chair, the carbon skeleton follows quite closely the diamond lattice; however, since this involves too close an approach between some of the hydrogen atoms, a compromise is reached between angle opening, torsion of bonds, and hydrogen repulsion.

As shown in Fig. 1, a C–C–C angle opening of 5 ° demands only an energy of 0.5 kcal/mole, of 10 °, 1.9 kcal/mole, while eclipsing a single bond in saturated hydrocarbons costs 2.8 kcal/mole [5]. Oscillation of the C–C–C angle in a $CH_2$ chain (normally 112 °) between 100 and 124 °, therefore, is as easy as rotation about a single C–C bond.

Crystal structures of some other medium and large ring compounds have been determined [6] and have confirmed the view that the angular (Baeyer) and torsional (Pitzer) strain are well balanced and, if physically possible, are both totally absent. Knowledge of the most stable orientation about single bonds thus becomes particularly important, since the shape of a large ring depends much more on the orientation of the chain members about each bond than on the exact value of the bond angles.

## Some Basic Stereochemical Facts

The most reliable information about the basic stereochemistry of the various molecular units comes from direct physical methods such as X-ray diffraction, electron diffraction, and microwave spectroscopy (rotational spectra). Other spectroscopic methods, such as electronic spectra (ultraviolet and visible), vibrational spectra (infrared and Raman), and nuclear magnetic resonance spectra, can also yield useful information but are rarely of comparable precision. Conclusions have also been drawn from dipole moments and thermodynamic data.

The stable conformations of a C–C single bond in a saturated carbon chain are illustrated in Fig. 2 [7], which shows the potential wells for the staggered positions,

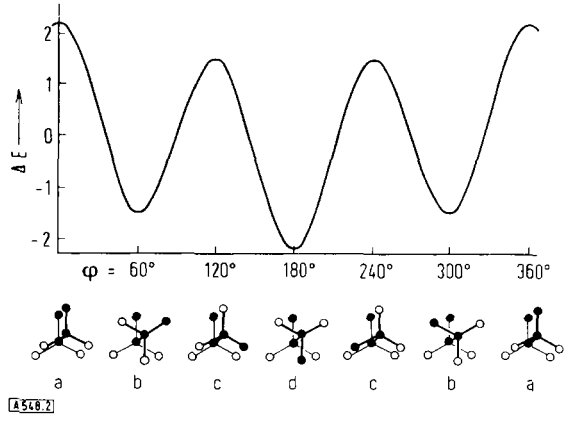

Fig. 2. Dependence of the potential energy (in kcal/mole) of a tetramethylene chain on the conformation of the central C–C bond [7]. The dihedral angle is denoted by φ.
*a* and *c*, eclipsed conformations; *b gauche* conformation; *d*, *anti* conformation.

[7] *M. Kobelt, P. Barman, V. Prelog*, and *L. Ruzicka*, Helv. chim. Acta *32*, 256 (1949).

separated, even in the case of ethane, by surprisingly high and theoretically unsatisfactorily explained barrier peaks at the eclipsed positions [8]. The lower energy of the *anti* (or *trans*) as compared to the two *gauche* conformations leads to a tendency for long paraffin chains to be essentially all-*anti* and extended at low temperatures, and this is unfavorable for cyclization. If the chain carries an alkyl branch, the adjacent C–C bond does not distinguish between the branch and the main chain, so that the probability of having a "kink" in the main chain, necessary for cyclization, increases; this is the simplest explanation for the *gem*-dimethyl effect [9] in cyclization processes. Carbon-carbon single bonds next to almost any group other than $CH_2$, $CH_3$, or heavy atoms (higher halogens), take up *gauche* as easily as *anti* conformations; thus a bend of the main chain becomes more probable next to double bonds, triple bonds, carbonyl groups, hetero-atoms, *etc.*, and cyclization is facilitated [10].

Fig. 3 shows how the stereochemistry of most of the structural elements and the adjoining atoms occurring in ring systems can be derived from that of saturated hydrocarbons by assuming that hydrogen atoms can be replaced with no essential stereochemical change by a lone electron pair in atoms like oxygen, nitrogen, and sulfur, and that double bonds can be considered as two bent bonds [11]. The barriers of rotation (kcal/mole) in the illustrated or in similar compounds are given at the bond in question. It is remarkable how similar they are, except those next to multiple bonds or to hetero-atoms engaged in partial conjugation (ester, amide), where the

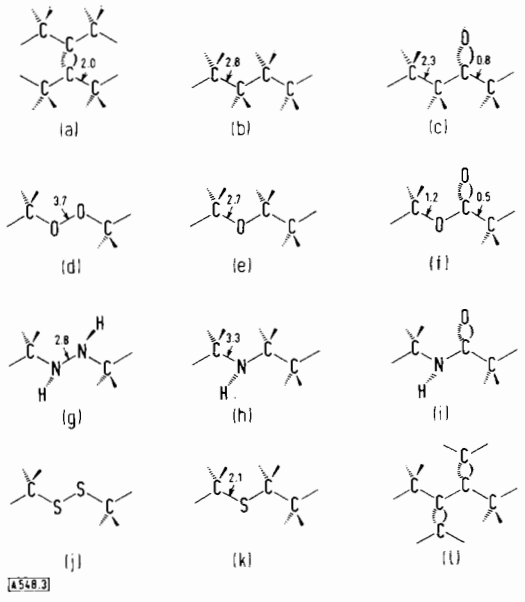

Fig. 3. Derivation of the stereochemistry of some structural elements from that of a saturated hydrocarbon. The numbers are energy barriers (kcal/mole) for rotation about the respective bonds.

values become much lower so as to make the chain more flexible. For the ether linkage (Fig. 3,e) both the rotational barrier and the conformation have been determined on dimethyl ether [12]; for the sulfide linkage (k) on dimethyl sulfide [13]; and the barrier in secondary amines (h) on dimethylamine [14].

Although only the *anti* conformation is shown in Fig. 3, it is likely that the *gauche* and *anti* conformations of the bond between carbon and hetero-atom in homologous compounds have comparable energies. Thus in crystalline polyoxymethylene [15] all C—O bonds are *gauche*: in polyethylene glycol [15] they are all *anti* (and the C—C bond *gauche*). The situation is less clear when two hetero-atoms are adjacent (Fig. 3; d, g, j). Thus it has been assumed generally that the torsional angle in hydrogen peroxide is 90 to 100 °. However, the observation that one of the possible values for the dihedral angle in hydrogen peroxide dihydrate [16] is 68 ° and that in sodium oxalate perhydrate [17] it is 180 ° indicates that it is a normal *anti-gauche* system; this is supported by the presence of perfectly chair-shaped six-membered tetraoxa rings in sodium peroxoborate [18] and in various dimeric cycloalkanone peroxides [19]. With hydrazine [20] there is agreement about a three-fold barrier and that *gauche* and *anti* forms coexist; even in bishydrazinezinc chloride [21] the torsional angle is 74 °. The situation is similar in tetrafluorohydrazine [22], but no conclusions could be reached for dimethylhydrazine [23]. For the disulfide group it has been assumed [24,25] that the normal dihedral angle is 90 °, although in some carbon-substituted open-chain systems like L-cystine [26] and its hydrochloride [27] it is as low as 74 and 79 °. In a six-membered 1,2-dithiane derivative, a perfect *gauche* value of 60 ° was found [25]. In linear polysulfides [28], too, the dihedral angles are all close to *gauche*, varying from 61 to 82 °.

Both hydrogens of a $CH_2$ group can be replaced by one bivalent group to form a double bond without disturbing the stereochemistry of the carbon chain, as shown for the ketone in Fig. 3,c. This basic carbon skeleton is the predominant one in methyl ethyl and diethyl ketone [29], and the same stereochemistry and low rotational barrier next to the carbonyl group has been established in numerous other carbonyl compounds, like aldehydes [30–32], acetyl derivatives [33,34], and acyl halides [30,33]. The barrier next to the carbonyl group (Fig. 3,c) was determined on acetone [14,35], that of the α,β bond on propionaldehyde [32]. For a double bond between two carbon atoms, the situation is similar (Fig. 3,a), but the torsional barrier in adjacent single bonds is only moderately reduced in mono- and *trans*-disubstituted [36] and 1,1-disubstituted [37] olefins, whereas it is much lower (0.6 to 1.4 kcal/mole) in *cis*-disubstituted olefins [36]. It is noteworthy that even in *cis*-2-butene [38] the conformation derived from Fig. 3,a is strictly obeyed even if this implies the closest possible hydrogen-hydrogen distance; conformers of higher 1-alkenes [39] follow the same pattern. Next to a C=N double bond the basic stereochemistry is the same, as is shown in the case of *N*-methylenemethylamine [40], with a torsional barrier for the adjoining single bond of 1.97 kcal/mole.

If an oxygen atom is next to the double bond, enol ethers are obtained whose conformation should be as in Fig. 3,f. Esters show a strong preference for the planar *anti* conformation (unfortunately often referred to as *cis* in formates) [41–43], and it seems reasonable to attribute this to partial double bond character in the C–O bond next to the carbonyl group. Except for formic acid [44] and its ethyl ester [45], there is no evidence for another conformation in open chains; a planar *cis*-ester would give eclipsed single bonds, and a non-planar *gauche*-ester would not be able to acquire double-bond character. It has been pointed out [46] that in lactones with a six-membered ring the ester group is *cis*-planar, but the examples quoted are all fused-ring systems favoring a boat conformation. In methyl vinyl ether a second (unstable) form has been observed [43], presumably because resonance stabilization in the planar *anti* form is less important in a C=C–O than in an O=C–O system; it is interesting that the latter is not planar *cis*, but nonplanar *gauche*. The partial double-bond character is probably also responsible for the lowered torsional barriers in the adjacent single bonds of esters (Fig. 3,f), although these were not determined on higher esters, but on acetic acid [30] and methyl formate [42]. The crystal structures of aliphatic carboxylic acids [47] and dicarboxylic acids [48,49] also demonstrate that torsion of the C–C bond next to the carbonyl group is particularly easy; the carboxyl group is usually oriented as shown in Fig. 3,f, in or close to the plane of the methylene chain, but sometimes it is twisted by up to 30° by packing forces [48].

The *N*-monosubstituted amide group (Fig. 3,i) is completely analogous to the ester group. The *anti*-conformation is strongly favored [50,51], and again only in formamides is there evidence [51] for another less stable isomer, supposed to be planar *cis*. The torsional barriers are not known, but they seem to be low in the single bonds on both sides. Thus there are small deviations from the ideal *anti* and *gauche* values (180° and 60°) in the N–C(α) bond of acetamide-like compounds [52,53] and in the α-helix of proteins [54], and a stronger deviation in the C–C(α) bond of the α-helix [54]. In less stable protein structures the deviations are much greater [54]. Since the double-bond character of the C–N bond (of formamide [55]) is only 25 %, the *cis*-hydrogen on nitrogen (Fig. 3,i) is not expected to be coplanar with N–C=O; deviations from planarity have been observed in *N*-acetylglycine [53] and formamide [55].

A similar situation arises in conjugated diolefins in which the central single bond has a preference for the *transoid* (s-*trans* or s-*anti*) conformation shown in Fig. 3,l, since it has double bond character. "Resonance" being no doubt less important here than in amides and esters, the "other form" may even be non-planar *gauche* instead of planar *cis*. Only the *transoid* (*anti*) conformer has been found in butadiene itself by electron diffraction [56] and vibrational spectra [57], and a vain search for the *cis*-conformer by microwave spectroscopy has been reported [58]. Similarly, fluoroprene [58] and isoprene [59] are planar *anti*, and the well-known linear shape of all-*trans*-polyenes and carotenoids implies also *anti*-conformation of the single bonds. Isomerization of hydrocarbons having two double bonds in a 1,3-dimethylcyclohexane [60] or a decalin [61] skeleton shows a preference for positions where the conjugated diene can assume an *anti*-conformation. On the other hand, when in rings of more than five members a *cisoid* conformation is structurally imposed, there exists no evidence that the diene is planar; on the contrary, the low intensity of ultraviolet absorption of 1,2-dimethylenecyclohexane [62] suggests a non-planar "*gauchoid*" conformation. The crystal structure of calciferol [63] shows that an analogous "*cis*"-diene system is non-planar with a torsional angle of 54°, close to the *gauche* conformation, but here, of course, steric hindrance may play a role [*]. Steric hindrance also blurs the picture in the β-ionone ring of vitamin A acid [64] and lower homologues [65,66], but it is interesting that in one of the crystal structures the ring double bond is *anti* and almost coplanar with the polyene system of the chain [65], whereas in the other cases [64,66] it is *gauchoid* with torsional angles of *ca.* 35 and 80°. When a C=C double bond is conjugated with an aldehyde group, as in acrolein, *anti*-preference for the enclosed single bond has been established [67], but when it is conjugated with a carboxyl group, almost planar *cisoid* conformations have been observed [64,65], presumably because the torsional barrier is further reduced by resonance in the hydrogen-bonded carboxyl group. Delocalization of the double bonds

must also be held responsible for the free or nearly free internal rotation of methyl substituents in aromatic systems, *e.g.* in methylpyridines[68]. Similarly, methyl groups next to trigonal boron, as in trimethylboron[69], and to cylindrically symmetrical sp carbon atoms, as in dimethylacetylene[70], are essentially free to rotate.

## Cycloalkanes and Simple Substituted Derivatives

The only strain-free saturated carbon skeletons are those which can be derived from the diamond lattice[10]. This means that only even-membered carbon rings $C_6$ and higher can have skeletons without torsional strain, but the 8-, 10-, and 12-membered (medium) rings are strained because of repulsion between hydrogen atoms pointing "inwards" (Fig. 4 and 5).

In rings larger than the 14-membered ones, many of the strain-free skeletons that can be derived using space-filling models, which do not allow torsional or angular strain[10], are supposedly unstable because they either contain more *gauche*-bonds than the necessary minimum or have too open structures that do not fill space efficiently. Adopting this *horror vacui* postulate, one arrives at the conclusion[10] that only the 14-, 18-, 22-, 26-, *etc.* membered rings can have the ideal "rectangular" conformation shown in Fig. 4, with two parallel long chains roughly at van der Waals distance linked at each end by $C_2$ bridges. The 16-, 20-, 24-, *etc.* membered rings must have $C_3$ bridges if they are to be without torsional strain, or may prefer to collapse, adopting some strain in order to have $C_2$ bridges and better internal van der Waals contacts (Fig. 5). Cyclododecane may change similarly to avoid the three hydrogen-hydrogen repulsions (Fig. 5).

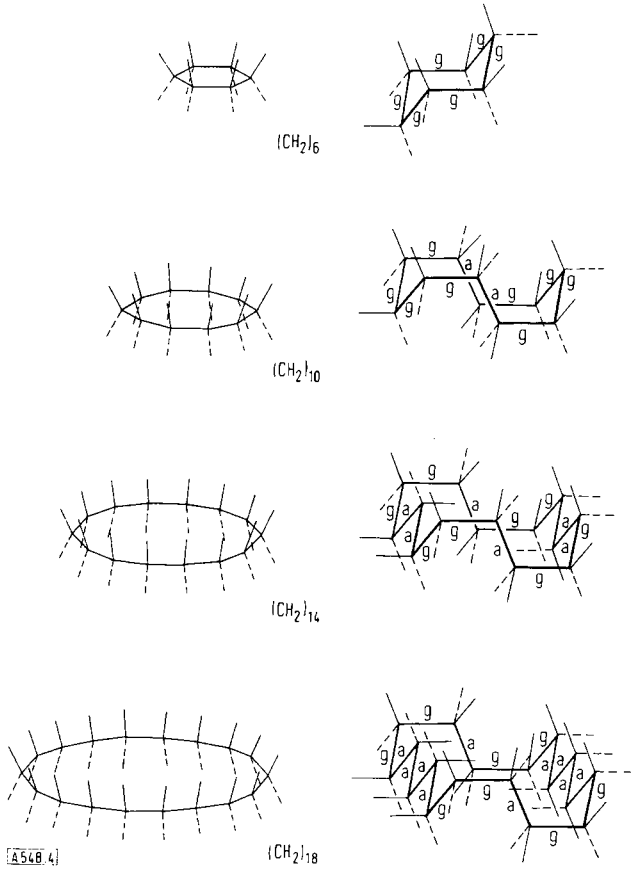

Fig. 4. Conformations of strain-free and compact cycloalkanes of general formula $(CH_2)_{4n+2}$. Right: actual conformation; left: hypothetical planar conformation. D and L substituents are indicated by —— and - - -, respectively. *g*, Bond, with *gauche* conformation; *a*, bond with *anti* conformation.

Structural determinations have confirmed the first three conformations in Fig. 4. The ring conformations of several derivatives of cyclodecane have been found to be almost identical and close to the ideal skeleton shown in Fig. 4. The crystal structures determined so far include two different modifications of *trans*-1,6-cyclodecanediammonium dichloride[71], the corresponding *cis*-isomer[72], cyclodecylammonium chloride[73], and *trans*-1,6-dibromocyclodecane[74]. The observed maximum C–C–C angle opening (to 120°) and deviation from a staggered position (up to 29°) both represent strains of about 1.3 kcal/mole (Fig. 1) and are therefore balanced. The crystal structure found for cyclotetradecane[75], as well as for the structurally equivalent 1,8-diazacyclotetradecane dihydrobromide[76], is very close to the quasi-rectangular one derived in Fig. 4, third row; in the latter compound, the cationic nitrogen atoms occupy the corner positions. For several higher cycloalkanes, early X-ray results[77] suggested two parallel straight polymethylene chains at van der Waals distance, but gave no details of the folding at each end. The recently determined crystal structure of cyclotetratriacon-

tane ($C_{34}$) has confirmed this[75] and established that the folding consists of the bond sequence

... *gauche, gauche, anti, gauche, gauche*, ...

as shown in Fig. 4. Since the cycloalkanes of the series $(CH_2)_{4n+2}$, therefore, seem to possess well-defined centrosymmetrical conformations, L and D substituents (on either side of the hypothetical flat ring which the Fischer and Haworth projections are based upon) have been marked in Fig. 4 in order to facilitate the discussion of steric relationships.

In the series of cycloalkanes $(CH_2)_{4n}$ (Fig. 5) the situation is less clear. Only for cyclododecane are conclusive X-ray results available[78]. Its approximately square conformation (Fig. 6,a) although deviating systematically from the diamond lattice, seems to be typical for this ring size, since it is also found in azacyclododecane

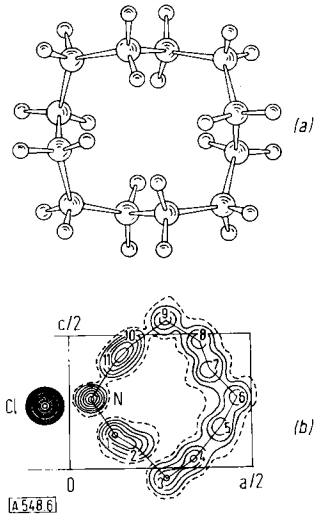

Fig. 6. Crystal structure of (a) cyclododecane [94] and (b) azacyclododecane hydrochloride [95].

hydrochloride[79], with the cationic $\overset{\oplus}{N}H_2$ group at a corner position (Fig. 6,b). In both compounds the torsional strain is similar to that found in cyclodecane derivatives, but the maximum bond angle is smaller (116–117°). In higher homologues $(CH_2)_{4n}$ the same amount of strain might be distributed over more bonds, and the regular increase of the longest period in the crystal lattice[77] suggests that the torsionally strained $C_2$ bridged compact conformations are preferred to the unstrained $C_3$ bridged open conformations.

For cyclooctane the conformational situation is still undecided; evidence has been obtained both for the saddle form[10,80] derived from the diamond lattice (shown in Fig. 5), and for a crown form[81]. In the isoelectronic cation of azacyclooctane hydrobromide, a twisted crown is indicated[6]. Machine computation, taking into account bond angle, torsional strain, and hydrogen repulsion, showed[82] that several cyclooctane conformations have comparable energies[*], and electron diffraction data on the gas could not be explained by any one single model, but fairly well with a mixture of several models[83][*].

The lowest member, cyclobutane, provides a striking demonstration of the necessity of the C–C single bonds to get away from the completely eclipsed conformations of a planar structure even at the expense of further reduction of the already very strained C–C–C angles to below 90°. Thus cyclobutane itself[84] is non-planar, and the angle between the planes of the two halves is 29° in bromocyclobutane[85].

The inherent strain in odd-membered cycloalkanes can be distributed in various ways without, or with only little, difference in energy. This uncertainty, or travelling of an "imperfection", has been termed pseudo-rotation and was first recognized in cyclopentane[86]. When substituents are introduced, certain symmetries, "envelope" and "half-chair"[86,87] are preferred. The detailed calculations by *Hendrickson* have led to a deeper understanding of pseudo-rotation also in the cyclohexane flexible form[5] (between "classical" and "twisted" boat), in the two conformational families ("boat" and "chair") of cycloheptane[5], and in medium rings[82]. The undetermined nature of odd-membered rings is also reflected in the crystal structure of cyclononylammonium bromide[88], which contains two similar conformers with C–C–C, angles up to 124° and deviations up to 44° from the staggered position of the bonds.

The alternation in conformational stability between even- and odd-membered rings is reflected in the melting points (sometimes a transition point), particularly of the larger rings[10]. Singly substituted cycloalkanes as well as saturated macro-heterocycles behave similarly[10].

## Cyclic Ketones

The cycloalkanones show a remarkable similarity with the cycloalkanes in melting point behavior[10]. The $CH_2$-scissoring vibration also follows the same splitting pattern through the medium ring region in the two series[89], and the higher symmetrical cyclic diketones ($C_{24}$, $C_{28}$) show the same feature of two parallel long

chains at van der Waals distances in the crystal [77], although details of the end folding and the location of the carbonyl groups are not known. In medium rings one would expect the carbonyl groups to occupy positions where transannular hydrogen repulsion could be relieved. In fact, the ultraviolet absorption of cyclodecane-1,2-dione indicates an *anti*-planar dicarbonyl system [90], which only fits the cyclodecane skeleton when two "interior" hydrogen atoms are removed (Fig. 7).

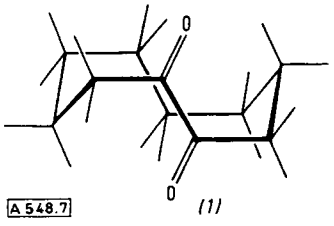

Fig. 7. Suggested conformation of cyclodecane-1,2-dione [90].

In view of the low torsional barrier in bonds adjacent to carbonyl groups, eclipsed bonds occur more easily; thus cyclobutanone is planar [91], cyclopentanone should prefer the "half-chair" and not the "envelope" conformation [87], and even 3,3,5,5-tetramethylcyclopentane 1,2-dione is planar [92]. In cyclohexanone the chair form should be of lowest enthalpy [86,93], having the single bonds adjoining the C=O group in their preferred conformation. However, the flexible boat form will be less Pitzer-strained than in cyclohexane, and since its entropy is favorable [94], the equilibrium may contain the boat form [95]. Most of the established cases of cyclohexane boat forms in non-condensed systems are ketones [95]. Neither *cis*- nor *trans*-2,5-dimethylcyclohexane-1,4-dione occur in the chair form [96]. Cyclohexane-1,4-dione itself has a substantial dipole moment in solution [97], and occurs as a distorted boat in the solid [98].

In larger rings, however, the flexibility introduced with the keto-group does not seem to manifest itself. When there is more than one carbonyl group in the ring, dipole interaction may stabilize or destabilize particular conformations [10].

## Lactones and Cyclic Polyesters

The planar *anti*- or *trans*-ester system can only be accommodated in rings of ten and more members by replacement of two $CH_2$ groups of the cycloalkane skeleton (Fig. 4). In fact, the 10-membered lactone is the first of the series of saturated monolactones [99] to be solid at room temperature (m.p. 32 °C). The discontinuities in boiling point, dipole moment, and rate of hydrolysis as function of ring size indicate that the transition from the less stable *cis*-ester configuration is completed in the 10-membered ring [100]. The low melting point (2 °C) [101] of the 12-membered monolactone is probably due to the considerable departure from planarity (155–163 ° instead of 180 °) in the *anti*-bonds. These bonds, where most of the Pitzer strain is concentrated, are the only places where the *anti*-ester group can be fitted into the molecule. In the 14-membered monolactone (m.p. 28 °C) [101] there are three possibilities of accommodating a strictly planar *anti*-ester group (Fig. 4).

The simplest ring systems containing two ester groups are the dilactones *(2)* (Fig. 8) and, with one ester group

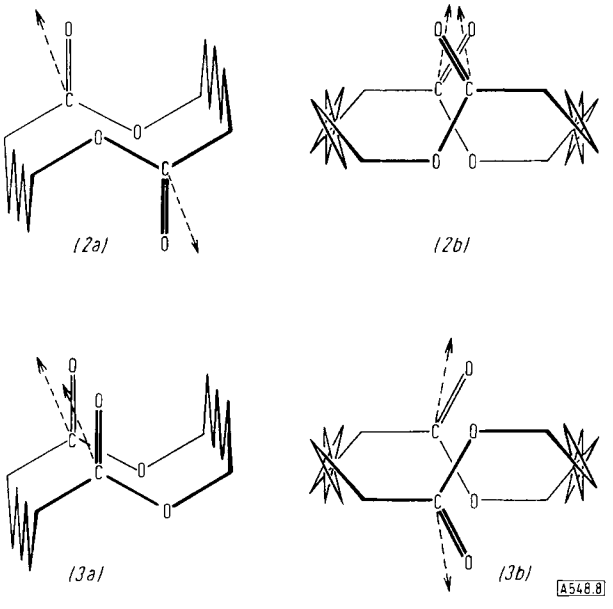

Fig. 8. Conformations of dilactones (top) and cyclic diesters (bottom). Left: odd number of $CH_2$ groups between ester groups; right: even number of $CH_2$ groups [102].

turned around, the symmetrical diesters *(3)*. In both series, the ester groups should tend to form the bridges between two parallel polymethylene chains at van der Waals distance, as the necessary *gauche* bonds at the corners are then obtained at no extra expense. When the number of $CH_2$ groups in each half is odd, there is no strain, but when it is even, there must be skeletal strain except if three-atom bridged open (hence unstable) conformations are adopted. The alternation of melting points (Fig. 9) of the dilactones [99] confirms this conclusion; the alternation may be accentuated in this case by dipole interaction [10]. In the series of symmetrical diesters *(3)* [102], the alternation has disappeared or become inverted (Fig. 9); although it is expected [10] that dipole interaction should in this case counteract

diesters (Fig. 10) are in agreement with the predictions from the models *(2)* and *(3)*. Also, X-ray results on the dilactones [103] show that, apart from the lowest members (number of $CH_2$ groups, $n$, five or six in each chain), they form two series, $n$ odd and $n$ even, in each of which there is a fixed increment of one unit cell dimension, corresponding to the increasing length of straight polymethylene chains as the series is ascended. The crystal structure of jacobine bromhydrin *(4)* [104], which contains a 12-membered diester ring, confirms the similarity with the parent hydrocarbon and the orientation of the

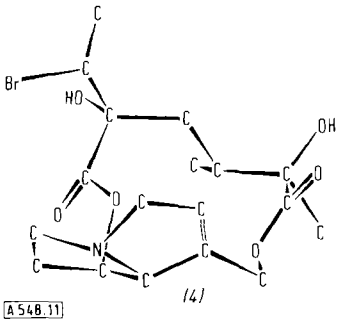

Fig. 11. Crystal structure of jacobine bromhydrin [104].

planar *anti*-ester groups (Fig. 11), although at one corner the ring is heavily strained by fusion with two 5-membered rings.

## Lactams, Cyclic Amides, Peptides, and Depsipeptides

The introduction of one or more amide groups into a cycloalkane should have the same conformational consequences as discussed for the ester group, but the intramolecular dipole interactions are expected to be more pronounced. Intermolecular hydrogen bonding should increase the heat of fusion and obscure subtle variations in the conformational part of the entropy of melting and, consequently, in the melting point alternation [101]. The smallest of the simple monolactams which has a

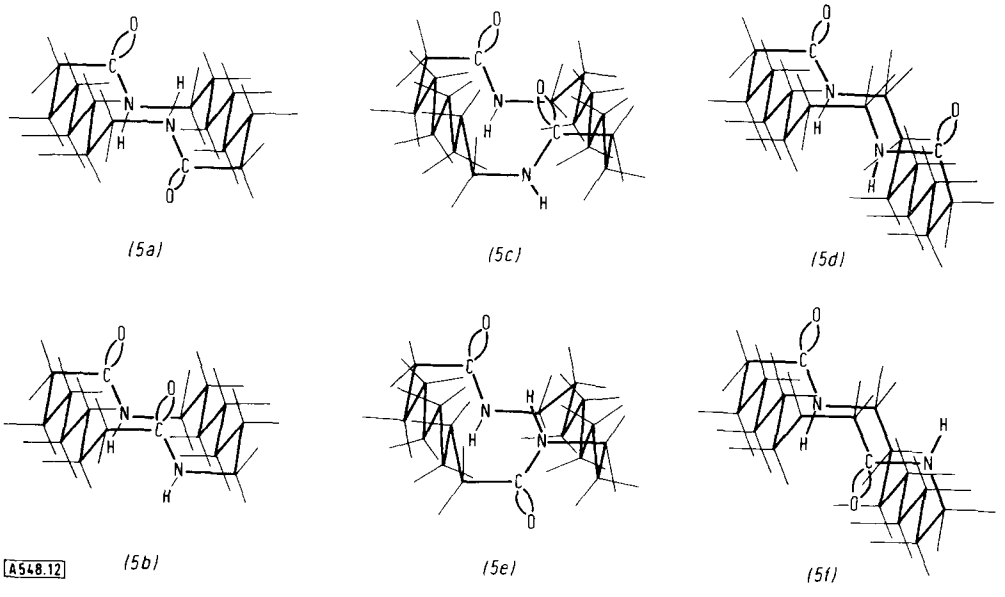

Fig. 12. Conformations of dilactams (top) and cyclic diamides (bottom) with odd (left) and even (middle and right) number of $CH_2$ groups between the amide groups in each half of the molecule [109].

high melting point[105,106] is the nine-membered ring, which is also the first to allow the stable *anti*- (or *trans*-) amide configuration in the solid[106]; however, no melting point alternation is observed[105] in higher monolactams. Dielectric constants[107] and infrared and ultraviolet spectra[106] show that the ten-membered ring is the smallest one present exclusively with an *anti*-amide group in solution, as was also observed for the *anti*-ester group.

The accentuated melting point alternation predicted[10] for the series of macrocyclic dilactams of the type *(5a)*

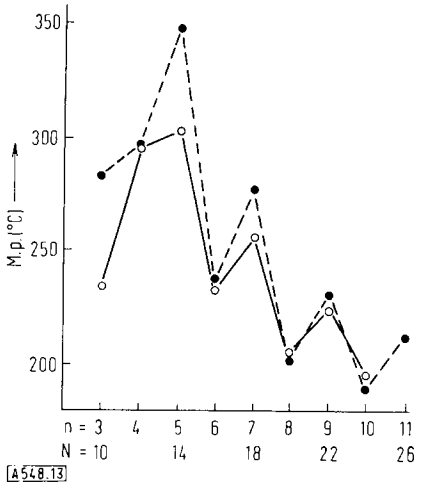

Fig. 13. Melting points of (●) dilactams [108] and (o) symmetrical cyclic diamides [109]. The figure differs from that in [109] in that the melting point of the highest dilactam (212 °C) [110] has been included, and the melting point of the lowest diamide (233—234 °C) [111] has been corrected.

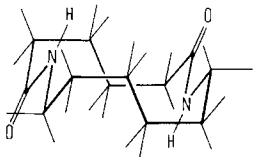
Abscissa: Upper row, number of $CH_2$ groups between the amide groups in each half of the ring, *n*; lower row: total number of ring members, *N*.

and *(5c)* (Fig. 12) has been confirmed[108] (Fig. 13), as has the attenuated alternation expected for the symmetrical cyclic diamides, *(5b)* and *(5e)*,[109] (Fig.13); the difference between the two series disappears as the amide dipoles become separated by longer saturated chains. By studying the $CH_2$-scissoring infrared bands assigned[112] to the *gauche*- and *anti*-conformations on either side of the amide group, and by using polarized infrared radiation, it was shown[113] not only that the 14-, 18-, and 26-membered dilactams have *gauche* bonds in both the N and C=O vicinal positions and, therefore, have conformations of the type *(5a)*, but also that this holds for the 12- and 16-membered dilactams, so that these have the compact strained conformations *(5c)*, and not the open strain-free ones *(5d)*. The same result was obtained[109] from an infrared study of association of cyclic diamides in dilute solution. Whereas the very stable 14-membered caprolactam dimer showed conformational homogeneity at least up to its melting point (348 °C), the 18-membered homologue has also an unstable crystal modification with C=O vicinal *anti* bonds[113]. This increasing flexibility with ring size is likewise seen in the 26-membered dilactam, which seems to contain not exclusively *anti* bonds within the polymethylene chains[113].

In the higher cyclic caprolactam oligomers the number of *anti* bonds increases[113], as is expected for stretched double chains, and the same is true for the cyclic oligoamides of adipic acid and hexamethylenediamine (Nylon 6,6). The lowest member of this latter series, the 14-membered diamide, has the C=O vicinal bonds only in *gauche* orientation[113]. At 150 °C the N-vicinal bonds are also *gauche*, but become increasingly *anti* at lower temperatures, so that at very low temperatures the only strain-free conformation, *(6)* (Fig. 14), is



*(6)*

Fig. 14. Suggested low-temperature conformation of hexamethylene adipamide.

adopted. The inherent well-known instability[114] of this isomer, compared with the caprolactam dimer of the same size, seems to stem from the presence of two extra non-vicinal *gauche* bonds and a less favorable dipole orientation.

Melting point alternations in homologous series of oligolactams have already been interpreted in detail[10] for the case of ε-aminocaproic acid[115] and ω-aminoundecanoic acid[116]. Recently, data have become available also for β-alanine[108], γ-aminobutyric acid[108], and δ-aminovaleric acid[117], and the following generalization can be made: In the general series

*(6a)*

high conformational stability, hence high melting points and high synthetic yields are expected when the number of ring atoms, $x(m + 2)$, is 14, 18, 22, 26, 30, *etc.* In addition, it is advantageous when the *gauche* bonds forming corners are not from the interior of the polymethylene chains, but those adjoining the amide groups, and this is only possible when *m* is odd (both "bridges" consist then of amide groups) or with $m = 4$ (one "bridge" only is an amide group). It can be seen from

Table 1 that the melting points of conformationally favored compounds are in fact higher than those of their immediate neighbors.

The cyclic peptides ($m = 1$) decompose at or before the melting point. The remarkable stability of cyclohexaglycyl[118], and the general preference[10, 119] for the formation, sometimes by doubling reactions, of hexa- and deca-peptides, thus finds a surprisingly simple explanation without the usual assumptions of intramolecular hydrogen bonding and dipole interaction. In the recently determined crystal structure of cyclohexaglycyl hemihydrate[120] the pseudo-cell contains two different centrosymmetrical molecules with planar *anti*-amide groups (Fig. 15). In one molecule (a) there

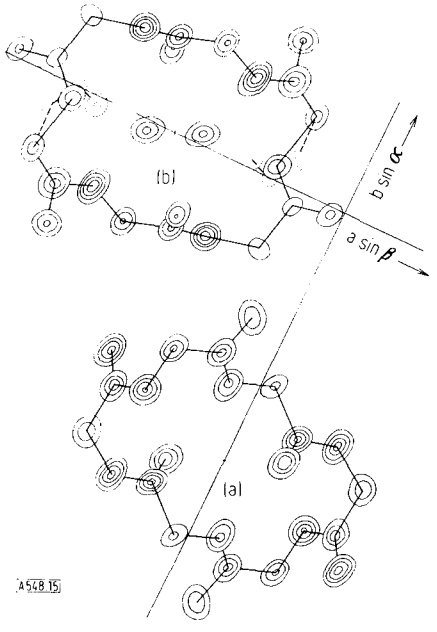

Fig. 15. Crystal structure of cyclohexaglycyl hemihydrate [120].
(a) Conformation with two weak intramolecular hydrogen bridges; (b) conformation without intramolecular hydrogen bridge. The two regions of high electron density in the center are water molecules above and below the ring.

are two weak internal hydrogen bonds, and the conformation is intermediate between the "crowded", flat, Pitzer-strained molecule and the "rectangular" puckered cyclooctadecane conformation (Fig. 16), and is quite different from other

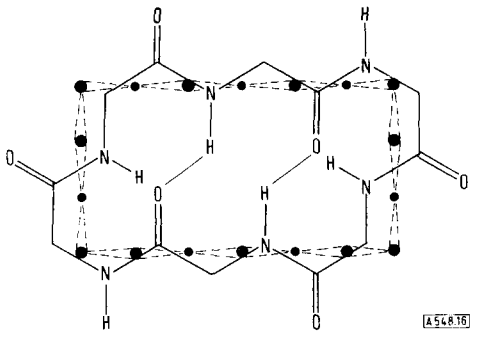

Fig. 16. The hypothetical flat cyclohexaglycyl molecule (full line) compared with the puckered cyclooctadecane conformation (broken line).

proposed[119] conformations. The second molecule (b) has no internal hydrogen bonds, but instead is hydrogen-bonded with water molecules. It may perhaps be concluded that in aqueous solution no internal hydrogen bonds exist, in accord with the finding[121] that *N*-methylacetamide is not associated in aqueous solution.

When α-amino acid residues other than glycine occur in cyclic peptides, size and orientation (D or L) of the substituents must also be considered. Fig. 17, formula

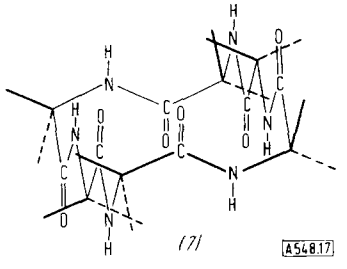

Fig. 17. Idealized conformation of a cyclic hexapeptide with D and L substituents marked —— and - - - -, respectively.

*(7)*, shows the idealized conformation of a cyclic hexapeptide with D- and L-substituents indicated; in the corners bulky substituents of any configuration can be accommodated, but the two remaining substituents must have opposite configuration if they are bulky. The frequent occurrence of D-amino acids in natural cyclic polypeptides[119] and depsipeptides[122], in contrast to their absence in open-chain polypeptides, and the high synthetic yield obtained in the cyclization of oligopeptides with mixed configuration, may, in part, be linked with this conformational feature.

The strong tendency for doubling in the cyclization of tri- and pentapeptides with formation of cyclic hexa- and decapeptides was explained by *Schwyzer*[119] as being due to a preceding hydrogen-bond association of two molecules. However, a concerted reaction of both ends of two peptide chains seems unlikely, and it has already been shown[121] that peptide association is insignificant in water solution and weak in tetrahydrofuran and dioxane, while doubling occurs even in water and methanol[123]. Recently, it has been demon-

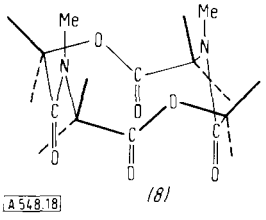
[123] *Yu. A. Ovchinnikov, V. T. Ivanov, A. A. Kiryushkin*, and *M. M. Shemyakin*, Doklady Akad. Nauk SSSR *153*, 122 (1963).

strated [123–125] that tripeptides and tridepsipeptides, which cannot associate lengthwise, nevertheless undergo doubling on cyclization. Thus, glycyl-L-prolyl-glycine [124,125] gives the cyclic hexapeptide as easily as does diglycyl-L-proline [124], although the prolyl unit carries no NH group; further, the tridepsipeptide glycyl-glycolyl-glycine, having an ester linkage instead of one of the amide links [125], and even *N*-methylated tridepsipeptides [123], cyclize with formation of double molecules. Doubling (and tripling) occurs also with tetradepsipeptides [123], *N*-methylated or not, but the yields of tetra-, octa- and dodeca-depsipeptides are generally lower and not significantly different [123], presumably because none of these compounds can have strain-free conformations (Table 1). *Shemyakin* [123] proposed on this basis a reaction sequence with a dilution-dependent final cyclization step.

The configurational sequence of the amino acids in oligopeptides (and of hydroxy acids in depsipeptides) has a profound influence on the cyclization yield. Thus, *Schwyzer* has reported [126] that while gramicidin S itself, which contains two D-phenylalanyl residues, was synthesized in good yield, the corresponding all-L-cyclodecapeptide, with two L-phenylalanyl residues, could not be obtained. Similarly, the cyclic pentapeptide was obtained in 57 % yield from glycyl-L-leucyl-glycyl-D-leucyl-glycine as against 41 % for the L,L-isomer [127], and in 39 % yield from glycyl-D-leucyl-L-leucyl-glycyl-glycine compared with 12 % for the L,L-isomer [128]. The cyclic hexapeptide, cyclophenylalanyl-glycyl-glycyl-phenylalanyl-glycyl-glycyl was mainly the *meso*-form, whether obtained from racemic tripeptides or diastereomeric hexapeptides [129]; when synthesized separately [129], the yield of the *meso*-form (D,L) was higher than for the optically active isomers (D,D and L,L). The same phenomenon was observed in the cyclization of glycyl-tyrosyl-glycyl-glycyl-benzylhistidyl-glycine [130]; when both asymmetric centers had the L-configuration, the yield of cyclic hexapeptide was 31 %, whereas it was 58 % (2/3 containing D-tyrosyl) when the tyrosine was racemic. In these cases there is enough room for the few bulky substituents at corner positions [cf. *(7)*], so that the yield variation must be due to differences in shape of the peptide chain before the final cyclization step. Such differences are indicated by the observation [128] that open-chain peptides containing both L- and D-amino acids have a smaller dielectric increment, hence a smaller distance between $-NH_3^+$ and $-COO^-$, than sterically homogeneous peptides. Although attempts have been made at a conformational analysis of such peptide (and depsipeptide) chains [128,131], these are not convincing because of admitted arbitrary assumptions, and lack of data for the conformational preferences about the C(α)-CO bond, and especially the C(α)-N and C(α)-O bonds. The only conclusion that seems certain is that the extended chain is favored by steric homogeneity, and that each opposite configuration introduces a bend, which cannot be clearly specified. This is particularly well demonstrated by a series of cyclization experiments [131] with diastereomeric tetradepsipeptides (*N*-methylvalyl-α-hydroxyisovaleryl-*N*-methylvalyl-α-hydroxyisovaleric acid); seven sterically heterogeneous isomers gave the cyclotetradepsipeptide in yields from 40 to 75 %, while the sterically homogeneous isomer gave only 8 %, accompanied by the doubling product (13 %). From Fig. 18, *(8)*, it is seen that the isopropyl side groups must all be at "corners" and have enough room in any of these isomers, so that the ring-strain in the end products can hardly differ.



*(8)*

## Cyclic Olefins and Annulenes

The introduction of a double bond into a cycloalkane makes strain-free conformations impossible for any ring size, and it has been pointed out [10] that almost all known cycloalkenes are liquids, reflecting their conformational instability. The exact stereochemistry of the cycloalkenes is not known, except for derivatives of cyclohexene and for cyclopentene [132]; the latter is not planar, but has the 4-$CH_2$ group bent out of the plane, presumably to avoid totally eclipsed 3,4- and 4,5-bonds, although some eclipsing in the 2,3- and 1,5-bonds is thereby introduced. Dihedral angles in single bonds adjoining the double bond have been calculated from NMR coupling constants for *cis*-cycloalkenes up to $C_{10}$ and for *trans*-cyclodecene [133]; the considerable deviations from the "correct" angles of 60 and 180 ° in 7 to 10 membered rings suggests that the departure from ideality is concentrated in these bonds with their lower torsional barrier. Since three-membered rings approach the stereochemistry of the double bond, the

respectively [*]. In the latter case, *trans*-13,13-dimethyl-13-azoniabicyclo[10.1.0]tridecane iodide (Fig.20) [135], it is interesting to note the strong resemblance of the 12-membered ring to the conformation of cyclododecane itself.

The heat of hydrogenation gives an idea of the relative strain in a cycloalkene compared with that of the corresponding cycloalkane, and also of the relative stabilities of *cis*- and *trans*-isomers. The data [136] in Table 2 show that in cyclooctene the *trans*-isomer is much more strained than the *cis*-isomer and higher *trans*-olefins; this strain is also reflected in the notable dipole moment [137] (0.82 D), as compared with that of *trans*-cyclodecene (0.15 D). The strain renders the molecule rigid as is demonstrated by the resolution into optical isomers [138]. Up to cyclodecene the *cis*-isomers have lower enthalpies than the *trans*-isomers; however, in

the symmetrical tetramethyl derivative (Table 2) this situation is reversed [139]. An explanation on the basis of the Dunitz conformation of cyclodecane, with all the methyl groups at two corners, has been proposed [139]; a *trans* double bond fits into the symmetrical position better (although not at all well!) than a *cis* double bond, which becomes highly strained (Table 3). This is also borne out by the observation [140] that the corresponding acetylene is reduced by sodium in liquid ammonia to a *cis*-olefin, with the double bond shifted to the neighboring position.

The enthalpy differences between *cis*- and *trans*-cycloalkenes are in good agreement with values obtained by equilibration of medium size cycloalkenes (Table 2) [141].

In the 11- and 12-membered rings the *trans*-isomer is preponderant, but surprisingly in the latter case this is not due to a lower enthalpy, but to the more favorable entropy of the *trans*-isomer. In larger rings the equilibrium is largely on the *trans*-side [142].

When two double bonds are present, strain-free skeletons become possible in particular cases, namely when the two double bonds are diametrically placed, have the same configuration, and are linked by odd-membered polymethylene chains [10] (Fig. 21). In the larger rings,

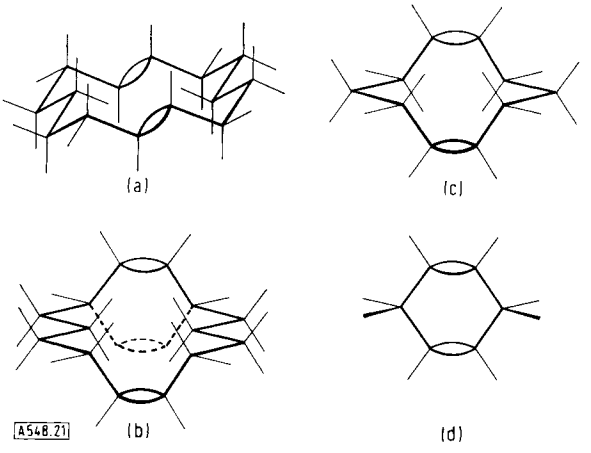

Fig. 21. Conformations of *trans,trans*- and *cis,cis*-cyclotetradeca-1,8-diene (a and b), of *cis,cis*-cyclodeca-1,6-diene (c), and of cyclohexa-1,4-diene (d).

like the 14-membered ring, the *trans,trans*-isomer (a) is favored because hydrogen interactions destabilize the *cis,cis*-isomer (b). In the 10-membered ring, the *trans, trans*-isomer of type (a) would have too formidable a $\pi$-electron repulsion, which can be avoided in the *cis,cis*-isomer (c); the 6-membered ring necessarily has a planar conformation. As no absolutely perfect conformation is possible for the conjugated cycloalkadienes (see below) one might expect that these at least partially deconjugate on equilibration to give preferentially diametric isomers in the case of (4 *n* + 2)-membered rings.

The experimental facts support these deductions. The melting points of diametrical *cis,cis*-cycloalkadienes

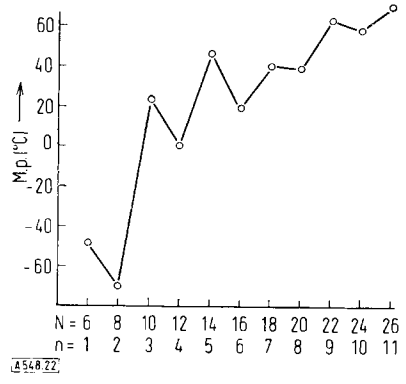

Fig. 22. Melting points of the *cis,cis*-cycloalkadienes

(Fig. 22) show the required alternation [143], and the corresponding *trans,trans*-isomers are alternately solids and liquids [144]. Equilibration of cyclohexadiene [61,145] gives 31 % of the 1,4-isomer, which shows that its energy is comparable with that of the statistically favored conjugated isomer. The vibrational spectra of the 1,4-isomer indicate a planar structure [146]. Equilibration of cycloocta-1,5-diene gives almost quantitatively the conjugated isomer [147] since all *cis,cis*-isomers must be Pitzer-strained; the *cis,trans*-1,5-isomer is also strongly Baeyer-strained and so rigid that it preserves its asymmetry even under pyrolytic conditions [148]. The 9-membered ring approaches the behavior expected for the 10-membered ring; equilibration of cyclononadienes thus gives 94 % of the most "diametrical" *cis,cis*-1,5-isomer and only 6 % of the 1,3-isomer [147], while equilibration of cyclodecadienes gives almost quantitatively the "diametrical" *cis,cis*-1,6-isomer [142], even though this position is disfavored statistically. The rigid, torsionally strain-free conformation in Fig. 21,c has been proposed for *cis,cis*-cyclodeca-1,6-diene [149] and for the *cis,cis*-1,6-dioxocyclodeca-3,8-diene [150]. The 1,5-isomers, on the other hand, must be strained, as evidenced by the fact that both the *trans,trans*- [151] and *cis,trans*-1,5-isomers [152] undergo valence isomerization to divinylcyclohexane. In cyclonona-1,5-diene even the *cis,cis*-isomer undergoes this kind of valence isomerization [153]. Higher cyclic diolefins have been isomerized at 200 °C with triethylborane [154]. Extensive deconjugation does take place; there remains only 10 % of conjugated isomer in the 12-membered ring, 25 % in the 13-membered, and in higher rings up to the 22-membered it never surpasses 50 %. Among the non-conjugated isomers the expected preference for the diametrical isomer in 14- and 18-membered, and lack of preference in 12- and 16-membered rings was confirmed [154]. The situation is complicated by the concurrent *cis,trans*-isomerization. With strong bases at room temperature the result is similar, but the preferences are more accentuated [142]. The much simpler problem of *cis,trans*-isomerization without migration of positional isomers has recently been studied [144] at room temperature. The results confirm (Table 3) the

strong preference for the *trans,trans*-isomer (although *cis,trans* is statistically favored) in the 14-, 18-, and 22-membered and the lack of preference in 16- and 20-membered rings. By comparing the equilibria at 25 and 75 °C (Table 3) it also becomes clear that these preferences are due to a low enthalpy in spite of an unfavorable entropy, hence indicate rigid, stable conformations.

The macrocyclic conjugated cycloalkadienes have been isolated from equilibrium mixtures of various positional isomers [155] and shown to have exclusively the *cis,trans*-configuration from the 12- to the 16-membered ring; in the 18-membered and higher rings the *trans,trans*-isomer occurs also. Models show that a relatively strain-free conformation with a planar *transoid cis,trans*-diene system first becomes possible in the 14-membered ring (Fig. 23,a); experimentally, cyclotetradeca-1,3-diene is

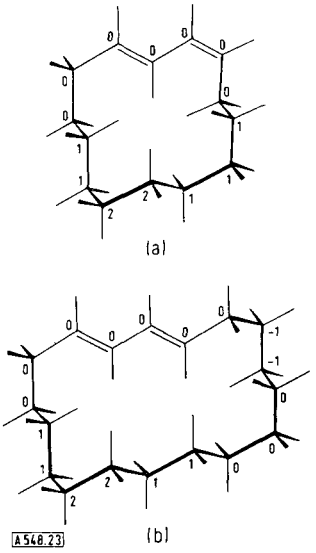

Fig. 23. Suggested conformations for (a) *cis,trans*-cyclotetradeca-1,3-diene and (b) *trans,trans*-cyclooctadeca-1,3-diene [155]. Atoms marked 0 are situated in the plane of the diene system, those marked 1 above, those marked 2 further above, while atoms marked -1 lie below the plane.

found to be the first to have a full intensity ultraviolet absorption [155]. Similarly, the 18-membered ring is the smallest which can accommodate a planar *transoid trans,trans*-diene system in an essentially strain-free conformation (Fig. 23,b) [155].

With three double bonds in a ring, "trigonal" ideal conformations with symmetrically placed *trans* double bonds, *(9)* (Fig. 24), become possible, but only for the

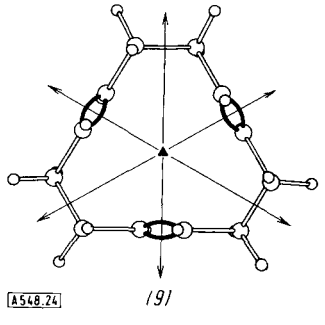

Fig. 24. Crystal structure of all-*trans*-cyclododeca-1,5,9-triene [156].

first member, all-*trans*-cyclododeca-1,5,9-triene, has such a strain-free conformation been established [156] by X-ray methods. Higher rings ($C_{18}$, $C_{24}$, *etc.*) would have intolerably large holes in the interior. The fact that among the known cyclododeca-1,5,9-triene isomers, the all-*trans* is by far the highest melting [157], may be a reflection of its particular conformational stability. A related structure with three *trans* double bonds in an 11-membered ring is present in humulene, and the conformation found [158] in its silver nitrate adduct,

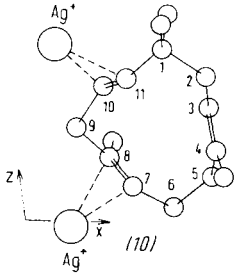

Fig. 25. Crystal structure of humulene (all-*trans*-1,1,4,8-tetramethyl-cycloundeca-3,7,10-triene) [158].

*(10)*, (Fig. 25), has main features in common with the 12-membered ring, *(9)*; most of its inherent strain is located in that part of the ring where one $CH_2$-group is missing.

Among the cyclononatrienes the all-*cis*-1,4,7-isomer seems to be the most stable [159] and its conformation has been proposed [159] to be a rigid crown (Fig. 26),

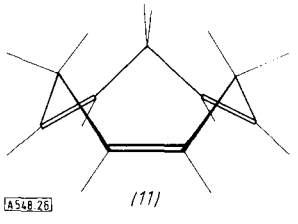

Fig. 26. Crystal structure of all-*cis*-cyclonona-1,4,7-triene [160].

subsequently confirmed by X-ray methods [160]. The single bonds must contain some Pitzer strain and the crystal structure [160] reveals that some strain is also introduced by transannular hydrogen repulsion; this is manifested in the heat of hydrogenation [160]. Equilibration of cyclooctatriene, on the other hand, shows that the conjugated all-*cis*-1,3,5-isomer is by far more stable than the 1,3,6-isomer [161], but it is not known whether the triene chromophore is planar. In cycloheptatriene it has been shown by spectral methods that not only are the protons of the $CH_2$ group non-equivalent [162], but that the molecule has a boat conformation [163] with a non-planar triene system, *(12)* (Fig. 27), as was confirmed recently by electron diffraction [164]; X-ray

diffraction on a derivative has led [165] to the same result. The dihedral angle between planes of adjacent double bonds, 54°, calculated from electron diffraction data [164], is so close to 60° that it must be concluded

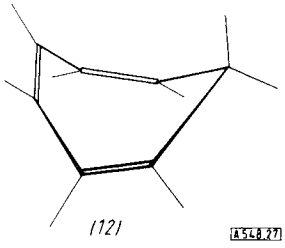

Fig. 27. Conformation of cycloheptatriene in the gas phase [164].

that the 2,3 and 4,5 single bonds prefer *gauchoid* to planar *cisoid* conformations. That this is not caused by angle strain is shown by the fact that the ring is strictly planar [166] as soon as the double bonds become delocalized (*e.g.*, 6 $\pi$-electrons on 7 atoms in the cycloheptatrienylium cation).

The cycloalkatetraenes of general formula

with two *cis,cis*-diene chromophores placed diametrically, show again melting point alternation with the number, *n*, of methylene groups in the connecting saturated chains [155]; the more rigid conformations of the high-melting members with odd *n* are also manifested by the sharper vibrational structure of the ultraviolet absorption bands.

Longer conjugated double bond systems, other than the annulenes (see below), have only been encountered as part of macrocyclic lactones, both natural (macrolide antibiotics [167]) and synthetic [168]. If one extrapolates from the model of Fig. 23,b, one is led to expect that an extended all-*trans* triene requires a 22-membered, a tetraene a 26-membered, and a pentaene a 30-membered ring in order to be "comfortable". It is interesting that all macrolide polyene antibiotics have ultraviolet spectra indicating an all-*trans* all-*anti* structure [167]. In only a few cases, however, is the ring size known; thus pimaricin [169] has a tetraene in a 26-membered ring, and lagosin [170], filipin [171], and fungichromin [172] have pentaene chromophores in 28-membered rings. The latter must therefore have a certain tension. Similar tensions must exist also in simple synthetic polyene macrolides [168] containing an all-*trans* triene in a 19-membered ring and an all-*trans* tetraene in a 24-membered ring.

In rings consisting of a closed loop of conjugated double bonds, like benzene and the annulenes, the main interest has centered on problems of aromaticity [173], or double bond localization *versus* delocalization (alternating or identical bond lengths). In addition to electronic factors, formulated in the well-known (and sometimes abused) *Hückel* rule, and steric factors, such as the possibility of having a planar structure with correct bond angles, conformational factors may also play a role. Thus in benzene, as well as in the flat [173,174] molecule of [18]annulene, *(14)* (Fig. 28), the localized structure

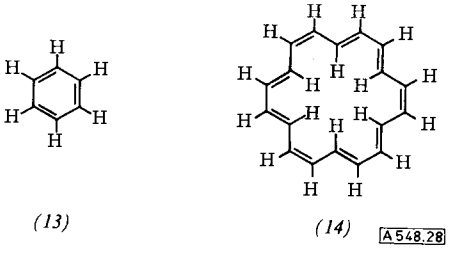

Fig. 28. Hypothetical planar localized double bond structures of benzene and [18]annulene.

(Kekulé structure) would have three eclipsed planar *cisoid* single bonds; since non-planar strain-free conformations with *gauchoid* single bonds are not possible here, the above bonds can only be avoided by delocalization. This may constitute an additional driving force for delocalization in the [4 *n* + 2] annulenes which also are aromatic according to *Hückel*. For cyclooctatetraene ([8]annulene), [16]-, and [24]annulene *(15)*, *(16)*, *(17)*, (Fig. 29), *etc.*, strain-free non-planar conformations with perfect *anti* and *gauche* single bonds linking localized double bonds are possible, so that there is no tendency for delocalization; just these rings happen

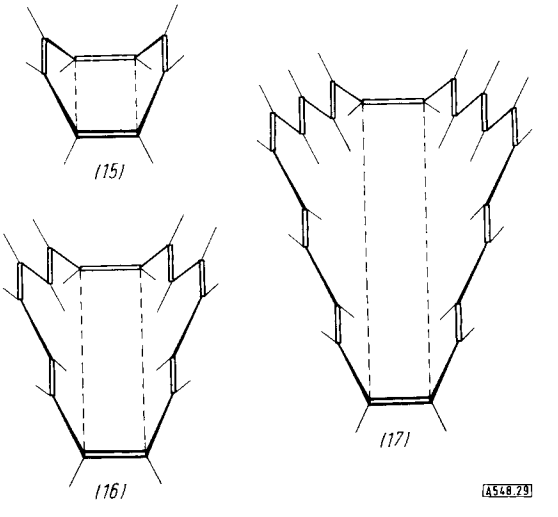

Fig. 29. Tub-shaped conformations of [8n]annulenes; *(15)* established for gaseous cyclooctatetraene [175]; *(16)* suggested for [16]annulene and *(17)* for [24]annulene.

also to be non-aromatic according to *Hückel*. For cyclooctatetraene the structure *(15)* has been established by electron diffraction [175], and from the data a dihedral angle of 57° between adjacent double bonds can be calculated, which is close to the perfect *gauche* conformation. The same dihedral angle is found also in the crystal structure of the carboxylic acid derivative [176]. That angle strain in the planar structure cannot be decisive for the non-planarity is indicated by the fact that when the electronic situation requires delocalization of the double bonds, as in the radical anion [177] and the dianion [177, 178], the ring becomes planar. X-ray data [179] show that [14]annulene does not have alternating bonds and that the carbon atoms are arranged in such a way that overcrowding in the interior is relieved, mainly by a serious in-plane distortion of the pyrene-like skeleton (Fig. 30). The relatively high melting point [180], 136 °C, indicates that this may be a

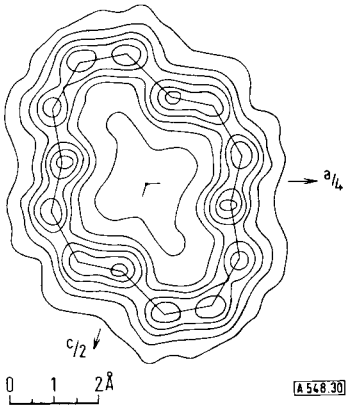

Fig. 30. Crystal structure of [14]annulene [179].

unique conformation, and the NMR spectrum below −40 °C shows the presence of a ring current [181], generally taken as a sign of aromaticity [173]. The coalescence of all NMR signals to one line at 20 °C indicates that the ring is nevertheless flexible enough to interconvert "inner" and "outer" hydrogen atoms [181].

For [18]annulene the X-ray data [173, 174] indicate a coronene-like, practically flat conformation (Fig. 31) and again no alternation in bond length. In [18]annulene trisulfide [182] there seems to be no ring current; the three *cisoid* single bonds are now part of "aromatic" thiophene rings, and delocalization of the double bonds over the large ring is no longer necessary.

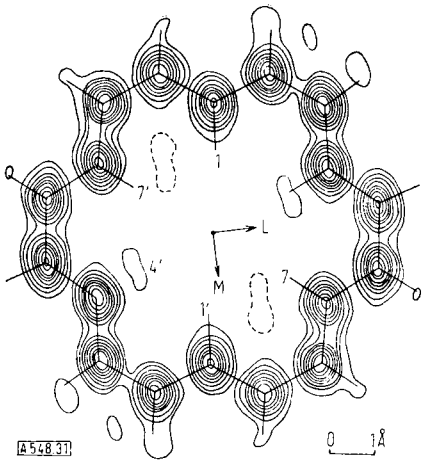

Fig. 31. Crystal structure of [18]annulene [173,174].

The melting point of [18]annulene is over 230 °C [183] and thus still higher than that of [14]annulene. A more rigid conformation of [18]annulene is suggested also by the higher temperature, 110 °C, required for the NMR signals of outer and inner protons, strongly split by the ring current at room temperature, to coalesce to one sharp line [181]. [16]Annulene [173, 184] melts already at 93 °C, and its single NMR line [173], indicating a "flexible" structure, is at the position observed for conjugated polyenes. The non-planar conformation *(16)* with alternating bonds is in accord with its properties, and the mixing of *cis* and *trans* double bond protons in the NMR spectrum can be explained by valence isomerization. For [20]annulene, not even non-planar conformations can be strain-free and accordingly this is a liquid [185]. The NMR spectrum of [24]annulene [186] is similar [173] to that of [16]annulene, indicating conjugated localized double bonds. The structure *(17)* seems to fit the ultraviolet spectrum, the chromophore being considered as two weakly coupled planar halves.

## Cyclic Acetylenes

One triple bond alone introduces the same conformational disorder into an even-membered cycloalkane as does one double bond, and it has been pointed out [10] that all known cycloalkynes are liquid. The requirement of the acetylenic grouping that four carbon atoms lie on a straight line evidently leads to a rapid increase of tension with diminishing ring size. Thus in the equilibrium at 100 °C between a cyclic acetylene and the corresponding cyclic allene (with only three collinear atoms) the percentage of acetylene changes from 74 % for the 11-membered, to 35 % for the 10-membered, and to only 7 % for the 9-membered ring [187].

Cyclooctyne has been isolated [188], and the enormous strain manifests itself in an explosive reaction with phenyl azide; nevertheless, the triple-bond character is essentially retained since the infrared absorption is at 4.53 $\mu$ as in higher homologues. The transient existence of lower-membered cycloalkynes ($C_7$, $C_6$, $C_5$) has been inferred from reaction products [189], but such intermediates may perhaps involve non-linear excited "acetylenes" having no triple bond character.

More subtle conformational details are revealed by the heats of hydrogenation of some tetramethyl derivatives of cyclodecyne [139]. Again, an explanation is possible on the basis of the Dunitz conformation of cyclodecane with *gem*-dimethyl groups at two corners; the symmetrically located triple bond in 5,5,8,8-tetramethylcyclodecyne is more easily accommodated and gives a smaller heat of hydrogenation than the asymmetrically placed triple bond in the 4,4,7,7-tetramethyl derivative.

Two acetylenic bonds diametrically placed in 14-, 18-, 22-membered rings *etc.* can give strain-free ring conformations, whereas in 12-, 16-, and 20-membered rings this is not possible, and a strong melting-point alternation (Fig. 32, lower curve) is observed [143]. By application of the postulate that a minimum of *gauche* bonds are accepted, conformations of the type *(18)* (Fig. 33) were proposed [143] for the former series and seemed to be supported by unit cell measurements [143]. However, the

complete structure determination of cyclotetradeca-1,8-diyne has revealed [103] that the conformation *(19)* (Fig. 33), with two unfavorable *gauche* bonds, is preferred in the crystalline state. Perhaps this conformation packs better; type *(18)* may still be preponderant in

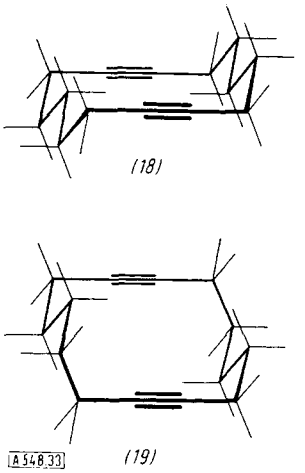

Fig. 33. Conformations of cyclotetradeca-1,8-diyne as proposed *(18)* [143] and as found in the crystal *(19)* [103].

solution. Recently, it has been shown [190] that with strong bases in dimethyl sulfoxide at 40 °C the triple bonds migrate (through intermediate allenes), and the equilibrium composition (Table 4), approached from

different pure isomers, confirms that the diametrical isomer is much preferred in 14- and 18-membered rings, but is a minor constituent in 16- and 20-membered

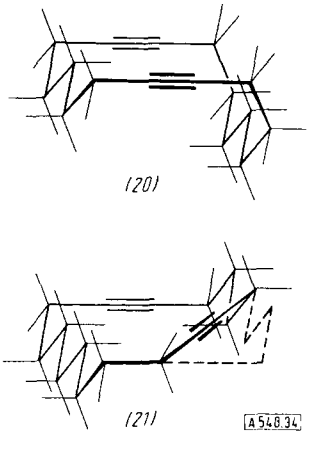

Fig. 34. Proposed conformations for the 1,8-isomer *(20)* and the 1,7-isomer *(21)* of cyclohexadecadiyne [190].

rings; the odd-numbered rings ($C_{13}$ and $C_{15}$) resemble the 14-membered ring. For the isomers expected for 16- and 20-membered rings, the conformation *(20)* was *a priori* a good candidate since a strain-free skeleton is possible, although it is not very compact and has two extra *gauche* bonds; the unexpected preference for a still less symmetrical isomer can be explained by assuming it to have the conformation *(21)* (Fig. 34) which, although a little strained, is more compact and has only one extra *gauche* bond [190].

Table 5. Synthetic yield, melting point, and equilibrium distribution of cycloalkadiyne isomers [190].

| M.p. (°C) | −3 | 28 | 30 | |
| % in equilibrium | 10 | 44 | 38 | 9 |

Table 5 shows that there is a parallel between a high melting point and preponderance of cycloalkadiynes in the isomer equilibrium [190]. The synthetic yield is seen to deviate somewhat from this pattern, because it also is dependent on the conformation of the open chain immediately before cyclization.

Among the numerous known polyacetylenic cyclic compounds containing diacetylenic groupings [143, 173] the conformation of only one series has been investigated, namely, the symmetrical cycloalkatetraynes

$\text{-}(CH_2)_n\text{-}C{\equiv}C\text{-}C{\equiv}C\text{-}(CH_2)_n\text{-}C{\equiv}C\text{-}C{\equiv}C\text{-}$.

Alternations in yield, stability, and melting point [143] (Fig. 32) led to the proposal of conformations analogous to those for the corresponding cycloalkadiynes, although these might have excessive interior holes. For the lowest member $n = 3$, X-ray data [191] indeed indicate a chair-like shape *(22)* (Fig. 35), later [192] also deduced for 1,6-dioxacyclodeca-3,8-diyne, *(23)*; the too short transannular distance between the diacetylenic groups

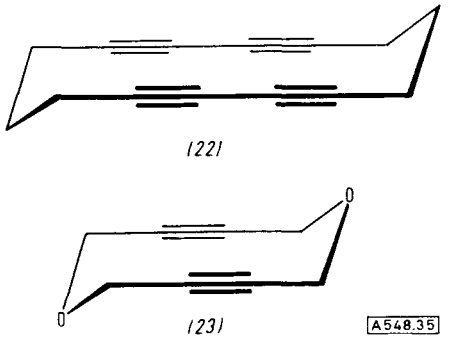

Fig. 35. Crystal structure of cyclotetradeca-1,3,8,10-tetrayne *(22)* [191] and of 1,6-dioxacyclodeca-3,8-diyne *(23)* [192].

explains the instability and the anomalous ultraviolet spectrum [191].

The stereochemistry of the fully conjugated ethylenic-acetylenic rings, the dehydroannulenes, has been elucidated by NMR methods [173, 186] and in a few cases confirmed by X-ray methods; thus both 5,11,17-tridehydro[18]annulene [193] and 1,8-didehydro[14]annulene [194] have the planar structures *(24)* and *(25)* (Fig. 36, 37).

## Rings Containing Phenylene Groups

An *ortho*-phenylene group in a ring compound should have essentially the same conformational consequence as a *cis* double bond, although the absence of a rotational barrier in the adjacent single bonds and the bulk of the aromatic ring may have some effect. Accordingly, most known benzocycloalkenes are liquid [10] or relatively low-melting [143]. Too few diametrical dibenzocycloalkadienes are known to permit general conclusions; in the case of dibenzocycloocta-1,5-diene the crystallo-

graphic data require a center of symmetry [195] as in the conformation *(26)* (Fig. 38). The crown conformation proposed [196] for cyclotriveratrylene, a derivative of tribenzocyclonona-1,4,7-triene, is analogous to that found [160] for all-*cis*-cyclonona-1,4,7-triene itself *(11)*. Crown conformations, with the benzene rings alternately above and below a plane, have been found to be the only ones possible with molecular models for even-membered oligo-*ortho*-phenylenes [197]; with tetraphenylene such a conformation is directly derivable from that of cyclooctatetraene, *(15)* [175].

*m*-Phenylene groups should be able to replace without strain three successive $CH_2$ groups in the middle of a straight chain of five or more $CH_2$ groups, such as can only occur in 14-membered and higher cycloalkanes. Too few examples are known with one or two such groups in a macrocyclic ring; only for [2,2]metacyclophane [198] has the conformation been established by X-ray methods and shown to have the centrosymmetrical *anti*-structure *(27)* (Fig. 39) and not *syn*; however,

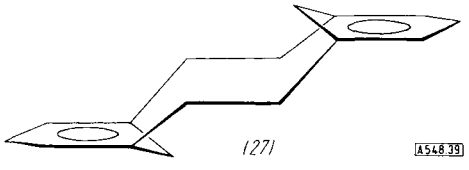

Fig. 39. Crystal structure of [2,2]metacyclophane [198].

this 10-membered ring is too rigidly strained (deformed benzene rings) to illustrate any general principle. The closest transannular distance between aromatic carbon atoms is only 2.69 Å, compared with 3.4 Å for graphite. Similar centrosymmetric conformations have been found for the 4,12-dimethyl derivative [199] and the analogous diaza derivative, di(pyridine-2,6-dimethylene) [200].

The *p*-phenylene group is linked linearly like the acetylene and diacetylene groups. Again, the known rings containing one such group, the [*n*]paracyclophanes, are liquids as are the cycloalkynes [10]. The smallest member known, the [8]paracyclophane [201], has its benzene ring bent from the planar configuration, as evidenced by the abnormal ultraviolet spectrum. The [9]paracyclophane [202] and higher homologues [203] have more normal spectra; nevertheless, even [10]- and [12]paracyclophane have slightly bent benzene rings [204]. The short saturated chain in these lower members stretches over and is in close contact with one face of the aromatic ring, as shown by the shift of the NMR signals of the $CH_2$-groups by the ring current in [9]- and [10]-paracyclophanes [205,206] and, less, in [12]paracyclophane [205], and by transannular reactions on solvolysis of [9]paracyclophane tosylates [206]. The rigidity of these structures is also demonstrated by the resolution [207] of an aromatic carboxylic acid derivative of [10]paracyclophane into the optical antipodes.

With two *p*-phenylene groups placed diametrically, the [*n*,*n*]paracyclophanes, an expected conformational stability for odd *n*, and instability for even *n*, is borne out by the observed [208] melting point alternation for $n > 3$ (Fig. 40) in complete analogy with the diametrical

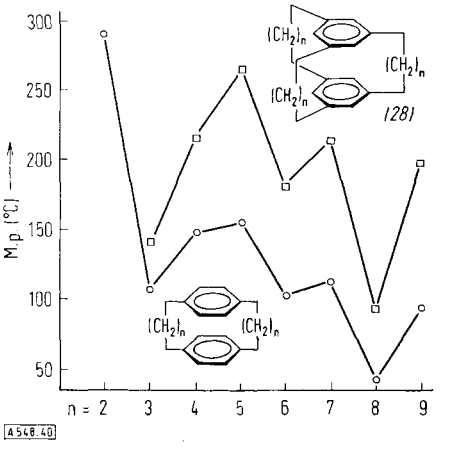

Fig. 40. Melting points of [*n*,*n*]paracyclophanes (lower curve) and of cage compounds of the type *(28)*, in which two benzene rings are symmetrically linked *via* three methylene bridges (upper curve) [208]. Abscissa: Number of $CH_2$ groups between the benzene rings.

cycloalka-diynes and -tetraynes (Fig. 32). Although the polymethylene chains do not need to have the maximal number of *anti*-bonds (cf. the acetylenic counterparts already discussed), this is nevertheless indicated to be the case by the similarity with the melting point curve of the multimacrocyclic cage analogues *(28)* (Fig. 40) [208], which have three equivalent polymethylene bridges linking two benzene rings in 1,3,5-position, since here no alternative strain-free conformation for even *n* with extra *gauche* bonds is possible. Further, in NMR spectra only the $\gamma$ and $\delta$ $CH_2$ groups show an abnormal chemical shift; when the chains are straight, these are the only ones that can direct their protons in between the two benzene rings. The crystal structure is known only for the two lowest members of the [*n*,*n*]-paracyclophanes ($n = 2$ and 3), but these are severely strained, as evidenced by the anomalous ultraviolet and infrared spectra [203,209]; the two aromatic rings avoid

coming too close by bending into a boat shape. In the case of [2,2]paracyclophane the molecule has really no freedom to choose, and the crystal structure, *(29)* (Fig. 41)[210], is as expected; it demonstrates, however,

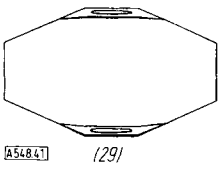

Fig. 41. Crystal structure of [2,2]paracyclophane [210].

that the strain is well distributed over the whole molecule and that the distance between the two aromatic planes, which is normally 3.4 Å (graphite), is here 3.09 Å in the middle and only 2.83 Å between linked atoms. The [3,3]paracyclophane has somewhat more freedom, and the strong $\pi$-electron repulsion causes the aromatic rings not only to bend but also to be displaced from a centered position, *(30)* (Fig. 42)[211]. When the

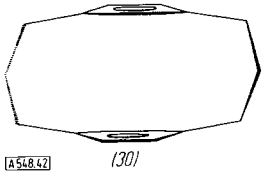

Fig. 42. Crystal structure of [3,3]paracyclophane [211].

repulsion is diminished by complex formation on one side[212], the structure presumably falls back into the centered position whereby bond angle strain is released; this is assumed[212] to be the driving force for the exceptionally strong tendency of *(30)* for complex formation with tetracyanoethylene.

A large number of other (unsymmetrical) paracyclophanes have been prepared by *Cram et al.*, and their physical properties studied, but information of conformational interest is limited to the distance between the two benzene rings. In the case of [1,*n*]paracyclophanes the synthetically available member[213] with the shortest polymethylene chain linking the 4- and 4'-positions of the diphenylmethane group is the one with $n = 7$, but spectral anomalies[213] appear also for $n = 8$ and 9 and are noticeable even for $n = 12$, indicating that the saturated chain draws the two benzene rings closer together and even deforms them. The limiting ring size for restricted rotation of the phenylene group in paracyclophanes is indicated by the resolution[214] of an aromatic carboxylic acid derivative of [3,4]paracyclophane and the failure to resolve[214] the corresponding derivative of [4,4]paracyclophane.

Ring systems composed of several different chemical groups (aromatic nuclei, multiple bonds, carbonyl groups, heteroatoms, *etc.*) have been extensively studied. However, such chemical and spectroscopic studies have been concerned mainly with the stereochemistry of *parts* of the ring, for example the question of planarity of chromophoric conjugated groups, or with transannular interactions of two such groups, or with the dependence of synthetic yield and resolvability on ring size, and no conclusions about the shape of the whole ring as such have been drawn.

Some X-ray results of such compounds merit mention; thus, the crystal structure of 1,2;7,8-dibenzocyclododeca-1,7-diene-3,5,9,11-tetrayne[215] reveals clearly curved diacetylene groups and well distributed angle strain, and the diolefin of [2,2]paracyclophane has a structure[216] strikingly similar to that of the parent compound *(29)*[210]. Of particular interest is the crystal structure of rifamycin B[217,218], in which an aliphatic bridge containing a diene conjugated with an amide group, an enol, and various substituents, spans over a naphthalenic system. Here again, abnormal chemical shifts of the NMR signals of two $CH-CH_3$ groups indicate that these are influenced by an aromatic ring current. The crystal structure[217] also reveals planar *anti*-amide groups, a correct stereochemistry next to double bonds, and a planar *transoid cis,trans*-diene. The latter feature seems to be general with such rings; thus, conjugated diene systems formed in the isomerization of macrocyclic hydrocarbons containing a phenylene group and two triple bonds prefer the *cis, trans*-configuration and the *anti*-conformation[219].

Several porphins have been examined by X-ray methods; perhaps unexpectedly, almost all of them show deviations from planarity attributable to steric hindrance. It has also been concluded[220] that these ring systems must be quite flexible, since the triclinic[220] and tetragonal[221] crystal forms of tetraphenylporphin have different conformations; the copper salt also is non-planar[222]. Similarly, nickel etioporphyrin I is non-planar[223], while nickeletioporphyrin II is flat[224]. The related phthalocyanines are planar[225].

The crystal structure of cyclotetramethylene tetranitramine[226] shows this molecule to contain an 8-membered puckered centrosymmetric ring, but this structure is too unusual to justify further discussion.

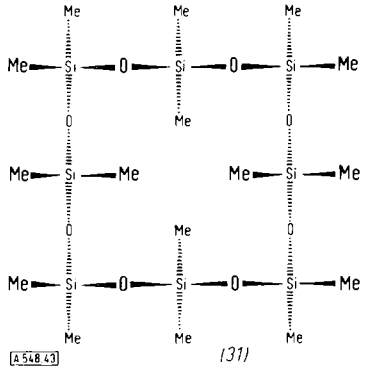
The term "inorganic ring" is limited here to compounds whose molecular entity is preserved in solution and which do not contain carbon as a ring member but may contain organic groups as substituents. A wide variety of such compounds is known [227]; interestingly, there is a natural tendency not only for the formation of 6-membered rings, but also a preference for 8-membered rings not paralleled in organic ring systems. Both planar and chair-shaped 6-membered inorganic rings are known [227], and even chair-shaped isocyclic hexamers of sulfur [24] and of diphenyltin [228] have been described.

Among the 8-membered rings, the crystal structure of orthorhombic sulfur, $S_8$ [229], as well as of the aza-derivatives heptasulfurimide $S_7NH$ [230], hexasulfurdiimide$(S_3NH)_2$ [230] and tetrasulfurtetraimide $(SNH)_4$ [231] reveal closely similar crown conformations with dihedral angles of 99 °, much wider than in open chains [28]. On the other hand, when the nitrogen atoms carry no hydrogen, as in sulfur nitride, $(SN)_4$ [232], the ring "chooses" a saddle conformation with the nitrogen atoms at the "corners" and dihedral angles close to 60 °, but the valence description of this structure poses problems [232]. With a fluorine substituent on each sulfur atom, as in tetrathiazyl fluoride, $(NSF)_4$ [233], the ring assumes again a saddle conformation, but this time with the sulfur atoms at the corners, and the SN bonds are alternately long and short. With only tetrahedrally linked ring atoms, as in cyclic oligomers of dimethyl(phosphino)borine, the situation is less confusing; thus the trimer [234] is a chair-shaped 6-membered ring and the tetramer [235] a saddle-shaped 8-membered ring with phosphorus at the corners, suggesting normal staggered single BP bonds.

Eight-membered rings containing alternating silicon and oxygen (cyclosiloxanes), silicon and nitrogen (cyclosilazanes), or phosphorus and nitrogen (cyclophosphonitriles) as ring atoms, do not seem to prefer definite conformations, in keeping with the extreme flexibility [236] of such chains. Thus, the crystal structure of octamethyl cyclotetrasiloxane [237] reveals a centrosymmetric 8-membered chair, while the analogous crystalline octamethyl cyclotetrasilazane [238] is a mixture of two conformations, one being identical with the above chair, the other something between a saddle and a boat. Octamethylcyclotetraphosphonitrile [239] approaches a perfect saddle with the phosphorus atoms at the corners, as does the analogous octakis(dimethylamino)cyclotetraphosphonitrile [240] [*], while the tetrameric phosphonitrilic chloride [241] has a more flattened ring intermediate between a boat and the above type of saddle. The corresponding fluoride [242] finally is planar or close to planar; in this latter case another crystalline form exists at low temperature [242].

Since the above data suggest a certain tendency for these ring bonds to be "staggered" and for bulky substituents to prefer corner positions, it is of interest to examine whether the conformations of larger rings can also be derived from the diamond lattice [10]. It turns out that three-atom bridges are required, not only in order to have the substituted atoms (Si, P) at corner positions, but also because the "hole" is needed to accommodate substituents from those Si or P atoms which are not at the corners. This type of conformation becomes first possible for 16-membered rings (octamers), and it is gratifying to find that this is exactly the conformation



(31)

Fig. 43. Crystal structure of hexadecamethylcyclooctasiloxane [243].

established by X-ray methods [243] for hexadecamethylcyclooctasiloxane *(31)* (Fig. 43). Analogous conformations are possible for 20-, 24-, *etc.* membered rings, but not for 14-, 18-, 22-, *etc.* membered ones, so that a melting point alternation would be expected. In the series of cyclic phosphonitrile fluorides [236] (Fig. 44) such an alternation is observed, but the alternation continues also to the lower members both in this series and for the cyclic phosphonitrilic chlorides [244] and the cyclic

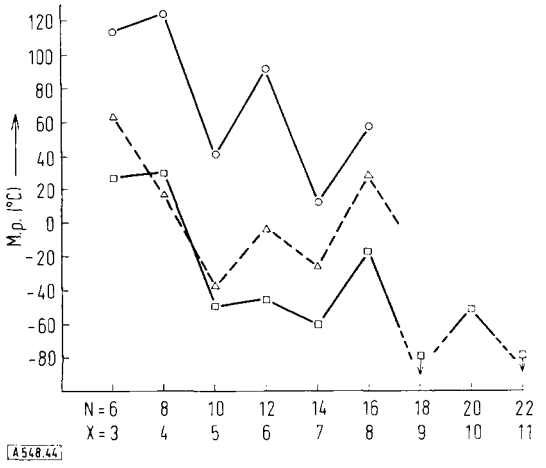

Fig. 44. Melting points of (o) cyclic phosphonitrile chlorides [244], of (□) cyclic phosphonitrile fluorides [236], and of (Δ) cyclic dimethylsiloxanes [245].

Abscissa: Upper row, total number of ring members, $N$; lower row, number of monomer units, $X$.

dimethylsiloxanes[245] (Fig. 44)[*]. This is somewhat surprising, since an analogous conformation for the 12-membered ring would have a severe transannular interaction. The striking similarity between the melting point curves in Fig. 44 may be a suggestion of isoelectronic structures, that is, tetrahedral positively charged phosphorus and "tetrahedral" negatively charged nitrogen. The additional ionic bonding might explain the shortening of the otherwise identical P–N bonds without hindrance to the almost "free" rotation which is suggested by the extreme flexibility[236,246] of these compounds. The bonding in cyclic phosphonitrile halides has for a long time remained controversial; the suggestion of electron delocalization and aromatic character[247] has been vigorously contested[248,249], one of the main counter-arguments being constancy[236,244,249] of the far-ultraviolet absorption along each of these series.

# Inorganic, Organometallic, and Organic Analogues of Carbenes

BY DR. O. M. NEFEDOV AND (IN PART) DR. M. N. MANAKOV [*]

N. D. ZELINSKII INSTITUTE OF ORGANIC CHEMISTRY OF THE USSR ACADEMY OF SCIENCES, MOSCOW (USSR)

*This review deals with inorganic, organometallic, and organic compounds, as well as with elements, that on the basis of their electronic structure and their reactions can be regarded formally as analogues of carbenes. These "carbene analogues" include in particular the compounds of monovalent boron, aluminum, nitrogen, and phosphorus; those of divalent silicon, germanium, tin, and lead; atomic oxygen; atomic sulfur; and atomic selenium. The preparation and chemical properties of the carbenes and their analogues are compared.*

## 1. Introduction

The chemistry of carbenes has undergone a remarkable development in recent years[1–6]. The unusual reactions of these compounds are attributable to the fact that they contain a carbon atom with a sextet of electrons, two of which do not participate in the bonding. Depending on the preparation of the carbenes, these electrons may be in the unpaired (triplet) or paired (singlet) state. Owing to the unsaturation, most carbenes are electrophilic[7]. By addition of two electrons to complete the octet, the carbene carbon atom reverts to the tetravalent state, with formation of one ($sp^2$) or two ($sp^3$) new bonds.

[5] *W. Kirmse*: Carbene Chemistry. Academic Press, New York-London 1964.

[6] *J. Hine*: Divalent Carbon. Ronald Press, New York 1964.

[7] Some so-called nucleophilic carbenes appear to be exceptions; see, *e.g.*, *H.-W. Wanzlick*, Angew. Chem. *74*, 129 (1962); Angew. Chem. internat. Edit. *1*, 75 (1962); *W. Kirmse*, Liebigs Ann. Chem. *666*, 9 (1963).

Many other elements have an electronic structure similar to that of carbene carbon atoms. *Volpin et al.* [8] characterized the "electronic analogue" of the carbenes by the following criteria:

1. At least one lone pair of s or p electrons (or two unpaired electrons) on the central atom;

2. at least one unoccupied p orbital (or two electrons in two p orbitals);

3. no unoccupied d level with a quantum number lower than that of the valence p electrons.

These features are found in the elements of Groups II and VI of the periodic system, as well as in compounds of the monovalent elements of Groups III and V, the bivalent elements of Group IV, and a few cations (*e.g.* $R_2N^+$, $RO^+$, $RS^+$, $Cl^+$, $Br^+$. However, many of the molecules and atoms mentioned react quite differently from the carbenes, whose characteristic property is the formation of one ($sp^2$) or two ($sp^3$) new covalent bonds. This chemical property will be regarded as a fourth criterion for carbene analogues.

For example, all cations of the types $R_2N^+$, $RO^+$, $Cl^+$ simply form a single ($sp^3$) covalent bond by accepting a pair of electrons from another atom or ion. These cations cannot be regarded as carbene analogues. The metals of Group II again satisfy only the first three conditions. They react with acids and halogens to form ionic salts. The metal M loses the valence electrons to form the cation $M^{2+}$, a reaction not observed with carbenes. Though Mg, Ba, and Ca react with aryl and alkyl halides to form compounds RMHal, corresponding to the insertion of carbenes into the C–Hal bond, the similarity is purely formal.

Thus of the numerous electronic analogues of carbenes, practically only a few compounds of elements of Groups III to V and the elements of Group VI in the atomic state remain as "chemical" analogues of carbenes. The present review deals with the preparation and properties of these compounds, and reactions that could proceed *via* such carbene analogues are also discussed.

## 2. Carbene Analogues with Elements of Group III

### a) Boron Compounds

Carbene analogues of the type :BR (R = halogen or H) are formed when energy is supplied to compounds of trivalent boron. For example, the action of a high-voltage or high-frequency electric discharge on $BCl_3$ vapor, without [9,10] or with added inert gas (argon, helium) [11], liberates :BCl, which was identified by its absorption and emission spectra. :BCl is formed also by UV discharge in $BCl_3$ [12,12a] and during flash photolysis of chlorides of trivalent boron, such as $BCl_3$, $B_2Cl_4$, or $(BCl)_4$ [13].

$$BCl_3 \xrightarrow{h\nu} :BCl + Cl_2$$

$$BCl_3 \xrightarrow[Hg]{h\nu} :BCl + HgCl_2$$

The :BCl liberated in this way has a life of about 0.01 sec [12], and can undergo insertion into the B–Cl bond as well as cyclopolymerization [13] and oxidation [12a].

$$BCl_3 + :BCl \underset{}{\overset{h\nu}{\rightleftharpoons}} B_2Cl_4$$

$$n{:}BCl \underset{}{\overset{h\nu}{\rightleftharpoons}} (BCl)_n$$

$$2{:}BCl + O_2 \longrightarrow 2\,BOCl \longrightarrow {}^2/_3\,(BOCl)_3$$

In the spontaneous dismutation of $B_2Cl_4$, which probably also proceeds *via* :BCl, *Urry et al.* [14] obtained not only the cyclotetramer $(BCl)_4$, but also stable free radicals of the composition $(B_{1.0}Cl_{0.9-1.1})_n$ and with a molecular weight of 650–750. These radicals are probably present as chains $\dot{Cl}B{-}(BCl)_{n-2}{-}\dot{B}Cl$.

By analogy with the formation of :BCl, it may be assumed that the polymers $(BH)_n$ formed by an electric discharge in diborane/hydrogen at a pressure of 10–15 mm Hg [15] result from the polymerization of borene, :BH.

$$B_2H_6 \longrightarrow [:BH] \longrightarrow 1/n\,(BH)_n$$

This assumption is supported by the formation of the analogous methylene ($:CH_2$) from hydrocarbons in an electric discharge [1].

The reaction of organoboron dichlorides $RBCl_2$ with alkali metals probably also proceeds *via* carbene analogues :BR. For example, when $C_6H_5BCl_2$ is heated with sodium, potassium, or a potassium-sodium alloy in toluene or xylene, the polymer $(BC_6H_5)_n$ ($n = 9$–12) is obtained [16], evidently from the initially formed monomeric phenylborene, $:BC_6H_5$.

$$C_6H_5BCl_2 \longrightarrow [:BC_6H_5] \longrightarrow 1/n\,(BC_6H_5)_n$$

The possibility of such a mechanism is suggested in particular by the formation of carbenes by the action of alkali metals on di-, tri-, and tetra-halogenomethanes [17].

### b) Aluminum Compounds

The monohalides of aluminum, :AlHal, are formed in the same way as :BCl when a UV discharge in a hydrogen discharge tube is passed through $AlBr_3$ vapor [12], or by a high-frequency discharge in $AlCl_3$, $AlBr_3$, or $AlI_3$ vapors [10]. The lifetime of :AlBr is approximately 0.01 sec [12].

## 3. Carbene Analogues with Elements of Group IV

### a) Silicon Compounds

The compounds of bivalent silicon and germanium are of great interest from the point of view of carbene chemistry. In contrast to halogenocarbenes, which are readily formed by the action of strong bases (ROM or RLi) on halogenomethanes[4], :SiHHal and :$SiHal_2$ cannot be prepared from $H_2SiHal_2$, $HSiHal_3$, or $SiHal_4$. These compounds give products formed by nucleophilic substitution of the halogen and even of the H atoms by the group RO or R of the reagent used, probably due partly to the fact that the Si–H and C–H bonds are polarized in different directions (*e.g.* $\overset{\delta\ominus}{H}-\overset{\delta\oplus}{SiCl_3}$ and $\overset{\delta\oplus}{H}-\overset{\delta\ominus}{CCl_3}$) and partly to the stronger ionic character of the Si–Hal bond[18].

Whereas $CH_4$ and $CCl_4$ decompose into carbon and hydrogen or chlorine at 800–900 °C, $SiCl_4$ at 900 °C gives a gas mixture with an intense absorption maximum at 3150 Å. Similar spectra are given by $SnCl_2$ and $PbCl_2$ ($\lambda_{max}$ = 3100 Å). From these observations and from thermodynamic calculations, it was concluded[19] that $SiCl_4$ decomposes to :$SiCl_2$ and chlorine. Similarly, :$SiCl_2$ is formed from $SiCl_4$ and silicon at high temperatures[19]; it reacts further with silicon to SiCl.

$$SiCl_4 + Si \xrightarrow[800\,^\circ C]{} 2:SiCl_2 \xrightarrow[1150\,^\circ C]{2\,Si} 4\,SiCl$$

The formation of a mixture of lower silicon chlorides, *e.g.* of average composition $SiCl_{2.61}$, when silicon and tetrachlorosilane are heated together to about 1000 °C was observed by other authors[20]. *Schäfer* and *Nickl*[21] showed by kinetic and thermodynamic studies that the reaction of $SiCl_4$ with Si begins at 800 °C and is reversible. The heat and entropy of formation of gaseous :$SiCl_2$ are 29.9 kcal/mole and 71.1 cal $mole^{-1}\,deg^{-1}$, respectively, at 298 °K[21]. The intermediate formation of :$SiCl_2$ is the basis of most high-temperature methods for the preparation of chlorosilanes and organochlorosilanes from silicon or its alloys[22–24]. Under the conditions used, the silicon dichloride readily undergoes insertion into chemical bonds, such as H–Cl, C–Cl, or Si–Cl bonds to give compounds of tetravalent silicon.

For example, the high-temperature process for the preparation of chlorosilanes from carborundum (SiC) and $SiCl_4$ vapor diluted with a carrier gas such as $H_2$ or $N_2$ is based on the reactions[22]:

$$SiCl_4 + H_2 \rightleftharpoons :SiCl_2 + 2\,HCl$$
$$SiCl_4 + SiC \rightleftharpoons 2:SiCl_2 + C$$
$$HCl + :SiCl_2 \longrightarrow HSiCl_3$$
$$H_2 + :SiCl_2 \longrightarrow H_2SiCl_2$$
$$SiCl_4 + (n-1):SiCl_2 \longrightarrow Si_nCl_{2n+2}$$

For the preparation of higher chlorosilanes $Si_nCl_{2n+2}$, the reaction mixture must be quenched, since :$SiCl_2$ disproportionates on slow cooling to Si and $SiCl_4$[21].

The "direct" synthesis of trichlorosilane and organochlorosilanes from silicon and hydrogen chloride or organic chlorides also proceeds *via* :$SiCl_2$[23,24]. On the basis of the rate of formation of $HSiCl_3$ from Si and HCl and of the influence of the addition of HCl on the "direct" synthesis of methylchlorosilanes, *Joklik* and *Bažant*[24] proposed the following reaction scheme:

$$2\,HCl + Si \longrightarrow :SiCl_2 + H_2$$
$$HCl + :SiCl_2 \longrightarrow HSiCl_3$$
$$CH_3Cl + :SiCl_2 \longrightarrow CH_3\text{–}SiCl_3$$

Better yields of dialkyldichlorosilanes and alkyltrichlorosilanes are obtained in the "direct" synthesis when copper is added to the silicon[23]. This catalytic action is attributed[23] to the formation of cuprous chloride in the reaction zone; this reacts with silicon to form :$SiCl_2$, which is then converted into the organochlorosilanes:

$$CH_3Cl + Cu \longrightarrow CH_3Cl{\cdot}Cu$$
$$2\,CH_3Cl{\cdot}Cu \longrightarrow 2\,CuCl + CH_4 + C + H_2$$
$$Si + 2\,CuCl \longrightarrow :SiCl_2 + 2\,Cu$$
$$CH_3Cl{\cdot}Cu + :SiCl_2 \longrightarrow CH_3\dot{S}iCl_2 + CuCl$$
$$CH_3Cl{\cdot}Cu + CH_3\dot{S}iCl_2 \longrightarrow (CH_3)_2SiCl_2 + CuCl$$
$$CH_3Cl{\cdot}Cu + :SiCl_2 \longrightarrow CH_3SiCl_3 + Cu$$

The above scheme is confirmed by the increase in yield of $(C_2H_5)_2SiCl_2$ from $C_2H_5Cl$ and silicon when small quantities (*ca.* 2%) of CuCl are added to the silicon, and by the increase in yield of $C_2H_5SiCl_3$ when larger quantities ($\gg$2%) of CuCl are added[24].

The feasibility of the formation of :$SiCl_2$ under the conditions of the "direct" synthesis (300–400 °C) was confirmed by thermodynamic calculations[23,25]. :$SiCl_2$ has been detected by mass spectrometry in the gaseous products of the reaction of Si with CuCl at 180–200 °C[25].

According to thermodynamic calculations and kinetic measurements, :$SiCl_2$ also occurs as an intermediate in the preparation of Si by reduction of tri- and tetrachlorosilanes with hydrogen at 1000–2000 °K[26].

Whereas carbenes readily form dimers, no dimerization has been observed in the case of :$SiCl_2$, which telomerizes or polymerizes in the absence of electron acceptors. For example, $Si_{10}Cl_{22}$, $Si_{20}Cl_{42}$, and $Si_{25}Cl_{52}$ were obtained[27] by the decomposition of $SiCl_4$ in an atmosphere of nitrogen or hydrogen at 1000–1250 °C.

$$n\,SiCl_4 \longrightarrow n\,[:SiCl_2] \xrightarrow{SiCl_4} Cl_3Si\text{–}(SiCl_2)_n\text{–}Cl$$

In addition to $SiCl_4$, $H_2$ can also act as a telogen in this reaction, as is shown by the formation of $Si_{10}Cl_{20}H_2$

and $Si_5Cl_{10}H_2$ from $SiCl_4$ in an atmosphere of hydrogen at 1150 to 1250 °C [27,28].

Similar polychlorosilanes having the composition $SiCl_{2.05-2.30}$, which may also be regarded as telomerization products of $:SiCl_2$ and $SiCl_4$ or $Si_2Cl_6$, are formed from hexachlorodisilane in the presence of trimethylamine or trimethylammonium halides at 80 to 100 °C [29] or in the presence of 2% of triethylamine in vacuum at room temperature [30].

$$n\,Si_2Cl_6 \xrightarrow[R_3N,\ R_3N\cdot HHal]{} Cl_3Si{-}(SiCl_2)_n{-}Cl + (n{-}1)SiCl_4$$

The thermal decomposition of $C_2H_5{-}SiCl_2{-}SiCl_3$ in the presence of $(CH_3)_3N{\cdot}HCl$ leads similarly to $(SiCl_2)_n$ and $C_2H_5{-}SiCl_3$ [29]; $(SiCl_{1.8})_n$ is formed when $Si_2Cl_6$ is heated with traces of $(C_2H_5)_3N$ [30]. The occurrence of $:SiCl_2$ as an intermediate in the decomposition of compounds of the type $RSiCl_2{-}SiCl_3$ (R = Cl or alkyl) is suggested not only by the composition of the resulting polymers, but also by the formation of dichlorocarbene when compounds of the type $RCCl_2{-}SiCl_3$ are heated [31].

The thermal reaction of $SiCl_4$ with Si has been used for the preparation of polymeric $(SiCl_2)_n$ ($n$ = 12–17) in the form of transparent, colorless or slightly yellow resins, which are readily soluble in organic solvents [32,33]. The probably cyclic $(SiCl_2)_n$ is formed above 900 °C, the yield and molecular weight increasing with rising temperature ($n$ increases from 12 at 900 °C to 16 at 1200 °C) [33]. The polymers prepared reduce $AgNO_3$ and $SbCl_3$ to the metals, and decompose to low molecular weight fragments $[(SiCl_2)_{n-a}$ to $:SiCl_2]$.

Similarly, when silicon tetrabromide is passed over silicon at 1200 °C in a high vacuum, the two substances form silicon dibromide $:SiBr_2$, which has been isolated in the polymeric form [34]. Reduction of the polymeric $(SiBr_2)_n$ with $LiAlH_4$ led to polymeric silylene $(SiH_2)_n$; alkylation with alkylmagnesium bromides gave polydialkylsilylenes $(SiR_2)_n$ (R=$CH_3$, $C_2H_5$, n-$C_3H_7$, or n-$C_4H_9$); and hydrolysis gave a polymeric acid of average composition $Si(OH)_{2.2}$.

Silicon difluoride can be prepared similarly to $:SiCl_2$ and $:SiBr_2$. $SiF_4$ vapor is led through a quartz tube packed with silicon powder at 1150–1200 °C in a high vacuum (residual pressure 0.04–0.2 mm Hg) [35,36]. $:SiF_2$ can also be prepared from carborundum (SiC) or calcium silicide ($CaSi_2$). Silicon difluoride exists as the monomer at −196 °C. Above −80 °C it gives a plastic polymer $(SiF_2)_n$, where $n \leq 16$. The "half-life" of gaseous $:SiF_2$ at room temperature is *ca.* 150 sec., *i.e.* at least 100 times greater than that of most carbenes [36].

According to *Schmeisser* and *Ehlers* [37], however, silicon difluoride prepared in this way, both in the monomeric and polymeric states, contains appreciable quantities of oxygen (≈ 0.3 atoms per atom of Si) derived from the quartz. $:SiF_2$ that is completely free from oxygen is formed on pyrolysis (700 °C) of hexafluorodisilane in a high vacuum [37].

$$Si_2F_6 \longrightarrow :SiF_2 + SiF_4$$

Polymeric $(SiF_2)_n$ is also obtained by the action of magnesium on dibromodifluorosilane in ether [38]. Probably, free $:SiF_2$ is involved as an intermediate by analogy with similar reactions of $CF_2Br_2$ and $CF_3Br$ [39]. The $(SiF_2)_n$ polymer generates on heating in vacuum to 200–400 °C all perfluorosilanes from $SiF_4$ to $Si_{14}F_{30}$ and a $(SiF)_x$ polymer or silicon. With 20% aqueous hydrofluoric acid $(SiF_2)_n$ forms silanes from $SiH_4$ to at least $Si_6H_{14}$ plus much hydrogen [36].

$:SiF_2$ reacts with $BF_3$ or $BCl_3$ at liquid nitrogen temperatures to form insertion products of type $Hal_2B(SiF_2)_nHal$, where $n$ = 2–4 and Hal = F or Cl [39a]. Under the same conditions $:SiF_2$ inserts readily into C–F bonds of trifluoroethylene [39b] and of perfluorobenzene [39c].

$$F_2C{=}CHF + :SiF_2 \longrightarrow$$

$$F_2C{=}CHSiF_3 + \begin{matrix} F_3Si & H \\ & C{=}C \\ F & F \end{matrix} + \begin{matrix} F_3Si & F \\ & C{=}C \\ F & H \end{matrix}$$

$$2\,C_6F_6 + 3\,:SiF_2 \longrightarrow C_6F_5SiF_3 + C_6F_4(SiF_3)_2$$

Addition of $:SiF_2$ to ethylene, acrylonitrile, 2,3-dimethyl-1,3-butadiene, and tetrafluoroethylene has been effected at −196 °C, the reaction with the last of these compounds leading to a solid polymer containing $SiF_2{-}SiF_2{-}CF_2{-}CF_2$ groups [35,39b].

Reaction of silicon difluoride with ethylene gives, among other products, cyclic adducts and some $C_2H_4SiF_2$ [39b].

$$H_2C{=}CH_2 + :SiF_2 \longrightarrow$$

$$\begin{matrix} H_2C{-}SiF_2 \\ | \quad\ | \\ H_2C{-}SiF_2 \end{matrix} + \begin{matrix} & H_2 & \\ H_2C & C & SiF_2 \\ | & & | \\ H_2C & & SiF_2 \\ & C & \\ & H_2 & \end{matrix} + C_2H_4SiF_2$$

Benzene and toluene give with $:SiF_2$ compounds of type $ArH(SiF_2)_n$, where $n$ = 2 to 8, in particular bicycles with $(SiF_2)_3$ bridges [39c].

R = H, $CH_3$

Infrared studies of silicon difluoride and its reactions with $BF_3$, $O_2$, CO, NO, and other molecules in low-temperature matrices at 20–50 °K indicates the occurrence of a reactive species, probably $(SiF_2)_2$ [39d].

Polymeric silicon diiodide, $(SiI_2)_n$, a solid, amorphous, orange substance, was obtained [40] when $SiI_4$ was passed over silicon in a high vacuum at 800–900 °C (yield *ca.* 1%). A similar polymer, $(SiI_{2.2})_n$, which is insoluble in the common organic solvents was obtained in a yield of 60 to 70% when a glow discharge was passed through $SiI_4$ vapor in a high vacuum [40].

$$n\,SiI_4 \longrightarrow (SiI_{2.2})_n + 0.9\,n\,I_2$$

In a high vacuum at 220–230 °C, $(SiI_{2.2})_n$ changes into $(SiI_2)_n$, from which polymeric silicon mixed dihalides can be prepared by treatment with chlorine or bromine in benzene at −30 to +25 °C [40]:

$$(SiI_{2.2})_n \longrightarrow (SiI_2)_n + SiI_4 + Si_2I_6$$
$$(SiI_2)_n + Cl_2 \longrightarrow (SiClI)_n$$
$$(SiI_2)_n + Br_2 \longrightarrow (SiBrI)_n$$

The benzene-soluble polymer $(SiI_2)_n$ probably is also formed in the pyrolysis of $SiI_4$ in high vacuum at 800 to 900 °C [40].

High-temperature reactions of silicon tetrahalides with silicon and the pyrolytic decomposition of hexahalogenodisilanes $Si_2Hal_6$ or tetrahalogenosilanes $SiHal_4$ are general methods for the preparation of silicon dihalides, $:SiHal_2$. In contrast to $:SiHal_2$, dichlorocarbene cannot be prepared from $CCl_4$ and activated charcoal at 1200–1300 °C [41]. Kinetic investigation of this reaction with the aid of mass spectrometry shows that $:CCl_2$ does not occur as intermediate [42].

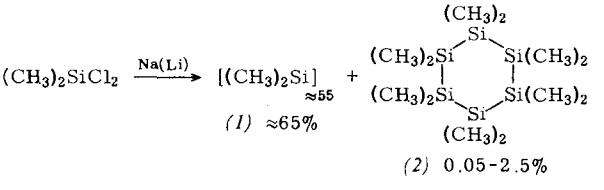
Silicon(II) dihalides are formed from halogen compounds of tetravalent silicon not only on heating, but also by the action of other sources of energy. For example, the telomers $Si_5Cl_{12}$ and $Si_6Cl_{14}$ have been prepared with the aid of a glow discharge in a mixture of gaseous $HSiCl_3$ and $H_2$ [43]. Passage of a mixture of $SiCl_4$ and $H_2$ through a glow discharge between Al electrodes (10000 V) in vacuum results in solid polymers of $(SiCl_2)_n$ and $(SiH_2)_n$ [43a]. On flash photolysis of $H_3SiCl$ or $H_3SiBr$, the fragments $:SiHCl$ or $:SiHBr$ occur in the absorption and fluorescence spectra in the region 4100 to 6000 Å [44].

Organic compounds of bivalent silicon and polymers thereof are obtained, unlike the halogen compounds, by reaction with metals. *Kipping et al.* [45] obtained polymers $[(C_6H_5)_2Si]_n$ from diphenyldichlorosilane and liquid sodium in the absence of solvents or in boiling toluene or xylene. *Gilman et al.* [46] later found that these products, which are also formed in the reaction of $(C_6H_5)_2SiCl_2$ with sodium, lithium, or magnesium in tetrahydrofuran, are essentially mixtures of the cyclopolymers $[(C_6H_5)_2Si]_n$ having $n = 4$ [47], 5, 6, and much greater than 6.

In our opinion the formation of these products may be attributed to cyclopolymerization of the intermediate diphenylsilylene which, unlike diphenylcarbene (formed *e.g.* from $(C_6H_5)_2CCl_2$ and lithium [17]), cannot dimerize. However, recent attempts [48] to identify $(C_6H_5)_2Si:$, which may be formed from $(C_6H_5)_2SiCl_2$ and lithium, by addition to cyclohexene were unsuccessful. [49].

Other diaryldichlorosilanes, *e.g.* $(p\text{-}CH_3\text{–}C_6H_4)_2SiCl_2$ [50], as well as phenoxydiphenylchlorosilane [51] react with sodium in the same way as $(C_6H_5)_2SiCl_2$.

Dialkyldichlorosilanes also react with alkali metals. Thus the reaction of $(CH_3)_2SiCl_2$ both with liquid sodium in benzene at 115–200 °C and *ca.* 16 atm [52] and with lithium in tetrahydrofuran at 250 °C and 50 atm [53] leads to a mixture of the polymer $[(CH_3)_2Si]_n$ *(1)*, where $n \approx 55$, with dodecamethylcyclohexasilane *(2)* [54].



*(1)* ≈65%

*(2)* 0.05–2.5%

The polydimethylsilylene $[(CH_3)_2Si]_n$ *(1)*, which is insoluble in organic solvents, and the cyclohexasilane *(2)* [54] were obtained in a total yield of 90–97% by the

[54] According to [53,60] the crystal form of *(2)* changes at 74 °C, and the compound sublimes above 120 °C, m.p. ≈140 °C. However, the publications [57,58] give m.p. 228–231 °C (with slight sublimation) and 248–250 °C (with preliminary heating of the block to 240 °C), respectively, in agreement with the data reported by *H. Gilman* and *R. A. Tomasi* [J. org. Chemistry *28*, 1651 (1963)].

reaction of $(CH_3)_2SiCl_2$ with lithium or sodium in tetrahydrofuran at atmospheric pressure between −60 and +70 °C[55–59]. This reaction yields linear and cyclic polymers in the ratio of from 9:1 to 1:3, depending on the conditions[57,58]. The reaction of dimethyldichlorosilane with an Na/K alloy in boiling tetrahydrofuran proceeds similarly (yield of *(1)* 13%, of *(2)* 81%[60].

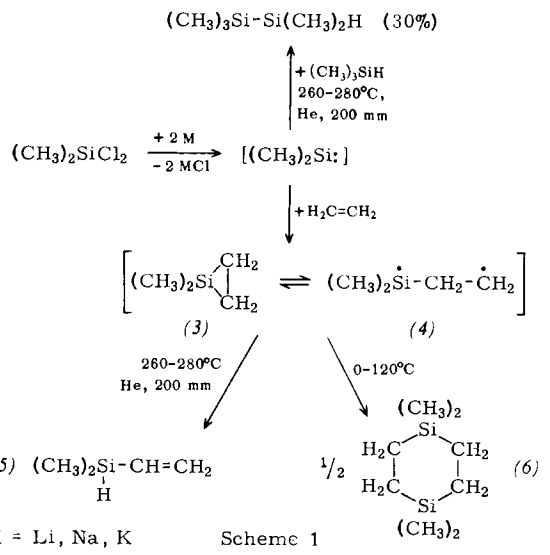
Similar products, *i.e.* the polymer $[(C_2H_5)_2Si]_n$, which is insoluble in organic solvents, and a crystalline cyclopolymer probably having the composition $[(C_2H_5)_2Si]_6$ or greasy or liquid polymers of the general formula $[(C_2H_5)_2Si]_n$, are formed in the reaction of $(C_2H_5)_2SiCl_2$ with lithium in tetrahydrofuran[56,58,59] or with sodium in boiling xylene[61] or toluene with added ethyl acetate[62].

By analogy with the reactions of halogenomethanes with lithium or lithium alkyls, in which carbenes are formed[63], $R_2Si$: is assumed to occur as intermediate in the reaction of dialkyldichlorosilanes with lithium or sodium[55,56,58,59].

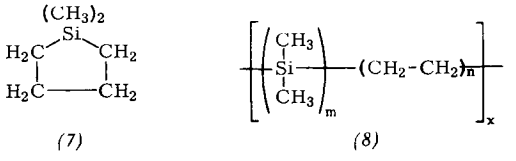
$$R_2SiCl_2 \xrightarrow[-LiCl]{2\ Li} R_2Si(Li)Cl \xrightarrow[-LiCl]{} [R_2Si:] \longrightarrow 1/n(R_2Si)_n$$

Scheme 1 shows a number of reactions that offer evidence of the intermediate formation of dimethylsilylene, $(CH_3)_2Si$:. These include the reaction of lithium with excess of dimethyldichlorosilane[64] and the addition of dimethylsilylene to trimethylsilane[65], to ethylene, and to a number of other olefins (isobutylene, 1-heptene, cyclohexene)[56,58,59,65,66].

The unstable primary products *(3)* and *(4)* can not only be stabilized by isomerization to form dimethylvinylsilane *(5)* or by dimerization to form the heterocycle *(6)*, but also by further reactions of *(4)* with ethylene

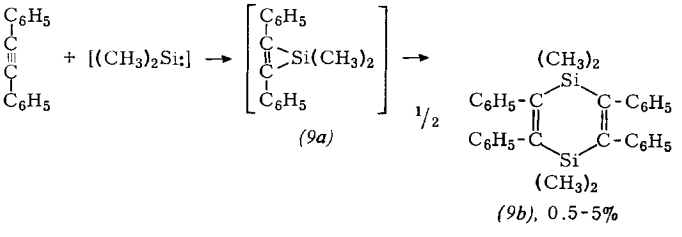


and dimethylsilylene to form 1,1-dimethyl-1-silacyclopentane *(7)* and a copolymer *(8)*, respectively.



The dimethylsilylene prepared in this way, which is probably in the singlet state, is characterized by low reactivity in electrophilic additions (*e.g.* the yields of *(6)*, *(7)*, and similar adducts are generally 2 to 10%). This can be attributed to the stabilizing influence of the unoccupied d orbitals of the silicon atom. In contrast to the alkylcarbenes, which very readily undergo the carbene-olefin or carbene-cyclopropane isomerization[5,61][*], dimethyl- and other dialkylsilylenes isomerize only to a maximum extent of 5% or not at all[57–59,65].

Dimethylsilylene is also assumed to be involved in the formation of the unsaturated heterocycle *(9b)*[67] from tolan, $(CH_3)_2SiCl_2$, and sodium in boiling xylene[8,68,69].



[*] The carbene-olefin and carbene-cyclopropane isomerizations may be illustrated by the equation

$$RR^1CH\text{-}CHR^2\text{-}\ddot{C}R^3 \longrightarrow RR^1CH\text{-}CR^2{=}CHR^3 + \begin{matrix} RR^1C\text{-}CHR^2 \\ \quad\ \diagdown C \diagup \\ \quad\ H \quad R^3 \end{matrix}$$

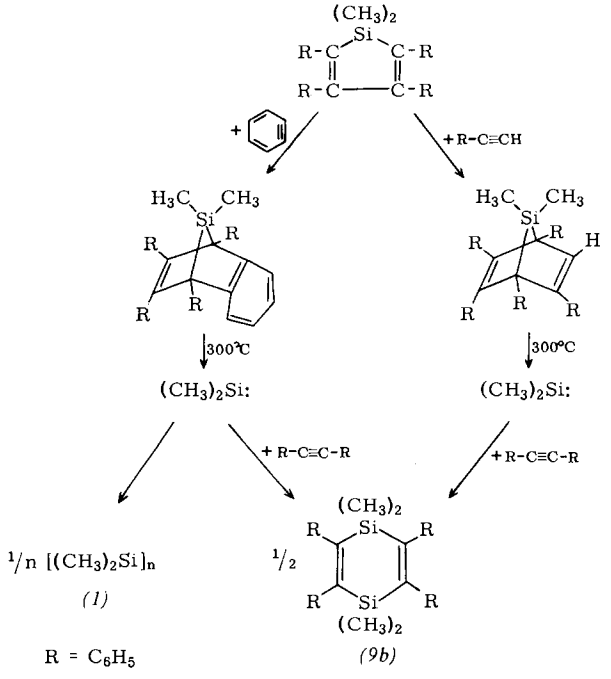
Monomeric and polymeric compounds of bivalent silicon can be obtained by the action of Grignard compounds having bulky substituents on bromosilanes [70].

$$2\,RMgBr + 2\,BrSiR'_3 \xrightarrow[-2MgBr_2]{} 2\,RSiR'_3 \xrightarrow[-R_2]{} R'_3Si{-}SiR'_3$$

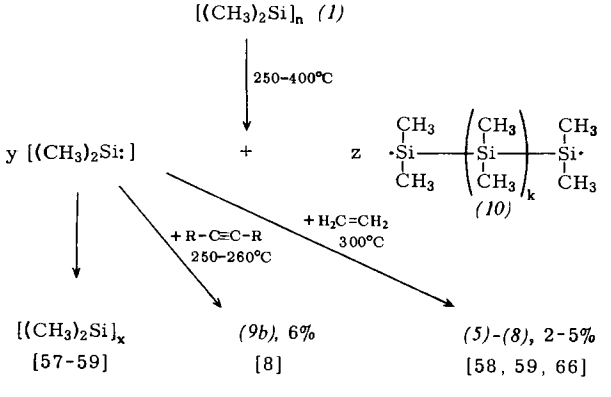
$$\xrightarrow[-R'_3SiR]{RMgBr} R'_3SiMgBr \xrightarrow[-R'MgBr]{} [:SiR'_2] \longrightarrow 1/n(SiR'_2)_n$$

R = sec-$C_4H_9$, tert-$C_4H_9$; R' = Br or R.

Dimethylsilylene was obtained [71] by thermolysis of adducts of 1,1-dimethyl-2,3,4,5-tetraphenyl-1-silacyclopentadiene with alkynes, *e.g.* benzyne or phenylacetylene.



The dimethylsilylene prepared in this way also adds to ethylene and other olefins to form heterocycles and linear hetero compounds of the type *(5)* to *(8)* [59]. Dimethylsilylene polymerizes to give, in the absence of acceptors, the polymer *(1)* [71]. Similarly diphenylsilylene was prepared from the adduct of 1,1,2,3,4,5-hexaphenyl-1-sila-2,4-cyclopentadiene with benzyne, and its polymerization and addition to tolan was achieved [71a].



R=$C_6H_5$

$0 \leqslant k < n$; $4 \leqslant x < n$

Dimethylsilylene probably is also formed, together with dimeric and polymeric biradicals *(10)*, in the pyrolysis of polymeric dimethylsilicon *(1)* in an inert atmosphere [8,57–59,66]. In the presence of acceptors (ethylene, tolan), adducts are formed; in the absence of acceptors, the biradicals recombine to give cyclic and linear polymer $[(CH_3)_2Si]_x$.

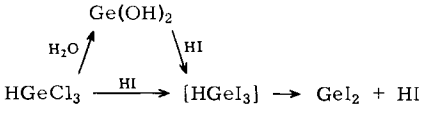
### b) Germanium Compounds

Germanium difluoride and particularly germanium diiodide, unlike the corresponding carbon and silicon dihalides, are stable even in the monomeric state. "Monomeric" here refers to the gaseous state; $GeI_2$ crystallizes in the brucite lattice, m.p. 48.5 °C. Solid $GeF_2$ is orthorhombic, m.p. 111 °C.

The classic preparation of germanium diiodide is the partial reduction of germanium tetraiodide with hypophosphorous acid [72] (75% yield):

$$GeI_4 + H_3PO_2 + H_2O \longrightarrow GeI_2 + H_3PO_3 + 2\,HI$$

$GeI_2$ is also formed [73] by the spontaneous decomposition of the unstable triiodogermane, which is prepared by exchange reactions from $HGeCl_3$ or its ether adducts [74].



Despite its stability, $GeI_2$ undergoes many reactions characteristic of carbenes and their analogues, though under more vigorous conditions. In particular, it inserts into C–I bonds [75–77]. This reaction is carried out in a sealed tube or in an autoclave.

$$Co_2(CO)_8 + GeI_2 \xrightarrow[THF]{\approx 20\,°;\ 10\ min} I_2Ge[Co(CO)_4]_2$$

$$RCH_2I + GeI_2 \xrightarrow[80–140\,°C]{} RCH_2GeI_3 \quad [75,76]$$

80–90%

$$C_6H_5I + GeI_2 \xrightarrow[160\,°C]{} C_6H_5GeI_3 \quad [76]$$

$$CF_3I + GeI_2 \xrightarrow[135\,°C]{} CF_3GeI_3 + (CF_3)_2GeI_2 \quad [77]$$

43% traces

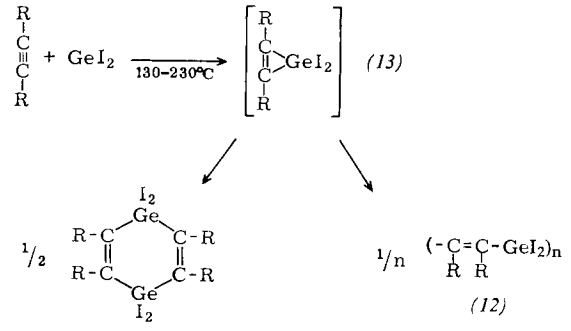
:$SiCl_2$ [78] and the carbenes, particularly methylene [79, 80], react similarly with organic halides. Germanium diiodide readily reacts with octacarbonyldicobalt [80a]:

$GeI_2$ also reacts with trialkyl- and triarylphosphines at about 130 °C to form adducts *(11)* that are formally analogous to phosphoranes [82].

$$R_3P + GeI_2 \longrightarrow R_3P{\cdot}GeI_2 \quad [81]$$
*(11)* R = alkyl, aryl

Like the dihalogenocarbenes [5,83], $GeI_2$ can add to CC triple bonds [8]. Like their silicon analogues [67] the germacyclopropenes *(13)* probably formed first are unstable and are converted into stable heterocycles *(14)* or polymers *(12)* [69,84].



R = H, $C_6H_5$

Nascent ethylene (liberated from 1,2-diiodoethane at 150 °C in a sealed tube) adds to $GeI_2$ to form a polymer $(CH_2{-}CH_2{-}GeI_2)_n$ [76].

$GeI_2$ can be added to isoprene and 2,3-dimethyl-1,3-butadiene in 1,4-position to form the corresponding heterocycles [84a]. This reaction with isoprene requires 3 hr at 60 °C, that with dimethylbutadiene is exothermic.

The stable monomeric germanium difluoride is obtained when germanium powder is heated with hydrogen fluoride (225 °C, 16 hours, 93% yield) [85].

$$Ge + 2HF \longrightarrow GeF_2 + H_2$$

$GeF_2$, like the silicon dihalides, also can be prepared from germanium and tetrafluorogermane at or above 100 °C [86].

$GeF_2$ readily forms the $GeF_3^{\ominus}$ ion and its salts, *e.g.* $CsGeF_3$ [85]. This formally corresponds to the equilibrium between dihalogenocarbenes and trihalogenomethyl anions [4,5]:

$$CHal_3^{\ominus} \rightleftharpoons :CHal_2 + Hal^{\ominus}$$

It is assumed [73] that germanium dibromide also exists as the monomer in solution. It is obtained in 56 to 65% yield by vacuum distillation of a solution of $HGeBr_3$ in aqueous hydrobromic acid or of a mixture with ether.

$GeBr_2$ can insert into polarized C-halogen bonds, and can add to CC triple bonds [73]:

$$H_2C{=}CH{-}CH_2Br + GeBr_2 \longrightarrow \underset{65\%}{H_2C{=}CH{-}CH_2{-}GeBr_3}$$

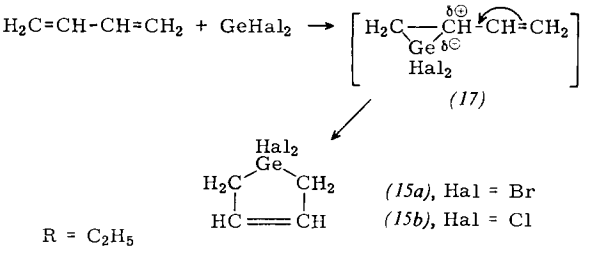
$$HC{\equiv}CH + GeBr_2 \longrightarrow 1/n(HC{=}CH{-}GeBr_2)_n$$

$GeBr_2$ reacts with butadiene at room temperature to give in 28% yield 1,1-dibromo-1-germa-3-cyclopentene *(15a)*, which is formally a 1,4-adduct [87]. Compound *(15a)* [73] or the dichloro derivative *(15b)* [74,88,89] is also formed when butadiene is passed through the ether adducts of tribromo- or trichlorogermane *(16)* [74]. The dichloro derivative *(15b)* is also formed, together with 2-butenyltrichlorogermane, by the reaction of butadiene with trichlorogermane [88,90]. The formation of germanium dihalides from trihalogenogermanes and particularly from their ether adducts *(16)* is attributable to the strong polarization of these compounds [74,89,91]. In addition to isomerization to the stable *(15)*, the unstable intermediate heterocycle *(17)* forms oligomers

$$HGeHal_3 \rightleftharpoons H^{\oplus} + GeHal_3^{\ominus}$$

$$[R_2O{\rightarrow}H{\cdots}OR_2]^{\oplus}GeHal_3^{\ominus} \rightleftharpoons [2\,R_2O{\cdot}H]^{\oplus} + GeHal_3^{\ominus}$$
*(16)*

$$GeHal_3^{\ominus} \rightleftharpoons GeHal_2 + Hal^{\ominus}$$



R = $C_2H_5$

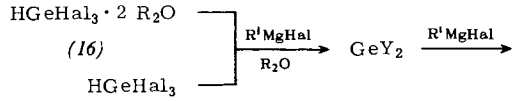
[91] Cf. method for the preparation of :$CHal_2$ by alkaline hydrolysis of $HCHal_3$ [4–6].

and polymers containing $CH_2-CH=CH-CH_2-GeHal_2$ units [88,89,92].

Trihalogenogermanes and their ether adducts react with other conjugated dienes to form similar compounds [90,92].

The ether adducts *(16)* have been found useful in many other reactions as sources of carbene-like compounds [74,89,90]. In particular, hydrolysis of *(16)* (and of $HGeHal_3$) leads to GeO or $Ge(OH)_2$. Organomagnesium and organolithium compounds cause the telomerization of germanium dihalides or their alkylation (arylation) products that is characteristic of carbenes and their analogues.

For example, the adducts *(16)* react with Grignard compounds to the polymers *(18)*.



$$R'-(GeY_2)_k-MgHal \xrightarrow[(R'Hal)]{R'MgHal} R'-(GeR'_2)_n-R' \quad [74,89]$$

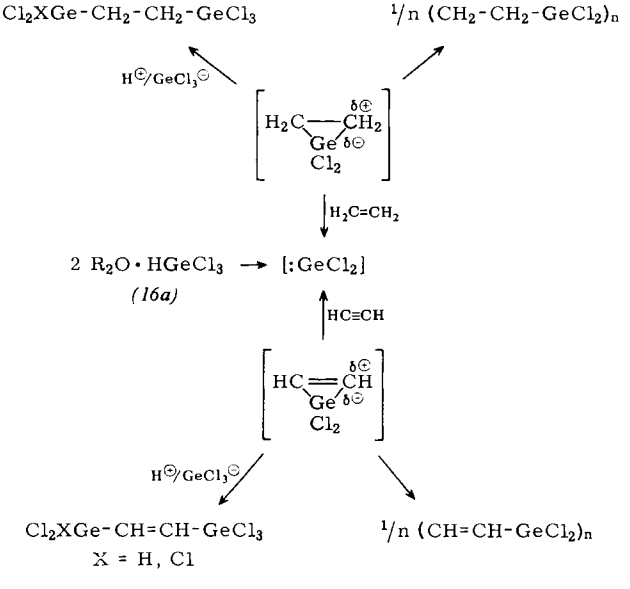
$R=C_2H_5$; $R'$ = Alkyl or Aryl; Hal = Cl, Br; Y = Cl, Br, Alkyl, or Aryl

The telomers *(18)* are formed also from $GeI_2$ and R'MgHal or R'Li [74,89].

The "carbene-like" character of the trihalogenogermanes, and in particular of their ether adducts *(16)*, is shown by their strong reducing action towards inorganic oxide salts and aromatic nitro compounds [74,93].

$GeCl_2$ is assumed to occur as an intermediate also in the reactions of trichlorogermane ether adducts *(16a)* with ethylene and acetylene [74,89,92]. Polymers containing $GeCl_2$ groups in the main chain are obtained also by the reaction of other olefins with $HGeCl_3$ in ether [92].

Corresponding to the preparation of $GeBr_2$ and $GeI_2$, germanium dichloride can be obtained from $HGeCl_3$ [94]



or its ether adduct [74,89], but only in the polymeric form. $(GeCl_2)_n$ is a solid which decomposes at about 140 °C. $(GeCl_2)_n$ and the monomeric germanium dihalides and their ether adducts dissolve readily in hydrochloric acid to form the trihalogenogermanes [74,89,95]. Germanium dichloride, probably also in the polymeric form, is formed when $GeCl_4$ vapor is passed over germanium powder at 350–430 °C [95].

Monomeric $GeCl_2$ in the form of its complex with dioxane, $C_4H_8O_2 \cdot GeCl_2$ is formed when trichlorogermane is mixed with dioxane [95a]. This complex reacts with 1,3-dienes, alkynes, benzyl chloride and other compounds similarly to the stable germanium dihalides and the ether complexes of trihalogermanes. $GeF_2$ forms the similar complex $(C_4H_8O_2)_x \cdot GeF_2$ ($x = 0.92–0.95$) with dioxane [85].

Chlorination of $(GeCl_2)_n$ leads to $GeCl_4$, hydrolysis to GeO, and the action of $H_2S$ to GeS. Heating yields subchlorides $(Ge_2Cl_3)_n$ and $(GeCl)_n$, or even Ge and $GeCl_4$ [74,95].

Unlike $GeF_2$, $GeBr_2$, and $GeI_2$, compounds of bivalent germanium with hydrogen or organic substituents are unstable in the monomeric state. $:GeH_2$ and $:GeR_2$ generally are liberated thermally or *via* organometallic compounds. For example, pyrolysis of the germanium hydrides $Ge_4H_{10}$ and $Ge_5H_{12}$ above 100 °C leads to germylene $:GeH_2$, which then polymerizes [96]. $:GeH_2$ and $(GeH_2)_n$ can be prepared also by reaction of bromobenzene with $NaGeH_3$ in benzene below −33 °C [97]. $NaGeH_3$ is obtained from $GeH_4$ and sodium in liquid ammonia.

$$NaGeH_3 + C_6H_5Br \longrightarrow [:GeH_2] \longrightarrow 1/n(GeH_2)_n$$

$$3(GeH_2)_n \xrightarrow[> 33\,^\circ C]{} n\,GeH_4 + 2(GeH)_n;$$

$$(GeH)_n \xrightarrow[180-300\,^\circ C]{} n\,Ge + n/2\,H_2$$

$(GeH_2)_n$, which is stable at room temperature, has also been prepared by reduction of tetrachlorogermane with $LiAlH_4$ in ether [98].

Dialkyl- and diarylgermanium dihalides $R_2GeHal_2$ react with alkali metals in the same way as $R_2SiHal_2$ to form linear and cyclic polymers $(R_2Ge)_n$. For example, $(C_6H_5)_2GeCl_2$ and sodium in boiling xylene give a cyclotetramer (35% yield) and a higher polymer (65% yield) [99].

The reaction proceeds probably *via* diphenylgermanium.

Diphenylgermanium may occur as an intermediate in the reaction of diphenyldichlorogermane with naphthalene-sodium in dimethoxyethane [99].

[97] *S. N. Glarum* and *C. A. Kraus*, J. Amer. chem. Soc. *72*, 5398 (1950).

[98] *E. D. Macklen*, J. chem. Soc. (London) *1959*, 1984; the yield of $GeH_4$ in this case was only 30%, whereas almost quantitative yields of $CH_4$ and $SiH_4$ are obtained under the same conditions from $CCl_4$ and $SiCl_4$, respectively.

[99] *W. P. Neumann* and *K. Kühlein*, Liebigs Ann. Chem. *683*, 1 (1965); further literature cited there.

$$(C_6H_5)_2GeCl_2 \longrightarrow [(C_6H_5)_2Ge:] \longrightarrow [(C_6H_5)_2Ge]_5 + [(C_6H_5)_2Ge]_6 + [(C_6H_5)_2Ge]_n$$
37% 17%

Dialkyldichlorogermanes react similarly with alkali metals. Thus reduction of $(CH_3)_2GeCl_2$ with lithium in tetrahydrofuran leads to dodecamethylcyclohexagermane *(19)* and a polymer *(20)* that is insoluble in the usual solvents [56–59, 100].

$$(CH_3)_2GeCl_2 \longrightarrow (CH_3)_2Ge(Li)Cl \longrightarrow [(CH_3)_2Ge:] \longrightarrow [(CH_3)_2Ge]_6 + [(CH_3)_2Ge]_n$$
*(19)* *(20)*

Under optimal conditions, the yields of *(19)* and *(20)* were as high as 70–80%. Monomeric dimethylgermanium was detected by the almost complete absence of low molecular weight polygermanes when lithium was added to a large excess of $(CH_3)_2GeCl_2$ [58] and by the addition of $(CH_3)_2Ge:$ to ethylene [56, 58, 59, 66].

Diethylgermanium $(C_2H_5)_2Ge:$ probably occurs as intermediate in the reaction of $(C_2H_5)_2GeCl_2$ with lithium in tetrahydrofuran, which leads mainly to insoluble polydiethylgermanium $[(C_2H_5)_2Ge]_n$ [58, 59]. Phenylgermanium chloride $C_6H_5(Cl)Ge:$ may be involved as intermediate in the reactions of $C_6H_5GeCl_3$ with alkali metals [101].

Polymers of bivalent germanium can be prepared by thermal or photochemical decomposition of polymeric germanium-mercury compounds [99].

$$(C_6H_5)_2GeH_2 + (C_2H_5)_2Hg \xrightarrow[-2\,C_2H_6]{} {}^1/_m \left( \begin{matrix} C_6H_5 \\ | \\ -Ge- \\ | \\ C_6H_5 \end{matrix} -Hg- \right)_m$$

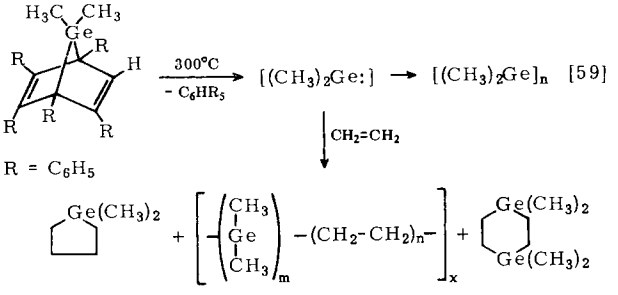
$$\xrightarrow[-Hg]{\Delta,\ h\nu} [(C_6H_5)_2Ge:] \longrightarrow [(C_6H_5)_2Ge]_4 + [(C_6H_5)_2Ge]_n$$
34% 66%

Neither $(C_6H_5)_2Ge:$ nor the polymers $[(C_6H_5)_2Ge]_n$ can be prepared by the action of $C_6H_5Li$, $C_6H_5MgBr$, or $(C_6H_5)_3Al$ on $GeI_2$. It must nevertheless be assumed that $(C_6H_5)_2Ge:$ is formed initially. Its formation is indicated in particular by the production of small quantities of triphenylgermane in the hydrolysis of $(C_6H_5)_3GeLi$, which was probably formed from $(C_6H_5)_2Ge:$ and $C_6H_5Li$ [102].

$$GeI_2 + 2\,C_6H_5Li \xrightarrow[-2\,LiI]{} [(C_6H_5)_2Ge:]$$
$$\downarrow C_6H_5Li$$
$$(C_6H_5)_3GeLi$$
$$\swarrow H_2O \qquad \searrow [(C_6H_5)_2Ge:]$$
$(C_6H_5)_3GeH$ Telomers

Diethyl- and di-n-butylgermanium is formed by the action of mercury dialkyls $R_2Hg$ on $GeI_2$ in ether [103]. However, these compounds immediately change into stable telomers.

Finally, $R_2Ge:$ can be obtained by thermal depolymerization of $(R_2Ge)_n$ [57–59, 66] and by pyrolysis of the phenylacetylene-germacyclopentadiene adduct [59].



### c) Tin Compounds

The halogen compounds of bivalent tin are obtained when tin is dissolved in halohydric acids [104]. They are stable in air.

$$Sn + 2\,HHal \longrightarrow SnHal_2 + H_2$$
Hal = Cl, Br, I

The difluoride is formed by the action of anhydrous hydrogen fluoride on tin [85] (8 hours at 200 °C). Tin diiodide can also be prepared from $SnCl_2$ and KI [104].

The unsaturated (carbene-like) character of the tin dihalides is shown in many addition reactions that are also characteristic of dihalogenocarbenes and their other analogues.

$$SnHal_2 + 1/2O_2 \longrightarrow OSnHal_2 \quad [105]$$

$$SnHal_2 + Hal_2 \longrightarrow SnHal_4 \quad [105]$$

$$SnI_2 + CH_3I \xrightarrow[4\ hr]{160\,^\circ C} CH_3SnI_3 \quad [106]$$
25%

$$2\,SnCl_2 + 2{:}CH_2 \longrightarrow 2\,[Cl_2Sn{=}CH_2] \xrightarrow{SnCl_2} 1/n(SnCl_2CH_2SnCl_2CH_2SnCl_2) \quad [105a]$$

$$\pi\text{-}C_5H_5Fe(CO)_2Cl + SnCl_2 \longrightarrow \pi\text{-}C_5H_5Fe(CO)_2SnCl_3 \quad [106a]$$

$$[\pi\text{-}C_5H_5Fe(CO)_2]_2 + SnHal_2 \longrightarrow [\pi\text{-}C_5H_5Fe(CO)_2]_2SnHal_2 \quad [106a, 106b]$$

$$[\pi\text{-}C_5H_5NiCO]_2 + SnCl_2 \xrightarrow[2hr,THF]{\approx 80°C} Cl_2Sn[\pi\text{-}C_5H_5NiCO]_2 \quad [106b]$$

$$[(C_6H_5)_3PCo(CO)_3]_2 + SnCl_2 \xrightarrow[THF]{\approx 80°C;\ 3\,hr} Cl_2Sn[(C_6H_5)_3PCo(CO)_3]_2 \quad [106b]$$

$$Co_2(CO)_8 + SnHal_2 \xrightarrow[THF]{\approx 20°C;\ 15\,min} Hal_2Sn[Co(CO)_4)_2 \quad [106b]$$

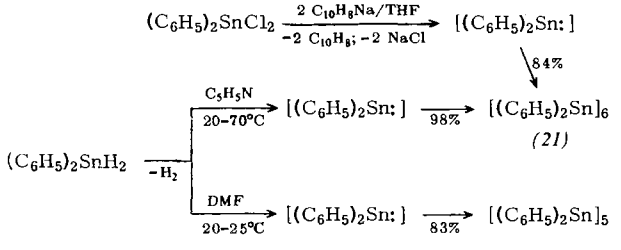
$SnCl_2$ and $SnBr_2$ can displace mercury from its dialkyl and in particular from its diaryl derivatives[107]:

$$R_2Hg + SnHal_2 \longrightarrow R_2SnHal_2 + Hg$$

$SnCl_2$ and its solutions in hydrochloric acid, as well as $SnCl_2$-ether adducts, have a strong reducing action towards inorganic salts, aromatic nitro compounds, and azides[93,107,108].

Preparation and properties of organic derivatives of bivalent tin have been reported by *Ingham et al.*[109] and by *Neumann*[110]. Dialkyl- and diaryltin, like their silicon and germanium analogues, are stable only in the polymeric form[110], although monomeric tin dialkyls and in particular monomeric diphenyltin were formerly thought to be fairly stable[111]. The polymeric nature of dibutyltin and diphenyltin has been deduced from the Mössbauer spectra[112].

The best methods for the preparation of cyclopolymers of diphenyltin $[(C_6H_5)_2Sn]_n$ are the catalytic decomposition of diphenyltin hydride in the presence of amines or amides[110, 113] and the action of naphthalenesodium on diphenyldichlorostannane[113].



Cyclohexamers of di-*p*-tolyl-, di-*p*-ethoxyphenyl-, di-*p*-biphenylyltin, and di-α- and di-β-naphthyltin have been obtained in high yields by catalytic decomposition of the corresponding diaryltin dihydrides[114].

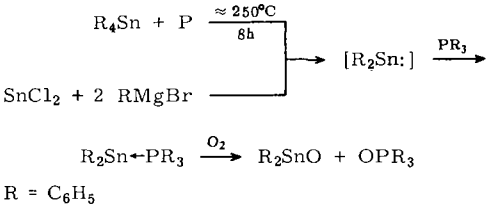
The cyclohexamer *(21)* is formed also by the action of alkali metals, zinc, or magnesium on $(C_6H_5)_2SnCl_2$ in tetrahydrofuran (yield 5–25%)[113]. However, the reaction of $C_6H_5MgBr$ with $SnCl_2$ in tetrahydrofuran leads to polymers *(22)* with $n = 13–14$, which are probably also cyclic[113]. The polymer *(22)* is formed also during the thermal dehydrobromination of diphenylbromostannane[115].

$$(C_6H_5)_2SnHBr \longrightarrow [(C_6H_5)_2Sn:] \longrightarrow 1/n[(C_6H_5)_2Sn]_n \quad (22)$$

Probably the cyclopolymers *(22)* readily undergo complete depolymerization. Their chemical properties show them to be typical carbene analogues. In particular, they are readily oxidized by atmospheric oxygen or hydrogen peroxide to $(C_6H_5)_2SnO$. They add sulfur and halogens to form $(C_6H_5)_2SnS$ and $(C_6H_5)_2SnHal_2$, respectively, and reduce $AgNO_3$ and $HgCl_2$ to the metals[109,113,116]. A particularly characteristic property of diphenyltin is its ability to undergo insertion into the S–S bond of dibenzyl disulfide[116]:

$$C_6H_5{-}CH_2{-}S{-}S{-}CH_2{-}C_6H_5 + 1/n[(C_6H_5)_2Sn]_n \longrightarrow (C_6H_5)_2Sn(S{-}CH_2{-}C_6H_5)_2$$

Like carbenes and other carbene analogues diphenyltin forms an easily oxidized complex $(C_6H_5)_2Sn{\cdot}P(C_6H_5)_3$ with triphenylphosphine[116a]:



Diphenyltin adds to compounds containing CC double bonds, *e.g.* tetrafluoroethylene[117].

$$x\,F_2C{=}CF_2 + x/n[(C_6H_5)_2Sn] \xrightarrow{h\nu} [(C_6H_5)_2Sn{-}CF_2{-}CF_2]_x$$

Diphenyltin, like carbene, can insert into C–Li bonds[109,118]:

$$SnCl_2 + 2\,C_6H_5Li \longrightarrow [(C_6H_5)_2Sn:] \xrightarrow{C_6H_5Li} (C_6H_5)_3SnLi$$

The tendency of polymeric diphenyltin to depolymerize and the biradical character of $(C_6H_5)_2Sn:$ are confirmed by the addition of free radicals[116,119].

$$(C_6H_5COO)_2 \xrightarrow{\Delta} 2\,C_6H_5COO\cdot \xrightarrow{2\,[(C_6H_5)_2Sn:]} \begin{matrix}(C_6H_5)_2Sn\text{-}Sn(C_6H_5)_2\\ C_6H_5COO\quad OCOC_6H_5\end{matrix} \quad [116]$$

$$(C_6H_5)_3C{-}N{=}N{-}C_6H_5 \xrightarrow{\Delta} C_6H_5\cdot \xrightarrow{[(C_6H_5)_2Sn:]} (C_6H_5)_3Sn\cdot \longrightarrow 1/2\,(C_6H_5)_3Sn{-}Sn(C_6H_5)_3 \quad [119]$$

$$C_6H_5{-}\underset{\underset{O}{\downarrow}}{\overset{\overset{\downarrow}{N}}{N}}{-}COCH_3 \xrightarrow{\Delta} C_6H_5\cdot + CH_3COO\cdot \xrightarrow{[(C_6H_5)_2Sn:]} 1/2\,(C_6H_5)_4Sn + 1/2\,(C_6H_5)_2Sn(OCOCH_3)_2 \quad [119]$$

Dialkyltin polymers are prepared like polymeric diaryltin, *e.g.* by reaction of alkylmagnesium halides or alkyl-lithium with tin dihalides[109,110,120] or with the ether adducts $2R_2O{\cdot}HSnCl_3$[89], by reaction of dialkyltin dihalides with alkali metals or organic bases[116]. Moreover, the formation of the cyclotetramer *(23)* has been observed during the reaction of excess of t-butylmagnesium chloride on t-butyltin chloride in boiling tetrahydrofuran[121].

$$(t\text{-}C_4H_9)_2SnCl_2 \longrightarrow \underset{(23)}{1/4[(t\text{-}C_4H_9)_2Sn]_4} \quad 56\%$$

The most suitable method for the preparation of dialkyltins is the catalytic or thermal dehydrogenation of the dialkyltin dihydrides; the degree of polymerization of the final product $(R_2Sn)_n$ in this case is mainly determined by the catalyst[110,120].

$$(C_2H_5)_2SnH_2 \xrightarrow[-H_2]{(C_2H_5)_2SnCl_2{\cdot}2\,C_5H_5N} [(C_2H_5)_2Sn:] \longrightarrow \underset{94\,\%}{1/9[(C_2H_5)_2Sn]_9} \quad [120]$$

$$(n\text{-}C_4H_9)_2SnH_2 \xrightarrow[-(CH_3)_2CHOH]{(CH_3)_2CO} (\text{or } \xrightarrow[-H_2]{100\,^\circ C}) \; [(n\text{-}C_4H_9)_2Sn:] \longrightarrow 1/n[(n\text{-}C_4H_9)_2Sn]_n \quad [122]$$

The preparation and decomposition of the dialkyltin dihydrides (and diaryltin dihydrides) can be carried out in a single process:

$$R_2SnCl_2 + 2(C_2H_5)_3SnH \xrightarrow[4-7\ hr]{100-120\,^\circ C} 1/n(R_2Sn)_n + 2(C_2H_5)_3SnCl + H_2 \quad [123]$$

R = $C_2H_5$, n-$C_4H_9$, $C_6H_5$.

Ethyltin bromide can be prepared similarly from $C_2H_5SnH_2Br$, the product again being polymeric[115].

The chemical properties of the tin dialkyls closely resemble those of the polymeric tin diaryls.

$$(R_2Sn)_n + n/2\,O_2 \longrightarrow n\,R_2SnO \quad [109]$$

$$[(C_2H_5)_2Sn]_9 + 9\,Cl_2 \xrightarrow[-70\,^\circ C]{} 9(C_2H_5)_2SnCl_2 \quad [120]$$

$$[(C_2H_5)_2Sn]_n + n\,HgCl_2 \longrightarrow n(C_2H_5)_2SnCl_2 + n\,Hg \quad [124]$$

$$[(C_2H_5)_2Sn]_n + n(C_6H_5)_2Hg \longrightarrow n(C_2H_5)_2Sn(C_6H_5)_2 + n\,Hg \quad [124]$$

$$[(C_2H_5)_2Sn]_n + n(C_6H_5COO)_2 \xrightarrow{\Delta} n(C_2H_5)_2Sn(OCOC_6H_5)_2 \quad [123]$$

R = Alkyl

Dialkyltin also readily inserts into C–Hal, Sn–Na, Sn–H, and apparently also Sn–Cl bonds.

$$[(C_2H_5)_2Sn]_n + nC_2H_5I \longrightarrow n(C_2H_5)_3SnI \quad [105]$$

$$[(n\text{-}C_4H_9)_2Sn]_n + n\,RHal \longrightarrow n\,(n\text{-}C_4H_9)_2Sn(Hal)R \quad [125]$$

R = n-$C_4H_9$, $C_6H_5$, $CH_2{=}CH{-}CH_2$, $C_6H_5{-}CH_2$; Hal = Br, Cl

$$[(CH_3)_2Sn]_n + n\,Na_2Sn(CH_3)_2 \longrightarrow n(CH_3)_2Sn(Na){-}Sn(Na)(CH_3)_2 \quad [126]$$

$$[(C_4H_9)_2Sn]_n + n\,H_2Sn(C_4H_9)_2 \longrightarrow n(C_4H_9)_2SnH{-}SnH(C_4H_9)_2 \quad [122]$$

$$(R_2Sn)_n + n\,R_2SnCl_2 \longrightarrow R_2SnCl{-}SnClR_2 \quad [116]$$

R = Alkyl or Aryl

In addition to the tin dialkyls and diaryls, many other organic and inorganic derivatives of bivalent tin have been prepared, mostly from tin dihalides, *e.g.*:

$$2SnBr_2 + 4NaOCH_3 \longrightarrow 2Sn(OCH_3)_2 \xrightarrow[-2\,HB(OCH_3)_2]{3\,B_2H_6} 2Sn(BH_4)_2 \quad [127]$$

### d) Lead Compounds

Lead dihalides should also exhibit properties of carbenes, but these should be much less pronounced than those of tin dihalides. For example, whereas chlorine adds irreversibly to $SnCl_2$ with formation of $SnCl_4$, $PbCl_4$ prepared similarly explodes spontaneously[104].

Organic derivatives of bivalent lead probably are formed in the reaction of Pb(II) salts with organometallic compounds.

$$PbCl_2 + 2\,CH_2{=}CH{-}CH_2{-}MgBr \longrightarrow (CH_2{=}CH{-}CH_2)_2Pb + MgCl_2 + MgBr_2 \quad [128]$$

$$Pb(NO_3)_2 + 2\,C_5H_5Na \longrightarrow (C_5H_5)_2Pb + 2\,NaNO_3 \quad [129]$$

$$PbCl_2 + 2\,ArMgBr \longrightarrow Ar_2Pb + MgCl_2 + MgBr_2 \quad [130,131]$$

$$PbCl_2 + 2\,C_6H_5Li \longrightarrow (C_6H_5)_2Pb + 2\,LiCl \quad [131]$$

Ar = $C_6H_5$, $CH_3{-}C_6H_4$

The compounds $R_2Pb$ formed under these conditions cannot generally be isolated, even as polymers, since they readily react further.

$$3\,R_2Pb \longrightarrow 2\,R_3Pb + Pb \; \textit{etc.}$$

$$2\,R_2Pb \longrightarrow R_4Pb + Pb \quad [128,131,132]$$

Reactions of $PbCl_2$ with organometallic compounds are used to prepare organic derivatives of quadrivalent lead [133], *e.g.*:

$$4\,C_6H_5Li + 2\,PbCl_2 \longrightarrow 2(C_6H_5)_2Pb \xrightarrow{2\,C_6H_5Li} 2\,(C_6H_5)PbLi$$

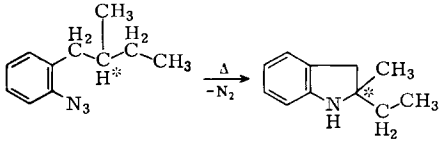
$$\xrightarrow{PbCl_2} [(C_6H_5)_3Pb]_2Pb \longrightarrow 1/2\,[(C_6H_5)_3Pb]_4Pb + 1/2\,Pb$$

## 4. Carbene Analogues with Elements of Group V

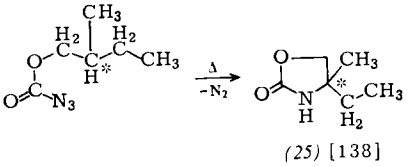
### a) Nitrogen Compounds

The compounds of univalent nitrogen, :NR or ·NR, which are known as imenes, nitrenes, or azenes, have been studied more fully than any other carbene analogues [134, 135]. Imenes and carbenes, which are prepared from azides and diazo compounds, respectively, were compared by *Kirmse* [136].

Of the more recent publications that were not mentioned in the reviews [134–136], we shall select only a few. Studies on intermolecular and intramolecular insertions of imenes into aliphatic C–H bonds were concerned with the direction and selectivities of these reactions, the relative reactivities of various imenes, and the optical activity of the resulting heterocyclic compounds, *e.g. (24)* and *(25)* [137, 138].

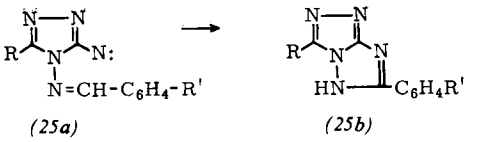


*(24)*



*(25)* [138]

The intramolecular cyclization of imene *(25a)*, formed by thermal decomposition of 3-azido-4-benzylideneamino-s-triazoles, gives triazolotriazoles *(25b)* [138a]:

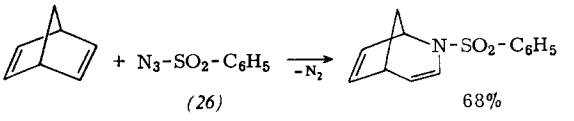


*(25a)* *(25b)*

R = H, $CH_3$, $C_2H_5$, $C_6H_5$; R′ = H, *p*-$CH_3$, *p*-$CH_3O$, *p*-Cl, *o*- and *p*-$NO_2$, *o*-$N_3$.

*Lwowski et al.* [138b] examined the stereospecificity of the addition of ethoxycarbonylimene to olefins.

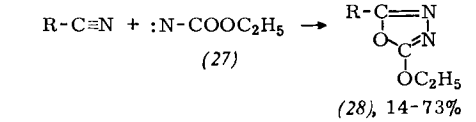
Phenylimene can insert into the Al–C bond [139]. Like the alkoxycarbonylimenes, it has a dehydrogenating and decarbonylating action on alcohols and aldehydes [140, 141]. An unusual reaction is that of the azide *(26)* with norbornadiene, which formally is an insertion of the phenylsulfonylimene into a C–C bond [142].



*(26)* 68%

The photolysis of phenyl azide in diethylamine leads to ring enlargement with the formation of 2-diethylamino-3*H*-azepine [142a].

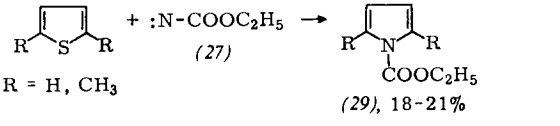
Another interesting reaction is that of ethoxycarbonylimene *(27)* with aliphatic nitriles, which leads to substituted 1,3,4-oxadiazoles *(28)* [143].



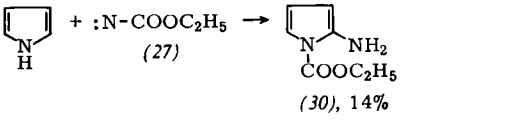
*(28)*, 14–73%

R = $CH_3$, iso-$C_3H_7$, $C_2H_5O$–$CH_2$–$CH_2$, $CH_2$=CH

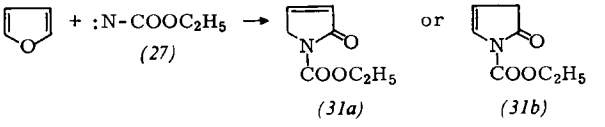
The reaction of ethoxycarbonylimene *(27)* with thiophene, pyrrole, and furan [144] leads to the heterocycles *(29)* to *(31)*.



R = H, $CH_3$ *(29)*, 18–21%



*(30)*, 14%



*(31a)* *(31b)*

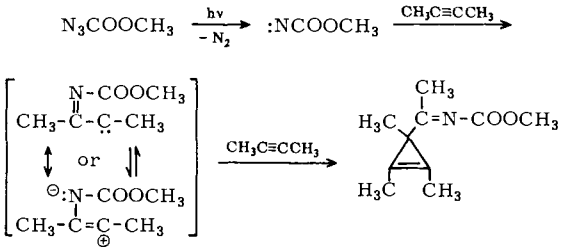
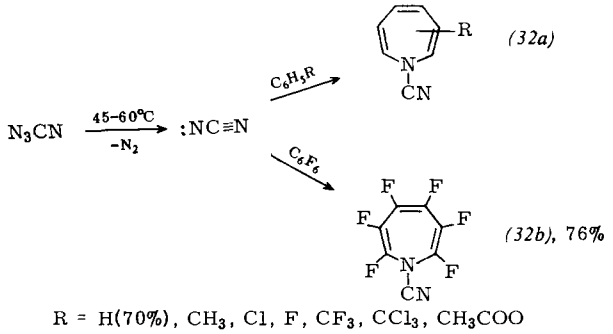
The 1,3-dipolar cycloaddition of alkoxycarbonylimenes to C≡C triple bonds leads usually to the corresponding oxazoles [144a]. However, formation of a cyclopropene derivative was recently observed [144b].

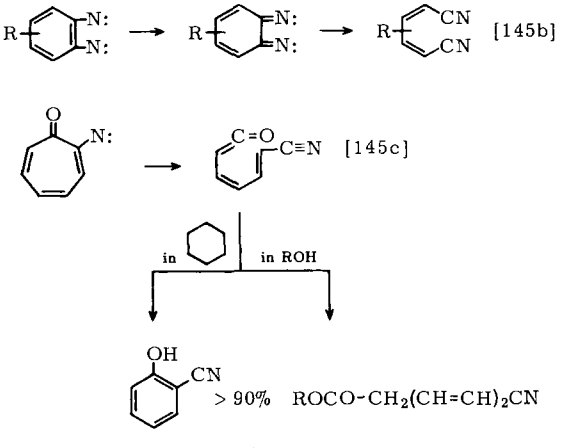


Reference should also be made to the synthesis of *N*-cyanoazepines *(32)* from cyanoimene and aromatic compounds [145].



R = H(70%), $CH_3$, Cl, F, $CF_3$, $CCl_3$, $CH_3COO$

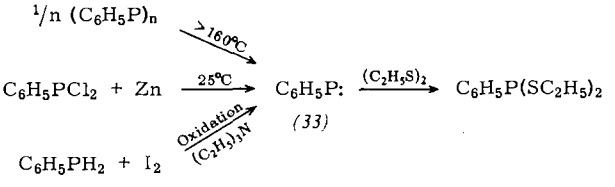
Combination reactions of the imene :NH, generated in the flash photolysis of isocyanic acid (HNCO), were discussed by *Back* [145a]. Aromatic imenes formed from azides isomerize intramolecularly to nitriles [145b, c].



The electron spin resonance spectra of various imenes have been studied [146–146b] and the bond energies, the lifetimes, and the electronic states of the alkoxycarbonylimenes, which were prepared by photolysis of the alkyl azidoformates in the gas phase, have been determined [147].

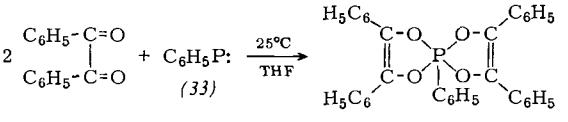
### b) Phosphorus Compounds

The most intensively studied of the compounds of univalent phosphorus is phenylphosphorus *(33)*, which can be prepared by dechlorination of phenyldichlorophosphine, by dehydrogenation of phenylphosphine, or by cleavage of the corresponding cyclopolymer, and which can be readily detected as the disulfide adduct [148].



Disulfides react similarly with diphenyltin [116] and methylene [149].

Phenylphosphorus *(33)* prepared from $C_6H_5PCl_2$ and zinc also adds to benzil [148].



Organic derivatives of univalent phosphorus, RP:, are assumed to occur as intermediates in the reactions of aryl- or alkyldichlorophosphines with magnesium or lithium in tetrahydrofuran, which lead to cyclic or linear polymers *(34)* [150]:

R = Alkyl or Aryl; $n = 4$ or 5

The reaction of organodibromophosphines with magnesium in ether/benzene follows a similar course [151] (R = $CH_3$, $C_2H_5$, $C_6H_5$; $n = 5$ or 6).

[150] *W. A. Henderson, M. Epstein*, and *F. S. Seichter*, J. Amer. chem. Soc. *85*, 2462 (1963); and literature cited there. Cf. [63,65, 66,98]. For preparation, properties, reactions, and structures of cyclopolyphosphines see also *A. H. Cowley*, Chem. Reviews *65*, 617 (1965).

[151] *W. Kuchen* and *W. Grünewald*, Chem. Ber. *98*, 480 (1965). Concerning the ring sizes of cyclopolyphosphines formed in these ways see *A. H. Cowley* and *R. P. Pinnell*, Inorganic Chem. *5*, 1459 (1966), and literature cited there.

RP: may occur as intermediate in other reactions used for the preparation of polymers.

$$RPH_2 \xrightarrow{H_2O_2} RP(O)H_2 \xrightarrow[-H_2O]{\Delta} [RP:] \longrightarrow 1/n(RP)_n \quad [150]$$

$$RPH_2 + RPCl_2 \xrightarrow[-2\,HCl]{\Delta} 2/n(RP)_n \quad [150]$$

$$C_6H_5PCl_2 \xrightarrow{LiAlH_4} [C_6H_5P:] \longrightarrow \underset{58\,\%}{1/n(C_6H_5P)_n} \quad [150]$$
*(33)*

$$4\,C_6H_5P(CO{-}NH{-}C_6H_5)_2 \xrightarrow[2\ hr]{180\,^\circ C} (C_6H_5P)_4 + 4(C_6H_5NH)_2CO + 4CO \quad [152]$$

$$CF_3{-}PI_2 + Hg \xrightarrow{20\,^\circ C} 1/n(CF_3P)_n + HgI_2 \quad [153]$$

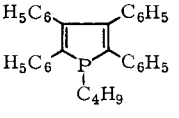
$n = 4$, 5, or 6

Derivatives of univalent phosphorus are formed in the pyrolytic or catalytic cleavage of some phosphines or diphosphines [153].

$$\left.\begin{array}{l}(CF_3)_2P{-}P(CF_3)_2 \xrightarrow[-(CF_3)_3P]{350\,^\circ C} \\ (CF_3)_2PH \xrightarrow[-HCF_3]{350\,^\circ C}\end{array}\right\} \longrightarrow [CF_3P:] \longrightarrow {}^1/_n\,(CF_3P)_n$$

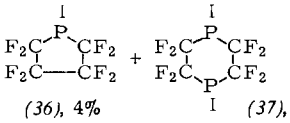
The polymers $(CF_3P)_n$, like the other polymeric carbene analogues, readily add halogenes to form $CF_3{-}PHal_2$; they are oxidized by oxygen to $(CF_3{-}PO_2)_x$ [153]. The organodifluorophosphines $RPF_2$ lose a molecule of fluorine at 20–40 °C to form the carbene analogues, which are then converted into the cyclopolymers [154]. Butylphosphorus *(35)*, which can add to alkynes, is formed by the catalytic cleavage of tributylphosphine [69]:

$$(C_4H_9)_3P \xrightarrow[I_2]{\Delta} \underset{(35)}{[C_4H_9P:]} \xrightarrow{2\,C_6H_5C{\equiv}CC_6H_5}$$



Finally, :PI could occur as intermediate in the formation of the heterocycles *(36)* and *(37)* from tetrafluoroethylene, red phosphorus, and iodine [155].

$$F_2C{=}CF_2 + P + I_2 \xrightarrow{300\,^\circ C}$$



*(36)*, 4% *(37)*, 27%

### c) Arsenic, Antimony, and Bismuth Compounds

The compounds of univalent arsenic, antimony, and bismuth and their polymers have been studied even less than the analogous phosphorus compounds. The unstable arylarsenes ArAs: are probably formed in the reduction of the arylarsonic acids, and are subsequently stabilized by cyclopolymerization [156].

$$ArAsO_3H_2 \xrightarrow{H_3PO_2} \underset{50-80\,\%}{[ArAs:]} \longrightarrow 1/6\,(ArAs)_6$$

$Ar = C_6H_5$, *p*- and *m*-$CH_3{-}C_6H_4$

Like the diorganotin dihydrides, phenylstibine, which is prepared at −196 ° to −60 °C, decomposes with evolution of hydrogen, giving first monomeric and then polymeric phenylantimony *(38)* [157]:

$$C_6H_5SbCl_2 \xrightarrow[{}^1/_2LiBH_4]{{}^1/_2LiAlH_4} C_6H_5SbH_2 \xrightarrow[-H_2]{\approx 20\,^\circ C} [C_6H_5Sb:] \longrightarrow \underset{(38)}{1/n(C_6H_5Sb)_n}$$

Similarly, polymeric $(C_6H_5Bi)_n$ *(39)* is formed *via* $C_6H_5Bi$: from $C_6H_5BiH_2$, which is prepared at −110 to −70 °C [157].

Oxidation of the polymer *(38)* by atmospheric oxygen leads to a polymer containing $-(C_6H_5)Sb(=O)-$ units. Unlike *(38)*, polymeric phenylbismuth *(39)* behaves towards oxygen and halogens in the same way as the other carbene analogues and their polymers:

$$\underset{(39)}{(C_6H_5Bi)_n} + n/2\,O_2 \longrightarrow n\,C_6H_5BiO$$

$$\underset{(39)}{(C_6H_5Bi)_n} + n\,Br_2 \longrightarrow n\,C_6H_5BiBr_2$$

## 5. Elements of Group VI as Carbene Analogues

Oxygen, sulfur, selenium, and tellurium atoms are carbene analogues on the basis of their electronic structure and their chemical properties. They undergo many carbene reactions, such as dimerization and polymerization, addition to double and triple bonds, and insertion into single bonds. The addition of atoms of group VI elements in the singlet state to the C=C double bond is strictly electrophilic, as in the case of singlet carbenes (Table 1). The reaction leads stereospecifically to three-membered rings.

Table 1. Reaction of carbenes and carbene analogues with olefins. The data are the relative rates ($k_1/k_2$) of addition of various reagents to olefins.

| Olefin | :$CCl_2$ [158] | :$CBr_2$ [159] | :O [160] | :S [161] | :Se [162] |
|---|---|---|---|---|---|
| $H_2C{=}CH_2$ | — | — | 1.00 | 1.00 | 1.00 |
| $CH_3{-}CH{=}CH_2$ | — | — | 5.8 | 3.6 | 2.6 |
| $C_4H_9{-}CH{=}CH_2$ | 0.023 | 0.07 | — | — | — |
| $C_2H_5{-}CH{=}CH_2$ | — | — | 5.8 | 3.6 | 7.1 |
| $(CH_3)_2C{=}CH_2$ | 1.00 | 1.00 | 25.0 | — | 44.7 |
| *trans*-$CH_3{-}CH{=}CH{-}CH_3$ | — | — | 28.3 | — | 56.0 |
| $(CH_3)_2C{=}CH{-}CH_3$ | 2.90 | 3.20 | 79.3 | — | — |
| $(CH_3)_2C{=}C(CH_3)_2$ | 6.60 | 3.50 | 101.8 | — | — |

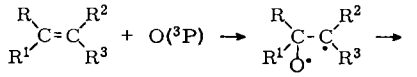
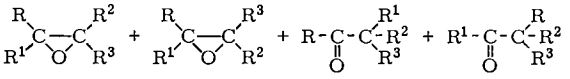
However, most of the reactions of molecular oxygen, sulfur, and selenium in which individual atoms could formally participate are not associated with preliminary dissociation or depolymerization of the molecules. Therefore most of these reactions will not be discussed.

### a) Oxygen

Atomic oxygen is usually produced by the passage of a high-voltage discharge through water vapor or molecular oxygen or by photolysis of nitrous oxide or nitrogen dioxide [160, 163]. Atomic oxygen, which is formed on UV irradiation ($\lambda$ = 2450–3700 Å) of $N_2O$ and $NO_2$, and which is in the ground triplet state ($^3P$), reacts as a triplet carbene with olefins and dienes, forming epoxides, aldehydes, or ketones [164, 165].





R, $R^1$, $R^2$ and $R^3$ = H, Alkyl, or Alkenyl

However, when nitrogen dioxide is irradiated with light of wavelength 2288 Å, an excited oxygen atom ($^1D$) is obtained, which can add to olefins in one step like a singlet carbene. This is seen from the greatly increased yield of epoxide [165].

Like that of the singlet carbenes the addition of excited oxygen $O(^1D)$ to olefins is stereospecific. However, the stereospecificity is somewhat relaxed by the transition $O(^1D) \rightarrow O(^3P)$ [165]. The reaction of atomic oxygen with lower olefins generally leads to an aldehyde and a carbene.

$H_2C{=}CH_2 + O \longrightarrow CH_2O + :CH_2$ [166]

$CH_3{-}CH{=}CH_2 + O \longrightarrow CH_3{-}CHO + :CH_2$ [166]

$F_2C{=}CF_2 + O(^3P) \longrightarrow CF_2O + :CF_2$ (triplet) [167]

Atomic oxygen can also attack aliphatic and aromatic C–H and even C–C single bonds [166, 168]. The formation of small amounts of acetaldehyde alongside formaldehyde as main product is explained by the insertion of atomic oxygen in C-H bonds during its reaction with ethylene [166].

$$CH_4 + O \longrightarrow CH_3OH$$

$$H_2C{=}CH_2 + O \longrightarrow H_2C{=}CHOH \longrightarrow CH_3{-}CHO$$

The reactions of oxygen and of sulfur with phosphines, carbenes, other carbene analogues, borontrialkyls *etc.* are very similar to the corresponding reactions of carbenes. However, the participation of atomic oxygen or sulfur in these reactions is very doubtful.

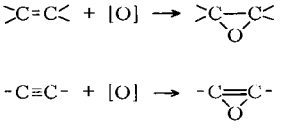
$R_3P + [O] \longrightarrow R_3PO$ [169]

$R_2C: + [O] \longrightarrow R_2CO$ [5,6]

$R_2Sn: + [O] \longrightarrow R_2SnO$ [109]

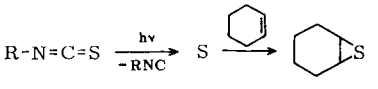
$R_3B + [O] \longrightarrow R_2BOR$ [170]

The Prileshayev reaction (oxidation of alkenes and alkynes by peracids or hydrogen peroxide [171]) formally resembles the reactions of carbenes.



### b) Sulfur

Atomic sulfur in solution occurs during the photochemical formation of isonitriles from isothiocyanates ($\lambda$ = 254 mμ), and can be detected like the carbenes by addition to cyclohexene [148].



Atomic sulfur is formed in the excited singlet state $S(^1D)$ in the gas phase occurs during the photolysis ($\lambda$ = 2290–2555 Å) of carbonyl sulfide at 25 °C [161, 172, 172a].

In the photolysis of COS in an inert gas at high pressures, the conversion of the initially formed $S(^1D)$ into the ground triplet state $S(^3P)$ is increased by collisions with the gas molecules [173]. The singlet sulfur can insert into C–H bonds of alkanes, cycloalkanes, and alkenes, whereas the triplet sulfur cannot; on the other hand, both types can add to C=C double bonds [161, 172–172b].

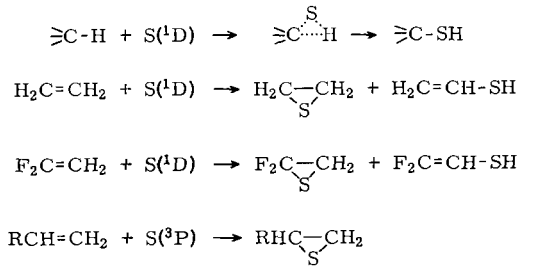
[172] *A. R. Knight, O. P. Strausz, et al.*, J. Amer. chem. Soc. *85*, 2349 (1963); *86*, 4243 (1964); *87*, 1443 (1965).

[172a] *K. S. Sidhu, E. M. Lown, O. P. Strausz*, and *H. E. Gunning*, J. Amer. chem. Soc. *88*, 254 (1966).

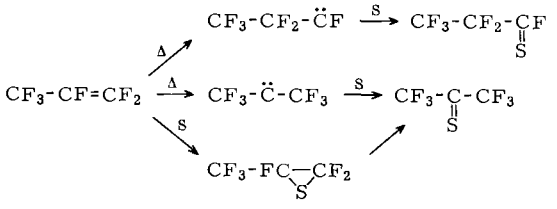
[172b] On reactions of sulfur atoms see also *H. E. Gunning*, Trans. Roy. Soc. Canada, Sec. 1–3, *2*, 293 (1964).



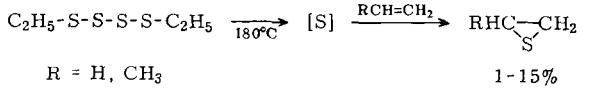
As was recently shown [172a] episulfides formed from *cis*- and *trans*-2-butene retain the geometry of the parent olefin (retention >87 and >98%, respectively) not only with singlet but with triplet-state sulfur as well.

The addition of sulfur atoms to 1,3-butadiene gives at least 91% of vinylthiirane, with thiophene (≤9%) as second major product [172a].

Atomic sulfur is thought to be involved in the reactions of hexafluoropropylene and tetrafluoroethylene with sulfur vapor at 400–500 °C [174, 174a]:



Atomic sulfur probably is formed when diethyl tetrasulfide is heated [175].



Molecular (polymeric) sulfur can undergo insertion into the Sn–Li bond to form the group SnSLi [176]. At 130–650 °C, it adds to olefins, dienes, and alkynes to form hetero chains and heterocycles [177]. However, it is unlikely that atomic sulfur is involved in these reactions.

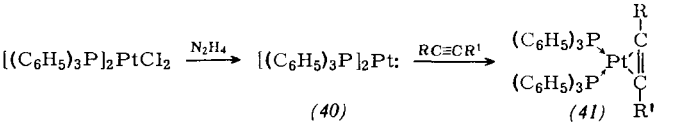
### c) Selenium and Tellurium

Atomic selenium in the excited state is formed during isothermal flash photolysis of carbon diselenide vapor, and adds electrophilically to olefins [162]. In the presence of an inert gas, *e.g.* nitrogen, the initially formed "hot" selenium atoms (lifetime *ca.* $10^{-4}$ sec) are deactivated and subsequently dimerize to form $Se_2$.

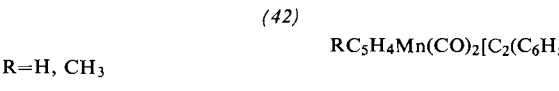
Like oxygen and sulfur, selenium and tellurium insert into the Sn–Li [178] and even Sn–C [179] bonds; however, the reaction probably does not involve preliminary depolymerization of the $Se_x$ and $Te_x$ molecules. $Se_x$ and $Te_x$ also react with tetrafluoroethylene [155], olefins, and acetylene [180].

## 6. Transition Metal Compounds with Carbene-like Properties

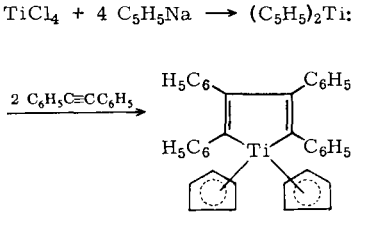
No carbene-like properties can be expected of free transition metals, in which the d levels with lower principal quantum numbers than those of the s and p valence electrons are not filled. However, some derivatives of these metals are formed by filling of the d levels to form complexes or "sandwich" structures. Such complexes could formally be expected to include carbene analogues. For example, the platinum complex $[(C_6H_5)_3P]_2PtCl$ is converted by hydrazine or other reducing agents into a carbene analogue *(40)*, which can add to alkynes to form the compounds *(41)* [181]. Compound *(40)* also forms unstable adducts with olefins [181].



The photolysis of derivatives of cyclopentadienylmanganese tricarbonyl with subsequent addition of tolan can also be formulated as proceeding *via* a carbene analogue *(42)*, though it probably involves displacement of CO by tolan [182].



The formation of the titanocene derivative could also be formulated as involving a carbene analogue [183]:



[173] Cf. the singlet-triplet transition of methylene in the gas phase [5, 6].

### 7. Carbene-like Properties of other Compounds

Some elements of the third and subsequent periods (phosphorus, antimony, sulfur, selenium, and others) can form five covalent bonds, *i.e.* can possess a stable decet of electrons.

Accordingly, many compounds of these elements exhibit carbene-like properties, even when the atom still possesses eight valence electrons. In particular, phosphoranes and phosphine oxides with covalent structures may be regarded as adducts of such carbene analogues with carbenes or oxygen [169].

$$R_3P + :CX_2 \longrightarrow R_3P{=}CX_2$$

$$R_3P + 1/2O_2 \longrightarrow R_3P{=}O$$

The reaction of phosphorus trihalides with compounds containing conjugated double bonds [184] appears to suggest carbene-like properties in the former:

$$H_2C{=}CH{-}CH{=}CH_2 + :PHal_3 \longrightarrow$$

Hal = Cl, Br

[184] *U. Hasserodt, K. Hunger,* and *F. Korte,* Tetrahedron *19,* 1563 (1963); *B. A. Arbuzov* and *A. O. Vizel,* Doklady Akad. Nauk SSSR *158,* 1105 (1964), and literature cited there. Cf. the 1,4-addition of other carbene analogues and carbenes to 1,3-dienes [73,74,87].

Sulfur and selenium dioxides form similar products with conjugated dienes [185]. $SO_2$ and $SeO_2$ add particularly readily to 2,3-di t-butyl-1,3-butadiene.

1,3-Dienes add easily not only $PHal_3$, but also alkyl- and aryldichlorophosphines $RPCl_2$. However, the adducts *(43)* are ionic and can be reduced smoothly with magnesium in THF to derivatives of three-covalent phosphorus *(44)* [186].

$$H_2C{=}CH{-}CH{=}CH_2 + RPCl_2 \longrightarrow$$

*(43)* $\xrightarrow[THF]{Mg}$ *(44)*

These results shows that compounds having carbene-like properties do not necessarily have the electronic arrangement of the carbenes. The central atoms of these compounds have no free p orbitals, but use vacant d orbitals to form the decet of electrons at the expense of pd hybridization.

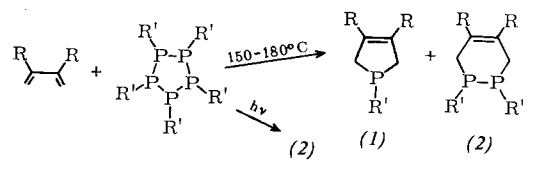
## Thermal and Photochemical Formation of Phospholenes and Tetrahydrophosphorins from Cyclophosphines and Dienes [1]

By Prof. Ulrich Schmidt and I. Boie

Chemisches Laboratorium, Universität Freiburg (Germany)

We have previously inferred the formation of phosphinidene (R–P:), on heating and irradiation of cyclophosphines $(R{-}P)_5$, from reactions leading to insertion into disulfide bonds [2], formation of 1,1'-spirobi(phosphadioxole) [2], and exchange of ring members of cyclopolyphosphines [3]. We have now observed addition of fragments formed thermally and photochemically from cyclophosphines to dienes.

Cyclophosphines were heated with dienes for 20 hr at 150 to 180 °C. On subsequent distillation a mixture of a phospholene *(1)* and a tetrahydro-1,2-diphosphorin *(2)* was obtained in a total yield of 40 to 60 %. These products were separated by fractional distillation. 1,2,3,6-Tetrahydro-1,2-diphosphorins *(2)* can be isolated in better yield and without simultaneous formation of phospholenes *(1)* by irradiation of the cyclophosphine-diene mixture with a high-pressure mercury vapor lamp.



The structures of the phospholenes and tetrahydro-1,2-diphosphorins (the latter are derivatives of a new ring system) follow from their compositions, molecular weights (determined mass-spectrometrically), and NMR spectra.

The tetrahydrophosphorins react rapidly with alkylating agents to give monophosphonium salts and with sulfur to give P,P'-bissulfides.

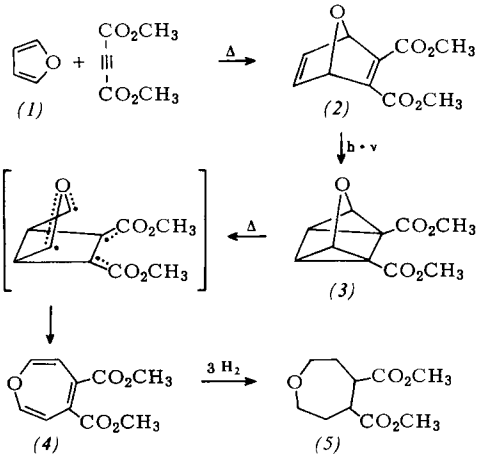
## A New Synthesis of the Oxepin System from Furan and Dimethyl Acetylenedicarboxylate

By Prof. H. Prinzbach, M. Arguëlles, and E. Druckrey

Laboratoire de Chimie organique de l'Université de Lausanne (Switzerland)

We have synthesized the 8 π-electron system *(4)* by the new reaction sequence represented as *(1)* → *(2)* → *(3)* → *(4)*.



On addition by portions of a total of 21 g (0.29 mole) of furan to a boiling etheral solution of 10 g (0.076 mole) of dimethyl acetylenedicarboxylate during 130 hr, the monoadduct *(2)* was obtained in 70 to 75 % yield[1]; it has $\lambda_{max}$ in ether at 288 mμ (ε = 1060) and a shoulder at 222 mμ (ε = 4260); its NMR spectrum in $CCl_4$ contains two signals at τ = 2.83 and τ = 4.43, showing some fine structure, as well as the $CH_3O$ singlet at τ = 6.24 (ratio 2:2:6); the fragments to be expected for the reverse change *(2)* → *(1)* were responsible for the main peaks (*m/e* = 210, 111, 68...) in the mass spectrum[2].

If the ester *(2)* in 0.06 M ethereal solution ($O_2$-free) is irradiated at −15 °C with light from a high-pressure mercury arc filtered through Vycor glass, it is isomerized to compound *(3)* in 55 to 60 % yield. This forms colorless crystals, m.p. 82–83 °C (from cyclohexane)[3],; its UV spectrum in ether shows only end absorption (ε 210 mμ = 2950); its NMR spectrum in $CDCl_3$ contains two doublets (J = 3.5 Hz) at τ = 5.12 and τ = 7.35 and a singlet at τ = 6.36 (ratio 2:2:6); reverse isomerization to *(2)* is only a minor reaction under electron impact[4], a base peak at *m/e* = 179 ($M-CH_3O$) being recorded alongside a very intense molecule ion ($M^+$=210).

Compound *(3)* is converted into the oxepin ester *(4)* from about 100 °C ($t_{½}$ = 48 min at 108 °C, 35 min at 113 °C, and 19 min at 118 °C; $E_a$ = 27.6 ± 2 kcal/mole; $k_0 = 7.9\times10^{13}$). For instance, 3.4 g of ester *(3)* was heated in 85 ml of xylene at 140 to 150 °C for 20 min, then about 10 % of a dimer was filtered off at room temperature and the product *(4)* was isolated by chromatography in benzene on $SiO_2$; it is an orange oil, yield 70–75 %, $\lambda_{max}$ (ethanol) = 304 mμ (shoulder, ε = 1400) and 269 mμ (ε = 2100); $\nu_{C=C}$ $(CH_2Cl)_2$ = 1635 and 1575 $cm^{-1}$. Its NMR spectrum is temperature dependent[5]: at 30 °C ($CCl_4$) it comprises two doublets (*J* = 5.0 Hz) at τ = 3.73 and τ = 4.94 and a $CH_3O$ singlet at τ = 6.28. There are strong peaks in the mass spectrum at *m/e* = 210 ($M^+$, base peak), 194 (M−O), 179 ($M-CH_3O$) and 163 ($M-O-CH_3O$). In the presence of prereduced $PtO_2$ the oxepin *(4)* rapidly absorbs 3 equivalents of $H_2$, giving a 75 % yield of product *(5)* whose structure is proved by elemental analysis and IR, NMR, and mass spectra. 1:1 Cycloadducts are formed by *(4)* with maleic anhydride or dimethyl acetylenedicarboxylate[5].

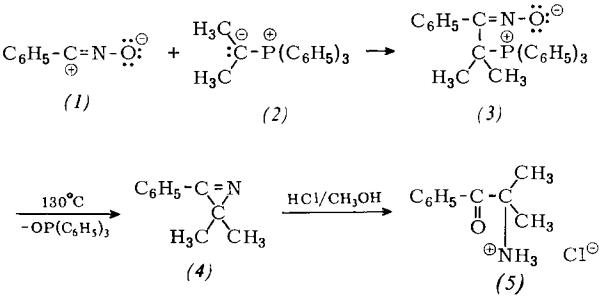
## Reactions of Benzonitrile Oxide with Alkylidenephosphoranes

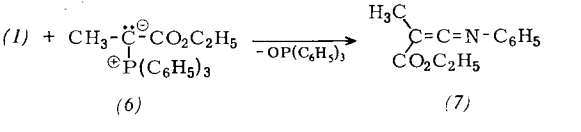
By Prof. H. J. Bestmann and R. Kunstmann

Institut für Organische Chemie der Universität Erlangen-Nürnberg (Germany)

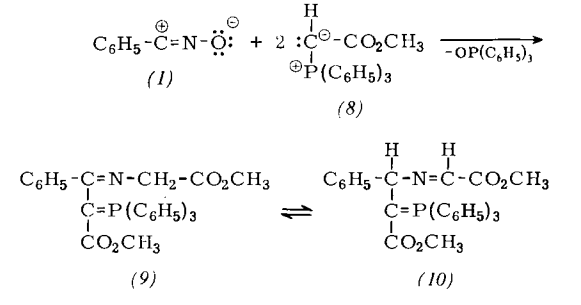
Benzonitrile oxide *(1)* adds (1-methylethylidene)triphenylphosphorane *(2)* in anhydrous benzene at room temperature, giving the betaine *(3)*, m.p. 122 °C, in 54 % yield. When heated in a rotating bulb-tube at 130 °C/0.05 mm, *(3)* eliminates triphenylphosphine oxide and gives the azirine *(4)* quantitatively as a distillate; *(4)* has a characteristic band at 5.7 μ in the IR spectrum and absorbs at 246 mμ in the UV[1] (NMR: singlet for the methyl protons at τ = 8.51, multiplet for the aromatic protons at τ = 2.3). Methanolic hydrochloric acid hydrolyses compound *(4)* to the amino ketone hydrochloride *(5)* (picrate, m.p. 174 °C; lit.[2] 175 °C).



Reaction of the nitrile oxide *(1)* with the phosphorane ethyl ester *(6)* in benzene affords the ketene imine derivative *(7)*, ethyl 3-phenylimino-2-methylacrylate, b.p. 140 °C/0.05 mm; characteristic IR band at 4.92 μ; yield 68 %. It cannot yet be decided at what stage in the reaction the phenyl group migrates, and so far no intermediate has been isolated. On alkaline hydrolysis, compound *(7)* yields methylmalonic acid and aniline.

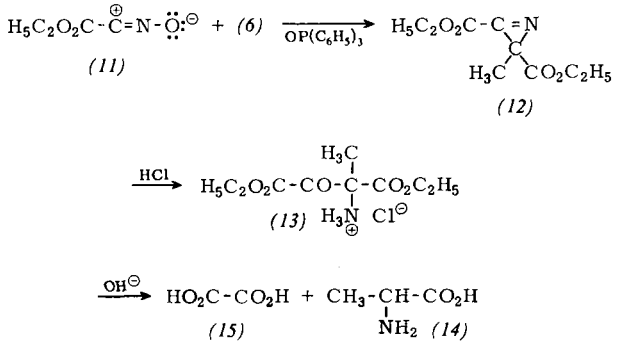


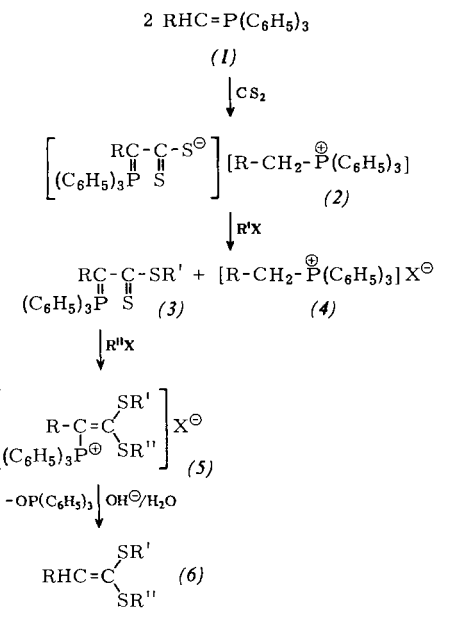
On treatment of benzonitrile oxide *(1)* with the phosphorane methyl ester *(8)*, two molecules of *(8)* react with one of *(1)*, affording to ylide *(9)*, m.p. 193 °C, in 67 % yield. The IR spectrum includes the ester-carbonyl band at 6.15 μ characteristically shifted as for phosphorus ylide esters[3]. NMR studies indicate that in solution this substance is in equilibrium with its tautomer *(10)*.



Elemental analysis of all the compounds prepared gave the expected C, H, and N values. The modes of reaction of alkylidenephosphoranes with nitrile oxides mentioned above are being studied in detail.

*Added in proof*: The azirine *(12)* has now been isolated from the products of the reaction of ethyl cyanoformate *N*-oxide *(11)* with *(6)* in boiling benzene (b.p. 80 °C/0.05 mm; yield 65 %; IR: broad bands with two shoulders at 5.7–5.8 μ; UV: $\lambda_{max}$ = 214, 267 mμ; $^1$H–NMR: singlet for methyl group attached to ring at τ = 8.33, 2 triplets for the ester methyl groups at τ = 8.54 and 8.72, 2 quartets for the ester methyl groups at τ = 5.51 and 5.82). A betaine analogous to *(3)* was not observed in this reaction.





benzene at 50 °C gives 2-(triphenylphosphoranylidene)dithiocarboxylic esters *(3)* and alkyltriphenylphosphonium salts *(4)*, the latter remaining undissolved whereas the compounds *(3)* pass into solution.

## A New Synthesis of Ketene Mercaptals

By Prof. H. J. Bestmann, R. Engler, and Dr. H. Hartung

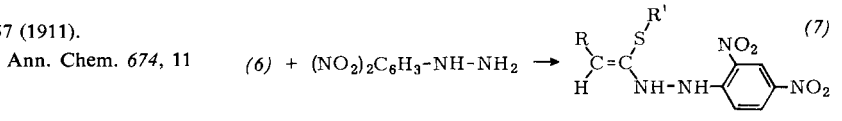
Institut für Organische Chemie,
Universität Erlangen-Nürnberg (Germany)

Reaction of the stable ylides diphenylmethylidene- and fluorenylidene-phosphorane with carbon disulfide gives polymeric or dimeric thioketenes [1].

If salt-free solutions of basic alkylidenephosphoranes *(1)* [2] in benzene are treated with carbon disulfide at room temperature (molar ratio 2:1), the yellow, stable phosphonium salts *(2)* (unsharp melting points) of 2-(triphenylphosphoranylidene)dithiocarboxylic acids are precipitated. Reaction of the salts *(2)* with an equimolar amount of alkyl halide in benzene at 50 °C gives 2-(triphenylphosphoranylidene)dithiocarboxylic esters *(3)* and alkyltriphenylphosphonium salts *(4)*, the latter remaining undissolved whereas the compounds *(3)* pass into solution.

The new ylides *(3)* are alkylated at the sulfur by alkyl halides to the phosphonium salts *(5)*, which afford the ketene mercaptals *(6)* on alkaline hydrolysis in boiling 20 % potassium hydroxide.

On treatment with aqueous $HgCl_2$ the ketene mercaptals *(6)* are converted into the carboxylic acids $RCH_2$–COOH; when R′ = R″they afford 2-[1-(alkylthio)-1-alkenyl]-1-(2,4-dinitrophenyl)hydrazines *(7)* [3] with 2,4-dinitrophenylhydrazine in phosphoric acid.



Elemental analysis gives the expected values for all the products. The IR and $^1$H–NMR data are evidence for structures *(3)*, *(5)*, *(6)*, and *(7)*.

## Existence of the $VO_2^+$, $TiO^{2+}$ and $ZrO^{2+}$ Cations

By Dr. K. Dehnicke and Dr. J. Weidlein

Laboratorium für Anorganische Chemie
der Technischen Hochschule Stuttgart (Germany)

*J. Selbin*[1] recently questioned the existence of the oxo-cations $VO_2^+$, $TiO^{2+}$, and $ZrO^{2+}$. However, their existence has been established recently.

The group $VO_2^+$ exists in the compound $VO_2Cl$, which according to its IR spectrum (300–1500 $cm^{-1}$) consists of discrete $VO_2Cl$ units (symmetry Cs)[2]. We have now recorded the IR spectrum of $VO_2Cl$ also between 33 and 300 $cm^{-1}$. It confirms the previously proposed structure[2]. The six fundamental vibrations to be expected for the point group $C_s$ can be observed (Table 1).

By fluorination of $VO_2Cl$ with $F_2$ at room temperature we obtained $VO_2F$ in practically 100 % yield. Its IR spectrum (Table 1) shows no evidence of a V–F stretching or deformation vibration. Number, positions, and intensities of the IR absorptions suggest discrete $VO_2^+$ (symmetry $C_{2v}$) and $F^-$ ions. $VO_2F$ reacts with an excess of $SbF_5$ at 200 °C quantitatively to give $VO_2^+ SbF_6^-$. The compound obtained exhibits the characteristic IR absorptions of the $SbF_6^-$ anion (symmetry $O_h$) of the class $F_{1u}$ and the three absorptions to be expected for the $VO_2^+$ cation, which show practically the same frequencies as in the spectrum of $VO_2^+F^-$ (Table 1). $VO_2F$ and $VO_2SbF_6$ are typical ionic compounds, stable up to 350 °C, very hygroscopic, and insoluble in nonpolar solvents.

Table 1. IR spectra of $VO_2Cl$ ($C_s$), $VO_2^+ F^-$ ($C_{2v}$), and $VO_2^+ SbF_6^-$ ($C_{2v}$, $O_h$).

[a] vs = very strong, s = strong, m = medium, w = weak, Sh = shoulder

$TiO^{2+}$ cations also occur in $Ti_2OF_6$[3] which, according to the IR spectrum, consists of $TiO^{2+}$ and $TiF_6^{2-}$ ions. For this a total of three IR-absorptions is expected, one for the cation (class $\Sigma^+$) and two for the anion (class $F_{1u}$). Table 2 shows that the number and the frequencies of the absorbtion bands are consistent with this[3]. When $TiOCl_2$ is treated with an excess of $SbF_5$ at 150 to 200 °C (3 hr), titanyl hexafluoroantimonate, $TiO^{2+}(SbF_6^-)_2$, is formed in nearly 100 % yield. This compound also shows the characteristic $TiO^{2+}$ frequency at 965 $cm^{-1}$ and the two absorptions of the complex anion (Table 2).

Table 2. IR-spectra of $TiO^{2+}TiF_6^{2-}$ and $TiO^{2+}(SbF_6^-)_2$.

| Class | $TiO^{2+}$ $TiF_6^{2-}$ | | $TiO^{2+}$ $(SbF_6^-)_2$ | | Assignment |
|---|---|---|---|---|---|
| | $\tilde{\nu}$ ($cm^{-1}$) | Int. | $\tilde{\nu}$ ($cm^{-1}$) | Int. | |
| $\Sigma^+$ | 964 | s | 965 | s | $\nu$ $TiO^{2+}$ |
| $F_{1u}$ | 541 | s | 675 | s | $\nu_{as}$ $MF_6$ |
| $F_{1u}$ | 333/311/291 | m | 285 | m | $\delta_{as}$ $MF_6$ |

The IR spectrum of $ZrOCl_2$[4], with a ZrO stretching vibration at 877 $cm^{-1}$, can be interpreted only by assuming a considerable double-bond character. Taking the rest of the spectrum the proposed model $\infty$ $ZrO^{2+}$ $(ZrOCl_4^{2-})\infty$ is the only reasonable one. The partial hydrolysis of $ZrCl_4$ in acetonitrile produces $ZrOCl_2$, which is probably an isomer having no ZrO bonds of higher order, as its highest absorption band is found at 675 $cm^{-1}$[5].

## Use of the *N*-(5,5-Dimethyl-3-oxo-1-cyclohexen-1-yl) Protective Group in Solid Phase Peptide Synthesis

By Dr. A. Deér[1]

Institute of Steroid Chemistry, Syntex Research, Palo Alto, California (U.S.A.)

In peptide synthesis by the Merrifield method on chloromethylated polystyrene resins[2], loss of the amine protecting group on detachment of the completed peptide chains was previously unavoidable. The free peptides formed must be separated from by-products with shorter chains by ion-exchange chromatography.

This difficult purification step can now be avoided by utilizing the high acid and base stability of the 5,5-dimethyl-3-oxo-1-cyclohexen-1-yl protecting group as well as the high degree of crystallinity of *N*-(5,5-dimethyl-3-oxo-1-cyclohexen-1-yl) peptides[3]. Thus, at the final stage of chain lengthening[4] an *N*-(5,5-dimethyl-3-oxo-1-cyclohexen-1-yl) amino acid is used.

Hydrolysis of the resin ester bond followed by filtration and acidification gives *N*-(5,5-dimethyl-3-oxo-1-cyclohexen-1-yl) peptides of high purity[5] by direct crystallization. The protecting group can be removed with bromine or nitrous acid[3,6].

| Peptide [a] | M.p. (°C) | $[\alpha]_D$ |

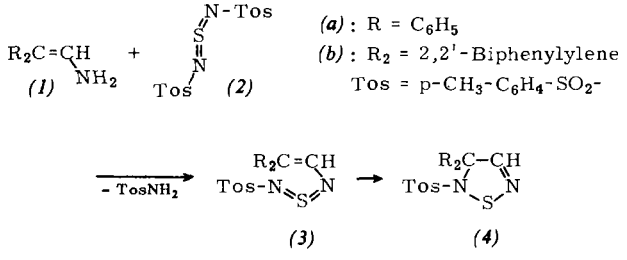
## 1,5-Cyclization of Vinyl-substituted Sulfur Diimides

By Prof. G. Kresze and Chr. Seyfried

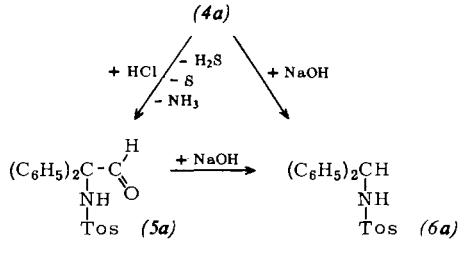
Organisch-Chemisches Institut,
Technische Hochschule München (Germany)

*S*-Arylsulfonylimido-2*H*-1,2,4-benzothiadiazines[2] are obtained by 1,6-cyclization on reaction of *N*-arylamidines $ArN{=}CR(NH_2)$, [R = H, alkyl, or aryl], *N*-aryl-isoureas, -isothioureas and -guanidines with *N*-sulfinylsulfonamides $OS{=}N{-}SO_2R$, arylsulfonylimidosulfur dichlorides $ArSO_2{-}N{=}SCl_2$, or sulfur di(arylsulfonylimides)[1] such as *(2)*. However, enamines[3] *(1)* with primary amino groups react to yield $\Delta^2$-1,2,5-thiadiazolines *(4)* by 1,5-cyclization.



In this way 4,4-diphenyl-5-tosyl-$\Delta^2$-1,2,5-thiadiazoline *(4a)*, m.p. 169–171 °, is formed when 2,2-diphenylvinylamine *(1a)* and an equivalent amount of sulfur di-(*p*-toluenesulfonyl-diimide) *(2)* are kept in anhydrous benzene at room temperature for one day. When 9-(aminomethylene)fluorene *(1b)* is used, the intermediate *(3b)* [violet-black needles, m.p. 121–122 °C; 51 % yield; IR bands at 1010 and 965 $cm^{-1}$ (? ν(N=S=N))] can be isolated after ½ hr at not more than 30 °C with exclusion of moisture. This intermediate forms the product *(4b)*, m.p. 165–167 °C, only when boiled in benzene or, faster, when heated to 140 °C.

The structures of compounds *(3b)*, *(4a)*, and *(4b)* have been proved by degradation, as well as by IR and NMR spectra: with cold 20 % NaOH, *(3b)* yields *p*-toluenesulfonamide, *(1b)*, and $SO_2$; when boiled for 3 hr with 20 % aqueous-alcoholic hydrochloric acid, *(4a)* yields $H_2S$, sulfur, $NH_3$, and *N*-(formyldiphenylmethyl)-*p*-toluenesulfonamide *(5a)* [m.p. 164 °C; yield 93 %; IR bands at 1725 $cm^{-1}$ ($\nu_{CO}$) and 3295 $cm^{-1}$ ($\nu_{NH}$); aldehyde-proton NMR signal at 9.36 ppm (in $CDCl_3$; TMS as internal standard)]; cold 20 % NaOH readily decarbonylates *(5a)* to *N*-(diphenylmethyl)-*p*-toluenesulfonamide *(6a)*, m.p. 155–156 °C.



Compounds *(6a)* and *(6b)* are formed directly, in 80 to 90 % yield, on treatment of *(4a)* or *(4b)*, respectively, with cold 20 % NaOH, the products being identical (IR spectrum and mixed melting point) with those described previously[4].

A quasi-electrophilic aromatic substitution with participation of a positive sulfur atom can be envisaged for the 1,6-cyclization of the *N*-arylamidines, and nucleophilic behavior of the toluenesulfonamide-nitrogen atom of *(3)* can be considered for the 1,5-cyclization of enamines *(1)*. In both cases α,β-unsaturated sulfur diimides occur as intermediates. It seems remarkable that reduction of the sulfur is involved in the 1,5-cyclization.

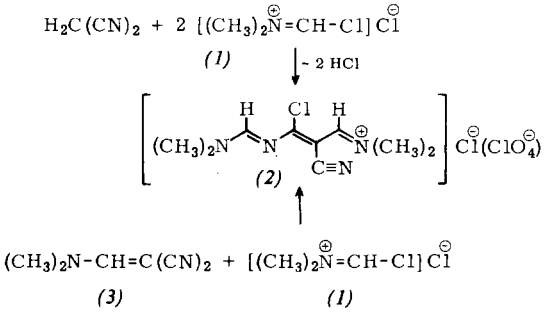
## Substituted Pyrimidine-5-carbonitriles by Vilsmeier Reaction of Malonodinitrile

By Dr. Ch. Jutz and W. Müller

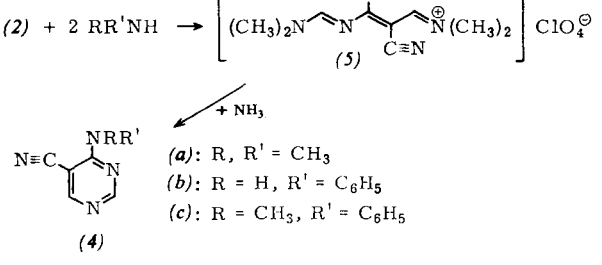
Organisch-Chemisches Institut,
Technische Hochschule München (Germany)

(Chloromethylene)dimethylammonium chloride *(1)* or dimethylformamide/$POCl_3$ (Vilsmeier reagent) readily react with malonodinitrile to give *N,N*-dimethyl-3-chloro-2-cyano-5-dimethylamino-4-aza-2,4-pentadienylideneammonium chloride *(2)*, which was isolated in 81 % yield as the corresponding perchlorate (yellow needles, m.p. 171 °C). Elemental analyses, UV ($\lambda_{max}$ = 382 mμ, log ε = 4.80 in $CH_3CN$), IR, and NMR spectra, and reactions confirm the structure *(2)*. In the $^1H$-NMR spectrum in trifluoroacetic acid with tetramethylsilane as internal standard there are four signals for the *N*-methyl groups (restricted rotation about the C–N bonds, anisotropy in the methine chain) at τ = 6.52 (3 H), τ = 6.45 (3 H), τ = 6.37 (3 H), and τ = 6.30 (3 H); the two methine protons appear as singlets at τ = 1.55 (1 H) and τ = 1.30 (1 H).



Since (dimethylaminomethylene)malonodinitrile *(3)*[1] also reacts smoothly with *(1)* to yield the salt *(2)*, the reaction with malonodinitrile probably occurs by way of *(3)*.

The chlorine atom of *(2)* can be replaced easily by bases, *e.g.* primary and secondary amines. When warmed with aqueous ammonium chloride or dilute ammonia solution, compound *(2)* undergoes ring closure and substitution to 4-dimethylaminopyrimidine-5-carbonitrile *(4a)* (white platelets, m.p. 114 °C in *ca.* 60 % yield). Reaction of *(2)* with an excess of aniline or *N*-methylaniline leads to azamethine salts *(5)*, which when warmed in dilute ammonia solution are cyclized to the pyrimidines *(4b)* and *(4c)*, respectively, in



total yields of 90 % [white needles, *(4b)*: m.p. 168 °C; *(4c)*: m.p. 92 °C].

*N,N-Dimethyl-3-chloro-2-cyano-5-dimethylamino-4-aza-2,4-pentadienylideneammonium perchlorate (2)*:

(a) 0.3 mole of compound *(1)* (prepared from 22 g of dimethylformamide and phosgene or 38 g of oxalyl chloride) and 0.1 mole of malonodinitrile in 60 ml of chloroform are heated on the water-bath; a vigorous reaction occurs and HCl is evolved. The chloroform is evaporated in vacuum, the residue is dissolved in a little ice-water, and $NaClO_4$ is added. The crystals are sucked dry, washed with water, dried, and recrystallized from acetonitrile/ether; yield 25.5 g (81 %) of *(2)*, yellow needles, m.p. 171 °C.

(b) 0.03 mole of compound *(1)* (from 2.2 g of DMF) and 0.02 mole of *(2)* are heated in 20 ml of chloroform for 1 hr. The product is isolated as in (a); yield 5.0 g (80 %) of *(2)*.

*4-Dimethylaminopyrimidine-5-carbonitrile (3a)*:

A solution of 0.02 mole of *(1)* in 50 ml of saturated aqueous $NH_4Cl$ is heated with 1 ml of conc. $NH_3$ solution for 10 min on a boiling water-bath. On cooling, needles of *(3a)* separate from the clear solution. These are extracted several times with chloroform, the united extracts are dried and evaporated, and the residue is recrystallized from 2-propanol or a little water; yield 1.70 g (58 %) of *(3a)*, white needles, m.p. 114 °C.

$^1$H–NMR spectrum in $CDCl_3$, TMS as internal standard: $\tau = 6.64$ (6 H) for $N$–$CH_3$, $\tau = 1.54$ (1 H), and $\tau = 1.40$ (1 H) for the ring protons.

*4-Methylanilinopyrimidine-5-carbonitrile (4b)*:

A mixture of 0.01 mole of *(2)* and 3.2 g of methylaniline in chloroform is heated for 15 min. Methylanilinium chloride and *(5c)* are precipitated by trituration with ether. Recrystallization from acetonitrile/ethyl acetate yields *(5c)*, m.p. 192 °C. When *(5c)* is heated in 20 ml of dilute $NH_3$, white needles of *(4c)* separate; recrystallization from ethanol/water yields 1.70 g (81 %), m.p. 92 °C.

$^1$H–NMR spectrum in $CDCl_3$, TMS as internal standard: $\tau = 6.45$ (3 H) for $N$–$CH_3$; $\tau = 2.38$–$2.80$ (5 H) for phenyl protons; $\tau = 1.60$ (1 H) and 1.30 (1 H) for the ring protons.

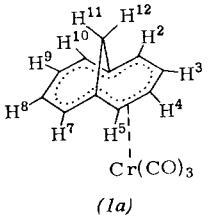
## Structure of Tricarbonyl-1,6-methanocyclodecapentaenechromium

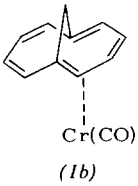
By Dr. H. Günther and Dr. W. Grimme

Institut für Organische Chemie, Universität Köln (Germany)

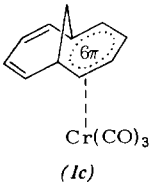
In certain cases determination of vicinal coupling constants between protons on neighboring C–C bonds permits a distinction between cyclic, conjugated, olefinic (localized) and aromatic (delocalized) π-electron systems[1,2]. We were interested in whether the ligand in tricarbonyl-1,6-methanocyclodecapentaenechromium *(1)*[3] retains a delocalized 10 π-electron system *(1a)* or whether it has an olefinic structure with fixed double bonds *(1b)* or is represented by a combination *(1c)* of a delocalized 6 π-electron system and an isolated diene.



*(1a)*



*(1b)*



*(1c)*

Chemical shifts (ppm) [a]

| $\tau_2 = \tau_5$ | $\tau_3 = \tau_4$ | $\tau_7 = \tau_{10}$ | $\tau_8 = \tau_9$ | $\tau_{11}$ | $\tau_{12}$ |
|---|---|---|---|---|---|
| 3.799 | 5.671 | 3.232 | 3.584 | 11.769 | 11.138 |

Coupling constants (Hz)

| $J_{2,3} = J_{4,5}$ | $J_{3,4}$ | $J_{2,4} = J_{3,5}$ | $J_{2,5}$ |
|---|---|---|---|
| 7.05 | 7.31 | 0.37 | 1.18 |

| 8.16 | 9.22 | 0.24 | 1.56 |

| $J_{2,11} = J_{5,11}$ | $J_{2,12} = J_{5,12}$ | $J_{7,11} = J_{10,11}$ | $J_{7,12} = J_{10,12}$ | $J_{11,12}$ |
|---|---|---|---|---|
| 0.91 | < 0.4 | < 0.3 | 1.08 | 8.90 |

[a] Tetramethylsilane (= 10.0 ppm) as internal standard; spectra were recorded in $C_6D_6$ at 60 MHz with a Varian A 60-A spectrometer.

The analysis of the $^1$H–NMR spectrum of *(1)* (see table) confirms the unsymmetrical arrangement of the carbonylmetal group[3]. The spectrum may be treated as a superposition of an AA'XX' and an AA'BB' system. Assignment of the resonance frequencies is based on spin-spin coupling between methylene and ring protons in the α-position (for which $J_{anti} > J_{syn}$)[4,1] as well as on double-resonance experiments[5]. The observation that $\tau_{11} > \tau_{12}$ is compatible only with the *anti*-arrangement of the tricarbonylmetal and the methylene group.

The vicinal coupling constants of the half-ring coordinated to the metal show no appreciable alternation, as was found, for example, for tricarbonylcycloheptatrienemolybdenum[6]. The reduction by *ca.* 2 Hz caused by complex formation, in comparison with corresponding values for free 1,6-methanocyclodecapentaene *(2)*[1], parallels the observations made with other metal complexes[7]. The vicinal coupling constants of the uncoordinated half-ring also show only minor alternation and are similar to the values for *(2)*. However, for structure *(1b)* and *(1c)* $J_{7,8}$ should exceed $J_{8,9}$, as studies of cyclic 1,3-dienes[8] show. The reduction by 0.8 Hz found for $J_{7,8}$ (and $J_{9,10}$) in comparison with the corresponding constant for *(2)* may be taken to indicate that the dihedral angle between the bonds C(7)–H(7) and C(8)–H(8) [and similarly C(9)–H(9) and C(10)–H(10)] is greater in *(1)* than in *(2)*.

The results thus favor structure *(1a)*, *i.e.*, the aromatic character of *(2)*[1,9] (a delocalized 10 π-electron system) is retained on complex formation[10].

## Aminolysis of C–C Linkages

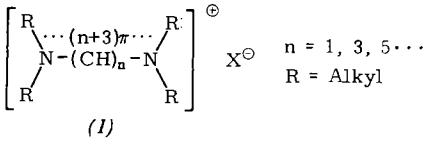
By H. E. Nikolajewski and Dr. S. Dähne

Institut für Optik und Spektroskopie der Deutschen Akademie der Wissenschaften zu Berlin (Germany)

and by Prof. B. Hirsch and Dr. E.-A. Jauer

Institut für Farbenchemie der Technischen Universität Dresden (Germany)

Polymethinecyanine dyes *(1)* that exist approximately in the ideal polymethine state[1] possess polar C–C bonds because of their strongly alternating π-electron density distribution. We have found that these bonds can be cleaved by amines to yield polymethinecyanines with shorter chains.



*(1)*

The rate of aminolysis increases with increasing chain length. Undecamethinecyanines *(1)*, n = 11, and nonamethinecyanines *(1)*, n = 9, are cleaved by strongly basic secondary amines even at room temperature, but heptamethinecyanines *(1)*, n = 7, only when boiled in alcoholic solution for several hours, whereas the pentamethinecyanines *(1)*, n = 5, are not degraded to trimethinecyanines *(1)*, n = 3, under these conditions.

When *N,N*-dimethyl-9-dimethylamino-2,4,6,8-nonatetraenylideneammonium perchlorate *(1)*, n = 9, R = $CH_3$, X = $ClO_4$[2], is boiled under reflux for 30 min with an excess of 8 % alcoholic dimethylamine the color of the solution changes from deep blue to purple; on cooling, nearly pure *N,N*-dimethyl-7-dimethylamino-2,4,6-heptatrienylideneammonium perchlorate *(1)*, n = 7, R = $CH_3$, X = $ClO_4$, is precipitated (yield 65 %).

The reaction can be considered as nucleophilic substitution at a positive methine group with formation of enamine.

In the reverse reaction, stable enamines[3] or 1,1-bisdimethylaminoethylene[4] may be substituted by cyanines *(1)*, thus increasing the length of the cyanine chain.

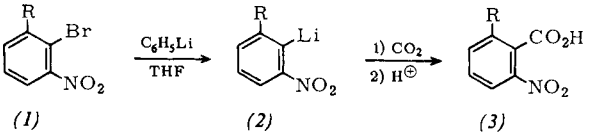
## Stable Nitroaryl-lithium Compounds[1]

By Dr. G. Köbrich and P. Buck

Organisch-Chemisches Institut,
Universität Heidelberg (Germany)

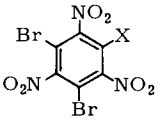
Nitro-substituted aryl-lithium compounds have not previously been prepared[2]. The *ortho*-position of nitrobenzene is not metalated by phenyl-lithium; instead, solely the nitro group is attacked and the phenyl-lithium is oxidized to lithium phenoxide[3].

We obtained the dark red *o*-nitrophenyl-lithium *(2a)* almost quantitatively on treating *o*-bromonitrobenzene with phenyl-lithium in tetrahydrofuran (THF) below −100 °C. The compound *(2a)*, and the derivatives *(2b)* and *(2c)* synthesized analogously, were characterized as the carboxylic acids *(3)*, and the compound *(4b)* as its hydrolysis product *(4c)*.



*(1)* *(2)* *(3)*

*(a)*: R = H; *(b)*: R = $CH_3$; *(c)*: R = $NO_2$



*(4a)*: X = Br
*(4b)*: X = Li
*(4c)*: X = H

| | Yield (%) | M.p. (°C) |
|---|---|---|
| *(1a)* → *(3a)* | 87–97 | 148 |
| *(1b)* → *(3b)* | 92 | 151–152 |
| *(1c)* → *(3c)* | 67 | 207 |
| *(4a)* → *(4c)* | 80 | 135 |

The influence of solvent and temperature on the ease of formation and stability of *(2a)* shows that halogen-metal exchange and reduction of the nitro group are competing reactions. Br/Li exchange to give *(2a)* [→ *(3a)*] and bromobenzene predominates at low temperature in THF, but if ether is used or the temperature is raised the degree of attack on the nitro group increases, as shown by the increasing yields of phenol.

| Temp. (°C) | In THF | | | In ether | | |
|---|---|---|---|---|---|---|
| | *(3a)* | Phenol | Bromobenzene | *(3a)* | Phenol | Bromobenzene |
| −102 | 87 % | 2 % | 87 % | 52 % | 31 % | 62 % |
| − 81 | 61 | 20 | 68 | 38 | 42 | |
| − 61 | 13 | 19 | 64 | 25 | 43 | 35 |
| − 41 | 6 | 24 | 58 | 0 | 52 | 36 |

With *m*- and, still more, *p*-bromonitrobenzene, phenoxide formation dominates even under conditions that are optimal for metalation; di- and tri-nitro aromatic compounds in which the nitro group is not forced out of the plane of the aromatic ring by bulky substituents, as it is in *(4)*, probably add phenyl-lithium to the ring, as has been found for Grignard compounds[4].

The discrepancies between the yields of *(3a)* and bromobenzene show that *o*-nitrophenyl-lithium decomposes appreciably above −80 °C; there is no indication of a benzyne intermediate in this reaction.

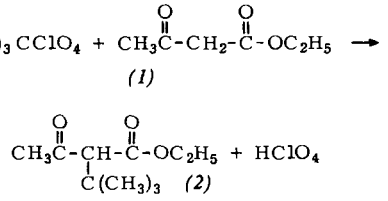
## Introduction of Tertiary Alkyl Groups into CH-Acidic Compounds

By Dr. P. Boldt and W. Thielecke[*]

Organisch-Chemisches Institut,
Universität Göttingen (Germany)

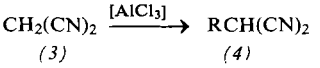
Malonodinitrile, malonic ester, and acetylacetone can be tert-butylated directly with t-butyl halides or isobutene in the presence of Lewis or Brönsted acids[1,2]. However, neither method proved preparatively useful with acetoacetic ester *(1)*[3].

We have obtained 2-t-butylacetoacetic ester *(2)* in 68 % yield by treating acetoacetic ester *(1)* with t-butyl perchlorate in nitromethane; 2-t-pentylacetoacetic ester was prepared (yield 65 %) similarly. The structure of the product *(2)*, b.p.



210 °C (corr.)/760 mm; $n_D^{20} = 1.4291$, was proved, by elemental analysis and NMR spectroscopy [δ = −1.05 (9, s); −1.27 (3, t, $J$ = 7 Hz); −2.13 (3, s); −3.18 (1, s); −4.15 (2, q, $J$ = 7 Hz) ppm [4]], and the mass spectrum is in agreement with the fragmentation scheme found for ethyl 2-alkylacetoacetates [5].

Further, we have used the reaction



to determine whether t-alkyl halides that are more bulky or have a greater tendency to eliminate hydrogen halide can be used in place of t-butyl bromide[1] in the acid-catalysed alkylation of CH-acidic compounds. The yields of alkylated malonodinitriles *(4)* are given in the table; the structures are proved by elemental analyses and NMR spectra.

| | R | Yield (%) | $^1$H—NMR data [4] δ (ppm) |
|---|---|---|---|
| *(4a)* |  | 57 | −0.97 (3, t; $J$ = 7 Hz)<br>−1.20 (6, s)<br>−1.61 (2, q; $J$ = 7 Hz)<br>−3.52 (1, s) |
| *(4b)* |  | 30 | −0.95 (6, d; $J$ = 6.5 Hz)<br>−1.14 (6, s)<br>*ca.*−1.8 (1, h; $J$ = 6.5 Hz)<br>−3.76 (1, s) |
| *(4c)* |  | 4 | −1.08 (9, s)<br>−1.26 (6, s)<br>−3,65 (1, s) |
| *(4d)* |  | 17 | −1.77 (12, s)<br>−1.80 (12, s)<br>*ca.*−2.15 (3, m)<br>−3.28 (1, s) |

Lewis acid catalysis also permits acidic methine protons to be replaced by t-alkyl groups: methylmalonodinitrile, t-butyl bromide, and aluminum chloride afford 3,3-dimethylbutane-2,2-dicarbonitrile in 38 % yield; its NMR spectrum includes δ = −1.23 (3, s) and −1.70 (1, s) ppm [4].

*2-t-Butylacetoacetic ester (2)*: A solution of 0.3 mole of $AgClO_4$ in 180 ml of nitromethane was added during 3 hr, with stirring, to a mixture of 0.9 mole of the ester *(1)*, 0.3 mole of t-butyl bromide, and 30 ml of nitromethane at 0 °C. The whole was kept for 3 hr at 0 °C, then filtered, washed with sodium hydrogen carbonate solution and water, dried, and freed from solvent. The excess of ester *(1)* in the distillation residue (0.425 mole) was hydrolysed by 45 hours' stirring with 425 ml of 1 N NaOH at 40 °C. The mixture was then cooled and extracted with ether, and the extracts were united, dried, and evaporated. Distillation of the residue afforded 37.8 g of product *(2)*, b.p. 95–98 °C/12 mm.

*Alkylation of malonodinitrile (3) (or methylmalonodinitrile)*: A solution of 0.1 mole of nitrile *(3)* and 0.1 mole of aluminum chloride in 30 ml of nitromethane was treated at −20 °C with 0.16 mole of t-alkyl bromide and kept at 3 °C for 16 hr [for *(4a)* and 3,3-dimethylbutane-2,2-dicarbonitrile; 48 hr for *(4b)* and *(4c)*; 10 days for *(4d)*]. After decomposition of the aluminum chloride ($NaHCO_3$ solution and ice) the mixture was steam distilled. The product *(4a)* or 3,3-dimethylbutane-2,2-dicarbonitrile that distilled after nitromethane was pure [*(4b)* was distilled, b.p. 82–84 °C/2 mm; *(4c)* was separated by gas chromatography (polyethylene glycol 20 M; 190 °C); *(4d)* crystallized after decomposition of the aluminum chloride and removal of the solvent].

## Isolation of Tetracyclo[6.3.1.$0^{2,6}$.$0^{5,10}$]dodecane and Pentacyclo[7.3.1.$1^{4,12}$.$0^{2,7}$.$0^{6,11}$]tetradecane (Diamantane) from Petroleum

By Dr. S. Hála and Prof. S. Landa

Synthetic Fuel and Petroleum Institute, College of Chemical Technology, Prague (Czechoslovakia)

and by Dr. V. Hanuš

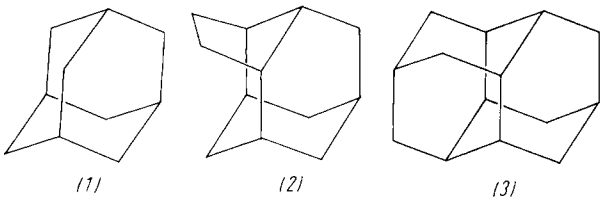
Physical Chemistry Institute, Academy of Sciences, Prague (Czechoslovakia)

Work with the naphthenic petroleum obtained in the region of Hodonin (Czechoslovakia) led some time ago to the isolation of adamantane [1] and recently to that of 1- and 2-methyladamantane [2]; we have now obtained from the same source two further crystalline naphthenes of adamantanoid structure, of which one is tetracyclic and the other pentacyclic.

These two hydrocarbons, which occur in the petroleum fraction boiling between 200 and 300 °C, give an adduct with thiourea on extractive crystallization; they concentrate in the lower portion of the column on separation by thermodiffusion. They can be purified by preparative gas chromatography and subsequent sublimation and crystallization.

The tetracyclic hydrocarbon $C_{12}H_{18}$, which was obtained with approximately 95 % purity [*], melts at 153–154 °C. The most abundant species in its mass spectrum are the molecule ion (relative intensity 100) and the fragments $C_6H_8^+$ and $C_6H_7^+$ (37 and 24, respectively), $C_9H_{11}^+$ and $C_9H_{12}^+$ (28 and 20, respectively), $C_7H_7^+$ (19), $C_{10}H_{13}^+$ (11), $C_3H_5^+$ (11), and $C_5H_7^+$ (10). In the IR spectrum the CH and $CH_2$ stretching bands (at 2935, 2920, 2905, 2865, and 2843 $cm^{-1}$) and the $CH_2$ deformation bands (at 1480, 1464, and 1450 $cm^{-1}$) are accompanied by others of medium or weak intensity, *e.g.*, at 1352, 1099, 1075, 996, 965, 928, and 881 $cm^{-1}$. In the $^1$H-NMR spectrum (Ha-100) the signals for the protons are between τ = 7.80 and 8.84, forming a complex multiplet comprising several overlapping, relatively narrow bands at τ = 8.05, 8.15, 8.27, 8.64, and 8.78; at τ = 8.35 to 8.51 there is a multiplet with resolved fine structure.

From these data we derive the adamantanoid structure tetracyclo[6.3.1.$0^{2,6}$.$0^{5,10}$]dodecane *(2)* for the hydrocarbon $C_{12}H_{18}$. This structure accords with the hydrogenative fission of the hydrocarbon on a nickel catalyst to, almost exclusively, methane, 2-methyladamantane, and adamantane.



(1) (2) (3)

The pentacyclic hydrocarbon $C_{14}H_{20}$, which crystallizes in optically isotropic octahedra, m.p. 237 °C, on slow sublimation, is pentacyclo[7.3.1.1$^{4,12}$.0$^{2,7}$.0$^{6,11}$]tetradecane *(3)*, which was recently synthesized[3] and called diamantane[4] (originally congressane[3]). The hydrocarbon $C_{14}H_{20}$ and authentic diamantane have the same melting point, an undepressed mixed melting point, and the same elution times on gas chromatography. The mass spectra also are identical and correspond[**] with the published mass spectrum of diamantane[3].

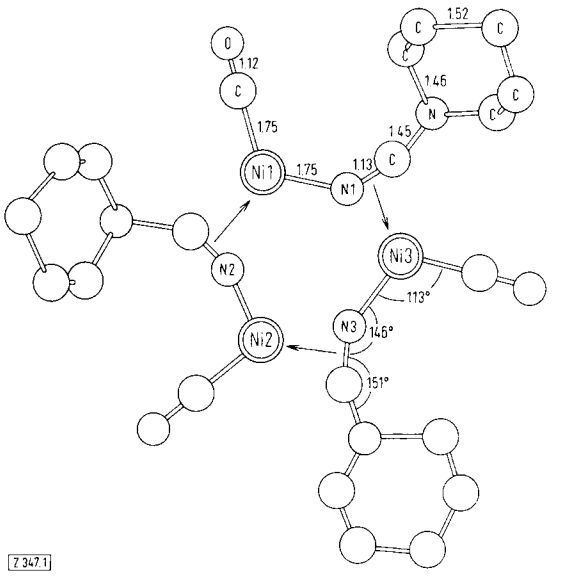
## Crystal Structure of Carbonyl-(piperidine-*N*-carbonitrile)nickel(0)

By Dr. K. Krogmann and Dr. R. Mattes

Laboratorium für anorganische Chemie,
Technische Hochschule Stuttgart (Germany)

The crystal structure of carbonyl(piperidine-*N*-carbonitrile)-nickel(0), $Ni(C_5H_{10}NCN)(CO)$, first prepared by *H. Bock* and *H. tom Dieck*[1] reveals a new type of π-complex, involving $C\equiv N$ triple bonds.

Six formula units are contained in the triclinic unit cell (space group P1) as two trimeric molecules. The nickel atoms of each trimer occupy the corners of an equilateral triangle, all having the same coordination of light atoms. Two nickel atoms (Ni-1 and Ni-2) are relatively close to nickel atoms of the adjacent trimer (3.20 Å), but no effect of metal-metal bonds on the coordination sphere can be detected. The figure shows a projection of the molecule on the plane of the three nickel atoms. Essential bond distances and angles (averaged) are included. All atoms of the CO and NCN groups are in the plane of the three Ni atoms or deviate from it by less than 0.3 Å. Every Ni atom is linked by σ bonds to a carbonyl-C and a cyano-N. Three of these monomers form the trimer using π-bonds from the cyano groups. There are no $>N{=}C{=}NR_2$ groups; these would be linear and perpendicular to the line Ni–Ni. Bond distances and angles are instead in accordance with $-N\equiv C-NR_2$ groups, and N and C atoms of the CN groups are equidistant from the π-bonded Ni atom (1.99 Å). The bond angles Ni–N–C–$NR_2$ might be expected as a result of the displacements of electron density in the π-system of the $N\equiv C$ group. The N atom of piperidine is not involved in bonding to Ni. The rings have the chair conformation; two CN groups are attached axially, and one is attached equatorially.



Z 347/1

The dimension of the unit cell are

| | |
|---|---|
| $a = 12.28$ Å | $\alpha = 105.6°$ |
| $b = 9.33$ Å | $\beta = 109.5°$ |
| $c = 12.31$ Å | $\gamma = 82.4°$ |

Volume (1278 Å$^3$) and formula weight (196.9) lead to the density $D$(calc) = 1.54 g/cm$^3$ whereas $D$(obs) = 1.53 g/cm$^3$.

1594 reflections ($CuK_\alpha$) were registered at room temperature on film, and intensities were measured photometrically[2]. Observable intensities were found only in the range of 0°–45° (overall temperature factor $B_0 \simeq 6$ Å$^2$). Coordinates of the Ni atoms could be found from a sharpened Patterson synthesis. Those of the light atoms (21 C, 6 N, 3 O) were found on successive Fourier syntheses and refined by least-squares methods, the $R$ factor decreasing from 45 % to 16 %.

## Preparation of Phosphorus Tribromide from the Elements

By Dr. F. Schröder

Institut für Anorganische Chemie,
Universität Hamburg (Germany)

Preparation of $PBr_3$ from the elements has hitherto required white phosphorus and/or use of a solvent[1,2], as well as complicated apparatus[2]. We have now converted red phosphorus into $PBr_3$ with bromine in the absence of a solvent, using a three-necked, round-bottomed flask (1 liter) equipped with a dropping funnel, a reflux condenser with drying tube, and a stirrer with a glass precision bearing. Red phosphorus powder (2 g-atoms) is very gently stirred and treated dropwise with 3 moles of bromine, slowly at first, then faster. The $PBr_3$ formed may contain suspended phosphorus and is distilled off. Water cooling can be used until the liquid $PBr_3$ appears. Previous passage of purified nitrogen through the apparatus and drying of the phosphorus avoids formation of small amounts of $P_2O_5$.

## A New Method for the Preparation of Alkali and Alkaline Earth Hydroxometalates

By Prof. R. Scholder and Dr. F. Schwochow

Institut für Anorganische Chemie,
Technische Hochschule Karlsruhe (Germany)

Hydroxometalates or, more generally, ternary hydroxides of alkali and alkaline-earth metals with more weakly basic metals have hitherto been prepared almost exclusively from aqueous solution. In this process a very high OH ion concentration, often 50 % and, in the extreme case of $Na_2[Mg(OH)_4]$[1], even over 70 % sodium hydroxide solution is usually necessary to shift the equilibrium in the direction

$$M(OH)_x + y\ OH^- \rightarrow [M(OH)_{x+y}]^{y-}.$$

The preparation is thus complicated, and the attainable purity of the products, particularly of alkalihydroxometalates, is not satisfactory.

The new method of preparation, consisting in direct, quantitative reaction of a finely powdered, almost stoichiometric mixture of the two hydroxide components at a relatively low temperature, is remarkably simple and affords much purer substances. In this way compounds of the type $Na_2[M(OH)_4]$ are obtained for M = Mn, Co, Ni, Cu, Zn, Cd, or Mg with at most 15 hours' heating between 50 °C (for Zn) and 140 °C (for Ni) under highly purified $N_2$. Similarly, hydrated $Fe_2O_3$ with NaOH at 80 °C affords $Na_5[Fe(OH)_8]$, and with partially dehydrated $Ba(OH)_2 \cdot 8\ H_2O$ at 90 °C $Ba_3[Fe(OH)_6]_2$.

It is surprising that an oxide MO can be used in place of the metal(II) hydroxide for preparation of compounds of the type $Na_2[M(OH)_4]$ if the reaction is carried out under $H_2O$-saturated $N_2$ at 50–100 °C (M = Cu, Zn, Cd, or Mg; not Ni).

The purity of the hydroxometalates obtained by the thermal method is illustrated by the observed ratios $MO:Na_2O:H_2O$ = 1:1.00–1.02:2.03–2.05 (total oxides[2] > 99 %). The products give very good X-ray powder diagrams.

Depending on the temperature of preparation (65 or 100 °C), $Na_2[Mg(OH)_4]$ is obtained in one of two modifications which have different X-ray diffraction patterns.

It has not yet been possible to obtain potassium hydroxometalates; however, preliminary thermal experiments with $Ca(OH)_2$ and NaOH in the range 3.5–4.5 NaOH:1 $Ca(OH)_2$ gave a new phase consisting of a ternary hydroxide which, according to the X-ray powder diagram, has the NaCl structure.

## Trichloromethanesulfinyl Isocyanate

By A. Senning

Chemical Institute, Aarhus University (Denmark)

In contrast to other aliphatic sulfinyl chlorides, trichloromethanesulfinyl chloride *(1)*[1] is converted by silver cyanate in boiling benzene into the corresponding isocyanate *(2)*, the first sulfinyl isocyanate reported. After filtration of the solution the benzene is distilled off and the residue is at once treated further. It contains about equal amounts of compounds *(1)* and *(2)*, as well as by-products. It was not possible to obtain the isocyanate *(2)* in a pure state because of the very similar boiling points [36–38 °C/1 mm for *(1)* and 42 °C/0.7 mm for the azeotropic mixture of *(1)* and *(2)*].

$$CCl_3SOCl + AgOCN \rightarrow CCl_3SONCO + AgCl$$
$$(1) \qquad\qquad (2)$$

When treated with water, an ethereal solution of the crude product containing the isocyanate *(2)* gives carbon dioxide and volatile decomposition products of the not isolable trichloromethanesulfinamide; with ammonia it affords trichloromethanesulfinylurea, $CCl_3SONHCONH_2$, m.p. 162 to 163 °C (decomp.), and with ethanol the urethane derivative $CCl_3SONHCOOC_2H_5$, m.p. 80–83 °C.

Direct reaction of amides with *(1)* is beset with difficulties, so that the isocyanate *(2)* is a valuable intermediate for preparation of *N*-trichloromethanesulfinyl-substituted compounds. The following are some characteristic IR bands[2]:

| $CCl_3SOR$, R = | Cl [1] | NCO | $NHCONH_2$ | $NHCO_2C_2H_5$ | $NHC_6H_5$ [1] |
|---|---|---|---|---|---|
| $\nu SO$ ($cm^{-1}$) | 1190 | 1190 | 1110 | 1110 | 1085–1095 |
| $\nu CO$ ($cm^{-1}$) | | | 1680–1700 | 1740 | |
| $\nu NCO$ ($cm^{-1}$) | | 2250 | | | |

## Crystal Structure of Violet Phosphorus

By H. Thurn and Prof. H. Krebs

Laboratorium für Anorganische Chemie,
Technische Hochschule Stuttgart (Germany)

Violet (Hittorf) phosphorus crystallizes in the monoclinic form, with space group P2/c, $a$ = 9.21, $b$ = 9.15, $c$ = 22.59 Å, $\beta$ = 106.1 °, and 84 atoms in the unit cell.

The structure is based on two units: a $P_8$ group in which the atoms are arranged as in $As_4S_4$[1], and a $P_9$ group. These units are linked, each through two further phosphorus atoms, to form infinite, tube-like structures of pentagonal cross-section (Fig. 1), which are bent somewhat "downwards" at the sites of the $P_8$ groups. This kind of linkage results in two planar, zigzag chains of phosphorus atoms being formed on two sides of the tubes (in Fig. 1 the atoms 1 to 8 and 9 to 16). This is the type of structure was previously assumed for violet phosphorus[2] and a similar structure was found for $HgPbP_{14}$[3].

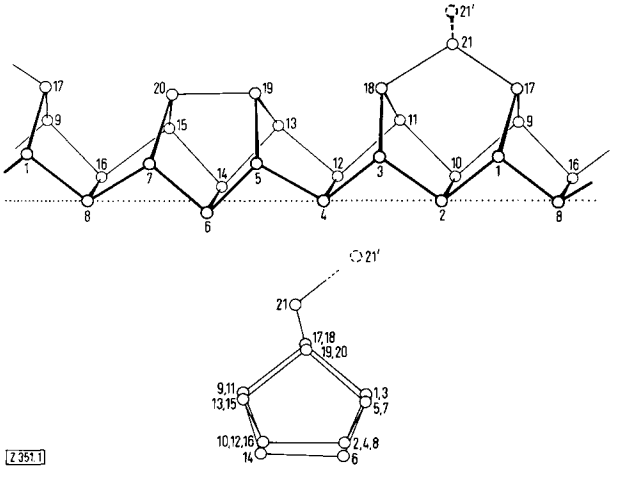

Fig. 1. Section of a "tube" of violet phosphorus. Above: parallel perspective. Below: projection parallel to the tube axis (end view).

The tubes are packed parallel to one another to form layers. Pairs of layers (*e.g.* aAaA and bBbB in Fig. 2) are connected *via* atoms 21 of the $P_9$ groups so that the axes of the tubes in the two layers form an angle of almost exactly 90°. As shown in Fig. 2, the tubes marked a and A of one layer are joined to the tubes marked b and B, respectively, in the second layer. Thus a double layer consists of two interlocking systems that, however, are not linked by chemical bonds.

These double layers are stacked in the direction of the *c*-axis so that each tube is above a gap between two tubes of the layer below; they are held together by van der Waals forces.

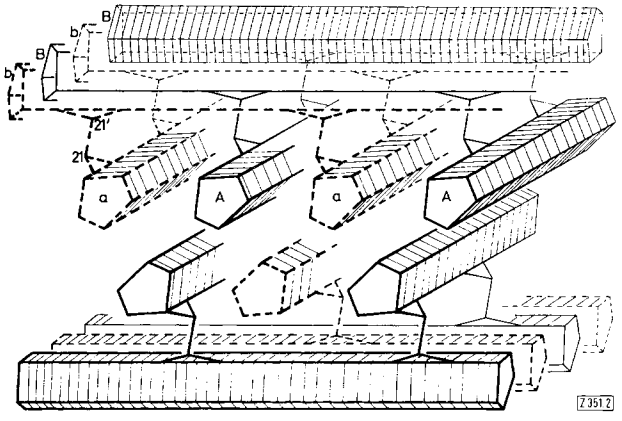

Fig. 2. Schematic representation of the structure of violet phosphorus. The "tubes" are represented by pentagonal prisms; in parts of the upper layer only one edge is drawn to show the linkage of the two halves of a double layer *via* atoms 21 and 21'.

The mean bond length is 2.219 Å, the mean bond angle 100.9°. The values diverging most from the mean are:

| | | | | |
|---|---|---|---|---|
| Bond | 21–21' | 2.178 Å | Angle 5–6–7 | 84.5° |
| | 19–20 | 2.298 Å | 13–14–15 | 86.5° |
| | | | 17–21–18 | 115.9° |

The *R*-value is 5.8 %.

The relatively complicated structure of violet phosphorus probably is due to the difficulty of satisfying all three pyramidal phosphorus valences with retention of the normal valence angle of somewhat over 100°. The complexity of the structure explains why glasses are first formed when white phosphorus is heated and the infinite crystal structure is formed only on long annealing.

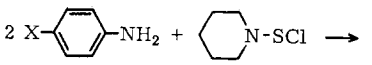
## *N*-Thioaniline, $C_6H_5N{=}S$, as Intermediate in the Decomposition of *N,N*'-Thiodianiline

By Dr. P. Tavs

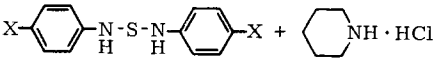
Shell Grundlagenforschung-Gesellschaft,
Schloß Birlinghoven/Siegkreis (Germany)

The *N,N'*-thiodianilines *(2a)–(2d)* were obtained by dropwise addition of piperidine-1-sulfenyl chloride [1] to a solution of the anilines *(1a)–(1d)* in anhydrous ether at −20 °C.

Compounds *(2b)–(2d)* were characterized by composition, IR spectra ($\nu_{N-H}$ = 3400–3420 $cm^{-1}$), and NMR spectra [tetramethylsilane as internal standard, AB spectrum unchanged from those of *(1b)–(1d)*, NH proton at $\tau \approx 4.1$ in



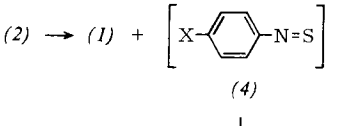
*(1)*



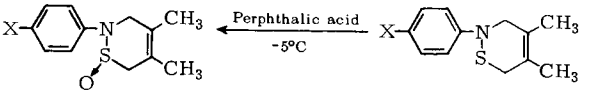
*(2)*

| *(2)* | M.p. (°C) | Yield (%) |
|---|---|---|
| *(a)*, X = H | Oil | 90 (crude) |
| *(b)*, X = Cl | 102–103 | 53 |
| *(c)*, X = Br | 106–108 | 55 |
| *(d)*, X = $NO_2$ | 208–210 | 66 |

$CS_2$]. Compounds *(2a)–(2c)* are stable for several months at −15 °C but decompose, with development of a blue color, within 2 to 6 weeks at room temperature, the anilines *(1a)* to *(1c)* being identified among the decomposition products. Compound *(2d)* is stable at room temperature. When compounds *(2a)–(2c)* are heated in an excess of boiling dimethylbutadiene for 6 hr, the 2-aryl-3,6-dihydro-4,5-dimethyl-1,2-thiazines *(3a)–(3c)* can be isolated by subsequent column chromatography and distillation. We assume that the hitherto unknown thioanilines *(4a)–(4c)* are intermediates in this reaction.



*(4)*



*(5)* *(3)*

| | *(5)*, M.p. (°C) | Yield (%) | *(3)*, B.p. (°C/0.1 mm) | Yield (%) |
|---|---|---|---|---|
| *(a)*, X = H | 79–80 (lit. [3] 79–80) | 53 | 103–105 | 22 |
| *(b)*, X = Cl | 150–151 | 46 | 117–120 | 32 |
| *(c)*, X = Br | 157–158 | 58 | 138–142 | 41 |

Compounds *(3a)–(3c)* were characterized by elemental analysis, IR spectra (no N–H stretching vibration, $\nu_{C=C}$ = 1650–1670 $cm^{-1}$, very weak), and NMR spectra [signals of the aromatic portion unchanged in comparison with those of *(1)* and *(2)*, ring methylene protons at $\tau$ = 6.2 and 7.2, C–$CH_3$ at $\tau$ = 8.3 (broad singlet), ratio of areas 2:2:6]. Compounds *(4a)–(4c)* were converted into 2-aryl-3,6-dihydro-4,5-dimethyl-1,2-thiazine 1-oxides with perphthalic acid. These products were the same as those obtained from the corresponding thionylanilines and dimethylbutadiene [2, 3] (m.p., mixed m.p., IR spectra).

*Experimental*:

*(1c)* → *(2c)*. 34.4 g (0.2 mole) of *p*-bromoaniline in 300 ml of anhydrous ether at −20 °C was treated dropwise with 15.1 g (0.1 mole) of piperidine-1-sulfenyl chloride. As soon as the temperature had risen to 0 °C the piperidinium chloride was filtered off and the ether distilled off at room temperature. The 34.5 g of yellow-brown residue crystallized when scratched and after two recrystallizations from methylene chloride afforded 20.1 g.

*(2a)* → *(3a)*. 18.0 g of crude product prepared as above from aniline and piperidine-1-sulfenyl chloride was warmed with 20 ml of dimethylbutadiene for 6 hr at 70 to 80 °C. The

residue remaining on evaporation was chromatographed on 850 g of silica gel (column 4×90 cm) with hexane/acetone (100:3). The first 300 ml of eluate contained 10.9 g of crude product *(3a)*. This was taken up in ether, and washed with 1 % hydrochloric acid and 1 % sodium hydrogen carbonate solution; the ethereal solution was dried, evaporated, and distilled. After a forerun of b.p. 35–103 °C/0.1 mm, 3.8 g of product *(3a)* was obtained.

*(3b)* → *(5b)*. 3.6 g (0.015 mole) of compound *(3b)* and 2.9 g (0.015 mole) of perphthalic acid in 32 ml of ether were kept at −5 °C for 2 hr. The solution was then washed several times with 1 % sodium hydrogen carbonate solution, dried, and evaporated. The 2.1 g of residue crystallized when scratched. When recrystallized twice from petroleum ether, the product *(5b)* (1.8 g) was identical (m.p., mixed m.p., IR spectra) with that obtained from *p*-aminobenzenesulfinyl chloride and dimethylbutadiene (20 hr, 70 °C, 68 %).

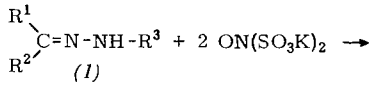
## Reaction of Phenylhydrazones with Dipotassium Nitrosobissulfate

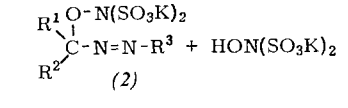
By Prof. H.-J. Teuber and K.-H. Dietz

Institut für Organische Chemie,
Universität Frankfurt/Main (Germany)

Reaction of dipotassium nitrosobissulfate, $ON(SO_3K)_2$, with phenols gives quinitrol-like substitution products [1], which decompose to quinones and dipotassium imidobissulfate, $HN(SO_3K)_2$, either spontaneously or under acid catalysis. Phenylhydrazones [*(1)*, $R^1$ = H, alkyl, aryl; $R^2$ = alkyl; aryl; $R^3$ = aryl] yield yellow, well crystalline azo compounds *(2)* on dehydrogenation at the nitrogen.



*(1)*



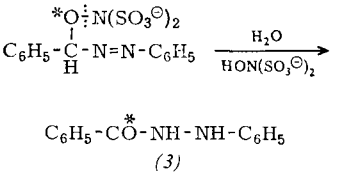
*(2)*

*Experimental*: 5 mmole of a phenylhydrazone in 120 ml of acetone are mixed with 10 mmole of dipotassium nitrosobissulfate in 120 ml of water containing 0.5 g of sodium acetate to give an orange-yellow solution, which, after 10 min, is evaporated at 50 °C to half its volume, washed with ether, and evaporated to dryness. Extraction of the residue with methanol, evaporation of the extract, and recrystallization of the resulting residue from 80 % ethanol give the yellow compound *(2)*, containing solvent of crystallization, almost quantitatively.

Compounds *(2)* are formed in this way from the phenylhydrazones of furfural, cinnamaldehyde, salicylaldehyde, *o*-chlorobenzaldehyde, *o*-, *m*-, and *p*-nitrobenzaldehyde, acetone, benzophenone, acetophenone, isobutyraldehyde, cyclohexanone, or cyclopentanone; the substituent in the hydrazone group may also be varied [2,3-, 2,4-, or 2,5-$(CH_3)_2C_6H_3$, *o*-$ClC_6H_4$, *p*-$NO_2C_6H_4$, or *p*-$CH_3C_6H_4$]. However, an *o*-nitrophenyl, 2,4-dinitrophenyl, or benzenesulfonyl substituent in the hydrazone group prevents the reaction, as does replacement of the hydrogen attached to nitrogen; semicarbazones also do not react.

Dipotassium *N*-(phenylazoalkoxy)imidobissulfates *(2)* correspond to the phenylazoalkyl hydroperoxides [*(2)*, −OOH replacing $-ON(SO_3K_2)_2$] [2] formed by autoxidation; the phenylazocarbinol acetates [*(2)* with −OAc replacing $-ON(SO_3K)_2$] [3] formed with lead tetraacetate, as well as the compounds produced with benzoyl peroxide [4]; nitrous acid [5], and diazonium salts (formation of formazans). The azo formulation of *(2)* follows from almost identical UV spectra ($\lambda_{max}$ in methanol: 400, 265–270, 215–218 mμ; log ε = 2.7, 4.7, 4.8) as well as instability of the corresponding alkyl derivatives (*(2)* with $R^3$ = alkyl). Substitution in the $R^1$, $R^2$, or $R^3$ groups by the nitrosobissulfate group is excluded by the NMR spectrum. They are reconverted into hydrazones *(1)*, as are phenylazohydroperoxides, on reaction with sodium dithionate, zinc/acetic acid, or hydrogen activated on Pd/$BaSo_4$. The formation of osotriazol from osazones possibly involves an intermediate corresponding to *(2)*.

Compound *(2)* with $R^1$ = H and $R^2$ = $R^3$ = $C_6H_5$ decomposes in 1/2 hr in aqueous solution at 90 °C to *N'*-phenylbenzhydrazide *(3)* and hydroxylimidobissulfuric acid [6,7]; benzoic acid and phenylhydrazine are formed also. Decomposition in $^{18}O$-labeled water shows that 6 % of the hydrazide is derived from the water (the hydrazide *(3)*, once formed, does not undergo exchange with water). However, decomposition of the substitution product *(2)* obtained from $^{18}ON(SO_3K)_2$ [8] affords an *N'*-phenylbenzhydrazide *(3)* whose oxygen is derived to the extent of more than 70 % from the nitrosobissulfate group, indicating the following mechanism.



*(3)*

The hydrolytic removal of the nitrosobissulfate group takes place *via* the quinitrol-like substitution product of the 1-methyl-2-naphthol analogue [9]. Apart from hydrolysis of the C–O instead of the N–O bond, the incomplete labeling of *(3)* could be due to the nitrosobissulfate group in *(2)* being bonded to the organic group partly *via* the nitrogen atom. The *o*-chlorobenzoic acid finally produced from *o*-chlorobenzaldehyde *via (1)* → *(2)* → *(3)* and further hydrolysis, shows the same labeling as *N'*-phenyl-*o*-chlorobenzhydrazide.

## The Dynamics of Sulfur Metabolism and the Utilization of Sulfur in the Animal Organism

*J. Landis* and *J. P. Montavon*, Zürich (Switzerland)

Single doses of [$^{35}$S]-L-methionine were given orally to growing rats whose rations included various amounts of sulfur-containing amino acids. With a deficiency of methionine the separation of $^{35}$S in the excrements was fairly constant during the first three days, *i.e.* it was independent of the size of the methionine deficit. When an excess of methionine was administered there was a relation between the excretion of $^{35}$S and the amount of the excess (large increase in excretion of $^{35}$S with increasing methionine excess). This relationship enables the utilization of methionine sulfur to be determined even if there is no deficiency of methionine and if no change in growth or nitrogen balance is observable.

A cystine content of about 0.3 % in the diet influenced the excretion of radioactive sulfur (administered as [$^{35}$S]-L-methionine) in the same way as an equivalent increase in methionine content as regards content of amino acid sulfur. A further increase in the cystine content of the diet was, however, without influence on the excretion of labeled sulfur. This result is interpreted as showing that, under the experimental conditions used, 50 to 60 % of the animals' total requirement of amino acid sulfur can be supplied as cystine, the total requirement being estimated from the excretion of $^{35}$S in the absence of cystine as 0.11 to 0.13 % of the diet (equivalent to a 0.5 to 0.6 % methionine content).

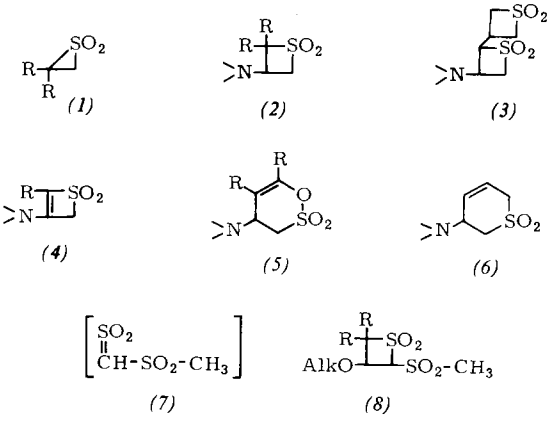
## Sulfenes

*G. Opitz*, Tübingen (Germany)

The intermediate formation of sulfenes $R'_2C{=}SO_2$ on elimination of HCl from sulfonyl chlorides with trialkylamines or on reaction of diazoalkanes with $SO_2$ can be recognized by means of trapping agents. Addition of diazoalkanes (when R′ = H) produces three-membered cyclic sulfones *(1)*, addition of enamines, dienamines, or ketene aminals gives four-membered cyclic sulfones *(2)*, *(3)*, or *(4)*, respectively, of 2-aminovinyl ketones yields six-membered cyclic sultones *(5)*, and of dienamines gives unsaturated six-membered cyclic sulfones *(6)* [in addition to *(3)*].



*(1)* *(2)* *(3)* *(4)* *(5)* *(6)* *(7)* *(8)*

In the absence of a trapping agent the sulfenes at once react further with the sulfonyl chloride or with the diazoalkane or $SO_2$, so that they have not hitherto been isolated or identified directly. We have now isolated methanesulfonylsulfene (methanesulfonylthioformaldehyde dioxide) *(7)* as its trimethylamine adduct[1]. This compound *(7)* is formed when methanesulfonyl chloride is treated with an excess of triethylamine in acetonitrile at −40 °C[2]; it is present as triethylamine adduct in the filtrate from the triethylamine hydrochloride; on addition of trimethylamine the more stable 1:1 trimethylamine adduct is precipitated, which can be isolated at room temperature without the need to exclude air. It gives the four-membered cyclic sulfones *(8)*[3], not merely with enamines, but also with vinyl ethers. The reaction leading to *(8)* can be effected also with methanesulfonyl chloride/triethylamine and vinyl ether in acetonitrile at −40 °C.

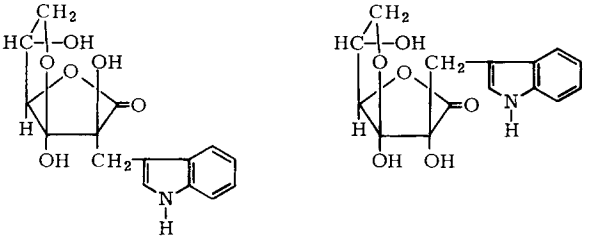
## Formation and Properties of Ascorbigen

*G. Kiss*, Zürich (Switzerland)

Two epimeric ascorbigens (A and B) are formed on reaction of L-ascorbic acid with 3-(hydroxymethyl)indole[1] by the method of *Virtanen et al.*[2]. Ascorbigen A, identical with the natural product, was obtained as main product (55–60 % yield). The yield of ascorbigen B was less than 20 %.



Ascorbigen A Ascorbigen B

Ascorbigens A and B result from reaction of the ascorbate anion at C-2 with the resonance-stabilized carbonium-iminium ion[3] formed from 3-(hydroxymethyl)indole; *O*-alkylation was not observed. Acid hydrolysis of ascorbigen A (pH 1.5–3.0; 37 °C) yields L-ascorbic acid.

The structure was established by elemental analysis, reactions (derivatives such as ascorbigenamide and ascorbigen methylglycoside) and spectroscopic data.

The ascorbigens can be determined in finely divided plant material by thin-layer chromatography. Ascorbigen A was found in macerated white cabbage, kohlrabi, cauliflower, and radish.

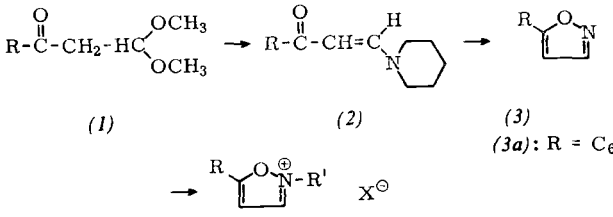
**The synthesis of isoxazolium salts unsubstituted in the 3-position** has been considerably improved by *B. D. Wilson* and *D. M. Burness*. These compounds, *e.g. (4a)*, can generate a peptide bond under mild conditions, like carbodiimides. The readily available compounds *(1)* are converted with piperidine to *(2)*, which yields on reaction with hydroxylamine isoxazoles *(3)*, which are free of isomers to better than 98%. Alkylation of *(3)* then renders the isoxazolium salts *(4)*.



*(1)* *(2)* *(3)*

*(3a)*: R = $C_6H_5$

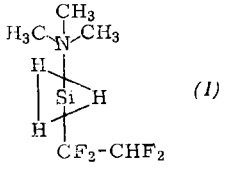
*(4)*

*(4a)*: inner salt: R = ; R' = $C_2H_5$; no $X^{\ominus}$

*(4b)*: R = R' = $CH_3$; $X^{\ominus}$ = *p*-toluenesulfonate

For the preparation of *(4a)*, m.p. 209.5–211 °C (decomp.), known as *Woodward*'s reagent K, *(3a)*, m.p. 21–22 °C, $n_D^{25}$ = 1.5832, is sulfonated with chlorosulfonic acid and ethylated. It can be prepared in an overall yield of 70%. Another example is *(4b)*, m.p. 111–112 °C, yield 80%. / J. org. Chemistry *31*, 1565 (1966) / –Bu. [Rd 542 IE]

A **pentacoordinate silicon complex** has been prepared by *R. N. Haszeldine* and co-workers from trimethylamine and 1,1,2,2-tetrafluoroethyl silane. Structure *(1)* can be assigned to the 1:1 adduct on the basis of infrared and NMR spectra: the Si–H stretching frequency is shifted from 2222 $cm^{-1}$ (in the starting silane) to 2155 $cm^{-1}$, *i.e.* the electron density on

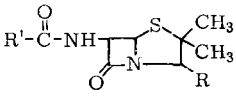


*(1)*

silicon is increased; the C–H bands appearing at 2780 $cm^{-1}$ in trimethylamine are missing, as has been generally observed when nitrogen donates its lone pair of electrons to some acceptor; the equivalence of all Si–H hydrogens in the NMR spectrum is in accordance with the trigonal bipyramidal structure *(1)*. The compound, a stable liquid, can be vacuum distilled (vapor pressure: 84 mm/20 °C); in the gas phase the compound dissociates to the parent compounds as shown by IR spectrum and molecular weight. / J. chem. Soc. (London) A *1966*, 889 / –Bu. [Rd 544 IE]

**The attenuation of sound waves in a single crystal of $NH_4Cl$** in the (100) direction close to the lambda transition temperature (about 242 °K) was measured by *C. W. Garland* and *C. F. Yarnell*. In the lambda transition, the ammonium ions pass from a state of fixed orientation to one of random orientation. In the immediate neighborhood of the lambda point, the attenuation coefficients measured during cooling differ appreciably from those found during heating (maximum rate of heating about 1 degree/hour). This difference can be explained by a model that requires mechanical instability in the neighborhood of the transition temperature. / J. chem. Physics *44*, 3678 (1966) / –Hz. [Rd 592 IE]

**Penicillinaldehydes** *(1)* can be prepared in an overall yield of 30 to 40% by a new three-stage synthesis. According to *L. C. Cheney et al.*, salts of thiocarboxylic acids *(2)* can be converted into the aldehydes *(1)* with commercial Raney nickel, without attack on the sensitive ring sulfur. Further reduction of *(1)* is prevented by the presence of *N,N'*-diphenylethylenediamine, which converts *(1)* into *(3)*. The crystalline imidazolidines *(3)* are reconverted into the aldehydes *(1)* by cleavage with *p*-toluenesulfonic acid monohydrate in a moist mixture of ether, acetone, and methylene



*(1)*: R = –CHO

*(2)*: R = –COSK

*(3)*: R = 
*(4)*: R = $-COO[HN(C_2H_5)_3]$

chloride (3:1:1). The thiocarboxylates *(2)* can be prepared from the ammonium salts *(4)* by treatment with ethyl chloroformate and alkali hydrogen sulfide. / J. org. Chemistry *31*, 1922 (1966) / –Bu. [Rd 548 IE]

**The recoil bromination of halogenobenzenes** has been studied by *M. Laser* and *E. Merz*, with the object of determining whether only bromine radicals are active in "hot" bromination. Bromobenzene/halogenobenzene (X = F, Cl, I) mixtures were exposed for several hours to a stream of thermal neutrons ($3–5\times10^{11}$ n/$cm^2$). Toluene was added to intercept "hot" and thermal bromine radicals. Nevertheless, all the isomeric bromination products (gas-chromatographic separation; radiochemical quantitative determination) of the starting materials were found, so that "hot" $^{82}Br$ formed in an (n,γ) reaction must have become capable of effecting an electrophilic substitution, probably as $^{82}Br^+$. Since the products of nuclear bromination were not formed in random proportions, the reaction at high temperatures must be mainly controlled by the entropy of activation (small energy term), in accordance with equation (1); this is explained by polarization and polarizability effects.

$$\ln(k_1/k_2) = ({}^aE_2 - {}^aE_1)/RT - ({}^aS_2 - {}^aS_1)/R \qquad (1)$$

| Bromination products | Relative rate constants | | | Relative overall bromination rate |
|---|---|---|---|---|
| | $k_{ortho}$ | $k_{meta}$ | $k_{para}$ | |
| Bromofluorobenzenes | 1.00 | 0.92 | 1.55 | 0 4 |
| Bromochlorobenzenes | 1.00 | 1.00 | 1.18 | 0.5 |
| Dibromobenzenes | 1.00 | 0.54 | 0.55 | 1.0 |
| Bromoiodobenzenes | 1.00 | 0.60 | 0.35 | 2.5 |

/ Radiochim. Acta *5*, 65 (1966) / –Hz. [Rd 591 IE]

**The new nuclide $^{52}Ti$** has been identified by *J. Facetti, J. Flegenheimer*, and *E. Trabal*. 1 g samples of $^6Li$-enriched $Li_2TiF_6$ were irradiated in the reactor at a neutron flux of $10^{12}$ n $cm^{-2}$ $sec^{-1}$; the nuclear reactions $^6Li(n,\alpha)T$ (2.67 MeV) and (in spite of the high potential barrier for T) $^{50}Ti(T,p)^{52}Ti$ took place. After "wet" chemical separation, the Ti fraction (secondary components: $^{18}F$, $^{56}Mn$) gave a typical β-decay curve with $\tau_{1/2} = 49 \pm 3$ min, which must be attributed to the nuclide $^{52}Ti$, since:

1. The known $^{52}V$ can be chemically separated as a daughter nuclide (precipitation with tetraphenylarsonium chloride), 2. the 1.42 MeV γ maximum of $^{52}V$ in the titanium sample decays with $\tau_{1/2} = 49$ min, and 3. if the vanadium is periodically "milked out" of the Ti solution, the γ-decay half-life of $^{52}V$ is always found to be $\tau_{1/2} \approx 4$ min. / Radiochim. Acta *5*, 143 (1966) / –Jg. [Rd 595 IE]

**Vitamine. Chemie and Biochemie** (Vitamins. Chemistry and Biochemistry). Edited by *J. Fragner*, translated from the Czech by *E. Hachová*. Vol. II. VEB Gustav Fischer Verlag, Jena 1965. 1st German ed., 770 pp., 33 figures, 83 tables, bound DM 78.20 (*ca.* $20).

The second volume of the handbook on vitamins is now available in a German translation [1]. It contains contributions by 26 authors on the following vitamins: folic acid, inositol, K vitamins, lipoic acid, nicotinic acid, pantothenic acid, pyridoxine, riboflavin, thiamine, tocopherol, and less-known exogenous factors. This volume also contains the full index. The subdivision of the individual chapters is the same as in the first volume, and the translation is generally better. The second volume contains 6027 literature references and 608 patent references, though the literature unfortunately is covered only up to about 1961.

This volume is again overloaded with facts or hypotheses that are now only of historic interest, and laborious searching is required in order to find the important facts. It is not clear, for example, why seven pages and a two-page table are devoted to a description of all known vitamin $B_6$ syntheses, even though only one of these is used industrially.

Owing to its adherence to the historical development, the text is often confusing. Thus it says on page 1123: "As was shown by *Calvin* and co-workers, lipoic acid plays an important part in photosynthesis, *i.e.* that of an electron acceptor in the transformation of the electromagnetic light energy into chemical energy". This is followed on the next page by".. the current hypotheses are mere assumptions in *Calvin*'s view, so that the question of the participation of lipoic acid in photosynthesis still remains unanswered".

On page 1120 it is stated that "*Reed* and *de Busk* showed, by paper chromatography, that lipoic acid forms a biologically active conjugate with thiamine or thiamine phosphate, which they called lipothiamide". The next page then states: "The biological importance of lipothiamide...was subsequently also disputed by the author of the original idea". The really important bonding of lipoic acid to the ε-amino group of lysine, on the other hand, is dismissed in a single sentence. The book also contains numerous errors and inaccuracies. Page 1080 gives an incorrect full-page scheme for the biosynthesis of the K vitamins. The methylnaphthoquinone skeleton is not formed by the combination of two $C_6$ units, but from a single carbon chain. The formula of tyrosine is given instead of phenylalanine on page 1078. On pages 1414 and 1415, lumichrome is confused with 6,7-dimethyl-8-ribityllumazine. The authors explain the function of the pyridine nucleotides in redox reactions with the following sentence: "In principle, this involves the reduction of the pentavalent nitrogen in the pyridine nucleus to the trivalent state and its reoxidation". Coenzyme III, which was shelved a long time ago, is mentioned in several places.

The present work cannot be recommended as a textbook. On the other hand, as a reasonably-priced reference work and as a handbook for the specialist, it offers a wealth of information.

*H. Grisebach* [NB 519 IE]

[1] Cf. Angew. Chem. *77*, 1046 (1965); Angew. Chem. internat. Edit. *4*, 1000 (1965).

**Guide to the Analysis of Pesticide Residues.** Edited by *H. P. Burchfield* and *D. E. Johnson*. U.S. Department of Health, Education, and Welfare: Public Health Service, Bureau of State Services (Environmental Health), Office of Pesticides, Washington 1965. 2nd Edit., Vols. 1 and 2, loose-leaf, total 584 sheets, 24 illustrations, 26 tables, together $ 12.75.

Many analytical methods have been developed in recent years, particularly in the USA, for the isolation and identification of even trace amounts of the toxicologically most important pesticide residues in water, soil, foods, or body fluids. However, the results of different laboratories can be appraised only if the analyses are carried out by comparable methods.

The present work therefore presents mainly standard procedures for the detection of residues of insecticidal chlorohydrocarbons, phosphates, and thiophosphates and of herbicidal chlorophenoxycarboxylic acids, which are to be used exclusively in investigations for the Public Health Service. The emphasis is on methods that permit simultaneously rapid and reliable detection of several pesticides in a single operation.

The individual stages of the analytical procedure are discussed in turn. Procedures are given first for the extraction of samples, then for the removal of interfering substances from the extract. The residues are identified and quantitatively determined almost exclusively by paper and thin-layer chromatography and by gas chromatography with an electron-capture detector or with microcoulometric recording; IR spectrography is used to confirm the results. Several variants of one operation are given. The substances for which each procedure is suitable and the conditions under which it can be used are indicated; from these data, the analyst can compile the best analytical procedure for his own purposes. The work also contains IR spectra of numerous reference substances and extensive lists of chemical names, trade names, and properties of the most common pesticides.

Only a few laboratories in Europe are engaged in analyses of this nature. This collection of established methods could contribute substantially to the introduction, in a short time, of more stringent supervision of pesticide residues here on the basis of experience in the USA. Though the work presupposes a certain familiarity with the problems of residue analysis, it helps to avoid extensive and costly preparatory work.

*H.-P. Thier* [NB 538 IE]

**Laboratoriumstechnik für Biochemiker** (Laboratory Techniques for Biochemists). Edited by *B. Keil* and *Z. Šormová*. Akademische Verlagsgesellschaft Geest & Portig, Leipzig 1965. 1st edit., 925 pp., 341 figs., 120 tables, bound DM 83.50 (about $ 20.–).

A series of books exists devoted especially to work in the biochemical laboratory, yet there is no general laboratory handbook, apart from the comprehensive volumes of "Hoppe-Seyler/Thierfelder" or "Methods in Enzymology".

The present book, published in 1965, is a translation of one that appeared in Prague in 1959. Although some additional references have been introduced into several of the chapters, many of the chapters have been taken over into the German edition without revision, with the result that the literature is covered only up to the middle of the 1950's. For instance, in chapters XV and XVI, which present a tabular review of the preparative methods and physicochemical constants for proteins, less than 1 % of the references cited (4 citations out of a total of 1112!) are dated later than 1955. The table giving the composition of proteins is also ten years old; and the table of buffers makes no mention of the tris buffer that is so commonly used today.

In the general section, constituting about a third of the whole, the basic techniques are discussed in detail, but the description of the physicochemical methods provides orientation rather than a direct introduction. The specialized section contains many chapters written comprehensively and with great expertise, *e.g.* the sections on biochemical preparations by the editors. As stated in the preface, emphasis is on proteins and nucleic acids throughout. In any new edition it would be advisable to equalize the treatment for all fields, even if some of them are of less immediate importance, and even perhaps with sacrifice of the tabulated reviews that belong preferably to a handbook.

In the preface *Bamann-Myrbäck*'s book (published in 1941) is recommended, but there is no reference to "Methods in Enzymology"(volume 1 appeared in 1955) or to "Hoppe-Seyler/Thierfelder" (whose publication began in 1953), and this is characteristic of the whole book. It is unintelligible why the editors agreed to translation of a six-year-old book without thorough revision. A purchaser who cannot examine the book before buying it and therefore relies on the repute of the authors will not discover for some time that he could have spent his money to better effect in other ways. In its outdated form this book cannot be recommended.

*H. Sund* [NB 498 IE]

**Submicro Methods of Organic Analysis.** By *R. Belcher*. Elsevier Publishing Company, Amsterdam 1966. 1st ed., ix, 173 pp., numerous illustrations, bound, Dutch fl. 27.50.

In this book, *Belcher* presents a summary of the submicro methods of organic analysis, which he and his school have systematically studied since 1951. The methods require 30 to 50 microgram samples, corresponding to a hundredfold decrease in sample size as compared with the classical micro methods. At present, however, they can be applied only to solids.

The organisation of the book corresponds to that of *Pregl*. The balance and the principal tools are described first. This is followed by the methods for the determination of the elements and of the functional groups, and the discussion is concluded with the determination of molecular weights. The only important determinations omitted are those of oxygen, the saponification value and the hydroxyl value. The methods used in most cases are conventional titration methods adapted to the submicro scale. According to the author, if the very detailed procedures are adhered to, the "maximum errors" are no higher than in the micro methods. The methods described in this book, however, are not intended to replace the classical methods, but are designed to be used when not enough substance is available for examination by milligram or decimilligram methods. In these cases this book will be of great assistance. *W. Pfab* [NB 515 IE]

**Friedel-Crafts and Related Reactions.** Edited by *G. A. Olah*. Vol. IV: Miscellaneous Reactions, Cumulative Indexes. Interscience Publishers, a Division of John Wiley & Sons, New York-London-Sydney 1965. 1st Edit., 1191 pp., numerous tables, bound £ 17/–/–.

Volume IV completes a bold and successful literary project. Since the word "related" includes all acid-catalysed reactions, whether they proceed in the presence of Lewis acids or Brönsted-Lowry acids, the subject matter touches on almost every field of organic chemistry. The reviewer has repeatedly had occasion to recommend the earlier volumes [1]. The last eight chapters are of the same quality in their conciseness and selection of material. These are followed by an extensive (870 pp.) and carefully edited author and subject index for the entire work.

The last volume deals in turn with the reactions of ethers, including cyclic ethers *(F. Johnson)*, the reactions of aromatic compounds with Lewis-acidic metal halides *(P. Kovacic)*, and the reactions of non-benzenoid aromatic compounds by *K. Hafner* and *K. L. Moritz*. These are followed by somewhat brief accounts of reactions with organometallic compounds *(G. A. Russell)*, reactions in organophosphorus chemistry *(G. M. Kosolapoff)*, and reactions in carbohydrate chemistry *(W. Wagner)*. The second to last chapter *(G. A. Olah* and *H. W. Quinn)* deals with metathetic reactions of salts, and *G. A. Olah* finally presents a review of applications.

It is to be hoped that the highly informative character of "Friedel-Crafts and Related Reactions" will be maintained in the future. *J. Gosselck* [NB 544 IE]

**The Molecules of Nature: A Survey of the Biosynthesis and Chemistry of Natural Products.** By *J. B. Hendrickson*. The Organic Chemistry Monograph Series. Editor *R. Breslow*. W. A. Benjamin, Inc., New York 1965. 1st ed., xiii, 179 pp., bound $7.00.

This book is one of a series of monographs intended to supplement the elementary instruction of undergraduate students in organic chemistry. The author rightly points out that the student today often is not acquainted with the fascinating problems of natural-product chemistry. The purpose of this book, therefore, is to fill this gap, and the author has succeeded admirably in achieving this aim.

The multitude of compounds nowadays can be arranged in a logical scheme on the basis of their biogenesis. Thus the first chapter surveys the biogenesis of the acetogenins (compounds synthesized from acetate, a better and more comprehensive term being "polyketides"), terpenes, and alkaloids. The emphasis is placed on the presentation of the chemical reactions, while the biological aspects are scarcely mentioned. The student could easily gain the impression that all the reaction paths described have been experimentally verified, though this is by no means the case.

In the following chapters, the chemistry of these classes of natural products is described with the aid of a few well-chosen examples. The reader is brought into contact with both the classical degradation reactions and the modern methods of structure elucidation. Stereochemical questions are discussed at various points.

Exercises, the solution of which will cause some trouble even to advanced workers, are skilfully fitted into the text, and the entire book demands intense participation on the student's part. The printing and the reproduction of formulae are excellent. The book is strongly recommended to the advanced chemistry student.

*H. Grisebach* [NB 518 IE]

**Interpretation of Organic Spectra.** Edited by *D. W. Mathieson*. Academic Press Inc., London-New York-Sydney 1965. 1st ed., ix, 179 pp., numerous illustrations, cloth $7.00.

The increasing use of spectroscopic methods for the determination of the structures of organic compounds presents a need for the teaching of these methods. The present book is based on practical exercises in summer courses; with the aid of examples (17 in NMR, 15 in infrared, and 10 in mass spectroscopy), it provides a practical introduction to the three most important methods of structural elucidation. The analysis of number of examples is first demonstrated in fair detail without previous description of the fundamental principles, in order that the reader may then be presented with spectra, without further explanation (but with solutions), to work out for himself.

Didactically and in the selection of the material the individual sections, unfortunately, are of varying standard. The NMR and infrared sections probably offer the newcomer a better introduction than the section on mass spectroscopy, which (*e.g.* in Problem 5) gives unnecessarily difficult examples, and does not refer to literature later than about 1958. The discussion of NMR data is concise and to the point, that of infrared and mass-spectroscopic data is rather lengthy; the infrared section evinces a pessimistic, critical attitude, while the other two sections offer the reader more hope of success in the analysis of spectra. In contrast to the pleasing external presentation of the book, one gains the impression on reading that some points in the text, in the formulae, and in the terminology have not been as carefully worked out as is necessary, particularly in a book intended for teaching. In the critic's opinion, this book is not to be recommended, at least for the beginner.

*W. Lüttke* [NB 505 IE]

ACETALS, Synth. of ~ by reacn. of diazoalkanes with t-butyl hypochlorite (SC) 420 [G.E. *78*, 448 (1966)]

Prepn. of *O,N*-~ of acyl isocyanates (SC) 841 [G.E. *78*, 826 (1966)]

Acetogenins, Biosynth. of Steroids, Terpenes, and ~ (Book Review) 148

Acetonitrile, Formation of coordination complexes in anhydrous ~ (CR) 142 [G.E. *78*, 151 (1966)]

Acetyl-CoA, Transport of ~ from the mitochondria into the cytoplasm (LA) 143

Acetylene, Novel synth. of adipic acid from ~ and acetic acid (SC) 415 [G.E. *78*, 388 (1966)]

Heterocycles from ~ derivs. (CR) 741 [G.E. *78*, 757 (1966)]

Benzene from ~ in Avocado pears (LA) 142

Acetyltransferase, Acetyl-CoA: D-amino acid α-*N*-~ (LA) 427

Acid-Base Equilibria (Book Review) 265

Acrylic compds., New prepn. of oligomers (LA) 978

Acrylonitrile, from propylene, ammonia, and atmospheric oxygen (FP) 642 from Chemie-Ing.-Techn. *38*, 701 (1966)]

Activation analysis, Use of ~ for determin. of traces in the white lead of paintings (CR) 679 [G.E. *78*, 720 (1966)]

Acylation, Simple method for selective ~ of cytidine on the 4-amino group (SC) 579 [G.E. *78*, 589 (1966)]

Acylcarbamoyl azides and sulfonylcarbamoyl azides (SC) 314 [G.E. *78*, 333 (1966)]

Acyl halides, Cleavage of aryl-substd. tert. amines by ~ (CR) 849 [G.E. *78*, 828 (1966)]

Acyl hypoiodites, Photochemical decarboxylation of ~ (LA) 145

Adamantane, Tetraalkyltetrasilicon hexachalcogenides with the ~ structure (LA) 977

Adipic acid, Novel synth. of ~ from acetylene and acetic acid (SC) 415 [G.E. *78*, 388 (1966)]

Adrenal hormones, Biochemie der Nebennierenrinden-Hormone (Biochemistry of the ~) (Book Review) 746

Adsorption, Electrochem. investigation of the ~ of surface-active materials at the phase boundary mercury/electrolyte (CR) 901 [G.E. *78*, 946 (1966)]

Alanine, Synth. of 3,3,3-trifluoro-~ and of 3,3,3-trifluoroalanyl peptides (SC) 600 [G.E. *78*, 640 (1966)]

Alcohol dehydrogenase, Reactivity and function of the thiol groups of ~ (LA) 142

Alcohols, as petrochemicals (FP) 646 from Chem.-Ing.-Techn. *38*, 837 (1966)]

Reacns. occurring on hydrogenation of unsatd. fatty ~ (CR) 900 [G.E. *78*, 944 (1966)]

Prepn. of hydrogen sulfate esters by reacn. of higher aliphatic ~ with sulfamic acid (CR) 902 [G.E. *78*, 946 (1966)]

Determin. of ~ in water by the ATR technique (LA) 324

Reacn. of lead(IV) chloride with vicinal diols (LA) 745

Aldehydes, Rearr. of α-substd. ~ (CR) 525 [G.E. *78*, 552 (1966)]

Synth. of nitriles from ~ (LA) 261

Lithium hydridotris-(t-butoxy)aluminate (LA) 616

Alkali metals, Reacn. of aryl azides with ~ (SC) 586 [G.E. *78*, 596 (1966)]

Alkaloids, Cyclic oxidn. products of lysine (SC) 131 [G.E. *78*, 118 (1966)]

Synth. of the central octacyclic structure of the principal calebash curare alkaloid, C-curarine-I (SC) 957 [G.E. *78*, 978 (1966)]

Isoquinoline ~. A Course in Organic Chemistry (Book Review) 329

Alkenes, see Olefins

Alkoxycarbonylation, of sec. and prim. amines by alkoxycarbonylmercury compds. (SC) 252 [G.E. *78*, 209 (1966)]

Alkylation, Synths. and reacns. of *O,N,N'*-trisubstd. isoureas (FP) 470 [G.E. *78*, 483 (1966)]

~ of amine oxides with sultones (SC) 419 [G.E. *78*, 391 (1966)]

~ by dialkoxycarbonium salts (SC) 675 [G.E. *78*, 714 (1966)]

Aryl-substd. dialkoxycarbonium ions as alkylating agents (SC) 676 [G.E. *78*, 715 (1966)]

Introduction of tertiary alkyl groups into CH-acidic compds. (SC) 1044 [G.E. *78*, 1058 (1966)]

Photo-~ (CR) 255 [G.E. *78*, 211 (1966)]

Sodium-catalysed ~ of 3-picoline (LA) 426

Alkylidenephosphoranes, Reacn. of ~ with halogenoacetic esters (SC) 308 [G.E. *78*, 335 (1966)]

Alkynes, Naturally occurring tetrayne and tetrayne-tetrol (LA) 526

Alkynylamines, Synth. of ~ from α-halogeno iminium salts and ketene *S,N*-acetals (SC) 584 [G.E. *78*, 593 (1966)]

Condensation of ~ with 1,3-dipolar compds., carbonyl compds., and Schiff bases (SC) 585 [G.E. *78*, 594 (1966)]

Allene, Progress in the chemistry of ~ (FP) 933 [G.E. *78*, 953 (1966)]

3-Alkyl- and 3,3-dialkyl-1-bromo-~-s (LA) 977

Allylalanes, Prepn. and rearr. of ~ (SC) 513 [G.E. *78*, 492 (1966)]

Allyl isocyanate, Free-radical initiated addn. of bromotrichloromethane to ~ (SC) 607 [G.E. *78*, 646 (1966)]

Allylnickel bromide, π-~ under the influence of phosphines and phosphites (SC) 897 [G.E. *78*, 941 (1966)]

Allyl-transition metal systems (FP) 151 [G.E. *78*, 157 (1966)]

Aluminate complexes, Butadienedimethyl-~ (SC) 663 [G.E. *78*, 675 (1966)]

Aluminum, Spectrochem. determin. of impurities in very pure ~ (CR) 679 [G.E. *78*, 720 (1966)]

Aluminum bromide, Color of solns. of ~ in benzenoid hydrocarbons (SC) 843 [G.E. *78*, 908 (1966)]

Aluminum compds., Compds. of phosphorus with Si and Al (FP) 53 [G.E. *78*, 80 (1966)]

Organometallic compd. with two-coordinated fluorine atoms (SC) 726 [G.E. *78*, 750 (1966)]

Chloro(dicyclopentadienyl)ethylzirconium and its reacn. with triethylaluminum (SC) 962 [G.E. *78*, 986 (1966)]

Reacn. of sulfonyl chlorides with alkyl-~ (CR) 903 [G.E. *78*, 947 (1966)]

~ with coordination number five (LA) 685

Phosphorus-~ with pentacoordinated aluminum (LA) 906

Americium, Tri(cyclopentadienyl)-~-(III) (SC) 134 [G.E. *78*, 112 (1966)]

Amides, Ammonothermal synth. of magnesium and beryllium ~ (SC) 247 [G.E. *78*, 208 (1966)]

Magnetic anisotropy of the amide group (SC) 899 [G.E. *78*, 943 (1966)]

Amidinium salts, Vinylogous guanidinium and ω,ω-diaminoacryl-~ (SC) 724 [G.E. *78*, 747 (1966)].

Amidothiophosphates, fluoroamidothio-, and fluorothiophosphates (CR) 256 [G.E. *78*, 272 (1966)]

Amination, *S*-~ of thioureas and thiourethanes (SC) 674 [G.E. *78*, 672 (1966)]

~-dehydration of nitromethane by tris(dimethylamino)arsine (LA) 905

Amines, Reacn. of alkyldichloro-~ with tetracarbonylnickel (SC) 123 [G.E. *78*, 114 (1966)]

Alkoxycarbonylation of sec. and prim. ~ by alkoxycarbonylmercury compds. (SC) 252 [G.E. *78*, 209 (1966)]

Equilibria between mono- and dibromo-~ (SC) 598 [G.E. *78*, 607 (1966)]

Aliphatic ~ from CO, steam, and $NH_3$ (SC) 843 [G.E. *78*, 908 (1966)]

Reacn. of isocyanates, isothiocyanates, or carbon disulfide with methylenedi-~ (SC) 844 [G.E. *78*, 827 (1966)]

Condensation products of squaric acid and tert. aromatic ~ (SC) 894 [G.E. *78*, 937 (1966)]

Synth. and reacns. of perchlorodien-~ (SC) 895 [G.E. *78*, 939 (1966)]

Arylammonium polyphosphates from *O,O,S*-trialkyl thiophosphates and aryl-~ (SC) 970 [G.E. *78*, 1019 (1966)]

New synth. of tetrakis(dimethylamino)-ethylene (SC) 972 [G.E. *78*, 984 (1966)]

Dehydrogenation of ~ derivs. with Hg-EDTA (CR) 257 [G.E. *78*, 273 (1966)]

Cleavage of aryl-substd. tert. ~ by acyl halides (CR) 849 [G.E. *78*, 828 (1966)]

Effect of chain length on the ability of aliphatic ~ to render quartz hydrophobic (CR) 902 [G.E. *78*, 946 (1966)]

New synth. of (t-alkyl)-~ (LA) 852

Condensations with β-oxo enamines (LA) 977

Amine oxides, Alkylation of ~ with sultones (SC) 419 [G.E. *78*, 391 (1966)]

Oxidn. of organoboranes with ~ (SC) 580 [G.E. *78*, 589 (1966)]

Amino acid, New method for the determin. of C-terminal ~-s (LA) 427

(5-Amino-4-carbamoylimidazolyl)-5-S-homocysteinylriboside, a new S-~ deriv. (LA) 978

*N*-Acetyl-L-histidine, the first acetylated basic ~ found in nature (LA) 978

Aminobenzotriazoles, Oxidn. of 1- and 2-~ (LA) 144

3-Amino-3-deoxy-D-glucose, Simple synth. of ~ (kanosamine) (SC) 967 [G.E. *78*, 1023 (1966)]

2-Aminoethylphosphines, Synth. of ~ (LA) 426

Aminolysis of C–C linkages (SC) 1044 [G.E. *78*, 1063 (1966)]

1-Amino-2-nitrocyclopentanecarboxylic acid, a naturally occurring nitro compd. (LA) 527

Aminoquinones, Nature of the bonding in ~ (SC) 599 [G.E. *78*, 639 (1966)]

Amino Sugars, The ~. The Chemistry and Biology of Compds. containing ~ (Book Review) 979

Ammonia, Apparatus for titrations in liq. ~ (FP) 554 [from Chemie-Ing.-Techn. *38*, 576 (1966)]

Aliphatic amines from carbon monoxide, steam, and ~ (SC) 843 [G.E. *78*, 908 (1966)]

γ-Radiolysis of liq. ~ in the presence of *p*-nitrophenol (CR) 737 [G.E. *78*, 778 (1966)]

Ammonium chloride, Attenuation of sound waves in a single crystal of $NH_4Cl$ (LA) 1051

Ammonolytic processes in liq. ammonia (CR) 322 [G.E. *78*, 340 (1966)]

Amylomaltase, Formation of oligomeric amyloses by the enzyme ~ (CR) 611 [G.E. *78*, 612 (1966)]

Amyloses, Formation of oligomeric ~ by the enzyme amylomaltase (CR) 611 [G.E. *78*, 612 (1966)]

Analgetic compds., Polyalkoxyestranes, a new group of ~ (LA) 683

Analysis, Electron pyrolysis, a new method of org. micro-~ (FP) 751 [G.E. *78*, 841 (1966)]

Modern methods of ~ (CR) 677 [G.E. *78*, 718 (1966)]

Nuclear Techniques in Analytical Chemistry (Book Review) 262

New Methods of Analytical Chemistry (Book Review) 264

Metallkundliche Analyse (Metallurgical ~) (Book Review) 685

Submicro Methods of Org. ~ (Book Review) 1053

Guide to the ~ of Pesticide Residues (Book Review) 1052

Treatise on Analytical Chemistry (Book Review) 980

Aniline, *N*-Thio-~, $C_6H_5N{=}S$, as intermediate in the decomposition of *N,N*-thiodi-~ (SC) 1048 [G.E. *78*, 1057 (1966)]

Anilines, Electronic effect of phosphorus in *p*-phosphorus-substd. dimethyl-~ (SC) 129 [G.E. *78*, 145 (1966)]

Anisoles, Electronic effect of phosphorus in *p*-phosphorus-substd. ~ (SC) 731 [G.E. *78*, 777 (1966)]

Anisotropy, Magnetic ~ of the amide group (SC) 899 [G.E. *78*, 943 (1966)]

Annulene, Attempted synth. of *anti*-1,6:8,13-bismethano[14]-~ (SC) 603 [G.E. *78*, 642 (1966)]

1,6-Methano[10]-~-2-amine and -2-ol (SC) 732 [G.E. *78*, 753 (1966)]

11-Methylene-1,6-methano[10]-~ and 1,6-methano[10]-~-11-ol (SC) 732 [G.E. *78*, 754 (1966)]

2,3-Didehydro-1,6-methano[10]-~ (SC) 733 [G.E. *78*, 755 (1966)]

1,6:8,13-Diepoxy[14]-~ (SC) 734 [G.E. *78*, 755 (1966)]

Triepoxy[18]-~ and epoxydiepithio-[18]-~ (LA) 325

Anthraquinodimethane, Diels-Alder reacns. of 9,10-~ (LA) 323

Anthraquinones, New principle of biosynth. involving seco-~ (SC) 728 [G.E. *78*, 752 (1966)]

Antibiotics, Recent results of ~ research (CR) 523 [G.E. *78*, 496 (1966)]

Chemistry of the ~ used in Medicine (Book Review) 688

Die Antibiotica (The ~) (Book Review) 906

Antibodies, Relation between synth. of ~ and metabolism of nucleic acids (CR) 610 [G.E. *78*, 611 (1966)]

Antigens, Relation of microbes to blood-group active substances (FP) 909 [G.E. *78*, 969 (1966)]

Reversible denaturation of a univalent antibody fragment (LA) 143.

Chloramphenicol-specific ~ (LA) 906

Antimony compds., Contributions to the chemistry of the binary compds. of the transition elements (FP) 58 [G.E. *78*, 64 (1966)]

Stereochemistry of pentaaryl derivs. of phosphorus, arsenic, and antominy (SC) 725 [G.E. *78*, 749 (1966)]

Triazidomethylium hexachloroantimonate (SC) 841 [G.E. *78*, 825 (1966)]

Homopolar and heteropolar halogeno esters of phosphorus, arsenic, and antimony (CR) 425 [G.E. *78*, 451 (1966)]

Chemistry of phosphorus, arsenic, and antimony halides (CR) 425 [G.E. *78*, 452 (1966)]

Oxide fluorides $AsOF_3$, $SbOF_3$, and $SbO_2F$ (LA) 851

Antioxidants, Atmospheric Oxidn. and ~ (Book Review) 981

Antischistosomal compds., New group of ~ (FP) 857 [G.E. *78*, 850 (1966)]

Aortas, Studies of mucopolysaccharides of normal and sclerotic human ~ (CR) 610 [G.E. *78*, 611 (1966)]

Apatite, Synth. and formula of biological and mineral carbonate-~ (SC) 669 [G.E. *78*, 679 (1966)]

Aroma essences, New facts about ~ (CR) 681 [G.E. *78*, 683 (1966)]

Aromatic compds., Labeling of aromatic halides by radiation-induced isotopic exchange (CR) 738 [G.E. *78*, 778 (1966)]

Bridged ~ (Book Review) 530

Arsenic compds., Contributions to the chemistry of the binary compds. of the transition elements (FP) 58 [G.E. *78*, 64 (1966)]

Stereochemistry of pentaaryl derivs. of phosphorus, arsenic, and antimony (SC) 725 [G.E. *78*, 749 (1966)]

Ligand exchange with compds. of quinquevalent arsenic (SC) 969 [G.E. *78*, 1018 (1966)]

Homopolar and heteropolar halogeno esters of phosphorus, arsenic, and antimony (CR) 425 [G.E. *78*, 451 (1966)]

Chemistry of phosphorus, arsenic, and antimony halides (CR) 425 [G.E. *78*, 452 (1966)]

Oxide fluorides $AsOF_3$, $SbOF_3$, and $SbO_2F$ (LA) 851

Arsines, Cleavage and addn. reacns. of silylphosphines and silyl-~ (SC) 418 [G.E. *78*, 391 (1966)]

Determin. of traces of ~ in inert-gas mixtures (CR) 677 [G.E. *78*, 718 (1966)]

Amination-dehydration of nitromethane by tris(dimethylamino)arsine (LA) 905

Arsonium salts, Radiation-chemical synth. of phosphonium salts and ~ (SC) 317 [G.E. *78*, 331 (1966)]

Ascorbigen, Formation and properties of ~ (CR) 1050 [G.E. *78*, 1066 (1966)]

Aspartate transcarbamylase, Regulatory and functional sub-units in ~ (LA) 427

Association of aliphatic hydroxy compds. in n-heptane (CR) 423 [G.E. *78*, 395 (1966)]

ate-Complexes, Structures and reacns. of organic ~ (FP) 351 [G.E. *78*, 355 (1966)]

Atomic absorption spectroscopy, Determin. of lead alkyls in gasoline (CR) 678 [G.E. *78*, 719 (1966)]

Automation of structure analysis (FP) 267, 511 [G.E. *78*, 289 (1966)]

Azaalkenes, Ring closure reacns. of polychloro-~ (SC) 960 [G.E. *78*, 982 (1966)]

Azapeptides, Peptide and ~ syntheses with α-*N*-[1-(1,2,4-triazolyl)carbonyl]-amino esters (SC) 593 [G.E. *78*, 602 (1966)]

Azapurines, Rearr. of amino[1,2,3]thiadiazolo[5,4-*d*]pyrimidines to mercapto-8-~ and its retrogression (SC) 587 [G.E. *78*, 596 (1966)]

Azepine, Dimerization of 1-methyl-~ (SC) 839 [G.E. *78*, 822 (1966)]

3-Azetidinols, Synth. of ~ (LA) 977

Azides, New metal-azide complexes (SC) 249 [G.E. *78*, 267 (1966)]

Reacn. of hexacarbonyltungsten with ~ (SC) 253 [G.E. *78*, 267 (1966)]

Reacn. of aryl ~ with alkali metals (SC) 586 [G.E. *78*, 596 (1966)]

Synth. of azide halides and nitride halides and some related structural problems (CR) 322 [G.E. *78*, 339 (1966)]

Azidoaniline, Thermolysis of derivs. of *o*-~ (LA) 143

*C*-Azido-*N*-sulfonylformamidines and their rearr. to 5-(*N*-sulfonylamino)-tetrazoles (SC) 520 [G.E. *78*, 548 (1966)]

Aziridines, Cycloaddn. on thermal cleavage of ~ in the presence of olefins (CR) 975 [G.E. *78*, 1024 (1966)]

Aziridinium tetrafluoroborate, Synth. of 2-oxazoline-2-amines and 2-thiazoline-2-amines by reacn. of ~ with isocyanates and isothiocyanates (SC) 667 [G.E. *78*, 677 (1966)]

Azoalkanes, Rearr. of phenyl-~ to phenylhydrazones (LA) 428

Azo compds., Chemistry of α-carbonyl-~ (FP) 372 [G.E. *78*, 376 (1966)]

Synth. of α,β-unsatd. ~ (LA) 617

Azosulfones, Cycloaddn. of ~ and sulfonylimines (SC) 416 [G.E. *78*, 389 (1966)].

Azulenes, Condensation products of squaric acid and azulenic hydrocarbons (SC) 893 [G.E. *78*, 937 (1966)]

Azuleno[5,6,7-*cd*]phenalene, a new quasi-aromatic system (SC) 516 [G.E. *78*, 493 (1966)]

BAKER-WILLIAMS FRACTIONS, Characterization of ~ by turbidimetric titration (CR) 609 [G.E. *78*, 610 (1966)]

Barium compds., Germyl compds. of strontium, barium, and zinc (SC) 522 [G.E. *78*, 549 (1966)]

Benzene, from acetylene in Avocado pears (LA) 142

Benzimidazole, New ~ cleavage with subsequent ring closure (SC) 835 [G.E. *78*, 904 (1966)]

Benzocyclobutene-1,2-dione, Photochemical reacns. of ~ (CR) 320 [G.E. *78*, 308 (1966)]

Benzonitrile oxide, Reacns. of ~ with alkylidenephosphoranes (SC) 1039 [G.E. *78*, 1059 (1966)]

1,3-Benzothiazin-4-one, New synth. of derivs. of isoquinoline and ~ (SC) 663 [G.E. *78*, 674 (1966)]

Benzothiazole derivs., Synth. of basic heterocyclic alkenes (LA) 259

Benzo[*b*]thiepin, Synth. of derivs. of ~ and ~ 1,1-dioxide (SC) 958 [G.E. *78*, 980 (1966)]

[1]Benzothiopyrano[4,3-*b*]indoles, a new group of pseudoazulenes (LA) 976

Benzo-1,2,3-triazin-4-ones, Unusual diazo-coupling reacn. (SC) 675 [G.E. *78*, 673 (1966)]

Benzyl anions, Reacns. of α,α-disubstd. ~ with carbonium ions. Synth. of *p*-quinodimethanes (SC) 517 [G.E. *78*, 545 (1966)]

Benzylidene, Methylphenylcarbene (α-methyl-~) (LA) 852

α-Benzylidene-γ-butyrolactone, Substd. ~ (LA) 259

9-Benzylidenefluorene, Electrolytic reductive dimerizn. of ~ (LA) 429

Benzyne, Oxidn. of 1- and 2-aminobenzotriazoles (LA) 144

Reacn. of ~ with styrene (LA) 684

Beryllium amides, Ammonothermal synth. of magnesium and ~ (SC) 247 [G.E. *78*, 208 (1966)]

Bicyclobutyl, Conformations of bicyclopropyl and ~ by electron diffraction (SC) 124 [G.E. *78*, 142 (1966)]

Bicyclo[3.1.1]heptane, Synth. of ~ (SC) 127 [G.E. *78*, 116 (1966)]

Bicyclo[3.2.0]heptene, Synth. of $\Delta^{3a,5a}$-~ and $\Delta^{4a,6a}$-bicyclo[4.2.0]octene (SC) 594 [G.E. *78*, 603 (1966)]

Bicyclo[2.2.0]hexa-2,5-diene, Dimethyl 1,4,5,6-tetramethyl-~-2,3-dicarboxylate (LA) 526

One-stage synth. of hexamethyl-Dewarbenzene from 2-butyne (SC) 669 [G.E. *78*, 716 (1966)]

Bicyclo[3.1.0]hex-2-ene, Photochem. formation of ~ and 3-vinylcyclobutene (LA) 904

Bicyclo[3.3.0]octane, 3,7-Dioxa-~ (LA) 527

Bicyclo[2.2.2]octan-2-one, Reductive fragmentation of 1-Methyl-4-tosyloxy-~ (SC) 316 [G.E. *78*, 335 (1966)]

Bicyclo[4.2.0]octene, Synth. of $\Delta^{3a,5a}$-bicyclo-[3.2.0]heptene and $\Delta^{4a,6a}$-~ (SC) 594[G.E. *78*, 603 (1966)]

Bicyclopropyl, Conformational analysis of ~ by vibrational spectroscopy (SC) 123 [G.E. *78*, 141 (1966)]

Conformations of ~ and bicyclobutyl by electron diffraction (SC) 124 [G.E. *78*, 142 (1966)]

Bilharziasis, New group of antischistosomal compds. (FP) 857 [G.E. *78*, 850 (1966)]

Biochemistry, Laboratoriumstechnik für Biochemiker (Laboratory Techniques for Biochemists) (Book Review) 1052

Biology Data Book (Book Review) 687

Biotin enzymes, Biosynth. of the ~ from apoenzyme and biotin (LA) 430

Biradicals, quinones, and semiquinones of the imidazole series (SC) 311 [G.E. *78*, 303 (1966)]

Bis(dialkylcarbamoyl)mercury, Prepn. of ~ compds. by carbonylation in amines (SC) 664 [G.E. *78*, 675 (1966)]

Bismethano[14]annulene, Attempted synth. of *anti*-1,6:8,13-~ (SC) 603 [G.E. *78*, 642 (1966)]

Blood-group active substances, Relation of microbes to ~ (FP) 909 [G.E. *78*, 969 (1966)]

Bonding, Types of ~ of sulfur in vulcanization processes (CR) 848 [G.E. *78*, 828 (1966)]

Electrons and Chemical ~ (Book Review) 265

Bond lengths in non-aromatic hydrocarbons (LA) 526

Bond orders, Force constants and ~ of nitrogen bonds (FP) 567 [G.E. *78*, 565 (1966)]

Boranes, Oxidn. of organo-~ with amine oxides (SC) 580 [G.E. *78*, 589 (1966)]

Prepn. of methyl- and ethyl-substd. monocarbahexaboranes(9) and dicarbaclovoheptaboranes(7) (SC) 580 [G.E. *78*, 590 (1966)]

New method for preparing 1,3,4-trithiadiborolanes and 1,3,5-trithiatri-~ (SC) 597 [G.E. *78*, 607 (1966)]

Prepn. of organocarboranes by hydroboration of alkyl-1-alkynyl-~ (SC) 730 [G.E. *78*, 777 (1966)]

Monocarbahexaborane(7) (LA) 258

Boron, Metallo-Boron Compounds, and ~ (Book Review) 264

Borate, Synth. of tetramethylammonium tetranitrato-~ (LA) 746

Borate glasses, Color centers in alkali ~ containing Co, Ni, or Cu (FP) 85 [G.E. *78*, 41 (1966)]

Borides, Transport reacns. of silicides and ~ of transition metals (SC) 839 [G.E. *78*, 822 (1966)]

Borolanes, New method for preparing 1,3,4-trithiadi-~ and 1,3,5-trithiatriboranes (SC) 597 [G.E. *78*, 607 (1966)]

Boron, Heterogeneous catalysis with elemental ~ and with nickel borides (CR) 525 [G.E. *78*, 552 (1966)]

~, Metallo-Boron Compounds, and Boranes (Book Review) 264

Boron compds., *o*-Carboranyl derivs. of ~ (LA) 323

Bis(dimethylamino)boronpentacarbonylmanganese (LA) 616

Cyclic boron-sulfur compds. (LA) 616

Boron Nitrogen Compds. (Book Review) 430

Boron imides, Monomeric ~ (SC) 842 [G.E. *78*, 825 (1966)]

Bromination, Recoil ~ of halogenobenzenes (LA) 1051

Bromine, Advances in the inorg. chemistry of ~ (FP) 280 [G.E. *78*, 313 (1966)]

Bromoamines, Equilibria between mono- and di-~ (SC) 598 [G.E. *78*, 607 (1966)]

Bromopyrogallol red, Photometric determin. of small amounts of tin with ~ (CR) 680 [G.E. *78*, 721 (1966)]

5-Bromouracil, γ-Radiolysis of ~ in oxygen-containing aq. solns. (CR) 740 [G.E. *78*, 780 (1966)]

Buffers, Twelve new ~ (LA) 615

Bullvalene, New synth. of the ~ system (SC) 590 [G.E. *78*, 599 (1966)]

Butadiene, Butadienedimethylaluminate complexes (SC) 663 [G.E. *78*, 675 (1966)]

Synth. of 2-alkylthio- and 2-arylthio-1,3-~-s (SC) 668 [G.E. *78*, 678 (1966)]

Butyraldehyde, α-Diazo-~ (LA) 684

Butyrolactones, Substd. α-benzylidene-γ-~ (LA) 259

CALEBASH curare alkaloid, Synth. of the central octacyclic structure of the principal ~, C-curarine-I (SC) 957 [G.E. *78*, 978 (1966)]

Calicene, Synth. and properties of 5,6-dimethyl-1,2,3,4-tetraphenyl-~ (SC) 602 [G.E. *78*, 642 (1966)]

Caprolactam, Prepn. of ε-~ from cyclohexanecarboxylic acid in liq. $SO_2$ (LA) 325

Carbaclovoheptaboranes(7), Prepn. of methyl- and ethyl-substd. monocarbahexaboranes(9) and di-~ (SC) 580 [G.E. *78*, 590 (1966)]

Carbahexaboranes(9), Prepn. of methyl- and ethyl-substd. mono-~ and dicarbaclovoheptaboranes(7) (SC) 580 [G.E. *78*, 590 (1966)]

Carbamoyl chlorides, Ring closure reacns. of N-(α-chloroalkylidene)-~ (SC) 960 [G.E. *78*, 981 (1966)]

Carbanion Chemistry, Fundamentals of ~ (Book Review) 748

Carbenes, Inorg., organometallic, and org. analogues of ~ (FP) 1021 [G.E. *78*, 1039 (1966)]

~, Elimination of hydrogen halide from benzo- and naphtho-thiazolium halides (SC) 126 [G.E. *78*, 115 (1966)]

Selective cleavage of a carbon-sulfur bond (LA) 258

Methylphenylcarbene (α-methylbenzylidene) (LA) 852

Carbimidoyl chlorides, *N*-(Alkoxycarbonyl)-~ (LA) 683

Carbocyanines, Detection of the forbidden transition in dimeric ~ at low temperatures (SC) 313 [G.E. *78*, 304 (1966)]

Carbodiimide, Synths. and reacns. of *O,N,N'*-trisubstd. isoureas (FP) 470 [G.E. *78*, 483 (1966)]

New methods of preparative organic chemistry VI. Synth. of isocyanates and ~-s (FP) 704 [G.E. *78*, 761 (1966)]

Optically active ~ (SC) 596 [G.E. *78*, 606 (1966)]

Hydrogenation of ~-s to *N,N'*-disubstd. formamidines (LA) 258

Carbohydrates containing N or S in the "hemiacetal" ring (FP) 495 [G.E. *78*, 501 (1966)]

Carbon, 7th Conference on ~ (CR) 135 [G.E. *78*, 148 (1966)]

Carbonate-apatite, Synth. and formula of biological and mineral ~ (SC) 669 [G.E. *78*, 679 (1966)]

Carbon compds., Rodd's Chemistry of ~ (Book Review) 433, 434

Carbon disulfide, Reacn. of isocyanates, isothiocyanates, or ~ with methylenediamines (SC) 844 [G.E. *78*, 827 (1966)]

Reacn. of D-glucosamine with ~ (SC) 964 [G.E. *78*, 980 (1966)]

Carbon monoxide, New methods in prep. org. chemistry VI. Ring closures with ~ (FP) 435 [G.E. *78*, 532 (1966)]

Aliphatic amines from ~, steam, and $NH_3$ (SC) 843 [G.E. *78*, 908 (1966)]

Transannular addn. of ~ to cycloocta-1,5-diene (LA) 616

Carbonium ions, Reacns. of α,α-disubstd. benzyl anions with ~. Synth. of *p*-quinodimethanes (SC) 517 [G.E. *78*, 545 (1966)]

Aryl-substd. dialkoxy-~ as alkylating agents (SC) 676 [G.E. *78*, 715 (1966)]

Carbonium salts, Alkylations by dialkoxy-~ (SC) 675 [G.E. *78*, 714 (1966)]

Carbon-sulfur bond, Selective cleavage of a ~ (LA) 258

Carbonylation, Prepn. of bis(dialkylcarbamoyl)mercury compds. by ~ in amines (SC) 664 [G.E. *78*, 675 (1966)]

Carbonyl azo compds., Chemistry of α-~ (FP) 372 [G.E. *78*, 376 (1966)]

Carbonyl compds., Condensation of alkynylamines with 1,3-dipolar compds., ~, and Schiff bases (SC) 585 [G.E. *78*, 594 (1966)]

Crystal structure of carbonyl(piperidine-*N*-carbonitrile)nickel(0) (SC) 1046 [G. E. *78*, 1064 (1966)]

Structure of tricarbonyl-1,6-methanocyclodecapentaenechromium (SC) 1043 [G.E. *78*, 1063 (1966)]

Carbonyl Group, Reacns. of the ~ in fluorinated ketones (FP) 947 [G.E. *78*, 1008 (1966)]

Carboranes, Prepn. of organo-~ by hydroboration of alkyl-1-alkynylboranes (SC) 730 [G.E. *78*, 777 (1966)]

Monocarbahexaborane(7) (LA) 258

*o*-Carboranyl derivs. of boron compds. (LA) 323

Carborane bis(thioethers), the first compds. containing carborane-sulfur bonds (LA) 976

Carboxamides. New synth. of *N*-(dichloromethylene)-~ (SC) 845 [G.E. *78*, 908 (1966)]

Amino-*N*-cyano-~ (LA) 684

Carboxylic acids, Synth. of ~ from 1,1-dichloroethylene (FP) 870 [G.E. *78*, 932 (1966)]

Carboxylic acid cycle, Photosynthetic, reductive ~ (LA) 853

Carcinogenic compds., Cycasin, a natural carcinogen (LA) 261

Cardiac infarcts, Use of tetrazolium salts in the early diagnosis of ~ (CR) 424 [G.E. *78*, 394 (1966)]

Carotenoids, Recent results in ~ chemistry (CR) 743 [G.E. *78*, 784 (1966)]

Casein, Progress in the chemistry of ~ (FP) 558 [G.E. *78*, 629 (1966)]

Catalase, Investigations by pulse radiolysis of reactivity of ~ towards hydrated electrons and free OH radicals (CR) 738 [G.E. *78*, 779 (1966)]

Catalysis, Model for the action of chymotrypsin (SC) 601 [G.E. *78*, 641 (1966)]

Heterogeneous ~ with elemental boron and with nickel borides (CR) 525 [G.E. *78*, 552 (1966)]

Catalysts, New ~ for the dimerization of ethylene and propene (SC) 584 [G.E. *78*, 593 (1966)]

Activity changes of Ziegler-Natta ~ by prepolymerizn. of small amounts of α-olefins (CR) 611 [G.E. *78*, 612 (1966)]

Cellulose, Depolymerizn. of ~ by $^{60}Co$-γ-radiation (CR) 738 [G.E. *78*, 779 (1966)]

Cell-wall polysaccharides, Significance of enterobacterial mutants for the chem. investigation of their ~ (FP) 198 [G.E. *78*, 172 (1966)]

Cesium, Rubidium and ~ (Book Review) 434

Cesium compds., Potassium, rubidium, and ~ thiomanganates(II) (SC) 134 [G.E. *78*, 113 (1966)]

Infrared spectra of cesium and tetraalkylammonium salts containing the anions $HCl_2^-$ and $DCl_2^-$ (LA) 617

Cesium fluoride is a donor of particularly active fluoride ions (LA) 852

Chemisorption, of gases on evaporated metal films (CR) 848 [G.E. *78*, 827 (1966)]

~ of nitrogen on various surfaces of tungsten single crystals (LA) 142

Chirality, Specification of molecular ~ (FP) 385 [G.E. *78*, 413 (1966)]

Chloramphenicol-specific antibodies (LA) 906

5-Chromanol derivs., New synth. of ~ and of dihydroseselin (SC) 415 [G.E. *78*, 389 (1966)]

Chromatin, Protein synth. in rat liver ~ and ~ fractions (SC) 592 [G.E. *78*, 601 (1966)]

Chromatography, Direct UV-spectrophotometric evaluation of thin-layer chromatograms (CR) 678 [G.E. *78*, 719 (1966)]

New analyt. sepn. of traces of material on dextran gel (CR) 680 [G.E. *78*, 721 (1966)]

Use of thin-layer ~ and infrared spectroscopy for elucidation of the thermolysis products of triphenylphosphine (CR) 680 [G.E. *78*, 721 (1966)]

Chromium compds., Tricarbonyl-(1,6-methanocyclodecapentaene)chromium (SC) 518 [G.E. *78*, 548 (1966)]

Structure of tricarbonyl-1,6-methanocyclodecapentaenechromium (SC) 1043 [G.E. *78*, 1063 (1966)]

Binuclear complexes of chromium and molybdenum with ethylenebis(diphenylphosphine) as bridging ligand (SC) 606 [G.E. *78*, 646 (1966)]

Complex methyl-~ (LA) 526

Chymotrypsin, Model for the action of ~ (SC) 601 [G.E. *78*, 641 (1966)]

Circular dichroism, Optical rotatory dispersion and ~ in organic chemistry (Book Review) 434

Claisen rearr. of compds. containing no hetero-atoms (LA) 618

Clays, Adsorption of methylene blue on ~ (SC) 247 [G.E. *78*, 208 (1966)]

Clinical chemistry, Klinische Chemie, Theorie und Praxis (~, Theory and Practice) (Book Review) 262

Cobalt, Color centers in alkali borate glasses containing ~, Ni, or Cu (FP) 85 [G.E. *78*, 41 (1966)]

Cobalt compds., Cyclopentadienylbis(trifluorophosphine)cobalt (SC) 247 [G.E. *78*, 208 (1966)]

Iodotetrakis(trifluorophosphine)cobalt(I) (LA) 977

Cobinamide, Conversion of ~ into cobyric acid (SC) 125 [G.E. *78*, 143 (1966)]

Cobyric acid, Conversion of cobinamide into ~ (SC) 125 [G.E. *78*, 143 (1966)]

Coenzymes, Nucleotides and ~ (Book Review) 264

Color centers, in alkali borate glasses containing Co, Ni, or Cu (FP) 85 [G.E. *78*, 41 (1966)]

Complexes, Allyl-transition metal systems (FP) 151 [G.E. *78*, 157 (1966)]

Structures and reacns. of organic ate-~ (FP) 351 [G.E. *78*, 355 (1966)]

~ formation and flower colors (FP) 791 [G.E. *78*, 834 (1966)]

Cyclopentadienylbis(trifluorophosphine)cobalt (SC) 247 [G.E. *78*, 208 (1966)]

New metal-azide ~ (SC) 249 [G.E. *78*, 267 (1966)]

~ formation between copper and organic disulfides (SC) 422 [G.E. *78*, 449 (1966)]

Spiroheterocyclic nickel carbonyl (SC) 516 [G.E. *78*, 547 (1966)]

Tricarbonyl-(1,6-methanocyclodecapentaene)chromium (SC) 518 [G.E. *78*, 548 (1966)]

Structure of tricarbonyl-1,6-methanocyclodecapentaenechromium (SC) 1043 [G.E. *78*, 1063 (1966)]

1,4-Diazabutadiene-metal carbonyls (SC) 520 [G.E. *78*, 549 (1966)]

Stabilized dialkylnickel compds. (SC) 581 [G.E. *78*, 591 (1966)]

π-Allylmethylnickel (SC) 582 [G.E. *78*, 591 (1966)]

Prepn. of carbonyl(chlorodifluorophosphine)nickel ~ (SC) 583 [G.E. *78*, 593 (1966)]

Crystal structure of carbonyl(piperidine-*N*-carbonitrile)nickel(0) (SC) 1046 [G.E. *78*, 1064 (1966)]

Binuclear ~ of chromium and molybdenum with ethylenebis(diphenylphosphine) as bridging ligand (SC) 606 [G.E. *78*, 646 (1966)]

Butadienedimethylaluminate ~ (SC) 663 [G.E. *78*, 675 (1966)]

Hydridopentakis(trifluorophosphine)-rhenium (SC) 836 [G.E. *78*, 820 (1966)]

π-Allylnickel bromide under the influence of phosphines and phosphites (SC) 897 [G.E. *78*, 941 (1966)]

Di(cyclooctatetraene)titanium and tri-(cyclooctatetraene)dititanium (SC) 898 [G.E. *78*, 942 (1966)]

Crystal structure of tri(cyclooctatetraene)dititanium (SC) 899 [G.E. *78*, 943 (1966)]

Formation of coordination ~ in anhydrous acetonitrile (CR) 142 [G.E. *78*, 151 (1966)]

(π - Cyclobutadienyl)(π - tetraphenylcyclobutadiene)-molybdenum and -tungsten carbonyl halides (LA) 259

Pentacoordinated silicon complex (LA) 1051

*trans*-effect of ligands in square-planar palladium(II) and platinum(II) ~ (LA) 427

Complex methylchromium compds. (LA) 526

Bis(dimethylamino)boronpentacarbonylmanganese (LA) 616

Compds. of aluminum with coordination number five (LA) 685

Sparingly soluble compd. of NaCl and racemic 2,3-bis-(*p*-aminophenyl)butane (LA) 746

Nitrosyl compds. of metals of the iron group with bivalent phosphine groups as bridging ligands (LA) 905

Phosphorus-aluminum compds. with pentacoordinated aluminum (LA) 906

Molecular ~ in Organic Chemistry (Book Review) 147

Complexometric titration, Die komplexometrische Titration (~) (Book Review) 430

Computer Programming for Chemists (Book Review) 980

Conformation, Conformational aspects of many-membered rings (FP) 1000 [G.E. *78*, 1070 (1966)]

Conformational analysis of bicyclopropyl by vibrational spectroscopy (SC) 123 [G.E. *78*, 141 (1966)]

~-s of bicyclopropyl and bicyclobutyl by electron diffraction (SC) 124 [G.E. *78*, 142 (1966)]

~-s of *trans*-1,2-dicyclopropylethylene and vinylcyclopropane (SC) 512 [G.E. *78*, 544 (1966)]

Conformational enantiomerism of a deriv. of cyclotriveratrylene (SC) 593 [G.E. *78*, 603 (1966)]

Sepn. of conformational isomers of a nitrosamine (SC) 728 [G.E. *78*, 751 (1966)]

Aliphatic semidiones; application of electron spin resonance to problems of ~ (CR) 974 [G.E. *78*, 989 (1966)]

~ Theory (Book Review) 747

Congressane, Hexaoxadiamantane and hexaoxadiphosphadiamantane (LA) 527

Coordination Chemistry (Book Review) 328

Copolymers, see Polymers

Copper, Color centers in alkali borate glasses containing Co, Ni, or ~ (FP) 85 [G.E. *78*, 41 (1966)]

Copper compds., Complex formation between copper and organic disulfides (SC) 422 [G.E. *78*, 449 (1966)]

Cortexone, Vertebrate hormone as defensive substance of the water beetle (*Dytiscus marginalis*) (SC) 421 [G.E. *78*, 392 (1966)]

Cortisol, Stimulation of RNA polymerase in liver nuclei by ~ *in vitro* (SC) 723 [G.E. *78*, 748 (1966)]

Coulomb potentials, Relation between ~ and positions of protons in crystalline hydroxo compds. (SC) 133 [G.E. *78*, 113 (1966)]

Coupling principles in org. dyes (FP) 984 [G.E. *78*, 1029 (1966)]

Cross-linking, Degradn. and ~ of polydimethylsiloxane in soln. under the influence of $^{60}$Co-γ-radiation (CR) 739 [G.E. *78*, 780 (1966)]

Crustacyanin, Quaternary structure and color of ~ (SC) 957 [G.E. *78*, 979 (1966)]

Crystal growth, Kinetics of ~ (FP) 67 [G.E. *78*, 130 (1966)]

Crystal Structure, Melting and ~ (Book Review) 980

Cumulenes, *cis-trans*-isomerism of 1,6-Diphenyl-1,6-di-t-butylhexapentaene (SC) 420 [G.E. *78*, 449 (1966)]

Curarine, Synth. of the central octacyclic structure of the principal calebash curare alkaloid, C-~-I (SC) 957 [G.E. *78*, 978 (1966)]

*N*-Cyanocarboxamides, Amino-~ (LA) 684

Cyanocyclopentadienyl anion, Reacns. of cyano-substituted ~ (SC) 420 [G.E. *78*, 449 (1966)]

Cycasin, a natural carcinogenic compd. (LA) 261

Cyclitols, Biosynth. of ~ (FP) 165 [G.E. *78*, 198 (1966)]

Cyclization, 1,5-~ of vinyl-substd. sulfur diimides (SC) 1042 [G.E. *78*, 1061 (1966)]

Electrolytic-reductive ~ of activated olefins (LA) 618

Cycloaddition, of azosulfones and sulfonylimines (SC) 416 [G.E. *78*, 389 (1966)]

~ on thermal cleavage of aziridines in the presence of olefins (CR) 975 [G.E. *78*, 1024 (1966)]

Cyclobutadiene, (π-Cyclopentadienyl) (π-tetraphenylcyclobutadiene)-molybdenum and -tungsten carbonyl halides (LA) 259

Cyclobutane, Rearr. of unsatd. compds. to cyclopropane and ~ derivs. (CR) 973 [G.E. *78*, 987 (1966)]

Cyclobutene, Photochem. formation of bicyclo[3.1.0]hex-2-ene and 3-vinyl-~ (LA) 904

Cyclobutenedione, Synths. and derivs. of squaric acid (FP) 888 [G.E. *78*, 927 (1966)]

Condensation products of squaric acid and azulenic hydrocarbons (SC) 893 [G.E. *78*, 937 (1966)]

Condensation products of squaric acid and tert. aromatic amines (SC) 894 [G.E. *78*, 937 (1966)]

Cyclodecadiene, Prepn. of *trans, trans*- and *cis,cis*-1,6-~ from *cis,trans*-1,5-~ (SC) 595 [G.E. *78*, 604 (1966)]

Cyclodecatriene, Reacns. of 4,5-dimethyl-*cis*-1,*cis*-4,*trans*-7-~ (SC) 961 [G.E. *78*, 983 (1966)]

Cylododecasulfur, $S_{12}$ (SC) 964 [G.E. *78*, 1020 (1966)]

Crystal structure of ~ (SC) 965 [G.E. *78*, 1020 (1966)]

Investigation of ~ by mass spectrometry (SC) 965 [G.E. *78*, 1021 (1966)]

Cyclohepta[*def*]fluorene (LA) 143

Cycloheptene, Diazomethane adds to picric acid (LA) 259

Cyclohexadiene, Intermediate occurrence of 1,2-~ (SC) 846 [G.E. *78*, 905 (1966)]

γ-Irradiation of 3-phenyl-1,4-~ in benzene (CR) 740 [G.E. *78*, 781 (1966)]

Cyclohexadiene-*cis*-1,2-dicarboxylic anhydride, Excited-state reacns. of 1,2,4,5-tetramethyl-3,5-~ (SC) 311 [G.E. *78*, 305 (1966)]

Cyclohexane, Reacn. of ω-dichlorotoluene with lithium and ~ (LA) 324

Cyclohexanecarboxylic acid, Prepn. of ε-caprolactam from ~ in liq. $SO_2$ (LA) 325

Cyclohexanediols, Reacn. of *cis*- and *trans*-1,2-~ with dihalogenomethanes (LA) 143

Cyclooctadiene, Transannular addn. of carbon monoxide to cycloocta-1,5-diene (LA) 616

Cyclooctatetraene, Structure of the ~ dimer of melting point 53 °C (SC) 130 [G.E. *78*, 117 (1966)]

Chlorination of ~ (SC) 585 [G.E. *78*, 595 (1966)]

Di(~)titanium and tri(~)dititanium (SC) 898 [G.E. *78*, 942 (1966)]

Crystal structure of tri(~)dititanium (SC) 899 [G.E. *78*, 943 (1966)]

Cyclooctatetraen (~) (Book Review) 430

Cyclopentadiene, Low-temperature photolysis of ~ (SC) 246 [G.E. *78*, 207 (1966)]

Chloro(dicyclopentadienyl)ethylzirconium and its reacn. with triethylaluminum (SC) 962 [G.E. *78*, 986 (1966)]

Cyclopentadiene-1,2,3,4-tetracarboxylate, Synth. of tetramethyl ~ (SC) 670 [G.E. *78*, 680 (1966)]

Cyclopentadienyl anions, Reacns. of cyano-substd. ~ (SC) 420 [G.E. *78*, 449 (1966)]

Cyclopentadienyl complexes, Cyclopentadienylbis(trifluorophosphine)cobalt (SC) 247 [G.E. *78*, 208 (1966)]

(π-Cyclopentadienyl) (π-tetraphenylcyclobutadiene)-molybdenum and -tungsten carbonyl halides (LA) 259

Cyclopentanecarboxylic acid, 1-Amino-2-nitro-~, a naturally occurring nitro compd. (LA) 527

Cyclophosphines, Thermal and photochem. formation of phospholenes and tetrahydrophosphorins from ~ and dienes (SC) 1038 [G.E. *78*, 1061 (1966)]

Cyclopolyphosphines, Exchange of ring members in ~ (SC) 316 [G.E. *78*, 307 (1966)]

Cyclopropane, Reacn. of substd. vinylsulfonium salts with CH-acidic compds. – a new route to polysubstd. ~-s (SC) 596 [G.E. *78*, 606 (1966)]

Rearr. of unsatd. compds. to ~ and cyclobutane derivs. (CR) 973 [G.E. *78*, 987 (1966)]

Allylmethyl-cyclopropylmethyl rearr. (LA) 904

Cyclopropyldiphenylmethylpotassium (α-cyclopropylbenzhydrylpotassium) (LA) 905

Cyclopropene, Interesting photochem. rearrs. of 3-acyl-~ derivs. (LA) 745

Cyclopropenyldiazomethane, Synth. and properties of diphenyl-~ (LA) 684

Cyclosilazanes, Silicon-nitrogen heterocycles (FP) 760 [G.E. *78*, 803 (1966)]

1,3-Cyclotetradecanediones, Synth. of ~ by ring enlargement (SC) 128 [G.E. *78*, 145 (1966)]

Cyclotriveratrylene, Conformational enantiomerism of a deriv. of ~ (SC) 593 [G.E. *78*, 603 (1966)]

Cysteine, New synth. of L-felenine (SC) 249 [G.E. *78*, 209 (1966)]

Elimination of $H_2S$ from ferredoxin and ~ methyl ester (SC) 840 [G.E. *78*, 824 (1966)]

~ in the active center of streptococcal proteins (LA) 143

Cytidine, Simple method for selective acylation of ~ on the 4-amino group (SC) 579 [G.E. *78*, 589 (1966)]

DECARBOXYLATION, Photochem. ~ of acyl hypoiodites (LA) 145

Decompositions, Kinetics of non-isothermal ~ (CR) 903 [G.E. *78*, 948 (1966)]

Dehalogenation, of perchloroketones with triphenylphosphine or trialkyl or triaryl phosphites (SC) 837 [G.E. *78*, 821 (1966)]

Dehydrobenzene, see Benzyne

Dehydrochlorination, Studies of the thermal ~ of poly(vinyl chloride) (CR) 607 [G.E. *78*, 608 (1966)]

Dehydrogenation of amine derivs. with Hg-EDTA (CR) 257 [G.E. *78*, 273 (1966)]

Denaturation, Reversible ~ of a univalent antibody fragment (LA) 143

6-Deoxy-D-*gluco*-dialdoheptose, Synth. of ~ and ring closure to 8(a),10(a)-dihydroxy-2,4,6-trioxaadamantane (SC) 665 [G.E. *78*, 673 (1966)]

Deoxyribonucleic acid, see Nucleic acid

Deoxyribonucleotides, see Nucleotides

Desulfuration, with hydroximoyl chlorides (SC) 314 [G.E. *78*, 308 (1966)]

~ of thio-acids with dimethyl sulfoxide (SC) 419 [G.E. *78*, 393 (1966)]

Detergents, Surface-active compds. (CR) 900 [G.E. *78*, 944 (1966)]

New synth. of surface-active urethanes of sucrose (CR) 900 [G.E. *78*, 944 (1966)]

Electrochem. investigation of the adsorption of surface-active materials at the phase boundary mercury/electrolyte (CR) 901 [G.E. *78*, 946 (1966)]

Deuterium, A simple method for the determin. of $D_2O$ in water (LA) 976

Dewar-benzene, see Bicyclo[2.2.0]hexa-2,5-diene 526, 669

Dewar-phthalic acid, Dimethyl 1,4,5,6-tetramethylbicyclo[2.2.0]hexa-2,5-diene-2,3-dicarboxylate (LA) 526

Diacetylene, Synth. of chloro-, bromo-, and iodo-~ (LA) 683

Dialkoxycarbonium salts, Alkylations by ~ (SC) 675 [G.E. *78*, 714 (1966)]

Aryl-substd. ~ as alkylating agents (SC) 676 [G.E. *78*, 715 (1966)]

Diamagnetism, Advances in molecular ~ (FP) 288 [G.E. *78*, 277 (1966)]

Diamantane, Isolation of Tetracyclo-[6.3.1.$0^{2,6}$.$0^{5,10}$]dodecane and pentacyclo[7.3.1.$1^{4,12}$.$0^{2,7}$.$0^{6,11}$]tetradecane (~) from petroleum (SC) 1045 [G.E. *78*, 1060 (1966)]

Hexaoxa-~ and hexaoxa-diphospha-~ (LA) 527

Diarsacyclohexane, 1,2-Diphenyl-1,2-diarsacyclopentane and 1,2-diphenyl-1,2-~ (LA) 260

Diarsacyclopentane, 1,2-Diphenyl-1,2-~ and 1,2-diphenyl-1,2-diarsacyclohexane (LA) 260

Diarylmethyl, Bis(2,5-di-t-butylphenyl)-methyl, a non-associating ~ (SC) 246 [G.E. *78*, 207 (1966)]

1,4-Diaza-2-boracyclopentane, Synth. of derivs. of 1,4-diaza-3,6-diboracyclohexane and ~ by reacn. of hydrogen cyanide with alkylboranes (SC) 723 [G.E. *78*, 748 (1966)]

1,4-Diazabutadiene-metal carbonyls (SC) 520 [G.E. *78*, 549 (1966)]

1,4-Diaza-3,6-diboracyclohexane, Synth. of derivs. of ~ and 1,4-diaza-2-boracyclopentane by reacn. of hydrogen cyanide with alkylboranes (SC) 723 [G.E. *78*, 748 (1966)]

3,4-Diazanorcaradiene (SC) 959 [G.E. *78*, 981 (1966)]

Diazirine, Diazoketone with a ~ ring (LA) 325

Diazoalkanes, Synth. of acetals by reacn. of ~ with t-butyl hypochlorite (SC) 420 [G.E. *78*, 448 (1966)]

α-Diazobutyraldehyde (LA) 684

Diazocarbonyl compds., New results in the preparative chemistry of ~ (CR) 257 [G.E. *78*, 211 (1966)]

Diazo coupling, An unusual ~ reacn. (SC) 675 [G.E. *78*, 673 (1966)]

Diazo group transfer, Mechanism and preparative importance (CR) 681 [G.E. *78*, 684 (1966)]

Diazoketones with a diazirine ring (LA) 325

Diazomethane, addition to picric acid (LA) 259

2-Diazo-1,1,1-trifluoropropane (LA) 745

1,1-Dichloroethylene, Synths. of carboxylic acids from ~ (FP) 870 [G.E. *78*, 932 (1966)]

Dichloroketene, New tropolone synth. using ~ (LA) 324

~ (LA) 615

ω-Dichlorotoluene, Reacn. of ~ with lithium and cyclohexane (LA) 324

Dictionary, New German/English ~ for Chemists (Book Review) 433

Elsevier's ~ of Industrial Chemistry in Six Languages (Book Review) 433

~ of Organic Compds. (Book Review) 688

Einheitliche Schreibweise in naturwissenschaftlichen Werken [Uniform Spelling in (German) Scientific Writing] (Book Review) 750

1,4-Dicyano-1,3-butadienes, Formation of *cis,cis*-~ (LA) 144

Di(cyclooctatetraene)titanium and tri-(cyclooctatetraene)dititanium (SC) 898 [G.E. *78*, 942 (1966)]

Dicyclopropylethylene, Conformations of *trans*-1,2-~ and vinylcyclopropane (SC) 512 [G.E. *78*, 544 (1966)]

Diels-Alder reacns., New preparative aspects (FP) 211 [G.E. *78*, 233 (1966)]

~ of 9,10-anthraquinodimethane (LA) 323

~. Organic Background, physicochem. aspects (Book Review) 981

1,6:8,13-Diepoxy[14]annulene (SC) 734 [G.E. *78*, 755 (1966)]

Dihydrooxazines, Recent synths. and reacns. of cyclic imidic esters (FP) 875 [G.E. *78*, 913 (1966)]

Dihydroseselin, New synth. of 5-chromanol derivs. and of ~ (SC) 415 [G.E. *78*, 389 (1966)]

Dihydroxycyclobutenedione, Synths. and derivs. of squaric acid (FP) 888 [G.E. *78*, 927 (1966)]

Condensation products of squaric acid and azulenic hydrocarbons (SC) 893 [G.E. *78*, 937 (1966)]

Condensation products of squaric acid and tert. aromatic amines (SC) 894 [G.E. *78*, 937 (1966)]

Diimine, Phenyl-~ (LA) 616

Diketenes, New reacn. of ~ with water (LA) 745

Dilatometric titration, Volume change as indicator for reacns. in soln. (SC) 310 [G.E. *78*, 304 (1966)]

Dilithiobenzenes, Synth. of 2-alkyl-1,3-~ and 2-alkylisophthalic acids (SC) 127 [G.E. *78*, 116 (1966)]

Dimethyl sulfide, Pulse radiolysis of ~ in aq. soln. (CR) 739 [G.E. *78*, 780 (1966)]

Dimethyl sulfoxide, Desulfuration of thio-acids with ~ (SC) 419 [G.E. *78*, 393 (1966)]

Di-2-naphthyltrisulfane 2-oxide, Prepn. of ~ (SC) 673 [G.E. *78*, 717 (1966)]

4,6-Dioxa-1-azabicyclo[3.3.0]octanes, Synth. of $\Delta^2$-oxazolines by reacn. of epoxides with $\Delta^2$-thiazolines (SC) 894 [G.E. *78*, 938 (1966)]

Dioxabicyclohexenes, Substd. ~ (LA) 526

3,7-Dioxabicyclo[3.3.0]octane (LA) 527

Dioxofluoroselenate, Postasium ~-(IV) (LA) 429

Dioxolane, 1,3-Dioxolan-2-yl hydroperoxide (SC) 253 [G.E. *78*, 269 (1966)]

Reacn. of *cis*- and *trans*-1,2-cyclohexanediols with dihalogenomethanes (LA) 143

Dioxolanylium salts, 4-Vinyl-1,3-~ (SC) 896 [G.E. *78*, 940 (1966)]

Diphosphabicyclohexadienylidene, Derivs. of phospha-2,5-cyclohexadien-4-one and 4,4'-diphosphabi-(2,5-cyclohexadienylidene) (SC) 588 [G.E. *78*, 598 (1966)]

Dipyridothiadiazepine, Synth. of a ~ deriv. (SC) 605 [G.E. *78*, 644 (1966)]

Disulfides, Complex formation between copper and organic ~ (SC) 422 [G.E. *78*, 449 (1966)]

Selective cleavage of a carbon-sulfur bond (LA) 258

Dithiane, Reacns. of trithiocarbonic acid with malonyl chloride (SC) 250 [G.E. *78*, 210 (1966)]

Dithiocane, Reacns. of trithiocarbonic acid with malonyl chloride (SC) 250 [G.E. *78*, 210 (1966)]

Dithiocarbamic acid, Synth. of free ~ (SC) 316 [G.E. *78*, 334 (1966)]

1,2-Dithiolium system, Proton activity in the ~ (SC) 513 [G.E. *78*, 529 (1966)]

Dithiophosphonates, Inner phosphonium and ammonium ~ (SC) 666 [G.E. *78*, 677 (1966)]

3,4-Divinyl-1,3,5-hexatriene, Tetravinylethylene (~) (LA) 852

DNA, see Nucleic acid

Docosanoic acid, 8,9,13-Triacetoxy-~ (LA) 260

Drug Research, Advances in ~ (Book Reviews) 263, 854

Dyes, Coupling principles in org. ~ (FP) 984 [G.E. *78*, 1029 (1966)]

ECDYSONE, Synth. of ~ (LA) 683

Ecdysterone, a new metamorphosis hormone of insects (SC) 248 [G.E. *78*, 269 (1966)]

Elasto-osmometry (CR) 608 [G.E. *78*, 609 (1966)]

Electrochemistry, Electrolytic reductive dimerizn. of 9-benzylidenefluorene (LA) 429

Kinetic data for irreversible electrochem. reductions (LA) 617

Electrolytic-reductive cyclization of activated olefins (LA) 618

Electrochem. oxidn. of iodide to iodate (LA) 851

Electrocyclic reacns., Explanation for the stereospecificity of ~ (LA) 261

Electron, Studies of chem. reacns. by pulse radiolysis: free ~-s and free radicals in aq. soln. (CR) 256 [G.E. *78*, 212 (1966)]

Study of fast chem. reacns. of ~-s and radicals by pulse radiolysis (CR) 975 [G.E. *78*, 988 (1966)]

Kinetics of reaction of the hydrated ~ with water (LA) 618

~-s and Chemical Bonding (Book Review) 265

Electronic effect of phosphorus, in *para*-phosphorus-substd. dimethylanilines (SC) 129 [G.E. *78*, 145 (1966)]

~ in *para*-phosphorus-substd. anisoles (SC) 731 [G.E. *78*, 777 (1966)]

Electronic Structure of Molecules. A New Approach (Book Review) 265

Electron pyrolysis, a new method of org. microanalysis (FP) 751 [G.E. *78*, 841 (1966)]

Electron Spin Resonance, Aliphatic semidiones; application of ~ to problems of conformation (CR) 974 [G.E. *78*, 989 (1966)]

Electrophoresis, Agar Gel ~ (Book Review) 854

Elektronenbrenzen, Electron pyrolysis, a new method of org. microanalysis (FP) 751 [G.E. *78*, 841 (1966)]

Enantiomers, Sepn. of ~ by gas chromatography (LA) 685

Enol phosphates, Proton-catalysed cleavage of ~ and phosphonates (SC) 836 [G.E. *78*, 820 (1966)]

Enterobacteriaceae, Significance of enterobacterial mutants for the chem. investigation of their cell-wall polysaccharides (FP) 198 [G.E. *78*, 172 (1966)]

Enzymes, Multienzyme complexes (FP) 785 [G.E. *78*, 865 (1966)]

Properties and mode of action of RNA polymerase (CR) 610 [G.E. *78*, 612 (1966)]

Formation of oligomeric amyloses by amylomaltase (CR) 611 [G.E. *78*, 612 (1966)]

Reactivity and function of the thiol groups of alcohol dehydrogenase (LA) 142

Homoserine dehydrogenase from *Rhodospirillum rubrum* (LA) 323

Regulatory and functional subunits in aspartate transcarbamylase (LA) 427

Acetyl-CoA:D-amino acid α-*N*-acetyltransferase (LA) 427

Digestion of ribonuclease A from ox pancreas by pancreas elastase (LA) 429

Biosynth. of the biotin ~ from apoenzyme and biotin (LA) 430

Isoleucyl-tRNA synthetase (LA) 853

Reactive copolymers of styrene as carriers for proteins and ~ (LA) 905

An enzyme that catalyses thiol-disulfide interactions in proteins (LA) 976

Les nucleases. Application à l'étude des acides nucleiques. (Nucleases. Their Application to the Study of Nucleic Acids) (Book Review) 145

Handbuch der physiologisch- und pathologisch-chemischen Analyse, für Ärzte, Biologen und Chemiker (Handbook of Physiological and Pathological Chemical Analysis, for Physicians, Biologists, and Chemists) (Book Review) 263

Epoxides, Addn. of ~ to 2-imidazolines (SC) 894 [G.E. *78*, 938 (1966)]

Synth. of $\Delta^2$-oxazolines by reacn. of ~ with $\Delta^2$-thiazolines (SC) 894 [G.E. *78*, 938 (1966)]

Formation of ~ on liquid-phase oxidn. of olefins (CR) 901 [G.E. *78*, 945 (1966)]

Epoxy[14]annulene, 1,6:8,13-Di-~ (SC) 734 [G.E. *78*, 755 (1966)]

Epoxy[18]annulene, Tri-~ and epoxydiepithio[18]annulene (LA) 325

Equilibria, Scrambling ~ and analysis of labile mixtures (FP) 341 [G.E. *78*, 401 (1966)]

Esters, Recent synths. and reacns. of cyclic imidic ~ (FP) 875 [G.E. *78*, 913 (1966)]

Estranes, Polyalkoxy-~, a new group of analgetic compds. (LA) 683

Ethers, Synth. of sulfonates by cleavage of ~ with sulfonic acids (LA) 325

New method for the rapid cleavage of ~ (LA) 427

Radical-pair mechanism of the Wittig rearr. of anionized ~ (LA) 684

Ethylene, New catalyst system for the dimerizn. of ~ and propene (SC) 584 [G.E. *78*, 593 (1966)]

Ethylmagnesium bromide, Solns. of ~ in ether (LA) 428

Ethylphosphonobromidothioate, Stereospecific synth. and hydrolysis of optically active *O*-ethyl ~ (SC) 668 [G.E. *78*, 716 (1966)]

Evolutionary aspects of the structure of proteins (FP) 798 [G.E. *78*, 856 (1966)]

Explosion of nitrogen trifluoride on active charcoal. – Reaction of $NF_3$ with carbon (SC) 317 [G.E. *78*, 336 (1966)]

FATTY ACIDS, Reacns. occurring on hydrogenation of unsatd. fatty alcohols (CR) 900 [G.E. *78*, 944 (1966)]

Felenine, New synth. of L-~ (SC) 249 [G.E. *78*, 209 (1966)]

Fermentation, Technology of the microbiological prepn. of org. substances (FP) 653 [from Chemie-Ing.-Techn. *38*, 813 (1966)]

Ferredoxin, Elimination of hydrogen sulfide from ~ and cysteine methyl ester (SC) 840 [G.E. *78*, 824 (1966)]

Redox properties of ~ (LA) 527

Ferrocene, Autocondensation of *N,N*-dimethylaminomethyl-~ (LA) 428

Chemistry of the Iron Group Metallocenes: ~, Ruthenocene, Osmocene (Book Review) 748

Flavan, Mechanism of the rearr. of ~ derivs. on reduction with $LiAlH_4/AlCl_3$ (SC) 842 [G.E. *78*, 826 (1966)]

Flotation, Concentration of hemoglobin solns. by ~ (CR) 903 [G.E. *78*, 947 (1966)]

Flower colors, Complex formation and ~ (FP) 791 [G.E. *78*, 834 (1966)]

Fluorene, Electrolytic reductive dimerizn. of 9-benzylidene-~ (LA) 429

Fluoride ions, Cesium fluoride is a donor of particularly active ~ (LA) 852

Fluorides, Structure and magnetism of ternary ~ (CR) 425 [G.E. *78*, 451 (1966)]

Spectroscopic studies of transition-metal ~ (CR) 744 [G.E. *78*, 782 (1966)]

Fluorinated ketones, Reacns. of the carbonyl group in ~ (FP) 947 [G.E. *78*, 1008 (1966)]

Fluorination, Partial ~ of methane by an electrochem. method (LA) 526

Fluorine Chemistry (Book Review) 979

Fluorine compds., Organometallic compd. with two-coordinated fluorine atoms (SC) 726 [G.E. *78*, 750 (1966)]

Fluoromethane, Prepn. of ~ in molten fluorides (SC) 314 [G.E. *78*, 307 (1966)]

Fluoroselenate, Potassium dioxofluoroselenate(IV) (LA) 260, 429

Fluorothiophosphates, Amidothio-, fluoroamidothio-, and ~ (CR) 256 [G.E. *78*, 272 (1966)]

Food additives, Analytical Methods for Pesticides, Plant Growth Regulators, and ~ (Book Review) 146

Foodstuffs, Die Bestandteile der Lebensmittel (The Constituents of ~) (Book Review) 431

Force constants and bond orders of nitrogen bonds (FP) 567 [G.E. *78*, 565 1966)]

Formamidines, *C*-Azido-*N*-sulfonyl-~ and their rearr. to 5-(*N*-sulfonylamino)-tetrazoles (SC) 520 [G.E. *78*, 548 (1966)]

Studies on ~ (CR) 321 [G.E. *78*, 339 (1966)]

Hydrogenation of carbodiimides to *N,N'*-disubstd. ~ (LA) 258

Formazans, Nature of tetrazolium salts and ~ (CR) 681 [G.E. *78*, 683 (1966)]

Fragmentation, Reductive ~ of 1-Methyl-4-tosyloxybicyclo[2.2.2]octan-2-one (SC) 316 [G.E. *78*, 335 (1966)]

Friedel-Crafts reacns., Friedel-Crafts and Related Reacns.(Book Review)531,1053

Fuel cells, Brennstoffelemente. Moderne Verfahren zur elektrochem. Energiegewinnung. (~. Modern Processes for Electrochemical Production of Energy) (Book Review) 326

Fuels, Chem. problems in the pyrometallurgical reprocessing of nuclear ~ (CR) 851 [G.E. *78*, 910 (1966)]

Fulminic acid, Structure of ~ (SC) 722 [G.E. *78*, 746 (1966)]

Fulvene containing less than 2% of impurities (LA) 430

Furantetracarboxylate, Formation of tetramethyl ~ from dimethyl acetylenedicarboxylate (SC) 579 [G.E. *78*, 588 (1966)]

Furazan 2-oxides (furoxans) (LA) 746

Furoxans, Furazan 2-oxides (~) (LA) 746

GALACTOSE, Stoffwechsel der Galaktose und ihrer Derivate (Metabolism of ~ and its Derivs.) (Book Review) 747

Gallium compds., Hydrogallinations (SC) 312 [G.E. *78*, 306 (1966)]

Gallogermoxanes, Organo-~, compds. containing the structural unit Ga-O-Ge (SC) 313 [G.E. *78*, 305 (1966)]

Gas analysis, Analyt. use of infrared spectroscopy with gratings. Quantitative analysis of gas traces (CR) 678 [G.E. *78*, 719 (1966)]

Gas chromatography, Determin. of the units in homo- and co-polymers of trioxane by pyrolysis ~ (CR) 608 [G.E. *78*, 608 (1966)]

Sepn. of enantiomers by ~ (LA) 685

Gases, Interaction of Metals and ~ (Book Review) 529

Gasoline, Determin. of lead alkyls in ~ (CR) 678 [G.E. *78*, 719 (1966)]

Gas-phase reacns., Kinetic relationships between reacns. in the gas phase and in soln. (FP) 78 [G.E. *78*, 73 (1966)]

Gel chromatography, New analyt. sepn. of traces of material on dextran gel (CR) 680 [G.E. *78*, 721 (1966)]

Determin. of mol. heterogeneity of polymers by ~ (CR) 608 [G.E. *78*, 609 (1966)]

Genetic code, Recognition of codes by pure tRNA species (LA) 853

Genetics, Selected Papers on Molecular ~ (Book Review) 431

Klassische und molekulare Genetik (Classical and Molecular ~) (Book Review) 528

Germacyclopentanes and -butanes (LA) 617

Germoxanes, Organogallo-~, compds. containing the structural unit Ga-O-Ge (SC) 313 [G.E. *78*, 305 (1966)]

Germyl compds. of strontium, barium, and zinc (SC) 522 [G.E. *78*, 549 (1966)]

Glasses, Color centers in alkali borate ~ containing Co, Ni, or Cu (FP) 85 [G.E. *78*, 41 (1966)]

Structure of ~ (FP) 544 [G.E. *78*, 577 (1966)]

Radiation-chem. formation and optical absorption spectra of org. sulfur radicals in org. ~ (CR) 740 [G.E. *78*, 781 (1966)]

Silicate Science (Book Review) 327

D-Glucosamine, Osazone formation by ~ (SC) 672 [G.E. *78*, 681 (1966)]

Reacn. of ~ with carbon disulfide (SC) 964 [G.E. *78*, 980 (1966)]

Glycolic acid, New route for the utilization of ~ (LA) 260

Glyoxylic acid, Prepn. of *N*-functional derivs. of ~ (SC) 837 [G.E. *78*, 823 (1966)]

Graphite, Reacns. of strongly electropositive metals with ~ and with metal dichalcogenides (CR) 904 [G.E. *78*, 948 (1966)]

Grignard compds., Unsolvated ~ (LA) 324

Solns. of ethylmagnesium bromide in ether (LA) 428

Hydrocarbon solns. of ~ (LA) 744

Allylmethyl-cyclopropylmethyl rearr. (LA) 904

Guanidinium salts, Vinylogous ~ and ω,ω-diaminoacrylamidinium salts (SC) 724 [G.E. *78*, 747 (1966)]

HAFNIUM, Sepn. of zirconium and ~ by liquid-liquid partition of their thiocyanates (FP) 15 [G.E. *78*, 19 (1966)]

Binary compds. of the transition elements (FP) 58 [G.E. *78*, 64 (1966)]

Halogen compds., Reduction of secondary and tertiary ~ under $S_N1$ conditions (LA) 978

Halogen-metal exchange between arylmetal and aryl-halogen compds. (LA) 746

Halogenoacetic esters, Reacn. of alkylidenephosphoranes with ~ (SC) 308 [G.E. *78*, 335 (1966)]

Halogenobenzenes, Recoil bromination of ~ (LA) 1051

Halogeno esters, Homopolar and heteropolar ~ of phosphorus, arsenic, and antimony (CR) 425 [G.E. *78*, 451 (1966)]

Halogen-oxygen exchange, Pentadiene-1,5-~ (CR) 680 [G.E. *78*, 722 (1966)]

Hammett constants of substituents containing phosphorus (SC) 595 [G.E. *78*, 605 (1966)]

Handbook, CRC ~ of Chemistry and Physics (Book Review) 907

Hemoglobin, Concentration of ~ solns. by flotation (CR) 903 [G.E. *78*, 947 (1966)]

Heptane, Association of aliphatic hydroxy compds. in n-~ (CR) 423 [G.E. *78*, 395 (1966)]

Heterocycles from acetylene derivs. (CR) 741 [G.E. *78*, 757 (1966)]

Heterocyclic chemistry, Advances in ~ (Book Review) 530, 853

Heterogeneity, Determin. of mol. ~ of polymers by gel-permeation chromatography (CR) 608 [G.E. *78*, 609 (1966)]

Heterosiloxanes, Synth. and reacns. of lithium chloromethyldimethylsilanolate (SC) 966 [G.E. *78*, 1022 (1966)]

Hexahalogenotitanates(III) (LA) 527

Hexaisopropenylbenzene, an inert polyolefin (LA) 261

Hexamethyldisiloxane, Isosteres of ~ and tris(trimethylsilyl)amine (SC) 312 [G.E. *78*, 306 (1966)]

Hexapentaene, *cis-trans*-Isomerism of 1,6-diphenyl-1,6-di-t-butyl-~ (SC) 420 [G.E. *78*, 449 (1966)]

Hexaoxadiamantane and hexaoxadiphosphadiamantane (LA) 527

Hexatriene, Tetravinylethylene (3,4-divinyl-1,3,5-~) (LA) 852

2-Hexen-4-yne, Rearr. of *cis*-1-chloro-~-4-yne, containing a vinylacetylene system (LA) 684

High-melting substances, Prepn. of ~ by pyrolysis (CR) 973 [G.E. *78*, 988 (1966)]

Histidine, *N*-Acetyl-L-~, the first acetylated basic amino acid found in nature (LA) 978

Homocysteine, (5-Amino-4-carbamoylimidazolyl)-5-S-homocysteinylriboside, a new S-amino acid deriv. (LA) 978

Homogeneity, Chem. ~ of binary copolymers (CR) 610 [G.E. *78*, 611 (1966)]

Homoserine dehydrogenase, from *Rhodospirillum rubrum* (LA) 323

Hormone, Hormonal system of plants (FP) 776 [G.E. *78*, 895 (1966)]

Chemistry and biochemistry of insulin (FP) 807 [G.E. *78*, 871 (1966)]

Vertebrate ~ as defensive substance of the water beetle (*Dytiscus marginalis*) (SC) 421 [G.E. *78*, 392 (1966)]

Ecdysterone, a new metamorphosis ~ of insects (SC) 248 [G.E. *78*, 269 (1966)]

Synthetic steroids with moulting ~ activity (SC) 673 [G.E. *78*, 680 (1966)]

Synth. of ecdysone (LA) 683

Biochemie der Nebennierenrinden-Hormone (Biochemistry of the Adrenal ~-s) (Book Review) 746

Hydrazine, Amination of ~-s to yield triazanes (SC) 578 [G.E. *78*, 587 (1966)]

Silyl derivs. of ~ and hydroxylamine (CR) 614 [G.E. *78*, 648 (1966)]

Hydrazones, *N*-Unsubstd. ~ (LA) 853

Hydroboration, Prepn. of organocarboranes by ~ of alkyl-1-alkynylboranes (SC) 730 [G.E. *78*, 777 (1966)]

Hydrocarbon, Tricyclo[4.3.1.$0^{1,6}$]deca-2,4,7-triene, an acidic alicyclic ~ (SC) 604 [G.E. *78*, 643 (1966)]

Alkylarenesulfonates derived from petroleum ~-s (CR) 901 [G.E. *78*, 945 (1966)]

Bond lengths in non-aromatic ~-s (LA) 526

Ability to selectively dissolve carcinogenic ~-s (LA) 851

Hydrogallinations (SC) 312 [G.E. *78*, 306 (1966)]

Hydrogenation, Reacns. occurring on ~ of unsatd. fatty alcohols (CR) 900 [G.E. *78*, 944 (1966)]

~ of carbodiimides to *N,N'*-disubstituted formamidines (LA) 258

Hydrogen cyanide, Structures and reacns. of the products of reacn. of ~ with hydrogen halides (CR) 425 [G.E. *78*, 452 (1966)]

Hydrogen halides, Structures and reacns. of the products of reacn. of hydrogen cyanide with ~ (CR) 425 [G.E. *78*, 452 (1966)]

Hydrogen ion activity, Influence of neutral salts on the ~ (CR) 141 [G.E. *78*, 151 (1966)]

1,5-Hydrogen shifts, Homolytic and heterolytic transannular ~ (LA) 429

Hydroperoxide, 1,3-Dioxolan-2-yl ~ (SC) 253 [G.E. *78*, 269 (1966)]

Oxidn. of sulfoxides with ~-s (SC) 893 [G.E. *78*, 937 (1966)]

1,4-Hydrostannation, Prepn. of *N*-stannylketenimines and ketene ethyl stannyl acetals by ~ of conjugated systems (SC) 514 [G.E. *78*, 545 (1966)]

Hydroximoyl chlorides, Desulfuration with ~ (SC) 314 [G.E. *78*, 308 (1966)]

Hydroxo compds., Relation between Coulomb potentials and positions of protons in crystalline ~ (SC) 133 [G.E. *78*, 113 (1966)]

Hydroxometalates, New method for the prepn. of alkali and alkaline earth ~ (SC) 1047 [G.E. *78*, 1102 (1966)]

Hydroxy compds., Association of aliphatic ~ in n-heptane (CR) 423 [G.E. *78*, 395 (1966)]

Hydroxylamine, Silyl derivs. of hydrazine and ~ (CR) 614 [G.E. *78*, 648 (1966)]

α-Hydroxy-β-oxosulfones (LA) 527

1-Hydroxy-2-thiouracil, Synth. of ~ (SC) 511 [G.E. *78*, 491 (1966)]

Hypnotica, 8-(Alkylthio)thiotheophyllines, a new group of ~ (LA) 683

IMIDAZOLE, Biradicals, quinones, and semiquinones of the ~ series (SC) 311 [G.E. *78*, 303 (1966)]

Imidazole-2-carbaldehyde, Prepn. and properties of ~ (SC) 674 [G.E. *78*, 715 (1966)]

Imidazolidinone, New group of antischistosomal compds. (FP) 857 [G.E. *78*, 850 (1966)]

2-Imidazolines, Addn. of epoxides to ~ (SC) 894 [G.E. *78*, 938 (1966)]

Imide derivs., Prepn. and polymerizn. of difunctional ~ (CR) 609 [G.E. *78*, 610 (1966)]

Imidic esters, Synths. and reacns. of cyclic ~ (FP) 875 [G.E. *78*, 913 (1966)]

Iminium salts, Synth. of alkynylamines from α-halogeno ~ and ketene *S,N*-acetals (SC) 584 [G.E. *78*, 593 (1966)]

Indenes, Alkyl-substd. ~ (LA) 527

Indigo, Theoretically and experimentally determined properties of the fundamental ~ chromophore (SC) 598 [G.E. *78*, 638 (1966)]

Indole compds. from bovine pineal glands (LA) 144

Infrared spectroscopy, Analyt. use of ~ with gratings. Quantitative analysis of gas traces (CR) 678 [G.E. *78*, 719 (1966)]

Use of thin-layer chromatography and ~ for elucidation of the thermolysis products of triphenylphosphine (CR) 680 [G.E. *78*, 721 (1966)]

Infrared spectra of cesium and tetraalkylammonium salts containing the anions $HCl_2^-$ and $DCl_2^-$ (LA) 617

Initiators, New ~ for low-temperature polymerizn. (SC) 253 [G.E. *78*, 268 (1966)]

Inorganic Chemistry, Advances in ~ and Radiochemistry (Book Review) 530, 907

Progress in ~ (Book Review) 531

Inositols, Biosynth. of cyclitols (FP) 165 [G.E. *78*, 198 (1966)]

Insecticide, Metabolism of thiodan in insects (SC) 730 [G.E. *78*, 775 (1966)]

Insects, Ecdysterone, a new metamorphosis hormone of ~ (SC) 248 [G.E. *78*, 269 (1966)]

Insulin, Chemistry and biochemistry of ~ (FP) 807 [G.E. *78*, 871 (1966)]

Biosynth. of ~ (LA) 427

Iodate, Electrochem. oxidn. of iodide to ~ (LA) 851

Iodide, Electrochem. oxidn. of ~ to iodate (LA) 851

Ion exchangers, Inorganic redox ~ (SC) 605 [G.E. *78*, 645 (1966)]

Iridium pentafluoride, Prepn. of ~ (LA) 428

Iron metabolism, Problems of ~ (FP) 633 [G.E. *78*, 664 (1966)]

Iron phosphorus chloride, Structure of metal compds. (CR) 682 [G.E. *78*, 684 (1966)]

Iron protein, Rubredoxin, a new crystalline ~ with a redox function (LA) 429

Iron(III) Sulfide (SC) 963 [G.E. *78*, 987 (1966)]

Isocyanates, New methods of preparative organic chemistry VI. Synth. of ~ and carbodiimides (FP) 704 [G.E. *78*, 761 (1966)]

Synth. of 2-oxazoline-2-amines and 2-thiazoline-2-amines by reacn. of aziridinium tetrafluoroborate with ~ and isothiocyanates (SC) 667 [G.E. *78*, 677 (1966)]

Reacns. of *N*-alkyl- and *N*-aryl-*S*-chloroisothiocarbamoyl chlorides with ~; synth. of 1,2,4-thiadiazolidine-3,5-diones (SC) 672 [G.E. *78*, 681 (1966)]

Synth. of ~ by fragmentation of sulfonylureas (SC) 724 [G.E. *78*, 746 (1966)]

Conversion of ~ into isothiocyanates by reacn. with *O,O'*-diethyl hydrogen dithiophosphate (SC) 725 [G.E. *78*, 748 (1966)]

Prepn. of *O,N*-acetals of acyl ~ (SC) 841 [G.E. *78*, 826 (1966)]

Reacn. of ~, isothiocyanates, or carbon disulfide with methylenediamines (SC) 844 [G.E. *78*, 827 (1966)]

Trichloromethanesulfinyl isocyanate (SC) 1047 [G.E. *78*, 1100 (1966)]

New synth. of ~ under mild conditions (LA) 615

Isocyanides, New method for the prepn. of ~ (LA) 526

Isoindoles, 2-Aryl-~ (SC) 967 [G.E. *78*, 984 (1966)]

Isoleucine, Prepn. of ~ from β-methylaspartic acid with the aid of *Escherichia coli* W (LA) 428

Isoleucyl-tRNA synthetase (LA) 853

Isophthalic acids, Synth. of 2-alkyl-1,3-dilithiobenzenes and 2-alkyl-~ (SC) 127 [G.E. *78*, 116 (1966)]

Isoquinoline, New synth. of derivs. of ~ and 1,3-benzothiazin-4-one (SC) 663 [G.E. *78*, 674 (1966)]

Acetylation of benzyl-~-s (CR) 613 [G.E. *78*, 647 (1966)]

Isoquinoline alkaloids, Course in Organic Chemistry (Book Review) 329

Isothiocarbamoyl chlorides, *N*-Aryl- and *N*-alkyl-*S*-(2-chloroalkyl)-~ (SC) 250 [G.E. *78*, 210 (1966)]

Reacns of *N*-alkyl- and *N*-aryl-*S*-chloro-~ with isocyanates; synth. of 1,2,4-thiadiazolidine-3,5-diones (SC) 672 [G.E. *78*, 681 (1966)]

Isothiocyanates, Synth. of 2-oxazoline-2-amines and 2-thiazoline-2-amines by reacn. of aziridinium tetrafluoroborate with isocyanates and ~ (SC) 667 [G.E. *78*, 677 (1966)]

Conversion of isocyanates into ~ by reacn. with *O,O'*-diethyl hydrogen dithiophosphate (SC) 725 [G.E. *78*, 748 (1966)]

Reacn. of isocyanates, ~, or carbon disulfide with methylenediamines (SC) 844 [G.E. *78*, 827 (1966)]

A convenient prepn. of ~ (SC) 963 [G.E. *78*, 985 (1966)]

Isotope effects in org. chemistry and biochemistry (FP) 920 [G.E. *78*, 993 (1966)]

Isotopes, The new nuclide $^{52}$Ti (LA) 1051

Isotopic exchange, Labeling of aromatic halides by radiation-induced ~ (CR) 738 [G.E. *78*, 778 (1966)]

Isourea, Synths. and reacns. of *O,N,N'*-trisubstd. ~-s (FP) 470 [G.E. *78*, 483 (1966)]

Isoxazolium salts, Synth. of ~ unsubstd. in the 3-position (LA) 1051

KANOSAMINE, Simple synth. of 3-amino-3-deoxy-D-glucose (~) (SC) 967 [G.E. *78*, 1023 (1966)]

Kerr effect at high pressures and its relation to the structure of molecules and liquids (CR) 742 [G.E. *78*, 782 (1966)]

Ketene mercaptals, New synth. of ~ (SC) 1040 [G.E. *78*, 1100 (1966)]

Ketene, Prepn. of *N*-stannylketenimines and ketene ethyl stannyl acetals by 1,4-hydrostannation of conjugated systems (SC) 514 [G.E. *78*, 545 (1966)]

Synths. with *N*-stannylketenimines and ~ ethyl stannyl acetals (SC) 515 [G.E. *78*, 546 (1966)]

Stereochemistry and mechanism of some reacns. of ~-s (CR) 320 [G.E. *78*, 340 (1966)]

Ketocarboxylic acids, Prepn. of satd. and unsatd. ~ from dicarboxylic anhydrides and alkylaluminum compds. (SC) 511 [G.E. *78*, 491 (1966)]

Ketones, Reacns. of the carbonyl group in fluorinated ~ (FP) 947 [G.E. *78*, 1008 (1966)]

Dehalogenation of perchloro-~ with triphenylphosphine or trialkyl or triaryl phosphites (SC) 837 [G.E. *78*, 821 (1966)]

New synth. of ~ (LA) 144

Wittig reaction with α,β-unsatd. ~ can involve formation of a three-membered ring (LA) 617

Condensations with β-oxo enamines (LA) 977

Kinetics of non-isothermal decompositions (CR) 903 [G.E. *78*, 948 (1966)]

LABELING of aromatic halides by radiation-induced isotopic exchange (CR) 738 [G.E. *78*, 778 (1966)]

Laboratory Techniques, Laboratoriumstechnik für Biochemiker (Laboratory Techniques for Biochemists) (Book Review) 1052

Lactam polymerizn., Oligoamides and their role in ~ (CR) 141 [G.E. *78*, 151 (1966)]

β-Lactams with exocyclic methylene groups (LA) 745

Lactones, Polymers containing lactone groups (FP) 994 [G.E. *78*, 1093 (1966)]

Lead alkyls, Determin. of ~ in gasoline (CR) 678 [G.E. *78*, 719 (1966)]

Lead(IV) chloride, Reacn. of ~ with vicinal diols (LA) 745

Lead compds., Use of activation analysis for determin. of traces in the white lead of paintings (CR) 679 [G.E. *78*, 720 (1966)]

Ligand Exchange, Nucleophilic ~ by phosphoranes (SC) 968 [G.E. *78*, 1018 (1966)]

~ with compds. of quinquevalent arsenic (SC) 969 [G.E. *78*, 1018 (1966)]

Lignin, New type of rearr. in the ~ field (SC) 843 [G.E. *78*, 821 (1966)]

~ Biochemistry (Book Review) 747

Liquid-liquid partition, Sepn. of zirconium and hafnium by ~ of their thiocyanates (FP) 15 [G.E. *78*, 19 (1966)]

Lithiobenzene, Synth. of 2-alkyl-1,3-di-~-s and 2-alkylisophthalic acids (SC) 127 [G.E. *78*, 116 (1966)]

Lithium compds., β-Hetero-substd. lithium alkyls and alkenyls (SC) 519 [G.E. *78*, 547 (1966)]

Stable nitroaryl-~ (SC) 1044 [G.E. *78*, 1062 (1966)]

Complex methylchromium compds. (LA) 526

Lithium hydridotris-(t-butoxy)aluminate (LA) 616

Liver chromatin, Protein synth. in rat ~ and chromatin fractions (SC) 592 [G.E. *78*, 601 (1966)]

Longifolene, Homolytic and heterolytic transannular 1,5-hydrogen shifts (LA) 429

Lysine, Cyclic oxidn. products of ~ (SC) 131 [G.E. *78*, 118 (1966)]

MACROMOLECULAR COLLOQUIUM (CR) 607 [G.E. *78*, 608 (1966)]

Madelung constants (FP) 95 [G.E. *78*, 52 (1966)]

Magnesium amides, Ammonothermal synth. of ~ and beryllium amides (SC) 247 [G.E. *78*, 208 (1966)]

Magnetic methods, Applications and limitations of ~ in free-radical chemistry (FP) 6 [G.E. *78*, 98 (1966)]

Magnetic properties, Landolt-Börnstein. Zahlenwerte u. Funktionen aus Naturwissenschaften u. Technik (Numerical Values and Functions from Science and Technology (Book Review) 685

Magnetism, Advances in molecular diamagnetism (FP) 288 [G.E. *78*, 277 (1966)]

Structure and ~ of ternary fluorides (CR) 425 [G.E. *78*, 451 (1966)]

Maleic anhydride, An adduct of ~ and tetrahydrofuran (LA) 976

Malonodinitrile, Substd. pyrimidine-5-carbonitriles by Vilsmeier reacn. of ~ (SC) 1042 [G.E. *78*, 1059 (1966)]

Manganese compds., Trifluoromethanesulfonylpentacarbonylmanganese (SC) 727 [G.E. *78*, 752 (1966)]

Bis(dimethylamino)boronpentacarbonylmanganese (LA) 616

Mass spectrometry, Mass spectra of weakly excited molecules (SC) 517 [G.E. *78*, 494 (1966)]

Investigation of cyclododecasulfur, $S_{12}$, by ~ (SC) 965 [G.E. *78*, 1021 (1966)]

Structure Elucidation of Natural Products by ~ (Book Review) 147

Meerwein, Scientific work of Hans ~ (FP) 333 [G.E. *78*, 347 (1966)]

Hans ~, the teacher and the man (FP) 338 [G.E. *78*, 353 (1966)]

Melting and Crystal Structure (Book Review) 980

Melts, Solubility in, and reacn. with, alkali chloride/$AlCl_3$ ~, of metal oxides and oxide halides (CR) 743 [G.E. *78*, 782 (1966)]

Mercaptals, New synth. of ketene ~ (SC) 1040 [G.E. *78*, 1100 (1966)]

Mercury, Electrochem. investigation of the adsorption of surface-active materials at the phase boundary ~/electrolyte (CR) 901 [G.E. *78*, 946 (1966)]

Mercury compds., Alkoxycarbonylation of sec. and prim. amines by alkoxycarbonyl-~ (SC) 252 [G.E. *78*, 209 (1966)]

Prepn. of bis(dialkylcarbamoyl)-~ by carbonylation in amines (SC) 664 [G.E. *78*, 675 (1966)]

Structural investigations on new ~ (CR) 142 [G.E. *78*, 151 (1966)]

Dehydrogenation of amine derivs. with Hg-EDTA (CR) 257 [G.E. *78*, 273 (1966)]

Metalates, New method for the prepn. of alkali and alkaline earth hydroxo-~ (SC) 1047 [G.E. *78*, 1102 (1966)]

Metal films, Chemisorption of gases on evaporated ~ (CR) 848 [G.E. *78*, 827 (1966)]

Metal-halogen exchange between arylmetal and aryl-halogen compds. (LA) 746

Metallocenes, Chemistry of the Iron Group ~: Ferrocene, Ruthenocene, Osmocene (Book Review) 748

Metallurgical Analysis, Metallkundliche Analyse (~) (Book Review) 685

Metals, Passivity of ~ (FP) 185 [G.E. *78*, 253 (1966)]

Reacns. of strongly electropositive ~ with graphite and with metal dichalcogenides (CR) 904 [G.E. *78*, 948 (1966)]

Nitrosyl compds. of ~ of the iron group with bivalent phosphino groups as bridging ligands (LA) 905

Interaction of ~ and Gases (Book Review) 529

Metal oxides, Solubility in, and reacn. with, alkali chloride/$AlCl_3$ melts, of ~ and oxide halides (CR) 743 [G.E. *78*, 782 (1966)]

Metamorphosis hormone, Ecdysterone, a new ~ of insects (SC) 248 [G.E. *78*, 269 (1966)]

Methacrylic esters, Stereochemistry of polymerizn. of ~ (LA) 683

Methanesulfenyl chloride, Prepn. of chlorobis(trifluoromethylthio)-~ and chlorofluoro(trifluoromethylthio)methanesulfenyl chloride (SC) 845 [G.E. *78*, 906 (1966)]

Methanesulfinyl isocyanate, Trichloro-~ (SC) 1047 [G.E. *78*, 1100 (1966)]

Methanetricarboxylates, Addn. of trialkyl ~ to 1-alkenes initiated by peroxides (SC) 586 [G.E. *78*, 595 (1966)]

Methanide (Dimethylsulfonio)(phenylsulfonyl)(vinylsulfonyl)-~ (SC) 971 [G.E. *78*, 1019 (1966)]

1,6-Methano[10]annulene, ~-2-amine and -2-ol (SC) 732 [G.E. *78*, 753 (1966)]

11-Methylene-~ and ~-11-ol (SC) 732 [G.E. *78*, 754 (1966)]

2,3-Didehydro-~ (SC) 733 [G.E. *78*, 755 (1966)]

1,6-Methanocyclodecapentaene, Tricarbonyl-(~)-chromium (SC) 518 [G.E. *78*, 548 (1966)]

Structure of tricarbonyl-~-chromium (SC) 1043 [G.E. *78*, 1063 (1966)]

Methionine, Biosynth. of ~ by bacteria (CR) 742 [G.E. *78*, 758 (1966)]

Dynamics of sulfur metabolism and the utilization of sulfur in the animal organism (CR) 1050 [G.E. *78*, 1066 (1966)]

β-Methylaspartic acid, Prepn. of isoleucine from ~ with the aid of *Escherichia coli* W (LA) 428

1-Methylazepine, Dimerizn. of ~ (SC) 839 [G.E. *78*, 822 (1966)]

Methylene blue, Adsorption of ~ on clays (SC) 247 [G.E. *78*, 208 (1966)]

Methylenenorcaradiene, A stable ~ (SC) 251 [G.E. *78*, 268 (1966)]

Methylmetal compds., Method for the prepn. of ~ (FP) 1 [G.E. *78*, 107 (1966)]

4-Methylosthenolic acid, Synth. of ~ by the Willgerodt-Kindler reacn. (SC) 125 [G.E. *78*, 114 (1966)]

Microbes, Relation of ~ to blood-group active substances (FP) 909 [G.E. *78*, 969 (1966)]

Microbiological prepn. of org. substances, Technology of the ~ (FP) 653 [from Chemie-Ing.-Techn. *38*, 813 (1966)]

Milk, Progress in the chemistry of casein (FP) 558 [G.E. *78*, 629 (1966)]

Mitochondria are not the only cell organelles with an oxidizing function (LA) 259

Mixtures, Scrambling equilibria and analysis of labile ~ (FP) 341 [G.E. *78*, 401 (1966)]

Molecular chirality, Specification of ~ (FP) 385 [G.E. *78*, 413 (1966)]

Molecular orbitals in Chemistry, Physics, and Biology. A Tribute to R. S. Mulliken (Book Review) 146

Molecular spectroscopy, Eighth European Congress on ~ (CR) 254 [G.E. *78*, 270 (1966)]

Molecular Weight, Osmosis, anomalous osmosis, and determin. of ~ (CR) 320 [G.E. *78*, 309 (1966)]

Kinetics and ~ distributions in anionic polymerizns. in weakly solvating solvents (CR) 608 [G.E. *78*, 609 (1966)]

Molybdenum, Analyt. Chemistry of Molybdenum (Book Review) 687

Molybdenum compds., Contributions to the chemistry of the binary compds. of the transition elements (FP) 58 [G.E. *78*, 64 (1966)]

Binuclear complexes of chromium and molybdenum with ethylenebis(diphenylphosphine) as bridging ligand (SC) 606 [G.E. *78*, 646 (1966)]

Isopolyanions of molybdenum(VI) (SC) 736 [G.E. *78*, 756 (1966)]

(π-Cyclopentadienyl)(π-tetraphenylcyclobutadiene)-molybdenum and -tungsten carbonyl halides (LA) 259

Monosaccharides, Gas-chromatographic detection of ~ in the septanose and open-chain forms (LA) 324

Mucopolysaccharides, Studies of ~ of normal and sclerotic human aortas (CR) 610 [G.E. *78*, 611 (1966)]

Multienzyme complexes (FP) 785 [G.E. *78*, 865 (1966)]

NAPHTHACENEQUINONES, New three-stage synth. of substd. ~ (LA) 745

Naphthoquinone, Constitution of the "classical" 3-hydroxy-1,2-~ (CR) 614 [G.E. *78*, 647 (1966)]

Natural products, Fortschritte der Chemie organ. Naturstoffe (Progress in the Chemistry of Org. ~ (Book Review) 529

Kunststoff-Handbuch. Aufbau, Verarbeitung, Eigenschaften und Anwendg. der synthetischen Werkstoffe (Handbook of Synthetic Industrial Materials. Structure, Processing, Properties, and Applications) (Book Review) 855

The Molecules of Nature: A Survey of the Biosynth. and Chemistry of ~ (Book Review) 1053

Nickel, Color centers in alkali borate glasses containing cobalt, ~, or copper (FP) 85 [G.E. *78*, 41 (1966)]

Nickel compds., Reacn. of alkyldichloroamines with nickel tetracarbonyl (SC) 123 [G.E. *78*, 114 (1966)]

Spiroheterocyclic nickel carbonyl (SC) 516 [G.E. *78*, 547 (1966)]

Stabilized dialkyl-~ (SC) 581 [G.E. *78*, 591 (1966)]

π-Allylmethylnickel (SC) 582 [G.E. *78*, 591 (1966)]

Bistritylnickel and tritylnickel chloride (SC) 583 [G.E. *78*, 592 (1966)]

Prepn. of carbonyl(chlorodifluorophosphine)nickel complexes (SC) 583 [G.E. *78*, 593 (1966)]

π-Allylnickel bromide under the influence of phosphines and phosphites (SC) 897 [G.E. *78*, 941 (1966)]

Crystal structure of carbonyl(piperidine-*N*-carbonitrile)nickel(0) (SC) 1046 [G.E. *78*, 1064 (1966)]

Heterogeneous catalysis with elemental boron and with nickel borides (CR) 525 [G.E. *78*, 552 (1966)]

Niobium compds., Contributions to the chemistry of the binary compds. of the transition elements (FP) 58 [G.E. *78*, 64 (1966)]

Nitride halides, Synth. of azide halides and ~ and some related structural problems (CR) 322 [G.E. *78*, 339 (1966)]

Nitriles, Synth. of ~ from aldehydes (LA) 261

Nitro compds., Stable nitroaryl-lithium compds. (SC) 1044 [G.E. *78*, 1062 (1966)]

Radiation-chem.reduction of aromatic~ (CR) 739 [G.E. *78*, 780 (1966)]

Nitrogen, Chemisorption of ~ on various surfaces of tungsten single crystals (LA) 142

Nitrogen bonds, Force constants and bond orders of ~ (FP) 567 [G.E. *78*, 565 (1966)]

Nitrogen compds., Houben-Weyl: Methoden der organ. Chemie (Houben-Weyl: Methods of Organic Chemistry) (Book Review) 528

Nitrogen-silicon heterocycles (FP) 760 [G.E. *78*, 803 (1966)]

Nitrogen trifluoride, Explosion of ~ on active charcoal. – Reaction of $NF_3$ with carbon (SC) 317 [G.E. *78*, 336 (1966)]

Nitromethane, Amination-dehydration of ~ by tris(dimethylamino)arsine (LA) 905

Nitroolefins, New photochemical rearr. of ~ (LA) 684

Nitrosamine, Sepn. of conformational isomers of a ~ (SC) 728 [G.E. *78*, 751 (1966)]

Nitrosobissulfate, Reacn. of phenylhydrazones with dipotassium ~ (SC) 1049 [G.E. *78*, 1101 (1966)]

Nitrosteroids, New prepn. of ~ (LA) 144

Nitrosyl compds. of metals of the iron group with bivalent phosphino groups as bridging ligands (LA) 905

3-Nitro-1,2,4,5-tetraisopropylbenzene, Two conformers of the ~ radical anion (LA) 853

NMR spectroscopy, Classification and analysis of NMR spectra (FP) 623 [G.E. *78*, 653 (1966)]

Applications of ~ in Organic Chemistry (Book Review) 147

Nobel Lectures, Physiology or Medicine (Book Review) 433

Nonexistent Compounds – Compds. of Low Stability (Book Review) 980

Norbornadiene, Cationic transannular polymerizn. of ~ (LA) 144

Norcaradiene. A stable methylene-~ (SC) 251 [G.E. *78*, 268 (1966)]

Nortricyclenes, Synth. of ~ from bicyclic ketones in a one-stage reacn. (SC) 248 [G.E. *78*, 266 (1966)]

Nuclear fuels, Chem. problems in the pyrometallurgical reprocessing of ~ (CR) 851 [G.E. *78*, 910 (1966)]

Nuclear magnetic resonance, see NMR spectroscopy

Nuclear Techniques in Analytical Chemistry (Book Review) 262

Nucleases, Les nucleases. Application à l'étude des acides nucleiques (~. Their Application to the Study of Nucleic Acids) (Book Review) 145

Nucleic acid, Synth. of Oligo- and polynucleotides (FP) 173 [G.E. *78*, 186 (1966)]

Nucleotide sequences of two serine-specific transfer ribo-~-s (SC) 422 [G.E. *78*, 392 (1966)]

Structure of an odd nucleoside from serine-specific transfer ribo-~ (SC) 590 [G.E. *78*, 600 (1966)]

Secondary structure of soluble ribo-~ (SC) 591, 847 [G.E. *78*, 601 (1966)]

Secondary structure of serine-specific transfer ribonucleic acid (SC) 671 [G.E. *78*, 682 (1966)]

Relation between synth. of antibodies and metabolism of ~-s(CR) 610 [G.E. *78*, 611 (1966)]

Fractionation and purification of tRNA (LA) 852

Recognition of codes by pure tRNA species (LA) 853

Purines, Pyrimidines, and Nucleotides, and the Chemistry of ~-s (Book Review) 264

Nucleoside, Structure of an odd ~ from serine-specific transfer ribonucleic acid (SC) 590 [G.E. *78*, 600 (1966)]

Synth. of *C*-methyl branched uracil ~-s (SC) 737 [G.E. *78*, 774 (1966)]

Nucleotide, Synth. of oligo- and poly-~-s (FP) 173 [G. E. *78*, 186 (1966)]

~ sequences of two serine-specific transfer ribonucleic acids (SC) 422 [G.E. *78*, 392 (1966)]

Oligo-~ synth. with a soluble polymer as carrier (SC) 601 [G.E. *78*, 640 (1966)]

Synth. of oligodeoxyribo-~-s with terminal 5'-phosphate groups (SC) 671 [G.E. *78*, 682 (1966)]

2,4,6-Triisopropylbenzenesulfonyl chloride to effect inter-~ linkages (LA) 615

~-s and Coenzymes (Book Review) 264

Purines, Pyrimidines, and ~-s, and the Chemistry of Nucleic Acids (Book Review) 264

Nylon oligomers, Synth. of ~ by the Merrifield method of peptide synth. on synthetic resins (CR) 610 [G.E. *78*, 611 (1966)]

OLEFIN, Allyl-transition metal systems (FP) 151 [G.E. *78*, 157 (1966)]

*trans*-Selective ~ synth. (SC) 126 [G.E. *78*, 115 (1966)]

Addn. of trialkyl methanetricarboxylates to 1-alkenes initiated by peroxides (SC) 586 [G.E. *78*, 595 (1966)]

*cis*-Selective ~ synths. (SC) 667 [G.E. *78*, 677 (1966)]

Formation of epoxides on liquid-phase oxidn. of ~-s (CR) 901 [G.E. *78*, 945 (1966)]

Cycloaddn. on thermal cleavage of aziridines in the presence of ~-s (CR) 975 [G.E. *78*, 1024 (1966)]

Hexaisopropenylbenzene, an inert poly-~ (LA) 261

Electrolytic-reductive cyclization of activated ~-s (LA) 618

New photochem. rearr. of nitro-~-s (LA) 684

Chemistry of Alkenes (Book Review) 329

Oligoamides, Synth. of monodisperse ~ on macromolecular carriers (SC) 417 [G.E. *78*, 390 (1966)]

~ and their role in lactam polymerizn. (CR) 141 [G.E. *78*, 151 (1966)]

Oligomers, New prepn. of ~ (LA) 978

Oligosaccharides (Book Review) 432, 620

Optical brighteners, Aryl-$\Delta^2$-pyrazolines as ~ (FP) 699 [G.E. *78*, 769 (1966)]

Optically active polymers, Methods and problems in the study of ~ (CR) 850 [G.E. *78*, 909 (1966)]

Optical rotation, Constantes sélectionnées pouvoir rotatoire naturel (Selected Values of Optical Rotatory Power) (Book Review) 749

Optical Rotatory Dispersion and Circular Dichroism in Organic Chemistry (Book Review) 434

Organometallic Synthesis (Book Review) 530

Osazone formation by D-glucosamine (SC) 672 [G.E. *78*, 681 (1966)]

Oscillometric analytical procedure with continuous recording (CR) 677 [G.E. *78*, 718 (1966)]

Osmocene, Chemistry of the Iron Group Metallocenes: Ferrocene, Ruthenocene, ~ (Book Review) 748

Osmometry, Elasto-~ (CR) 608 [G.E. *78*, 609 (1966)]

Osmosis, anomalous osmosis, and determn. of mol. wt. (CR) 320 [G.E. *78*, 309 (1966)]

Osthenolic acid, Synth. of 4-methyl-~ by the Willgerodt-Kindler reacn. (SC) 125 [G.E. *78*, 114 (1966)]

4-Oxa-1,6-diazabicyclo[3.3.0]octane, Addn. of epoxides to 2-imidazolines (SC) 894 [G.E. *78*, 938 (1966)]

1,4,2-Oxathiazoles, Formation of 1,3,4-thiadiazoles and 1,4,2-~ from thioketenes (SC) 970 [G.E. *78*, 1023 (1966)]

Oxazines, Recent synths. and reacns. of cyclic imidic esters (FP) 875 [G.E. *78*, 913 (1966)]

Diene synths. of heterocyclic compds. (CR) 614 [G.E. *78*, 648 (1966)]

Oxazolines, Recent synths. and reacns. of cyclic imidic esters (FP) 875 [G.E. *78*, 913 (1966)]

Synth. of 2-~-2-amines and 2-thiazoline-2-amines by reacn. of aziridinium tetrafluoroborate with isocyanates and isothiocyanates (SC) 667 [G.E. *78*, 677 (1966)]

Synth. of $\Delta^2$-~ by reacn. of epoxides with $\Delta^2$-thiazolines (SC) 894 [G.E. *78*, 938 (1966)]

Polymerizn. of 2-~ (CR) 612 [G.E. *78*, 613 (1966)]

Oxepin, A new synth. of the ~ system from furan and dimethyl acetylenedicarboxylate (SC) 1039 [G.E. *78*, 1057 (1966)]

Oxidation, Die Oxydation organischer Verbb. mit Sauerstoff (~ of Organic Compds. with Oxygen) (Book Review) 327

~ Mechanisms (Book Review) 620

Atmospheric ~ and antioxidants (Book Review) 981

Oxidation states, Micromethod for analytical determin. of lower ~ (CR) 678 [G.E. *78*, 719 (1966)]

Oxide halides, Solubility in, and reacn. with, alkali chloride/$AlCl_3$ melts, of metal oxides and ~ (CR) 743 [G.E. *78*, 782 (1966)]

Oxocations, Recent developments in the chemistry of transition metal ~ (FP) 712 [G.E. *78*, 736 (1966)]

Existence of the $VO_2^+$, $TiO^{2+}$, and $ZrO^{2+}$ cations (SC) 1041 [G.E. *78*, 1065 (1966)]

Oxotetrahalogenorhenates(V) (LA) 616

Oxygen, Die Oxydation organischer Verbb. mit Sauerstoff (The Oxidn. of Org. Compds. with ~) (Book Review) 327

PAINTINGS, Use of activation analysis for determin. of traces in the white lead of ~ (CR) 679 [G.E. *78*, 720 (1966)]

Palladium compds., Structure of metal compds. (CR) 682 [G.E. *78*, 684 (1966)]

*trans*-Effect of ligands in square-planar palladium(II) and platinum(II) complexes (LA) 427

Pancreas elastase, Digestion of ribonuclease A from ox pancreas by ~ (LA) 429

Paracyclophane with intramol. electron donor-acceptor action (LA) 852

Passivity of metals (FP) 185 [G.E. *78*, 253 (1966)]

Penicillinaldehydes (LA) 1051

Pentacyclotetradecane, Isolation of Tetracyclo[6.3.1.$0^{2,6}$.$0^{5,10}$]dodecane and pentacyclo[7.3.1.$1^{4,12}$.$0^{2,7}$.$0^{6,11}$]tetradecane (diamantane) from petroleum (SC) 1045 [G.E. *78*, 1060 (1966)]

Pentadienone, Pentadiene 1,5-halogen-oxygen exchange (CR) 680 [G.E. *78*, 722 (1966)]

Peptide, Synths. of ~-s by means of activated units bound to resins (SC) 310 [G.E. *78*, 303 (1966)]

~ synth. *via* *N*-(1-imidazolylcarbonyl)- and *N*-(1-imidazolylthiocarbonyl)-amino esters (SC) 315 [G.E. *78*, 334 (1966)]

Synth. of monodisperse oligoamides on macromolecular carriers (SC) 417 [G.E. *78*, 390 (1966)]

~ and aza-~ synths. with α-*N*-[1-(1,2,4-triazolyl)carbonyl]amino esters (SC) 593 [G.E. *78*, 602 (1966)]

Synth. of 3,3,3-trifluoroalanine and of 3,3,3-trifluoroalanyl ~-s (SC) 600 [G.E. *78*, 640 (1966)]

Use of the *N*-(5,5-dimethyl-3-oxo-1-cyclohexen-1-yl) protective group in solid phase ~ synthesis (SC) 1041 [G.E. *78*, 1064 (1966)]

Synth. of nylon oligomers by the Merrifield method of ~ synth. on synthetic resins (CR) 610 [G.E. *78*, 611 (1966)]

Cyclic penta-~ cyclo-Gly-Lys-Gly-Lys-Gly, hydrolysis by trypsin (LA) 143

Automatic equipment for the synth. of poly-~-s (LA) 324

New method for the determin. of C-terminal amino acids (LA) 427

Perchlorobutadienyl sulfides, Alkyl ~ and their reacns. (SC) 895 [G.E. *78*, 939 (1966)]

Perchlorodienamines, Synth. and reacns. of ~ (SC) 895 [G.E. *78*, 939 (1966)]

Perhalogenomethyl groups, Prepn. and properties of substances with *N*- or *S*-~ (CR) 848 [G.E. *78*, 829 (1966)]

Peroxide, New initiators for low-temperature polymerizn. (SC) 253 [G.E. *78*, 268 (1966)]

Synth. and decomposition of org. ~-s (CR) 523 [G.E. *78*, 496 (1966)]

Bis(trifluoromethylsulfonyl) ~ and trifluoromethyl trifluoromethanesulfonate (LA) 258

Perrhenic acid, Solid ~ (SC) 315 [G.E. *78*, 336 (1966)]

Pesticide residues, Guide to the analysis of ~ (Book Review) 1052

Pesticides, Analytical Methods for ~, Plant Growth Regulators, and Food Additives (Book Review) 146

Pharmaceutical exhibition, Therapy congress and ~ (CR) 318 [G.E. *78*, 337 (1966)]

Phase equilibria, Studies of ~ as basis for fractionation of polymers (CR) 609 [G.E. *78*, 610 (1966)]

Phase separation in solutions of polydisperse polymers (CR) 611 [G.E. *78*, 612 (1966)]

Phenol dehydrogenation, A new type of ~ (LA) 976

Phenolic compds., Biochemistry of ~ (Book Review) 432

Phenylazoalkanes, Rearr. of ~ to phenylhydrazones (LA) 428

Phenyldiimine (LA) 616

Phenyleneditropylium difluoroborate, Synth. of ~ (LA) 325

Phenyl esters, Lithium hydridotris-(t-butoxy)aluminate (LA) 616

Phenylhydrazones, Reacn. of ~ with dipotassium nitrosobissulfate (SC) 1049 [G.E. *78*, 1101 (1966)]

Phenylhydrazones, Rearr. of phenylazoalkanes to ~ (LA) 428

Phosphabenzene, 2,4,6-Triphenyl-~ (SC) 846 [G E *78*, 907 (1966)]

Phosphacyclohexadiene, 4-Methylene-2,5-~ (SC) 589 [G.E. *78*, 598 (1966)]

Phosphacyclohexadienone, Derivs. of phospha-2,5-cyclohexadien-4-one and 4,4'-diphosphabi-(2,5-cyclohexadienylidene) (SC) 588 [G E. *78*, 598 (1966)]

Phosphates, Proton-catalysed cleavage of enol ~ and phosphonates (SC) 836 [G.E. *78*, 820 (1966)]

Phosphine, Exchange of ring members in cyclopoly-~-s (SC) 316 [G.E. *78*, 307 (1966)]

Cleavage and addn. reacns. of silyl-~-s and silylarsines (SC) 418 [G.E. *78*, 391 (1966)]

Prepn. of carbonyl(chlorodifluoro-~)-nickel complexes (SC) 583 [G.E. *78*, 593 (1966)]

Triphenylcyclotri-~-dipotassium (SC) 587 [G.E. *78*, 597 (1966)]

Binuclear complexes of chromium and molybdenum with ethylenebis(diphenyl-~) as bridging ligand (SC) 606 [G.E. *78*, 646 (1966)]

Hydridopentakis(trifluoro-~)rhenium (SC) 836 [G.E. *78*, 820 (1966)]

Dehalogenation of perchloroketones with triphenyl-~ or trialkyl or triaryl phosphites (SC) 837 [G.E. *78*, 821 (1966)]

Prepn. of α,β-unsatd. ~-s and ~ sulfides (SC) 847 [G.E. *78*, 907 (1966)]

π-Allylnickel bromide under the influence of ~-s and phosphites (SC) 897 [G.E. *78*, 941 (1966)]

Thermal and photochem. formation of phospholenes and tetrahydrophosphorins from cyclo-~-s and dienes (SC) 1038 [G.E. *78*, 1061 (1966)]

Use of thin-layer chromatography and infrared spectroscopy for elucidation of the thermolysis products of triphenyl-~ (CR) 680 [G.E. *78*, 721 (1966)]

Radiation-chem. synth. of dichloro-2-chloroalkyl-~-s (CR) 740 [G.E. *78*, 781 (1966)]

Synth. of 2-aminoethyl-~-s (LA) 426

Nitrosyl compds. of metals of the iron group with bivalent phosphino groups as bridging ligands (LA) 905

Iodotetrakis(trifluorophosphine) cobalt(I) (LA) 977

Phosphine sulfides, Prepn. of α,β-unsatd. phosphines and ~ (SC) 847 [G.E. *78*, 907 (1966)]

Phosphinidene, Exchange of ring members in cyclopolyphosphines (SC) 316 [G.E. *78*, 307 (1966)]

Phosphites, Dehalogenation of perchloroketones with triphenylphosphine or trialkyl or triaryl ~ (SC) 837 [G.E. *78*, 821 (1966)]

π-Allylnickel bromide under the influence of phosphines and ~ (SC) 897 [G.E. *78*, 941 (1966)]

Phospholenes, Thermal and photochem. formation of ~ and tetrahydrophosphorins from cyclophosphines and dienes (SC) 1038 [G.E. *78*, 1061 (1966)]

Phospholipids. Chemistry, Metabolism and Function (Book Review) 148

Phosphonates, Proton-catalysed cleavage of enol phosphates and ~ (SC) 836 [G.E. *78*, 820 (1966)]

Phosphonium salts, Radiation-chemical synth. of ~ and arsonium salts (SC) 317 [G.E. *78*, 331 (1966)]

Inner phosphonium and ammonium dithiophosphonates (SC) 666 [G.E. *78*, 677 (1966)]

Phosphonobromidothioate, Stereospecific synth. and hydrolysis of optically active *O*-ethyl ethyl-~ (SC) 668 [G.E. *78*, 716 (1966)]

Phosphonodithioates. Inner phosphonium and ammonium ~ (SC) 666 [G.E. *78*, 677 (1966)]

Phosphoranes, Reacn. of alkylidene-~ with halogenoacetic esters (SC) 308 [G.E. *78*, 335 (1966)]

Stereochemistry of pentaaryl derivs. of phosphorus, arsenic, and antimony (SC) 725 [G.E. *78*, 749 (1966)]

Bis(2,2′-biphenylylene)phosphorane and the Bis(2,2′-biphenylylene)phosphoranyl radical (SC) 968 [G.E. *78*, 985 (1966)]

Reacns of benzonitrile oxide with alkylidene-~ (SC) 1039 [G.E. *78*, 1059 (1966)]

Nucleophilic ligand exchange by ~ (SC) 968 [G.E. *78*, 1018 (1966)]

Phosphorins, Thermal and photochem. formation of phospholenes and tetrahydro-~ from cyclophosphines and dienes (SC) 1038 [G.E. *78*, 1061 (1966)]

Phosphorus, Crystal structure of violet ~ (SC) 1047 [G.E. *78*, 1101 (1966)]

Phosphorus compds., with silicon and aluminum (FP) 53 [G.E. *78*, 80 (1966)]

Electronic effect of phosphorus in *para*-phosphorus-substd. dimethylanilines (SC) 129 [G.E. *78*, 145 (1966)]

Electronic effect of phosphorus in *para*-phosphorus-substd. anisoles (SC) 731 [G.E. *8*, 777 (1966)]

Hammett constants of substituents containing phosphorus (SC) 595 [G.E. *78*, 605 (1966)]

Existence of ternary compds. of phosphorus with sulfur and hydrogen (SC) 898 [G.E. *78*, 942 (1966)]

Homopolar and heteropolar halogeno esters of phosphorus, arsenic, and antimony (CR) 425 [G.E. *78*, 451 (1966)]

Chemistry of phosphorus, arsenic, and antimony halides (CR) 425 [G.E. *78*, 452 (1966)]

Aluminum-~ with pentacoordinated aluminum (LA) 906

Methoden der organischen Chemie (Methods in Organic Chemistry) Vol. XII, Part 2. Organische Phosphorverbindungen (Organic ~) (Book Review) 262

Topics in Phosphorus Chemistry (Book Review) 264

Phosphorus tribromide, Prepn. of ~ from the elements (SC) 1046 [G.E. *78*, 1102 (1966)]

Phosphorylation, Correlation between ~ and chlorophyll-b dissociation in photosynth. (SC) 522 [G.E. *78*, 550 (1966)]

Photoalkylations (CR) 255 [G.E. *78*, 211 (1966)]

Photochemistry, Excited-state reacns. of 1,2,4,5-tetramethyl-3,5-cyclohexadiene-*cis*-1,2-dicarboxylic anhydride (SC) 311 [G.E. *78*, 305 (1966)]

Photochemical reacns. of benzocyclobutene-1,2-dione (CR) 320 [G.E. *78*, 308 (1966)]

Photo-oxidative cyclizn. of quercetin pentamethyl ether (LA) 145

Photochem. decarboxylation of acyl hypoiodites (LA) 145

New photochemical rearr. of nitroolefins (LA) 684

Interesting photochem. rearrs. of 3-acylcyclopropene derivs. (LA) 745

Photolysis, Low-temperature ~ of cyclopentadiene (SC) 246 [G.E. *78*, 207 (1966)]

Photosynthesis, Correlation between phosphorylation and chlorophyll-b dissociation in ~ (SC) 522 [G.E. *78*, 550 (1966)]

Photosynthetic, reductive carboxylic acid cycle (LA) 853

Phthalocyanine, Reduction of ~ to tri- and tetra-lithium ~ (SC) 972 [G.E. *78*, 1022 (1966)]

Physical Organic Chemistry, Advances in ~ (Book Review) 432

3-Picoline, Sodium-catalysed alkylation of ~ (LA) 426

Picric acid, Diazomethane adds to ~ (LA) 259

Piperidine-*N*-carbonitrile, Crystal structure of carbonyl(piperidine-*N*-carbonitrile)nickel(0) (SC) 1046 [G.E. *78*, 1064 (1966)]

Piperidinoses, Carbohydrates containing nitrogen or sulfur in the "hemiacetal" ring (FP) 495 [G.E. *78*, 501 (1966)]

Plant growth regulators, Analytical Methods for Pesticides, ~, and Food Additives (Book Review) 146

Plants, Hormonal system of ~ (FP) 776 [G.E. *78*, 895 (1966)]

Plastics, Kunststoffbestimmungsmöglichkeiten (Characterization of ~) (Book Review) 619

Platinum, *trans*-Effect of ligands in square-planar palladium(II) and ~-(II) complexes (LA) 427

Polarized light, Spectroscopy with ~ (FP) 478 [G.E. *78*, 457 (1966)]

Polyacids, New methods and results in the study of ~ (FP) 689 [G.E. *78*, 725 (1966)]

Isopolyanions of molybdenum(VI) (SC) 736 [G.E. *78*, 756 (1966)]

Poly-3,4-acrolein, Acid-catalysed degradn. of ~ (CR) 611 [G.E. *78*, 613 (1966)]

Polydimethylsiloxane, Degradn. and cross-linking of ~ in soln. under the influence of $^{60}$Co-γ-radiation (CR) 739 [G.E. *78*, 780 (1966)]

Polymers, Methods for the synth. of uniform ~ (FP) 862 [G.E. *78*, 887 (1966)]

~ containing lactone groups (FP) 994 [G.E. *78*, 1093 (1966)]

Oligonucleotide synth. with a soluble ~ as carrier (SC) 601 [G.E. *78*, 640 (1966)]

Synth. of graft and block co-~ (CR) 322 [G.E. *78*, 309 (1966)]

Determin. of the units in homo- and co-~ of trioxane by pyrolysis gas chromatography (CR) 608 [G.E. *78*, 608 (1966)]

Determin. of mol. heterogeneity of ~ by gel-permeation chromatography (CR) 608 [G.E. *78*, 609 (1966)]

Characterizn. of Baker-Williams fractions by turbidimetric titration (CR) 609 [G.E. *78*, 610 (1966)]

Studies of phase equilibria as basis for fractionation of ~ (CR) 609 [G.E. *78*, 610 (1966)]

Synth. of nylon oligomers by the Merrifield method of peptide synth. on synthetic resins (CR) 610 [G.E. *78*, 611 (1966)]

Chem. homogeneity of binary co-~ (CR) 610 [G.E. *78*, 611 (1966)]

Phase sepn. in solutions of polydisperse ~ (CR) 611 [G.E. *78*, 612 (1966)]

Study of structural changes in bio-~ by chem. relaxation (CR) 612 [G.E. *78*, 613 (1966)]

Prepn. of star-shaped ~ by anionic polymerization (CR) 612 [G.E. *78*, 614 (1966)]

Methods and problems in the study of optically active ~ (CR) 850 [G.E. *78*, 909 (1966)]

Reactive co-~ of styrene as carriers for proteins and enzymes (LA) 905

Encyclopedia of ~ Science and Technology, Plastics, Resins, Rubbers, Fibers (Book Review) 148

Condensation ~ by Interfacial and Soln. Methods (Book Review) 749

Polymerization, New initiators for low-temperature ~ (SC) 253 [G.E. *78*, 268 (1966)]

Kinetics and mol.-wt. distributions in anionic ~-s in weakly solvating solvents (CR) 608 [G.E. *78*, 609 (1966)]

Co-~ in systems with a ~-depolymerizn. equilibrium (CR) 612 [G.E. *78*, 613 (1966)]

Cationic transannular ~ of norbornadiene (LA) 144

Stereochemistry of ~ of methacrylic esters (LA) 683

Polymethinecyanine dyes, Aminolysis of C-C linkages (SC) 1044 [G.E. *78*, 1063 (1966)]

Polymethine dyes, Coupling principles in org. dyes (FP) 984 [G.E. *78*, 1029 (1966)]

Polyolefin, Hexaisopropenylbenzene, an inert ~ (LA) 261

Polypeptides, Automatic equipment for the synth. of ~ (LA) 324

Polyphosphates, Arylammonium ~ from *O,O,S*-trialkyl thiophosphates and aryl amines (SC) 970 [G. E. *78*, 1019 (1966)]

Polypropylenes, Synth. of *meso*-, racemic, and (−)-(4*R*:6*R*)-2,4,6,8-tetramethylnonane (LA) 261

Polyquinazolinediones, New thermostable aromatic ~ (LA) 906

Polyradicals, Poly-4-vinyltriphenylmethyl ~ (SC) 838 [G.E. *78*, 905 (1966)]

Polysaccharides, Significance of enterobacterial mutants for the chem. investigation of their cell-wall ~ (FP) 198 [G.E. *78*, 172 (1966)]

Methods in Carbohydrate Chemistry (Book Review) 327

Poly(vinyl chloride), Studies of the thermal dehydrochlorination of ~ (CR) 607 [G.E. *78*, 608 (1966)]

Poly(vinyl dithioacetals), Investigation of ~ and their use as radiation-protecting substances (CR) 609 [G.E. *78*, 610 (1966)]

Poly(*N*-vinylphenylmaleic imide), Thiols can be selectively and irreversibly removed from aqueous solns. by ~ (LA) 615

Polyvinylpyrrolidone, Soln. properties of ~ (CR) 607 [G.E. *78*, 608 (1966)]

Potassium compds., Potassium, rubidium, and cesium thiomanganates(II) (SC) 134 [G.E. *78*, 113 (1966)]

Association of potassium bromide in the vapor phase (LA) 683

Metastable $K^+$ ions produced by electron impact (LA) 852

Cyclopropyldiphenylmethylpotassium (α-cyclopropylbenzhydrylpotassium) (LA) 905

Preparative organic chemistry, New methods in ~ – Ring closures with carbon monoxide (FP) 435 [G.E. *78*, 532 (1966)]

New methods in ~ – Synths. of thiocarboxamides (FP) 447 [G.E. *78*, 517 (1966)]

New methods in ~ – Synth. of isocyanates and carbodiimides (FP) 704 [G.E. *78*, 761 (1966)]

Prismane, Octamethyltetracyclo-[2.2.0.0$^{2,6}$.0$^{3,5}$]hexane-1,4-dimethanol, a new deriv. of ~ (SC) 519 [G.E. *78*, 494 (1966)]

Propane, 2-Diazo-1,1,1-trifluoro-~ (LA) 745

Propene, Acrylonitrile from ~, ammonia, and atmospheric oxygen (FP) 642 [from Chemie-Ing.-Techn. *38*, 701 (1966)]

New catalyst system for the dimerization of ethylene and ~ (SC) 584 [G.E. *78*, 593 (1966)]

10-Propyl-*trans*-5,9-tridecadienyl acetate, the sexual attractant of *Pectinophora gossypiella* (Saunders) (LA) 978

Protactinium, Chemistry of ~ (FP) 23 [G.E. *78*, 85 (1966)]

Physical Chemistry of ~ (CR) 137 [G.E. *78*, 118 (1966)]

Protease inhibitors, Isolation of ~ (SC) 735 [G.E. *78*, 775 (1966)]

Protective group, Use of the *N*-(5,5-dimethyl-3-oxo-1-cyclohexen-1-yl) ~ in solid phase peptide synthesis (SC) 1041 [G.E. *78*, 1064 (1966)]

Protein, Quaternary structure of ~-s (FP) 231 [G.E. *78*, 217 (1966)]

Progress in the chemistry of casein (FP) 558 [G.E. *78*, 629 (1966)]

Evolutionary aspects of the structure of ~-s (FP) 798 [G.E. *78*, 856 (1966)]

Chemistry and biochemistry of insulin (FP) 807 [G.E. *78*, 871 (1966)]

~ synth. in rat liver chromatin and chromatin fractions (SC) 592 [G.E. *78*, 601 (1966)]

Cysteine in the active center of streptococcal ~-s (LA) 143

New method for the determin. of C-terminal amino acids (LA) 427

Rubredoxin, a new crystalline iron ~ with a redox function (LA) 429

Reactive copolymers of styrene as carriers for ~-s and enzymes (LA) 905

Mammalian ~ Metabolism (Book Review) 146

An enzyme that catalyses thiol-disulfide interactions in ~-s (LA) 976

The ~-s: Compositions, Structure, and Function (Book Review) 327

Proton activity in the 1,2-dithiolium system (SC) 513 [G.E. *78*, 529 (1966)]

Proton positions, Relation between Coulomb potentials and ~ in crystalline hydroxo compds. (SC) 133 [G.E. *78*, 113 (1966)]

Pseudoazulenes, [1]Benzothiopyrano-[4,3-*b*]indoles, a new group of ~ (LA) 976

Pulse radiolysis, Studies of chem. reacns. by ~: Free electrons and free radicals in aq. soln. (CR) 256 [G.E. *78*, 212 (1966)]

Investigations by ~ of reactivity of catalase towards hydrated electrons and free OH radicals (CR) 738 [G.E. *78*, 779 (1966)]

Study of the radical anion $SO_4^-$ by ~ (CR) 738 [G.E. *78*, 779 (1966)]

~ of dimethyl sulfide in aq. soln. (CR) 739 [G.E. *78*, 780 (1966)]

Study of fast chem. reacns. of electrons and radicals by ~ (CR) 975 [G.E. *78*, 988 (1966)]

Purines, Pyrimidines, and Nucleotides, and the Chemistry of Nucleic Acids (Book Review) 264

Purine synths., Novel ~ (SC) 666 [G.E. *78*, 679 (1966)]

Pyran, Synth. of 1'-methylspiro[3*H*-naphtho[2,1-*b*]-pyran-3,2'(1,2-dihydroquinoline)] (SC) 416 [G.E. *78*, 389 (1966)]

Pyrazolines, Aryl-$\Delta^2$-~ as optical brighteners (FP) 699 [G.E. *78*, 769 (1966)]

5-Pyrazolone, Synth. of ~ and 2-substd. ~-s (SC) 665 [G.E. *78*, 676 (1966)]

Pyridine, Synth. of 2,4,6-tricyano-~ 1-oxide from nitroacetonitrile (SC) 846 [G.E. *78*, 906 (1966)]

Pyridinium ions, Reacns. of nucleophiles with ~ (CR) 973 [G.E. *78*, 1025 (1966)]

Pyrimidine-5-carbaldehyde, Synth. of ~ (SC) 671 [G.E. *78*, 717 (1966)]

Pyrimidine-5-carbonitriles, Substd. ~ by Vilsmeier reacn. of malonodinitrile (SC) 1042 [G.E. *78*, 1059 (1966)]

Pyrimidinedithiones, One-step synth. of fused ~ (SC) 309 [G.E. *78*, 333 (1966)]

Pyrimidines, Novel approaches to the synth. of some heterocycles containing nitrogen (FP) 35 [G.E. *78*, 28 (1966)]

New synth. of 5-substd. ~ (SC) 131 [G.E. *78*, 144 (1966)]

Purines, ~, and Nucleotides, and the Chemistry of Nucleic Acids (Book Review) 264

Pyrimidinethiones, One-step syntheses of fused ~ (SC) 308 [G.E. *78*, 332 (1966)]

Pyrolysis, Prepn. of high-melting substances by ~ (CR) 973 [G.E. *78*, 988 (1966)]

Pyrometallurgical reprocessing, Chem. problems in ~ of nuclear fuels (CR) 851 [G.E. *78*, 910 (1966)]

Pyruvate, Primary process in the thiamine pyrophosphate catalysis of the decarboxylation of ~ (LA) 527

Pyrylium salts, Synth. of chlorinated ~ (SC) 418 [G.E. *78*, 448 (1966)]

QUANTUM chemistry, Methods and applications of ~. Part I: Physical and mathematical basis (FP) 823 [G.E. *78*, 789 (1966)]

Quantum Mechanics in Chemistry (Book Review) 748

Quantum-theoretical estimates of chemical reactivities (CR) 974 [G.E. *78*, 1024 (1966)]

Quartz, Effect of chain length on the ability of aliphatic amines to render ~ hydrophobic (CR) 902 [G.E. *78*, 946 (1966)]

Quaternary structure, of proteins (FP) 231 [G.E. *78*, 217 (1966)]

~ and color of crustacyanin (SC) 957 [G.E. *78*, 979 (1966)]

Quercetin, Photo-oxidative cyclization of ~ pentamethyl ether (LA) 145

Quinazolines, Novel approaches to the synth. of some heterocycles containing nitrogen (FP) 35 [G.E. *78*, 28 (1966)]

*p*-Quinodimethanes, Reacns. of α,α-disubstd. benzyl anions with carbonium ions. Synth. of ~ (SC) 517 [G.E. *78*, 545 (1966)]

*o*-Quinol acetates, Chemistry of ~ (CR) 850 [G.E. *78*, 910 (1966)]

Quinol derivs., Synth. of basic heterocyclic alkenes (LA) 259

Quinone, Biradicals, ~-s, and semi-~-s of the imidazole series (SC) 311 [G.E. *78*, 303 (1966)]

Nature of the bonding in amino-~-s (SC) 599 [G.E. *78*, 639 (1966)]

Advances in the chemistry of ~-s (CR) 741 [G.E. *78*, 783 (1966)]

Biochemistry of ~-s (Book Review) 619

Quinoxaline, New synth. of ~ di-*N*-oxides (LA) 260

RACEMATES, Sepn. of enantiomers by gas chromatography (LA) 685

Radiation chemistry, Preparative and kinetic aspects of ~ (CR) 737 [G.E. *78*, 778 (1966)]

Chemische Veränderungen von Stoffen durch energiereiche Strahlung (Chemical Changes of Materials by Energy-rich Radiation) (Book Review) 686

Radiation-protecting substances, Investigation of poly(vinyl dithioacetals) and their use as ~ (CR) 609 [G.E. *78*, 610 (1966)]

Radical anion, Study of the ~ $SO_4^-$ by pulse radiolysis (CR) 738 [G.E. *78*, 779 (1966)]

Two conformers of the 3-nitro-1,2,4,5-tetraisopropylbenzene ~ (LA) 853

Radicals, Applications and limitations of magnetic methods in free-radical chemistry (FP) 6 [G.E. *78*, 98 (1966)]

Bis-(2,5-di-t-butylphenyl)methyl, a non-associating diarylmethyl (SC) 246 [G.E. *78*, 207 (1966)]

Biradicals, quinones, and semiquinones of the imidazole series (SC) 311 [G.E. *78*, 303 (1966)]

Free-radical initiated addn. of bromotrichloromethane to allyl isocyanate (SC) 607 [G.E. *78*, 646 (1966)]

Poly-4-vinyltriphenylmethyl poly-~ (SC) 838 [G.E. *78*, 905 (1966)]

Bis(2,2'-biphenylylene)phosphorane and the bis(2,2'-biphenylylene)phosphoranyl radical (SC) 968 [G.E. *78*, 1018 (1966)]

Studies of chem. reacns. by pulse radiolysis: Free electrons and free ~ in aq. soln. (CR) 256 [G.E. *78*, 212 (1966)]

Radicals, Study of fast chem. reacns. of electrons and ~ by pulse radiolysis (CR) 975 [G.E. *78*, 988 (1966)]

Radiation-chem. formation and optical absorption spectra of org. sulfur ~ in org. glasses at –196 °C (CR) 740 [G.E. *78*, 781 (1966)]

Organosilicon ~ (LA) 260

Radical-pair mechanism of the Wittig rearr. of anionized ethers (LA) 684

Landolt-Börnstein. Zahlenwerte u. Funktionen aus Naturwissenschaften u. Technik (Numerical Values and Functions from Science and Technology) (Book Review) 685

Radiochemistry, Advances in Inorg. Chemistry and ~ (Book Review) 530, 907

Radionuclide Tables, Radionuklid-Tabellen (~) (Book Review) 262

Rare Earth Metals, High-Temperature Compounds of ~ with Nonmetals (Book Review) 620

Chemistry of the Rare-Earth Elements (Book Review) 981

Reaction Mechanisms, Organic ~ (Book Review) 854

Reactivities, Quantum-theoretical estimates of chemical ~ (CR) 974 [G.E. *78*, 1024 (1966)]

Rearrangement of amino[1,2,3]thiadiazolo[5,4-*d*]pyrimidines to mercapto-8-azapurines, and its retrogression (SC) 587 [G.E. *78*, 596 (1966)]

Mechanism of the ~ of flavan derivs. on reduction with $LiAlH_4/AlCl_3$ (SC) 842 [G.E. *78*, 826 (1966)]

New type of ~ in the lignin field (SC) 843 [G.E. *78*, 821 (1966)]

~ of unsatd. compds. to cyclopropane and cyclobutane derivs. (CR) 973 [G.E. *78*, 987 (1966)]

~ of *cis*-1-chloro-2-hexen-4-yne, containing a vinylacetylene system (LA) 684

Radical-pair mechanism of the Wittig ~ of anionized ethers (LA) 684

New photochemical ~ of nitroolefins (LA) 684

Interesting photochem. ~ of 3-acylcyclopropene derivs. (LA) 745

Allylmethyl-cyclopropylmethyl ~ (LA) 904

Redox ion-exchangers, Inorg. ~ (SC) 605 [G.E. *78*, 645 (1966)]

Reduction, Lithium hydridotris-(t-butoxy)aluminate (LA) 616

Kinetic data for irreversible electrochem. ~-s (LA) 617

~ of secondary and tertiary halogen compds. under $S_N1$ conditions (LA) 978

Reductones, New route to ~ (LA) 905

Relaxation processes, Symposium on molecular ~ (CR) 139 [G.E. *78*, 120 (1966)]

Resolution of ethyl *p*-tolyl sulfoxide into optical antipodes (LA) 977

Rhenates, Oxotetrahalogeno-~-(V) (LA) 616

Rhenium compds., Hydridopentakis(trifluorophosphine)rhenium (SC) 836 [G.E. *78*, 820 (1966)]

Ribonuclease, Digestion of ~ A from ox pancreas by pancreas elastase (LA) 429

Ribonucleic acid, see Nucleic acid

Riboside, (5-Amino-4-carbamoylimidazolyl)-5-S-homocysteinyl-~, a new S-amino acid deriv. (LA) 978

Ring closure, New methods in prep. org. chemistry VI — ~ with carbon monoxide (FP) 435 [G.E. *78*, 532 (1966)]

~ reacns. of polychloroazaalkanes (SC) 960 [G.E. *78*, 982 (1966)]

~ reacns. of *N*-(α-chloroalkylidene)-carbamoyl chlorides (SC) 960 [G.E. *78*, 981 (1966)]

New synth. of large rings (SC) 961 [G.E. *78*, 983 (1966)]

Ring enlargement, Synth. of 1,3-cyclotetradecanediones by ~ (SC) 128 [G.E. *78*, 145 (1966)]

Ring Index (Book Review) 907

Rings, Conformational aspects of many-membered ~ (FP) 1000 [G.E. *78*, 1070 (1966)]

RNA, see Nucleic acid

RNA Polymerase, Stimulation of ~ in liver nuclei by cortisol *in vitro* (SC) 723 [G.E. *78*, 748 (1966)]

Mol. properties and mode of action of ~ (CR) 610 [G.E. *78*, 612 (1966)]

Rotational isomerism in vinylcyclopropanes (SC) 251 [G.E. *78*, 266 (1966)]

Rubidium and Caesium (Book Review) 434

Rubidium compds., Potassium, rubidium, and cesium thiomanganates(II) (SC) 134 [G.E. *78*, 113 (1966)]

Rubredoxin, a new crystalline iron protein with a redox function (LA) 429

Ruthenium, Analytical Chemistry of ~ (Book Review) 686

Ruthenocene, Chemistry of the Iron Group Metallocenes: Ferrocene, ~, Osmocene (Book Review) 748

SCHIFF bases, Condensation of alkynylamines with 1,3-dipolar compds., carbonyl compds., and ~ (SC) 585 [G.E. *78*, 594 (1966)]

Semiconducting properties of polymeric ~ (LA) 429

Schistosomiasis, New group of antischistosomal compds. (FP) 857 [G.E. *78*, 850 (1966)]

Schizophrenics, Serotonin synergist in the blood of ~ (LA) 144

Scrambling equilibria and analysis of labile mixtures (FP) 341 [G.E. *78*, 401 (1966)]

Secoanthraquinones, New principle of biosynth. involving ~ (SC) 728 [G.E. *78*, 752 (1966)]

Secondary structure of soluble ribonucleic acids (SC) 591, 847 [G.E. *78*, 601 (1966)]

Selenate, Potassium dioxofluoro-~ (IV) (LA) 260

Selenides, Contributions to the chemistry of the binary compds. of the transition elements (FP) 58 [G.E. *78*, 64 (1966)]

Semiconducting properties of polymeric Schiff bases (LA) 429

Semidiones, Aliphatic ~; application of electron spin resonance to problems of conformation (CR) 974 [G.E. *78*, 989 (1966)]

Semiquinones, Biradicals, quinones, and ~ of the imidazole series (SC) 311 [G.E. *78*, 303 (1966)]

Septanose, Gas-chromatographic detection of monosaccharides in the ~ and open-chain forms (LA) 324

Serotonin synergist in the blood of schizophrenics (LA) 144

Sexual Attractant, 10-Propyl-*trans*-5,9-tridecadienyl acetate (LA) 978

Silane, Organometallic compd. with two-coordinated fluorine atoms (SC) 726 [G.E. *78*, 750 (1966)]

Chlorotris(trimethylsilyl)-~ (LA) 616

Silanolate, Synth. and reacns. of lithium chloromethyldimethyl-~ (SC) 966 [G.E. *78*, 1022 (1966)]

Silicides, Transport reacns. of ~ and borides of transition metals (SC) 839 [G.E. *78*, 822 (1966)]

Silicon, Reacns. of elementary ~ (FP) 462 [G.E. *78*, 475 (1966)]

Silicon, Tetraalkyltetra-~ hexachalcogenides with the adamantane structure (LA) 977

Silicon compds., Compds. of phosphorus with silicon and aluminum (FP) 53 [G.E. *78*, 80 (1966)]

Pentacoordinated silicon complex (LA) 1051

Stereochemistry, Mechanism and Silicon (Book Review) 620

Organo-~ (Book Review) 979

Silicon-nitrogen heterocycles (FP) 760 [G.E. *78*, 803 (1966)]

Silicon radicals, Organo-~ (LA) 260

Siloxane, Isosteres of hexamethyldi-~ and tris(trimethylsilyl)amine (SC) 312 [G.E. *78*, 306 (1966)]

Synth. and reacns. of lithium chloromethyldimethylsilanolate (SC) 966 [G.E. *78*, 1022 (1966)]

Compds. of aluminum with coordination number five (LA) 685

Silver(I) complexes, Structure of metal compds. (CR) 682 [G.E. *78*, 684 (1966)]

Silylamine, Isosteres of hexamethyldisiloxane and tris(trimethylsilyl)amine (SC) 312 [G.E. *78*, 306 (1966)]

Silylarsine, Cleavage and addn. reacns. of silylphosphines and ~-s (SC) 418 [G.E. *78*, 391 (1966)]

Silyl compds., *N*-Trimethylsilyl-substd. sulfurous diamides and monoimides; *N*-alkyl-*N'*-phenyl(sulfur diimides) (SC) 729 [G.E. *78*, 776 (1966)]

~ of hydrazine and hydroxylamine (CR) 614 [G.E. *78*, 648 (1966)]

Silyl ethers, Synth. of substd. vinyl trialkyl-~ (LA) 427

Silyl hypochlorites, Triorgano-~ (SC) 727 [G.E. *78*, 751 (1966)]

Silylphosphines, Cleavage and addn. reacns. of ~ and silylarsines (SC) 418 [G.E. *78*, 391 (1966)]

Silylsilane, Chlorotris(trimethylsilyl)silane (LA) 616

Snake-venom protease, Specificity of ~ (LA) 323

Sodium compds., Sparingly soluble compd. of NaCl and racemic 2,3-bis-(*p*-aminophenyl)butane (LA) 746

Solids, Surface tension of ~ (FP) 299 [G.E. *78*, 321 (1966)]

Functional groups on the surfaces of ~ (FP) 533 [G.E. *78*, 617 (1966)]

Solution reactions, Kinetic relationships between reacns. in the gas phase and in soln. (FP) 78 [G.E. *78*, 73 (1966)]

Solutions, Structure formation and molecular mobility in water and in aq. ~ (FP) 106 [G.E. *78*, 1 (1966)]

Sound waves, Attenuation of ~ in a single crystal of $NH_4Cl$ (LA) 1051

Spectra, Radiation-chem. formation and optical absorption ~ of org. sulfur radicals in org. glasses at −196 °C (CR) 740 [G.E. *78*, 781 (1966)]

Steroid Spektrenatlas (Atlas of Steroid ~) (Book Review) 685

High-Resolution ~ of Inorg. and Related Compds. (Book Review) 687

Interpretation of Org. ~ (Book Review) 1053

Spectroscopy with polarized light (FP) 478 [G.E. *78*, 457 (1966)]

Theoretically and experimentally determined properties of the fundamental indigo chromophore (SC) 598 [G.E. *78*, 638 (1966)]

Eighth European Congress on Molecular ~ (CR) 254 [G.E. *78*, 270 (1966)]

Spectroscopic studies of transition-metal fluorides (CR) 744 [G.E. *78*, 782 (1966)]

Determn. of alcohols in water by the ATR technique (LA) 324

Coincidence Tables for Atomic ~ (Book Review) 328

Spinels, Relations between structural and electrical properties of vanadium ~ (CR) 424 [G.E. *78*, 394 (1966)]

Spiran, Synth. of 1'-methylspiro[3*H*-naphtho[2,1-*b*]-pyran-3,2'(1,2-dihydroquinoline)] (SC) 416 [G.E. *78*, 389 (1966)]

Squaric acid, Synths. and derivs. of ~ ~ (FP) 888 [G.E. *78*, 927 (1966)]

Condensation products of ~ and azulenic hydrocarbons (SC) 893 [G.E. *78*, 937 (1966)]

Condensation products of ~ and tert. aromatic amines (SC) 894 [G.E. *78*, 937 (1966)]

*N*-Stannylketenimines, Prepn. of ~ and ketene ethyl stannyl acetals by 1,4-hydrostannation of conjugated systems (SC) 514 [G.E. *78*, 545 (1966)]

Synths. with ~ and ketene ethyl stannyl acetals (SC) 515 [G.E. *78*, 546 (1966)]

Stereochemistry of polymerizn. of methacrylic esters (LA) 683

Stereospecific synth. and hydrolysis of optically active *O*-ethyl ethylphosphonobromidothioate (SC) 668 [G.E. *78*, 716 (1966)]

Steroids, Mass spectra of weakly excited molecules (SC) 517 [G.E. *78*, 494 (1966)]

Synthetic ~ with moulting hormone activity (SC) 673 [G.E. *78*, 680 (1966)]

New prepn. of nitro-~ (LA) 144

Biosynth. of ~, Terpenes, and Acetogenins (Book Review) 148

Steroid Spektrenatlas (Atlas of ~ spectra) (Book Review) 685

Stibine, Determin. of traces of arsine in inert-gas mixtures in presence of a large excess of ~ (CR) 677 [G.E. *78*, 718 (1966)]

Streak samples, Importance of ultramicroanalysis of ~ for trace analysis (CR) 677 [G.E. *78*, 718 (1966)]

Strontium compds., Germyl compds. of strontium, barium, and zinc (SC) 522 [G.E. *78*, 549 (1966)]

Structure analysis, Automation of ~, Part II: Automation of the evaluation (FP) 267, 511 [G.E. *78*, 289 (1966)]

Styrene, Reacn. of benzyne with ~ (LA) 684

Reactive copolymers of ~ as carriers for proteins and enzymes (LA) 905

Submicro Methods of Org. Analysis (Book Review) 1053

Succinyl-coenzyme A, Succinyl phosphate as intermediate in the biosynth. of ~ (LA) 259

Succinyl phosphate as intermediate in the biosynth. of succinyl-coenzyme A (LA) 259

Sucrose, New synth. of surface-active urethanes of ~ (CR) 900 [G.E. *78*, 944 (1966)]

Sugar mercaptals, Synth. from ~ (CR) 424 [G.E. *78*, 394 (1966)]

Sulfamic acid, Prepn. of hydrogen sulfate esters by reacn. of higher aliphatic alcohols with ~ (CR) 902 [G.E. *78*, 946 (1966)]

Sulfane oxide, Prepn. of di-2-naphthyltrisulfane 2-oxide (SC) 673 [G.E. *78*, 717 (1966)]

Sulfate, Study of the radical anion $SO_4^-$ by pulse radiolysis (CR) 738 [G.E. *78*, 779 (1966)]

Sulfate esters, Prepn. of hydrogen ~ by reacn. of higher aliphatic alcohols with sulfamic acid (CR) 902 [G.E. *78*, 946 (1966)]

Sulfenes (CR) 1050 [G.E. *78*, 1066 (1966)]

Sulfene stable at −40 °C (SC) 594 [G.E. *78*, 604 (1966)]

Sulfides, Contributions to the chemistry of the binary compds. of the transition elements (FP) 58 [G.E. *78*, 64 (1966)]

Alkyl perchlorobutadienyl ~ and their reacns. (SC) 895 [G.E. *78*, 939 (1966)]

Sulfonates, Alkylarene-~ from petroleum hydrocarbons (CR) 901 [G.E. *78*, 945 (1966)]

Synth. of ~ by cleavage of ethers with sulfonic acids (LA) 325

Sulfones, Oxidn. of sulfoxides with hydroperoxides (SC) 893 [G.E. *78*, 937 (1966)]

Sulfonium salts, Reacn. of substd. vinyl-~ with CH-acidic compds., new route to polysubstd. cyclopropanes (SC) 596 [G.E. *78*, 606 (1966)]

Sulfonium Methanide, (Dimethylsulfonio)(phenylsulfonyl)(vinylsulfonyl)-methanide (SC) 971 [G.E. *78*, 1019 (1966)]

Sulfonyl-carbamoyl azides, Acyl- and ~ (SC) 314 [G.E. *78*, 333 (1966)]

Sulfonyl chlorides, Reacn. of ~ with alkylaluminum compds. (CR) 903 [G.E. *78*, 947 (1966)]

Sulfonylimines, Cycloaddn. of azosulfones and ~ (SC) 416 [G.E. *78*, 389 (1966)]

Sulfonylureas, Synth. of isocyanates by fragmentation of ~ (SC) 724 [G.E. *78*, 746 (1966)]

Sulfoxide, Resoln. of ethyl *p*-tolyl ~ into optical antipodes (LA) 977

Sulfoxides, Oxidn. of ~ with hydroperoxides (SC) 893 [G.E. *78*, 937 (1966)]

Sulfur, Cyclododeca-~, $S_{12}$ (SC) 964 [G.E. *78*, 1020 (1966)]

Crystal structure of cyclododeca-~ $S_{12}$ (SC) 965 [G.E. *78*, 1020 (1966)]

Investigation of cyclododeca-~, $S_{12}$, by mass spectrometry (SC) 965 [G.E. *78*, 1021 (1966)]

Types of bonding of ~ in vulcanization processes (CR) 848 [G.E. *78*, 828 (1966)]

Carborane bis(thioethers), the first compds. containing carborane-~ bonds (LA) 976

Sulfur amides, *N*-Trimethylsilyl-substd. sulfurous diamides and monoimides; *N*-alkyl-*N'*-phenyl(sulfur diimides) (SC) 729 [G.E. *78*, 776 (1966)]

Sulfur compds., Existence of ternary compds. of phosphorus with sulfur and hydrogen (SC) 898 [G.E. *78*, 942 (1966)]

Cyclic boron-~ (LA) 616

Sulfur diimides, 1,5-Cyclization of vinyl-substd. ~ (SC) 1042 [G.E. *78*, 1061 (1966)]

Sulfur metabolism, Dynamics of ~ and the utilization of sulfur in the animal organism (CR) 1050 [G.E. *78*, 1066 (1966)]

Sulfur nitride, Ring expansion of the thiotrithiazyl cation (LA) 261

Sulfur radicals, Radiation-chem. formation and optical absorption spectra of org. ~ in org. glasses at −196 °C (CR) 740 [G.E. *78*, 781 (1966)]

Sulfurous amides, *N*-Trimethylsilyl-substd. sulfurous diamides and monoimides; *N*-alkyl-*N'*-phenyl(sulfur diimides) (SC) 729 [G.E. *78*, 776 (1966)]

Sultones, Alkylation of amine oxides with ~ (SC) 419 [G.E. *78*, 391 (1966)]

Surfaces, Functional groups on the ~ of solids (FP) 533 [G.E. *78*, 617 (1966)]

Surface-active compds., see Detergents

Surface tension of solids (FP) 299 [G.E. *78*, 321 (1966)]

Symmetry in Chemistry (Book Review) 748

Synthetic Methods of Chemistry (Book Review) 529

TANTALUM compds., Contributions to the chemistry of the binary compds. of the transition elements (FP) 58 [G.E. *78*, 64 (1966)]

Technical Chemistry, Ullmanns Encyklopädie der technischen Chemie (Ullman's Encyclopedia of ~) (Book Review) 618

Technical Organic Chemistry, Grundriß der Technischen Organischen Chemie (Fundamentals of ~) (Book Review) 619

Tellurides, Contributions to the chemistry of the binary compds. of the transition elements (FP) 58 [G.E. *78*, 64 (1966)]

Tellurophene, Synth. of ~ and its 2,5-disubstd. derivs. (SC) 896 [G.E. *78*, 940 (1966)]

Terpenes, Biosynthesis of Steroids, ~, and Acetogenins (Book Review) 148

Tetracyanooxirane, Synth. of ~ (LA) 324

Tetracyclododecane, Isolation of Tetracyclo[6.3.1.$0^{2,6}$.$0^{5,10}$]dodecane and pentacyclo[7.3.1.$1^{4,12}$.$0^{2,7}$.$0^{6,11}$]tetradecane (diamantane) from petroleum (SC) 1045 [G.E. *78*, 1060 (1966)]

Tetracyclohexane, Octamethyltetracyclo-[2.2.0.$0^{2,6}$.$0^{3,5}$]hexane-1,4-dimethanol, a new deriv. of prismane (SC) 519 [G.E. *78*, 494 (1966)]

Tetrahydrofuran, High yields of *cis*-2,5-bis(hydroxymethyl) −~-s by permanganate oxidn. of 1,5-dienes (LA) 325

An adduct of maleic anhydride and ~ (LA) 976

Tetrahydroquinazolines, Novel approaches to the synth. of some heterocycles containing nitrogen (FP) 35 [G.E. *78*, 28 (1966)]

Tetrakis(dimethylamino)ethylene, New synth. of ~ (SC) 972 [G.E. *78*, 984 (1966)]

Tetramethylnonane, Synth. of *meso*-, racemic, and (−)-(4*R*:6*R*)-2,4,6,8-~ (LA) 261

Tetramethylzirconium, Prepn. of ~ (SC) 516 [G.E. *78*, 495 (1966)]

Tetranitratoborate, Synth. of tetramethylammonium ~ (LA) 746

1,3,6,8-Tetraoxacyclodecane, Reacn. of *cis*- and *trans*-1,2-cyclohexanediols with dihalogenomethanes (LA) 143

Tetrayne, Naturally occurring ~ and ~-tetraol (LA) 526

Tetrazene, "Thermolysis" of 3-ethyl-2-tetrazobenzothiazoline (SC) 132 [G.E. *78*, 146 (1966)]

Crystal structure of 1,4-bis-(3-ethyl-1,2-dihydrobenzothiazol-2-ylidene)-~ (SC) 133 [G.E. *78*, 147 (1966)]

Tetrazobenzothiazoline, "Thermolysis" of 3-ethyl-2-~ (SC) 132 [G.E. *78*, 146 (1966)]

Tetrazoles, *C*-Azido-*N*-sulfonylformamidines and their rearr. to 5-(*N*-sulfonylamino)-~ (SC) 520 [G.E. *78*, 548 (1966)]

Tetrazolium salts, Use of ~ in the early diagnosis of cardiac infarcts (CR) 424 [G.E. *78*, 394 (1966)]

Nature of ~ and formazans (CR) 681 [G.E. *78*, 683 (1966)]

Theophyllines, 8-(Alkylthio)thio-~, a new group of hypnotica (LA) 683

Therapy congress and pharmaceutical exhibition (CR) 318 [G.E. *78*, 337 (1966)]

Thiadiazepine, Synth. of a dipyrido-~ deriv. (SC) 605 [G.E. *78*, 644 (1966)]

1,2,5-Thiadiazole, New synth. of ~ and some of its derivs (SC) 514 [G.E. *78*, 493 (1966)]

New general synth. of ~-s (LA) 745

1,2,4-Thiadiazolidine-3,5-diones, Reacns. of *N*-alkyl- and *N*-aryl-*S*-chloroisothiocarbamoyl chlorides with isocyanates; synth. of ~ (SC) 672 [G.E. *78*, 681 (1966)]

1,3,4-Thiadiazoles, Formation of ~ and 1,4,2-oxathiazoles from thioketenes (SC) 970 [G.E. *78*, 1023 (1966)]

Thiadiazolopyrimidines, Rearr. of amino-[1,2,3]thiadiazolo[5,4-*d*]pyrimidines to mercapto-8-azapurines, and its retrogression (SC) 587 [G.E. *78*, 596 (1966)]

Thiamine, Primary process in the ~ pyrophosphate catalysis of the decarboxylation of pyruvate (LA) 527

Thiazine, Diene synths. of heterocyclic compds. (CR) 614 [G.E. *78*, 648 (1966)]

Thiazoline, "Thermolysis" of 3-ethyl-2-tetrazobenzo-~ (SC) 132 [G.E. *78*, 146 (1966)]

Crystal structure of 1,4-bis-(3-ethyl-1,2-dihydrobenzothiazol-2-ylidene)tetrazene (SC) 133 [G.E. *78*, 147 (1966)]

Synth. of 2-oxazoline-2-amines and 2-~-2-amines by reacn. of aziridinium tetrafluoroborate with isocyanates and isothiocyanates (SC) 667 [G.E. *78*, 677 (1966)]

Synth. of 2-oxazolines by reacn. of epoxides with 2-~-s (SC) 894 [G.E. *78*, 938 (1966)]

Thiazolium halides, Elimination of hydrogen halide from benzo- and naphtho-~ (SC) 126 [G.E. *78*, 115 (1966)]

Thiazolo derivs., Synth. of novel heterocyclic ~ (SC) 605 [G.E. *78*, 645 (1966)]

Thin-layer chromatography, Direct UV-spectrophotometric evaluation of thin-layer chromatograms (CR) 678 [G.E. *78*, 719 (1966)]

Use of ~ and infrared spectroscopy for elucidation of the thermolysis products of triphenylphosphine (CR) 680 [G.E. *78*, 721 (1966)]

Thio-acids, Desulfuration of ~ with dimethyl sulfoxide (SC) 419 [G.E. *78*, 393 (1966)]

Thioaldoses, Carbohydrates containing nitrogen or sulfur in the "hemiacetal" ring (FP) 495 [G.E. *78*, 501 (1966)]

*N*-Thioaniline, $C_6H_5N{=}S$, as intermediate in the decomposition of *N*,*N*-thiodianiline (SC) 1048 [G.E. *78*, 1057 (1966)]

Thiocarboxamides, New methods in prep. org. chemistry VI – Synths. of ~ (FP) 447 [G.E. *78*, 517 (1966)]

Thiodan, Metabolism of ~ in insects (SC) 730 [G.E. *78*, 775 (1966)]

Thioethers, Synth. of 2-alkylthio- and 2-arylthio-1,3-butadienes (SC) 668 [G.E. *78*, 678 (1966)]

Carborane bis(thioethers), the first compds. containing carborane-sulfur bonds (LA) 976

Thioketenes, Formation of 1,3,4-thiadiazoles and 1,4,2-oxathiazoles from ~ (SC) 970 [G.E. *78*, 1023 (1966)]

Thiol-disulfide interactions, An enzyme that catalyses ~ in proteins (LA) 976

Thiols can be selectively and irreversibly removed from aqueous solns. by poly-(*N*-vinylphenylmaleic imide) (LA) 615

Thiomanganates, Potassium, rubidium, and cesium ~-(II) (SC) 134 [G.E. *78*, 113 (1966)]

Thiophosphates, Arylammonium polyphosphates from *O*,*O*,*S*-trialkyl ~ and arylamines (SC) 970 [G.E. *78*, 1019 (1966)]

Amidothio-, fluoroamidothio-, and fluoro-~ (CR) 256 [G.E. *78*, 272 (1966)]

Thiotrithiazyl cation, Ring expansion of the ~ (LA) 261

Thioureas, *S*-Amination of ~ and thiourethanes (SC) 674 [G.E. *78*, 672 (1966)]

Thiourethanes, *S*-Amination of thioureas and ~ (SC) 674 [G.E. *78*, 672 (1966)]

Thymidine, 5'-*O*-Methyl-~ (SC) 735 [G.E. *78*, 752 (1966)]

Tin, Photometric determn. of small amounts of ~ with bromopyrogallol red (CR) 680 [G.E. *78*, 721 (1966)]

Titanates, Hexahalogeno-~-(III) (LA) 527

Titanium, The new nuclide $^{52}$Ti (LA) 1051

Titanium compds., Di(cyclooctatetraene)-titanium and tri(cyclooctatetraene)dititanium (SC) 898 [G.E. *78*, 942 (1966)]

Crystal structure of tri(cyclooctatetraene)dititanium (SC) 899 [G.E. *78*, 943 (1966)]

Existence of the $VO_2^+$, $TiO^{2+}$, and $ZrO^{2+}$ cations (SC) 1041 [G.E. *78*, 1065 (1966)]

Organic Chemistry of Titanium (Book Review) 908

Titration, Apparatus for ~-s in liq. ammonia (FP) 554 [from Chemie-Ing.-Techn. *38*, 576 (1966)]

Volume change as indicator for reacns. in soln. (SC) 310 [G.E. *78*, 304 (1966)]

Modern methods for electrical indication of ~-s (CR) 524 [G.E. *78*, 524 (1966)]

Interpretation of potentiometric and photometric ~ curves obtained on recording apparatus (CR) 677 [G.E. *78*, 718 (1966)]

Novel pulse process with digital readout for automatic ~ (CR) 679 [G.E. *78*, 720 (1966)]

Die komplexometrische Titration (Complexometric ~) (Book Review) 430

~ in Non-aq. Solvents (Book Review) 750

pH und potentiometrische Titrierungen (pH and Potentiometric ~-s) (Book Review) 908

Toluenesulfonyl perchlorate, Solns. of ~ (LA) 527

Trace analysis, Importance of ultramicroanalysis of streak samples for ~ (CR) 677 [G.E. *78*, 718 (1966)]

Analyt. use of infrared spectroscopy with gratings. Quantitative analysis of gas traces (CR) 678 [G.E. *78*, 719 (1966)]

Use of activation analysis for determin. of traces in the white lead of paintings (CR) 679 [G.E. *78*, 720 (1966)]

Spectrochem. determin. of impurities in very pure aluminum (CR) 679 [G.E. *78*, 720 (1966)]

Handbuch der Spurenanalyse (Handbook of ~) (Book Review) 145

Transannular addition of carbon monoxide to cycloocta-1,5-diene (LA) 616

Transition elements, Contributions to the chemistry of the binary compds. of the ~ (FP) 58 [G.E. *78*, 64 (1966)]

Transition metal oxocations, Recent developments in the chemistry of ~ (FP) 712 [G.E. *78*, 736 (1966)]

Transport reacns. of silicides and borides of transition metals (SC) 839 [G.E. *78*, 822 (1966)]

8,9,13-Triacetoxydocosanoic acid (LA) 260

Triazidomethylium hexachloroantimonate (SC) 841 [G.E. *78*, 825 (1966)]

Trichloromethanesulfinyl isocyanate (SC) 1047 [G.E. *78*, 1100 (1966)]

Tri(cyclopentadienyl)americium(III) (SC) 134 [G.E. *78*, 112 (1966)]

Triazanes, Amination of hydrazines to yield ~ (SC) 578 [G.E. *78*, 587 (1966)]

Triazoles, New benzimidazole cleavage with subsequent ring closure (SC) 835 [G.E. *78*, 904 (1966)]

Tricarboxylic acids, Addn. of trialkyl methanetricarboxylates to 1-alkenes initiated by peroxides (SC) 586 [G.E. *78*, 595 (1966)]

2,4,6-Tricyanopyridine 1-oxide, Synth. of ~ from nitroacetonitrile (SC) 846 [G.E. *78*, 906 (1966)]

Tricyclodecatriene, Tricyclo[4.3.1.$0^{1,6}$]-deca-2,4,7-triene, an acidic alicyclic hydrocarbon (SC) 604 [G.E. *78*, 643 (1966)]

Tri(cyclooctatetraene)dititanium, Di(cyclooctatetraene)titanium and ~ (SC) 898 [G.E. *78*, 942 (1966)]

Crystal structure of ~ (SC) 899 [G.E. *78*, 943 (1966)]

Trifluoroalanine, Synth. of 3,3,3-~ and of 3,3,3-trifluoroalanyl peptides (SC) 600 [G.E. *78*, 640 (1966)]

Trifluoromethanesulfonic acid, Bis(trifluoromethylsulfonyl) peroxide and trifluoromethyl trifluoromethanesulfonate (LA) 258

Trifluorophosphine complexes, Cyclopentadienylbis(trifluorophosphine)-cobalt (SC) 247 [G.E. *78*, 208 (1966)]

2,4,6-Triisopropylbenzenesulfonyl chloride to effect internucleotide linkages (LA) 615

2,4,6-Trioxaadamantane, Synth. of 6-deoxy-D-*gluco*-dialdoheptose and ring closure to 8(a),10(a)-dihydroxy-~ (SC) 665 [G.E. *78*, 673 (1966)]

Trioxane, Determn. of the units in homo- and co-polymers of ~ by pyrolysis gas chromatography (CR) 608 [G.E. *78*, 608 (1966)]

Triphenylcyclotriphosphinedipotassium (SC) 587 [G.E. *78*, 597 (1966)]

Tris(dimethylamino)methane, Synth. and reacns. of ~ (SC) 132 [G.E. *78*, 147 (1966)]

Trisulfane 2-oxide, Prepn. of di-2-naphthyl-~ (SC) 673 [G.E. *78*, 717 (1966)]

Trithiadiborolanes, New method for preparing 1,3,4-~ and 1,3,5-trithiatriboranes (SC) 597 [G.E. *78*, 607 (1966)]

Trithiatriboranes, New method for preparing 1,3,4-trithiadiborolanes and 1,3,5-~ (SC) 597 [G.E. *78*, 607 (1966)]

Trithiocarbonic acid, Reacns. of ~ with malonyl chloride (SC) 250 [G.E. *78*, 210 (1966)]

Trivial Names, Trivialnamenkartei (Card Index of Organic ~) (Book Review) 326

Tropolone, New ~ synth. using dichloroketene (LA) 324

Trypsin, Cyclic pentapeptide cyclo-Gly-Lys-Gly-Lys-Gly, hydrolysis by ~ (LA) 143

Tungsten, Oxidn. of ~ (LA) 142

Chemisorption of nitrogen on various surfaces of ~ single crystals (LA) 142

Tungsten compds., Contributions to the chemistry of the binary compds. of the transition elements (FP) 58 [G.E. *78*, 64 (1966)]

Reacn. of tungsten hexacarbonyl with azide (SC) 253 [G.E. *78*, 267 (1966)]

Prepn. and properties of tungsten dioxide diiodide (SC) 421 [G.E. *78*, 451 (1966)]

(π-Cyclopentadienyl) (π-tetraphenylcyclobutadiene)-molybdenum and -tungsten carbonyl halides (LA) 259

Tungsten(V) oxide trichloride (LA) 851

Turbidimetric titration, Characterization of Baker-Williams fractions by ~ (CR) 609 [G.E. *78*, 610 (1966)]

URACIL, Synth. of *C*-methyl branched ~ nucleosides (SC) 737 [G.E. *78*, 774 (1966)]

γ-Radiolysis of 5-bromo-~ in oxygen-containing aq. solns. (CR) 740 [G.E. *78*, 780 (1966)]

Uranium nitrides, Prepn. and X-ray investigation of higher ~ (SC) 726 [G.E. *78*, 750 (1966)]

Urethanes, New synth. of surface-active ~ of sucrose (CR) 900 [G.E. *78*, 944 (1966)]

VALENCE Theory (Book Review) 908

Vanadium chlorimide trichloride, Prepn. and crystallographic data of ~ (SC) 417 [G.E. *78*, 450 (1966)]

Vanadium compds., Existence of the $VO_2^+$, $TiO^{2+}$, and $ZrO^{2+}$ cations (SC) 1041 [G.E. *78*, 1065 (1966)]

Vanadium spinels, Relations between structural and electrical properties of ~ (CR) 424 [G.E. *78*, 394 (1966)]

Verrucarine, Recent results of antibiotics research (CR) 523 [G.E. *78*, 496 (1966)]

Vilsmeier reacn., Substd. pyrimidine-5-carbonitriles by ~ of malonodinitrile (SC) 1042 [G.E. *78*, 1059 (1966)]

Vinyl compds., New prepn. of oligomers (LA) 978

3-Vinylcyclobutene, Photochem. formation of bicyclo[3.1.0]hex-2-ene and ~ (LA) 904

Vinylcyclopropane, Rotational isomerism in ~-s (SC) 251 [G.E. *78*, 266 (1966)]

Conformations of *trans*-1,2-dicyclopropylethylene and ~ (SC) 512 [G.E. *78*, 544 (1966)]

Vinylsulfonium salts, Reacn. of substd. ~ with CH-acidic compds., new route to polysubstd. cyclopropanes (SC) 596 [G.E. *78*, 606 (1966)]

Vinyl trialkylsilyl ethers, Synth. of substd. ~ (LA) 427

Vitamins, Struktur und Synthese von Vitaminen (Structure and Synth. of ~) (Book Review) 326

Chemistry of the ~ (Book Review) 749

Vitamine, Chemie und Biochemie (Vitamins, Chemistry and Biochemistry) (Book Review) 1052

von Auwers-Skita rule (LA) 325

Vulcanization, Types of bonding of sulfur in ~ processes (CR) 848 [G.E. *78*, 828 (1966)]

WATER, Structure formation and molecular mobility in ~ and in aq. solns. (FP) 106 [G.E. *78*, 1 (1966)]

Water beetle, Vertebrate hormone as defensive substance of the ~ (*Dytiscus marginalis*) (SC) 421 [G.E. *78*, 392 (1966)]

White lead, Use of activation analysis for determin. of traces in the ~ of paintings (CR) 679 [G.E. *78*, 720 (1966)]

Willgerodt-Kindler reacn., Synthesis of 4) methylosthenolic acid by the ~ (SC-125 [G.E. *78*, 114 (1966)]

Wittig reacn., Substituted α-benzylidene-γ-butyrolactones (LA) 259

~ with α,β-unsatd. ketones can involve formation of a three-membered ring (LA) 617

Wittig rearr., Radical-pair mechanism of the ~ of anionized ethers (LA) 684

XENON dichloride (LA) 744

X-Ray analysis, Automation of structure analysis, Part II: automation of the evaluation (FP) 267, 511 [G.E. *78*, 289 (1966)]

ZEATIN, Synth. of ~ (LA) 746

Ziegler-Natta catalysts, Activity changes of ~ by prepolymerizn. of small amounts of α-olefins (CR) 611 [G.E. *78*, 612 (1966)]

Zinc compds., Germyl compds of strontium, barium, and zinc (SC) 522 [G.E. *78*, 549 (1966)]

Zirconium compds., Sepn. of zirconium and hafnium by liquid-liquid partition of their thiocyanates (FP) 15 [G.E. *78*, 19 (1966)]

Binary compds. of the transition elements (FP) 58 [G.E. *78*, 64 (1966)]

Prepn. of tetramethylzirconium (SC) 516 [G.E. *78*, 495 (1966)]

Chloro(dicyclopentadienyl)ethylzirconium and its reacn. with triethylaluminum (SC) 962 [G.E. *78*, 986 (1966)]

Existence of the $VO_2^+$, $TiO^{2+}$, and $ZrO^{2+}$ cations (SC) 1041 [G.E. *78*, 1065 (1966)].
