have also been employed in the quantitative study of exchange reactions, and microwave spectroscopy holds some promise. The first two of these methods can be used on relatively labile systems since the interacting molecules are rapidly separated from each other in the initial stages of the analysis. Another promising technique for labile systems would be column or thin-film sorption chromatography from a liquid medium at very low temperatures. However, high-resolution NMR spectroscopy appears to be the most generally applicable method for the quantitative study of scrambling reactions between complicated molecules because the relative areas of the peaks are exactly proportional to the relative amounts of the corresponding active nuclei, and because many molecules may be seen "in depth".

Further, one can generally determine within about a day whether or not a given system may adequately be studied by this method, compared to the weeks or months needed to optimize the conditions for chromatographic analyses.

## 2. Theoretical Treatment of Exchange Equilibria

### a) Exchange Equilibria Involving Simple Compounds

Of all equilibrium reactions in a single phase, the scrambling of two or more substituents about a given kind of central atom or non-exchangeable moiety is the simplest type, since this process is merely a rearrangement of covalent bonds – with the total number of σ-bonds of any type remaining constant. Many such reactions have essentially zero enthalpies, being fully entropy-controlled [14,15]. This behavior occurs to the extent to which Pauling-type bond energies are additive [16]. The equilibrium constants of such entropy-controlled scrambling reactions may be calculated from the statistics of random sorting of the substituents. If there are ν sites for exchange on the central atom or moiety, Q, on which two kinds of monofunctional substituents, T and Z, are being exchanged, there are (ν + 1) possible compounds, $QZ_iT_{\nu-i}$, where i = 1, 2, ... (ν + 1), and (ν − 1) independent equilibrium constants of the form:

$$K_i = [QZ_{i+1}T_{\nu-i-1}][QZ_{i-1}T_{\nu-i+1}]/[QZ_iT_{\nu-i}]^2 \qquad (a)$$

where i = 1, 2 ... (ν − 1). Consider, for example, the system $OPCl_3/OPBr_3$ for which Q = (OP), ν = 3, Z = Br, T = Cl and for which the (ν − 1) = 2 independent equilibrium constants are:

$$K_1 = [OPCl_3][OPClBr_2]/[OPCl_2Br]^2 \qquad (b)$$

$$K_2 = [OPCl_2Br][OPBr_3]/[OPClBr_2]^2 \qquad (c)$$

By quantitative $^{31}P$-NMR spectroscopy [15] the values $K_1 = 0.41$ and $K_2 = 0.34$ were found, both of which are not far from the value $K_1 = K_2 = 0.33$ calculated for a random distribution of substituents. Deviations from randomness are also small for the exchange of Br and Cl on other central atoms or moieties, such as carbon [17] ($CCl_4/CBr_4$) and tin [18] ($SnCl_4/SnBr_4$). On the other hand, the scrambling of chlorine atoms with dimethylamino groups on any central atom or moiety [7,10,11] is found to be highly non-random, *i.e.* to have a sizable enthalpy. For example, the enthalpies of formation of $PCl_2[N(CH_3)_2]$ and $PCl[N(CH_3)_2]_2$ from $PCl_3$ and $P[N(CH_3)_2]_3$ are +4.8 and +4.0 kcal/mole, respectively [19], corresponding to *ca.* $10^{-8}$ for the equilibrium constants of the form of Eqs. (b) and (c). For scrambling of substituents on the transition metals [20], there may also be sizable contributions to the enthalpy due to association (an effective increase in ν by use of d-orbitals in the σ-bond structure), since solution non-idealities are reflected in the equilibrium constants.

Simple molecules which consist of exchangeable monofunctional substituents bonded to a central atom or moiety are called *neso*-compounds [*] and their scrambling equilibria are noteworthy for two reasons:

a) When the molecules form approximately ideal solutions, the deviations from randomness of the equilibria offer a good means of characterizing the interactions between two substituents bonded to the same atom or moiety.

b) The findings may be extrapolated to exchanges of parts between more complicated molecules (see next paragraph), since the pertinent thermodynamics generally are little affected by structural variations more than one atom removed from the site of the exchange.

### b) Exchange of Parts Between Complicated Molecules

For inorganic molecules in which the molecular backbone consists of two kinds of atoms alternating with each other ("heteropolymers" [22], including branched and crosslinked molecules) as well as for those based on chains of like atoms ("catenation" or "homopolymers" [22]), any exchange process may be simulated by a series of steps involving the splitting of two molecules each into two pieces or of one molecule into three pieces and interchanging the molecular portions. Chemically meaningful (*i.e.* nontrivial) exchanges can be represented formally by the interchange of a monofunctional substituent for a larger piece of a molecule, the interchange of two pieces differing in size or in atomic arrangement, or ring scission involving affixing the cut ends of another molecule to the cut ends of the cyclic structure. Although it is possible to set up equilibrium constants for interactions among the many molecules of various sizes [straight and branched chains and cyclic molecules (including rings with chain segments on them and perhaps connecting them, fused-ring structures, *etc.*)] which may be in equilibrium with respect to exchange of parts, it is better to simplify the problem so

[*] A term taken from silicate chemistry [21] meaning a small "island" structure (νῆσος = island). In the sense in which *neso* has been employed in equilibrium chemistry, it stands for the smallest member of a family of compounds; *i.e.* methane is the *neso*-compound of the paraffinic hydrocarbons and orthophosphoric acid is the *neso*-compound of the polyphosphoric acids.

[22] *D. N. Hunter*: Inorganic Polymers. Wiley, New York 1963.

that only the essentials of the large set of resulting equilibrium constants need be considered. Such simplification has recently been treated with the aid of stochastic graph theory [23].

In this treatment it is proved that the host of equilibrium constants involving the many possible interchanges among all of the molecules may be replaced by a much smaller number involving molecular segments (which may be large and overlapping). As in the simple scrambling of the monofunctional substituents of *neso*-compounds (*e.g.* Cl *vs.* Br in mixtures of $CCl_4$ and $CBr_4$), one can compare experimental equilibrium data pertaining to the ring-free molecular segments with theoretical values calculated on the basis of statistical randomness.

A useful concept for discussing deviations from randomness is the reorganizational heat order [23], $\rho$. This

### c) Generalized Treatment of Exchanging Molecules [23]

Let us now consider atoms or moieties Q having $\nu$ sites for exchangeable substituents and fill these sites with either bifunctional (Z) or monofunctional (T) substituents. This model corresponds to a "heteropolymer" [22] and can be applied to the "homopolmers" by letting Z stand for a bond between a pair of Q atoms. By scrambling the Z and T substituents around the Q's, we obtain a set of $(\nu + 1)$ "building units" (shown here by non-stoichiometric formulae), ranging from the $QT_\nu$ *neso*-molecule through the end group $QZT_{\nu-1}$, the middle $QZ_2T_{\nu-2}$, the threeway branched $QZ_3T_{\nu-3}$, to the most branched building unit $QZ_\nu$. Examples of a molecule and its constituent building units are given for $\nu = 4$ and $\nu = 6$ in Fig. 5.

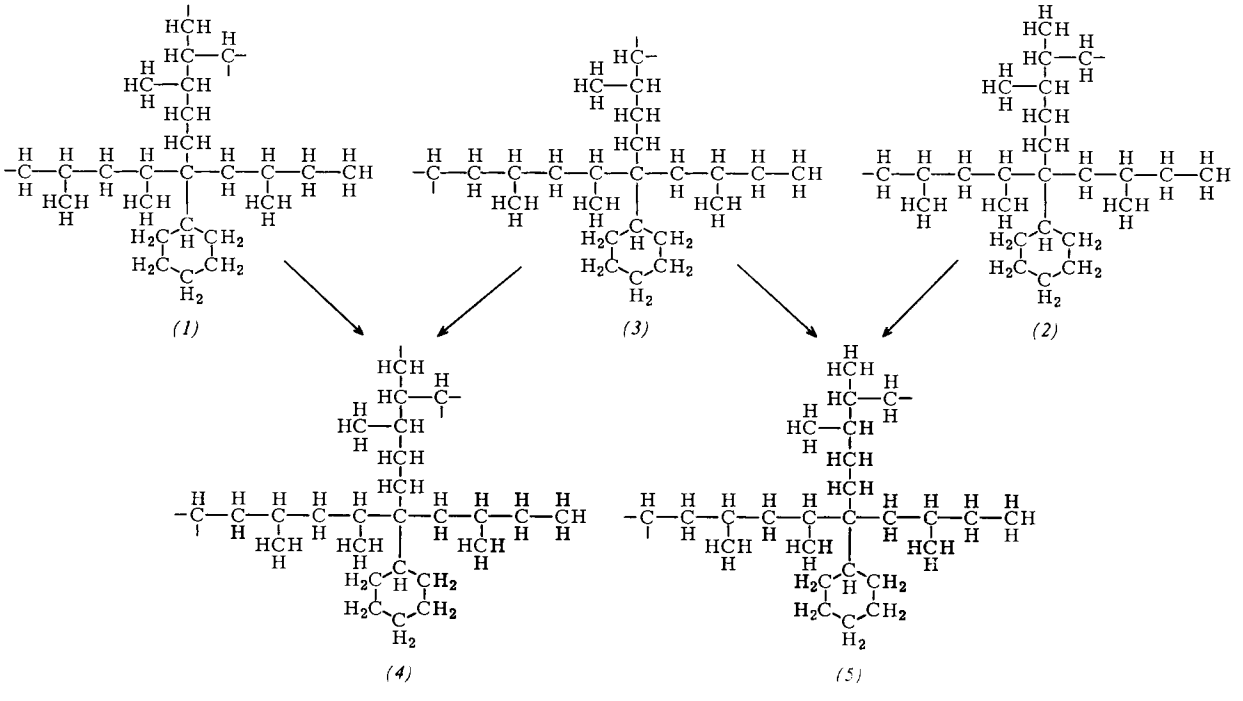

Fig. 4. Example of the application of the mathematical theory of graphs [23] to paraffinic hydrocarbons. If $[(1)][(2)] \neq [(4)][(5)]$, $\rho \geq 11$. If in addition such mergings of all larger graphs which differ only at the boundary result in an equality, then $\rho = 11$.

denotes the number of atoms (or repeating groups of atoms) in the longest block of atoms which is not a random overlay of the next smaller blocks (cf. Fig. 4). When the ring-free portion of a system is random with respect to the sorting of the atoms or other smallest exchangeable units, $\rho$ is zero. In this case, monofunctional substituents interchange randomly with pieces of chains so that for the class of "heteropolymers" there is no energetic distinction between the monofunctional substituents and the bridging atoms with respect to scrambling interchanges, and for "homopolymers" the chain atoms are not thermodynamically distinguishable from the substituents in a sorting process. A widely applicable theoretical treatment is found for $\rho = 1$, where the probability of attachment of an atom or exchangeable moiety is influenced only by its nearest bonded neighbors.

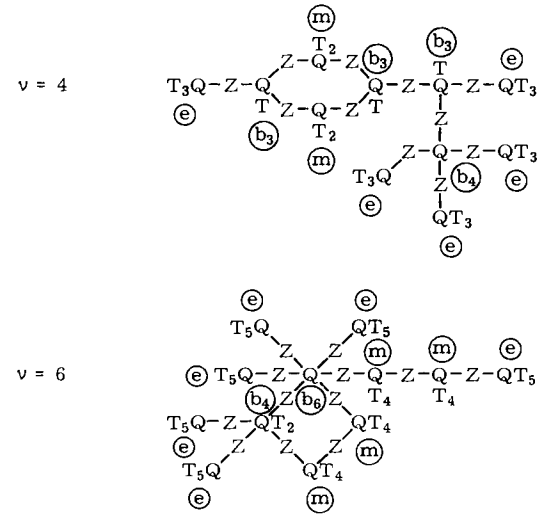

Fig. 5. A molecule in each general system $QT_\nu/Q_2Z_\nu$ [23] corresponding to $\nu = 4$ and $\nu = 6$, with e = end, m = middle, and bj = j-way branched building units.

[23] *D. W. Matula, L. V. D. Groenweghe*, and *J. R. Van Wazer*, J. chem. Physics *41*, 3105 (1964).

For $\rho \leqslant 1$, the equilibria between all molecules and parts of molecules which do not contain rings are completely described by a minimum of $(\nu-1)$ independent equilibrium constants. The set of equilibrium constants described by Eq. (a) (but now involving building units) fully represents the deviations from randomness for the ring-free portion of a system for which $\rho = 1$. For $\rho = 0$, the equilibrium constants $K_i$ have predetermined values [14] and the system is fully entropy-controlled with zero enthalpies for exchange of all parts between any ring-free molecules or ring-free molecular segments. As in the reactions of the *neso*-molecules, $K_i$ may be calculated from the statistics of random sorting of the Z and T substituents on the Q moiety. For $\rho = 1$, the equilibrium constants of Eq. (a) do not correspond to a random arrangement but the resulting building units, $QZ_iT_{\nu-i}$, are randomly arranged in the ring-free molecular structures so that the ring-free system is fully defined by the $(\nu-1)$ constants of Equation (a). For higher values of $\rho$, it is necessary to employ more equilibrium constants involving larger blocks of atoms than appear in the building units of the form $QZ_iT_{\nu-i}$. In such cases, overlapping of these blocks precludes additive stoichiometry. However, for $\rho = 1$, additive stoichiometry may be achieved by dividing the bridging substituents Z in half, so that the building unit previously symbolized by $QZ_iT_{\nu-i}$ may be written in stoichiometric form as $QZ_{i/2}T_{\nu-i}$ and the resulting family of compounds can be represented by the system $QT_\nu/Q_2Z_\nu$.

### d) Infinite Molecules and the Gel Point [24]

In the system $QT_\nu/Q_2Z_\nu$ in which the molecules consist of $\nu$-functional moieties Q connected by bridges Z, with T groups as the monofunctional substituents, infinite or wall-to-wall molecules occur when there are not enough end groups to terminate the tree-like branched-chain molecules resulting from the presence of building units having a functionality of 3 or larger. If the branched building units are not incorporated in a ring, the statistical reasoning shows that for $\rho \leqslant 1$ the total number of end groups will have to be at least 3 per three-way branch, 8 per four-way branch, 15 per five-way branch, and 24 per six-way branch in order to keep the system free of infinite polymers. Ring closure reduces the need for end groups since, by joining two chain segments per ring closure, it is unnecessary to cap off this pair of segments by end groups in order to keep the molecule finite. When the exchange of parts between molecules is rapid, infinite molecules will exhibit flow through a making-and-breaking process. Alternatively, for slow exchange the viscosity of the system will increase precipitously as the critical composition (the "gel point") at which infinite network molecules first appear is approached from the low-molecular-weight side.

### e) Ring-Chain Equilibria [23]

There is as yet no satisfactory theoretical treatment of ring-chain equilibria. Usually just one or two sizes of rings are found in systems in which small cyclic molecules are present at equilibrium. When there are no fused-ring systems, this means that only a few ring-chain equilibrium constants are needed, *viz.* one for each size of ring.

Although specific NMR peaks sometimes may be assigned to cyclic molecules, direct observation often is not possible, and the amounts of ring structures must be determined by difference. Since, as stated above, ring closures effectively make excess end groups, or, in other words, middle groups present in simple rings are effectively removed from the chain population, the presence of simple rings should make the observed amount of the short-chain molecules larger than the amount calculated on the assumption of no cyclic molecules. When $\rho \leqslant 1$ it is therefore possible to estimate the amount of simple ring molecules from the deviation of the observed amount of a short-chain molecule, say the di-chain, from that calculated assuming the absence of rings. Equilibrium constants similar to those of Eq. (a) apply only to the ring-free portion of the molecules, and the presence of simple cyclic molecules causes a continuous increase in such equilibrium constants as the amount of bridging units is increased with respect to the monofunctional substituents. Correcting this increase by subtracting the number of middle groups present in the simple cyclic molecules so as to give a constant value for the equilibrium constant represents another way of estimating the amount of rings when they cannot be directly measured. In either of these methods of indirect estimation of the amount of cyclic molecules, one would expect that the ring-chain equilibrium constants should remain constant within experimental error, and this offers a check of whether one is on the right track.

### f) Rings and Infinite Molecules [23]

The third technique for indirectly estimating ring populations is comparison of the experimentally observed "gel point" with the value calculated on the assumption that no rings are present. If branched building units are incorporated into ring structures which appear as components of finite molecules, the observed "gel point" will occur at an equilibrium composition corresponding to more branched groups than the gel-point composition calculated for the absence of rings. At present, a detailed theory for quantitative calculation of the amount of rings from this type of data is not available. We are developing such a theory using the assumption that the probability of pairs of bonding sites on a given atom in rings is the same as in chains. According to this, it is six times more probable that a fourway branch and three times more probable that a threeway branch group be in a ring than a middle group at the same concentration. We believe that this concept may be combined with numerical values of the ring-chain constants for the various sizes of rings (as evaluated for simple rings composed solely of middle groups) to give a quantitative measure (with proper accounting for volume changes in the reaction) of the relative amounts of all rings, whether or not these rings contain branched building units.

## 3. Kinetic Measurements and Interpretation

Relatively rapid changes at constant temperature in the amount of a given molecular structure can be measured NMR-spectroscopically by scanning back and forth over the corresponding resonance peak and measuring the change in peak area with time. With this technique, points spaced 1–2 minutes apart on a rate curve can be readily obtained. For slow processes at elevated temperatures, it is generally satisfactory to quench a sample quickly, take its spectrum at room temperature, and put it back in the furnace for another period of time. Occasionally we have obtained good results by making up a series of like tubes, each of which is quenched and used for measurement, to give the separate points of the rate curve.

Lifetimes for exchange processes in the range of $10^{-4}$ to *ca.* $10^{-1}$ sec can be estimated from NMR line broad-

[24] *P. J. Flory*: Principles of Polymer Chemistry. Cornell University Press, Ithaca 1953, p. 47.

ening and coalescence [3] (see Fig. 7). When the group bearing the magnetically active nuclei can interchange among several chemically non-equivalent sites, this technique yields an average value for the exchange lifetime. Estimations of the over-all order of a reaction can be made by measuring the variation with solvent concentration of the NMR line broadening.

A serious problem in treating kinetics of equilibrium processes is the number of independent steps involved. Thus in an all-*neso* system in which two kinds of substituents are exchanged (through four-center intermediates) on a central moiety having $\nu$ exchangeable sites, there are $\nu(\nu-1)$ second-order rate constants needed to describe the system. In some examples in which there are no problems in gathering data on the $(\nu+1)$ *neso*-compounds involved, it is difficult to establish even the order of the constituent reactions, much less to prove the mechanism.

## III. Examples of Chemical Systems

The study of single-phase liquid systems carried out thus far in our laboratory has been directed at the elucidation of four questions:

a) If two substituents are exchanged on a given central atom, how far will the resulting equilibrium deviate from that corresponding to random sorting of the substituents? Most of the work done to answer this question has been carried out with *neso*-compounds, but the data on all-*neso* systems will not be reviewed here.

b) What reorganizational heat order is required for an adequate quantitative treatment of equilibrium data involving families of molecules and what is the quickest and most satisfactory experimental way for obtaining these data?

c) At the composition where one would expect to obtain relatively long chains, how much are these chains shortened through formation of rings; *i.e.* what are the ring-chain equilibrium constants and can they be predicted?

d) How fast is equilibrium achieved, and can this rate be predicted either through reaction-mechanism theory or otherwise?

In the following discussion, we shall emphasize work done to answer questions b) and c).

Any family of compounds, the molecules of which can interchange parts with each other, can be discussed in terms of a chemical system between the *neso*-molecules, $QT_\nu$, and the compounds, $Q_2Z_\nu$, corresponding to the completely branched structures. Thus the family of aliphatic hydrocarbons may be treated in terms of exchange of hydrogen atoms for neighboring carbon atoms on a given carbon so that the system ranges from the *neso*-compound, $CH_4$, to the completely crosslinked structure, which is diamond. Thus the paraffin family is described by the system $CH_4/[C]$ (diamond) [1,23]. Similarly, the methyl polyborates [25] in which equilibrium is achieved by exchange of methoxy groups for bridging oxygen atoms around a boron atom is described by the system $(CH_3O)_3B/B_2O_3$ and the family of sodium polyphosphates [26] by the system $Na_3PO_4/P_2O_5$; these two families of compounds may be represented even more broadly by $(CH_3)_2O/B_2O_3$ and $Na_2O/P_2O_5$. Where groups do not readily exchange, *e.g.*, the two hydrogen atoms per carbon atom in the polyoxymethylenes and the single alkyl group per silicon in the polymonoalkylsiloxanes, we take the same approach. Thus the polyformaldehyde chains obtained by exchanging hydroxy groups with bridging oxygen atoms [27] are encompassed by the system $CH_2(OH)_2/[CH_2O]$ or more broadly by the system $H_2O/[CH_2O]$, and the polymonoalkylsiloxanes [28] by $CH_3SiX_3/[CH_3SiO_{3/2}]$.

### 1. Arsenic(III) Compounds

The families of compounds represented by the system $AsX_3/As_2O_3$ have been studied by NMR spectroscopy [29–31] and by ebullioscopy and cryoscopy [32]. In the NMR work, interpretable data were obtained for over-all X:As mole ratios ranging from 3 to 1; the colligative studies were necessarily restricted to mole ratios between 3 and 2.5.

#### a) Polyarsenous Oxide Fluorides [29]

For X = F, the $^{19}$F-NMR spectra of mixtures of nine different compositions gave 90 data points corresponding to the relative areas of the ten resonances per composition. These resonances correspond to various arrangements of the four types of building units:

| $AsF_3$ | $F_2AsO_{1/2}-$ | $FAs(O_{1/2}-)_2$ | $As(O_{1/2}-)_3$ |
|---|---|---|---|
| *neso*, *n* | end, *e* | middle, *m* | three-way branch, *b* |

One resonance signal is due to $AsF_3$; three resonances are attributable to end groups, that is to (i) an end group attached to another in the molecule $F_2AsOAsF_2$, as well as (ii) an end attached to a middle, and (iii) an end attached to a branch point in larger molecules. These may be denoted by **e***e*, **e***m*, and **e***b*, where the directly observed group, **e**, is shown in boldface type. Likewise, the remaining six resonances are attributed to middle groups corresponding to the various ways *e*, *m*, and *b* can be arranged around the observed middle group, **m**; *i.e.*, *e***m***e*, *e***m***m*, *e***m***b*, *m***m***m*, *m***m***b*, *b***m***b*. A typical spectrum showing all ten of these resonances is presented in Fig. 6.

At this point it might be of interest to review the technique used to arrive at the assignments given in Fig. 6.

[29] *J. R. Van Wazer*, *K. Moedritzer*, and *D. W. Matula*, J. Amer. chem. Soc. *86*, 807 (1964).

[30] *M. D. Rausch*, *J. R. Van Wazer*, and *K. Moedritzer*, J. Amer. chem. Soc. *86*, 814 (1964).

[31] *J. R. Van Wazer*, *K. Moedritzer*, and *M. D. Rausch*, J. chem. Physics *42*, 3302 (1965).

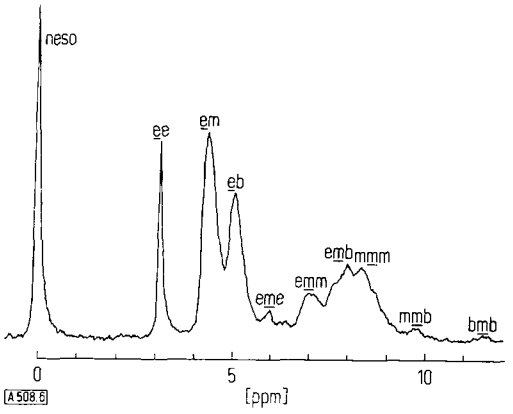

Fig. 6. $^{19}$F-NMR spectrum of a mixture equilibrated at 120 °C in the system [29] $AsF_3/As_2O_3$; over-all F:As mole ratio = 1.25. The symbols e, m, and b refer to end, middle, and branch structure-building units, respectively, and the group giving the particular resonance is underlined. Data obtained on a Varian HR-60 spectrometer at 56.444 Mc/sec and sample spinning in 5 mm precision tubes. The chemical shift reference is $AsF_3$, with field strength increasing from left to right.

When only small amounts of $As_2O_3$ are added to $AsF_3$ and the mixture is equilibrated, the product will be all or nearly all the end-end molecule, $F_2AsOAsF_2$, and therefore the first new peak to appear at F:As ratios near 3:1 is assigned to **ee**. The next peaks to appear on further decrease of the F:As ratio (dissolution of more $As_2O_3$) are due to the *eme* molecule. Here two signals are expected, one representing end groups next to the central middle group, **em**, and another (having one quarter of the area) representing the middle between the two end groups, *e***m***e*. Thus the general location of resonances for end and middle groups are established in relation to that of the *neso*-compound $AsF_3$ which is easily identifiable by its chemical shift. Further increase of the relative amounts of $As_2O_3$ in these mixtures results in longer chain molecules, such as *emme*, *emmme*, *etc.*, and also in branched species. The branch groups cannot be detected by $^{19}$F-NMR directly but their relative concentration can be calculated from the NMR data and the composition of the mixture. Even though the numbers of branch points are obtained by difference, the material balances still give a good check of the peak assignments, since the number of branches must increase monotonically with decreasing F:As mole ratio. The presence of branches leads to another type of end-group resonance corresponding to an end group next to a branch group, **eb**. There are also a series of different middle groups in longer chains, such as ***emm*** and ***mmm***, and the middle groups next to branch groups, ***emb***, ***mmb***, and ***bmb***.

The appearance of three signals resulting from end groups and six from middle groups indicates that the $^{19}$F chemical shift of a particular building unit depends only on the nature of the building units directly attached to it; building units one removed from these do not cause a resolvable effect.

The areas of the three peaks assigned to end groups reach a maximum value near the composition F:As = 2:1, and those of the middle groups increase from the composition 3:1 to that of 1:1.

Although the NMR peak for the *neso*-compound, $AsF_3$, stands out by itself, the regions where end and middle groups absorb are close together; but considering the sharpness of the peaks and the separations between them, the assignment in Fig. 6 appears reasonable. The validity of this assignment is established [29] by the material-balance calculations, together with the equilibrium constants ($K_1$ and $K_2$, discussed below), and the good agreement of the group of 90 NMR peak areas with the values calculated on the basis of random sorting of the building units into molecules.

Fig. 6 shows that the *neso* and **ee** peaks are sharp, as expected for molecules not undergoing rapid exchange. By this criterion, the *e***m***e* peak should also be sharp, but it is so small in the spectrum shown that its sharpness is lost in the noise. The **em** peaks and **eb** peaks are broad because there are various arrangements farther out in the molecule which would show up as separate peaks if the resolution were better (*i.e.* the *e***m** arrangement may be present in structures such as *e***m***e*, *e***m***me*, *e***m***be*$_2$, *etc.*). Throughout most of the composition range between the pure *neso*-molecule and the gel point, the end structures predominate so that the peaks corresponding to ends are the principal ones in the majority of this kind of NMR spectrum. Except for the *e***m***e* and *e***m***m* arrangements, even more structural variations are encountered for peaks involving middle groups, with the greatest number of possible arrangements corresponding to the ***bmb*** peak which is generally the most broad or diffuse. The odd shape of the *e***m***b* peak in Fig. 6 probably represents rather large weighting of some of these more distant arrangements as compared to others.

From the 90 pieces of information corresponding to the nine different compositions studied by $^{19}$F-NMR, the values of the equilibrium constants

$$K_1 = [neso][\text{middles}]/[\text{ends}]^2 \quad \text{(d)}$$

$$K_2 = [\text{ends}][\text{branches}]/[\text{middles}]^2 \quad \text{(e)}$$

were found to be $K_1 = 0.33 \pm 0.06$ (standard deviation) and $K_2 = 0.31 \pm 0.02$. These constants are very similar to those of Eqs. (b) and (c). It was originally stated [29] that the number of rings in the system above the gel point is insignificant. However, later quantitative calculations with these equilibrium constants have shown that the relative amount of the *ee* molecule is a quite insensitive measure of the amount of ring structures.

### b) Colligative Measurements

Cryoscopic and ebullioscopic measurements have recently been discussed by *Thilo* and *Flögel* [32]. The theoretical treatment is identical to that given for $\rho = 1$ in our publications. The equilibrium constants, $1/K_n$, for the reactions

$$As_nO_{n-1}Cl_{n+2} + As_2OCl_4 \rightleftharpoons As_{n+1}O_nCl_{n+3} + AsCl_3 \quad \text{(f)}$$

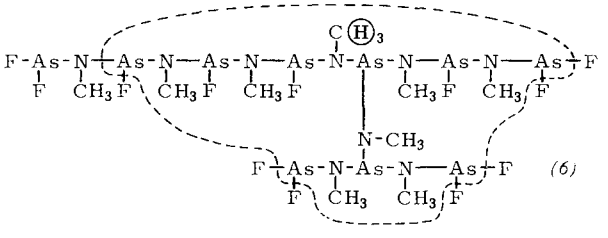
can be shown to be constant and identical for all values of n only on the assumption that the reorganizational heat order, $\rho$, is unity and that branches are disallowed. Simple mathematical manipulation also shows that, with no branches, four times the $K_s$ or K given by *Thilo* and *Flögel* is equal to the $K_1$ in the form of Eq. (a), so that the colligative measure-

[32] *E. Thilo* and *P. Flögel*, Z. anorg. allg. Chem. *329*, 244 (1964).

ments offer a simple way of determining one, *viz.* $K_1$, of the $(\nu-1)$ equilibrium constants, $K_i$, describing the equilibria in the chain portion of the system, assuming $\rho = 1$. Since the number of branches and of rings in the composition region accessible to study by cryoscopic and ebullioscopic measurements is necessarily small, even in those cases where ring-chain equilibria favor cyclic molecules, the discussion by *Thilo* and *Flögel* in terms of only unbranched chains is a reasonable approximation in the composition range which they studied.

### c) Poly(fluoroarsenous methylimides)[30]

This family of compounds corresponding to the system $AsF_3/As_2(NCH_3)_3$ is particularly interesting in that the chemical shift of the hydrogen of a methylimino bridge is sensitive to the arrangement of fluorine atoms and methylimino bridges on the neighboring arsenic atoms. A very complicated spectrum results in which 18 resonances are distinguishable. This means that the chemical shift of the encircled hydrogens [formula *(6)*] gives information about the arrangement of all atoms within the dotted line.



*(6)*

### d) Exchange Rates[29–31]

From the broadening and coalescence of the NMR peaks with increasing temperature, as exemplified by Fig. 7, the lifetime for the exchange of fluorine atoms,

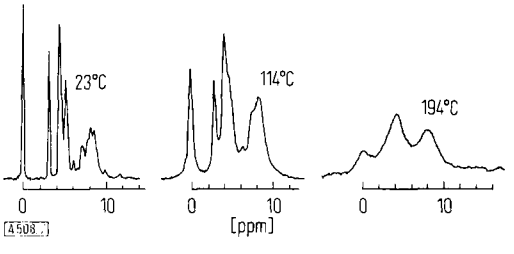


Fig. 7. $^{19}$F-NMR spectra as a function of temperature for an $AsF_3/As_2O_3$ mixture [29]; over-all F:As mole ratio 1.25. Conditions as in Fig. 6.

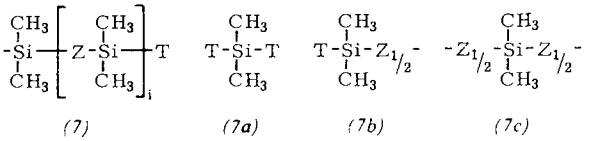
methoxy groups, or methylimino bridges between chemically different sites may be measured, together with the activation energy for the process. The exchange lifetimes of molecules based on arsenic atoms bridged with either oxygen atoms or methylimino groups are found to be small fractions of a second at room temperature. The corresponding activation energy is also small, being only several kcal/mole. Since slow flow is observed beyond the gel point in the $AsF_3/As_2O_3$ system, and the activation energy for flow is the same as that for exchange of fluorine atoms between different sites, it is evident that in systems where the molecules exchange parts at a rapid rate, flow of even infinitely large molecules can occur through such exchange.

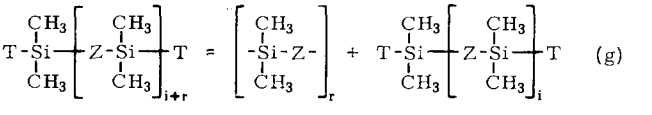
For molecules having the structure *(7)*, where T is an exchangeable substituent such as a halogen, methoxy, dimethylamino, *etc.*, and Z is a bridging oxygen[33], sulfur[34], or methylimino group[35], there will be an equilibrium between *neso*-molecules *(7a)*, end groups *(7b)*, and middle groups *(7c)*, corresponding to one constant, $K_1$, as given by Eq. (a) with $\nu = 2$ and Q = $(CH_3)_2Si$. In addition, the middle groups may combine to give rings. These systems of molecules are readily studied by means of the $^1$H-NMR signals of the dimethylsilicon moiety.



*(7)* *(7a)* *(7b)* *(7c)*

### a) Equilibrium with Cyclic Structures

Ring-chain equilibria are particularly interesting in these systems. The equilibrium (g) was found to be more strongly shifted in the direction of cyclic molecules with Z being successively oxygen, methylimino, and sulfur:



(g)

where for the chain molecules $\rho \approx 1$; the subscript r denotes the number of silicon atoms in the ring.

At 120 °C, the equilibrium constant corresponding to Eq. (g) is about 0.5 moles/l for Z = O, 40 for Z = $NCH_3$, and 2000 moles/l (estimated) for Z = S, where T = Cl and r = 3. As might be expected, there is a rather large enthalpy change connected with the equilibria between small cyclic molecules. For Z = S, there is an enthalpy difference of −3.3 kcal per Si atom for the conversion of three dimeric into two trimeric rings. Many more quantitative data of this type are needed in order to allow prediction of whether rings or chains will dominate in a particular system.

### b) α,ω-Dichloropolydimethyl-*N*-methylsilazanes[35]

In equilibrium mixtures of chain and ring compounds corresponding to T = Cl and Z = $NCH_3$ in *(7)* the distribution of molecules can be characterized from theNMR signals of the methyl groups on the silicon as well as from that of the methyl group on the bridging nitrogen. A typical spectrum is shown in Fig. 8, from which it

[33] *K. Moedritzer* and *J. R. Van Wazer*, J. Amer. chem. Soc. *86*, 802 (1964).

[34] *K. Moedritzer, J. R. Van Wazer*, and *C. H. Dungan*, J. chem. Physics *42*, 2478 (1965).

[35] *J. R. Van Wazer* and *K. Moedritzer*, J. chem. Physics *41*, 3122 (1964).

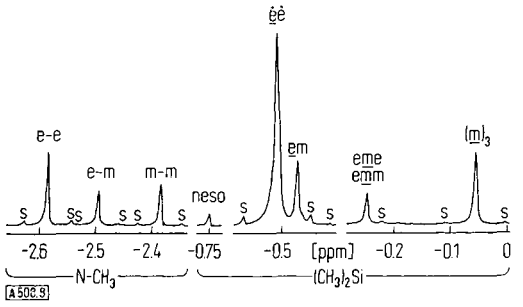


Fig. 8. $^1$H-NMR spectrum of a mixture [35] of molecules equilibrated at 120 °C in the system $(CH_3)_2SiCl_2/[(CH_3)_2Si(NCH_3)]$; over-all $Cl:(CH_3)_2Si$ mole ratio 0.78. Data obtained on a Varian A-60 spectrometer at 60.000 Mc/sec with sample spinning in precision tubes and a sweep width of 50 cps full scale. The symbol s refers to $^{29}$Si satellites, corrections for which must be made when they are buried under neighboring peaks.

can be seen that the resonances corresponding to the methylimino bridge are considerably downfield from those corresponding to the dimethylsilicon moiety. The relative areas of certain peaks in these spectra are fixed. Thus the *e*—*e* resonance corresponds to the single methyl of the bridging $CH_3N$ group, whereas the **ee** signal comes from the four methyl groups of the pair of dimethylsilicon moieties in the molecule so that the areas of these peaks must always be in the ratio of 1:4. Likewise, the *e*—*m* resonance is again due to a single methyl group whereas the **em** resonance results from the two methyl groups on the terminal silicon atom. The *m*—*m* resonance in the spectrum of Fig. 8 corresponds to both chains and rings, hence its area must be half the sum of the areas of the peaks denoted as *e***m***e* and *e***m***m* plus $(\mathbf{m})_3$.

### c) Kinetic Data

The kinetics of the reaction between equimolar amounts of silicon in a ring compound and in the *neso*-molecule is shown [33] in Fig. 9 for X = Cl and Z = O. The same information is presented [35] in Fig. 10 for X = Cl and $Z = NCH_3$. The fact that the kinetic pattern in Fig. 9 is considerably more complicated than that in Fig. 10 is attributable to a difference in the rate of the first step

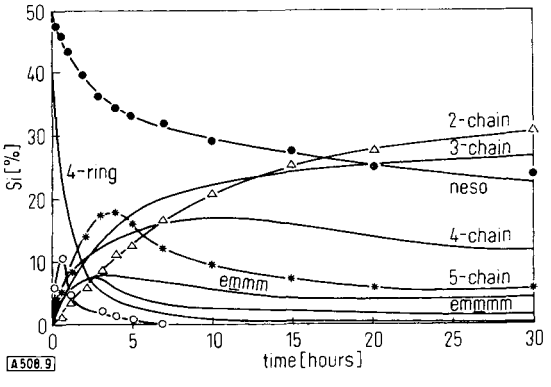

Fig. 9. Variation with time of the distribution of total silicon present in various molecules or building units during equilibration [33] at 200 °C of a mixture of one mole of dichlorodimethylsilane with 1/4 mole of octamethylcyclotetrasiloxane using 0.5 wt.-% $AlCl_3$ as catalyst. To avoid confusion, experimental points are shown only for the *neso*-compound (●), the di-chain (△), the penta-chain (*), and the large molecules (big rings or long-chains) (○).

(whereby the *neso*-compound reacts with the ring to give a chain) as compared to the rates of succeeding steps. When $Z = NCH_3$, this reaction is slower than the succeeding reactions whereby the *neso* and chain compounds equilibrate; when Z = O, this reaction is at least as rapid as the succeeding ones.

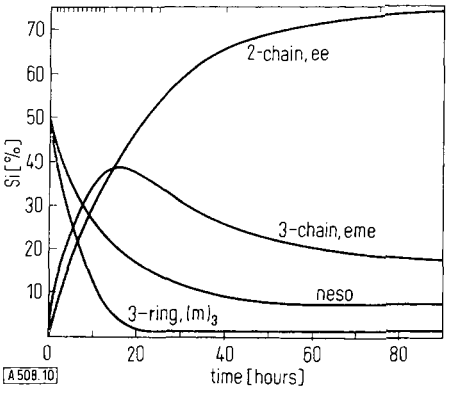

Fig. 10. Variation with time of the percentage of total silicon present in various molecules during equilibration [35] at 120 °C of a mixture of one mole of dichlorodimethylsilane with 1/3 mole of nonamethylcyclotrisilazane. The marks along the top of this figure denote the times at which the data were obtained.

In siloxanes [33] (Z = O) the interaction of tetrameric rings to give larger rings (octameric, dodecameric, *etc.*) or long chains terminated by trace amounts of ends (perhaps impurities) is the process occurring at the beginning of the reaction:

j (4-ring) → large rings or long chains

The early and prominent maximum noted for the five-membered chains shows that the following reaction is also initially prominent:

*neso*-compound + 4-ring → 5-chain

The rapid diminution in the amount of long chains or large rings after passing through a maximum is most probably attributable to:

*neso*-compound + long chains or large rings → shorter chains

The subsequent diminution of the amount of five-membered chains is caused by several reactions such as:

5-chain + *neso*-compound → 2 (3-chain)

or perhaps

5-chain + 3 *neso*-compound → 4 (2-chain)

After about 15 hours under the experimental conditions of Fig. 9 all of the different species of molecules are in the process of exchanging parts with each other so that any theoretical explanation of the right-hand end of the curves of Fig. 9 must involve reactions between many different molecules, as must be the case at the final dynamic equilibrium. For further examples, see [36–40].

## IV. Concluding Remarks

### 1. Summary

In this brief review, we have attempted to point up the importance of chemical equilibria in structural inorganic chemistry and to show how the kind and yield of various molecules may be treated quantitatively. Because of the importance of kinetic control in organic chemistry and because the chemistry of carbon compounds is by far the most advanced branch of general and descriptive chemistry, preparative inorganic chemists have often overemphasized the value of reaction-mechanism theory to their studies and have thereby neglected the powerful quantitative approach of thermodynamics which may be used in equilibrated systems. The general theorems for treating in terms of small molecular segments the multitude of equilibria present in families of compounds have been surveyed superficially with the hope that the interested reader will turn to the original papers for details. In these days of high-speed computers, not only physical-inorganic chemists, but also those interested solely in preparative work can advantageously employ the theoretical ideas discussed above.

### 2. Future Developments

#### a) Theory

Atomic-interaction theories are being developed for correlation and prediction of the deviations from randomness in the equilibria involving chains. Work is also under way on the theoretical basis of ring-chain equilibria and the time needed to reach equilibrium in various systems. The concept of order of environment within molecules can be extended to the interpretation of what might be called atomically additive properties, such as density, refractive index, or bulk magnetic susceptibility. In addition, we are studying several examples of the effect of solution nonideality on deviations from randomness in equilibria.

#### b) Analysis

New and improved analytical techniques for assaying molecules in mixtures are surely to be expected in a reasonably near future. In particular, nuclear magnetic resonance spectrometers of very high resolution will become available with improvements in field-strength uniformity of superconducting magnets. These should allow one to see molecules in considerably greater depth than is possible today, as well as to extend practical high-resolution NMR to samples having the natural abundance of chemically interesting nuclei such as $^{13}C$, $^{15}N$, $^{29}Si$, $^{77}Se$, $^{111}Cd$ or $^{113}Cd$, $^{119}Sn$, $^{125}Te$, $^{195}Pt$, $^{199}Hg$, and $^{207}Pb$, all of which have spin $1/2$. Moreover, with very high field strengths, it will be possible to measure much more rapid exchange rates and to observe uncoalesced resonances under conditions where either exchange or quadrupole broadening now makes the spectra difficult and sometimes impossible to interpret. Another way of increasing the range of elements that can be studied by NMR is to use isotopic enrichment of those magnetically suitable nuclei which are naturally present in low abundance (*e.g.* $^{29}Si$).

# Structures and Reactions of Organic ate-Complexes

BY DR. W. TOCHTERMANN

ORGANISCH-CHEMISCHES INSTITUT DER UNIVERSITÄT HEIDELBERG (GERMANY)

*Some years ago, Wittig [1] pointed out that ate-complexes are characterized by anionic activation of the substituents attached to the central atom. The behavior of these compounds thus contrasts with that of the onium-complexes [2] studied by Meerwein, which are characterized by cationic activation of the ligands. These two types of complexes form together two complementary aspects of organic coordination chemistry [5].*

## A. Introduction

ate-Complexes, according to *Wittig* [1], are compounds having the structure $M_{n-z}[ZR_n]$, in which a complex anion $[ZR_n]^{(n-z)-}$ is associated with a cationic partner (such as an electropositive metal). The name "ate-complex" was chosen because in chemical nomenclature complex anions are given a name having the suffix "-ate" [3, 4]. The positive center in onium-complexes

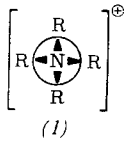
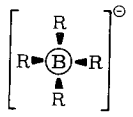
[5] Metal-carbon π-complexes are excluded from the following discussion.

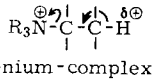
[*e.g. (1)*] contributes to the cationic activation of the ligands by an inductive effect. On the other hand, the negative charge in the ate-complexes [*e.g. (2)*] activates all the substituents anionically by an inductive effect which may facilitate the removal of a ligand as an anion or may lead to an increase in the mobility of hydrogen as hydride on a carbon $\alpha$ or $\beta$ to the central atom.



*(1)*



*(2)*



onium-complex

ate-complex

*(3)* onium-ate-complex

It is also to be expected that in coordination compounds with an "onium-ate" structure [*e.g. (3)*], which result from the combination of a Lewis acid with a Lewis base, the reactivities of the ligands may be substantially altered by adduct formation.

The ligands are anions or molecules exhibiting donor properties, usually owing to the presence of a lone pair of electrons. Complex formation is related to the tendency of the central atom to assume the energetically favorable electronic configuration of the nearest inert gas. However, the tendency towards complex formation and the stability of the complexes depends also on the charge and size of the groups and on the bond energy of, for example, the new metal-carbon bond, which can also be appreciably affected by other factors, such as the interaction between the d-orbitals of the metal and the p-orbitals of the ligand [5].

## B. Complex Organolithium Compounds

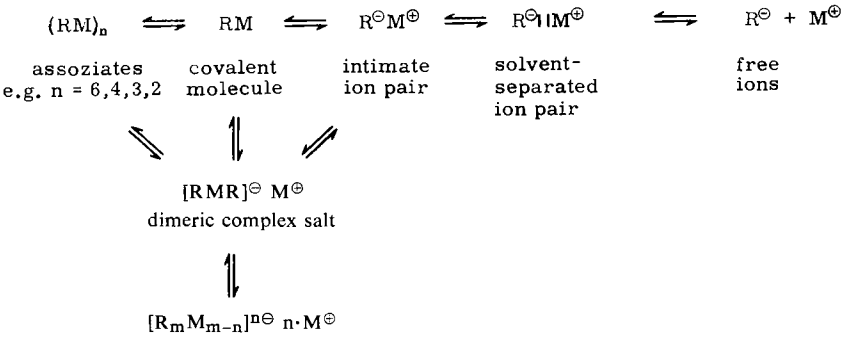
### 1. General

Organolithium compounds RLi (R = alkyl, aryl) exist in solution as associates $(RLi)_n$, where n can vary widely depending on the concentration, the solvent, and the nature of the group R [6–10]. The ability of lithium ions in aqueous solution to form complexes according to

$$Li^+ + X^{n-} \rightleftharpoons [LiX]^{(n-1)-}$$

was discovered by *Schwarzenbach* [11] during investigations on complexes with iminoacetic acid derivatives.

*Wittig* [8] discussed the dimerization of phenyl-lithium in ether in terms of self-complexing with formation of the ate-complex *(4)*. In this case, however, as is also found by molecular-weight determinations on the analogous triphenylzincate, triphenylberyllate, and tetraphenylborate complexes, the lithium ions remain predominantly in the vicinity of the complex anion. In solvents of relatively low dielectric constants (ether, acetone), solvation is sufficient only for the formation of ion pairs and higher aggregates [12]. Ion associates of this nature are very common [13a], and even organometallic compounds which exist in ether mainly as ion pairs have very low dissociation constants [13b]. The association, self-complexing, ionization, and dissociation of organometallic derivatives of alkali metals generally involve many steps, and can according to *Ebel* be represented as follows [13c, 13d]:



Predominantly "free" ions are to be expected only in dilute aqueous solutions of lithium or sodium tetraphenylborate [13e].

$[C_6H_5{-}Li{-}C_6H_5]Li$ *(4)* $Ca[Al(i\text{-}OC_3H_7)_4]_2$ *(5)* $Cu[Al(OC_2H_5)_4]_2$ *(6)*

It is also found in several cases that when two different alkoxides combine, dissociation is not promoted but

suppressed. Thus in contrast to the calcium alkoxides, the complex *(5)* can be vacuum distilled without decomposition, and copper tetraethoxyaluminate *(6)* even dissolves (probably as the monomer) in benzene[14].

## 2. Crystal Structure and Association in the Gas Phase and in Nonpolar Solvents

X-ray analyses of crystalline ethyl-lithium[15] showed that the molecules form pairs of layers held together by van der Waals forces, which can be relatively easily displaced with respect to one another. These double layers are built up from $(C_2H_5Li)_4$ units, each of which consists of two strongly associated ethyl-lithium dimers. The four lithium atoms form an almost regular tetrahedron, which has a methylene group situated above each face. Since ethyl-lithium may be regarded as an electron-deficient compound, bonds of this type are probably also responsible for the complex crystal structure. The carbon-lithium bond in this case is largely covalent[16], as is manifested also in the low electrical conductivity[17] and the small dipole moment[18].

t-Butyl-lithium exists in benzene and in hexane as the tetramer. On the basis of spectroscopic studies, this tetramer was assumed to have a tetrahedral structure, in which the four lithium atoms and the four α-carbon atoms of the t-butyl groups occupy the vertices of two interpenetrating tetrahedra[19]. The complex is thought to be held together by four equivalent four-center electron-deficient bonds:

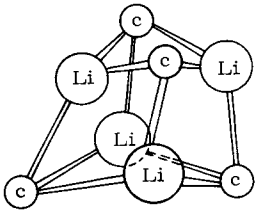

Fig. 1. Structural unit of tetrameric t-butyl-lithium [19].

This structure, which is similar to that of tetrameric tetramethylplatinum[20], has also been proposed by *Brown*[21] for the tetramer present in ethyl-lithium vapor and in solutions. The mass spectrum of saturated ethyl-lithium vapor[22] at 80–95 °C shows it to consist predominantly of $Li_6R_6$ and $Li_4R_4$ units in roughly equal concentrations. The structure therefore probably is cyclic, since there would be no reason for the predominance of hexameric and tetrameric units if the structure were linear:

$$C_2H_5{-}Li \ldots C_2H_5{-}Li \ldots C_2H_5{-}Li$$

*(7)*

In the hexameric lithium compound, which also predominates in solution (ethyl-lithium and n-butyl-lithium are hexameric both in benzene and in cyclohexane[21,23,24]), the six lithium atoms are thought to form a nucleus in a chair form, with the alkyl groups situated on the periphery of the structure[25]. Each lithium atom is again bonded to three carbon atoms and *vice versa*. The four-center bond involves an $sp^3$-orbital of the carbon, together with the orbitals of three lithium atoms, and each lithium atom is involved in three such bonds.

The strong inclination of organolithium compounds to form associates can be attributed to the tendency of lithium to fill its empty 2p-orbitals, which have only a slightly higher energy than the 2s-level[13c].

Information about the structures of organolithium compounds has also been obtained from infrared spectra[26,27]. The asymmetric and symmetric C–H stretching vibrations of methyl-lithium are displaced to lower wave numbers; this phenomenon is generally found with bridging methyl groups[28]. In agreement therewith, both bridging methylene groups with the characteristic decrease in frequency *and* non-bridging terminal methyl groups are found in ethyl-lithium. However, frequency shifts of this type do not appear to be confined to compounds with electron-deficient structures. A similar situation is found for the α-methylene groups of tetraalkylborates[29]; here the displacement of the C–H stretching frequency may be due to the inductive effect of boron.

## 3. Organolithium Compounds in Basic Media

It has long been known that organolithium compounds are much more reactive in solvents such as ether than in hydrocarbons[6], and many attempts have been made to elucidate the degree of association of these compounds and their interactions with these solvents[8]. The addition of even relatively small quantities of a Lewis base (ether, *etc.*) has a marked influence on the behavior of lithium alkyls in hydrocarbons[30–32], as was shown

[14] *H. Meerwein* and *Th. Bersin*, Liebigs Ann. Chem. *476*, 113, 138 (1929).

[15] *H. Dietrich*, Acta crystallogr. *16*, 681 (1963). *E. Weiss* and *E. A. C. Lucken* found a similar situation in the case of methyl-lithium (J. organomet. Chemistry *2*, 197 (1964).

[16] *G. Fraenkel, D. G. Adams*, and *J. Williams*, Tetrahedron Letters, *1963*, 767 assign an ionic character of about 20% to the C-Li bond on the basis of NMR studies. From theoretical considerations, *H. F. Ebel* [13c] gives a value of 27% for methyl-lithium. A much higher value is given in *L. Pauling*: The Nature of the Chemical Bond. Cornell University Press, Ithaca, N.Y., 2nd Edit., 1948.

[17] Fused ethyl-lithium does not conduct electricity: *Fr. Hein, E. Petzchner, K. Wagler*, and *F. A. Segitz*, Z. anorg. allg. Chem. *141*, 161 (1924).

[18a] *M.T. Rogers* and *A. Young*, J. Amer. chem. Soc. *68*, 2748 (1946).

[18b] *M.T. Rogers* and *T.L. Brown*, J. physic. Chem. *61*, 336 (1957).

[18c] *V. N. Vasil'eva, T. V. Talalaeva, E. N. Gur'yanova*, and *K. A. Kocheskov*, Izv. Akad. Nauk SSSR, Otd. Khim. Nauk *1960*, No. 9, 1549–1552; Chem. Abstr. *55*, 6971f (1961). Values between 0.8 and 1.5 D were found for the dipole moments of several alkyl-lithium molecules, depending on the concentration and the solvent. Appreciably higher values are expected for ion pairs such as are formed by lithium perchlorate in dioxane [18a].

by the discovery [33a, b] of a solvated dimer $(n\text{-}C_4H_9Li)_2 \cdot (C_2H_5)_2O$, the structure of which is shown in Fig. 2.

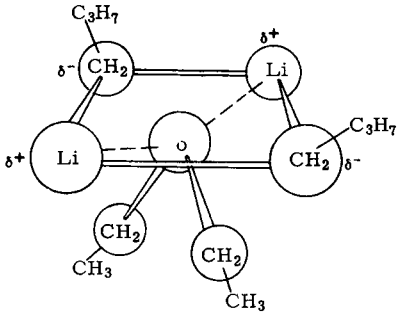

Fig. 2. Structure of a butyl-lithium/diethyl ether adduct [33a].

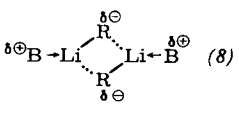
When ether is added to a solution of n-butyl-lithium in hexane, the vapor pressure of the ether decreases below that found in the absence of butyl-lithium, and the dielectric constant of the solution increases considerably, until the quantity of ether equivalent to the 2:1 complex has been added. In the NMR spectrum, the position of the α-methylene proton signal of the butyl-lithium changes only until all the n-butyl-lithium has been converted into the 2:1 complex; the addition of more ether has no further effect, so that any further changes in the reactivity of the organometallic component are probably due simply to a general solvent effect [33a].

On the basis of NMR studies on complexes of 9-fluorenyl-lithium with tetrahydrofuran and with 1,2-dimethoxy-ethane, *Dixon* [33c] recently concluded that the lithium cation and the coordinated Lewis bases (THF or dimethoxy-ethane) lie above the plane of the aromatic carbanion.

The Lewis-acidic character of the alkyl-lithium polymers is shown also by complex formation between ethyl-lithium and triethylamine in benzene, which was detected by *Brown* [24] from the dielectric constants and freezing-point depressions of the solutions.

This result is best explained in terms of an initial addition of one or two molecules of amine to the hexameric lithium compound; this weakens and breaks the bond framework, forming tetrameric and dimeric ethyl-lithium units. These in turn coordinate with triethylamine, so that a sequence of complex equilibria can exist, depending on the concentration of the base. If the arrangement of the six lithium atoms in the hexamer is assumed to be octahedral, the ethyl groups attached can occupy only six of the eight octahedral faces, and the amine can therefore add on to the two remaining faces.

Although no details about the hybridization of the lithium orbitals are known at present, it may be assumed that in multi-center bonds of this type, one or two orbitals of each lithium atom remain empty, and these are available for the addition of a donor which leads to dissociation of the hexamer, tetramer, *etc.* Any complex formation with an electron donor, *e.g.* the in dimer *(8)*, causes considerable anionic activation of the



*(8)*

alkyl groups, thereby increasing the reactivity of the alkyl-lithium compounds.

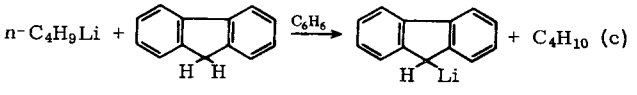
On the basis of NMR data, *Fraenkel* [16] assumed that ethyl-lithium, ethylmagnesium bromide, and diethylmagnesium exist in ethereal solutions as strongly associated salts of carbanions; this prompted further spectroscopic studies on organolithium compounds [24], but these failed to produce any evidence for the presence of solvated ion pairs. However, NMR spectroscopy does not appear to be a very sensitive method for the detection of organometallic compounds having different degrees of association or solvation [13, 16, 24, 61].

Kinetic studies show, on the other hand, that the reactions of organolithium compounds are preceded by dissociation equilibria [31, 32, 34]; this supports the view that the monomer is the reacting species, although it may be present only in small concentrations.

The rate r of the metalation of fluorene with n-butyl-lithium in benzene is found to obey the relation (a), *i.e.* the actual reaction is preceded by the formation of the monomer in the equilibrium (b).

$$r = k[n\text{-}C_4H_9Li)_6]^{1/6}\,[\text{fluorene}] \qquad (a)$$

$$(n\text{-}C_4H_9Li)_6 \rightleftharpoons 6\,n\text{-}C_4H_9Li \qquad (b)$$



*Waack* and *West* [34d] recently showed that benzyl-lithium, allyl-lithium, and phenyl-lithium also react as the monomers in the metalation of triphenylmethane in tetrahydrofuran [34e]. The relative reactivities:

benzyl-lithium > allyl-lithium > n-butyl-lithium > phenyl-lithium > vinyl-lithium > methyl-lithium

indicate that the rate-determining step in the metalation is a nucleophilic attack on the hydrogen of the substrate.

## 4. Complexes with Lithium Halides and Organometallic Compounds of Alkali Metals

The most important organolithium complexes, apart from those with amines and ethers (among which the complexes of dioxane with aryl-lithium derivatives are noteworthy for their low solubility and their ease of isolation [33b, 35]), are those formed with lithium halides and organometallic compounds of other alkali metals.

Salt-free solutions of lithium compounds are more reactive than solutions containing salt; this fact is often

[35] *N. G. Chernova* and *B. M. Mikhailov,* Zhur. Obschei Khim. *25,* 2280 (1955); Chem. Abstr. *50,* 9365f, 11996i (1956); J. gen. Chem. USSR *25,* 2249 (1956); *B. M. Mikhailov* and *N. G. Chernova,* Zhur. Obschei Khim. *29,* 222 (1959); Chem. Abstr. *53,* 21843h (1959).

utilized in metalations and polymerizations [36–38]. *Wittig* and *Lange* [36a] obtained the crystalline phenyl-lithium/LiBr 2:1-adduct from solutions of phenyl-lithium in ether containing LiBr, and *Glaze* and *West* [39] isolated adducts of lithium halides and alkyl-lithium compounds. The ratio RLi:LiBr in the adduct depends on its preparation, but the products appear to be mixtures of LiBr with 1:1 complexes. The butyl-lithium/LiBr adduct is hydrolysed rapidly by water, but reacts only slowly with atmospheric oxygen. When suspended in pentane, this complex gives a negative Gilman color test [40]; a positive test is obtained only with its dissociation products formed by addition of ether. Thus organolithium compounds can be deactivated to substances that are easily handled, and from which the active reagent can be regenerated by addition of ether.

The deactivation is probably due to the fact that LiBr is a stronger Lewis acid than organolithium compounds and so forms coordination compounds that are more stable than the complexes of RLi with itself. However, it is not yet settled whether these adducts have ionic structures such as *(9)* or *(10)*, or whether they are electron-deficient compounds.

$[RLiX]^{\ominus}Li^{\oplus}$ *(9)* $[Li_2R]^{\oplus}X^{\ominus}$ *(10)*

Using ethyl-lithium/lithium ethoxide complexes, *Brown* [40a] showed that, unlike ethers and amines, alkoxides do not cause appreciable dissociation of the ethyl-lithium hexamer into more reactive species. Corresponding remarks could also apply to the unreactive RLi/LiBr adducts.

The efficiency of *e.g.* phenyl-lithium as an initiator in the anionic polymerization of styrene depends on the quantity of lithium halide added, and this fact has been used for the detection of the 1:1 complex RLi·LiBr and for the determination of the equilibrium constant K [38,40b].

$$K = \frac{[R\text{-}Li\cdot LiX]}{[R\text{-}Li]\,[LiX]}$$

K = 13.5 l/mole (20 °C; THF; R = $C_6H_5$; X = Br)

K = 115 l/mole (20 °C; THF; R = $CH_2{=}CH-$; X = Br)

The complexes of organolithium compounds with organosodium, organopotassium, and organocesium compounds, which were discovered by *Wittig* [41], have acquired some preparative importance. Their preparation is based on the fact that the dimer of phenyl-lithium in ether [7,8] may be formulated as a complex ion pair *(4)*, in which one lithium atom acts as the coordination center, the other as the cationic partner of the negative complex ion. It should therefore be possible to replace $Li^+$ by another metal cation without affecting the complex character; this was confirmed by the isolation of the colorless complex *(11)*, which is sparingly soluble in ether.

$[C_6H_5{-}Li{-}C_6H_5]Na\cdot(C_2H_5)_2O$ *(11)*

Whereas ether is rapidly decomposed by phenylsodium, the complex *(11)*, which is obtained from phenyl-lithium, diphenylmercury, and sodium or from chlorobenzene, sodium, and phenyl-lithium, is stable in ether for some days. The stability of these 1:1-complexes decreases rapidly from lithium to cesium as cation.

Solutions of *(11)* in ether stabilize phenylsodium, probably because the sodium ions of *(11)* greatly reduce the solubility of phenylsodium. The decomposition of phenylsodium can therefore be prevented by the addition of an ethereal solution of LiBr, which gives rise to the complex *(11)* in accordance with the reactions [42]:

$$C_6H_5Na + LiBr \rightarrow C_6H_5Li + NaBr \quad (d)$$
$$C_6H_5Li + C_6H_5Na \rightarrow (11)$$

Complexes with alkyl-lithium compounds can also be prepared. The limit of applicability of ether assolvent is reached with the particularly reactive sodium dibutyl-lithiate. The reactivities of the complexes are between those of the organolithium and the organosodium compounds themselves, and they have proved particularly useful for the metalation of diphenylmethane and triphenylmethane, anisole, 1,3-dimethoxybenzene, diphenyl sulfide, triphenylamine, and triphenylphosphine. In the metalation of anisole with *(11)* to *o*-methoxyphenyl-lithium, a conversion of 71 % is obtained in two days, whereas salt-free phenyl-lithium gives only 17 % conversion in the same period.

Phenyl-lithium and ammonium salts *(12)* react to form ammonium ylides [43,44], which are stabilized by coordination with LiBr to give *(13)*. On the other hand,

the ylide *(13a)* obtained in the same manner, but with *(11)* as proton acceptor, decomposes into polymethylene and trimethylamine, or undergoes a Stevens rearrangement to form ethyldimethylamine, since NaBr is a much weaker complexing agent than LiBr. This behavior has been used in two cases for the formation of cyclopropane rings. Thus *(11)* and *(14)* react in the presence of cyclohexene to give 7-n-butoxy-*(15a)* or 7-phenoxy-norcarane *(15b)* [45].

*Eberhardt* [46] used the ate-complexes *(16)* and *(17)* (prepared from potassium hydride or potassium + butyl-lithium) as catalysts for the reaction of ethylbenzene with ethylene. Whereas neither potassium hydride nor n-butyl-lithium reacts with ethylbenzene at room temperature, *(16)* reacts immediately with liberation of butane, the solution turning red and *(18)* being formed. The latter adds to ethylene to form *(19)*, which undergoes ring closure to give 1-methylindane *(20)* with loss of hydride from the aromatic ring. The complex hydride *(21)* adds to ethylene to give a new alkyl-hydride complex *(22)*, which in turn reacts with ethylbenzene to begin the cycle once again. In addition to products of higher molecular weight, a total of 70 % of 1-methylindane *(20)* and sec-butylbenzene is obtained [the latter product resulting from the hydrolysis of *(19)*] from ethylene and ethylbenzene.

## C. Complex Organoberyllium Compounds

Elements of Groups II and III of the periodic table have an even greater tendency than lithium to form dimeric and polymeric electron-deficient structures in organometallic compounds and hydrides, and have a pronounced Lewis acid character. With organometallic compounds of alkali metals they form ate-complexes, and with electron donors such as amines, phosphines, and ethers they form adducts $R_nZ \leftarrow Z'R_m$.

In complexes with alcohols and secondary amines, the combination of cationic activation of a hydrogen atom in the donor part of the molecule with anionic activation of an alkyl group in the acceptor part leads to extreme readiness to undergo eliminations. Thus *(23)* loses methane to form *(24)*, which contains an N–Be–N–Be–N–Be ring [47].

$$3\,(CH_3)_2\overset{\ominus}{B}e\text{–}\overset{\oplus}{N}H(CH_3)_2 \xrightarrow{44^\circ C} 3\,CH_4 + [CH_3Be\text{–}\ddot{N}(CH_3)_2]_3$$

*(23)* $\qquad$ *(24)*

ate-Complexes of dialkylberyllium derivatives have also been obtained by the action of sodium hydride on dimethylberyllium and on diethylberyllium; the product is probably *(25)* [48a]. Complex salts of diethylberyllium with alkali metal fluorides and cyanides have also been reported [48b].

 *(25)*

In 1952, *Wittig* and *Hornberger* [49] obtained lithium hydridodiphenylberyllate *(26)* by fusion of diphenylberyllium with lithium hydride; they studied the complex (which can provide one hydride ion for reduction) to establish its suitability for the conversion of acyl chlorides into aldehydes. This reduction can be carried out *via* the amide *(27)*, which is obtained from the acyl chloride and carbazole; however, higher yields are obtained with other complex hydrides such as lithium tetrahydridoaluminate, lithium hydrido-tri-n-butoxyborate, and lithium hydridodiphenylzincate. This method was used for the preparation of unsaturated polyene aldehydes, such as cinnamaldehyde and 9-phenylnona-2,4,6,8-tetraenal.

 + $Li[HBe(C_6H_5)_2]$

*(27)* $\qquad$ *(26)*

$\longrightarrow$  + $(C_6H_5)_2Be$ + 
With the aid of an electron-attracting system, it is possible to draw the lone electron pair on the nitrogen into a cyclic π-electron system, so increasing the rate of nucleophilic additions to the carbonyl group. This principle led independently to simple syntheses of aldehydes by the action of lithium tetrahydridoaluminate on *N*-methylanilides [50], acyl imidazolides [51], and acyl pyrazolides [52]. Aldehydes are now

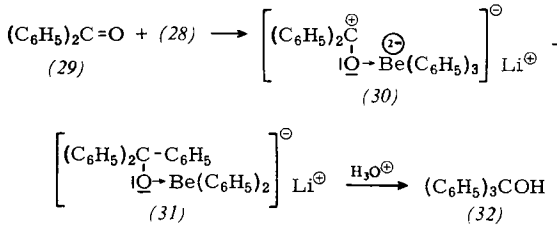
easily accessible by the reaction of amides, nitriles, or acyl chlorides with complex aluminum hydrides[53,54].

Diphenylberyllium reacts with phenyl-lithium to form lithium triphenylberyllate[8] *(28)*. This compound is very stable, suffers practically no decomposition in solution, gives a negative Gilman color test at room temperature[40], and does not metalate fluorene. The rate of metalation of fluorene shows that the tendency of the adducts $[(C_6H_5)_3Z]^{\ominus}Li^{\oplus}$ to dissociate into phenyllithium and diphenylmetal increases in the order:

$$[(C_6H_5)_3Be]Li < [(C_6H_5)_3Zn]Li < ([C_6H_5)_3Mg]Li < [(C_6H_5)_3Cd]Li < [(C_6H_5)_2Hg + C_6H_5Li]$$

*(28)*

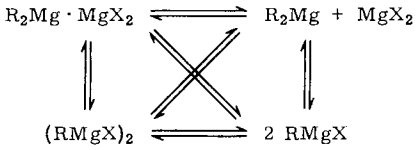
As in inorganic complexes[55], the stability of the complex decreases as the size of the central atom increases. Although *(28)* is inert towards fluorene *(i.e.* it does not dissociate to give phenyl-lithium), it reacts with benzophenone *(29)* to give triphenylmethanol *(32)* in 45 % yield; one must therefore conclude that the ate-complex *(28)* as a whole reacts with the ketone. In contrast to $[(C_6H_5)_4B]Li$, the central atom of *(28)* does not possess a complete octet of electrons in the outer shell; this deficiency can be compensated by addition to the carbonyl oxygen atom to form *(30)*, (yellow, halochromism, cf. Section F. 6):



A molecular-weight determination shows that the ate-complex *(28)* is partially associated in ether. In 1,2-dimethoxyethane at 100 °C, however, it appears to dissociate into phenyl-lithium and diphenylberyllium, since the solution can be used for the metalation of fluorobenzene, so permitting the generation of dehydrobenzene[56].

## D. Complexes of Organomagnesium Compounds

Organomagnesium compounds are extremely important in organic syntheses[6,57,58]. The constitution of Grignard compounds has been the subject of many discussions in recent years, and this question is still not settled[16,59–63c]. Knowledge available at present indicates that the following equilibria are possible, and that the positions of these equilibria depend on the groups R and X (Cl, Br, I), on the solvent, and on the concentration.



The kinetics of the reactions of organomagnesium compounds with ketones are very difficult to interpret because of the problems associated with the constitution of the organometallic compounds[64–69].

*Smith* and *Su*[68a] found simple relationships by following spectroscopically the reaction of 2,4-dimethyl-4′-(methylthio)benzophenone with methylmagnesium bromide, which leads to a 1:1-complex absorbing at 355 mμ. The equilibrium constant K (6.2 l/mole) for complex formation was determined, but it was impossible to distinguish between the kinetic schemes (e) and (f).

$$\text{Ketone} + CH_3MgBr \overset{K}{\rightleftharpoons} \text{1:1-complex} \xrightarrow{k} \text{product}\ [68b] \qquad \text{(e)}$$

$$\text{1:1-Complex} \overset{K}{\rightleftharpoons} \text{ketone} + CH_3MgBr \xrightarrow{k} \text{product} \qquad \text{(f)}$$

*House*[67,69] studied the mechanism of the addition of diethylmagnesium and ethylmagnesium bromide to ketones in the hope of elucidating the factors which in-

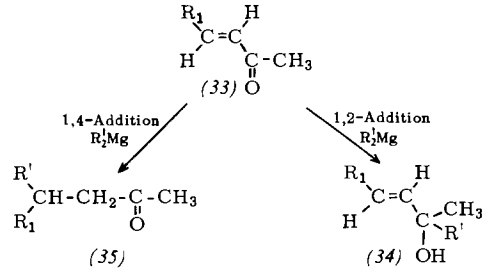
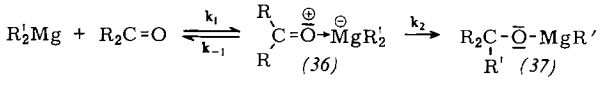
[68b] A similar mechanism was also proposed by *N. M. Bikales* and *E. J. Becker*, Canad. J. Chem. *41*, 1329 (1963), for the addition of methylmagnesium bromide (which was, however, formulated as the dimer) to benzophenone in tetrahydrofuran.

[69] *H. O. House* and *H. W. Thompson*, J. org. Chemistry *28*, 360 (1963).

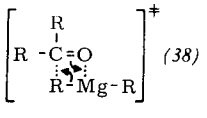
fluence the ratio of 1,2- to 1,4-addition to α,β-unsaturated ketones. On the one hand, the reaction order appears to be the same for both types of addition; on the other, $MgBr_2$ does not accelerate the addition of diethylmagnesium or ethylmagnesium bromide to diethyl ketone, nor does it affect the ratio of 1,2- to 1,4-addition in the reaction with *trans*-pent-3-en-2-one *(33)*, $R_1 = CH_3$, or *trans*-4-phenylbut-3-en-2-one *(33)*, $R_1 = C_6H_5$, to form *(34)* or *(35)*.



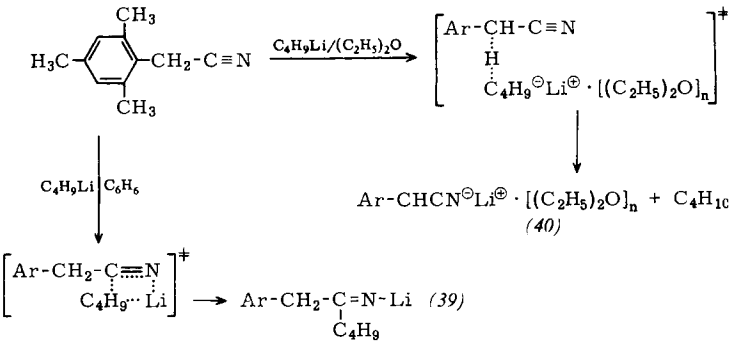
*House's* results [67] are compatible with reversible addition of the magnesium compound to form a complex *(36)*, which then rearranges to give the alkoxide *(37)*. In the system diisopropyl ketone/diethylmagnesium, a transient color that could be due to *(36)* has in fact



been observed; however, spectroscopic measurements have not been possible owing to the high rate of the reaction. *Smith's* results [68] also point to complexes of the type *(36)* as intermediates in which an alkyl residue can easily migrate from the negative magnesium to the carbon; however, since mechanisms (e) and (f) cannot at present be distinguished, direct addition to form *(37)* cannot be completely ruled out. *(38)* has been suggested as a possible transition state in this reaction. The normal

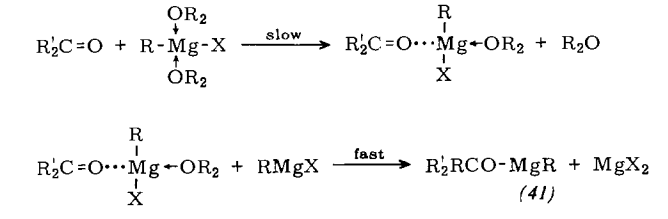


1,2 addition of organomagnesium compounds to C=O (as well as to C≡N and C=N) bonds would then, according to *Dessy* and *Paulik* [70], involve "assisted four-center mechanisms". In many reactions, nucleophilic or electrophilic assistance is provided by coordination in a part of the molecule adjacent to the reaction center. In the reactions discussed here, the coordination of the nucleophilic heteroatom (O,N) to the metal could assist the attack of the alkyl group R on the carbon to form a new C–C bond. Thus the ability of the organometallic compound to donate a carbanion to another reactant is increased, *i.e.* the anionic activation is intensified by formation of an ate-complex [1]. Coordinative assistance may also be provided by the solvent, as can be seen from the difference in the behavior of butyl-lithium in benzene and in ether [reaction to form preferentially *(39)* or *(40)*] [70, 71].



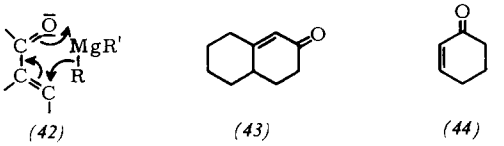
*Ashby* and *Smith* [61] regard the transition state *(38)* as unlikely, and offer the following possible explanations (among others) for the difference in the reactivities of $R_2Mg$ and RMgX and for the appreciable decline in the reaction rate after 50 % conversion in the addition to ketones:

$$2\ RMgX \rightleftharpoons (RMgX)_2$$



The displacement of one molecule of the ether from the complex is regarded as rate-determining, and compound *(41)* would then react more slowly than the Grignard reagent.

It has often been suggested that the 1,4-addition of Grignard compounds to unsaturated ketones involves a six-membered cyclic transition state *(42)*. However, doubt has also been cast on this proposal, since cyclic unsaturated ketones with a *transoid* arrangement of the conjugated system, *e.g.* *(43)* and *(44)*, give comparable quantities of 1,4-adduct [69, 72a]. The addition mechanism is thought to be similar to that of the Michael addition [69].



Ether and dioxane adducts [6] of organomagnesium compounds, as well as an ate-complex *(45)* obtained from diphenylmagnesium and phenyl-lithium, are also known [8]. Although *(45)* dissociates into its components in ether, it appears in some cases to react in the undissociated form. Thus reaction with benzalaceto-

## E. Complexes with Elements of Groups Ib and IIb as the Central Atom

ate-Complexes of all three Group Ib elements are known [72b]. Yellow methylcopper, obtained from methyl-lithium and CuI, is insoluble in ether; when a second mole of methyl-lithium is added, the compound is decolorized and dissolves, owing probably to the formation of lithium dimethylcuprate(I) *(48)* [73]. The diamagnetic complex acetylides *(49)* and *(50)* studied by *Nast* and *Pfab* [74] can be isolated, but they are extremely readily hydrolysed.

| $Li[Cu(CH_3)_2]$ | $K_2[Cu(C{\equiv}C{-}R)_3]$ | $K[Cu(C{\equiv}C{-}R)_2]$ |
|---|---|---|
| *(48)* | *(49)* | *(50)* |

R = H, $CH_3$, $C_6H_5$

No such coordination compounds of bivalent copper can be isolated, since copper(II) ions [75] enter into coupling reactions with both alkynyl and cyanide ions in liquid ammonia. It has been shown that only some of the copper ions are initially reduced to the diphenylethynylcuprate(I) anion *(51)*, accompanied by the formation of diphenylbutadiyne *(52)*.

$$3\,[Cu(NH_3)_4]^{2+} + 6\,IC^{\ominus}{\equiv}C\text{-}C_6H_5 \xrightarrow{NH_3}$$

$$\underset{(51)}{[\overset{II}{Cu}(NH_3)_4]^{2+}[\overset{I}{Cu}(C{\equiv}C\text{-}C_6H_5)_2]^{-}{}_2 \cdot (NH_3)_x} + \underset{(52)}{C_6H_5\text{-}C{\equiv}C\text{-}C{\equiv}C\text{-}C_6H_5}$$

Compound *(51)*, which gives a green solution, loses ammonia when the solvent is evaporated, and is oxidized further to *(52)*. The unstable violet (x = 12) and green (x = 2) complexes *(53)* can be isolated with ethylenediamine ("en").

$$(51) \longrightarrow 3\;Cu\text{-}C{\equiv}C\text{-}C_6H_5 + (x+4)NH_3 + 1/2\;(52)$$

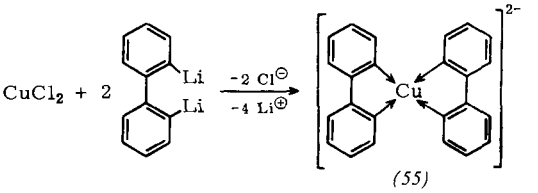
$$[Cu(en)_2]\,[Cu(C{\equiv}C\text{-}C_6H_5)_2]_2 \cdot (NH_3)_x \quad (53)$$

ate-Complexes *(54)* are involved also in the formation of open-chain and cyclic poly-*o*-phenylenes such as *o*-bi-, *o*-tetra-, and *o*-hexaphenylene [76] from 2,2′-dilithiobiphenyl and transition metal chlorides, since the products depend on the nature of the metal, the number of benzene rings in the coupling product often being equal to the coordination number of the metal.

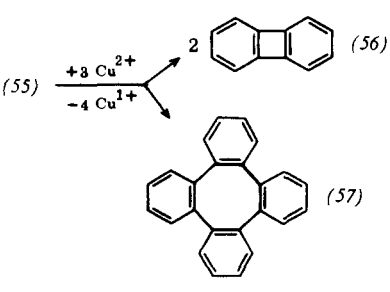
$$M^{2+} + n\,biph^{2-} \rightarrow [M(biph)_n]^{(2n-2)-} \xrightarrow{+(n-1)\,M^{2+}} n\,M + (biph)_n$$

*(54)*

This is confirmed by mechanistic studies carried out by *Wittig* and *Klar* [77] on the action of Cu(II) and Cu(I) salts. The reaction of $CuCl_2$ with 2,2′-dilithiobiphenyl (molar ratio 2:1) to give a 60 % yield of *o*-tetraphenylene *(57)* and 3 % of *o*-biphenylene *(56)* can be explained in terms of a copper(II) ate-complex *(55)*. Under the influence of further copper(II) ions, *(55)* undergoes oxidative coupling to form the cyclopolyenes *(56)* and *(57)*.



*(55)*



The products of the reaction of cuprous chloride with 2,2′-dilithiobiphenyl, which proceeds *via* the complexes *(58)* and *(59)*, include after hydrolysis not only *o*-quaterphenyl (the principal product), but also *o*-tetraphenylene and *o*-octiphenyl, since *(59)* either suffers hydrolysis or undergoes further oxidative coupling.

The organocopper complexes were detected by iodolysis, 55 % of 2,2‴-diiodo-*o*-quaterphenyl being obtained from ether-soluble *(59)*. The ate-complex *(59)* must be very stable, since in the absence of excess copper ions, it gives good yields on reaction with iodine even after two weeks.

[72b] In many cases, the rather unstable organometallic derivatives of the elements of this group are stabilized by addition of donors (phosphines, amines, *etc.*).

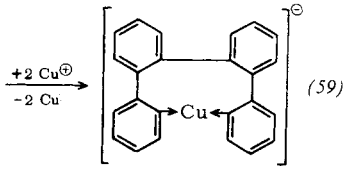
(58)



(59)

Other complexes that have recently been synthesized are lithium diphenylaurate(I) *(60)* [78], potassium dialkynylargentate(I) *(61)* [79] and potassium dialkynylaurate(I) *(62)* [79]. A complex of trivalent gold containing an organic ligand, *i.e.* sodium trichlorophenylaurate(III), was described as early as 1931 [80].

| $Li[Au(C_6H_5)_2]$ | $K[Ag(C{\equiv}C{-}R)_2]$ | $K[Au(C{\equiv}C{-}R)_2]$ |
|---|---|---|
| *(60)* | *(61)* | *(62)* |
| $R = H, CH_3, C_6H_5$ | | $R = C_6H_5$ |

Compounds *(61)* and *(62)*, which are strong electrolytes in liquid $NH_3$, are colorless, readily hydrolysable complexes, the ligands of which can be readily replaced by cyanide ion.

The stability of anionic complexes of organomercury, organocadmium, and organozinc complexes increases markedly in that order. Not only were diethylzinc and ethylzinc iodide among the first organometallic compounds described [81], but the first ate-complex, sodium triethylzincate *(63)*, was prepared by *Wanklyn* in about 1858 from diethylzinc and sodium [82].

$$3\,(C_2H_5)_2Zn + 2\,Na \rightarrow Zn + 2\,Na[Zn(C_2H_5)_3]$$

*(63)*

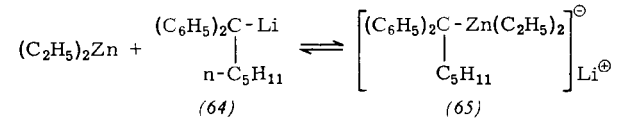
Compounds of the types $M[ZnR_3]$ and $M_2[ZnR_4]$ can be prepared either by the action of a strongly electropositive metal on the organozinc compound or from the components RM and $R_2Zn$ [8, 49, 83]. Conductivity measurements [7, 17, 84] provided important information about the behavior of alkali metal alkyls dissolved in other metal alkyls. Whereas ethylsodium is infusible and ethyl-lithium is non-conducting, whether alone or in benzene, all the alkali metal alkyls studied conduct electricity when dissolved in diethylzinc, the molar conductivities decreasing in the following order:

$$KC_2H_5 > NaC_2H_5 \gg LiCH_3 > LiC_2H_5 > LiC_6H_5$$

Though electrolysis ultimately leads to the decomposition of diethylzinc, it can be shown that an equilibrium must exist in accordance with (g), but not in accordance with (h).

$$Zn[Na(C_2H_5)_3] \overset{(h)}{\rightleftharpoons} NaC_2H_5 + (C_2H_5)_2Zn \overset{(g)}{\rightleftharpoons} Na[Zn(C_2H_5)_3]$$

The molar conductivity is of the order expected for a salt largely associated to ion pairs in a solvent of low dielectric constant [85]. From spectroscopic studies on the ate-complex *(65)* obtained from 1,1-diphenyl-n-hexyl-lithium *(64)* and diethylzinc, *Waack* and *Doran* [86] obtained information about the dissociation constant, the bond energy, and the change in charge on complex formation.



*(64)* *(65)*

Addition of diethylzinc to the deeply colored solution of *(64)* in tetrahydrofuran ($\lambda_{max}$ = 496 mμ) leads to a decrease in extinction and to the appearance of a new maximum ($\lambda_{max}$ = 375 mμ) due to *(65)*. The reversibility of complex formation was demonstrated by removal of the diethylzinc from the equilibrium with butyl-lithium; the equilibrium constant was found to be 103 l/mole in THF/hexane at room temperature, and the energy of the new carbon-zinc bond is estimated to be about 19 kcal/mole.

NMR studies show that the complex formation *(64)* → *(65)* leads to a displacement of the aromatic proton signals to lower fields, while the signals due to the methylene protons of the ethyl groups attached to the zinc are displaced to higher fields. With the aid of an empirical relationship [87] between the change in electron density and the resulting change in chemical shift, it can be estimated that on adduct formation, the electron density on the benzene rings in *(64)* decreases by about 0.36, while a corresponding increase takes place in the diethylzinc moiety in *(65)*. This excess negative charge probably is localized mainly on the zinc.

The phenyl complexes of zinc and cadmium [8] also dissociate in solution, the rate of metalation of fluorene increasing in the order:

$$[(C_6H_5)_3Zn]Li < [(C_6H_5)_7Zn_2]Li_3 < [(C_6H_5)_3Cd]Li$$

*(66)* *(67)* *(68)*

The less acidic fluorobenzene is not metalated by *(66)*, even at 100 °C [56]. The most stable of these adducts,

*(66)*, is monomeric in ether, while *(67)* undergoes partial dissociation to phenyl-lithium and *(66)* under these conditions. Molecular-weight determinations on diphenylmercury alone and in the presence of phenyl-lithium confirm previous chemical experience that organomercury compounds have no appreciable tendency to form complexes. However, complex anions have been obtained with trifluoromethyl ligands on mercury as the central atom [88].

## F. Complexes of Organoboron and Organoaluminum Compounds

### 1. Alkylborates

The stability of the ate-complexes reaches a maximum with Group III elements such as boron and aluminum, since here the addition of electron donors to $ZR_3$ always completes the octet in the outermost shell of the central atom Z. Moreover, in the series $Li[Li(C_6H_5)_2]$, $Li[Be(C_6H_5)_3]$, and $Li[B(C_6H_5)_4]$, the strength with which the phenyl groups are bound increases with the valence and charge of the central atom, *i.e.* in the order $Li < Be < B$.

The chemistry of organoboron and organoaluminum compounds, particularly of the hydrides and alkyl derivatives, has been described in numerous reviews and monographs, which naturally also devote due space to the coordination chemistry of boron [6,53,89–92] and of aluminum [6,93–96].

Trialkyl- and triarylboranes have a strong tendency to complete their octet by coordination. More than 100 years ago *Frankland* [97] found that trimethylborane reacts with ammonia and potassium hydroxide solutions, and in this way he probably prepared (but did not isolate) the first organic borate complex:

$$(CH_3)_3B + KOH \rightarrow K[(CH_3)_3BOH] \quad (69)$$

The alkylborates are readily obtainable, generally either from trialkylboranes, alkyl halides, and sodium [Eq. (i)] [98] or from trialkylboranes and organometallic compounds of alkali metals [Eq. (j)] [29,89,99]. ate-Complexes are also obtained by the action of complex borohydrides on olefins and acetylenes [98b,100].

$$(CH_3)_3B + CH_3Cl + 2\,Na \xrightarrow{-NaCl} Na[B(CH_3)_4] \quad (i)$$

$$R{-}M + B(CH_3)_3 \longrightarrow M[B(CH_3)_3R] \quad (j)$$

$$Na[R_3BH] + CH_2{=}CH{-}R' \longrightarrow Na[R_3B{-}CH_2{-}CH_2{-}R'] \quad (k)$$

$$Na[R_3BH] + HC{\equiv}CR' \longrightarrow Na[R_3B{-}C{\equiv}C{-}R'] + H_2 \quad (l)$$

Some of these complexes have unusual properties, such as solubility in benzene [*e.g.* $LiB(CH_3)_3C_2H_5$] and low melting points [*e.g.* $NaB(C_2H_5)_3H$] [99] so that, as in certain aluminum complexes [94,96], structures containing electron-deficient bonds may have to be considered as well as salt-like structures. The alkali metal tetraalkylborates, which are extremely unstable in air, were characterized by conversion into the more stable tetramethylammonium and tetrabutylphosphonium derivatives, which are sparingly soluble in water [29].

The transfer of negative charge from the boron to the ethyl groups in the ate-complex $Li[B(C_2H_5)_4]$ is reflected in the NMR spectrum, where the signals due to the α-methylene groups are located upfield by 0.5 p.p.m. from that of tetramethylsilane [29,100a]. In oxonium salts, on the other hand, the signals due to the α-methyl or α-methylene protons occur at considerably lower τ values in comparison with the analogous neutral compounds [100b].

The borates $M[BR_4]$ are stable in pure water, but are rapidly hydrolysed on addition of acetic acid; however, only 25 % of the expected quantity of hydrocarbon is liberated rapidly, the remainder being released more slowly. The hydrolysis appears to involve fast protonation of $M[BR_4]$ with loss of one mole of alkane [Eq. (m)], followed by slow hydrolysis of the trialkylborane [Eq. (n)] (cf. also [53,101,102]). In reaction (n), the carbonyl oxygen of the acid probably becomes coordinated to the boron to form *(70)*, and the proton then makes an intramolecular attack on an anionically activated alkyl group. Since *(71)* has a

$$M[BR_4] + CH_3COOH \xrightarrow{fast} MOAc + R_3B + RH \quad (m)$$

$$R_3B + 3\,CH_3COOH \xrightarrow{slow} 3\,RH + B(OAc)_3 \quad (n)$$

smaller tendency than *(70)* to coordinate with another molecule of acid, further hydrolysis proceeds more slowly.

The trialkylboranes[53,103] and the complexes $M[BR_4]$[29] are rapidly oxidized by oxygen. The oxidation of trialkylboranes with aqueous alkaline hydrogen peroxide, which also involves a borate complex *(72)* as an intermediate[53], is important for the conversion of olefins into alcohols by hydroboration. This mechanism, involving the anionic migration of an alkyl group R from boron to oxygen, is in agreement with the retention of configuration that is always observed.

$$R_3B + {}^{\ominus}|O-O-H \longrightarrow [R_3B-O-O-H]^{\ominus} \xrightarrow{-OH^{\ominus}} R_2BOR \text{ etc.}$$

*(72)*

However, an oxidation mechanism of this type is unlikely with the borates $M[BR_4]$, since here the central atom is fully coordinated. Moreover, the oxidation of lithium tetrabutylborate, which leads mainly to n-butanol, does not proceed by dissociation into butyl-lithium and tributylborane. It has been suggested, therefore, that oxygen is inserted directly into the boron-carbon bond, or that a hydroperoxide is formed on the α-carbon atom of the butyl group[29].

The anionic activation of the ligands in ate-complexes may lead not only to a reversible dissociation into the donor and acceptor pair, but also, owing to the transfer of charge from the boron to the adjacent carbon atom in $M[BR_4]$, this carbon atom should tend to lose hydrogen as hydride.

The reverse process, *i.e.* the removal of a proton from the α-carbon atom of onium-complexes, led *Wittig*[43,104] to the "ylides". Thus the inductive attraction of electrons by the central atom in ammonium and phosphonium salts facilitates the formation of anions in the presence of strong proton acceptors, leading *e.g.* from *(12)* and *(73)* to trimethylammonium methylide[44] and methylenetriphenylphosphorane *(74)*, respectively, the parent compounds of the ammonium and phosphonium ylides.

$$\left[(C_6H_5)_3P-\underset{\underset{H}{|}}{\overset{\overset{H}{|}}{C}}-H\right]^{\oplus} Br^{\ominus} \xrightarrow[-LiBr,\ -C_6H_6]{+C_6H_5Li}$$

*(73)*

$$(C_6H_5)_3\overset{\oplus}{P}-\overset{\ominus}{C}H_2 \longleftrightarrow (C_6H_5)_3P=CH_2$$

*(74)*

The Hofmann degradation of quaternary ammonium salts with organolithium compounds also proceeds by initial formation of an ylide *(75)*, followed by β-elimination, *i.e.* it may be regarded as an α′,β-elimination[43,105,106].

$$(CH_3)_2\overset{\oplus}{N}(\overset{\alpha'}{CH_2}\overset{\ominus}{})(H)(H\text{-}\overset{\alpha}{C}\overset{\beta}{C}H_2\text{-}CH_3) \longrightarrow (CH_3)_3N + CH_3\text{-}CH{=}CH_2$$

*(75)*

The deprotonation of the *N,N*-dimethylpyrrolidinium system *(76)* may result in a Grob fragmentation[107] of the ring system[108].

$$\underset{H_3C}{\overset{X^{\ominus}}{\overset{H}{\underset{H}{\overset{\oplus}{N}}}}}\underset{CH_3}{} \xrightarrow[-C_6H_6,\text{-LiBr}]{+C_6H_5Li} \left[\underset{H_3C}{\overset{H}{\underset{H}{\overset{\oplus}{N}}}}\underset{CH_3}{}\right]^{\ominus} \longrightarrow \underset{CH_2}{\overset{CH_2}{\|}} + \underset{CH}{\overset{CH_2}{\|}}\underset{N(CH_3)_2}{}$$

*(76)*

*Jäger* and *Hesse*[109], on the other hand, treated lithium tetrabutylborate *(77)* with hydride acceptors such as benzyl chloride, benzhydryl chloride, and triethyloxonium fluoroborate.

$$Li^{\oplus}\left[(C_4H_9)_3B-\underset{\underset{\delta^-H}{|}}{\overset{\overset{H}{|}}{C}}-C_3H_7\right]^{\ominus} + C_6H_5CH_2Cl \xrightarrow{-LiCl}$$

*(77)*

$$C_6H_5-CH_3 + (C_4H_9)_3\overset{\ominus}{B}-\overset{\oplus}{C}H-C_3H_7$$

*(78)*

The "inverse" ylide *(78)*, in which the positive charge is situated on the carbon and the negative charge on the boron, could not be isolated, but the final products are consistent with its occurrence as an intermediate[109a]. The boron ylide *(78)* undergoes intramolecular anionotropic rearrangement, with migration of a butyl group, to form di-n-butyl-(1-propylpentyl)borane *(79)*, which is capable of undergoing eliminations (to form dibutylborohydride and 3- and 4-octenes) and additions[110].

$$\underset{C_4H_9}{\overset{(C_4H_9)_2B^{\ominus}\text{-}\overset{\oplus}{C}H\text{-}C_3H_7}{\longrightarrow}} \longrightarrow (C_4H_9)_2B-\underset{C_4H_9}{\overset{C_3H_7}{\underset{H}{C}}}$$

*(78)* *(79)*

Thus the final product obtained from *(79)* is a mixture of 3-octene and 4-octene, together with octanols formed by oxidation during the hydrolysis. The stabilization of *(78)* by conversion into *(79)* may be regarded as the counterpart of the Stevens rearrangement of nitrogen ylides.

*Köbrich* and *Merkle*[110a] recently rearranged the borate salt *(79a)*, *via* the supposed boron ylide intermediate

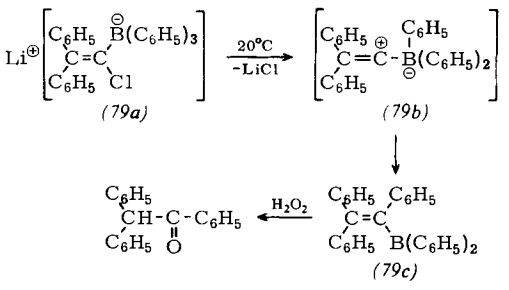
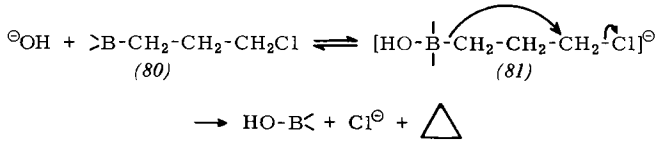
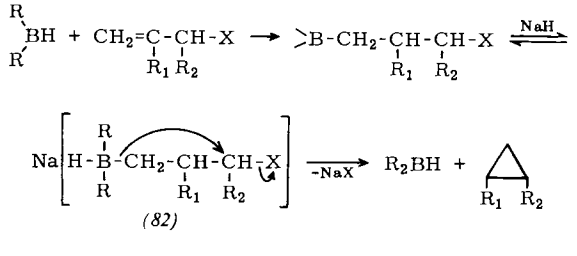
*(79b)*, to the isomer *(79c)*, as indicated by subsequent oxidation to benzhydryl phenyl ketone:



Another example of the reactions of alkylborate complexes is the elegant synthesis of cyclopropane derivatives by *Hawthorne*'s method [111]. In this synthesis, 3-halopropylboranes *(80)* (obtainable by hydroboration of allyl halides) are converted into cyclopropane derivatives by treatment with aqueous alkali metal hydroxide; the product obtained from allyl chloride is cyclopropane itself. The presence of a base is essential to ensure fast reaction, since the increased anionic activation of the alkyl group in the complex *(81)* facilitates the displacement of the chloride ion from the γ-carbon atom. *Binger* and *Köster* [100] improved this synthesis of three-membered rings by the use of sodium hydride. Since the dialkylborane used for hydroboration in the



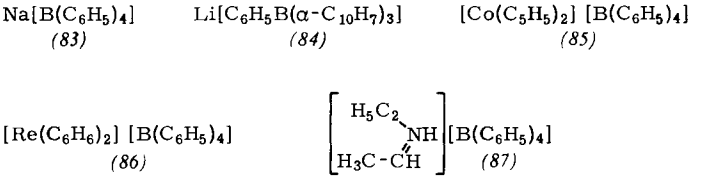
first step is regenerated on cleavage of the ate-complex *(82)*, the overall reaction corresponds to the formation of a three-membered ring system from sodium hydride and an allyl compound.



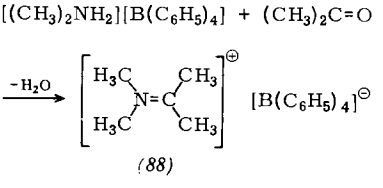
## 2. Arylborates

The most important of the arylborate complexes is sodium (or lithium) tetraphenylborate (Kalignost) *(83)* [112], since this reagent precipitates potassium, rubidium, cesium, silver, thallium, ammonium, and phosphonium cations from aqueous solution, in which the borate complex is completely stable [113].

The complex salt *(84)*, which is readily obtainable from tri-α-naphthylborane and phenyl-lithium, also precipitates many cations ($NR_4$, K, Cs, Rb, Ag, Pb, Hg, Fe), the borates of which being even less soluble than the tetraphenylborates [114]. Thus organic amines in concentrations of 1 mg/10 ml of water can be quantitatively determined with *(84)*, but not with Kalignost. The latter can also be used for the isolation of cationic metal-aromatic π-complexes, as has been shown in the cases of the bis(cyclopentadienyl)cobalt(III) *(85)* [115] and dibenzenerhenium(I) *(86)* [116] complexes. Moreover, the immonium cations [117], which are very unstable even as the tetrafluoroborates and hexachloroantimonates, can be protected against hydrolysis by fast precipitation from aqueous solution with Kalignost [see *(87)*].



Stable immonium tetraphenylborates of this type, *e.g.* *(88)*, can also be obtained directly from alkylammonium tetraphenylborates and ketones or aldehydes [108b, 117].



Reactive cations in general can exist only in the presence of complex anions with very low polarizabilities and low nucleophilic strengths (cf. also triethyloxonium fluoroborate). For example, the first stable tetraphenylbismuthonium salt was isolated as the tetraphenylborate [118].

An interesting group of arylborates comprises the spiro compounds such as *(89)*, which are extremely stable and can be prepared either from 2,2'-dilithiobiphenyl [119] or by decomposition of the complex *(90)* [120]. Asymmetric

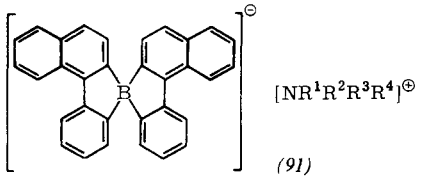
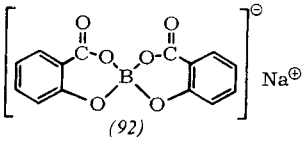
(89) (90)

substitution of such borospiranes leads to optical antipodes, as *Torssell*[121] showed by resolution of *(91)* with an optically active ammonium salt.



(91)

The coordination compound *(92)* containing four boron-oxygen bonds was resolved by *Boeseken* 40 years ago (cf.[121]).



(92)

The stability of *(83)* towards hydrolysis can be further increased by replacement of a phenyl group with a cyanide group as in sodium triphenylcyanoborate *(93)*[112], which is decomposed by aqueous acid only at

$$Na^{\oplus}[(C_6H_5)_3B^{\ominus}\text{-}C{\equiv}N|] \longleftrightarrow [(C_6H_5)_3B^{\ominus}\text{-}C^{\oplus}{=}\underline{\underline{N}}^{\ominus}]^{\ominus}Na^{\oplus}$$

(93)

100 °C. The withdrawal of electrons from the boron atom to the positively charged carbon atom leads to extra reinforcement of the boron-phenyl bonds, and the attack of a proton on this bond during acid hydrolysis becomes more difficult.

In lithium cyanotrihydridoborate *(94)*, the cyano group again decreases the activity of the hydrogen as hydride[112, 122], so that *(94)* does not react with excess of hydrocyanic acid, even at 100 °C. Whereas lithium tetrahydridoborate is slowly decomposed even by water, and decomposes rapidly in the presence of acids, *(94)* liberates hydrogen only when warmed in concentrated mineral acid solutions (quantitatively at 100 °C). Recently prepared

$$Li[BH_4] + HCN \xrightarrow[100°C]{(C_2H_5)_2O} Li[H_3B\text{-}C{\equiv}N] \quad (94)$$

$Li[(C_6H_5)_3BR]$

complexes include the vinyl and allyl compounds *(95)* to *(97)*[123].

According to *Meerwein*[124], esters of boric acid react with alcohols to form complex alkyloxo acids *(98)*, which are much more strongly acidic than the alcohols and can be titrated with bases. Complexes of this type, in which an alcohol has been converted into a relatively strong acid by complex formation, are formed with Lewis acids of many elements[2, 55].

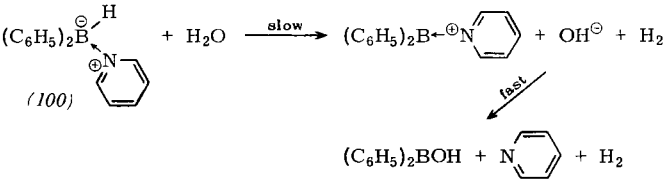
$$(RO)_3B + HOR' \rightarrow H[(RO)_3BOR'] \quad (98)$$

An interesting problem was that of the possibility of achieving a formal dissociation of the benzene molecule into a proton and a complex anion by a suitable sequence of reactions, *i.e.* whether lithium tetraphenylborate could be converted into the corresponding acid *(99)*.

$$\underset{(83)}{Li[B(C_6H_5)_4]} \xrightarrow[-LiCl]{HCl/H_2O} \underset{(99)}{[H_3O]^{\oplus}} + [B(C_6H_5)_4]^{\ominus}$$

When a cold aqueous solution of *(83)* is acidified, all of the added acid can be back-titrated with bases; when the addition is carried out in the warm, however, it leads to rapid formation of triphenylborane and benzene[112]. It appears from kinetic studies[125] that a benzene ring in the tetraphenylborate anion suffers electrophilic attack by a proton with formation of a zwitterionic complex, which then decomposes into benzene and triphenylborane. Thus acid hydrolysis of tetraphenylborate proceeds by the same mechanism as the cleavage of phenylboronic acid into benzene and boric acid, which is known as a "protodeboronation"[126].

Hydrolysis of the pyridine-diphenylborane adduct in acetonitrile leads to diphenylborinic acid, hydrogen,



(100)

and pyridine[127]. On the basis of the kinetic isotope effects observed in the hydrolysis of the deuterated complex ($k_H/k_D$ = 1.52) and in the deuterolysis ($k_H/k_D$ = 6.9) a transition state *(101)*, corresponding to electrophilic substitution on the carbon, was proposed[128].

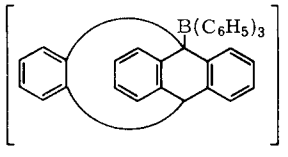
### 3. Complexes with Tritylsodium

The ate-complexes obtained from tritylsodium with Lewis acids such as triphenylborane, triphenylaluminum, and diphenylberyllium occupy a special position since, owing to steric factors, some of these complexes dissociate strongly in accordance with Eq. (o), as is shown by the bright red color of their solutions [129, 133, 135].

$$Na[(C_6H_5)_3C\text{-}Z(C_6H_5)_n] \rightleftharpoons (C_6H_5)_3CNa + (C_6H_5)_nZ \qquad (o)$$

Z = B, Al, Be

Since the tritylsodium-triphenylborane adduct is colored even in the crystalline state, it was presumed that the electron pair of the trityl anion is not covalently bonded to boron, but is delocalized over the phenyl groups, as in tritylsodium itself [129].



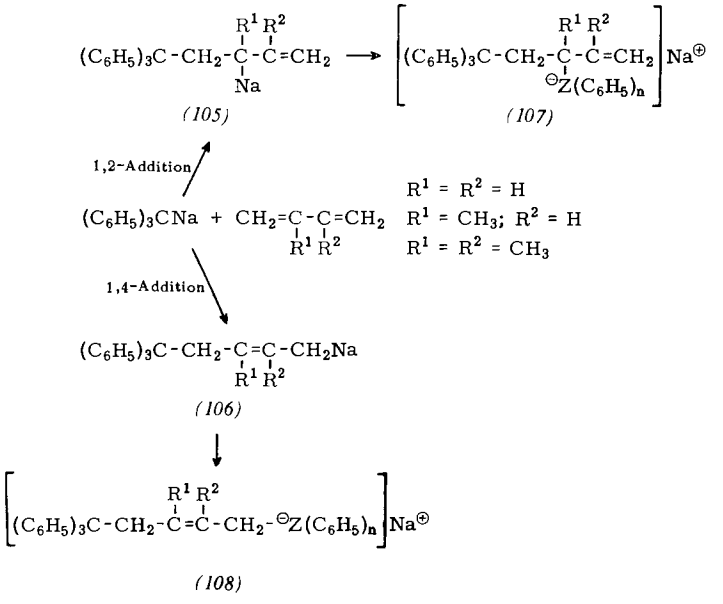
*(102)*

On the other hand, the colorless ate-complex *(102)* obtained from triptycyl-1-lithium and triphenylborane is not detectably dissociated, and is stable even in water [130]. In the colorless triptycyl-1-lithium, mesomeric delocalization of the carbanion electron pair is impossible, in contrast to tritylsodium; moreover, the steric conditions in *(102)* are more favorable for adduct formation. Complexes *(103)* and *(104)* are also relatively stable [131]. The triphenylsilyl group in *(104)* cannot be replaced by a phenyl group by use of phenyllithium.

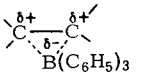
$[(C_6H_5)_3Ge\text{–}B(C_6H_5)_3]Li$ *(103)*

$[(C_6H_5)_3Si\text{–}B(C_6H_5)_3]Li$ *(104)*

Lewis base/Lewis acid pairs such as tritylsodium/triphenylborane, which do not react irreversibly with each other, permit the reaction of, for example, tritylsodium with a suitable substrate to form a new organosodium compound, which can be trapped immediately with triphenylborane. The polymerization of butadiene derivatives with tritylsodium as initiator [132] has been studied in this way; the organometallic compounds formed, *(105)* and *(106)*, do not polymerize by further addition to the diene, but can be trapped as the ate-complexes *(107)* and *(108)* in the presence of Lewis acids $(C_6H_5)_nZ$ (triphenylborane, triphenylaluminum, diphenylberyllium, diphenylmagnesium) [133]. Since the adducts *(107)* and *(108)* and the hydrocarbons formed on hydrolysis can be studied spectroscopically, the proportions of 1,2- and 1,4-addition can be estimated. It is found that as the stability of the ate-complexes *(107)* and *(108)* decreases (B > Al > Be > Mg), the course of the polymerization approaches that followed in the absence of complexing agents.

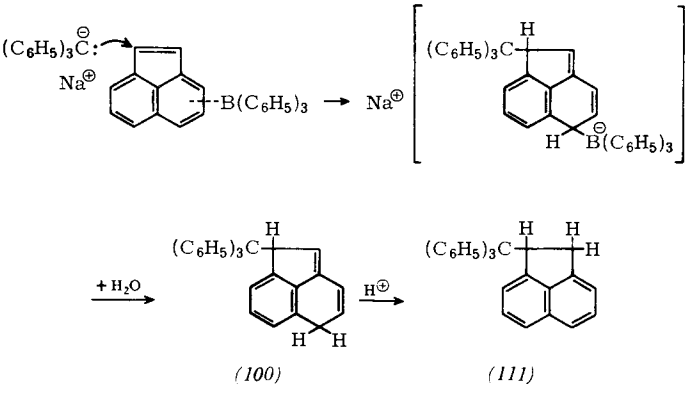


The interesting discovery that the relatively inert 2,3-dimethylbutadiene is not attacked by tritylsodium alone, but forms an adduct *(107)* when triphenylborane is present, and that the dehydrochlorination of vinyl chloride with tritylsodium is accelerated by triphenylborane, indicates that the boron compound promotes reactions at the double bond, possibly by formation of a π-complex *(109)*



*(109)*

The polymerization of acenaphthylene controlled with tritylsodium in the presence of triphenylborane [129] leads, by a supposed 1,6-addition of the Lewis base/Lewis acid pair followed by hydrolysis, to the unsaturated hydrocarbon *(110)*. This rearranges in the presence of acids to 1-tritylacenaphthene *(111)*.



The fact that triphenylborane does not form adducts with bulky organometallic compounds of alkali metals, *e.g.*

[129] *G. Wittig, H. G. Reppe*, and *Th. Eicher*, Liebigs Ann. Chem. *643*, 47 (1961).

[130] *G. Wittig* and *W. Tochtermann*, Liebigs Ann. Chem. *660*, 23 (1962).

[131] *D. Seyferth, G. Raab*, and *S. O. Grim*, J. org. Chemistry *26*, 3034 (1961).

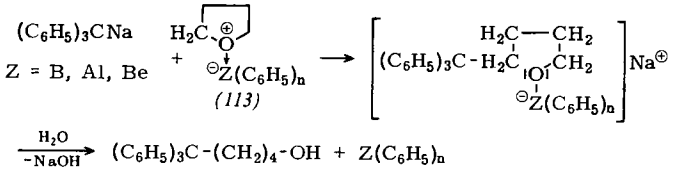
[132] *K. Ziegler* and *L. Jakob*, Liebigs Ann. Chem. *511*, 45 (1934).

[133] *G. Wittig* and *H. Schloeder*, Liebigs Ann. Chem. *592*, 38 (1955); *G. Wittig* and *D. Wittenberg*, *ibid. 606*, 1 (1957).

*(112)*, or that where such adducts are formed they are largely dissociated, permits the formation of C=C double bonds with elimination of metal hydride [1, 134].

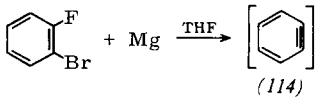
$$(C_6H_5)_2NaC-CH_2-CH_2-CNa(C_6H_5)_2 + 2\,(C_6H_5)_3B \rightarrow$$
*(112)*
$$2\,Na[HB(C_6H_5)_3] + (C_6H_5)_2C{=}CH-CH{=}C(C_6H_5)_2$$

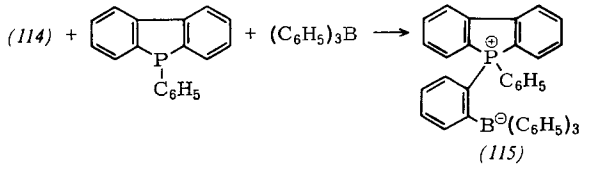
The ability of such acid-base pairs to attack suitable molecules nucleophilically and electrophilically at the same time provides a new method for the cleavage of cyclic ethers such as tetrahydrofuran, 2,5-dihydrofuran, coumaran, and dioxane. In the onium-ate-complex *(113)*,



the ether linkage is weakened to such an extent that nucleophilic attack of tritylsodium on α-carbon atom, which also carries a partial positive charge, leads to ring scission [134, 135].

The Lewis acid/Lewis base pair triphenylborane/2,2′-biphenylylenephenylphosphine has been found useful for the detection of dehydrobenzene; the betaine *(115)* is formed [136].



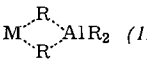


Reviews have appeared on the complex adducts of boranes and boron halides with electron donors [6, 89, 90, 137], as well as on aminoboranes [138] and radical-anions of boron compounds [6].

## 4. Alkylaluminates

*Ziegler* [93–95] and *Lehmkuhl* [96] have recently reviewed alkylaluminium complexes, which have become important also in industrial processes.

Here it need only be emphasized that the low conductivities, the volatilities, and the solubilities in non-polar solvents of the complexes $M_m[AlR_4]_n$ indicate that in addition to ionic structures, structures containing electron-deficient bonds *(116)* must also be considered, depending on the alkali or alkaline-earth cation (particularly where M = $C_2H_5Mg$, Mg, Li, Ca, and Sr) [138a].



*(116)*

$2\,[Al(C_2H_5)_4]^{\ominus}\,[Ca(THF)_2]^{2\oplus}$ *(117)*

The conductivities of molten alkali metal and alkaline-earth metal tetraethylaluminates indicate that the salt-like character increases with the atomic number of M [94, 96].

On solvation of the cation by electron donors, *e.g.* as in *(117)*, the tendency towards ionization is found to increase. Thus the conductivity of calcium tetraethylaluminate can be greatly increased by the addition of tetrahydrofuran [96].

## 5. Arylaluminates

Although lithium tetraphenylaluminate [139] gives a negative Gilman color test [40], it is readily hydrolysed by water, unlike lithium tetraphenylborate. The hydrolysis probably does not proceed *via* an equilibrium between $Li[Al(C_6H_5)_4]$ and free phenyl-lithium + triphenylaluminum, since $Li[Al(C_6H_5)_4]$ does not give carbinols either with benzophenone or with esters of benzoic acid. The ease of hydrolysis of $Li[Al(C_6H_5)_4]$ in comparison with $Li[B(C_6H_5)_4]$ is due partly to size relationships and to the difference in electronegativity between the central atom and carbon. Moreover, intermediates with coordination numbers higher than four are possible in the case of aluminum. $Li[Al(C_6H_5)_4]$ reacts with acyl chlorides such as benzoyl and acetyl chlorides to form ketones (benzophenone and acetophenone). In this case the aluminate complex must react as a whole with the acyl chloride, which probably attacks the aluminum-carbon bond electrophilically.

$$Li[Al(C_6H_5)_4] + R-CO-Cl \xrightarrow[-LiCl,\,-Al(C_6H_5)_3]{} C_6H_5-CO-R$$
$$R = C_6H_5;\ CH_3$$

This example illustrates how the reactivity of an organometallic compound can be either increased or decreased (as shown above for phenyl-lithium, which alone gives carbinols with acyl chlorides) by complex formation; this is referred to by *Wittig* [1] as an "accelerando" or "ritardando" effect.

Whereas in organolithium compounds (see Section B.3) complex solvation of the lithium cation by Lewis bases increases the tendency towards ionization and dissociation, and hence the reactivity, complex formation with a Lewis acid such as triphenylaluminum (which engages the lone electron pair of the potential carbanion) leads to a decrease in reactivity; depending on the nature of the complexing agent, this may result either in retardation or in complete suppression of reactions otherwise characteristic of the lithium compound.

[134] *G. Wittig* and *A. Rückert*, Liebigs Ann. Chem. *566*, 101 (1950); *G. Wittig* and *W. Stilz*, *ibid. 598*, 85, 93 (1956). This elimination is mechanistically the counterpart of the formation of tetraphenylbutadiene from tetraphenylbutane-1,4-diol with acids; see the discussion in [1].

[138a] See also *K. Mach*, J. organomet. Chemistry *2*, 410 (1964).

[139] *G. Wittig* and *G. Keicher*, Naturwissenschaften *34*, 216 (1947); *G. Wittig* and *O. Bub*, Liebigs Ann. Chem. *566*, 113 (1950).

Sodium tetraphenylaluminate was recently prepared from sodium tetraethylaluminate and benzene [Equation (p)]; the anionic displacement of the ethyl groups by phenyl groups is catalysed by sodium alkoxide or phenylsodium, so that the true reactant, *i.e.* phenylsodium, can be continuously replaced as it is consumed [96].

$$Na[Al(C_2H_5)_4] + 4\,C_6H_6 \xrightarrow{NaOR(NaC_6H_5)} Na[Al(C_6H_5)_4] + 4\,C_2H_6 \quad (p)$$

## 6. Triphenylaluminum and Carbonyl Compounds

In contrast to $Li[Al(C_6H_5)_4]$, triphenylaluminum reacts slowly with ketones to form carbinols [139]. When allowed to stand for 16 days at room temperature with benzophenone, it gives triphenylmethanol in 23 % yield [140]. The carbonyl oxygen presumably contributes a lone pair of electrons to complete the electron octet of the aluminum, with rapid and possibly reversible formation of an adduct *(118)*; the rate-determining step is

$$(C_6H_5)_2C^{\oplus}\text{-}\underline{O}\text{-}^{\ominus} + Al(C_6H_5)_3 \rightleftharpoons \left[(C_6H_5)_2C^{\oplus}\text{-}\underline{O}\text{-}Al^{\ominus}(C_6H_5)_3\right] \quad (118)$$

$$\longrightarrow (C_6H_5)_2C(C_6H_5)\text{-}\underline{O}\text{-}Al(C_6H_5)_2 \quad (119)$$

the conversion of this adduct into *(119)* by anionic migration of a phenyl group from the now negatively charged aluminum to the positively charged carbon. This is consistent with the fact that benzaldehyde in boiling xylene reacts with triphenylborane to give diphenylmethanol, though only in moderate yield [141].

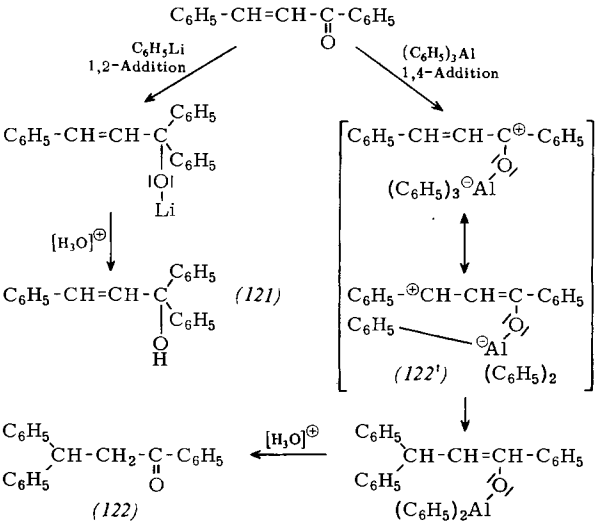
Although the reactions of benzophenone with phenyllithium and with triphenylaluminum (which together form the complex $Li[Al(C_6H_5)_4]$) lead to the same product, *viz.* triphenylmethanol, the reaction with phenyl-lithium (which gives a carbanion more readily) proceeds more rapidly in ether solution. Since the anionic activation of the group R in RLi is generally increased by the addition of donors, a fast and reversible addition of the carbonyl oxygen of ketones to the Li in RLi has been suggested [142].

The initial formation of complexes of the type *(118)* is also indicated by the transient yellow to red color observed during the reaction of triphenylaluminum with ketones such as benzalacetophenone, which indicates resonance-stabilized adducts such as *(120)*.

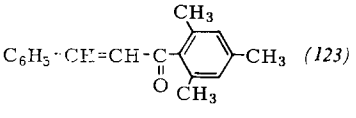
$$C_6H_5\text{-}CH{=}CH\text{-}C^{\oplus}(C_6H_5)\text{-}\underline{O}\text{-}(C_6H_5)_3Al^{\ominus} \longleftrightarrow C_6H_5\text{-}{}^{\oplus}CH\text{-}CH{=}C(C_6H_5)\text{-}\underline{O}\text{-}(C_6H_5)_3Al^{\ominus} \quad (120)$$

Halochromic effects of this type were observed and interpreted by *Pfeiffer* [143] and *Meerwein* [144] for the interaction of aluminum halides and aluminum alkyls with aldehydes and ketones.

*Wittig* and *Schliesser* [145] studied the addition of phenyllithium and triphenylaluminum to unsaturated aldehydes and ketones in relation to 1,2- and 1,4-addition, *e.g.* to form *(121)* or *(122)*.



Where the carbonyl group is sterically unhindered, as in cinnamaldehyde, both reagents add in the 1,2-position. If, on the other hand, attack on the C=O group is sterically hindered, phenyl-lithium still adds preferentially in the 1,2-position, but $Al(C_6H_5)_3$ adds exclusively in the 1,4-position. When the hindrance is particularly strong, as in 1-mesityl-3-phenylpropenone *(123)*, in which a phenyl anion cannot add to the carbonyl carbon from any direction, both $Al(C_6H_5)_3$ and $LiC_6H_5$ are restricted to 1,4-addition.



In order to check whether the easy 1,4-addition proceeds from an adduct *(122')* *via* a six-membered cyclic transition state, $Al(C_6H_5)_3$ was treated with 1,5-diphenylpenta-2,4-dienone *(124)*. The only product obtained was 1,3,5-triphenylpent-4-enone *(125)*, which is formed by 1,4-addition; no 1,6- or 1,2-addition products were detected.

[142] *C. G. Swain* and *L. Kent*, J. Amer. chem. Soc. *72*, 518 (1950); see also *P. D. Bartlett* in *H. Gilman*: Organic Chemistry. Wiley, New York 1953, Vol. 3, p. 96.

[143] *P. Pfeiffer*, *K. Kollbach*, and *E. Haack*, Liebigs Ann. Chem. *460*, 138 (1928).

[144] *H. Meerwein*, *G. Hinz*, *H. Majert*, and *H. Sönke*, J. prakt. Chem. [2] *147*, 226 (1937).

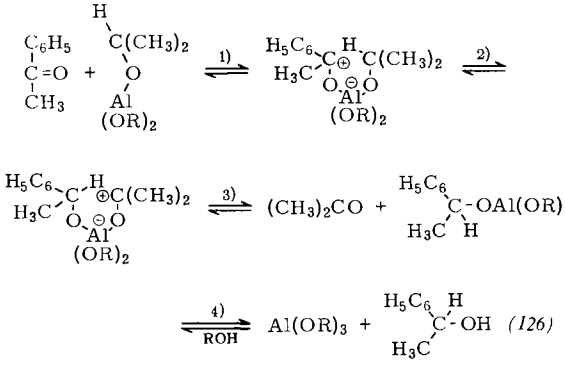
[145] *W. Schliesser*, Dissertation, Universität Tübingen, 1953.

Whereas the results obtained by *House*[67,69] make a six-membered transition state in the 1,4-addition of organomagnesium compounds to unsaturated ketones appear unlikely (see the end of Section D), no 1,4-addition product is obtained in the reaction of $Al(C_6H_5)_3$ with 2-cyclohexenone. The only products, apart from a little of the 1,2-addition product, are polymers. Thus in the case of aluminum, it is necessary to consider the possibility that the 1,4-addition actually takes place *via (122')*, proceeding through a six-membered cyclic transition state.

### 7. Hydride Shifts

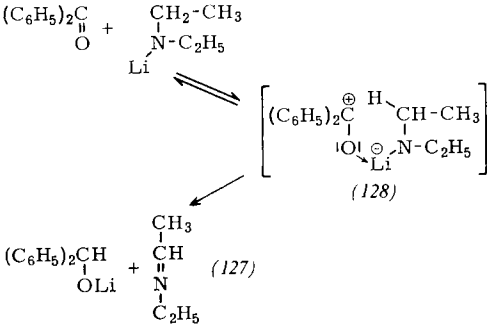
The addition of triphenylaluminum to ketones is closely related in its mechanism to the reduction of carbonyl compounds (and to the Oppenauer oxidation) with triethylaluminum[144], esters of boric acid[146], aluminum alkoxides[147,148], and Grignard compounds[149]. In this reduction, a hydride ion can move from one carbon atom to another because of a favorable steric arrangement and the anionic activation of the hydrogen due to the negative central atom[150]. The reduction with aluminum alkoxides involves the following steps:

1. coordination of the ketone with the monomeric or polymeric alkoxide,
2. hydride shift,
3. separation of the ketone formed in step 2 from the complex,
4. alcoholysis of the mixed alkoxide to form the alcohol obtained.



On the basis of NMR studies, *Shiner* and *Whittacker*[151] postulated fast, reversible complex formation of the trimeric and tetrameric aluminum isopropoxides[152] with acetone in toluene without previous dissociation of the alkoxide into the monomer. The spectroscopically studied formation of 1-phenylethanol *(126)* from acetophenone and trimeric or tetrameric Al-isopropoxide in benzene/isopropanol is much slower than that of acetone; it follows that the rate-determining step in this case is not the hydride shift *(2)*, as is usually assumed, but the alcoholysis of the mixed alkoxide *(4)*.

The question arises of whether the coordinating tendency of lithium is sufficient to induce a redox reaction *via* a coordination step (as is possible with boron, aluminum, and magnesium derivatives). *Wittig*[153] recently used lithium diethylamide to reduce benzophenone to lithium diphenylmethoxide, the secondary amine being converted into the Schiff base *(127)* by "Oppenauer oxidation". Since *(127)* is metalated by lithium diethylamide and adds to excess ketone (directed



aldol condensation[153,154]), the system benzophenone/lithium *N*-benzylanilide, in which secondary reactions of this nature do not occur, was studied kinetically. The formation of the Schiff base was found to be first order with respect to each of the components. Since a transient color, probably due to *(128)*, appears in the course of this reaction, the question again arises of whether the hydride shift takes place *via* an onium-ate-complex *(128)*[155].

The reducing action of metalated amines was already known from the reductive dehalogenation of a number of aryl halides[156–159], and the oxidation product, *i.e.* the Schiff base, had even been isolated in one case[157a]. However, the nucleophilic displacement of the halide ion by a hydride ion, as was previously postulated[156b,157b], seems less likely than the transfer of lithium hydride to dehydrobenzene.

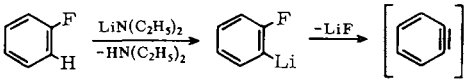
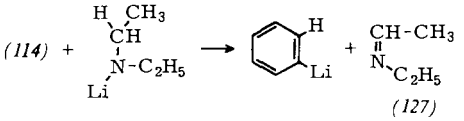
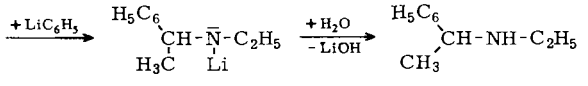
The hitherto unexplained discovery[160] that the principal product obtained from fluorobenzene, phenyllithium, and diethylamine (1:2:1) is 1-phenyldiethylamine *(130)* can also be explained in this way. Dehydrobenzene and lithium diethylamide react by a hydride



*(114)*



*(127)*



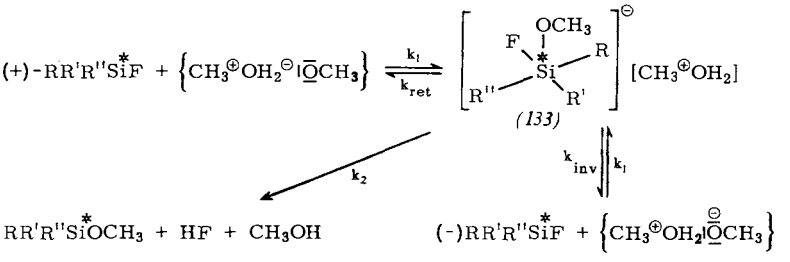
*(129)* *(130)*

shift to form phenyl-lithium and the Schiff base *(127)*, which is trapped by addition of phenyl-lithium to form *(129)*; this is converted on hydrolysis into the amine *(130)*.

in t-butanol or pentane, in which no other perceptible reaction occurs, can also be explained, according to *Sommer* and *Rodewald*[163], only by assuming a complex *(133)* containing 5-coordinate silicon, particularly since the methoxysilane $RR'R''SiOCH_3$ cannot occur as an intermediate. The addition of a methoxide anion to the silicon would lead to the adduct *(133)*, in which the fluorine and the three organic ligands form the base of a tetragonal pyramid with the methoxy group at the apex.

The intermediate *(133)* itself, which probably exists as a methanol-stabilized ion pair, would be optically active and could be re-converted into RR'R''SiF, either with retention or inversion of configuration, depending on which substituents (*e.g.* R and R'' or R' and F) move towards the methoxy group as the latter leaves; the silicon atom in *(133)* need not lie in the same plane as the substituents R,R',R'', and F. The observations can naturally also be explained in terms of a 6-coordinate silicon complex with two methoxy groups, although such an intermediate is less likely.

Salts of a complex silicate *(134)* in which the central atom is attached to three molecules of catechol were reported as early as 1931[164]. Compounds of this type can be readily prepared from tetraethyl orthosilicate, catechol, and amines[165]; this reaction can also be used

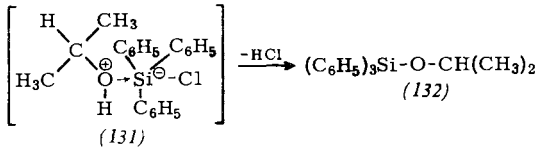


*(133)*

## G. Complexes with Group IV Elements

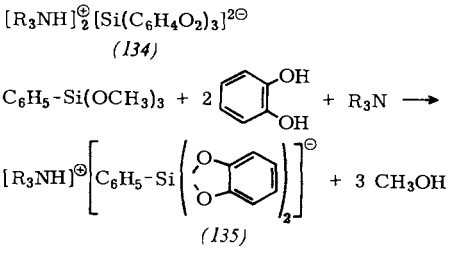
Using its d-orbitals silicon can expand its outer shell to accommodate more than eight electrons, so that substitutions on 4-coordinate silicon may proceed *via* 5-coordinate intermediates or by a type of $S_N2$ mechanism[161,167].

Kinetic studies[162] on the reaction of 2-propanol with triphenylchlorosilane in the presence of hydrochloric acid indicate, *e.g.*, an intermediate containing 5-coordinate silicon *(131)*, which decomposes to form triphenylisopropoxysilane *(132)*. The racemization of optically active α-naphthylphenylmethylfluorosilane with methanol



*(131)* *(132)*

for the synthesis of derivatives *(135)* which may contain 5-coordinate silicon. The method fails with coordination compounds containing more than one Si–C



*(134)*

*(135)*

bond. However, the structure of anions such as *(134)* has not yet been fully elucidated, since according to *Weiss*[166] they are dimeric, and can therefore be formulated with a coordination number of either 4 or 6 for the silicon. Attempts to resolve *(134)* into optical antipodes have so far been unsuccessful[166].

[160] *W. Merkle*, Dissertation, Universität Freiburg, 1942.

[163] *L. H. Sommer* and *P. G. Rodewald*, J. Amer. chem. Soc. *85*, 3898 (1963).

[164] *A. Rosenheim, B. Raibmann*, and *G. Schendel*, Z. anorg. allg. Chem. *196*, 160 (1931).

[165] *C. L. Frye*, J. Amer. chem. Soc. *86*, 3170 (1964).

[166] *A. Weiß, G. Reiff*, and *A. Weiß*, Z. anorg. allg. Chem. *311*, 151 (1961).

It is also likely that substitution in organotin compounds involves the formation of ate-complexes with more than eight electrons in the outermost shell of the tin atom. According to *Dessy* [167], nucleophilic assistance by anions is important in the acetolysis of tri-n-butyltin hydride in dimethyl sulfoxide (and in aprotic solvents in general), since lithium salts, which can be added to form *(136)*, cause a marked increase in the rate of the reaction. In the ate-complex *(136)* [168], the hydrogen is more mobile as hydride, and so becomes more accessible to attack by acetic acid.

$$(n\text{-}C_4H_9)_3SnH + LiX \xrightarrow[DMSO]{fast} \left[(n\text{-}C_4H_9)_3Sn\begin{matrix}X\\H\end{matrix}\right]^{\ominus} Li^{\oplus}$$

*(136)*

$$(136) \xrightarrow[CH_3COOH]{slow} (n\text{-}C_4H_9)_3SnOAc + H_2 + LiX$$

Nucleophilic assistance and acceleration probably occur in many nucleophilic substitutions involving elements with an incomplete octet or which can expand their outer shell.

The transmetalation reaction (q) [169], which is characteristic of organotin and organolead compounds, and which has recently been used for the preparation of vinyl-lithium and allyl-lithium compounds [170], could also involve ate-complexes such as *(137)*, with 5- or 6-coordinate metal, as intermediates. Reaction (q) in-

$$R_4M + R'Li \rightleftharpoons [R_4MR']Li \rightleftharpoons R_3MR' + RLi \qquad (q)$$

$M = Sn, Pb$ ? *(137)*

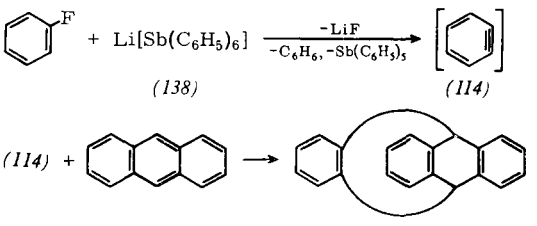
volves a series of equilibria and proceeds in the cases studied (R = propenyl) with retention of the geometrical configuration of the group R in $R_4Sn$ [170].

Salts containing complex organotin anions and large organic cations have been known for some time [171, 172].

## H. Complexes with Elements of Groups V and VI

Pentaphenylphosphorus, -arsenic, -antimony, and -bismuth [173] are covalent compounds with the unusual coordination number of 5, in which the outermost shell of the central atom contains ten electrons. Pentaphenylantimony, which reacts with phenyl-lithium to form the isolable lithium hexaphenylantimonate *(138)*, was the first of the pentacovalent compounds of the Group V elements to which an anion was added to give twelve electrons in the outer shell of the central atom [173].

In solution, *(138)* exists in equilibrium with $Sb(C_6H_5)_5$ and $LiC_6H_5$, as is shown by the fact that fluorene can be metalated by the solution. The slight dissociation corresponds to the use of phenyl-lithium at very low concentrations, and enabled *Wittig* and *Benz* [174] to develop a simple one-stage preparation of triptycene from *(138)*, fluorobenzene, and anthracene. "Free" phenyl-lithium would largely suppress the Diels-Alder reaction of dehydrobenzene with anthracene by addition to the former.



*(138)* *(114)*

*(114)*

Compound *(138)* can be used for the metalation of chloroform or benzyl chloride. In the presence of cyclohexene up to 60 % of dichloronorcarane and 15 % of phenylnorcarane are obtained [56]. The anionic ligand exchange between tetraphenylstibonium bromide and methyl-lithium, which ultimately leads to pentaphenylantimony, could also proceed *via* ate-complexes *(139)* [175, 176].

$$[(C_6H_5)_4Sb]Br \xrightarrow[-LiBr]{+2CH_3Li} [(C_6H_5)_4Sb(CH_3)_2]Li$$

*(139)*

$$\xrightleftharpoons[+C_6H_5Li]{-C_6H_5Li} [(C_6H_5)_3Sb(CH_3)_2]$$

$$[(C_6H_5)_4Sb]Br + C_6H_5Li \xrightarrow[-LiBr]{} (C_6H_5)_5Sb$$

Conversely, on reaction of pentaphenylantimony with butyl-lithium, 47 % of the pentabutylantimony was found, after hydrolysis, as tetrabutylstibonium tetraphenylborate, while methyl-lithium with pentaphenylantimony yields pentamethylantimony [177]. Since no ate-complex is formed by combination of phenyl-lithium with pentaphenylphosphorus [173, 178] or pentaphenylarsenic [173], an equilibrium similar to that of *(138)* appears to lie very much to the side of the dissociation products. Although the phosphorus [177, 178] and arsenic [179] compounds undergo ligand exchange with organolithium compounds without difficulty, it is not certain whether ate-complexes occur as intermediates (which seems likely), or whether the substitutions proceed by an $S_N2$-type mechanism.

[174] *G. Wittig* and *E. Benz,* Tetrahedron *10*, 37 (1960).

[175] *G. Wittig* and *K. Torssell,* Acta chem. scand. *7*, 1296 (1953).

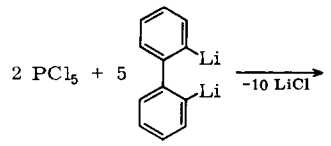
[176] The only pentaalkyl derivative obtained so far is pentamethylantimony.

[177] *G. Wittig* and *G. Steinhoff,* unpublished work.

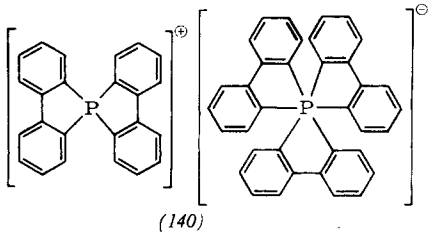
[178] *M. Schlosser* and *T. Kadibelban,* personal communication.

[179] *D. Hellwinkel,* personal communication.

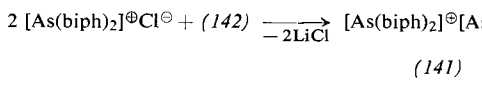
*Hellwinkel* [179,180] has found that phosphorus and arsenic can form stable complexes *(140)* and *(141)* in which they have the coordination number 6. These



*(142)*



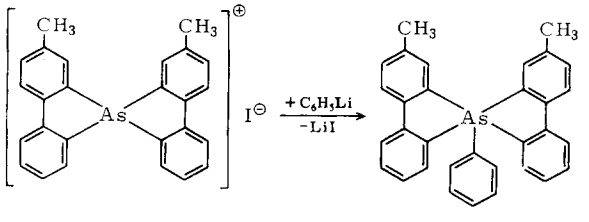
*(140)*



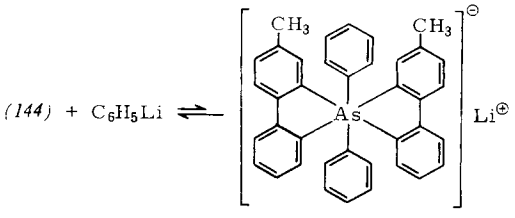
*(141)*

complexes can be cleaved by alkali metal halides; the product obtained from *(140)* + NaI is sodium tris(2,2'-biphenylylene)phosphate(V), which can be resolved into optical antipodes, so that the octahedral structure of this complex can be regarded as certain.

The loss of optical activity observed when the optically active arsonium iodide *(143)* is treated with phenyl-lithium may be due to reversible addition of further $LiC_6H_5$ to the active initial product *(144)* to form the ate-complex *(145)*, which would necessarily lead to the racemization of *(144)* [181].



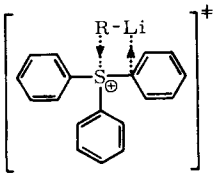
*(143)* *(144)*



*(145)*

[180] *D. Hellwinkel*, Angew. Chem. *76*, 756 (1964); *77*, 378 (1965); Angew. Chem. internat. Edit. *4*, 356 (1965); Chem. Ber. *98*, 576 (1965).

Attempts to prepare $Li[Te(C_6H_5)_5]$ have been unsuccessful [182]. *Franzen* and *Merz* [183] observed rapid ligand exchange between triarylsulfonium and triaryltelluronium salts and organolithium compounds. The authors favor the assumption that the exchange proceeds neither *via* an intermediate containing 4-coordinate sulfur or tellurium nor *via* a 5-coordinate ate-complex, but that it involves a cyclic transition state *(146)* of the sulfonium or telluronium stage, in which the aryl or alkyl group of the organolithium compound acts as the donor and the lithium cation as the acceptor.



*(146)*

However, other possible routes must also be considered in the case of tellurium, since *Hellwinkel* and *Fahrbach* [179] have shown that tetraaryltellurium derivatives undergo rapid substituent exchange with organolithium compounds [*].

## I. Conclusion

This review attempts to demonstrate that the basic concept of anionic activation of ligands in ate-complexes, as a counterpart to cationic activation in onium-complexes, is a useful one. Further investigations will have to show the extent to which these views can be generalized.

*I wish to thank Prof. Dr. Dr. h.c. G. Wittig for valuable discussions and for access to his unpublished results, as well as for critical examination of the manuscript, for which I am also grateful to Dr. H. F. Ebel, Dr. H. Küppers, and Dr. J. R. F. Fairbrother.*

# The Chemistry of α-Carbonyl Azo Compounds

BY PRIV.-DOZ. DR. E. FAHR AND DR. H. LIND

CHEMISCHES INSTITUT DER UNIVERSITÄT WÜRZBURG (GERMANY)

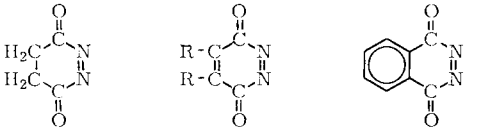
*α-Carbonyl azo compounds such as diesters of azodicarboxylic acids, diacylazo compounds, and esters of arylazocarboxylic acids are highly reactive. They add e.g. to amines, aromatic compounds, olefins, CH acids, Grignard and diazo compounds, aldehydes, ketones, and ketenes. These reactions can be used for the preparation of triazanes, hydrazones, oxadiazoline, azomethinimine, and diazetidine derivatives, etc. α,α'-Dicarbonyl azo compounds are among the strongest dienophiles known.*

## 1. Introduction

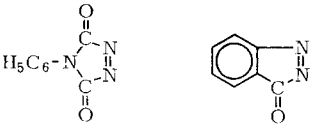
α-Carbonyl azo compounds contain one carbonyl function (R–N=N–CO–R', R–N=N–COOR') or two carbonyl functions (R–CO–N=N–CO–R', ROOC–N=N–COOR') adjacent to the azo group. These substances take part in a wide variety of reactions, and differ from the aliphatic and aromatic azo compounds in the pronounced reactivity of their N=N group. The present paper is concerned mainly with work published during the past two decades and with largely unpublished investigations carried out by the authors and their collaborators.

## 2. Preparation

α-Carbonyl azo compounds are generally prepared by oxidation of hydrazine derivatives. Methods that have proved particularly suitable include oxidation with halogens[1–4], concentrated nitric acid[5,6], and *N*-bromosuccinimide in pyridine[7,8], and (for aroylazo compounds) treatment of the hydrazine derivative with $HgCl_2$ or $AgNO_3$ to convert it into the metal derivative, which is then treated with iodine or bromine[9–15]. The extremely unstable α-carbonyl azo compounds *(1)* to *(5)* have been prepared by oxidation of the hydrazine compounds with lead(IV) acetate[16,17] or t-butyl hypochlorite[18,19,19a].



*(1)* *(2a)*: R = H, *(2b)*: R = F *(3)*



*(4)* *(5)*

The preparation[20] of bis(azodicarboxylic acid) derivatives such as

$ROOC–N=N–COO–(CH_2)_n–OOC–N=N–COOR$

and their possible technical applications[21] have been described.

Azodicarboxamides and phenylazocarboxamides are most easily obtained by reaction of the esters with ammonia. The same reaction with primary amines gives *N*-

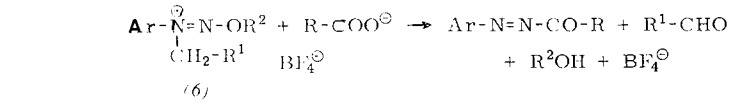
substituted amides (cf. Section 4.2.1 [22]). An interesting method for the preparation of α-carbonyl azo compounds having the structure Ar–N=N–CO–R (R = aryl or alkyl) was discovered by *Hünig* and *Eicher* [23], who obtained these compounds in yields between 75 and 100 % by the reaction of alkoxydiazenium salts *(6)* with carboxylate ions at room temperature (Ar = $C_6H_5$ and substituted phenyl; R = $C_6H_5$, substituted phenyl, and alkyl; $R^1$ = H, $C_6H_5$, and alkyl; $R^2$ = $CH_3$, $C_2H_5$).



*(6)*

the question of the geometrical structure of the α-carbonyl azo compounds remained unanswered for a long time. Most authors believed that the diesters of azodicarboxylic acids have the *trans* structure [25a–27]. *Schenck* and *Kopp* [28,29] recently converted diethyl azodicarboxylate into a photostationary system containing about 30 % of diethyl *cis*-azodicarboxylate by exposure to light of wavelength 300–370 mμ. This *cis* compound is much more reactive than the *trans* form (cf. Section 4.8), but can be stored for long periods in the dark (half-life at room temperature: $14 \times 10^3$ min), and is readily converted into the *trans* form by light or with the aid of a catalyst.

Table 1. α-Carbonyl azo compounds: position of the carbonyl stretching band; maxima and molar extinctions of the bands due to the n→π* and π→π* transitions.

| α-Carbonyl azo compound | Carbonyl stretching band ($cm^{-1}$) [35] | n→π* [34] | | π→π* [34] | |
|---|---|---|---|---|---|
| | | $\tilde{\nu}_{max}$ ($cm^{-1}$) | $\varepsilon_{mol}$ | $\tilde{\nu}_{max}$ ($cm^{-1}$) [38] | $\varepsilon_{mol}$ |

## 3. Structure and Spectroscopic Behavior of α-Carbonyl Azo Compounds

Although *Hartley* [24] showed as early as 1937 that azobenzene exists in the *trans* form, and can be converted into the labile *cis* form by ultraviolet radiation, The infrared-spectroscopic data in Table 1 show that the carbonyl stretching frequency of α-carbonyl azo compounds is appreciably higher than the "normal" values of 1750–1735 and 1725–1705 $cm^{-1}$ found for saturated esters and ketones, owing to the influence of

[22] Phenylazocarboxamides are also formed on oxidation of phenylsemicarbazides with $NaNO_2$ in glacial acetic acid [141a, 141d], on hydrolysis of phenylazo cyanides [*A. Hantzsch* and *O. W. Schultze*, Ber. dtsch. chem. Ges. *28*, 2073 (1895)], on reaction of phenylhydrazinehydroxamic acids with acetic anhydride [141b], and from *N*-nitrosophenylhydrazinecarboxamides [*O. Widman*, Ber. dtsch. chem. Ges. *28*, 1925 (1895); cf. also *J. H. Boyer* and *J. A. Hernandez*, J. Amer. chem. Soc. *78*, 5124 (1956)].

[29] *H.-R. Kopp*, Dissertation, Universität Göttingen, 1962.

the N=N group. Thus the effect of this group on the C=O frequency is similar to that of a halogen atom in the α-position. In azodibenzoyl (1740 $cm^{-1}$) and phenylazodibenzoyl (1719 $cm^{-1}$), the increase in the C=O frequency due to the presence of the azo group is partly cancelled by the mesomeric effect of the phenyl nucleus. As expected on theoretical grounds, the esters of phenylazocarboxylic acid fall between the diesters of azodicarboxylic acid and the azodiaroyl compounds, whereas *N,N*-dimethyl phenylazocarboxamide has a particularly low C=O frequency (1690 $cm^{-1}$) owing to the mesomeric influence of the amide nitrogen adjacent to the carbonyl group.

The position of the N=N stretching band of α-carbonyl azo compounds has not yet been determined. *Le Fèvre et al.*[25b] believe that the relatively wide band at about 1780 $cm^{-1}$ in the infrared spectra of the diesters of azodicarboxylic acid is due to superposition of the carbonyl and the azo stretching bands[30]. *Chaco* and *Rabjohn*[1], on the other hand, are of the opinion that the band which they found at 1610 $cm^{-1}$ for diethyl azodicarboxylate and at 1635 $cm^{-1}$ for ethyl t-butylazocarboxylate is due to the N=N stretching vibration. *Simon* and *Wagner*[26] and *Dubov* and *Ginsburg*[31] assigned the band at 1555 $cm^{-1}$ (diethyl azodicarboxylate[26]), 1562 $cm^{-1}$ (K salt of azodicarboxylic acid[26]), and 1553 $cm^{-1}$ (diisopropyl azodicarboxylate[31]) in the Raman spectrum to the N=N stretching vibration.

The absorption spectra of α,α′-dicarbonyl azo compounds (Table 1) contain the band due to the $n \rightarrow \pi^*$ transition between 20850 and 24700 $cm^{-1}$, with molar extinctions between 37 and 56, and (except in dimethyl, diethyl, and di-isopropyl azodicarboxylates[39]) the band due to the $\pi \rightarrow \pi^*$ transition, which is difficult to assign, between 35000 and 41900 $cm^{-1}$ ($\varepsilon_{mol}$ between 1000 and 32800). In the case of the phenylazocarbonyl compounds, the $n \rightarrow \pi^*$ band is situated between 21800 and 23900 $cm^{-1}$ ($\varepsilon_{mol}$ between 88 and 146), while the $\pi \rightarrow \pi^*$ band lies between 33600 and 37700 $cm^{-1}$ ($\varepsilon_{mol}$ between 10000 and 24300)[40]. The $n \rightarrow \pi^*$ band is very suitable in many cases for the quantitative determination of α-carbonyl azo compounds and for the spectrophotometric study of their reactions.

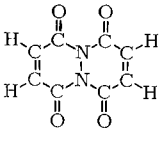
## 4. Reactions of α-Carbonyl Azo Compounds

Any classification of the reactions of α-carbonyl azo compounds can only be tentative, since it is necessary in many cases (particularly those of earlier work) to check not only the reaction course proposed by the authors, but also the structures of the products.

### 4.1. Thermal and Photochemical Decompositions

Diesters of azodicarboxylic acid have high thermal and photochemical stabilities. Thermal decomposition occurs only above 100 °C, sometimes explosively[41]. Irradiation for several hours at room temperature with a high-pressure mercury-vapor lamp causes only slight changes[29, 42].

On the other hand, diacylazo compounds and the cyclic α-carbonyl azo compounds *(1)* to *(5)* are much less stable. The latter decompose even below 0 °C[16–19], and some of them undergo polymerization. Compound *(2a)* loses $N_2$ to form *(7)* even at −30 °C.



*(7)*

The stability of the azodiaroyl compounds depends on the aroyl residue[43], being increased by electron-donating substituents and decreased by electron-withdrawing substituents on the aromatic nucleus[4]. When heated, azodiaroyl compounds decompose into nitrogen and aroyl radicals, which initiate secondary reactions[14, 44–47, 47a]. Thus azodibenzoyl in boiling xylene gives only 37 % of the maximum possible quantity of nitrogen, the other products including tribenzoylhydrazine, benzoic acid, 2,5-diphenyl-1,3,4-oxadiazole, and a little benzil[46]. The kinetics of the decomposition was studied by *Leffler* and *Bond*[12]. The decomposition of aliphatic diacylazo compounds over copper oxide can be used for the preparation of 1,2-diketones[11].

[30] With the aid of a grating spectrometer we resolved the band at 1786 $cm^{-1}$ in the spectrum of diethyl azodicarboxylate in carbon tetrachloride into the principal band at 1786 $cm^{-1}$ and a weak shoulder at 1779 $cm^{-1}$ [32].

[47a] *C. G. Pitt*, J. org. Chemistry *30*, 3242 (1965).

The products obtained on photochemical decomposition of azodibenzoyl in benzene are the same as those formed on thermal decomposition [4].

The salts of azodicarboxylic acid, which can be obtained by hydrolysis of the esters, decompose on acidification to give carbon dioxide and diimine [48]. Similarly, phenylazocarboxylic acid gives phenyldiimine, the intermediate formation of which was demonstrated by trapping with aldehydes to form hydrazides [49–50a]. The alkali metal salts of the arylazocarboxylic acids (prepared by hydrolysis of the amides or esters) can be used as arylating agents (preparation of organomercury, organoarsenic, and organoantimony compounds) [51].

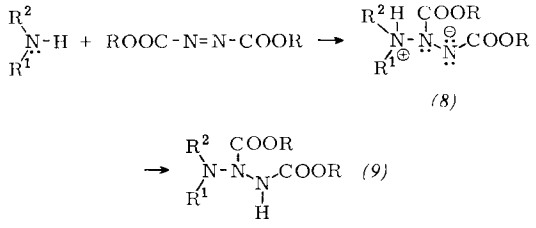
### 4.2. Electrophilic Addition

#### 4.2.1. Substitutive Electrophilic Addition to Amines

The reactions of the diesters of azodicarboxylic acid with amines are among the earliest known reactions of α-carbonyl azo compounds. Primary aliphatic amines lead to azodicarboxamides [52–54]. Piperidine and β-aminopyridine behave analogously [55].

$$ROOC{-}N{=}N{-}COOR \xrightarrow{+2R'NH_2} R'NH{-}OC{-}N{=}N{-}CO{-}NHR'$$

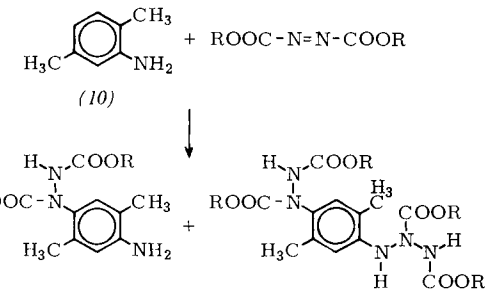
The reaction follows an entirely different course when secondary aliphatic amines are used. In this case, addition of the amine to a boiling solution of the ester in ether leads to an electrophilic attack of the ester (probably with initial formation of the betaine *(8)* [2]) and formation of a triazane *(9)*.



*(8)*

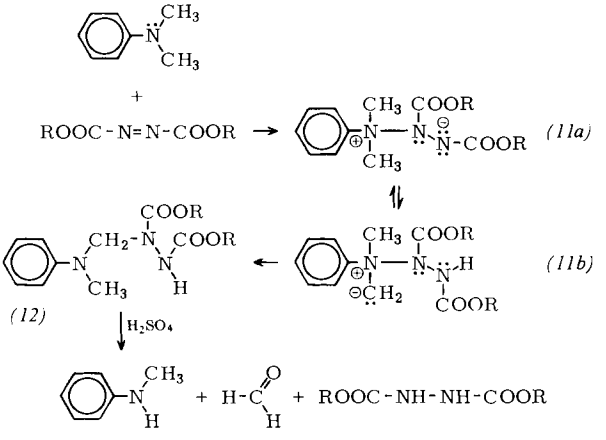
*(9)*

Aromatic amines represent a special case, since some of these (*e.g.* aniline, *o*-toluidine, and *p*-toluidine) yield the triazane derivative *(9)*, whereas others (*e.g.* α- and β-naphthylamine) undergo ring substitution [52,54,56,57]. Both modes of reaction are observed simultaneously with 2,5-dimethylaniline *(10)* [52].



*(10)*

Tertiary amines such as *N,N*-dimethylaniline add to diesters of azodicarboxylic acid under mild conditions. The products, presumably formed by ylide rearrangement of the intermediate *(11b)* [2,58], are the hydrazinedicarboxylic acid derivatives *(12)*, which decompose into secondary amines, aldehydes, and diesters of hydrazinedicarboxylic acid on treatment with boiling 2N sulfuric acid [2,59]. *Diels* suggested this reaction as a method of dealkylating tertiary amines [59,60].



*(11a)*

*(11b)*

*(12)*

*Huisgen* and *Jakob* [58] showed that the attack of the azodicarboxylate on the tertiary amine is electrophilic. They observed that the rate of this reaction increases with the basicity of the amine.

*N,N'*-Dimethyl and *N,N'*-diethylazodicarboxamide behave in the same way as the diesters of azodicarboxylic acid [52]. Azodibenzoyl undergoes a similar reaction with *N,N*-dimethylaniline at room temperature to form *N*-methylaniline, 1,2-dibenzoylhydrazine, formaldehyde, and *p*-(1,2-dibenzoylhydrazino)dimethylaniline [44,61,63].

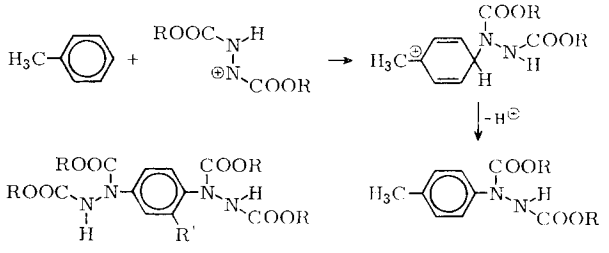
### 4.2.2. Substitutive Electrophilic Addition to Aromatic Compounds

Another type of electrophilic addition is the reaction of α,α′-dicarbonyl azo compounds with aromatic compounds (*e.g.* hydrocarbons and ethers), which proceeds with ring substitution to yield the hydrazinedicarboxylic acid derivatives *(13)* [62–65]. Depending on the aromatic system, the reaction sometimes takes place when the reactants are simply warmed in an inert solvent, but it generally requires the addition of catalytic quantities of acid.



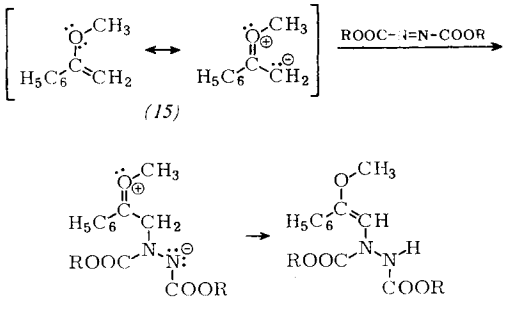
*(14a)*: R′ = $CH_3$, *(14b)*: R′ = H  *(13)*

On addition of a little concentrated sulfuric acid, diethyl azodicarboxylate reacts exothermically with toluene to give a mixture of the 1:1 and 1:2 adducts *(13)* and *(14a)*. Under the same conditions, benzene gives the 1:2 adduct *(14b)*, even when present in excess with respect to the diethyl azodicarboxylate [62].

The reaction of mesitylene with diesters of azodicarboxylic acid in the presence of $BF_3$ has been described by *Carlin* and *Moores* [66].

### 4.2.3. Substitutive Electrophilic Addition to Olefins

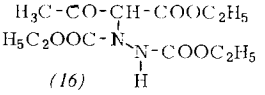
Esters of azodicarboxylic acid add electrophilically to vinyl ethers such as *(15)* to form hydrazine derivatives [67, 68].



*(15)*

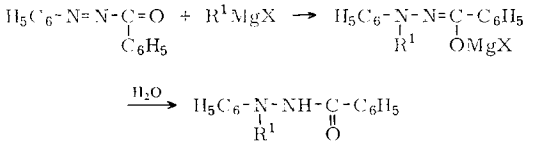
### 4.2.4. Electrophilic Addition to CH Acids and Grignard Compounds

Diethyl azodicarboxylate and esters of phenylazocarboxylic acid react with sodium salts of CH acids such as acetoacetic ester, cyanoacetic ester, and acetylacetone to form substituted hydrazines [69, 70]; for example, diethyl azodicarboxylate and sodium acetoacetate give the compound *(16)*.



*(16)*

α-Carbonyl azo compounds such as benzoylazobenzene, azodibenzoyl, and diesters of azodicarboxylic acid undergo 1,4-additions with Grignard reagents to form substituted hydrazides, *e.g. (17)* [7, 71].



*(17)*

### 4.2.5. Electrophilic Addition to Diazo Compounds

α,α′-Dicarbonyl azo compounds such as esters of azodicarboxylic acid, azodibenzoyl, and azodiacetyl react readily with diazoalkanes and diazoacetic esters to liberate nitrogen. However, the products are not, as had been assumed [72–75], derivatives of the diaziridine system *(18)* [76], but either hydrazones *(23)* or oxadiazolines *(19)* [77–81, 81a–81c], depending on the reaction conditions. The diazo compound first undergoes

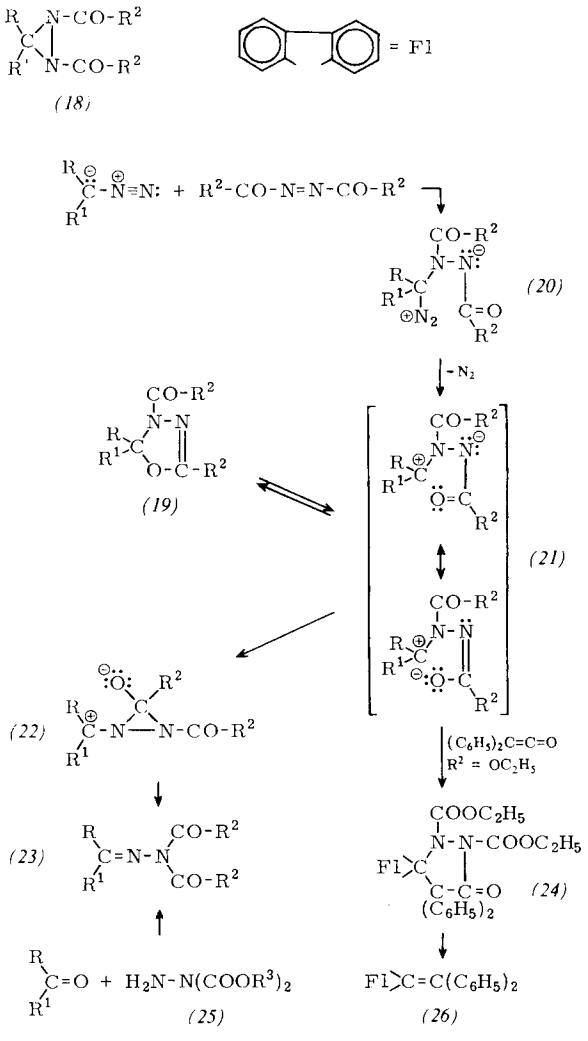
[81c] *Bettinetti* and *Capretti* [81a] discuss an oxadiazoline structure for the product of the reaction of diphenyldiazomethane with azodibenzoyl. We have however shown that it has the dibenzoylhydrazone structure *(23e)* [79].

electrophilic attack by the α,α′-dicarbonyl azo compound, probably with formation of the diazonium compound *(20)*, which then decomposes into *(21)* with liberation of nitrogen.



*(19a)*: R/R¹ = Fl; R² = OR³
*(19b)*: R/R¹ = Fl; R² = $OC_2H_5$
*(19c)*: R = H; R¹ = COOR⁴; R² = OR³
*(19d)*: R/R¹ = Fl; R² = $CH_3$
*(19e)*: R = H; R¹ = COOR³; R² = $C_6H_5$
*(19f)*: R = R¹ = H; R² = $C_6H_5$
*(23a)*: R/R¹ = Fl; R² = OR³
*(23b)*: R = H; R¹ = COOR⁴; R² = OR³
*(23c)*: R = H; R¹ = CO–R⁴; R² = OR³
*(23d)*: R/R¹ = Fl; R² = $C_6H_5$
*(23e)*: R = R¹ = R² = $C_6H_5$
*(23f)*: R = H; R¹ = CO–R⁴; R² = $C_6H_5$
*(23g)*: R/R¹ = Fl; R² = $CH_3$

The subsequent reaction of *(21)* depends on the groups R, R¹, and R², and on the reaction conditions. In the products obtained from diazofluorene and diesters of azodicarboxylic acid, a new form of ring/chain isomerism is observed. The products exist in the solid state as oxadiazolines *(19a)*; in solution, on the other hand, an equilibrium [80] is established between *(19a)* and the isomeric form *(21)* [82]. Thus the oxadiazoline *(19b)* in mixed solvents has isosbestic points at 242 and 263 mμ (measured in dichloromethane/n-heptane).

[82] For nomenclature see *R. Huisgen* and *A. Eckell*, Tetrahedron Letters *1960*, 5; *R. Huisgen, R. Grashey, P. Laur*, and *H. Leitermann*, Angew. Chem. *72*, 416 (1960).

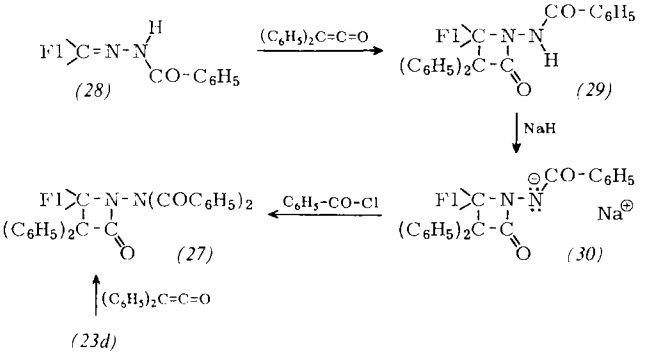
The azomethinimine *(21b)* [R/R¹=biphenylylene ("Fl"), R² = $OC_2H_5$] can also be trapped by 1,3-dipolar addition with diphenylketene to form *(24)*, the structure of which has been proved, *inter alia*, by degradation to the olefin *(26)*. As the dielectric constant of the solvent and the temperature increase, the equilibrium *(19)* ⇌ *(21)* is displaced to the right. Above 50 °C, *(21)* starts to undergo irreversible isomerization to the ester *(23a)* of the hydrazonedicarboxylic acid (where R² = $OC_2H_5$), probably *via* the azomethinimine *(22)*. The structure *(23)* can be proved by comparison with the products obtained when fluorenone reacts with asymmetric diesters of hydrazinedicarboxylic acid.

The reaction of diphenyldiazomethane with diethyl azodicarboxylate also leads to the intermediate *(21)* (where R = R¹ = $C_6H_5$, R² = $OC_2H_5$), which undergoes 1,3-dipolar reactions with dimethyl acetylenedicarboxylate and phenylisocyanate [81a, 81b].

The reaction of diazoacetic esters with diesters of azodicarboxylic acid below 80–100 °C leads to the oxadiazolines *(19c)*, which do not isomerize either in solution or when heated alone [83]. The same reactants above 80–100 °C give the isomeric ester *(23b)* of hydrazonedicarboxylic acid.

Even diazoketones are sufficiently nucleophilic to react with diesters of azodicarboxylic acid; however, a reaction temperature of over 100 °C is necessary. The raction yields esters *(23c)* of hydrazonedicarboxylic acids, which can very readily be broken down into the α-oxoaldehydes (yields between 75 and 93 %, determined as the osazones). The reaction can also be carried out in the sugar series [84].

The reaction of diazofluorene, diphenyldiazomethane, or diazoketones with azodibenzoyl yields the dibenzoylhydrazones *(23d)*, *(23e)* [81c], and *(23f)*. Compound *(23d)* reacts with diphenylketene to give the azetidinone *(27)*, the structure of which was proved by synthesis from the monobenzoylhydrazone *(28)* [79].

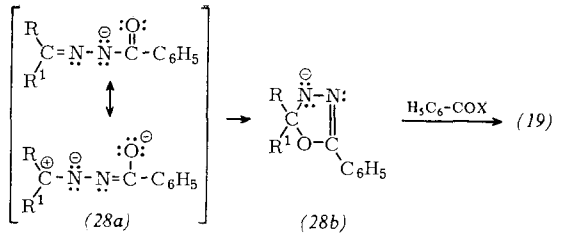


Compound *(28)* reacts with diphenylketene to give the azetidinone *(29)*, which reacts in turn with sodium hydride to form the anion *(30)*. Benzoylation of *(30)* leads to *(27)*.

The obvious "proof" of the dibenzoylhydrazone structure [*(23d)*, *(23e)*, *(23f)*] by reaction of the monobenzoylhydrazone with metallic sodium or potassium, or with sodium hydride to the anion *(28a)*, is not reliable, since the oxadiazoline *(19)* can also be formed in this case *via* *(28b)*. In the method used, this possibility is ruled out by the fact that the C=N bond is fixed in *(29)* by diphenylketene.

[83] An exception is the oxadiazoline obtained from ethyl diazoacetate and dibenzyl azodicarboxylate, which isomerizes to the ester of the hydrazonedicarboxylic acid when heated [77].

[84] *E. Fahr* and *F. Scheckenbach*, Liebigs Ann. Chem. *655*, 86 (1962).

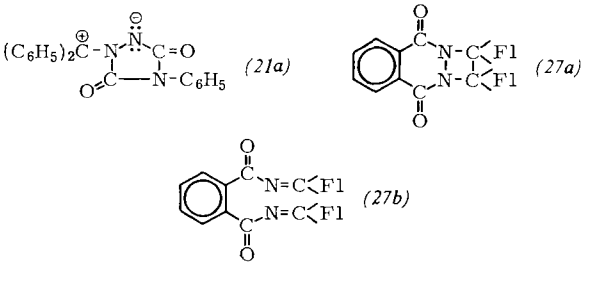


(28a) (28b) (19)

The proof of the structure of the dibenzoylhydrazone *(23d)* by synthesis from *(28)* [85] made possible the use of infrared spectra to verify the dibenzoylhydrazone structure of the products obtained by the reaction of diazoketones with azodibenzoyl.

The reaction of diazofluorene with azodiacetyl, on the other hand, leads to the oxadiazoline *(19)*. Diazofluorene and azodicarboxamide react to form fluorenone semicarbazone [77]. When *(19d)* is heated, it rearranges to give the diacetylhydrazone *(23g)*. The action of diazoacetic esters or diazomethane [79,81] on azodibenzoyl leads to the oxadiazolines *(19e)* or *(19f)*. α,α'-Dicarbonyl diazo compounds having the structure R–CO–$CN_2$–CO–R', such as methyl benzoyldiazoacetate, benzoyldiazoacetone, dibenzoyldiazomethane, and diazodimedone, as well as azibenzil (1-diazo-2-oxo-1,2-diphenylethane) are not sufficiently nucleophilic for reaction with α,α'-dicarbonyl azo compounds. Attempts to force the reaction by heating lead to decomposition of the diazo compounds into nitrogen and a carbene; the carbene rearranges to the ketene, which either adds to the azo compound or dimerizes and resinifies (cf. Section 4.8).

Cyclic α,α'-dicarbonyl azo compounds react in different ways with diazo compounds. Thus *(4)* reacts with diphenyldiazomethane to form the cyclic azomethinimine *(21a)* [81a, 81b], whereas the reaction of *(3)* with diazofluorene leads to the unstable tricyclic diazetidine derivative *(27a)*, which isomerizes when heated to yield *(27b)* [79].



(21a) (27a) (27b)

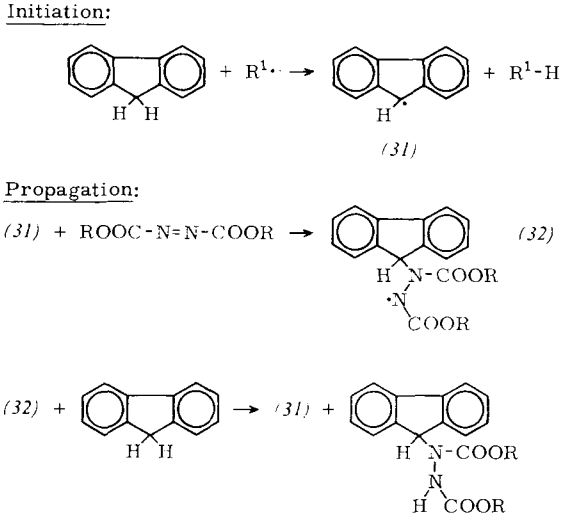
## 4.3. Substitutive Addition by a Free-Radical Chain Mechanism

### 4.3.1. Addition to Aromatic Side Chains and Olefins

*Huisgen, Jakob, Siegel,* and *Cadus* [62] carried out an extensive study in which they found that the reaction of aromatic compounds with diesters of azodicarboxylic acid formally follows the same pattern as the halogenation of aromatic compounds. In polar media, electrophilic ring substitution takes place, whereas in the presence of free-radical initiators this reaction is replaced by free-radical addition to side chains [86].

To induce such a free-radical reaction, it is not essential to add free-radical initiators; if the reaction mixture is heated to a sufficiently high temperature, the dissociation of the azodicarboxylate in accordance with ROOC–N=N–COOR → 2 ROOC· + $N_2$ yields free radicals which can initiate the reaction.

The reaction conditions can therefore be chosen in such a way as to direct the addition either into the ring or into the side chain [62].

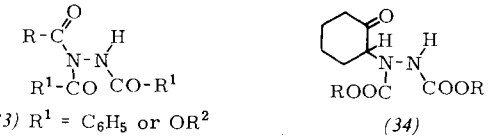


(31) (32)

Similar behavior is observed in the substitution of the allyl position in some cyclic mono-olefins with diesters of azodicarboxylic acid [58, 67]. In this case, however, the free radical substitution may compete with substitution *via* a cyclic transition state (cf. Section 4.4).

### 4.3.2. Addition to Aldehydes and Ketones

Aldehydes react readily with diesters of azodicarboxylic acid and with azodibenzoyl to give the hydrazine derivative *(33)*. The reaction proceeds by a free-radical chain mechanism [58, 44, 87]. As was shown by *Huisgen* and *Jakob* [58], free-radical and ionic mechanisms compete in the reaction of cyclohexanone with diesters of azodicarboxylic acid; however, both mechanisms lead to the same product *(34)*.



(33) $R^1$ = $C_6H_5$ or $OR^2$ (34)

## 4.4. Substitutive Addition to Olefins via a Cyclic Transition State

Olefins behave in various ways towards diesters of azodicarboxylic acid. The latter add by an ionic mechanism

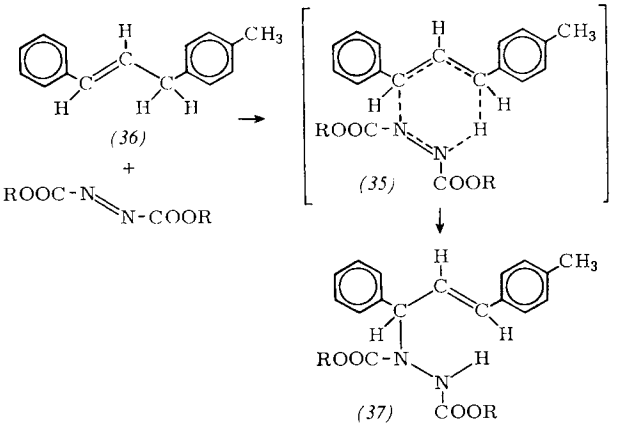
[85] The rather laborious proof of the structures of *(23d)* and *(27)* was necessary because, according to [81], the reaction of esters of diazoacetic acid and diazomethane with azodibenzoyl leads to oxadiazoline derivatives, so that we originally also assigned an oxadiazoline structure to the product obtained from diazofluorene and azodibenzoyl; cf. [80].

[86] *Horner* and *Naumann* [44] also proposed a free-radical mechanism for the addition of esters of azodicarboxylic acid to tetralin.

[87] *K. Alder* and *T. Noble*, Ber. dtsch. chem. Ges. *76*, 54 (1943).

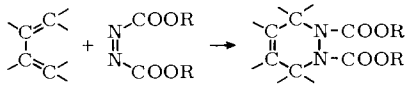
to the β-C atom of vinyl ethers, whereas the reaction with cyclic mono-olefins leads to substitutive addition by a free-radical chain mechanism. Sterically unhindered 1,3-dienes and styrene give diene reactions. Diesters of azodicarboxylic acid can also add to olefins in the allyl position with shift of the double bond [88]; this reaction in many cases proceeds by a mechanism [67] that cannot be influenced either by free-radical initiators or inhibitors or by polar catalysts. The reaction proceeds in a one-step process *via* the cyclic transition state *(35)* (formulated for the reaction of the olefin *(36)* with diesters of azodicarboxylic acid to form *(37)* [67]). A similar transition state [89] has been proposed for the reaction of acyclic aliphatic olefins and 1,3- and 1,4-cyclohexadiene [90–94].

The reaction of 1,2- or 1,4-dihydronaphthalene proceeds not only *via* the cyclic transition state, but also to a small extent by a free-radical mechanism [67]. The reaction of cycloheptatriene with azodicarboxylates probably also involves a cyclic transition state [95,96].



Some reactions of olefins with α-carbonyl azo compounds cannot be unambiguously assigned a mechanism (see [97]).

α,α′-Dicarbonyl azo compounds are among the strongest dienophiles known. The reaction with dienes was first observed by *Diels*, *Blom* and *Koll* [98] for diethyl azodicarboxylate and cyclopentadiene.



Other suitable diene components, apart from cyclopentadiene [5,98,99,105], include butadiene, isoprene, substituted butadienes, and cylic dienes [100–109,93,94]. Whereas 2,3-dimethylbutadiene gives the diene adduct, the addition does not take place with 2,5-dimethylhexa-2,4-diene and 2,4-dimethylpenta-1,3-diene because of steric hindrance [93,13,94], and substitutive addition occurs instead. Anthracene also gives an unstable adduct *(38)* [65,101,103,110], which is converted into the ring-substituted derivative *(39)* on treatment with acid [101,111].

The behavior of 1,3-cyclohexadiene as the diene component depends on the conditions. *Cohen* and *Zand* [104, 104a] obtained a diene adduct, whereas *Gillis* and *Beck* [93] observed substitutive addition to form the hydrazinedicarboxylic acid derivative. *Franzus* [91,92]

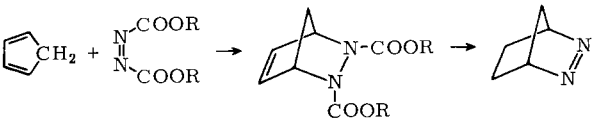
[111] The acid cleavage of the diene adduct obtained from diesters of azodicarboxylic acid and cyclopentadiene was studied by *J. K. Stille* and *T. Anyos*, J. org. Chemistry *27*, 3352 (1962).

showed that the diene reaction and the substitutive addition occur simultaneously. Diaroylazo compounds also take part in diene reactions [105, 13, 106, 112], and the reaction of styrene with azodicarboxylates can be interpreted as a diene reaction [100, 68, 113, 119].

Detailed kinetic studies have shown that the diene reaction of the azodicarboxylates is faster in polar than in non-polar solvents, and that the reaction in non-polar solvents is accelerated by the addition of acid. Moreover, the reactivities of the azodicarboxylates decrease with increasing size of the alkoxycarbonyl group. Thus the dimethyl ester reacts 5 to 6 times as rapidly as the diethyl ester [33], while the di-t-butyl ester reacts only with the more active diene components [7]. The reaction of cyclopentadiene with substituted azodibenzoyl derivatives is accelerated by electron-attracting substituents on the aromatic ring [105].

Particularly marked dienophilic activity is shown by *cis*-α,α′-dicarbonyl azo compounds; for example, diethyl *cis*-azodicarboxylate reacts about 30 times as rapidly as the "normal" diethyl azodicarboxylate [28, 29, 104a]. The cyclic azo compounds *(1)* to *(4)* react even at temperatures far below 0 °C [16, 18, 19, 19a].

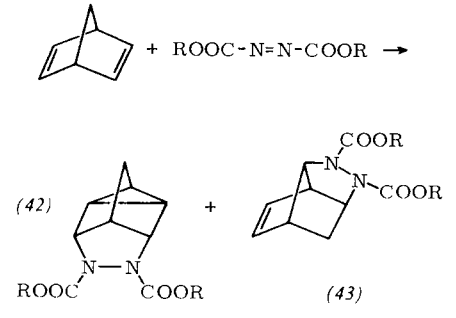
Diene reactions with diesters of azodicarboxylic acid, followed by hydrolysis, decarboxylation, and oxidation of the diene adduct, provide an excellent method for the preparation of cyclic azo compounds [98, 5, 108, 104, 94, 114, 115]. *Diels et al.* [98] used this method to prepare the bicyclic azo compound *(41a)*, which they converted into *(41b)* by hydrogenation, hydrolysis, decarboxylation, and oxidation.



*(41a)* *(41b)*

According to *Corey* and *Mock* [116], hydrolysis and decarboxylation of the adduct *(38)*, which is obtained from anthracene and diethyl azodicarboxylate, leads to the product *(40)*, which decomposes when heated to anthracene and diimine.

Monocarbonyl azo compounds do not give diene reactions, with the exceptions of the cyclic compound *(5)* and ethyl cyanoazocarboxylate [103].



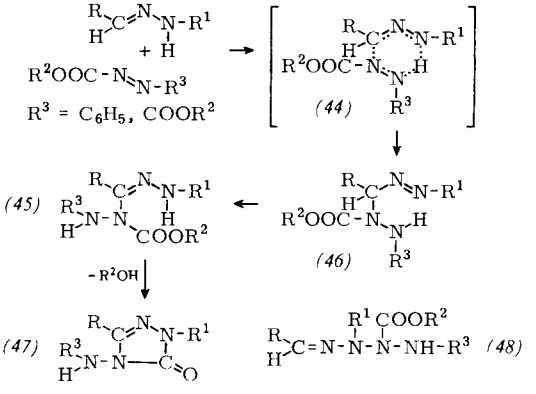
*(42)* *(43)*

Norbornadiene reacts with diesters of azodicarboxylic acid in a reaction known as a "homoconjugated Diels-Alder addition" to give a mixture of *(42)* and *(43)* [117, 118].

### 4.6. Addition to Aldehyde Phenylhydrazones

The reaction of aldehyde phenylhydrazones with diesters of azodicarboxylic acid or esters of phenylazocarboxylic acid leads to 1:1 adducts, for which *Busch, Müller,* and *Schwarz* [120] proposed the tetrazane structure *(48)*, whereas *Gillis* and *Daniher* [121] proposed the isomeric hydrazidine structure *(45)*. The adducts are readily converted into the triazoline derivatives *(47)* by heat or by treatment with acid or alkali.

However, ultraviolet, NMR, and infrared spectroscopic studies by the present authors showed that the adducts possess the azohydrazino structure *(46)* [122, 123]. On careful dissolution in pyridine, they isomerize to the very unstable hydrazidines *(45)*, which lose alcohol to form *(47)*. We believe that this reaction also involves a cyclic transition state *(44)*.



*(44)* *(45)* *(46)* *(47)* *(48)*

### 4.7. Reactions of Diesters of Azodicarboxylic Acid with Hydrazines, Hydrazides, and Hydrazones

Phenylhydrazine and *o*-tolylhydrazine react very vigorously, even at room temperature, with diethyl azodicarboxylate. In addition to diethyl hydrazinedicarboxylate, we obtained benzene (43 % yield) or toluene (63 % yield). Benzoylhydrazine or acetylhydrazine reacts with diethyl azodicarboxylate to give 1,2-dibenzoylhydrazine (73 % yield) or 1,2-diacetylhydrazine (41 % yield), with vigorous evolution of nitrogen [123].

The reactions of the aryl- and acylhydrazines with diesters of azodicarboxylic acid can be explained either

[112] *Y. S. Shabarov, N. I. Vasilev,* and *R. Y. Levina,* Doklady Akad. Nauk SSSR *129*, 600 (1959), Chem. Abstr. *54*, 14259 (1960).

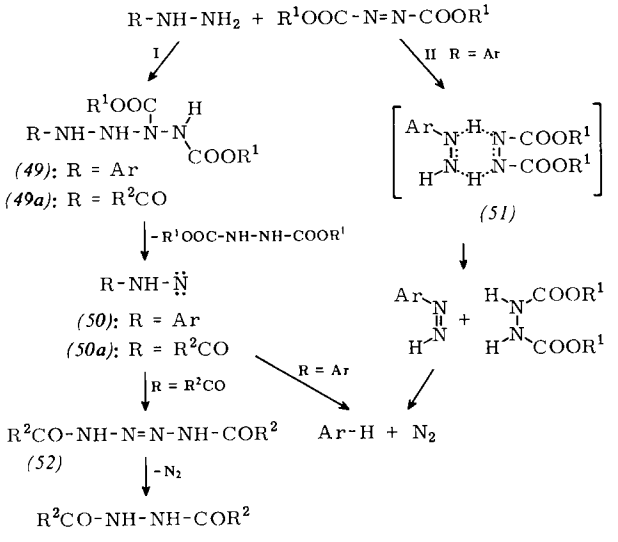
[123] *H. D. Rupp,* Dissertation, Universität Würzburg, 1964.

(as in the case of the amines) as an electrophilic addition (route I) of the ester to form the tetrazane *(49)* or *(49a)*, which then decomposes into the diester of hydrazinedicarboxylic acid and the fragment *(50)* or *(50a)*, or as a direct dehydrogenation (route II), possibly *via* the transition state *(51)* for the arylhydrazines [124]. *(50)* then loses nitrogen to form the hydrocarbon, whereas *(50a)* is converted into the diacylhydrazine *via* the intermediate tetrazene *(52)* [125].

Attempts to isolate the tetrazane derivatives *(49)* and *(49a)* and the tetrazenes *(52)* or to intercept the fragments *(50)* and *(50a)* were unsuccessful [123].



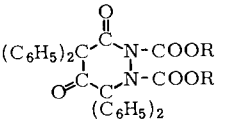
Asymmetric dialkyl- and diarylhydrazines react with azodicarboxylates to form tetrazenes [126]. The reaction is probably similar to that of acylhydrazines.

The action of diethyl azodicarboxylate on hydrazones (the hydrazones of benzaldehyde, benzophenone, and fluorenone were studied) leads to azines (yields: 30, 41, and 33 %, respectively), probably *via* the diazo compound [123]. This reaction can again be interpreted as involving a tetrazane similar to *(49)*, which decomposes into the diazo compound and the diesters of hydrazinedicarboxylic acid.

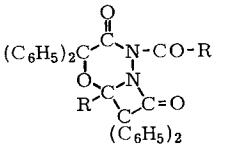
### 4.8. Cycloadditions of α-Carbonyl Azo Compounds to Ketenes and Olefins

The reaction of a ketene with an α-carbonyl azo compound was first studied by *Ingold* and *Weaver* [119]. On mixing diethyl azodicarboxylates with diphenylketene, these authors obtained a 1:2 adduct, for which they proposed the structure *(53)*. We have found that this adduct has the structure *(54)* [127–129].

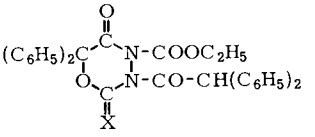
When heated with ethanol, *(54)* is converted into *(55)*; this reacts with alkali to form diphenylacetic acid and *(56)*, while with dilute acid it gives *(57)*. Moreover, when *(54)* is boiled in water, or better, with dilute acid, it forms *(57)*, which is converted into benzilic diphenylacetic hydrazide *(59)* on treatment with alkali. Compound *(56)* reacts with dilute acid to give *(58)*, which can be converted into *(57)* by reaction with diphenylacetyl chloride. When heated, *(54)* is



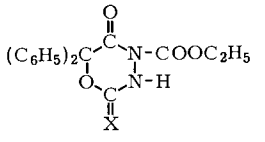
*(53)*



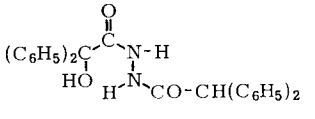
*(54)*: R = $OC_2H_5$



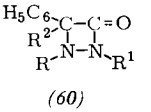
*(55)*: X = $(OC_2H_5)_2$
*(57)*: X = O



*(56)*: X = $(OC_2H_5)_2$
*(58)*: X = O



*(59)*



*(60)*

*(60a)*: $R = R^1 = COOC_2H_5$; $R^2 = C_6H_5$
*(60b)*: $R = R^1 = CO{-}C_6H_5$; $R^2 = C_6H_5$
*(60c)*: $R = R^1 = COOC_2H_5$; $R^2 = COOCH_3$
*(60d)*: $R = R^2 = C_6H_5$; $R^1 = COOC_2H_5$
*(60e)*: $R^1 = R^2 = C_6H_5$; $R = COOC_2H_5$

converted into a 1:1 adduct by irreversible elimination of diphenylketene [130]; this 1:1 adduct is also obtained, together with *(54)*, by the reaction of diphenylketene with diethyl azodicarboxylate. Its structure is not yet certain [131].

The first step in the formation of the bicyclic substance *(54)* is probably the formation of the $-CO-N(COOC_2H_5)$ linkage *(61)*, which is favored by the amide resonance. This is followed by ring closure to give either diazetidinone *(60a)* or the unstable 1,3,4-oxadiazine derivative *(62)*, which is stabilized by addition of diphenylketene to form *(54)*.

Azodibenzoyl also forms a 1:2 and a 1:1 adduct with diphenylketene [132]. Infrared-spectroscopic comparison with *(54)* and alkaline degradation to *(59)* show that the 1:2 adduct has the bicyclic structure *(54)* with R = $C_6H_5$ [133]. The 1:1 adduct is the diazetidinone *(60b)* [132].

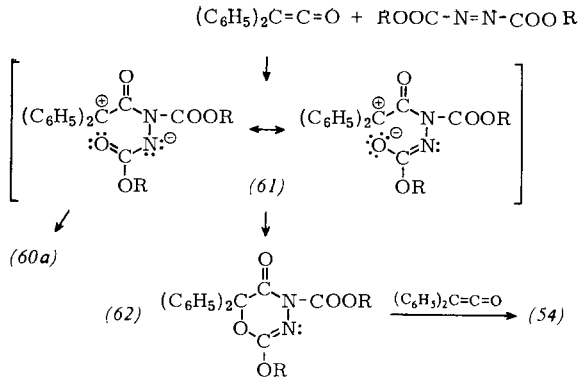
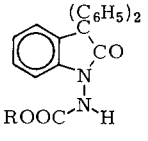
[133] *A. Jung.* Diploma Thesis, Universität Würzburg, 1963.



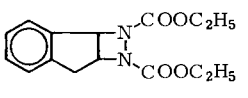
As pointed out in Section 4.2.5., α,α'-dicarbonyl diazo compounds do not react with α,α'-dicarbonyl azo compounds, but decompose at sufficiently high temperatures to give an α-ketocarbene, which rearranges to a ketene. However, in the thermal and photochemical decomposition of the esters of acetyl-, propionyl-, and benzoyldiazoacetic acids and of benzoyldiazoacetone, dibenzoyldiazomethane, diazodimedone, and esters of 3-diazo-2-oxosuccinic acid in the presence of diethyl azodicarboxylate, we observed addition of the azo compound to the resulting ketene only with the benzoyl- and propionyldiazoacetic esters. Methyl benzoyldiazoacetate gives the diazetidinone *(60c)*, while ethyl propionyldiazoacetate gives a viscous oil which cannot be purified [42,133].

The structure of the 1:1 adduct obtained in the reaction of phenylazocarboxylates with diphenylketene was established by *Bird* [134]. It is not the diazetidinone *(60d)* [119], but the diazetidinone *(60e)*. The latter isomerizes in the presence of hydrochloric acid/ethanol to *(63)*.

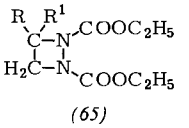


*(63)*

Diesters of azodicarboxylic acid also have been observed to add across olefinic double bonds to form diazetidine derivatives. Thus diethyl azodicarboxylate reacts with indene to form the compound *(64)* [135]; vinyl ethers and vinyl esters give the diazetidines *(65)*. The diethyl *cis*-azodicarboxylate reacts much more rapidly than the *trans* isomer [136].



*(64)*



*(65)*

R = H; $R^1 = OC_2H_5$
R = H; $R^1 = COOCH_3$
$R = CH_3$; $R^1 = COOCH_3$

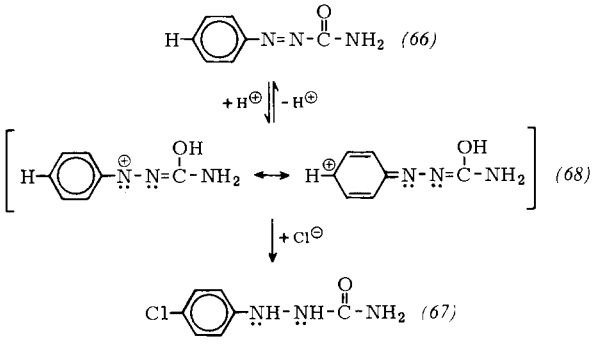
Diethyl azodicarboxylate adds analogously to tetramethoxy- and tetrafluoroethylenes [137,138] and to difluoroallene [139].

### 4.9. The Reaction of Arylazocarbonyl Compounds with Concentrated Hydrochloric or Hydrobromic Acid

Arylazocarboxamides [140] react with concentrated hydrochloric acid, even at room temperature, to form arylhydrazocarboxamides with halogen substituents at the ring [141b–141d]. Thus phenylazocarboxamide *(66)* gives the compound *(67)*. If position 4 is occupied, the chlorine atom enters position 2 or 6. A β-naphthyl group α to the azo group is substituted first in position 1, then in position 6 [141a]. A similar reaction was observed with hydrobromic acid [141a]. On the basis of investigations by *Kniese* [142], we believe that this reaction does not proceed by initial addition of hydrogen halide to the azo bond followed by rearrangement to give the hydrazo derivative (as was supposed by *Quilico* and *Justoni* [141c]), but that it involves nucleophilic substitution by chloride ions *via* the mesomeric ion *(68)*.



Surprisingly, the reaction of phenylazobenzoyl with concentrated hydrochloric acid leads to the *o*-substituted product *(69)* [143]. The first step in this reaction could be the addition of HCl to the N=N bond.

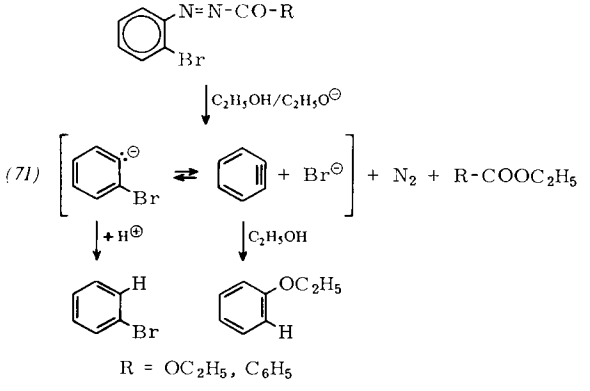
### 4.10. Decompositions with Bases

α-Carbonyl azo compounds decompose in alcoholic solution, sometimes very vigorously, on addition of bases. The addition of potassium acetate or alkoxide to diethyl azodicarboxylate in ethanol, even in the cold, leads to the vigorous formation of nitrogen, diethyl carbonate, and diethyl hydrazinedicarboxylate [144, 123]. When diethyl dicarboxylate is decomposed in methanol, ethyl methyl carbonate is formed. Similar decomposition products are obtained from the extremely unstable 1:1 adducts of alcohols with esters of azodicarboxylic acid, which are formed when the alcoholic solutions are allowed to stand. The adducts are thought to have the structure *(70)* [123].

*Hoffmann* [145] studied the decomposition of ethyl 2-bromophenylazocarboxylate and 2-bromophenylazobenzoyl in ethanol under the action of ethoxide. The products obtained led him to assume that the reaction proceeds by fragmentation *via* phenyl anions *(71)* and dehydrobenzene. *Cohen* and *Nicholson* [145a], however, showed that the decomposition of phenylazobenzoyl with methanol in acidic or alkaline solutions leads to the formation of phenyl radicals.



Oxidative cleavage of phenylhydrazide protecting groups from peptides probably also proceeds by fragmentation of the phenylazocarbonyl intermediate [146a]. The reaction of phenylazocarbonyl compounds having the structure

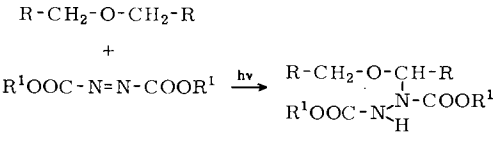
$$H_5C_6CH_2-O-CO-NH-CHR-CO-N=N-C_6H_5$$

with esters of amino acids in the presence of triethylamine can be used for the synthesis of peptides [146b]. The phenylazocarbonyl compounds are obtained by oxidation of the hydrazo compounds with *N*-bromosuccinimide.

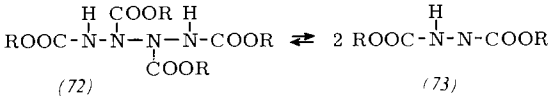
When phenylazobenzoyl in methanol is decomposed with acid or alkali, it forms nitrogen, methyl benzoate, benzene, 2-benzoyl-1,1-diphenylhydrazine, and 1-benzoyl-1,2-diphenylhydrazine. A free-radical mechanism with initial formation of phenyldiimine was proposed [147].

### 4.11. Photochemical Reactions

It was mentioned in Section 3 that "normal" diethyl azodicarboxylate is converted by radiation into the very reactive *cis* form. When the ester is irradiated in the presence of ethers, substitutive addition takes place in the α-position [104a, 148, 148a].



Irradiation in isopropanol yields hydrazinedicarboxylates and acetone together with the tetrazane *(72)*, which dissociates when heated at 80 °C into the radicals *(73)* [148, 29].



Irradiation of a mixture of diesters of azodicarboxylic acid with acetaldehyde yields diacetyl and diesters of hydrazinedicarboxylic acid [148]. Attempts to make nitrenes react with azodicarboxylates in the presence of ultraviolet radiation have been described by *Lwowski et al.* [149], *Hancock* [150], *Jung* [133], and *Königsdorfer* [79].

### 4.12. Miscellaneous Reactions

Diesters of azodicarboxylic acid are good hydrogen acceptors [9]. They can be titrated with sodium iodide in acetic acid [9, 58]. Azodibenzoyl reacts with isopropanol to give acetone and dibenzoylhydrazine [47].

The reaction of diethyl azodicarboxylate with trifluoronitrosomethane leads to the oxatriazetidine derivative *(74)* [151]. With benzonitrile oxide *(75)*, the oxatriazoline derivative *(76a)* is formed, which rearranges to *(76c)* *via* *(76b)* [152a, 152b]. Diethyl phosphite gives *(77)* [153]. The reaction of diethyl azodicarb-

# Specification of Molecular Chirality

BY R. S. CAHN [1], SIR CHRISTOPHER INGOLD [2], AND V. PRELOG [3]

*The topological analysis of chiral molecular models has provided the framework of a general system for the specification of their chirality. The application, made in and before 1956, of this system to organic-chemical configurations is generally retained, but is re-defined with respect to certain types of structure, largely in the light of experience gained since 1956 in the Beilstein Institute and elsewhere. The system is now extended to deal, on the one hand, with organic-chemical conformations, and, on the other, with inorganic-chemical configurations to ligancy six. Matters arising in connexion with the transference of chiral specifications from model to name are considered, notably that of the symbiosis in nomenclature of expressions of the general system and of systems of confined scope.*

## 1. Scope, Divisions, and Definitions

### 1.1. Scope of this Paper

Two papers, published in 1951 and 1956, hereinafter called Papers I [4] and II [5], describe a method, the sequence-rule method, for specifying the absolute configuration of enantiomers on the self-contained basis of a few general rules. This condition precludes dependence on genetic assumptions, and on conventions of nomenclature and formulation, all matters that cannot be comprised within a few rules. The method achieves its independence, and hence its relative simplicity, by working directly with the space model. The model is built only from atoms and bonds. However, the specifying labels, which the sequence-rule method attaches primarily to the model, are made succinct enough to be taken therefrom into the name of the substance.

An important general aspect of Papers I and II is that they, along with the present continuation paper, represent a contribution to the still unformed subject of chemical topology. That is why, although the applications are chemical, the basic concepts are topological. It is, of course, because they are topological that they can be defined sharply, and also permanently, despite the ever-changing face of chemistry.

Paper I was limited to optical isomers dependent on asymmetric carbon atoms or other octet-forming asymmetric atoms. Paper II took as its more extended scope optical isomers, whether involving asymmetric atoms or not, but still limited to structures of atoms with no more than four directed bonds.

The present paper has two purposes. The first is to consolidate the method throughout the field covered in Paper II, in the light of the experience which has been accumulated

since that paper appeared. A number of investigators [6] have called our attention to special difficulties, which they have most helpfully discussed with us. By far the most searching of all the tests to which the method has been subjected is that which has arisen in the Beilstein Institute from its adoption for the description of configuration in the 4th Edition of Beilstein's "Handbuch der organischen Chemie". The letters of the late Prof. *F. Richter*, and, since his death on 22nd November 1961, of Dr. *O. Weissbach*, analysing the results of their joint study of the method, have been an important source of inspiration to us in the writing of the relevant sections of the present paper.

There are two sections concerned essentially with consolidating the already occupied area. In Section 2, we deal with the analysis of configuration in structures of atoms with up to four directed bonds, and with its specification on the space model. A few applications of the procedure are modified, and some others are more closely prescribed than before, with improvement, as we think, both to the conceptual unity of the method, and to the ease of its use in some of the more difficult types of application. A number of examples are given, including some due to Prof. *Richter* and Dr. *Weissbach*, most of which have been constructed *ad hoc* in order to illustrate difficulties of various kinds. In Section 3, we take up certain special, essentially practical, problems concerned with the transfer of stereochemical specifications from the molecular model to within the framework of nomenclature.

The second purpose of this paper is to extend, as was foreshadowed in Paper II, the application of the sequence rule, beyond the basal area covered in Paper II and Sections 2 and 3 of this paper. We move out from it in two directions, which were, in fact, considered for exploration at the time of writing Paper II, though the final conclusion then was that Chemistry was not experimentally advanced enough to require either development. But since then, the situation has changed sufficiently, we think, to justify reversing that conclusion.

In the first of the extensions now proposed, which is described in Section 4, a starting-point, already given by *Klyne* and one of us [7], is made the basis of a use of the sequence rule to specify enantiomeric conformations in structures of atoms having up to four directed bonds, chiefly, of course, carbon conformations. In the second extension, described in Section 5, we take the first step in raising the covalency limit, or, more properly expressed, the ligancy limit above four, by proposing an application of the sequence rule in the specification of group-arrangements about an atom of maximum ligancy six. We prefer the terms "ligancy", "quadriligant", *etc.*, because they refer to the number of bonds formed but are non-committal as to bond-type, whereas the terms "covalency", "quadricovalent", *etc.*, imply theories as to the type of bond. Moreover the term "ligating" atom carries no implication as to how the atom becomes bound, whether by co-ordinating as an electron donor or acceptor, or by colligating [*] as a radical; and this, as a genetic implication, is of a type that we like to avoid.

This is as far as we go. But one can foresee that in the future these extensions themselves will require filling-out, and that further extensions, for example, to higher than primary protein structures, to ligancies higher than six, and to polyatomic elemental clusters, will be wanted. However, it would seem premature to map these areas before they are better explored.

[6] Professors *S. J. Angyal*, *H. Dahn*, *E. L. Eliel*, *K. Mislow*, and *O. Th. Schmidt* and Drs. *K. R. Hanson*, *S. J. Tauber*, and *R. S. Tipson*, as well as (the late) Professor *F. Richter* and Dr. *O. Weissbach*, to all of whom we are deeply grateful.

[7] *W. Klyne* and *V. Prelog*, Experientia *16*, 521 (1960).

[*] This term (cf. *C. K. Ingold*: Structure and Mechanism in Organic Chemistry. Cornell University Press, Ithaca, New York, 1953, pp. 5, 205) suits our general preference for "ligating" and its congeners. The syllable "co" signifies like participation by the involved atoms, as in "covalency".

Chemists habitually use the word "asymmetry" (and its grammatical congeners) in two different senses, sometimes without appreciating the difference. One sense is correct, and the other is so loose that it must be considered incorrect. Yet many authors must have felt, as we have, the embarrassment of having, either to avoid the word, or to complicate statements containing it with some periphrase contrived to indicate in which of its two senses it is to be understood. It will be convenient now to end this difficulty.

The symmetry of any molecular model consists in the totality of independent symmetry operations of (a) rotation (by sub-multiples of $2\pi$) round the axes of symmetry, (b) reflexion in planes of symmetry, and (c) combinations of such a rotation and a reflexion, which will bring the molecule into coincidence with itself. Only when no symmetry operation can so convert the molecule, has the molecule no symmetry. Only then may it be called "asymmetric" in the correct usage of that term.

Thus Cabcd has no symmetry whatever, and therefore the term "asymmetric carbon atom" is entirely correct, if the atom's surroundings are taken into account, as is always intended.

Asymmetry is a sufficient condition for the existence of optical enantiomers. But it is not, though it is sometimes referred to as if it were, the necessary and sufficient condition. We need a separate word for that.

The necessary and sufficient condition is that reflexion in a plane converts the model into a non-identical one, that is, one which cannot be superposed on the original by translations and rotations only. The model then has two non-identical forms, inter-related by a reflexion, that is, two enantiomeric forms: it has the topological property of handedness. Its possibilities of symmetry are much restricted; but they are not eliminated. Obviously, it cannot have any symmetry of types (b) and (c) above, which require superposability after a reflexion. But there is no such ban on symmetry of type (a). A model which has no element of symmetry except at most axes of rotation may be called *chiral*. Thus *chirality* expresses the necessary and sufficient condition for the existence of enantiomers. Chirality means handedness, and, in our context, topological handedness [*].

[*] This useful word was brought to our attention by Professor *K. Mislow*, who referred us to Webster's Dictionary (2nd Edition), where "chiral" is defined as "Of, or pertaining to the hand, specifically turning the plane of polarisation of light to either hand", and to two articles by *Whyte* [8] on the history of the word. It has occurred in the literature of physics since 1904, when it appeared in a publication [9] by *Lord Kelvin* of lectures delivered at earlier dates, in particular one of 1884 rewritten in 1903, and one of 1893 in which it is defined to mean topological handedness. Today its meaning is broadened to include the spin-handedness of elementary particles. However, we shall be concerned only with its original meaning of space-handedness.

[8] *L. L. Whyte*, Nature (London) *180*, 513 (1957); *182*, 198 (1958).

[9] *Lord Kelvin*: Baltimore Lectures. C. J. Clay and Sons, London 1904, pp. 436, 619.

An unambiguous division of the overall field of topological chirality must itself be topological. For the problem is to describe a space relation, and the primary classification should therefore be concerned with the types of geometrical relation requiring to be described, not with where the forces come from which make them what they are. Thus, the main framework for the classification of chirality has to be geometrical. To introduce theories of chemical bonding, or structural energetics, at this fundamental level would create great difficulties.

It was in this understanding that, in Paper II, we introduced a primary division of chirality (there called "asymmetry", or sometimes, "dissymmetry") into central, axial, and planar chirality, a classification which is based only on the three-dimensional nature of space. The chiral centre is an abstraction of the asymmetric atom: the space about it, when unoccupied, is undifferentiated in its three dimensions, and certain differences in its occupation have to be established in order to produce chirality. A chiral centre that is not the seat of an atom can be contemplated (Sub-section 2.8). A chiral axis does distinguish one dimension from the other two, and hence lesser differences in the occupation of the surrounding space are sufficient for the development of chirality. A chiral plane distinguishes two dimensions from the remaining one, and again reduced differences in the occupation of the ambient space suffice to create chirality.

A given chiral structure may contain one or more of some or all of these elements of chirality. The first step in the procedure for specifying chirality is to factorise the overall chirality into as many chiral centres as are present, and, if their specification leaves that of the overall chirality incomplete, into chiral axes, or chiral planes, or both, as far as necessary. This procedure of factorisation was implied in Paper II, but was not formally stated as a rule.

It is well known that, whilst the chiral sense of different elements of chirality can commonly be varied independently, some elements in some structures may be so stereospecifically linked that that cannot be done. However, this does not interfere with the assigning of specific designations of chirality to such elements.

The above broad geometrical lay-out is unequivocal and universal, as long as it is not upset by non-geometrical considerations, for example, by theories of bonding, or of structural energetics, or by chemical classifications. Nevertheless, the practical problem does sometimes arise of arranging a convenient symbiosis between these geometrical concepts, which are sharply definable, and chemical concepts, which it may be impossible satisfactorily to define, but which do convey distinctive general ideas. The difficulty is not so much that the geometrical and chemical concepts are not co-extensive, but that the margins of the latter carry a penumbra.

We meet this type of problem unavoidably, as a result of our decision to apply the sequence rule to conformations.

These terms have come down, the one through a long history, and the other through a short one, each carrying a generally distinctive set of ideas. Yet history has never produced satisfactorily distinguishing definitions. It results from this that the newer concept of conformation has an agreed area of application, an agreed area of non-application, and a penumbra.

We shall take it that conformations arise from pure rotations around the internuclear lines of formally single bonds. However, the concept of conformation became important as a result of the discovery that rotation around the C–C bond of ethane is resisted, and that therefore some of the arising conformations are stable with respect to all small relative displacements of the atoms, and thus are molecular states, now commonly called conformational isomers, rotational isomers, conformers, or rotamers. Such molecular states will have a first claim on our attention in applying the sequence rule, but conformations which are not molecular states will have a claim, because their relation to conformers has to be considered in many connexions.

We now ask what types of resistance to rotation are qualified to produce a conformer. The type present in ethane would universally be considered to be so qualified. However, the restriction on rotation round a single bond, caused by its inclusion in a small ring, might not be considered as so qualified: it could be argued that the incapacity of the bond for rotation is not a situation for which the bond is primarily responsible. But what is to be said, if the inhibition arises because some attached groups are too large to pass one another? Neither is that the primary responsibility of the bond. A range of such intermediate situations can be found which constitute the penumbra.

Let us examine another approach. As is emphasised in the different histories of the concepts of configuration and conformation, the energy barriers that protect configurations are usually much larger than those which separate conformers. Thus stable optical activity is widespread throughout the realm of configuration, having created the multitude of practical problems of specifying chirality, to deal with which the sequence-rule system was devised. On the other hand, in the domain of conformation, stable optical activity is much less common, and, indeed, is largely associated with the area of the penumbra. For several reasons, no sharp distinction between configurational and conformational molecular states can be based on barrier heights. No delimiting energy figure could be exclusively justified. Most actual barrier heights are unknown.

We must explain our concern with this matter of the penumbra. We wish to specify, in particular, the chirality of conformations about the C–C bond. This amounts to specifying the space relations of the maximum of six atoms bound to the $C_2$-unit, given that the configurations of the two sets of three, of which the set of six is composed, are pre-determined. By introducing unsaturation at either end, or at both ends, of the $C_2$-unit,

specialisations can be created, in which the six atoms become reduced to five, composed of sets of three and two, and to four, composed of two pairs. However, in spite of this last specialisation, the problem of conformational specification as a whole is different enough from that of the configurational specification of four groups about an asymmetric atom, or about any of the general elements of chirality, the centre, axis, or plane, to determine that we must in general apply the sequence rule to configuration and to conformation in different ways. We need not now go into the difference; the present point is simply that its existence requires us carefully to examine the margins between configuration and conformation.

Conformations which are not molecular states present no procedural dubiety. The penumbra has to do with molecular states. We might try to draw a sharp boundary between the alternative procedures by inventing some particular definition of a conformer, which either includes the penumbral area, or takes some other prescribed course through or around it. Whatever definition we set down, we cannot expect its universal acceptance, either in general or for our particular purpose.

Let us consider, for example, the following classification of molecular states, which gives to conformers a scope embracing the whole penumbral area. By configuration is meant the space-arrangement of a model representing a molecular state with neglect of the distinctions between varieties of that state which differ only as after relative rotations of groups directly bonded together, about the internuclear lines of their intervening, formally single bonds; and by a conformational molecular state (conformational isomer, rotational isomer, conformer, rotamer) is meant a space-arrangement which signalises such a distinction, and identifies such a variety-state.

This definition includes not only examples of the general nature of those which formed the historic foundations of the subject of conformation. It includes also cases in which rotation round a single bond is prevented by interactions of groups possibly some bonds away from the single bond in question, as in biaryls; or by the locking of the single bonds in rings which in turn create non-bonded group-interactions, as in *para*-cyclophanes. These situations are today accepted by many as configurational, as, indeed, those of stereoisomerism in the biaryl series were for a decade before the fundamental discovery of 1936 by *Kemp* and *Pitzer* concerning ethane. For these reasons among others, we do not expect our wide-limit definition of conformations to be unanimously acceptable, and so we have to devise a means by which the necessary definiteness of the sequence-rule system can co-exist with such a penumbral area of allowably diverse opinions.

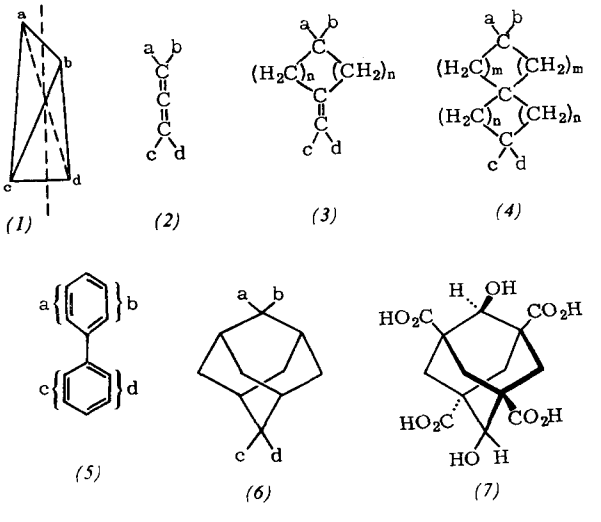
The whole penumbral area falls into two parts, one contained within the broader field of axial chirality, and the other within that of planar chirality. These primary geometrical divisions of chirality refer only to the topological relations requiring to be described, and do not ask the question of whether their chemical origins are configurational or conformational. Thus, the dubieties which arise are concerned, not with whether some case or class of cases should be treated as configurational or conformational, but with whether it should be treated on a basis indifferent to that question, or by a specifically conformational method, when allowed by the wide-limit definition given above. We discuss the two parts of the penumbral area in the next two sub-sections.

### 1.5. Conformation and Axial Chirality

The chirality of four groups arranged out-of-plane in pairs about an axis, as diagrammatically illustrated by the elongated tetrahedron *(1)*, was discussed in Paper II. With no distinction at all between its four groups, a, b, c, d, the tetrahedron has a four-fold alternating axis of symmetry, which becomes the chiral axis when differences of any kind between the groups import chirality. It was noted in Paper II that fewer differences in groups are required to produce chirality about an axis than are necessary for chirality about a centre. Thus the four groups, shown as abcd in *(1)*, need not all be different: so long as a and b are different, and c and d are different, *(1)* will be chiral, even if identities arise between the pairs, as in ab, ac, or ab, ab.

This form of chirality was illustrated in Paper II with examples of four kinds typified by allenes*(2)*,alkylidenecycloalkanes *(3)*, spirans *(4)*, and biaryls *(5)*. To these, we must now add a fifth type, the adamantoids *(6)*, one of which *(7)* has already been optically resolved [10]. All these illustrations may be taken to represent more general classes, in which some carbon atoms may be replaced by stereochemically similar hetero-atoms, such as nitrogen. The classes typified by *(2)*, *(3)*, *(4)* and *(6)* are clearly configurational. The class typified by *(5)* is conformational by our wide-limit definition. All five classes display stable optical activity.

Evidently two views are possible as to how chirality of type *(5)* should be specified. One is that, because, by the definition given above, the enantiomers are conformational isomers, they should be specified by the method



[10] *H. Stetter* and *O. E. Bänder*, Chem. Ber. *88*, 1535 (1955).

devised to cope with conformations. The other is that, because, in all the five types *(2)–(6)*, all that is being specified is the similar space-relations of the four groups abcd, and not the forces that hold them where they are, it would be suitable, and perhaps convenient, to specify all in the same way, and hence as forms of axial chirality.

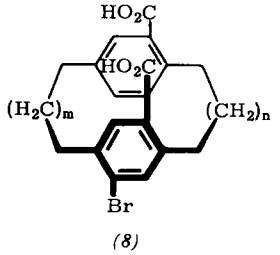
We think that both points of view must be considered tenable; and rather than presuming exclusively to decide between them, we should prefer that both methods of specifying the chirality of biaryls would be regarded as available. That is to say, biaryls would be treated, either as examples of axial chirality, as illustrated in Paper II and additionally in Sub-section 2.6 below, or by the appropriate specialisation of the treatment of conformational chirality, as discussed in Section 4 below. Of course, if the method is to be left to choice, the results must be expressed in forms which disclose the choice. We do that in the sequel by using contrasting symbolisms in the two methods.

### 1.6. Conformation and Planar Chirality

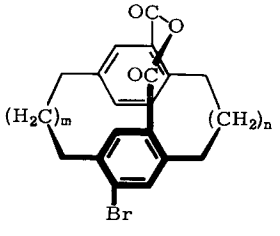
As explained in Paper II, a plane of chirality is derived by desymmetrisation of a plane of symmetry in such a way that chirality depends on a distinction between one side of the plane and the other, and on a pattern of three groups (of which two or even all three may be equivalent). These are basic conditions, not changed at all by the fact that planar chirality is discussed again in Sub-section 2.7 below, where some modifications of procedure are introduced. Most, though not all, of the examples available at present belong to the chemical class of bridged rings with bridge-heads in aromatic rings.

Once again, alternative approaches to the specification of chirality arise in a part of the general field of planar chirality. For some examples fall within the wide-limit definition of conformations given above, and some do not. Yet those which do and those which do not may be geometrically very similar. In order to bring out the distinction, two *para*-cyclophanes, closely resembling two illustrated in Paper II, are represented at *(8)* and *(9)*.

The dicarboxylic acid *(8)* is a conformational isomer by the definition. For its enantiomer differs from it as would the result of a conceptual rotation of both benzene rings through 180° about their *para*-situated arylmethylene bonds. We may note in passing that the acid which differs from *(8)* as after a conceptual rotation of one benzene ring only, an acid which would normally



*(8)*



*(9)*

be regarded as a position isomer of *(8)*, is by the same definition a conformational isomer.

On the other hand, the anhydride *(9)* is not a conformational isomer, even by the definition. For the rings cannot now be rotated, not even in imagination, without the introduction of deformations other than rotational. The enantiomeric product of such rotation bears a permanent bending deformation, inasmuch as the valency angle of the single-bonded oxygen atom has been widened from $\Theta$ to $2\pi-\Theta$. If this is not immediately obvious, it can be made so by imagining the oxygen atom to be replaced by Cab, an ordinary asymmetric carbon atom, in *R*-form say, which will clearly have to go into *S*-form in the enantiomer, a conversion which, at best, involves bending the pair of bonds to the carbonyl groups past the pair to the atoms a and b, and reciprocally.

Here we have two examples, which are broadly similar geometrically, and closely related chemically, both belonging to the domain of planar chirality. Yet one falls within the scope of the definition of conformers given above, whilst the other does not, and is thus inevitably configurational. The chirality of the anhydride *(9)* can be specified by only one sequence-rule method, namely, that applicable to planar chirality. However, alternative procedures are possible for specifying the chirality of the dicarboxylic acid *(8)*. Either it can be treated, like its anhydride, as an example of planar chirality; or it can be specified by an application of the procedure devised for conformations (Section 4).

Again our view is that both methods should be considered available, and that the one used should be left to choice, which the resulting specification would disclose.

### 1.7. Chirality and the Helical Model: Helicity

A helix is characterised by a helical sense, a helical axis, and a pitch (ratio of axially linear to angular properties). Thus, helicity is a special case of chirality, because it implies two additional properties. When a natural object or process has all the three properties, the helical model, just because it provides so well-filled-in a portrait, may be the easiest abstract model to recognise and use, even though it summarises more properties than may be relevant to the matter under discussion. Of course, when a chiral object has not all the helical properties, nor by a simple adaptation can be given them, the specialised helical model is inapplicable, and the object belongs to the general case of chirality.

A familiar example of the use of the specialised helical model, when valid, for less specialised purposes, is that of the spinning elementary particle in free space. It has helicity; and, in reference to it, the term "helicity", is frequently used in discussions to which only part of its full meaning, only helical sense (*i.e.* chirality), is relevant.

Our concern is with molecular structures. In some, for example, some secondary protein structures, a well-developed helical arrangement contributes to chirality. The chirality of conformations is most conveniently referred to the helical model, so we have reason enough

to follow precedent in using the helical model, when applicable and particularly convenient, even though the only one of its several properties which is relevant to our considerations is its sense.

As to this, right- or left-handed helicity associates a right- or left-handed turn, as the case may be, with axial translation away from the observer; and to reverse the helix with respect to the observer makes no difference. We shall propose designations for right- and left-handed helicity in Sub-section 2.1.

## 2. Chirality to Ligancy Four: Modifications and Additions

### 2.1. The Sequence-Rule Procedure to Ligancy Four

This method of specifying chirality works directly with the space-model. The models treated are of conventionally approximated valence-bond structures. We defer to Sub-section 2.2 the stating of the conventions, because we want to change one of them. As allowed by the ligancy limit, electron-octet valence-bond structures are employed.

Conceptually, all atoms other than hydrogen are complemented to quadriligancy by providing them, as far as necessary, with imaginary bonds and atoms to bind, as follows. First, they are provided, respectively, with one or two duplicate representations of any ligands to which they are doubly or triply bonded; and then their unsaturation, if any, of unshared valency electrons or incomplete valency electron shells is satisfied with phantom atoms of atomic number zero.

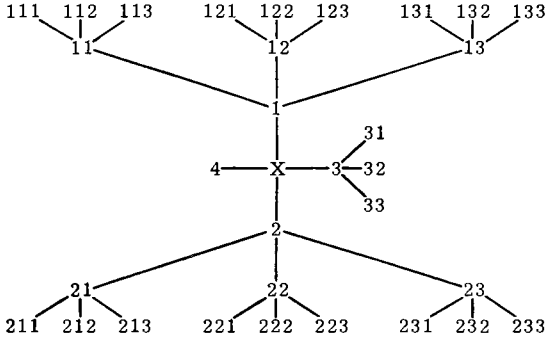
The chirality of such a formalised valence-bond structure is now factorised into chirality in the occupation of space about the identifiable chiral elements, first the centres, and then, as far as necessary, the axes and planes of chirality. The elements are then stereochemically characterised by the following procedure applied to each in any applicable order.

For the purpose of characterising an element of chirality, for example, an asymmetric atom, the ligands associated with it are put into a priority sequence, and the most important of the characters used for this purpose is atomic number. Thus, the ligands about an asymmetric atom are arranged in order of decreasing atomic number of the atoms by which they are bound to it; or, if the relative order of two ligands cannot thus be decided, it is determined by a similar comparison of atomic numbers of the next atoms in the ligands, or, if this fails, of the next: so one works outward, always first towards atoms of higher atomic number, where there is any choice, until a decision is obtained.

In this outward exploration along the bonds, we thus follow paths of highest precedence. It is so important to be clear as to what this means that we here repeat the detailed prescription, illustrated by formula *(10)* and given in Paper I, for the ordering by atomic number of the ligands about an asymmetric atom. The ligands are placed in order of decreasing atomic numbers of selected sets of their atoms, the sets being selected, and so used, successively, as fas as necessary, as follows.

First set: To an asymmetric atom let four atoms, 1, 2, 3, and 4 be directly bound. Then the atoms 1, 2, 3, 4 constitute the first set.

Second Set: Let 1 and 2 be any two atoms of identical atomic number in the first set. To 1 let there be directly bound atoms 11, 12, 13, ...., here arranged as far as possible in order of decreasing atomic number. To 2 let there be directly bound atoms 21, 22, 23, ...., similarly here arranged. Then the second set contains 11 and 21, unless these have the same atomic number, when it contains instead 12 and 22, unless these also have the same atomic number, when it contains instead 13 and 23. The complete second set is to be composed by applying this procedure to every pair of ligands whose atoms of the first set have the same atomic number.



*(10)*

Third Set: Let the atoms 1 and 2 have identical atomic number, and let the atoms 11, 12, ...., and 21, 22, ..., be identical in atomic number in pairs, 11 with 21, 12 with 22, and so on throughout. Then the atoms of the third set are selected from the atoms 111, 112, ...., directly bound to atom 11 and here arranged in order of decreasing atomic number as far as possible, and from the atoms 211, 212, ...., directly bound to atom 21, and similarly here arranged, as were the atoms of the second set from the atoms, 11 12, ...., directly bound to atom 1, and the atoms 21, 22, ..., directly bound to atom 2; unless all the atoms from which the atoms of the third set might thus have been selected are identical in atomic number in pairs, each of the series 111, 112, ...., with one of the series 211, 212, ..., when the atoms of the third set are similarly selected from the similarly arranged atoms 121, 122, ...., directly bound to atom 12, and likewise the atoms 221, 222, ...., bound to atom 22; and so on. The complete third set of atoms is to be composed by applying this procedure to every pair of ligands having relationships of identity similarly to those assumed for the ligands to which the atoms 1 and 2 belong.

Higher Sets: The method for selection of the $(n + 1)$th set of atoms is to be developed from that of the $n$th set as was that of the third set from that of the second set.

In case outward exploration by this method does not order the ligands completely, because of the absence of a distinction of atomic number between certain of the ligands, the exploration is repeated with respect to such ligands using characters other than atomic number as basis for comparisons made at each step of exploration.

In Paper I, it was proposed to order ligands having only isotopic differences by reference to atomic mass-numbers, higher mass-numbers taking precedence over lower. In Paper II, it was proposed to order ligands which had only stereochemical differences by reference to these differences, with a prescribed order for *cis* and *trans* differences, and also for enantiomeric features.

In Paper II, the further generalisation was made of using this procedure not only for centres of chirality, but also, with suitable adaptations, for axes and for planes of chirality.

The object of the procedure, however applied, is to arrange the ligands associated with an element of chirality in a sequence. The succeeding processes are simple. The sequence is allowed to trace a path on the space-model, and the chiral sense of the path, designated in a prescribed way, then classifies the element of chirality.

The procedure was summarised in Paper II in a schedule of consecutively applicable rules, the various characters, used for the comparisons made during exploration of the ligands, being covered in a series of consecutively applicable sub-rules. This schedule is reproduced in a revised form below. Two changes of substance are made, which set up a new sub-rule, and renumber and rearrange some of the older sub-rules. The reasons for these changes are explained in Sub-sections 2.3 and 2.4. The special nomenclature used in Sub-rule (3) is explained in Sub-section 2.4, and the symbols *M* and *P*, which appear in Sub-rules (4) and (5) are defined later in the present Sub-section.

Ligancy Complementation. *All atoms other than hydrogen are complemented to quadriligancy by providing respectively one or two duplicate representations of any ligands to which are doubly or triply bonded, and then any necessary number of phantom atoms of atomic number zero.*

Factorisation Rule. *Overall chirality is factorised into elements, which are treated in the order, centres first, and then axes, and finally planes, as far as necessary.*

Sequence Rule. *The ligands associated with an element of chirality are ordered by comparing them at each step in bond-by-bond explorations of them, from the element, along the successive bonds of each ligand, and, where the ligands branch, first along branch-paths providing highest precedence to their respective ligands, the explorations being continued to total ordering by use of the following* Standard Sub-rules, *each to exhaustion in turn, namely*:

(0) *Nearer end of axis or side of plane precedes further.*

(1) *Higher atomic number precedes lower.*

(2) *Higher atomic mass-number precedes lower.*

(3) *Seqcis precedes seqtrans.*

(4) *Like pair R,R or S,S precedes unlike R,S or S,R; and M,M or P,P precedes M,P or P,M; and R,M or S,P precedes R,P or S,M; and M,R or P,S precedes M,S or P,R; also p precedes s.*

(5) *R precedes S; and M precedes P.*

Chirality Rule. *Among ligands of highest precedence the path of their sequence is followed from the preferred side of the model, that is, the side remote from the group of lowest precedence, and, according as the path turns to right or left, the element is assigned the chiral label R or S, or, if pseudo-asymmetric, r or s.*

In planar chirality, the preferred side of the model may be said to be on that side of the chiral plane which contains an atom, called the "pilot atom", which we shall define, and show how to identify, in Sub-section 2.7.

When the specialised helical model is applicable, and is to be used, a different rule of assignment will be required. The helix may immediately identify itself in the molecular model, as do the helices of secondary structures (Sub-section 2.8). In the area of conformations (Section 4), a limited use of the Sequence Rule is made in order to identify the helix. Supposing the helix to have been identified, it is necessary only to specify its sense. For this purpose, we propose the following rule of assignment:

Helicity Rule. *According as the identified helix is left- or right-handed, it is designated "minus" and denoted by M, or designated "plus" and denoted by P.*

There are some areas, notably, as explained in Sub-sections 1.4–1.6, around the margins of the field of conformations, and also, as will be observed in Sub-section 2.8, in the field of secondary structures, where two methods of specifying chirality are left open, one of which would use the Chirality Rule, whilst the other would employ the Helicity Rule. In the most important of these areas, notably in the biaryl series, *R* and *S* by the former correspond respectively to *M* and *P* by the latter. One result of the choice of symbols for designating helicity is the mnemonic that, in alphabetical order, *R* and *S* correspond to *M* and *P*, respectively, in the field mentioned.

### 2.2. Valence-Bond Conventions: Multiple-Bond Unsaturation and Aromaticity

The sequence rule has to be applied to valence-bond structures, though structural valency is an approximation concept, indeed, one which seriously loses precision in the presence of any form of unsaturation.

For this reason, four conventions, defining the valence-bond approximation by which an unsaturated molecule was to be represented for the purpose of applying the sequence rule, were proposed in Paper I [4]. They were as follows:

(a) *Hyperconjugation is neglected.*

(b) *Contributions by d orbitals to bonds of quadriligant atoms are neglected.*

(c) *A mesomeric system is represented by its usual valence-bond structure or structures. By "usual" is meant selected, first, to have fewest formal charges and radical centres, and then, given this, with preference for multiple bonds and conjugated systems of them, and chief preference for closed-conjugated systems.*

(d) (Now discarded). A mesomeric system with several usual valence-bond structures is represented by one of them, selected by a special rule, which was enunciated.

Convention (b) excludes double-bonded structures of, *e.g.*, sulphoxides and sulphinates. Under convention (c), charges are minimised and double bonds introduced subject to convention (b), and hence subject to such exclusions. We do not restate the rule contained in convention (d), because the present proposal is to discard it, and, indeed, to change the whole direction of convention (d). We must first explain the need for a change.

By far the most important area to which convention (d) applies is that of the six-membered aromatic rings. These always have several Kekulé-type structures,which can all be taken as usual valence-bond structures. Some subsidiary areas are covered by the convention, but they present only minor variations of the same problem of ambiguity in double-bond arrangement. The special rule in the old convention (d) for the selection of a particular arrangement was unequivocal, but it was excrescent to the logic of the sequence rule; and (as Prof. *Richter* and Dr. *Weissbach* convinced us) experience has proved that it is undesirably intricate in some of its applications.

Now the treatment of systems to which convention (d) applies is a last step, and so is dependent on earlier steps, in the treatment of multiple-bond unsaturation as a whole. Even though it is only in the last step that the difficulties mentioned have arisen, we cannot appropriately change that step in isolation, but must revise the treatment of unsaturation more generally.

We have had three aims in mind in designing the revision now to be proposed. One was to retain a maximum of orthodoxy in assignments of configuration to the traditional and didactically basic cases of molecular chirality, such as tartaric and lactic acids, glyceraldehyde, and serine. Another was to improve the logical unity of the sequence-rule procedure. The third aim was the practically important one of simplifying the more involved applications of the sequence rule in the field of polyunsaturated systems.

The treatment of unsaturation now proposed, and its relation to the former treatment, may be explained with the aid of a simple example. Let us consider a molecule containing one asymmetric carbon atom, and, as a feature of unsaturation, one carbonyl group. We shall assume that the ordering of ligands about the asymmetric atom is being accomplished on the basis of atomic number, that is, by Sub-rule (1). Following the fundamental sequence-rule method, we conceptually travel from the asymmetric atom along each of its bonds, recording their characters by the atoms found at their further ends, in numerically coded form for ordering, as the atomic numbers of these atoms. Then, having arrived by way of a bond at an atom, we explore similarly all its other bonds. And we repeat this procedural step as far as it is material. When we arrive at carbonyl-carbon, we record its double bond as two single bonds both ending on oxygen: for purposes of accountancy, we refer to one as terminating on the real oxygen atom, and the other on its duplicate representation. The old procedure stopped there; but it is an illogical place to stop; and the new proposal is that the procedure should be continued through one further and complementary step. This step is that, having arrived by way of a bond at carbonyl-oxygen, we explore its (only) other bond, which ends on carbon. Thus, for numerical coding with a view to ordering, we represent C=O, not, as before by C–O , but by C—O ,
(O) (O) (C)
where (O) and (C) are duplicate representations of the double-bonded atoms.

Generalising from this illustration, we see that the amended formulation of multiple bonds for application of the sequence rule involves adding, not merely at the first-encountered end, but at *each* end of each double or triple bond, one or two duplicate representations, as the case may be, of the atom at its other end.

This method has the simplifying effect, particularly helpful in the field of unsaturated ring compounds, that one has not necessarily to keep a strict account of which is the end of a multiple bond that is first encountered in the exploratory process. The same answers would follow if the multiple bonds were conceptually supplied with the duplicate representations of atoms before the exploration was begun. This simplification in turn opens the way to a simpler convention (d), one not involving an excrescent special rule.

It may be noted in passing that we could have achieved a similar though not identical result by an instruction to treat double and triple bonds as rings, in particular, as two-membered rings and bridged rings, respectively. This would obviate reference to duplicate representations of atoms; but we find duplicate representations, like phantom atoms, an aid to accounting, and hence prefer to retain them. As before, all real atoms other than hydrogen, and all duplicate representations, are made up to ligancy four with phantom atoms. The full representation of carbonyl thus becomes C———Ooo ,
(O)ooo (C)ooo
where o denotes a phantom atom.

This amended formulation of multiple bonds is immediately applicable to non-mesomeric unsaturated systems. They are subject only to the structure-defining conventions (a) and (b).

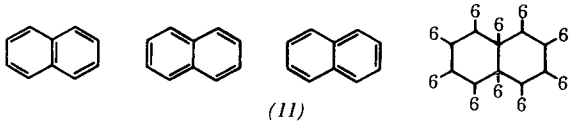
It is immediately applicable also to mesomeric systems with a uniquely usual valence-bond structure. They are governed by conventions (a), (b), and (c), the last being an instruction to employ the unique structure. It was noted in Paper I that a large number of types of mesomeric system fall into this general case, and that one important type which does so is that of the hererocyclic five-membered-ring aromatic molecules. Quite generally, the unique structure is a least polar one; and this is true for the five-ring aromatics, the unique structures of which have two-double-bonded non-dipolar rings, with no uncertainty as to double-bond positions. This applies even to sydnones, for which the overall structure is dipolar, but the ring is not. In some five-ring aromatics, the complication of prototropy arises: this is discussed in Sub-section 3.5.

It is in the field of mesomeric systems with several usual valence-bond structures that the amended formulation of multiple bonds is most helpful. The primary

area here is that of those even-membered rings whose unsaturation is expressible in fully-closed conjugated systems of double bonds. The field embraces the six-membered aromatic rings, and some even-rings in molecules not typically aromatic, for instance, that in cyclo-octatetraene, and the ten-membered ring (but not the component rings) of azulene. In all these rings, the closed-conjugated double bonds can be inserted in two ways, and our concern is to prevent this Kekulé-type ambiguity from producing an ambiguity of sequence-rule result.

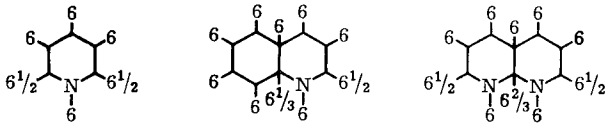
We may interpolate here, as a comment on the two immediately preceding paragraphs, that the application of common treatment to aromatic and non-aromatic systems should occasion no surprise. For we are dealing with valence-bond structures, and have no concern with molecular energetics, and hence none with aromaticity as such. Aromaticity is another chemical concept which conveys a distinctive set of ideas, but is incapable of satisfactory definition, and hence has an area of application, one of non-application, and a penumbra.

With the revised formulation of multiple bonds, it is easy to arrange that the ambiguity of double-bond distribution in closed-conjugated even-rings shall lead to no ambiguity of sequence-rule result. Actually, this consequence follows inevitably and without more ado, provided that the rings are homocyclic: if they were the only problem, no convention (d) at all would be required. For in them, the delocalised valency of each ring-carbon binds only carbon, and hence can be supplied with a duplicate representation of carbon. Thus the various usual valence-bond structures give the same representation to which to apply the sequence rule, as illustrated for naphthalene, and thus for a naphthyl residue in a chiral molecule, in *(11)*. The duplicate representation is here denoted by its atomic number 6, instead of by (C), for comparison with the group of cases next to be considered.



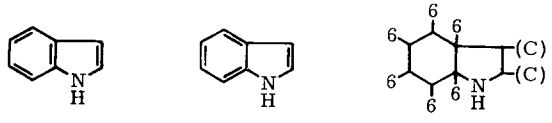
*(11)*

In the homocyclic series, the representation is so automatic that it is immaterial whether we regard it as derived from one selected valence-bond structure, or from a blend. Actually the latter idea is the better for adaptation to closed-conjugated even-rings containing one or more hetero-atoms. In such systems, a ring atom may be concurrently part-binding atoms of more than one kind, and hence, in the blend, may be binding an average atom of fractional atomic number. As any ring-atom must have either two or three next-neighbour ring-atoms, we conventionalise the possible proper fractions to $^1/_3$, $^1/_2$, or $^2/_3$, by assuming for simplicity equal partitioning of the delocalised valency among the next-neighbour atoms, as illustrated at *(12)–(14)*, where the figures denote the atomic numbers of the blended duplicate representations.



*(12)* *(13)* *(14)*

The importance of distinguishing between systems with unique, and with several, usual valence-bond structures, and, in particular, between odd-rings and closed-conjugated even-rings in aromatic molecules containing both, should be emphasized. Only in the even-ring of a residue of indole, for example, are the usual structures different, and therefore to be blended. To mark the distinction, the duplicate representations of carbon, blended or otherwise, are denoted by two kinds of symbols in formula *(15)*, which, it will be noted, contains no fractional atomic numbers, because the hetero-atom belongs to the unique odd-ring part of the structure.

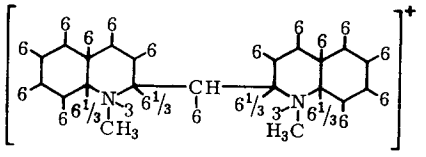


*(15)*

The "primary" field of mesomeric systems with several usual valence-bond structures to be blended is that just considered, the field of *closed-conjugated even-atomic rings*. But a "secondary" field of such exists, *viz.* that of the *mesomeric odd-atomic ion and radical systems*, as we illustrate below. The two types of system may be present together, and may be overlapped. Two odd-atomic systems may be overlapped in a bivalent ion or di-radical, which may thus be even-atomic overall.

An odd-atomic mesomeric system of the "secondary" field may be endless or ended. In either case, we shall express the unsaturation with a maximum of formal double-bond conjugation; and we shall have a plurality of usual valence-bond structures. The system will possess a phantom atom. Typically, this will occupy different positions in those valence-bond structures which have to be blended. Thus it will be present, though delocalised, in the blend. As examples, we may consider the cyclopentadienylide ion, the tropylium ion, the phenalenylide ion, the acetylacetonate ion, and the cyanine dyes. In some of these, blending does not fractionate atomic numbers only into halves and thirds. In the cyclopentadienylide ion, each of the five delocalised carbon valences is taken to contribute to the extent of one-fifth to the binding of the phantom atom, and hence to the extent of four-fifths to the binding of carbon, wherefore it is associated with the atomic number $(4/5)\times 6$. In the tropylium ion, and likewise in the phenalenylide ion, the phantom atom can have any of seven positions, and thus the delocalised valency at each such position is taken to contribute to the extent of one-seventh to the binding of the phantom atom, and is accordingly associated with the atomic number $(6/7)\times 6$. In the acetylacetonate ion, each oxygen atom has a delocalised valency, which in one of our valence-bond structures binds carbon and in the other a phantom atom, and hence is associated with the atomic number $(1/2)\times 6$. The nitrogen atoms of the cyanine dyes are in the same situation, as is illustrated in formula *(16)*. All these conventionalised structures, here de-

scribed as for parent ions, hold for residues of the ions, as they might be encountered in chiral ions requiring to be treated by the sequence rule.



*(16)*

Just as, when blending in the "primary" field of closed-conjugated even rings, we divide a delocalised bond equally (into halves or thirds), irrespective of the symmetry of the model, so in the "secondary" field, we blend structures of a mesomeric odd-atomic ion system with an equal division of the delocalised bond to the phantom atom, irrespective of the symmetry of the model. Thus the phantom atom representing the ionic charge in the pyrrolylide ion, the pyrazolylide ion, or the imidazolylide ion, is taken as bound equally by each of the five ring atoms, so that only four-fifths of the delocalised bond of each ring atom is available for equal division between nearest-neighbour atoms in the ring. Again what is here said of the simple ions will apply when they are substituted to give chiral ions.

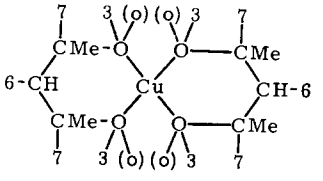
When one or more systems of the "primary" field in which we blend usual valence-bond structures, and one or more systems of the "secondary" field, are overlapped, blending is effected with structures which maximally retain "primary" systems, in accordance with convention (c). The phantom atom in the indenylide ion, or in the indolylide ion, is thus delocalised only between positions 1 and 3; and in the fluorenylide ion or in the carbazolylide ion, it is localised on position 9. Chiral or other substituents in the benzo-rings make no difference to these locations. Triarylmethyl cations, anions, and radicals, are taken with a maximum of "primary" systems, that is, in fully benzenoid form, with the phantom atom therefore localised on the central atom. Accordingly, a conventionalised structure, thus prepared for application of the sequence rule, is in no way dependent on the actual (not exactly known) electron distribution, and substituents, chiral or otherwise, though they might make a great difference to the actual electron distribution, make no difference to the conventionalised structure.

When two ionic systems of the "secondary" field are overlapped, as in the pentalene-di-ide ion, we distribute the bonds to their respective phantom atoms additively and independently. In this example, two-fifths of the delocalised bond of each ring-junction atom, and one-fifth of that of each other ring atom, that is, ten-fifths altogether, are concerned with binding the two phantom atoms.

Having explained the reasons for, and the scope, substance, and method of application, of the new convention (d), we may now formally enunciate it:

(d) *(New) A mesomeric system with several "usual" valence-bond structures is represented by their blend, in which each delocalised bond is assumed equally to bind the next-neighbour atoms of the system, the atomic number characterising the bond being the arithmetic mean of those of these atoms. Delocalised bonds to phantom atoms are taken as equally divided between their several positions.*

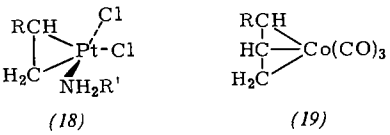
In the treatment of σ-bonded metal derivatives of mesomeric ions, the metal atom is given a bond to each ligating atom of each ligand. In σ-chelated derivatives, the model may contain one or more systems belonging to the "secondary" field of blending, wherein, typically, phantom atoms are delocalised. In cupric acetylacetonate *(17)*, each chelate ligand thus has mono-oxonium character, and carries three phantom atoms, one of which is delocalised. Metal porphyrins are chelated σ-complexes, and an example of this class is given in Section 5.4.



*(17)*

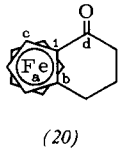
When a metal is π-bonded to a non-conjugated double or triple bond, then, in the valence-bond structure prepared for application of the sequence rule, the multiplicity of the bond is reduced by unity, and the atoms of the bond are made to bind the metal by single bonds, as illustrated for an olefin-platinum complex in *(18)*. When a metal is π-bonded to a conjugated unsaturated system, whether radical, ion, or molecule, for example, an allyl radical, a cyclopentadienylide ion, a cyclohexadienylium ion, a 1,3-diene, or benzene or a derivative, all the unsaturated atoms concerned in the binding of the metal are similarly made to bind it with single bonds, with a corresponding reduction in the formal unsaturation of the ligand, as illustrated for an allyl-cobalt complex in *(19)*. The resulting formulae are limiting with respect to the (not exactly known) degree to which the unsaturation electrons are binding the metal, and thus substituents, although they might alter the actual electron distribution, make no difference to the conventionalised π-bonded structures. The need for blending does not now arise. The convention covering this type of situation is therefore as follows:

Convention for π-Complexes. *Those ligating atoms of an unsaturated ligand which are π-bonded to a metal atom are taken each to bind that atom with a single bond, their quadriligancy being preserved by reducing by unity the multiplicity of the multiple bonds in which they participate within the ligand.*



*(18)*

*(19)*



*(20)*

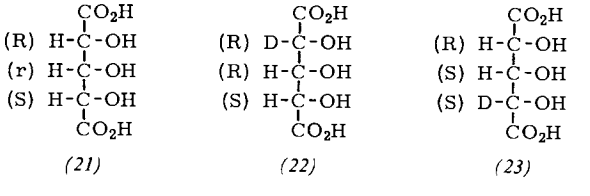
The use of such structures in the assignment of chiral symbols may be illustrated by reference to the optically resolved ferrocene ketone *(20)*, the represented configuration having been determined by *Schlögl* and *Falk*[11] for the enantiomer having $[\alpha]_D = +580°$ in

ethanol. Each of the five carbon atoms of the substituted cyclopentadienyl ring is an asymmetric atom, but the chirality of the whole molecule will be specified if we designate the chirality of any one of these atoms, conveniently C-1, the one most preferred by the Standard Sub-rules. In the sequence required for its designation, the first member, a, which is the iron atom, lies below the plane of the other three members, b, c, and d, as marked on *(20)*. Hence C-1 is *S*, and the ferrocene might be designated [*] as 1*S*.

### 2.3. Precedence of Sub-Rules: Ordering by Mass-Number

The rules scheduled in Sub-section 2.1, the Factorisation Rule, the Sequence Rule, with its Standard Sub-rules, and the Chirality Rule, are the fundamentals of sequence-rule procedure. Furthermore, the order of the rules and sub-rules is an essential part of the procedure, because stated specifications of chirality would be meaningless unless the order of use of the rules were known. We have to have a firm order, one in which opportunistic variations are not allowed. Therefore an order may not be prescribed which renders the sequence-rule system inoperable in some part of its legitimate field.

When Paper II was written, it was felt that, as ordering by isotopic differences would seldom be required, the mass-number sub-rule might conveniently be made the last sub-rule. It has, however, been pointed out to us by Prof. *Richter* and Dr. *Weissbach* that this prevents the sequence rule from specifying correctly chiral forms that can be derived by asymmetric isotopic substitution in a parent compound such as *(21)* or *(24)*. Compounds *(22)* and *(23)* are derived thus from the parent compound*(21)*. Had the mass-number sub-rule been allowed to remain last, they could not have been assigned the correct specifications shown: in both, the central atom would have been specified as *R* by the same earlier sub-rule that specified the central atom of *(21)* as *r*; and this would have been a *reductio ad absurdum*, inasmuch as *(22)* and *(23)* are enantiomers.



*(21)* *(22)* *(23)*

In order to avoid this difficulty, and reach the correct assignments shown, we prescribe that all ordering by material differences should be done before any ordering by stereochemical distinctions. Therefore, in the schedule of rules in Sub-section 2.1, the mass-number sub-rule has been re-numbered (2), and brought to a position immediately following the atomic-number sub-rule (1).

Similar arguments can be developed with respect to the internal order of the two former stereochemical sub-rules, now expanded to three, and numbered (3), (4), and (5). But in this case, the same principles of decision require that, as before, differences of geometrical isomerism be treated before chiral differences. The chief reason is that the sub-rules employing the latter are "parasitic" on the other sub-rules, requiring as intake-material, not merely the model itself, but also the answers that the other sub-rules give: wherefore, unless Sub-rules (4) and (5) were last, specifications in structures with many chiral centres could depend on the indeterminate order [*] in which the various chiral centres were specified.

The finally obtained order of the sub-rules, though reached essentially on pragmatical grounds, has a certain logical tidiness. Material differences are dealt with in sub-rules (1) and (2) before stereochemical in sub-rules (3) to (5); and, within each class, the grosser distinction is used before the finer, elemental before isotopic material differences, and differences involving scalar magnitude before those of vector-sense alone among stereochemical distinctions.

### 2.4. Ordering by Stereochemical Differences

The ordering of two groups, A and A′, which are identical except for a stereochemical difference, is based on Sub-rules (3) to (5).

We must first explain the special nomenclature that has been introduced into Sub-rule (3). This sub-rule was formerly written "*cis* precedes *trans*", and an explanation was added, of which it is easy to lose sight, unless signalised, as now, in the notation.

Applications of the terms *cis* and *trans* to group arrangements about an atom-pair XY in a double bond or ring have developed traditionally but irregularly, inasmuch as it has never been generally prescribed which substituent of a pair ab in Xab, and which of a pair cd in Ycd, are fiducial for the assignment of *cis* and *trans* labels to the whole arrangement abX=:::=Ycd. It is not our business to revise the nomenclature of geometrical isomerism; but we have to have a regulated method of supplying the geometrical labels that we require in the course of assigning chirality by the sequence rule. Our labels, now distinguished as *seqcis* and *seqtrans*, will not always correspond to the traditional ones *cis* and *trans*. But ours are mere scaffolding: they disappear in the final assignments of chirality; and hence they do not get embodied in chemical nomenclature. As a definition we may write:

> Seqcis and seqtrans. *An atom-pair is called seqcis or seqtrans according as the sequence-rule-preferred ligand bound to each atom of the pair is cis or trans with respect to the other such ligand.*

We assign our labels, *seqcis* and *seqtrans*, to the atom-pair XY, with respect to a double bond or ring to which it belongs, by taking as fiducial the sequence-rule-preferred substituent of the pair ab, and the preferred

[11] *K. Schlögl* and *H. Falk*, Angew. Chem. *76*, 570 (1964); Angew. Chem. internat. Edit. *3*, 512 (1964); *H. Falk* and *K. Schlögl*, Mh. Chem. *96*, 266 (1965).

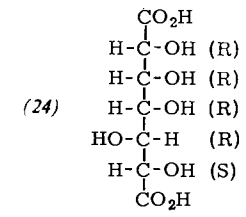
[*] In Professor *Schlögl*'s papers it is called *R*, and for this we are to blame, having expressed to him our agreement with that designation before our generalised treatment of metal π-complexes had been developed.

[*] We have no rules, and could not have any general rules, prescribing the order in which different chiral centres are to be assigned: feasibility is the sole condition (cf. Sub-section 2.1).

one of the pair cd. If atoms of the pair XY belong simultaneously to several rings, so that some of its substituents with respect to one ring are parts of other rings, the pair XY should first be assigned by this method a geometrical label with respect to each ring; and then, in case these labels are different, we accept as effective that which depends on the most preferred substituent of all, or the more preferred pair of fiducial substituents. The atoms of the pair XY might belong each to one of two co-planar double bonds in a series of cumulated double bonds, as in a cumulene; but, provided that a conventional label, *cis* or *trans*, could describe, the stereochemical relation of the fiducial substituents at X and Y, we shall apply a label *seqcis* or *seqtrans* to the atom-pair XY. And we shall use a similar method when double-bonds in such as cumulated system are replaced by rings, as in alkylidenecycloalkanes or spirans.

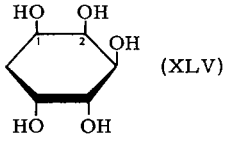
Having thus recognised the *seqcis* or *seqtrans* geometrical character of all relevant atom-pairs, we order the groups A and A′, as far as Sub-rule (3) allows, by exploring them for geometrical character, comparatively and in steps, from the chiral element outwards. If we number the atoms in A and in A′ independently from the chiral element, our first comparison is of the 1,2-atom-pair in A with the 1,2- in A′, the second is of the 1,3-pair in A with the 1,3-in A′, and so on, the general order being 1,2 > 1,3 > 2,3 > 1,4 > 2,4 > 3,4 > ..., where > means "precedes". Sub-rule (3) is applied to the first distinction encountered.

The previous sub-rule that *R* precedes *S* is replaced by Sub-rules (4) and (5), of which Sub-rule (4) is new. These sub-rules employ chirality specifications assigned to other elements of chirality. Such chirality specifications, when spread over two groups A and A′ that are not differentiated by the previous sub-rules, generate a true element of chirality, if at least one pair of specified elements of chirality in the group A is diastereoisomeric with the corresponding pair in the group A′. The new Sub-rule (4), which prescribes that *R,R* or *S,S* precedes *R,S* or *S,R*, and generally that a pair of specifications of like individual priority (see Sub-rule 5) precedes a pair of unlike, deals with this situation. The groups A and A′ are explored for already assigned pairs of specifications, comparatively, and in outward steps, the order of the comparisons, with the previous numbering, being 1,2 > 1,3 > 2,3 > ..., as above. Sub-rule (4) is applied to the first difference encountered. Formula *(24)* is a simple example of its application. Sub-rule (4) also prescribes that *r* precedes *s*. These symbols can by themselves distinguish such diastereoisomeric differences as are the subject of this sub-rule. The specification of chirality of an atom X in a structure of the type {*(RSr)*, *(RSs)*, a,b}X would exemplify this application. The earlier sub-rule that *R* precedes *S*, now generalised in Sub-rule (5), is used to assign chirality symbols to an atom X in combinations such as $(R_1,S_1,R_2,S_2)$X. This sub-rule is also used to specify diastereoisomerism characterised by pseudo-asymmetry of the type (*R*,*S*,a,b)Y. We specify pseudo-asymmetry, as before, by the symbols *r* and *s*, noting that they are unchanged on reflexion of the model.



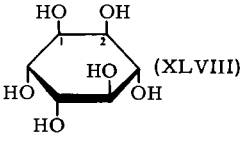
*(24)* - according to Sub-rule (4)

Turning to illustrations, we must first correct a mistake in Paper II, pointed out to us by the friends already mentioned [6]. This is that, in some of our assignments to cyclitols, we forgot, despite having stated it, that the geometrical characters, now denoted by *seqcis* and *seqtrans*, are internal to either group A or A′, and do not describe a relation of such a group to some other group of the complete set AA′bc. The formulae which were mis-labelled on this account, with their original numbers from Paper II, are reproduced below, but in association with the correct chiral assignments [*]:



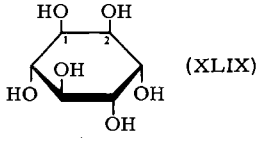
(XLV)

(1R, 2R, 4R, 5R)



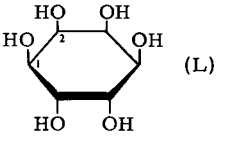
(XLVIII)

(1S, 2R, 3R, 4R, 5R, 6S)



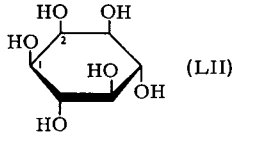
(XLIX)

(1S, 2R, 3R, 4S, 5S, 6S)



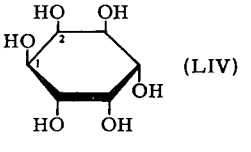
(L)

(1R, 2R, 3S, 4S, 5R, 6S)



(LII)

(1R, 2s, 3S, 4R, 5s, 6S)



(LIV)

(1S, 2r, 3R, 4R, 5r, 6S)

We refer finally to some of the further examples that have come under discussion [6]. In the anhydride *(25)*, C-3 is symmetric, as in the free acid, and hence receives no label. In hydroshikimic acid *(26)*, and its diastereoisomer *(27)*, C-1 and C-4 are asymmetric, and are labelled by Sub-rule (3). In the myoinositol ether,

[*] The convenient "local" system of cyclitol notation, the so-called "fractional" system, illustrated in Paper II, automatically specifies absolute configuration, even within the type $(Xab)_n$, if the numbering system, applied within that type, and illustrated in the inositol series $(CH{-}OH)_6$ is employed. This system is applicable when no unambiguous starting-point for numbering is given by the constitution, apart from any stereospecificity, as, for example, in cyclic systems of the series $(Xab)_n$, $(Xab{-}Ycd)_n$, $(Xab{-}Ycd{-}Ycd)_n$, $(Xab{-}Ycd{-}Zef{-}Ycd)_n$, ... The numbering system involves so placing the ring horizontally that at least as many fiducial groups (OH in the examples) point upward as downward, and that lowest numbers may mark the former when the ring is numbered clockwise from above. Thus the (−)- and (+)-inositols, (XLVIII) and (XLIX), are specified as to absolute configuration by their local-system prefixes (1,2,4/3,5,6)- and (1,2,5/3,4,6)-, respectively. Although no additional symbols are required, one could signalise each enantiomer with an additional configurational symbol, such as 4*R* or 4*S*: one need not fall back on symbols that signify optical rotation only. It will be clear that the numbers used in this system satisfy our requirement of suggesting no genetic relations between the atoms of (XLVIII) and those of (XLIX).

bornesitol *(28)*, and its diasteroisomer *(29)*, C-1 and C-4 are labelled by Sub-rule (3), and the difference at C-1 shows in the symbols for its chirality.

Example *(30)* has been contrived as a case of special complexity, inasmuch as the specification of chirality of C-7 depends on a stereochemical difference between the 1,2- and 4,5-atom-pairs, each belonging to two rings with respect to which it has opposite geometrical descriptions. However, the specification is not difficult to follow. With respect to its five-membered ring, the

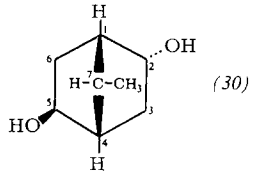
*(29)*

(1S, 2S, 3R, 4R, 5S, 6S)



*(30)*

1,2-atom-pair carries the fiducial substituents 6-$CH_2$ and 2-OH, which are *cis*. With respect to the six-membered ring, the fiducial substituents carried by the same atom-pair are 7-CHMe and 2-OH, which are *trans*. The latter fiducial pair is the more preferred, and hence the 1,2-atom-pair is *seqtrans*. Similarly, the 4,5-atom-pair is *seqcis*. Hence the chirality of C-7 is described as *S*, and the specifying prefix for compound *(30)* is (2*R*, 5*S*, 7*S*) [*].

[*] In applying the stereochemical Sub-rules as prescribed in the text, we do not reflect, in the final description, *R* or *S*, of the asymmetric atom under specification, *all* the details of the stereochemistry on which that description depends. Thus, when a specification depends on ordering groups by Sub-rule (3) or (4), we do not show in the final symbol by which of their atom-pairs they were ordered, whether by the 1,2-pairs, or 1,3-, or other pairs; and when ordering by Sub-rule (5), we do not finally show by which atoms the groups were ordered.

This failure to express part of the provided data must in principle open the possibility of lost distinctions in the resulting descriptions, so that two stereochemically different models would receive the same description. Actually, such cases seem so rare that we think that it would be a mistake to to elaborate descriptions as a routine, though they can easily be elaborated in order to separate them when required. No case has yet been realised experimentally, and the only ones yet thought of, as far as we know, both by Dr. *Weissbach*, are two pairs among the 44 diastereoisomers of $X(ab)_{10}$, *e.g.*, of cyclodecanedecaols.

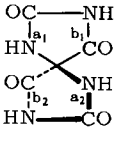
## 2.5. Central Chirality: Symmetry and its Procedural Consequences

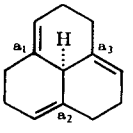
We have not previously considered what types of symmetry can be accepted by a quadriligant chiral centre. Such a centre can fall into any of the following four symmetry classes. The most familiar and by far the most extensive class is that of no symmetry ($C_1$ in Schoenflies symbols), as in Cabcd, the asymmetric carbon atom.

The next higher symmetry class, among those to which chiral centres can belong, contains one two-fold axis (class $C_2$). An illustration can be derived from achiral Caabb by making each ligand b related differently to the a's, and each ligand a differently to the b's, as can be done by connecting each ligand a with a separate b in equivalent rings. This proceeding destroys the two previously present planes of symmetry, but it retains the two-fold rotational axis. The resulting spiro-compound, (ab)C(ab), is chiral. Its two-fold axis passes through the mid-point between the a's, the atom C, and the mid-point between the b's.

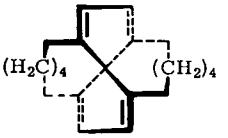
As an example, we may take the spiro-hydantoin *(31)*, treated in Paper II, as we now know, incorrectly, on the basis of axial chirality. Its chiral centre, the spiro-atom, has, as its next neighbours, two equivalent nitrogen atoms, and two equivalent carbon atoms; and the specification of its chirality provides a further application of the general principle, illustrated in Paper II, that when a choice has to be made between equivalents for the leading place in a sequence, the choice is immaterial, provided that, once made, its consequences are followed through. Here we may take, as first member of the sequence, either of the next-neighbour nitrogen atoms, say, $a_1$. The first consequence of this choice is that the other next-neighbour nitrogen atom, $a_2$, must constitute the second member of the sequence. Of the next-neighbour carbon atoms, that which occupies the same ring as the most preferred nitrogen atom will take the third place. It will be $b_1$. The reason is that exploration from it, outwards and round the ring, will lead to the more preferred nitrogen atom, $a_1$, whereas the comparison exploration from the other next-neighbour carbon atom, $b_2$, round the other ring will similarly lead to the less preferred atom, $a_2$, of the next-neighbour



*(31)*



*(32)*



*(33)*

The elaboration would consist simply in showing the atom-pairs used in applying Sub-rule (3) or (4), or the atoms used in applying Sub-rule (5), by means of a superscript associated with the final symbol of chirality; but we suggest using Greek letters, rather than numbers, for outward-enumeration of the stereochemically compared groups, in order to avoid confusion with nomenclatural enumeration in the model as a whole. In one of the pairs mentioned above, of cyclodecanedecaols *(30a)* and *(30b)*, the symbols for the asymmetric atoms, based on Sub-rule (3), are elaborated as described, whilst the symbols for the pseudo-asymmetric atoms, based on Sub-rule (5), require no elaboration.

nitrogen atoms. The sequence is thus completed, and it shows that the model represented at *(31)* is an *S*-enantiomer.

The third of the symmetry classes into which a chiral centre may fall contains one three-fold axis as its only symmetry (class $C_3$). An illustration can be derived from achiral Caaab by connecting the a's in cyclic sequence with three like bridges that have no transverse symmetry-plane. This gives, to each ligand a, identical differences of relationship with other a's. It destroys the previous three planes of symmetry, but retains the three-fold axis. The hexahydrophenalene *(32)* will serve as an example. Its chiral centre, the carbon atom common to its three rings, may be assigned its symbol of chirality by the method just illustrated. Any of its three, equivalent, next-neighbours, say, $a_1$, may be placed first in sequence. The second will be that other one, $a_2$, from which outward exploration, along the route of highest precedence, that is, starting with a double bond, leads the more directly to it. The model shown is an *S*-enantiomer.

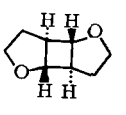
The fourth symmetry class available to a chiral centre has three two-fold axes of symmetry (class V). The case can be derived from tetrahedral Caaaa be connecting the a's cyclicly as in *(33)*, with four bridges of two kinds introduced alternately, each bridge having a transverse plane of symmetry. In the resulting double spiran, the original six planes of symmetry, and the four three-fold axes of symmetry, are destroyed, and only the three two-fold axes remain. The chirality of the central atom is specified as in the preceding examples. Any of its four, equivalent, next-neighbour atoms may be placed first in sequence, and then that which shares the five-ring with it will come second, and that which does not share a ring with it will come third. The model represented is in the *R*-configuration.

We may consider the relation of a tetrahedral atom to higher symmetry classes, in particular, to the class of highest chiral symmetry within the scope of quadriligancy, *viz.* the class T, which is characterised by four three-fold and three two-fold rotational axes of symmetry. It is possible to build a molecule of symmetry T round a tetrahedral atom by bridging in pairs with six like bridges four like tetrahedral atoms directly bound to it, each bridge containing a plane of chirality which destroys planes of symmetry, but preserves a two-fold rotational axis between the atoms bridged. The bridges might, for example, be *trans*-olefinic, of the form $-(CH_2)_n-CR=CR-(CH_2)_n-$. The chiralities of the chiral planes being alike, the four three-fold axes of rotation will be preserved, and hence the overall symmetry will be T. But no symbol of chirality can be assigned to the central atom, and the chirality of the structure derives from its outer planes of chirality. We have here described a chiral envelope, and we shall describe and illustrate the simpler case of a chiral girdle in Sub-section 2.7.

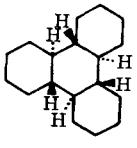
A further problem in the detailed method of designating the chirality of chiral centres in the presence of rotational axes of symmetry arises when such axes inter-relate *equivalent chiral centres*[*]. It may then happen that outward exploration of two ligands belonging to one centre, along routes of highest precedence, will lead, without producing on the way any distinction useful for ordering, for one ligand, back to the original chiral centre, and, for the other, to its symmetry-equivalent. When that happens, we give precedence to the ligand which has not led back to the original chiral centre. The situation is highly specialised, but it needs, in extension of the Sequence Rule, a Rule for Equivalent Centres, as follows:

Rule for Equivalent Centres. *Of two ligands at a chiral centre, whose only distinction is that, on exploration under the Sequence Rule, one leads to the original centre whilst the other leads to an equivalent centre, the latter takes precedence in the sequence of ligands.*

An example, belonging to the $C_2$ symmetry class, is furnished by structure *(34)*. The stereochemistry of these compounds has been discussed[12]. The inner ring consists of two pairs of equivalent chiral centres, and in formula *(34)* all are in *R*-form. Specifying the chirality of any of them involves giving that one of its ligands, which starts with CH in the same hetero-ring, lower precedence than that which starts with the other CH. This order follows from our preference, when a distinction depends on it, for a route which, in the comparative exploration, does not return to the original chiral centre.



*(34)*



*(35)*

An example of higher symmetry is provided by the *trans*-perhydrotriphenylene *(35)*. It belongs to the class $D_3$, having one three-fold and three two-fold rotational axes of symmetry. The central ring consists of six equivalent chiral centres, which, as here illustrated, are all in *R*-form. The process of specifying any of them is as in the previous example. It may be worth noting that, in both examples, exploratory routes of highest precedence (leading round the central ring in opposite ways) yield no distinction, wherefore, at the first branching point, exploration is continued along the routes next in precedence (which lead round the separate lateral rings).

### 2.6. Axial Chirality: Scope, Procedure, and Symmetry

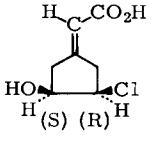
We mentioned in Sub-section 1.5 the derivation of axial chirality by the giving of one dimension to an original chiral centre. We referred also to the five main areas of application of the concept of axial chirality, namely, to allenes, alkylidenecycloalkanes, spirans, biaryls, and

[*] A similar problem arises in infinite regular polymers, when such equivalence is produced by a translation, without or with rotation.

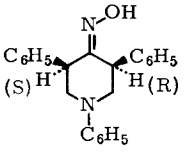
[12] *M. Farina* and *G. Bressan*, Makromolekulare Chem. *61*, 79 (1963); *G. Natta* and *M. Farina*, Tetrahedron Letters *1963*, 703; *M. Farina*, *ibid.* *1963*, 2097.

adamantoids, along with their respective isomorphs. In these areas, the axis of chirality is derived by desymmetrization from a four-fold alternating axis of symmetry: that is its fundamental property. To mention the chemical classes which provide examples of axial chirality is not, of course, to suggest laying aside the Factorisation Rule, in accordance with which the chirality of many alkylidenecycloalkanes and spirans, for example, will be fully specified in terms of chiral atoms, without requiring recourse to an axis of chirality.

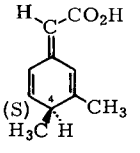
Discussion has shown [6] that our original statement in Paper II on the *scope of axial chirality* needs amplification with respect to certain special types of case. Thus, the alkylidenecycloalkane and piperidone oxime, shown at *(36)* and *(37)*, do not fall within the scope of axial chirality, though they might, perhaps, have been thought to do so. The reason that they do not is that, when the chiral centres in the rings have been assigned, the remaining matter is purely one of geometrical isomerism, outside the province of the sequence rule. Once the rules for assigning the *cis* and *trans* labels have been determined, the stereochemical specifications can be finished. (In the meantime, the exocyclic double bonds might provisionally be labelled *seqcis* in the forms here represented.) Example *(38)* also has nothing to do with axial chirality; for C-4 is an asymmetric carbon atom, and the description of the exocyclic double bond, as *cis* or *trans*, is out of our hands.



*(36)*



*(37)*



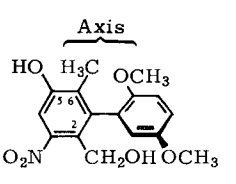
*(38)*

The other matter of scope concerns the chiral spirans. It is understood that spirans are a chemical class, and not a chirality class, and that therefore they can extend into more than one chirality class (Sub-section 1.3). They may exhibit either central or axial chirality, and in either case may either be asymmetric or possess rotational axes of symmetry. Examples *(31)* and *(33)* illustrate centrally chiral spirans with symmetry $C_2$ and V, respectively. Formula *(4)* on p. 388 represents an axially chiral spiran without symmetry. But by replacing the end-groups cd by ab, it could be given symmetry $C_2$, without losing its axially chiral character.

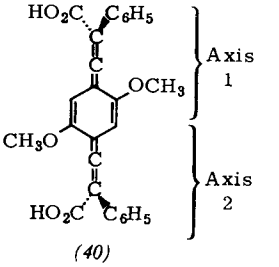
A *change of procedure* is now proposed in the choice for ordering of groups about an axis, when more groups are present than are needed for the specification of chirality. The first atom of each such group must be an atom bound directly to the chiral axis; but there are, for instance, four such atoms (the carbon atoms 2,3,5, and 6) in each ring of a biphenyl compound, whereas we need no more than two in each ring.

Sub-rule (0) has to be taken into account. It prescribes that groups about the near end of an axis take precedence over groups about the far end. It never matters which end is taken as the near end, provided that the choice, once made, is adhered to. In Paper II, we had this sub-rule in mind when proposing that the nearest and furthest pairs of groups should be chosen. It now would seem more convenient if, on the contrary, we take the extended tetrahedron *(1)* (p. 388) as defined by the pairs nearest together of groups that lie one pair on each of the planes that intersect along the axis.

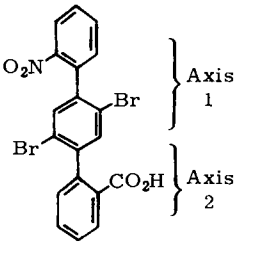
The arguments for doing this, due entirely to Prof. *Richter* and Dr. *Weissbach*, are (a) that the fiducial groups are then more often those most intimately concerned in producing the chirality, especially in the biaryl series where choice is most often necessary; and (b) that by giving chiral axes a minimum effective range, we can deal more easily with molecules containing several. These points are shown in the examples *(39)–(42)*, in each of which the chiral descriptions would be changed by allowing the axis or axes more than minimal effective lengths, whilst in two cases an overlapping of axes would result. In example *(42)*, we have, beyond the effective axis, a geometrical configuration requiring to be specified as *cis* or *trans*, when the methods for doing so are provided.



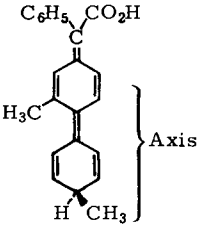
*(39)*



*(40)*



*(41)*



*(42)*

It should be noted that, when ordering groups, which necessarily start with first off-axis atoms, for instance, with the 2- and 6-carbon atoms of one ring in a biphenyl, we allow exploration over the whole molecule. It follows that the order of the 2- and 6-atoms is not always determined solely by the 2- and 6-side-chains. Example *(39)* has been chosen to illustrate the point. Here, the methyl-bearing carbon atom derives precedence over the methylol-bearing one by virtue of an exploration from the former through the carbon atom which bears the phenolic hydroxyl group.

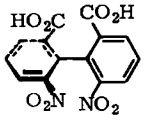
The Selection Rule for Axial Chirality, which defines the groups that are to be taken as fiducial, is as follows:

> **Selection Rule for Axial Chirality.** *The fiducial groups shall be the pairs nearest together of groups, directly bonded to atoms on the axis, that lie one pair in each of the planes of atoms that intersect along the axis.*

This revised procedure changes one of the axial assignments in Paper II, that of the formula there numbered (LXXIV), which would now be described as an

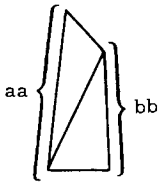
*S*-enantiomer. The new procedure does not change any of the designations tabulated by *Mislow*[13] of known absolute configurations in the biaryl series.

The illustrations of axial chirality given in Paper II, and here up to this point, have been random as to *symmetry classification*, with the result that one symmetry class is not yet illustrated. Within the limit of atomic quadriligancy, axial chirality can be found in three symmetry classes. The first ($C_1$ in Schoenflies symbols), represented in a general form by *(1)* on p. 388, and illustrated by *(39)*, has no symmetry. The second (class $C_2$), represented by *(44)*, and exemplified by *(43)*, has one two-fold axis. The third (class V), which we now want to consider, has three two-fold axes.

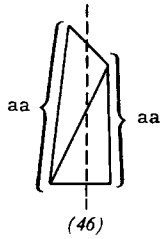


*(43)*

*(44)*



*(45)*



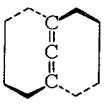
*(46)*

Starting from *(44)*, we can develop the more highly symmetrical form of axial chirality, by connecting like groups with bridges having transverse planes of symmetry as in *(45)*. This only adds a stereochemical distinction to the constitutional one between the members of either a,b-pair, and hence it does not change the symmetry ($C_2$). We can now abolish the constitutional distinction, as in *(46)*, and, because the stereochemical distinction is here preserved, chirality is retained. But the new structure contains three two-fold rotational axes (symmetry V). Naturally, one of these, the axis of chirality (marked), remains unique, as the only four-fold alternating axis when the stereochemical distinction, on which chirality depends, is destroyed by opening the aa-rings into four independent a-groups. The other axes become indistinguishable, as they should, as completely equivalent two-fold rotational axes.

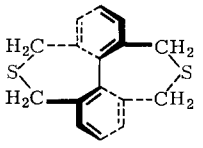
It is easy to allot a symbol of chirality to *(46)*, as follows. The ends of the chiral axis are alike, but we know (Paper II) that it is immaterial which end we select as the "near" end when applying Sub-rule (0). Again, as illustrated several times in Sub-section 2.5, it is immaterial which of two equivalent atoms, in this case the two a-atoms of the selected near end, we choose as first in sequence. The other a-atom of the near end will be second, and that a-atom of the far end, from which exploration round the ring would lead to the first atom of the sequence, will come third. Structure *(46)* has the *R*-configuration.

[13] *K. Mislow*, Angew. Chem. *70*, 683 (1958).

A simple molecule having the symmetry of *(46)* is the bicyclic allene, whose *R*-enantiomer is shown at *(47)*. The first optically active compound of symmetry V to be prepared is the biaryl bis-sulphide, the *R*-form of which is shown at *(48)*. *Mislow* and *Glass*[14] obtained this compound, the *R*-enantiomer of which had $[\alpha]_D^{26} = +415°$.



*(47)*



*(48)*

An axis may be pseudo-asymmetric. If one of the ligand-pairs ab in structure *(44)* consisted of *R* and *S* modifications of the same substituent, we should expect two diastereoisomers, which would both be optically inactive, because each molecule now has a plane of symmetry. We should distinguish them by the lowercase symbols, *r* and *s*.

### 2.7. Planar Chirality: Procedure and Symmetry

A procedure for the specification of planar chirality was proposed in Paper II. We now wish to modify the method in a way that allows it to be prescribed more closely.

The first step is the selection of a plane of chirality, which must be derived by desymmetrisation of a plane of symmetry; but this easily satisfied geometrical condition may leave open various possibilities. In Paper II it was considered convenient to choose a plane containing as many atoms as possible; and in the illustrations there presented, atoms were brought on to the chiral plane by deformations giving structures which could be quite unlike the natural ones. The first change we would now make is to disallow such drastic formalism, and to employ only natural planes of atoms (with at most minor idealisation) as in systems of unsaturated, including conjugated unsaturated, and aromatic atoms, and the atoms directly bound to such systems. When a structure contains several chiral planes as thus defined, it is obviously necessary, at least in so far as the planes are non-equivalent, that the chiral description of each should indicate the plane to which it refers. Such non-equivalent planes may be stereospecifically unlinked or linked; but even if they are linked, in the sense that the chirality of one determines that of all, we consider that it would render interpretation easier and less liable to error, to specify them all.

The second step, which we do not modify, is to identify a preferred side of the plane, a "nearer" side under Sub-rule (0) of the Sequence Rule, that is, the side containing the locus from which observation of the model is made in applying the Chirality Rule, which requires remoteness of the locus from the lower precedences of the "further" side. This preferred side is identified by

[14] *K. Mislow* and *M. A. W. Glass*, J. Amer. chem. Soc. *83*, 2780 (1961); *Idem*, *H. B. Hopps*, *E. Simon*, and *G. A. Wahl*, *Jr.*, *ibid. 86*, 1710 (1964).

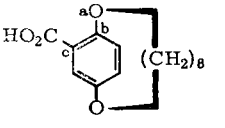
finding, among atoms of the set directly bound to the atoms of the plane, that which is most preferred by the Standard Sub-rules (1)–(5). In making the determinative comparisons, each atom is considered in the environment of the whole molecule, not merely in that of the set, or the relevant side of the chiral plane. The most preferred atom of the set directly bound to the plane, the leading atom or "pilot" atom, as we may call it, marks the preferred side of the plane. We call it the "pilot" atom, because of its function in the step next to be considered.

This third step is to develop the chirality-specifying sequence. And here we propose another departure from our previous procedure: instead of developing the sequence adjacently to the chiral plane, we develop it in the plane. So we pass from the already identified, off-plane, pilot atom to the in-plane atom to which it is directly bound, or, if there are several such, to that preferred by the Standard Sub-rules. This atom is now identified as the first atom of the inplane sequence, the atom of highest precedence in the pattern to which the Chirality Rule will be applied. The second atom in the sequence is that one of the in-plane atoms directly bound to it, which is most preferred by the Standard Sub-rules. The third in sequence is that atom (other than the first) directly bound to the second, which is most preferred by the same Sub-rules. As the sequence is to be continued until the Chirality Rule can be applied, a condition that might sometimes necessitate development of the sequence to more than three atoms (for instance, if linear acetylenic systems had to be passed through), we must add to the above the general prescription that the *n*th atom in sequence is that (other than the *n*-2nd) directly bound to the *n*-1st, which is most preferred by the Sub-rules. In making these comparisons by means of the Standard Sub-rules, we take the whole molecule, and not the plane only, as the relevant environment of each atom considered. We had an off-plane locus from which to observe the chiral plane, and now we have an in-plane sequence of the necessary number, three or more, of atoms to observe from the locus. We are accordingly in a position to apply the Chirality Rule.

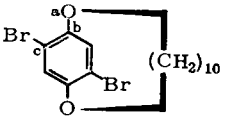
We summarise this procedure in the following Selection Rule for Planar Chirality, which defines the atoms that are to be taken as fiducial:

> Selection Rule for Planar Chirality. *Of atoms directly bound to atoms in the plane, that most preferred by the Standard Sub-rules, the pilot atom, marks the side of the plane from which, under the Chirality Rule, an in-plane sequence is observed; and the sequence starts with the in-plane atom directly bound to the pilot atom, and continues, to and through other atoms, by way of a succession of bonds along that in-plane path, which at each branch leads to the atom more preferred by the Standard Sub-rules.*

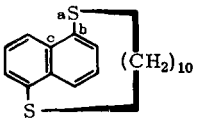
This change of method does change several assignments of chirality in Paper II (but none by other authors). *Lüttringhaus* and *Gralheer*'s quinol and naphthalene-1,5-dithiol polymethylene ethers, examples (LXXIX), (LXXX), and (LXXXIII) of Paper II, are shown at *(49)–(51)*, in what we must now call *R*-form. In each, the aromatic plane is taken as the chiral plane, and the in-plane sequence is marked a, b, c. In two of the examples, two equivalent sequences may be found: they give the same chiral specification. *Cram*'s cyclophane-type acid and anhydride, examples (LXXXV) and (LXXXVI) of Paper II, are shown at *(52)* and *(53)*, in *R*- and *S*-form, respectively, when aromatic planes are taken as chiral planes. The in-plane sequences are as marked. The reason for the change of label between the acid and anhydride is that the pilot atom in the former is a methylene-carbon atom, whereas in the latter it is an anhydride-oxygen atom. In the anhydride, two equivalent chiral planes are present.



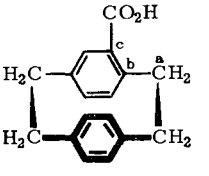
*(49)*



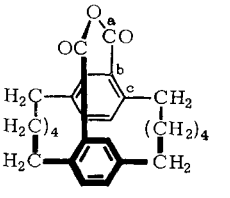
*(50)*



*(51)*



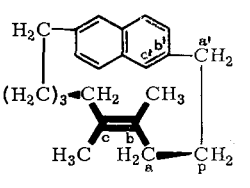
*(52)*



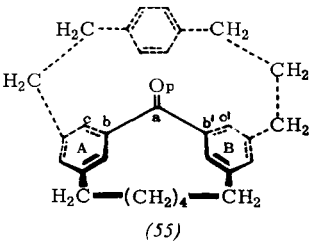
*(53)*

In the acid and anhydride depicted at *(8)* and *(9)* on p. 389, the aromatic planes constitute two non-equivalent chiral planes. The acid is in *R*-form with respect to the plane of the unbrominated benzene ring, and in *S*-form with respect to that of the brominated ring. In the anhydride these labels become reversed, for the reason just explained in another example. Obviously, the descriptions of chirality must show (for example, by numbering) to which planes they respectively refer.

Two further examples (as yet unrealised) will illustrate how two chiral planes may have a common pilot atom, and even a common atom among their in-plane sequences. Structure *(54)* has an ethylene plane and a naphthalene plane, and the carbon marked p is pilot for both. The marked sequences show that the model is *R* about the ethylene plane and *S* about the naphthalene plane. In structure *(55)* the benzenoid planes A and B are twisted from the plane abb′ about the lines ab and ab′, respectively; and so the carbonyl-oxygen, p, is off both planes, and is pilot to both; whilst the carbonyl-carbon, a, is the common first atom of the two in-plane sequences. The model is thus *R* about plane A, and *S* about plane B. Again one sees the need to attach indications of location to these descriptions of chirality.



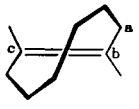
*(54)*



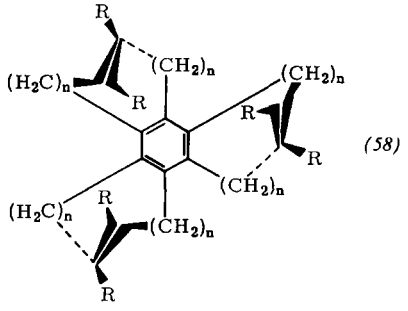
*(55)*

The *trans*-cyclo-olefins offer examples of planar chirality. Some compounds of this type have been optically resolved by Cope and his co-workers, who for *trans*-cyclo-octene itself have determined the absolute configurations of the enantiomers[15]. The double-bonded carbon atoms, and the four atoms bound to them, now provide the plane of chirality. There are two equivalent in-plane sequences, one of them marked a, b, c in *(56)*, and it follows from either that the *R*-enantiomer is being represented. Two of the three atoms in either in-plane sequence are equivalent.

*(56)*



*(57)*

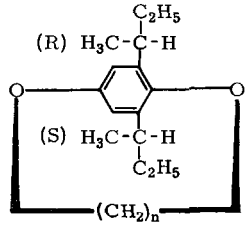


*(58)*

We conclude this sub-section with some remarks on the *symmetry classes* allowed in planar chirality. The examples already mentioned fall into two classes. Examples *(8)* and *(9)* on p. 389, and *(49)* and *(52)* above, have no symmetry (class $C_1$). Examples *(50)*, *(51)*, *(53)*, and *(56)* have one two-fold axis of rotation ($C_2$). The next higher class would have three two-fold axes of rotation (V). No case of such has yet been demonstrated, but a possible case would be furnished by a bis-(*trans*-polymethylene)ethylene, such as *(57)*. Again, the double-bonded atoms and the atoms bound to them define the chiral plane. There are now four equivalent off-plane atoms, any of which could be chosen as pilot to the corresponding in-plane sequence. Of course, there are four equivalent in-plane sequences. But whichever we work with, the result is the same: our diagram represents the *R*-form. Once again, two atoms of any of the in-plane sequences are equivalent.

We may consider the relation of an atomic plane to higher symmetry classes having chirality. An atomic plane of symmetry $D_{2ph}$ can be made the centre of a chiral molecule of symmetry $D_p$, characterised by one *p*-fold and *p* two-fold rotational axes of symmetry. We could, for example, build such a molecule round a central benzene ring ($p = 3$), by bridging its three pairs of *ortho*-situated bonds with three independent and completely equivalent bridges, each with a centrally situated plane of chirality in some definite, common, chiral form. Each bridge will destroy the plane of symmetry between the *ortho*-bonds, as well as that containing the bonds, but will preserve the two-fold rotational axis between the bonds. We might employ *trans*-olefin bridges, as in formula *(58)*. The chiralities of their planes being alike, the three-fold axis of rotation of the molecule is preserved, and the molecule has symmetry $D_3$. It is chiral, but its chirality depends on its girdle of chiral planes, which, however, induce no fixed chirality in the plane of the central ring.

A plane may be pseudo-asymmetric. If the path in the chiral plane turns in a particular sense only because of the distinction between symmetrically placed *R* and *S* varieties of the same group, as in the 2,6-di-s-butylquinol polymethylene ether *(59)*, we should expect two diastereoisomers both optically inactive, because each contains a plane of symmetry. We would distinguish them by the lower-case designations, *r* and *s*.



*(59)*

## 2.8. Secondary Structures

This chemical term of structural classification arose with the growth of our knowledge of protein structure. It has never been adequately defined; but it conveys a distinctive idea, which can be generalised. To what extent it will become generalised as chemistry advances, it is not possible to foresee.

The most celebrated example is the hydrogen-bonded α-helical form of polypeptides, first recognised by *Pauling* and *Corey*[16]. It is shown in *(60)*, opened out after making a cut parallel to the helical axis. If this projection is wrapped into a cylinder by joining the points AA, and the points BB, behind the paper, the peptide chain will describe an *M*-helix, whilst, if the junctions are made in front of the paper, the chain will describe a *P*-helix. It has been made very probable, both theoretically[17] and practically[18], that polypeptides derived from L-enantiomers of primary amino-acids favour the *P*-helix. Any such polypeptide has an optical rotation derived partly from the chirality of the primary structural units, and partly from the chirality of the secondary helical form. It has been estimated[19] that the partial rotation due to the *P*-helix of poly-*S*-alanine in chloroform is $[\alpha]_D = +82°$.

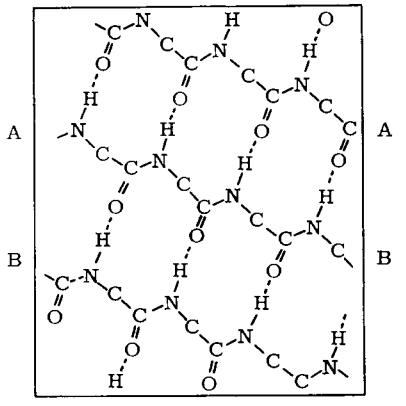
[19] *A. R. Downie, A. Elliott, W. E. Hanby*, and *B. R. Malcolm*, Proc. Roy. Soc. (London) A *242*, 325 (1957).

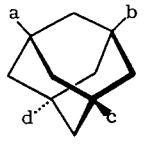
The helicenes, such as those with which axial chirality was illustrated in Paper II, might well, on grounds of obviousness, be treated as secondary structures. In the example shown at *(61)*, the benzene rings form an *M*-helix, and thus the chiral description *M*, as applied to the whole model, is very easily interpreted.



*(60)*

*(61)*

The adamantoid series could provide chiral structures, which might conveniently be treated as secondary, inasmuch as their gross structure is as obviously tetrahedral and amenable directly to the Chirality Rule, as that of the helicenes is obviously helical and directly responsive to the Helicity Rule. Although it has not yet been done, it would certainly be possible to substitute the four tertiary hydrogen atoms of adamantane with four different groups, as in *(62)*. The four carbon atoms thus made quaternary would all be asymmetric, and they could, of course, be specified separately with respect to their chirality as asymmetric atoms. But their chiralities are so interlinked that they can collectively produce only one pair of enantiomers. And so it would seem more convenient to specify their chirality, and hence that of the structure, collectively, by reference to a centre of chirality taken at the unoccupied centroid of the adamantane frame.



*(62)*

A still simpler chirally central, secondary structure would be furnished by the tetrahedral $X_4$ unit, well-known in inorganic chemistry, though not yet known in chiral form.

Catenanes are necessarily handled as secondary structures. The secondary chirality of any pair of interlinked rings may be described by selecting the most preferred and the next most preferred atoms, a and b respectively, of one ring, and the most preferred and next most preferred atoms, c and d, respectively, of the other ring, arranging the atom-pairs ab and cd as remotely from each other as possible, and then fitting them to the tetrahedron *(1)* on p. 388. If the pairs ab and cd are identical, we may use the tetrahedron *(44)* on p. 400. In either case, the Standard Sub-rules and the Chirality Rule are applied as for axial chirality [*].

## 3. Chirality to Ligancy Four: Nomenclature Problems

### 3.1. Specification of Chirality in Names

The specification of the chirality of a compound by the sequence-rule procedure is rigidly defined by the space-model. No such rigid procedure can be applied for adding symbols of chirality to the name of a compound, since that name may vary according to which of the various permissible systems of nomenclature is used, the purpose which the name serves, or linguistic characteristics.

In Paper II we recommended that the symbols of chirality be placed in front of the otherwise complete name, in parentheses, accompanied by any necessary indications of location, as, for instance, in (*R*)-2-methylpentan-1-ol, (2*S*,4*R*)-4-hydroxyproline, or (*S*)-methyl lactate. Partly owing to experience at the Beilstein Institute, for an account of which again we are indebted to the late Professor *F. Richter*, it now seems that this simple direction needs expansion or modification in various circumstances.

As a simple variant, of complete generality, it is immaterial if, for convenience in an index or for some linguistic reason, the symbols are written after the name, as in 4-hydroxyproline-(2*S*,4*R*). We adhere, however, to our view that these symbols of chirality should not normally be inserted in the interior of a name, for reasons given in Paper II (nevertheless see below, especially Sub-section 3.3).

In the remainder of this Section, we deal with five types of case, attempting to show by examples where general types of variation may be required; but one set of these cases, that discussed in Sub-section 3.4, needs some further preliminary remark.

We shall consider in Sub-section 3.4 how far it is necessary or desirable separately to include in a name the specifications of chirality for all the chiral elements present, in particular, the centres of chirality. Obviously, one must include them all when they could be independently inverted, as, *e.g.*, could those of (2*S*,4*R*)-4-hydroxyproline. However, structures exist in which such independent inversion is impossible, as, *e.g.* in camphor, which, despite its two chiral centres, has only two possible configurations, *viz.* 1*S*,4*S* and 1*R*,4*R*.

The routine of specifying all such stereospecifically linked chiral centres (at least if non-equivalent and non-enantiomeric) was established in Paper II. We favour a similar principle of individual treatment for chiral elements generally, because the resulting descriptions can be checked against one another, so providing more

[*] This is the central point in part of a paper by *S. J. Tauber* [20], to which the reader is referred for much interesting detail and development.

[20] *S. J. Tauber*, J. Res. nat. Bur. Standards *67* A, 591 (1963).

security against error; and furthermore, because we then have no need of any general rules to determine which of a stereospecifically linked assembly of chiral elements should be treated as titular for the assembly. This is a broad guiding principle, one to be applied reasonably. Cases will arise, for instance, among adamantoids and among ferrocenes, in which the inconvenience of specifying the chirality of every one of a considerable number of linked chiral elements will provide a dominating argument for not doing so. When linked chiral elements are equivalent or enantiomeric, it will usually be easy to decide (and will largely depend on whether other chiral elements are present) what elisions or condensations of chiral symbols can be made without risk of obscurity.

Against this general background, we have to recognize the important opportunities for simplifying the notation of chirality, which arise when some part of the name of a compound defines the relative configurations of a number of its chiral centres. How advantage may be taken of these opportunities is discussed in Sub-section 3.4.

### 3.2. Mixtures of Stereoisomers

The sequence rule has to analyse and specify some definite structure, and hence it must deal with one structure at a time. A racemate is a mixture of two structures – even when they do pack into the same crystal. But such a mixture is handled and described often enough to make it advisable to apply to it a single name, as though it were a compound in the molecular sense, and not only, at most, in the phase-rule sense.

When there is only one element of chirality, so that only one racemate can be formed, this may be designated (±), or, when appropriate, DL, or, in sequence-rule symbolism, (*RS*). We adopt here this alphabetical order *RS* as normal for the components of the composite symbol, in order that special significance may attach to its inversion to *SR*, as noted below.

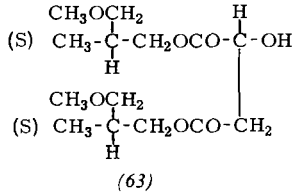
When in a component of a racemate there is more than one element of chirality, the one cited first (normally that which is located by the lowest number) is written *RS*, and the remainder are written as *RS* or *SR* in such a way that the first letter of each pair is associated with *R* of the first-cited pair and the second with *S* of the first-cited pair. For example, the racemate composed from (2*R*,3*S*)- and (2*S*,3*R*)-3-chlorobutan-2-ol would be designated (2*RS*,3*SR*)-; the other racemate would be designated (2*RS*,3*RS*)-.

Mixtures, which are racemic with respect to some centres but optically active with respect to others, could, if necessary, be named by simple extension of this method. A not uncommon case is that of the "failed resolution", involving, for example, an unseparated mixture of the salts (*R*)-base (*R*)-acid and (*R*)-base (*S*)-acid. The obvious course is to name this as (*R*)-base (*RS*)-acid.

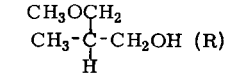
### 3.3. Broken Numbering

Collection of *R*,*S* symbols in front of a complete name is possible only when each can be unambiguously located. Ambiguity arises when the numbering of the complete name involves independent sets of numerals; such "broken numbering" is not infrequent, as many esters, amines, and compounds with side-chains present this feature.

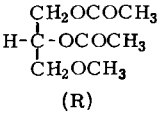
It may then become necessary to place each stereochemical symbol next to its appropriate partial name, as in (*R*)-s-butyl (*S*)-lactate, or in (*R*)-α-methylbenzyl-(*S*)-β-methylphenethylamine. However, it cannot be too strongly emphasised that *R*,*S* symbols invariably refer to the whole molecule, not to any component parts *per se*. It is equally fundamental that *R*,*S* symbols do not refer to any actual or supposed chemical precursors; for example, the compound *(63)* is bis-(*S*)-3-methoxy-2-methylpropyl (*S*)-malate, even though it is the ester of the (*R*)-alcohol *(64)* and (*S*)-malic acid. Obviously this principle applies equally when the complication of broken numbering is absent: a simple case is (*R*)-glycerol 1,2-diacetate 3-methyl ether *(65)*, which has the label *R*, whether it be made from (*S*)-glycerol 1-methyl ether *(66)* or (*R*)-glycerol 1,2-diacetate *(67)*. A group can have an *R* or *S*, not in its own right, but only in the particular compound to which that symbol is assigned.



*(63)*

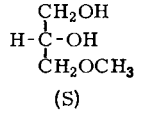


*(64)*



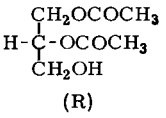
(R)

*(65)*



(S)

*(66)*



(R)

*(67)*

### 3.4. Chirality Symbols in Trivial Names that Specify Configurations

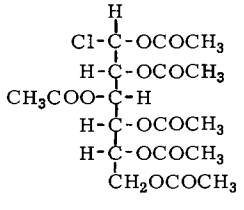
It was argued, particularly in Paper II, that a general system such as the present one need not displace a satisfactory "local" system within its own field. We suggest, however, that the general system may helpfully be "mixed" with a local system when the field of application of the latter is exceeded. It seems desirable now to illustrate how this mixing may be done, by examples that we shall choose from three of the widest local systems.

#### 3.4.1. Carbohydrates

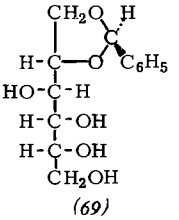
In a name such as methyl α-D-glucopyranoside, the prefix α and the syllable "gluc" jointly specify the relative configurations at positions 1, 2, 3, 4, and 5; the prefix D denotes a genetic relation at position 5 to

(+)-glyceraldehyde; and now our later-acquired knowledge of the absolute configuration of (+)-glyceraldehyde allows us also to specify absolute configurations on the basis of a name such as methyl α-D-glucopyranoside. Thus, unless it is desired to tie this stereochemistry to a general system, by writing, for instance, (1*S*,5*R*)-methyl glucopyranoside, the customary name suffices.

When, however, the limits of the local system are exceeded, as they are, for example, in compounds *(68)* and *(69)*, then to mix-in the sequence-rule system provides simple descriptions: compound *(68)* becomes (1*R*)-1-chloro-D-glucitol hexa-acetate, and compound *(69)* becomes (*R*)-1,2-*O*-benzylidene-D-glucitol.



*(68)*



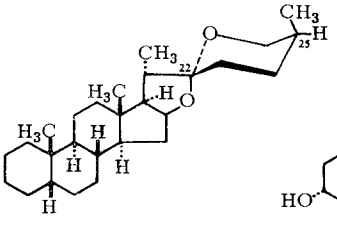
*(69)*

### 3.4.2. Inositols

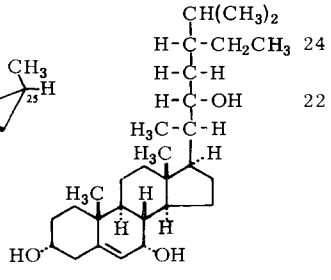
Optically active inositols are commonly distinguished from one another, either by use of prefixes denoting the relative stereochemistry of the ring atoms, or by a numerical device. As long as these practices give satisfaction, it is unnecessary to displace them by sequence-rule procedures. Absolute configurations of optically active compounds may be conveniently denoted by mixing-in the *R* or *S* symbol, as in the name (4*R*)-inositol for the laevorotatory compound (XLVIII) (p. 396). Mixing-in has wider scope in the name of an optically active compound derived from a cyclitol that is itself inactive. This was in fact done by *Angyal* and *Gilham*[21] when they named compound *(28)* (p. 397) (1*R*)-1-*O*-methylmyoinositol, a name entirely in consonance with the principles here advocated. We accept the general proposals by *Angyal* and *Gilham* for mixing in this field.

### 3.4.3. Steroids

For steroids, a small number of trivial names, and the symbols α and β, were originally used to denote relative configuration, and were coupled with an arbitrary method of writing the formulae. Here too, later knowledge showed that the arbitrary choice coincided with absolute configuration; and the trivial names and the prefixes α and β are commonly used now with an absolute connotation, and are well understood. Among steroids in particular, the relative stereochemistry of various parts of the molecule is of great importance for the chemical, physical, and pharmacological properties of the substances; so here it is particularly desirable to retain the simple local system in so far as it is unambiguous. It can certainly be retained for groups singly attached to the main tetracyclic ring system A–D. Where, however, spiro or other rings are attached, whose planes deviate strongly from the planes of the main system, the limits of the local system of trivial names and simple α and β symbols are exceeded. In these circumstances, to mix-in the sequence-rule system can be of value; and the chirality at positions in such attached rings, including the spiro atom itself, may well be expressed by sequence-rule symbols. Further, similar mixing-in may be appropriate for chirality in an open side-chain. This paper is not the place to discuss the merits of the various proposed systems in detail[22]; it will suffice to illustrate the mixing by reference to two compounds *(70)* and *(71)* selected from *Mueller* and *Pettit*'s paper. Compound *(70)* may be named (25*S*)-5β-spirostan or (22*R*,25*S*)-5β-spirostan, according to whether it is decided that the name spirostan by itself does or does not specify the stereochemistry at position 22 (a matter still under debate by specialists)[22]; and compound *(71)* may be termed (22*S*,24*R*)-stigmast-5-ene-3α,7α,22-triol.



*(70)*



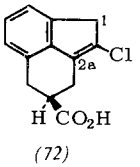
*(71)*

### 3.5. Molecules of Uncertain Structure

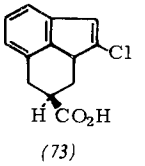
When there is uncertainty about the structure of a molecular model, a similar uncertainty may attach to the sequence-rule symbol to be applied. For example, prototropic substances present this problem: it may be necessary to specify chirality completely for a prototropic substance in spite of the structural uncertainty.

This must be done by choosing one of the possible structures – any convenient one. Often the choice will be self-evident, as for carbazole or fluorene; in other cases it must be indicated in the name chosen, *e.g.* 1-phenylazo-2-naphthol or 1,2-naphthoquinone 1-(phenylhydrazone), or again in the numbering chosen, *e.g.* 4-chloroimidazole or 5-chloroimidazole.

In practice it will be very rare that the different prototropic structures require different chiral symbols. If, however, such cases do arise, all that is needed is that the chiral symbol fits the name adopted. Thus, if one



*(72)*



*(73)*

were in doubt between structures *(72)* and *(73)*, one might arbitrarily select *(72)* and give its name as (4*S*)-2-chloro - 1,3,4,5 - tetrahydroacenaphthylene - 4 - carboxylic acid, or select *(73)* and give its name as (4*R*)-2-chloro-2a,3,4,5-tetrahydroacenaphthylene-4-carboxylic acid.

### 3.6. Specification of Axial, Planar, and Secondary Structural Chirality

It will often be desirable, for the sake of clarity, to indicate which type of chiral element, a centre, axis, or plane, is being specified as *R* or *S*. As axial and planar elements of chirality are less commonly used than are asymmetric atoms, we suggest that, when the symbols *R* and *S* apply to axes or planes of chirality, a signal to that effect should be associated with the symbols. We propose to add italic letters *a* (for axial) and *p* (for planar) immediately before the corresponding *R*'s and *S*'s, or *r*'s and *s*'s.

Whilst this would not be essential in simple cases such as (*aR*)-6,6′-dinitrodiphenic acid *(43)* (p. 400) it may be that a name such as (*aR*, α*R*, α′*R*)-6,6′-dilactoyldiphenic acid would be clearer than without the *a*; and it would be clearer still if written as (*aR*)-6,6′-di-(*R*)-lactoyldiphenic acid. In describing the quinol polymethylene ether *(59)* (p. 402), the symbol *pr* would bring out the distinctive character of the form of stereoisomerism being specified.

If a structure contains more than one chiral axis or plane, it is necessary when they are not stereospecifically linked, and in our view desirable in general when they are thus linked, separately to specify the chirality of each (cf. Sub-section 3.1). In every case one must identify the chiral element with its description, as by attaching some locating numbers or letters to the symbols *a* and *p*, in a form such as *x*,*y*-*aR*, where *x* and *y* locate the axis *a*.

The helicene *(61)* (p. 403) can be treated as a secondary structure; but it contains, and could be specified through, its two, stereospecifically linked, non-equivalent, chiral axes, both duplicated by the symmetry ($C_2$) of the structure. The model shown is *R* about the more interior, and *S* about the more exterior, biaryl axes. Formulae *(40)* and *(41)* (p. 399) illustrate structures with two chiral axes, which are not stereospecifically linked; this means that stereoisomers are possible in which the chirality of one axis only is reversed. It is obviously necessary in these cases to specify the chirality about each axis, even though in *(40)* the symmetry ($C_2$) of the structure renders the two equivalent. Formulae *(8)* and *(9)* (p. 389) and formulae *(54)* and *(55)* (p. 401) illustrate structures with non-equivalent chiral planes. As explained already, we consider it desirable to specify chirality about each plane separately, and to associate plane-identifying numerals with each chiral specification.

The assignment to secondary structures of chiralities *R* and *S* or *M* and *P* is again a circumstance which we think should be signalised in the notation; and so we propose to introduce for this purpose the prefix *sec*, to be placed, like *a* or *p*, immediately before the chiral symbol, as in *secR* or *secM*. The adamantoid enantiomers *(62)* (p. 403) would be designated *secR* and *secS*. The helicene enantiomer shown at *(61)* (p. 403) would be termed *secM*. Catenanes are secondary structures with axial chirality, but it would probably be sufficient to describe them as *secR* or *secS*.

## 4. Conformational Chirality to Ligancy Four

### 4.1. Basis of Treatment

The description of molecular conformations can be treated, according to a proposal by *Klyne* and one of us [7], in terms of partial conformations about the individual single bonds. One can thus specify, for a single bond between quadriligant atoms, the spatial relations between the two sets of up to three groups thereto bound. A fiducial group is chosen from each set by means of the following Conformational Selection Rules, and then the smallest torsion angle between the two fiducial groups will specify the conformation:

(A) *If all the groups of a set are different, the group most preferred by the Standard Sequence Sub-rules (p. 391) is fiducial.*

(B) *If an identity among the groups of a set leaves one group unique, the unique one is fiducial.*

(C) *If all the groups of a set are identical, that which provides the smallest torsion angle is fiducial.*

If the magnitude of the angle is only approximately known, semiquantitative terms (or their abbreviations), namely, synperiplanar (*sp*), synclinal (*sc*), anticlinal (*ac*), and antiperiplanar (*ap*), are used to describe conformations whose torsion angles are within ±30° of 0°, ±60°, ±120°, and 180°, respectively.

This system embodies the concept of a Conformational Helix, which may be defined as follows:

> Conformational Helix. *The single bond about which conformation is to be specified is made the axis, and the smallest torsion angle between the fiducial groups is made to define the pitch and sense of the helix (p.389).*

Right- and left-handed helices, thus defined, correspond to + and − torsion angles, and are designated by the Helicity Rule (p. 391) as *P* ("plus") and *M* ("minus"), respectively. A result of this symbolism is that, if, upon a specification of configuration in terms of *R* and *S*, one wishes to superpose a specification of conformational relations, the two types of description remain clearly distinguished.

Some generalisation is needed to provide for the specification of conformations in their widest possible connotation within the ligancy limit of four. The concept of phantom atoms is useful. They mark non-bonded electron-sites, and thus have their own individual spatial positions relative to neighbouring real atoms. They must therefore be considered, equally with real atoms, among the sets of "groups" from which fiducial groups have to be selected, as described above, for the

purpose of specifying conformation. For example, on account of Conformational Selection Rule (B), the phantom atom is fiducial in the amino-group.

The duplicate representations of atoms by the help of which multiple-bond unsaturation is represented are in a different case. They have no space-positions separate from those of their originals. Hence the only effect of introduced double bonds, whether localised, or blended as, for instance, in aromatic systems, is to create special cases by reducing below maximum the number of spatially distinct off-axis groups about a single bond, whose relative positions determine conformation. The two trios of groups flanking the single bond in the general case may, in the presence of unsaturation, degenerate to a trio and a pair, or to two pairs. The fiducial group of a pair, as of a trio, is to be chosen by the Selection Rules given above.

The introduction of a triple bond can reduce an original trio of groups to a single group. But, except in special circumstances, the latter is on-axis, and hence without conformational interest.

The number of conformational isomers that could be formed by relative rotation about just one single bond cannot be greater than the numbers of those torsional potential-energy hollows that are deep enough to contain total-energy levels. With like off-axis groups on either flank of the bond, the energy hollows will be equivalent. The number of them will be the least common multiple of the numbers of groups in the sets flanking the bond: two sets of three groups each will give three energy hollows, two sets of two will give two, and one set of three and one of two will give six. With inequalities between the groups, the number of energy hollows may rise as far as the product of the numbers of groups in the sets. The energy hollows will, however, tend rapidly to insignificance as their number rises, owing to increasing compensation in the angular variation of individual group-interaction energies. Potential-energy hollows, which are significant for conformational molecular states, very frequently arise because differences among the groups on either flank of the single bond enlarge some energy hollows at the expense of others. Thus, a theoretical maximum of six energy hollows might be represented by either three or two conformationally significant energy hollows, the remainder being reduced out of significance, or even out of existence. A theoretical maximum of three energy hollows may contain only two that are conformationally effective, the third having become either insignificant or non-existent. Of course, the number of significant energy hollows may in some cases be reduced to one; then conformational isomerism disappears. Thus, the most important cases for our considertation are those in which rotation round a single bond produces either three or two conformationally significant energy hollows. Each energy hollow must be deep enough to contain the ground energy-state of a conformational isomer, so protected that it either has been or could conceivably be isolated, or that it either has had or could conceivably have its separate existence proved by physical methods.

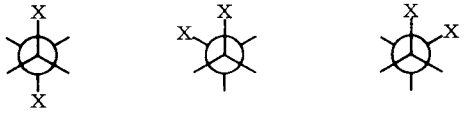
Out of these two important basic situations, one involving three, and the other two suitably stable torsional orientations about a single bond, develop all the compound situations, in which the conformational isomers arise from restricted rotation around several single bonds. In the absence of equivalences between such bonds, and in the absence of mutual interference, the number of conformational isomers will be the product of the numbers produced during rotation about the bonds, one at a time. However, these possibly large numbers are commonly much reduced by symmetry-equivalences, and very drastically by mutual interference as in rings.

We shall sometimes, either for convenience or lack of better knowledge, write of energy hollows as though they were symmetrically placed between their flanking barriers, even though it is well understood that intramolecular interactions, or intermolecular forces as in crystals, may render that assumption untrue.

### 4.2. Conformations Involving Three Torsional Energy Hollows [23]

We may take the 1,2-dihalogenoethanes as prototype examples. They have three conformationally isomeric forms, namely, the two enantiomeric synclinal forms, and the one antiperiplanar form, shown in *(74)–(76)*, where X denotes halogen.

The existence of such isomers [24] is shown, in the first place, by the Raman and infrared spectra of 1,2-dichloro- and 1,2-dibromo-ethane. Each spectrum consists of two superposed spectra, one of which fades as the temperature is reduced, thus indicating isomers of different stabilities in equilibrium. The low-temperature spectra show that the more stable isomers have the



Antiperiplanar *(74)* (M)-Synclinal *(75)* (P)-Synclinal *(76)*

antiperiplanar form. This conclusion is supported by the dipole moments, which fall as the temperature is reduced. The antiperiplanar isomers can be isolated in pure form merely by cooling: the solid substances consist of these pure isomers. From the effects of temperature on the spectra of the gases, it is inferred that the synclinal forms of 1,2-dichloro- and 1,2-dibromo-ethane are less stable by 1.2 and 1.5 kcal/mole, respectively, than their antiperiplanar forms.

In the n-propyl halides, whether as gases or as liquids, the balance of stability between the synclinal and antiperiplanar conformers, though somewhat small, is in

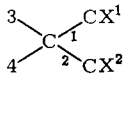
[23] *D. J. Millen* in *P. B. D. de la Mare* and *W. Klyne*: Progress in Stereochemistry. Butterworths Scientific Publications, London 1962, Vol. 3, Chapter 4.

[24] *S. Mizushima*: Structure of Molecules and Internal Rotation. Academic Press, New York 1954, Chapters 2 and 3.

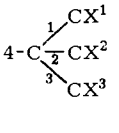
the opposite direction [25,26]. However, the solid chloride and the solid bromide are both pure antiperiplanar forms [26,27], presumably because these more symmetrical forms, despite their lesser molecular stability, have the larger lattice energies. The synclinal form of ethylene chlorohydrin is more stable by 1.0 kcal/mole than the antiperiplanar, in the gaseous and in the liquid state, and now the solid substance consists entirely of the synclinal racemate [28].

For the purpose of showing how several equivalent systems of three energy hollows in torsions about single bonds may yield conformational isomers limited in number by symmetry, we next consider the assemblies of *contiguous equivalent bonds*, illustrated by a trimethylene dihalide, a methylidynetrimethyl trihalide, and a pentaerythritol tetrahalide, each with like halogen atoms.

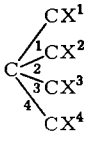
The energetically favoured conformations about each carbon-carbon bond will be assumed to be *M*- and *P*-synclinal and antiperiplanar, that is *Msc*, *Psc*, and *ap* in symbols, which we can here with convenience contract to *M*, *P*, and *a*, respectively, since other bond conformations are not in question. In order to locate these partial conformations, it is convenient to number 1–4 the bonds of the non-halogen-bearing carbon atom, and correspondingly number 1, 2, *etc.*, the halogens, as shown at *(77)–(79)*. Then, the numbers of the bonds being cited as pre-subscripts, and of the halogens as post-superscripts, the symbols ${}_2a^1$, ${}_2M^1$, and ${}_2P^1$, for example, will mean that halogen-1 is antiperiplanar, *M*-synclinal, and *P*-synclinal, respectively, to bond-2.



*(77)*



*(78)*



*(79)*

Each molecule has fewer than the 9, 27, or 81 conformationally distinct isomeric forms, which would be allowed in the absence of structural equivalences. The trimethylene dihalide has two achiral forms and two enantiomeric pairs (one asymmetric). The methylidynetrimethyl trihalide has three achiral forms and four enantiomeric pairs (three asymmetric). The pentaerythritol derivative has three achiral forms and three enantiomeric pairs (two asymmetric). The various conformers are specified in the Table by the method described above. Pairs of enantiomers are indicated by braces.

It should be understood that the conformational descriptions given in the Table are far from unique. For example, the model of any one conformer of a pentaerythritol halide can be numbered in 24 ways; and for

Table 1. Conformers with equivalent contiguous bonds in $H_{4-n}C(CH_2X)_n$.

| *(88)* | ${}_2a^1, {}_1a^2, {}_4a^3, {}_3M^4$ \| ${}_2a^1, {}_1a^2, {}_4a^3, {}_3P^4$ | $C_1$; asymmetric. |
| *(89)* | ${}_2a^1, {}_1M^2, {}_4P^3, {}_3M^4$ \| ${}_2a^1, {}_1P^2, {}_4M^3, {}_3P^4$ | $C_1$; asymmetric. |

any fixed placing of the numbers, for instance, one satisfying the conditions ${}_2a^1 \equiv {}_3M^1 \equiv {}_4P^1$, these three completely equivalent descriptions will be available to specify the conformation of halogen-1; wherefore there will be 81 ways of describing that one conformation of the pentaerythritol halide. Some of these descriptions are more immediately informative than others as to the chiral status of the conformation; and, in the Table, we have chosen, often from among a number of alternatives that would have served equally well, descriptions which signalise in an obvious way the achiral and chiral forms, and the enantiomeric pairs among the latter.

The conformations of those trimethylene dihalides which are numbered in the Table are schematically represented at *(80)–(83)* below. The vibration spectra of trimethylene dichloride, dibromide, and di-iodide, each as liquid and in crystalline form, have been studied by *Brown* and *Sheppard* [29], who were able thus to specify certain features of the symmetry of the isomers present, and to distinguish fairly certainly between antiperiplanar and synclinal partial conformations about the carbon-carbon bonds. They found that the molecules of the stable solid forms of all three dihalides contain two synclinal partial conformations, and concluded that these forms consist of the $C_2$ racemates (one chiral variety at 82), because the $C_s$ *meso*-form *(81)* is expected to be rendered unstable by pressure between the halogen atoms. The iodide was obtained also in a metastable solid form, the molecule of which contains two antiperiplanar partial conformations, and

[25] *E. Hirota*, J. chem. Physics *37*, 283 (1962).

[26] *C. Komaki, I. Ichishima, K. Kuratani, T. Miyazawa, T. Shimanouchi*, and *S. Mizushima*, Bull. chem. Soc. Japan *28*, 330 (1955).

[27] *J. K. Brown* and *N. Sheppard*, Trans. Faraday Soc. *50*, 535 (1954).

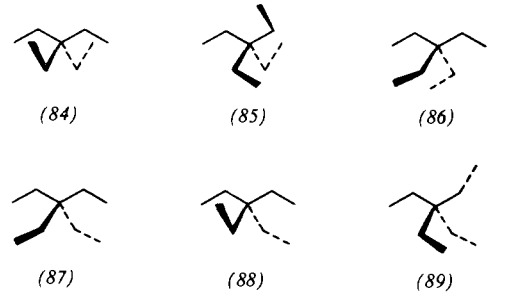
[28] *S. Mizushima, T. Shimanouchi, T. Miyazawa, K. Abe*, and *M. Yasumi*, J. chem. Physics *19*, 1477 (1951).

[29] *J. K. Brown* and *N. Sheppard*, Proc. roy. Soc. (London) A *231*, 555 (1955).

hence must be the $C_{2v}$ isomer *(80)*. The liquid dihalides were mixtures. Their main component was in each case the isomer of the stable solid form, the $C_2$ racemate. All three liquids contained a second isomer, shown by its spectrum to have one synclinal and one antiperiplanar partial conformation, and therefore to be the $C_1$ racemate [one chiral form at *(83)*]. The liquid dibromide and the liquid di-iodide contained a third isomer, characterised by two antiperiplanar partial conformations; this was the $C_{2v}$ isomer *(80)*. This di-iodide was identified with the metastable solid form of that dihalide.

*(80)* *(81)* *(82)* *(83)*

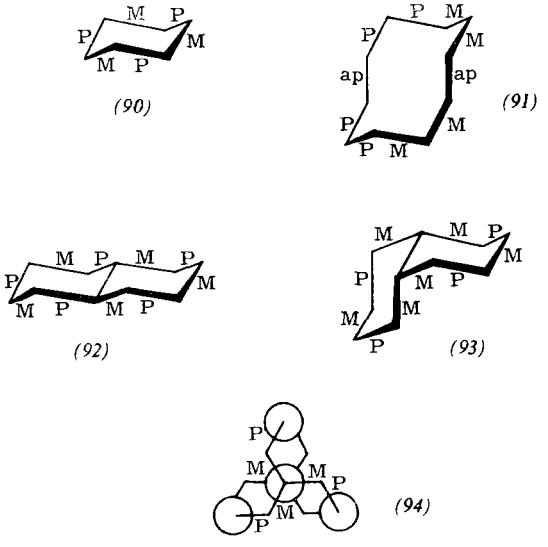
*Gilman* and his co-workers[30] isolated tetra-*o*-tolylsilane, $Si(C_6H_4Me\text{-}o)_4$, in four (optically inactive) forms having m.p.'s 145, 228, 300, and 344 °C, together with a possible fifth form of m.p. 270 °C. They stated that four *meso*-forms and two racemic mixtures (eight isomers in all) should be expected, but did not indicate what assumptions underlay this computation. If we assume four equivalent systems of three energy hollows, in which each methyl can bear the same space-relations to the three bonds holding other *o*-tolyl groups as each halogen in a pentaerythritol halide bears to the three bonds holding other halogenomethyl groups, we must expect isomers corresponding to the pentaerythritol isomers listed in the Table, namely, three achiral forms and three racemates (nine isomers in all). The forms of those numbered in the Table are shown at *(84)–(89)*. They can be derived by applying, with due allowance for enantiomers, conformations *(80)–(83)* independently to the 1,2-pair and the 3,4-pair of $CH_2Br$ groups, the upper and lower pairs, respectively, in *(84)–(89)*, and then eliminating overlap from the overall conformational representations thus obtained.



*(84)* *(85)* *(86)*

*(87)* *(88)* *(89)*

Conformations are strongly limited and selected by ring-formation. The chair-form conformation of cyclohexane has alternate *M*- and *P*-synclinal partial conformations about the ring-bonds *(90)*. An important conformation of cyclodecane[31] has two diametrically opposite antiperiplanar bonds, and, elsewhere, the balanced arrangement of *M*- and *P*-synclinal bonds shown at *(91)*. A *trans*-decalin composed of chair-form six-rings has an antiperiplanar bridge-bond, and otherwise alternate *M*- and *P*-synclinal ring-bonds *(92)*. A *cis*-decalin built from chair-form six-rings is chiral; one enantiomer has the bridge-heads joined by two tetramethylene loops of *MPMPM*-synclinal bonds (to specify them in order), as in *(93)*, and the other spans the bridge-heads by two *PMPMP*-loops. In 9,10-tetramethylene-*cis*-decalin, either all three tetramethylene loops are *MPMPM*, as shown in the Newman projection *(94)*, or else all are *PMPMP*.



*(90)* *(91)*

*(92)* *(93)*

*(94)*

### 4.3. Conformations Involving Two Torsional Energy Hollows

The normal conformation of hydrogen peroxide has been determined in a spectroscopic investigation by *Cross* and his co-workers[32]. There are only two effective energy hollows in the torsional potential-energy curve. These contain the energy levels of the *M*- and *P*-anticlinal conformations. Their valency angles are 94.8 °, and their torsion angles are ±119.8 °. Between the energy hollows rise, on the one hand, a synperiplanar barrier of 3.7 kcal/mole and, on the other, an antiperiplanar barrier of 0.85 kcal/mole.

The most important examples of optically stable conformers dependent on two energy hollows associated with torsions about single bonds are those of the biaryl series. These molecules have axial chirality, which may be specified, as has been described (Sub-section 2.6), on the basis of the Chirality Rule (p. 391). However, as already explained (Sub-section 1.5), we hold it allowable to regard the enantiomerically related structures as being conformationally distinct, and hence as suitable also for specifying chirality on the basis of the Helicity Rule (p. 391).

Throughout this field of examples, assignments *R* and *S* by the former method respectively correspond to assignments *M* and *P* by the latter, provided that the same sets of groups are employed in the two methods.

[30] *G. N. Russell Smart, H. Gilman,* and *H. W. Otto,* J. Amer. chem. Soc. *77*, 5193 (1955).

[31] *J. D. Dunitz* and *V. Prelog,* Angew. Chem. *72*, 896 (1960).

[32] *R. L. Redington, W. B. Olson,* and *P. C. Cross,* J. chem. Physics *36*, 1311 (1962).

And now that we have changed our procedure (cf. Sub-section 2.6) for choosing fiducial groups in the specification of axial chirality, making the effective chiral axes as short as possible, instead of, as formerly, as long as possible, the groups used for the defining of axial chirality in biaryl applications will always be the same as those, necessarily adjacent to the biaryl torsion bond, which are employed for the purpose of specifying its partial conformation.

These matters could be illustrated with a number of the biaryl examples treated in Paper II or in Sub-section 2.6 of this paper. It may suffice here to refer to formula *(39)* (p. 399). The axially chiral molecule represented is in the *R*-configuration, or, if we prefer, the *M*-conformation.

The second main group of examples of optically stable conformers conceptually derivable from two energy hollows in torsions around single bonds – often, in this area, around trunnion-like pairs of bonds – is in the group of the cyclophanes, or, more generally, that of bridged rings with aromatic bridge-heads. As described in Sub-section 2.7, these molecules have planar chirality, which may be specified on the basis of the Chirality Rule. However, some of the examples fulfil the wide definition of conformers given on p. 388; and, as explained in Sub-section 1.6, we consider it permissible to specify chirality of the conformations about the relevant bonds by means of the Helicity Rule. For such a specification, we propose to apply the Helicity Rule to the same atoms as served for the specification of planar chirality, namely, the pilot atom p and the atoms a, b, c, of the associated planar sequence (see p. 401), the torsion bond among the overall sequence of atoms p, a, b, c, being the bond a–b. This procedure yields, in this group of examples, a simple relation between the symbols of planar chirality and those of helicity: *R* and *S* correspond here, in contrast to the biaryls, to *P* and *M*, respectively.

A number of the examples of planar chirality given in Paper II, and several of those given in this paper, could be used in illustration. Thus, the planar chirality of the molecule *(8)* (p. 389) is *S* for the plane of the brominated benzene ring, and *R* for the plane of the other benzene ring. The corresponding conformational helicities are seen to be *M* and *P*, respectively. Similarly, the symbol *R* for the planar chiralities of molecules *(49)*, *(50)*, and *(52)* (p. 401) corresponds to the symbol *P* for the helicities of the conformations about the single bonds selected as described above.

### 4.4. Conformational Secondary Structures

The possibility of describing the chirality of secondary structures is attractive in that one may often thus achieve comprehensive but succint specifications. This was illustrated by means of the helicenes, in Sub-section 2.8. Among the conformations discussed in Sub-section 4.3, there are two in which a secondary-structural feature of readily definably chirality can be recognised.

The more obvious is 9,10-tetramethylene-*cis*-decalin, one chiral conformation of which is represented in *(94)*, on p. 409. It has been pointed out that each of the three tetramethylene loops in this molecule consists of five synclinal partial conformations in the chiral order *MPMPM*. We now note that the combined translation and rotation of a right-hand helix will carry the first atom of any of the three loops into the last atom of the same loop. This feature, if regarded as one of secondary structure, would allow the Helicity Rule to confer on the conformation as a whole the single symbol *P*, or, if the suggestion in Sub-section 3.6 is followed, *secP*, as an alternative to the longer designation in terms of individual partial conformations.

The other example is *cis*-decalin, one chiral conformation of which is shown in *(93)*. The same conformation could be represented more stereographically by a Newman projection, derived from *(94)* by omission of one tetramethylene loop. Each of the remaining loops would again be conformationally defined by the identical conformational order of its bonds, namely, *MPMPM*. And again the two ends of each loop would bear an identical helical inter-relation, which would allow the Helicity Rule to describe the whole conformation more simply as *P*, or, as we should prefer, *secP*.

## 5. Central Chirality to Ligancy Six

### 5.1. Outline of the Sequence-Rule Procedure for Ligancies Five and Six

By far the most important ligancy higher than four, for which the specification of chirality has yet presented any practical problems, is ligancy six of the octahedral atoms. These include non-metals, such as sexiligant phosphorus in the tris-2,2′-biphenylylenephosphate(VI) ion [33]; but the main family of examples comprises the transition metals in their six-co-ordinate complexes. We shall discuss in detail only the co-ordinatively sexiligant octahedral structures. The chirality of a quinqueligant atom could be specified after extension of its ligancy to six by means of a phantom atom, in a manner similar to that in which we specify the chirality of a trigonal pyramidal atom after extension of its ligancy to four. However, since we know of no molecule whose chirality depends on that of a configurationally stable, chiral, quinqueligant atom, we shall for the present refrain from detailing such a procedure. We shall also not attempt to treat ligancies higher than six, whether of atoms of the heavier elements, or of polyatomic elemental clusters.

We shall have to describe positional relations on the octahedral co-ordination figure in a more detailed way than has been done before. But we can start from some already used descriptions. *Werner*'s designations of the geometrical relations of pairs of ligands as *cis* or *trans*, according as they terminate an edge or body-diameter of the octahedron, are generally accepted.

[33] *D. Hellwinkel*, Angew. Chem. 76, 756 (1964).

*Werner* numbered the octahedron, with 1 and 6 in *trans*-positions, and 2–5 in cyclic order *cis* to each. Our method of distinguishing stereoisomers involves numbering the octahedral model according to that prescription, but allowing its unspecified features, namely, those of where to start, and in what sense to take the cyclic order, to be determined by a sequence of the ligands, as described hereunder. Having thus numbered the octahedral model, we designate its chiral sense according to a pattern read in the numbers.

The problem of arranging six ligands in sequence, for the purpose of specifying their spatial positions about a centre, is neither necessarily nor advantageously solved in the same way as for four ligands. Four points are the fewest that can constitute a three-dimensional figure, and hence possibly provide a chiral figure. When we have only four ligands, their properties have to determine the sequence which is required to describe the chirality of their space-distribution. With six ligands, more than this necessary minimum of working data would be furnished were exactly the same method followed; and then, some very difficult problems of selection would arise. We avoid these by designing our sequence of ligands, to be, not the sole instrument for placing a sequence of numbers on the octahedral model, but the means of completing a spatial distribution of numbers already delimited by the geometrical pre-condition of their octahedral arrangement.

With this simpler requirement in view, we have some freedom to adjust our sequence-forming procedure in order to reduce the intricacies that two features of co-ordination structures would otherwise frequently create.

The first feature is the occurrence about a chiral centre of identical ligands, as is possible when the total number of ligands exceeds four. In order to deal with this, we use the circumstance that, just because the number exceeds four, we are not dependent only on their internal properties in order to secure a chirality-defining sequence. We can allow their internal properties to order them as far as may be, and then leave co-operation with the octahedral pre-condition, implied in the Werner pattern of numbering, to complete the sequence-in-space.

The second feature of octahedral structures that could create considerable complications is the frequent occurrence of chelate ligands. However, we can largely forestall these difficulties by devising a special procedure, as described in the next Sub-section, for ordering groups in sequence.

The general circumstance which forces on us an elaboration of our procedure of chiral specification, when we come to complexes, is that, with more than four ligands to be arranged about a chiral centre, the various relations of geometrical isomerism, and the relations of chirality, arise together. Our procedure must therefore be competent to specify both, and not the latter only. That is why, after arranging the ligating atoms in sequence, we put in an additional step that takes the octahedral geometry into account, namely, the step of numbering the groups on the octahedron. At that stage, the geometrical isomerism, apart from any associated chirality, is completely described. All is then ready for the final step, which is to specify chirality.

Our procedure is thus as follows. With an octahedral structure, as with any molecule, the first step is to apply the *Factorisation Rule* (p. 391), so separating the chiral elements, in particular, the sexiligant chiral centre with the detailed description of which this Section is concerned.

Independently of ligancy, centres, axes, and planes of chirality are treated in that order. To the sexiligant chiral centre we apply in the second step the *Octahedral Sequence Rule* (Sub-section 5.2), which is a rule designed to order the ligating atoms in a "linear" series of priorities. The third step is to apply the *Octahedral Numbering Rule* (Sub-section 5.3), so assigning to the ligating atoms a set of numbers, which takes joint account of the already determined priorities and of the octahedrally geometrical relations. The geometrical relations, apart from chirality, are then fully specified, and the only remaining step, the fourth, is to apply the *Octahedral Chirality Rule* (Sub-section 5.4), so specifying the chiral sense of the sexiligant atom. We proceed now to describe these steps in detail.

### 5.2. The Octahedral Sequence Rule and its Sub-Rules

Our procedure must allow for ligands, which range from unidentate to sexidentate ligands. The classes from bidentate to sexidentate constitute the chelate ligands. They could create formidable complications, if we should try to handle them only by the machinery provided to deal with atomic ligancies of four and less. For they build rings round the sexiligant atom, bridged and even multiply bridged rings if the ligand is more than bidentate; and then the sexiligant atom becomes a common bridge-head of all the rings, and sometimes a spiro-atom in addition. It would be possible, but usually intricate, to explore such ring structures by means only of the Standard Sub-rules (p. 391). However, we offer below an extended system of sub-rules, better adapted to cope with such situations. The position of complex chemistry, as a main division of chemistry, potentially comparable with organic chemistry, justifies such a special measure. The extended system is comprised in three "Octahedral Sequence Sub-rules", as we may call them, which are to be successively applied. The second of these new sub-rules incorporates the Standard Sub-rules. We shall first describe the new sub-rules, and then state them formally.

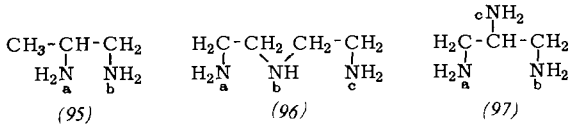
First, the ligands are ordered by classes, according to the number of atoms in each which are bound directly to the same sexiligant atom, a number which it will be convenient to call the *denticity* of a ligand. The denticity classes are ordered on the basis that higher denticities precede lower. The unidentate, that is, the non-chelate ligands will thus constitute the last class.

Secondly, the ligands of each denticity class are ordered, as far as possible, within their class. A ligand now takes its order from a *leading ligating atom*, which is a selected

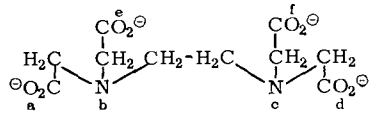
one of its terminal ligating atoms, or, if none is terminal as in an endless ligand, a selected one of its ligating atoms, selection being made by applying the Standard Sub-rules to the combined ligand. By "terminal" ligating atom is meant a terminal member of a series of ligating atoms contained in a ligand, regardless of whether or not it is at an extreme end of the ligand. The leading ligating atom of a non-chelate ligand is, of course, the only ligating atom that the ligand possesses. In each denticity class, the leading ligating atoms of the ligands, and hence the ligands themselves, are set in order, within the collective precedence of their denticity class, with terminal before non-terminal leading atoms, and otherwise as prescribed by the Standard Sub-rules (p. 391).

Thirdly, the ligating atoms of each chelate ligand are ordered within the collective precedence of the ligand. Apart from the leading ligating atom, the precedence of ligating atoms within a ligand is based on position in the ligand alone, and not on the properties used by the Standard Sub-rules. The leading ligating atom is given the first place; and then, proceeding from it along the longest continuous chain of linked atoms that leads to a terminal ligating atom, the successively situated ligating atoms, and, thereafter, the ligating atoms in the successively situated branches from that chain, are given successively lower places, all within the collective precedence of the chelate ligand. Direction round a cyclic ligand is taken as from the leading ligating atom to that one of the ligating atoms next on each side of it, which is given precedence over the others by the Standard Sub-rules. Any remaining ambiguity of direction in a bridged-ring ligand is resolved by taking at a bridgehead that path which would be preferred by the Standard Sub-rules.

In illustration of the described procedure, the internal priorities of the ligating atoms in some chelate ligands, assumed maximally ligated to the same central atom, are indicated by letter-labels (a > b > c > d, *etc.*) in formulae *(95)–(98)*. The first two of these are unbranched ligands, and the second two are branched ligands. In the latter, the ligating atoms in branches receive lower priorities than any in the main series. The only use of the Standard Sub-rules in these examples is to determine which of the non-equivalent ligating atoms of propylenediamine *(95)* is to be made the leading ligating atom.



*(95)* *(96)* *(97)*



*(98)*

We may now formally state the Octahedral Sequence Sub-rules which are to be successively applied:

(1) *Ligands of higher denticity precede those of lower.*

(2) *The leading ligating atom of a ligand being its terminal ligating atom most preferred by the Standard Sub-rules, or, in an endless ligand, the ligating atom which is so most preferred, the ligands are ordered, ended before endless, and otherwise as their leading ligating atoms would be ordered by the Standard Sub-rules.*

(3) *The ligating atoms of a ligand are ordered according to position, with diminishing precedence from the leading ligating atom along the longest continuous chain of atoms that leads to a terminal ligating atom, and thereafter in the successively situated branches from that chain. The sense of the succession in a cyclic ligand is taken as from the leading ligating atom to that next ligating atom which is preferred by the Standard Sub-rules, or, in case a choice remains, by following the path preferred by the Standard Sub-rules.*

### 5.3. The Octahedral Numbering Rule and its Sub-Rules

The Octahedral Sequence Rule gives to the differing ligating atoms a "linear" sequence, which has now to be converted into an "octahedral" sequence, by the use of a numbering scheme, preconditioned to describe octahedral arrangements, but capable of registering such information contained in the linear sequence as is significant for the description of the geometrical relations of the ligating atoms.

The pattern of the octahedral numbering scheme is *Werner*'s. This is prescribed in the first two of the following set of four sub-rules. The last two of these sub-rules adapt the priorities of the ligating atoms, as given by the Octahedral Sequence Rule, to the octahedral numbering pattern. The Octahedral Numbering Sub-rules, which are to be successively applied, are as follows:

(a) *The numbers 1 and 6 mark trans-positions.*

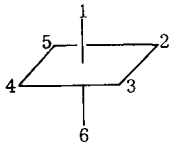
(b) *The numbers 2–5 form a cyclic sequence.*

(c) *With the number 1 is associated the ligating atom which is most preferred by the Octahedral Sequence Rule; or, in case a choice is open, that most preferred ligating atom which allows the least preferred possible to be associated with the number 6; or, if a choice is still open, that which allows more preferred ligating atoms to be associated with lower numbers in the range 2–5.*

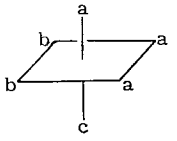
(d) *The numbers 2–4 are successively associated with the most preferred of the ligating atoms remaining available to each.*

In order to show how the Octahedral Numbering Sub-rules work with sexiligant atoms, we number some illustrative formulae, in the first place achiral formulae, below. Chelate ligands are represented by symbols such as A–A, A–B, B–A–B, the leading ligating atoms of which are A, A, and B, respectively. The order of precedence of the ligating atoms, as this would be given by the Standard Sub-rules, is taken to be A > B, *etc.* It is assumed, as is the usual situation, that successive ligating atoms of chelate ligands ligate in *cis*-positions.

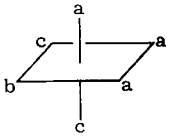
Non-chelate ligands are represented by a, b, *etc.* Their order, as given by the Standard Sub-rules, is taken to be a > b, *etc.*



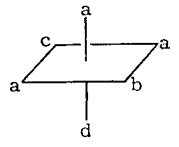
*(99)*



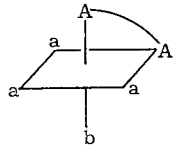
*(100)*



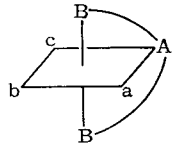
*(101)*



*(102)*



*(103)*



*(104)*

A set of numbers consistent with the Octahedral Numbering Sub-rules (a) and (b) is shown at *(99)*. The formulae *(100)–(104)* are so drawn that these numbers can be superposed on them by a translation alone, consistently with the Numbering Sub-rules (c) and (d). Now these are all achiral structures, and it is an easily proved characteristic of such that they can be numbered by the Octahedral Numbering Sub-rules in two completely equivalent ways, only one of which is illustrated in the diagrams. The alternative numberings are all obtainable by mirror-reflexions. For *(100)*, we reverse the positions of the numbers 2 and 3, and also 4 and 5. For *(101)*, we reverse 1 and 3, and also 5 and 6. For *(102)*, we reverse numbers 2 and 4; for *(103)*, numbers 3 and 5; and for *(104)*, 1 and 6. In every case, either of the alternative distributions of numbers on the octahedron, if carried into the name of the structure, produces an identical name, which, conversely, uniquely defines the achiral structure.

Formulae *(105)–(119)* illustrate application of the Octahedral Numbering Sub-rules to chiral structures. Again the formulae are so drawn that the numbering shown at *(99)* can be superposed by a pure translation consistently with the Octahedral Numbering Sub-rules. For many such structures, the numbering thus obtained is the only allowable one. But for others it is one of two or more completely equivalent number-distributions, inter-related by rotations. Structures *(113)*, *(116)*, and *(119)* each have two, structure *(117)* has four, and structure *(114)* has six such equivalent number-distributions. Obviously, these apparent alternatives, lead to the same name, which conversely, describes the same model, except only with respect to its chirality.

### 5.4. The Octahedral Chirality Rule

The Numbering Sub-rules are such that, when any chiral structure, such as one of those shown at *(105)* to *(119)*, is reflected in a plane, and the resulting structure is re-numbered, the result is the same as if the numbering as well as the structure, had suffered the reflexion. In other words, any chiral isomer and its enantiomer have their ligating atoms identically numbered, and, if the numbers are incorporated in a name, are represented by the same name. Thus the numbering system takes care of every feature of diastereoisomerism, excepting only associated chirality.

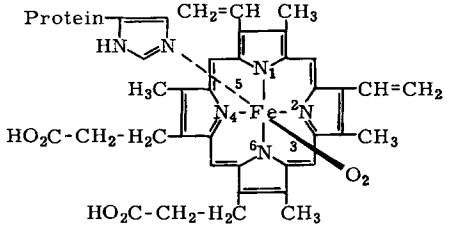
The outstanding matter of the specification of chirality is, however, very easily dealt with by reference to the numbering. The rule for so doing is as follows:

> **Octahedral Chirality Rule.** *The chiral centre of the numbered model is specified as R or S, according as the path of the numbers 1, 2, 3 in order appears right- or left-handed from the side of the model remote from 4, 5, 6.*

According to this rule, all the structures figured at *(105)–(119)* are in *R*-form. So also is that represented by *(120)*, which shows the iron atom and one valence-bond structure of the haem of the oxygen-myoglobin adduct[34]. The iron atom is σ-complexed, and two phantom atoms must make up the ligancy deficiencies in the two tertiary nitrogen atoms present in any valence-bond structure. Tertiary and quaternary nitrogen atoms in any such structure are always linked by conjugation, in the manner, already illustrated in the cyanine ion *(16)* (p. 394). Hence, in the blended structure, each of the four nitrogen atoms carries half a phantom atom, and each nitrogen atom and each ring-carbon atom has

[34] *J. C. Kendrew, H. C. Watson, B. E. Strandberg, R. E. Dickerson, D. C. Phillips,* and *V. C. Shore,* Nature (London) *190*, 666 (1961); cf. *R. E. Dickerson* in *H. Neurath*: The Proteins. Academic Press, New York 1964, Vol. 2, p. 634.

a delocalised valency. The atomic numbers associated with these delocalised valencies are 3 for nitrogen atoms, $6^1/_3$ for carbon atoms adjacent to nitrogen, and 6 for other carbon atoms. The Octahedral Sequence Subrules place the quadridentate ligand ahead of the nonchelate ligands, and identify in the former the leading ligating atom, and the sense of the cyclic ordering. Thus, the first two ligating atoms will belong to the vinyl-bearing pyrrole rings, and their relative order will follow from comparative explorations from N-1 to vinyl-2 and from N-2 to methyl-6 (if we distinguish the substituted pyrrole moieties with their side-chains by the numbers here attached to their nitrogen atoms). Then, the Octahedral Numbering Rule completes the association of ligating atoms with numbers on the octahedron, as shown in *(120)*, and the designation of chirality follows.



*(120)*

### 5.5. Symmetry in Central Chirality with Ligancy Six

Octahedral chiral systems can belong to any of the following five symmetry classes. First, there is the asymmetric class, $C_1$, illustrated by models *(105)* to *(111)*, *(115)*, and *(118)*. Next higher in symmetry stands the $C_2$ class, which has one two-fold rotational axis as its only symmetry, and is illustrated in models *(113)*, *(116)*, and *(119)*. Then comes the $C_3$ class, which has one three-fold rotational axis as its only symmetry, as illustrated in model *(112)*. Above that stands the V class, whose symmetry comprises three two-fold rotational axes, as exemplified by model *(117)*. Finally, the highest class, $D_3$, whose symmetry is constituted from one three-fold and three two-fold rotational axes, is exemplified by model *(114)*. In these five classes, the "multiplicities" (of group theory), or "symmetry numbers" (of statistical mechanics), are also the numbers of equivalent number-distributions on the octahedral figure, namely, one, two, three, four, and six, respectively.

The first octahedral complexes to be assigned absolute configurations were of the $D_3$ class. The self-contained method of diffraction by a favourable crystal structure of X-rays of a critical wavelength [35] was applied to the ion tris(ethylenediamine)cobalt(III) by *Saito* and his coworkers [36], who thus showed that the isomer with $[M]_D = +600°$ in water has structure *(114)* (AA = en), and so is the *R*-enantiomer. By a comparative analysis of the relevant circular dichroism spectra, Mason and his co-workers have correlated this configuration with those of a number of other complexes of like symmetry, and thus have established that $[Cr(en)_3]^{3+}$ giving $[M]_D = +300°$, $[Co(ox)_3]^{3-}$ giving $[M]_D = -7500°$, and $[Cr(ox)_3]^{3-}$ giving $[M]_D = +8000°$ in water, all have the *R*-configuration [37]. These workers have given the rule, applying to complexes with $D_3$ symmetry of $d^3$ and $d^6$ metals, that according as the longest-wave, spin-allowed absorption along the axis of the uniaxial crystal has a positive or negative rotational strength, the configuration of the complex will be *R* or *S*. They also evolved a second self-contained method of determining absolute configuration, a method wholly based on the theoretical analysis of suitable circular dichroism spectra. Thus they showed [38], without reference to any substance of known chirality, that (−)-tris-(*o*-phenanthroline)ruthenium(II) has the *R*-configuration *(114)* (AA = *o*-phen).

Again, by comparative analyses of circular dichroism spectra, the same workers have shown [37] that certain ions of $C_2$ symmetry, *viz.* (+)-*cis*-diammine- and (+)-*cis*-dicyano-(bisethylenediamine)cobalt(III), have the *R*-configuration *(113)* (AA = ethylenediamine; a = $NH_3$, $CN^-$).

They have similarly shown that some $C_1$ (asymmetric) ions, *viz.* (+)-*cis*-chloro-, (+)-*cis*-bromo-, and (+)-*cis*-aquo-ammine(bisethylenediamine)cobalt(III), have the *R*-configuration *(111)* (AA = ethylenediamine; a = $Cl^-$, $Br^-$, $OH_2$; b = $NH_3$).

### 5.6. Secondary Structures Involving Ligancies Six

When a unique helical relation is apparent in a structure, the Helicity Rule (p. 391) affords a particularly easy description of the chirality. We have applied this description to conformations and to secondary structures; and, because of its convenience when applicable, we have treated as secondary some organic structures which are so only marginally, such as the helicenes. We now propose a similar liberty in the field of octahedral structures, again taking advantage of the circumstance that the term "secondary structure" is not defined.

Octahedral structures with three *cis*-pairs of ligating atoms, like within each pair, but either like or unlike as between the pairs, contain a helical axis. This property bears no uniform relation to symmetry. Some, though not all, $C_1$ structures, which, being asymmetric, contain no axis of symmetry, nevertheless possess a helical axis. Model *(110)* is an example: it has *secM*-helicity. A $C_2$ structure may have zero, one, or two helical axes. Such axes never coincide with the symmetry axis. Model

[36] *Y. Saito, K. Nakatsu, M. Shiro,* and *H. Kuroya,* Acta crystallogr. *8*, 729 (1955).

[37] *R. E. Ballard, A. J. McCaffery,* and *S. F. Mason,* Proc. chem. Soc. (London) *1962*, 331; *A. J. McCaffery* and *S. F. Mason, ibid. 1962*, 388; Trans. Faraday Soc. *59*, 1 (1963); Mol. Physics *6*, 359 (1963); *S. F. Mason,* Quart. Reviews *17*, 57 (1963); *A. J. McCaffery, S. F. Mason,* and *B. J. Norman,* Chem. Commun. *1965*, 132; *A. J. McCaffery, S. F. Mason,* and *R. E. Ballard,* J. chem. Soc. (London) *1965*, 2883.

[38] *A. J. McCaffery* and *S. F. Mason,* Proc. chem. Soc. (London) *1963*, 211.

*(113)* has two helical axes: about one it has *secM*, and about the other *secP*-helicity. All $D_3$ structures, without exception, contain four helical axes. One of these is co-incident with the three-fold axis of symmetry. None of the other three helical axes is co-incident with any of the three two-fold axes of symmetry. Model *(114)* is an example: with respect to the helical axis co-incident with the three-fold symmetry axis, it has *secM*-helicity: with respect to any of the other three helical axes, it has *secP*-helicity. The former assignment of helicity will probably be preferred on grounds of obviousness, but it is clearly not definitive unless the relevant axis of helicity is specified.

This discussion would modify the helicity symbols given to ions of $C_2$ symmetry, referable to model *(113)*, in a paper [39] which appeared while the present paper was in press: P($C_2$) would become *secP* or *secM*, according to the helical axis chosen; or, in the system which is always unequivocal, it would be *R*. The symbols *M* and *P* should refer to a helical axis, such as those shown in end-projection in the alternative representations *(113')* of *(113)*. Under octahedral geometry, the rotational axis $C_2$ is not a helical axis, because, *inter alia*, the chelate ligands AA spread apart along the direction of $C_2$.

## A Novel Synthesis of Adipic Acid from Acetylene and Acetic Acid

By Dr. J. DiPietro and Dr. W. J. Roberts

Research Laboratories of Celanese Corporation of America, Summit, New Jersey (U.S.A.)

It is known that carboxylic acids are formed when acetic acid is reacted with olefins in the presence of radical-producing agents [1,2].

We wish to report a novel synthesis of adipic acid by the free-radical addition of acetic acid to acetylene. A rocking bomb was charged with 1.8 kg of glacial acetic acid and 3.3 g (0.02 mole) of di-t-butyl peroxide. The bomb was then closed, purged with $N_2$ and heated. Once the temperature of the solution inside the bomb had reached 110 °C, anhydrous acetylene gas (4.94 g) was slowly introduced. The bomb was rocked and heated up to 120 ± 5 °C for 18 hours, after which it was cooled down to room temperature. The liquid portion of the reaction mixture was then distilled under nitrogen until most of the acetic acid was removed. Addition of cold $H_2O$ separates water-clear crystals of adipic acid from an oily product; the latter possesses a molecular weight of about 300, with a carboxyl content of 36 % by weight and has no unsaturation detectable by infrared spectroscopy. Based on the acetylene charged the yield of adipic acid was 10 %. Unreacted acetylene (64 %) can be recovered.

It remains to be established whether the reaction proceeds step-wise through the formation of vinylacetic acid, or by a simultaneous free-radical addition of two moles of acetic acid to acetylene. It is of interest in this respect that vinylacetic acid, when added to a large excess of boiling acetic acid in the presence of di-t-butyl peroxide, yields adipic acid.

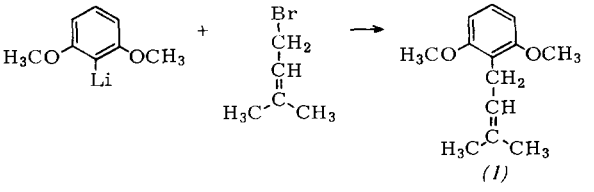
## New Synthesis of 5-Chromanol Derivatives and of Dihydroseselin [1]

By Dr. K.-H. Boltze and Dr. H.-D. Dell

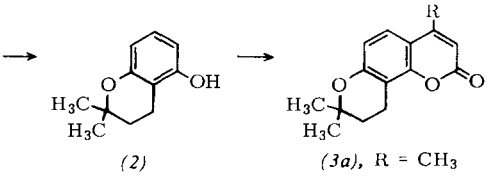
Chemische Abteilung der Troponwerke, Köln-Mülheim (Germany)

Dihydroseselin *(3b)* [2] previously has been obtained by cyclization from osthenol or, during ether cleavage, from osthol [3] (two-stage synthesis; 3.7 % yield).

2-Lithioresorcinol dimethyl ether, prepared from resorcinol dimethyl ether and phenyl-lithium [4], was treated with 3-methyl-2-butenyl bromide, affording the new compound 2-(3-methyl-2-butenyl)resorcinol dimethyl ether *(1)*, a colorless liquid of b.p. 101 °C/0.55 mm, $n_D^{20} = 1.5320$ (98 % yield). Ether cleavage of this product by heating with pyridinium chloride at 210–220 °C for 5 h gave 2,2-dimethyl-5-chromanol (dihydro-β-tubanol) *(2)* as yellowish needles, m.p. 120–122 °C (from light petroleum, b.p. 80–100 °C) in 74 % yield. This procedure constitutes a new and simple synthesis of compound *(2)*, which was previously obtained from 5-methoxycoumarin in five stages (15–36 % yield; 1.9–4.6 % overall yield) or from dihydro-2-isoprenylresorcinol in mediocre yield.



*(1)*



*(2)* *(3a)*, R = $CH_3$
*(3b)*, R = H

When kept with 1 mole of ethyl acetoacetate in the four-fold volume of concentrated $H_2SO_4$ at room temperature (24 h) or when heated with malic acid and concentrated $H_2SO_4$ until gas evolution ceases [molar ratio *(2)*:malic acid:$H_2SO_4$ = 1:1:15], compound *(2)* affords 3',4'-dihydro-4-methylseselin *(3a)*, needles, m.p. 164.5–165 °C (from 2-propanol/water; *ca.* 60 % yield), or 3'4'-dihydroseselin *(3b)*, m.p. 104–105 °C (from light petroleum; *ca.* 50 % yield), respectively.

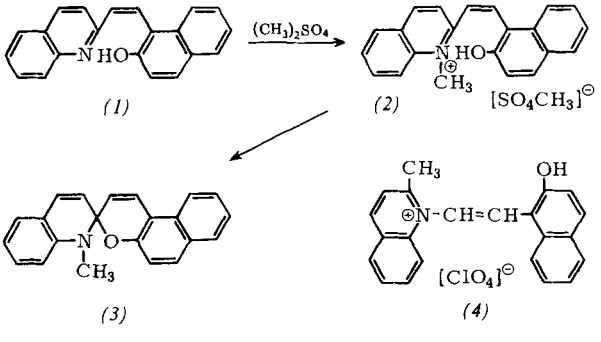
## Synthesis of 1'-Methylspiro[3*H*-naphtho[2,1-*b*]-pyran-3,2'(1,2-dihydroquinoline)]

By Dr. C. Schiele and H. O. Kalinowski

Forschungsinstitut der Telefunken AG., Ulm (Germany)

It has hitherto been assumed that 1'-methylspiro[3*H*-naphtho-[2,1-*b*]pyran-3,2'(1,2-dihydroquinoline)] *(3)* can be isolated only in an intramolecularly ionised form, as "spirain" [1].

We have found that compound *(3)* is obtained as spiran if quinaldine and 2-hydroxy-1-naphthaldehyde are heated with anhydrous $ZnCl_2$ at 150 °C for 1.5 hr and the resulting compound *(1)* is then treated in ethanolic suspension with methyl sulfate. The product, 2-[2-(2-hydroxy-1-naphthyl)vinyl]-1-methylquinolinium methyl sulfate *(2)*, can be cyclized to the spiran *(3)* by means of a basic ion-exchange resin (Merck III) in methanol. Yields amount to *ca.* 80 % calculated on *(1)*.



*(1)* *(2)* *(3)* *(4)*

Compound *(3)* forms yellow needles, m.p. 205–206 °C, from methanol; it is converted by acid into salts corresponding to *(2)*. Its infrared spectrum includes the $\nu C_{spiro}$-O stretching vibration at 970 $cm^{-1}$, characteristic of spiropyrans [2], that is absent from the spectra of compounds *(2)* and *(4)*. Compound *(3)* is, to the best of our knowledge, the first spiran of pyran and quinoline.

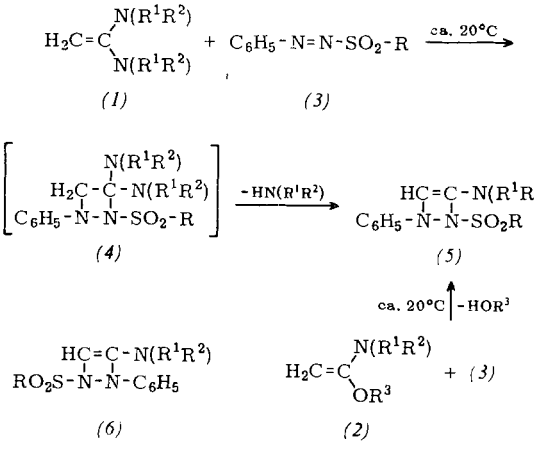
## Cycloaddition of Azosulfones and Sulfonylimines

By Doz. Dr. F. Effenberger and Dipl.-Chem. R. Maier

Institut für Organische Chemie der Technischen Hochschule Stuttgart (Germany)

Ketene N,N-acetals *(1)* and ketene O,N-acetals *(2)* containing hydrogen in the 2-position afford β-substitution products when treated with compounds such as isocyanates and isothiocyanates that contain an electrophilic double bond system [1,2].

However, azosulfones *(3)* [3] and *N*-sulfonylimines *(7)* [4] react with ketene N,N-acetals *(1)* by cycloaddition, affording the hitherto unknown 1,2-dihydro-1,2-diazetes *(5)* (Table 1) and 1,2-dihydroazetes *(9)* (Table 2), respectively. Ketene O,N-acetals *(2)* and azosulfones *(3)*, under comparable conditions, also give 1,2-dihydro-1,2-diazetes *(5)*.



*(1)* *(3)* *(4)* *(5)* *(6)* *(2)*

Table 1. 1,2-Dihydro-1,2-diazedes *(5)* obtained from *(1)* or *(2)* and *(3)* in benzene.

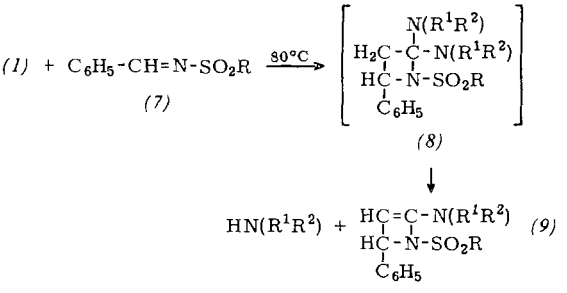
| | | $CH_3$ | $CH_3$ | $C_2H_5$ | $C_6H_5$ | 60.2 | 142–144 |
| | | $CH_3$ | $CH_3$ | $C_2H_5$ | $p$-$CH_3$–$C_6H_4$ | 67 | 148 |



*(1)* + *(7)* → *(8)* → *(9)*

Table 2. 1,2-Dihydroazetes *(9)* from *(1)* and *(7)* in benzene at 80 °C.

| *(1)* $R^1 + R^2$ | *(7)* R | *(9)* Yield [%] | M.p. [°C] |
|---|---|---|---|
| $-(CH_2)_5-$ | $C_6H_5$ | 68 | 132–133 |
| $-(CH_2)_5-$ | $p$-$CH_3$–$C_6H_4$ | 60 | 179–181 |
| $-(CH_2)_5-$ | $p$-Cl–$C_6H_4$ | 66.8 | 196–198 |
| $-(CH_2)_2-O-(CH_2)_2-$ | $C_6H_5$ | 35 | 146–149 |
| $-(CH_2)_2-O-(CH_2)_2-$ | $p$-$CH_3$–$C_6H_4$ | 34.3 | 166 |

Equimolar quantities of the ketene derivative *(1)* or *(2)* and the sulfonyl derivative *(3)* or *(7)*, separately dissolved in anhydrous benzene, are mixed and, depending on the reactivity of the sulfonyl derivative, are kept at room temperature for 2 days or heated under reflux for 2 hr. After removal of the benzene by distillation, the products, which mostly separate as oils, crystallize when rubbed with ether or petroleum ether and can be obtained analytically pure by recrystallization from acetonitrile or ethyl acetate. Elemental analysis, molecular weight determinations, as well as infrared and NMR spectra show these to be 1,2-dihydro-1,2-diazetes and -azetes, respectively. The 1:1 adducts *(4)* and *(8)* that are presumably formed as primary products could not be isolated under the conditions used.

The direction of cycloaddition of the sulfonylimines *(7)* is proved by NMR investigations (AB spectrum at $\delta \approx 6.7$ ppm, $J_{AB} = 17$ cps). However, formation of the isomeric compound *(6)* in reactions of azosulfones *(3)* could not be excluded, although we consider formation of compounds *(5)* more probable because of the electronic influence of the sulfonyl group on the N=N double bond.

*N*-Sulfonylimines *(7)* react also with 4-(cyclohexen-1-yl)-morpholine *(10)* (molar ratio 1:1, in boiling benzene), although the latter is less reactive than compounds *(1)* and *(2)*; cycloaddition affords compounds *(11)* (elemental analysis, molecular weight determination, infrared and NMR spectra). Compounds *(11)* are hydrolysed to ketones *(12)* in acidic solution.

## Synthesis of Monodisperse Oligoamides on Macromolecular Carriers[1]

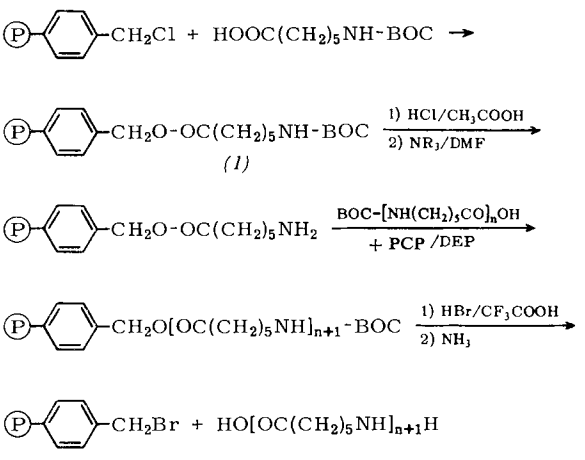
By Priv.-Doz. Dr. M. Rothe and Dipl.-Chem. Hj. Schneider

Organisch-Chemisches Institut der Universität
Mainz (Germany)

We have worked out a synthesis of molecularly homogeneous linear oligomers $H[NH(CH_2)_5CO]_nOH$ of 6-aminohexanoic acid with a degree of polymerization up to n = 11 by using *Merrifield*'s procedure[2] for the synthesis of peptides (covalent bonding to an insoluble macromolecular carrier of the oligoamide chain that is to be extended stepwise)[3]. For formation of the amide linkage we have used phosphorous ester chlorides[4], which have not been previously used for this purpose; they give quantitative conversions, even in heterogeneous reaction with the oligomers bound on the carrier, which is a prerequisite for homogeneity of the products.

For instance, *N*-t-butoxycarbonyl-mono- or -bis-(6-aminohexanoic acid), m.p. 41 °C or 66 °C, respectively, was converted by *o*-phenylene chlorophosphite (PCP) into a mixed anhydride, and this was treated on a shaker at 100 °C with 6-aminohexanoic acid *(1)* bound as benzyl ester to the carrier (chloromethylated polystyrene, cross-linked with 2 % of divinylbenzene, particle size 200–400 mesh). The mode of linkage of the monomer to the carrier and removal of the butoxycarbonyl protecting group and, after several repetitions of the process, of the whole oligomer chain, will be evident from the reaction scheme below and is performed under standardized conditions[2].

Excess of starting material and by-products can be easily removed by means of diethyl phosphite (DEP) as solvent, even when higher butoxycarbonyl-oligoamides are used as "carboxyl components" in the chain extension.



The molecular homogeneity of the oligoamides obtained was established by thin-layer electrophoresis at pH 1.9 and 0.3. The products were identified by comparison with authentic specimens[4,5].

Yields were in excess of 90 % for the lower, water-soluble oligoamides and 60 to 70 % for the higher oligoamides that were more difficult to isolate.

The prospects for synthesis of much longer, monodisperse chains by this procedure appear to be good, since solubility difficulties that have so far precluded the preparation of homogeneous macromolecules do not occur.

## Preparation and Crystallographic Data of Vanadium Chlorimide Trichloride, $Cl_3VNCl$

By Dr. J. Strähle and Dr. H. Bärnighausen

Chemisches Laboratorium der Universität Freiburg
(Germany)

The compound $Cl_3VNCl$ is remarkable in that it contains a metal-nitrogen multiple bond and is a metal derivative of chloramine. It was first obtained on reaction of chlorazide with vanadium tetrachloride[1]. We have now found a more expedient preparation of $Cl_3VNCl$, which eliminates the

necessity of working with the sensitive and explosive compounds $ClN_3$ and $VCl_4N_3$ (obtained as intermediate):

$$VN + 2\,Cl_2 \rightarrow Cl_3V{=}N{-}Cl$$

At the reaction temperatures required (between 120 and 140 °C) the product sublimes and deposits in the cooler part of the apparatus as needle-shaped crystals, often twinned; the vanadium tetrachloride formed as by-product is removed in the stream of chlorine (*ca.* 4 liters/hr). In three hours, 500 mg of vanadium nitride can be converted.

Weissenberg photographs and Buerger precession diagrams show that $Cl_3VNCl$ is triclinic with lattice parameters

| | | |
|---|---|---|
| $a = 7.64$ Å | $b = 7.14$ Å | $c = 5.91$ Å |
| $\alpha = 112.4°$ | $\beta = 94.9°$ | $\gamma = 107.8°$ |

The volume of the unit cell set up by *Delaunay's* method [2] is 276.6 Å$^3$. This value is about twice that estimated for one molecule from the ionic increments [3], so that the unit cell must contain two formula units of $Cl_3VNCl$. From these results a value of 2.48 g/cm$^3$ is derived for the density.

It is not yet possible to decide between the two space groups P1 and $P\bar{1}$, but preliminary results of a complete structure determination make the centrosymmetric space group appear the more probable.

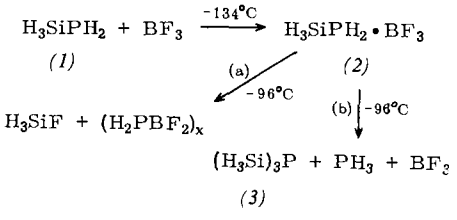
## Cleavage and Addition Reactions of Silylphosphines and Silylarsines [1]

By Dr. C. R. Russ and Prof. Dr. A. G. MacDiarmid

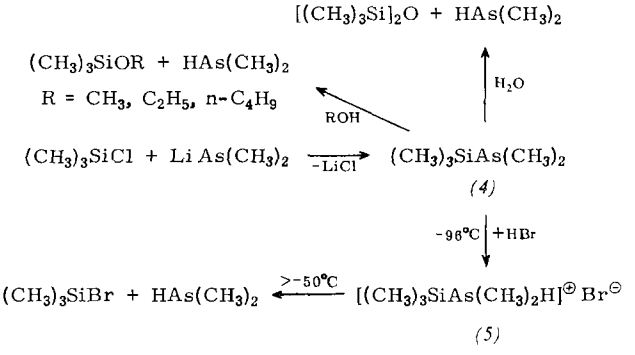
John Harrison Laboratory of Chemistry and
Laboratory for Research on the Structure of Matter
Philadelphia, Penn. (U.S.A.)

Silylphosphine *(1)* [2] and $BF_3$ form an adduct *(2)* at −134 °C which decomposes at −96 °C in two ways:



Reactions (a) and (b) occur to approximately equal extents. Trisilylphosphine *(3)* is apparently less susceptible to attack by $BF_3$ than *(1)*, as evidenced by the coexistence of $BF_3$ and *(3)* during separation.

Dimethyl(trimethylsilyl)arsine *(4)*, m.p. −87.6 °C, b.p. 136.4 °C, was obtained in 76 % yield by the reaction of dimethylarsinyl-lithium with chlorotrimethylsilane. At −96 °C *(4)* forms an adduct *(5)* with HBr, which decomposes quantitatively between −50 °C and room temperature to bromotrimethylsilane and dimethylarsine. Compound *(4)* is hydrolysed instantly and almost quantitatively by pure water at room temperature to dimethylarsine and hexamethyldisiloxane; it also reacts rapidly with alcohols to give trimethylsilyl ethers. It does not react with ammonia or dimethylamine.



The Si–As bond in *(4)* is cleaved by a deficit of $CH_3I$ at room temperature to give iodotrimethylsilane, trimethylarsine, and a little tetramethylarsonium iodide.

Reaction betwen *(4)* and $BF_3$ commences at −50 °C, but heating at 90 °C is required for quantitative formation of bis(dimethylarsinyl)boron fluoride and fluorotrimethylsilane. In contrast to the reaction with dimethyl(trimethylsilyl)-amine [3], phosphorus pentafluoride reacts with *(4)* above −50 °C to give fluorotrimethylsilane, phosphorus trifluoride, and the adduct *(6)* of $PF_5$ and tetramethyldiarsine.

Carbon disulfide was found to insert in the Si–As bond in *(4)* just as it inserts in the Si–N bond [4]. The product, *S*-trimethylsilyl-*C*-dimethylarsinyl dithioformate *(7)*, decomposes completely at 90 °C.

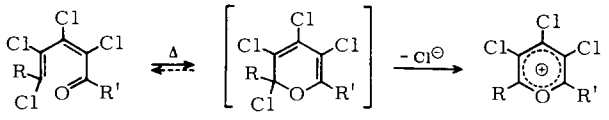
## Synthesis of Chlorinated Pyrylium Salts

By Prof. Dr. A. Roedig, Dr. M. Schlosser, and
Dipl.-Chem. H.-A. Renk

Institut für Organische Chemie
der Universität Würzburg (Germany)

A pentachloro-2*H*-pyran has been considered as an intermediate in the chloroaldehyde-carbonyl chloride rearrangement of perchloro-2,4-pentadienal [1] on the basis of results obtained in kinetic investigations [2]. We have now found that this aldehyde and other chlorinated pentadienals and pentadienones *(1)* afford complex pyrylium salts *(2)* when warmed with Lewis acids [$SnCl_4$ or $SbCl_5$ in $CS_2$, or $FeCl_3$ in $CS_2$ (with a little ether)] for 10 to 15 h at 40–50 °C. A prerequisite for ring closure is that the α,β-double bond in *(1)* is in the *cis*-configuration [3] and for salt formation that at least one halogen atom is in the δ-position. It is thus probable that the pentadienone tautomerizes to a 2*H*-pyran, which is converted into the pyrylium cation on abstraction of a chloride ion.

δ-Chlorinated *cis*-2,4-pentadienoyl chlorides *(1)* with R = H or $C_6H_5$ and R′ = Cl react in the same way but more slowly (reaction time: 4 days).



*(1)* *(2)*

| R | *(2)* R′ | Anion | Decomp. p. [°C] | Yield [%] | Method |
|---|---|---|---|---|---|
| Cl | H | $SnCl_5^{\ominus}$ | 170–171.5 | 87 | [a] |
| | | | | 27.6 | [b] |
| H | H | $FeCl_4^{\ominus}$ | 155–160 | 13 | [a] |
| Cl | $C_6H_5$ | $SnCl_6^{2\ominus}$ | 177–183 | 40.9 | [a] |
| | | $SnCl_5^{\ominus}$ | 176–180 | 17.2 | [b] |
| $C_6H_5$ | H | $SnCl_5^{\ominus}$ | 118–120 | 60 | [a] |
| $C_6H_5$ | $C_6H_5$ | $FeCl_4^{\ominus}$ | 219–222 | 52 | [a] |
| | | $SbCl_6^{\ominus}$ | 128–133 | 28.9 | [a] |
| | | $ClO_4^{\ominus}$ | 240 | 20 | [c] |

[a] From aldehyde or ketone.
[b] From acid chloride.
[c] From the chloroferrate with $NaClO_4$ in acetonitrile.

The pyrylium salts can be stored only if completely free from solvent and with rigid exclusion of air and moisture. The tetrachloro derivatives (R = Cl) are particularly sensitive. They decompose rapidly in moist air with formation of the corresponding 2-pyrones.

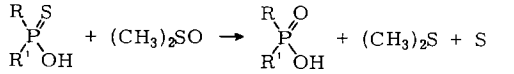
## Desulfuration of Thio-Acids with Dimethyl Sulfoxide

By Dr. M. Mikołajczyk

Institute of Organic Chemistry of the Polish Academy of Sciences, Lodz (Poland)

It was found that *O,O*-diethyl hydrogen thiophosphate *(1)* and *O*-ethyl hydrogen ethylthiophosphonate *(2)* are converted into the sulfur-free analogues when allowed to stand with an equimolar amount of dimethyl sulfoxide for one week at 20 °C. Yields are about 75–80%. After reaction the dimethyl sulfide formed is distilled off and the residue is dissolved in methanol and filtered from sulfur.



*(1)*, R = R′ = $OC_2H_5$
*(2)*, R = $OC_2H_5$, R′ = $C_2H_5$

Diphenyldithiophosphinic acid *(3)* undergoes a strongly exothermic reaction with 2 moles of dimethyl sulfoxide, yielding similarly (up to 90%) the sulfur-free acid.

$(C_6H_5)_2PS_2H + 2\,(CH_3)_2SO \rightarrow (C_6H_5)_2PO_2H + 2\,(CH_3)_2S + 2\,S$
*(3)*

Monothioacetic acid is also desulfurated by dimethyl sulfoxide; the yield is 70% after one week at 20 °C.

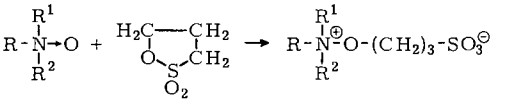
## Alkylation of Amine Oxides with Sultones

By Dr. W. D. Willmund

Wissenschaftliches Laboratorium, Henkel & Cie., Düsseldorf (Germany)

Alkoxyammonium halides are formed on reaction of tertiary amine oxides with alkyl halides [1].

We have found that alkylation of tertiary amine oxides with 1,3-propanesultone *(1)* in acetone or ethanol leads to alkoxyammonium sulfobetains *(2)*. Reaction conditions: dropwise addition of an equimolar amount of sultone to a boiling solution of the amine oxide in acetone, removal of the crystalline sulfobetaine after 2 hr, washing with acetone and vacuum drying. For pyridine oxide: reaction in the melt or in a little ethanol.



*(1)* *(2)*

| R | $R^1$ | $R^2$ | *(2)*, M.p. [°C] | *(2)*, Yield [%] |
|---|---|---|---|---|
| $C_{12}H_{25}$ | $CH_3$ | $CH_3$ | 172 | 64.6 |
| $C_{14}H_{29}$ | $CH_3$ | $CH_3$ | 174 | 79 |
| $C_{16}H_{33}$ | $CH_3$ | $CH_3$ | 175.5 | 70.3 |

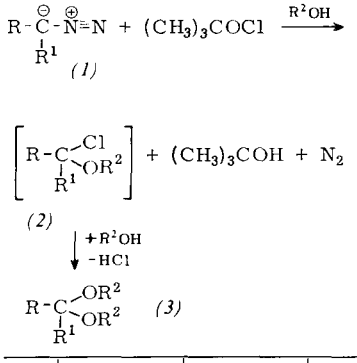
## Synthesis of Acetals by Reaction of Diazoalkanes with t-Butyl Hypochlorite [*]

By Prof. Dr. H. Baganz and Dr. H.-J. May

Institut für Organische Chemie der Technischen Universität Berlin (Germany)

Organic sulfur chlorides react with diazoalkanes to give aldehyde derivatives[1]. Corresponding reactions are not yet known for the analogous oxygen compounds, *i.e.* esters of hypochlorous acid.

We have found that diazoalkanes *(1)* are converted by t-butyl hypochlorite in the presence of alcohols into acetals *(3)* in good yields. The α-halogeno ethers *(2)* postulated as intermediates cannot be isolated.



| | R | $R^1$ | $R^2$ | Yield [%] |
|---|---|---|---|---|
| *(3a)* | H | H | $C_2H_5$ | 70 [a] |
| *(3b)* | H | H | n-$C_3H_7$ | 76 [a] |
| *(3c)* | H | H | 2 $R^2$ = $-CH_2CH_2-$ | 57 [a] |
| *(3d)* | $C_6H_5$ | H | $C_2H_5$ | 49 [b] |
| *(3e)* | $C_6H_5$ | $C_6H_5$ | $C_2H_5$ | 43 [b] |
| *(3f)* | R + $R^1$ = 9-Fluorenylidene | | $C_2H_5$ | 63 [c] |

[a] Determined by gas chromatography.
[b] Determined as 2,4-dinitrophenylhydrazone.
[c] Isolated in quantity.

Most methods for preparation of acetals depend on removal of water formed during the reaction from the equilibrium mixture. The present method avoids these difficulties and may therefore be important in special cases.

*Experimental*:

An ethereal solution of 0.2 mole of a diazoalkane (previously dried over KOH pellets) is treated with 100 ml of the anhydrous alcohol and cooled to −10 °C. 21.7 g (0.2 mole) of t-butyl hypochlorite is then dropped in slowly with stirring. The mixture is colorless at the end of the addition. The hydrogen chloride formed, and the solvent, are then removed under slightly diminished pressure and the residue is distilled or recrystallized.

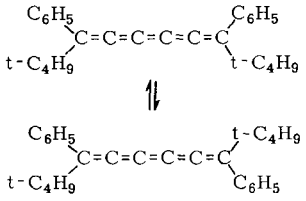
## cis-trans-Isomerism of 1,6-Diphenyl-1,6-di-t-butylhexapentaene [1]

By Prof. Dr. R. Kuhn, Dr. B. Schulz, and Dr. J. C. Jochims

Max-Planck-Institut für Medizinische Forschung, Heidelberg (Germany)

*Van't Hoff*'s prediction[2] that *cis-trans*-isomerism should occur in hexapentaenes has so far not been confirmed. We tried unsuccessfully to apply to the homologous hexapentaene[4] the methods with which we separated the *cis*-form (m.p. 142–143 °C) from the *trans*-form (m.p. 127–128 °C) of 1,4-diphenyl-1,4-di-t-butylbutatriene[3]. The hexapentaene was obtained crystalline only in one form (m.p. 128 °C).



The nuclear magnetic resonance spectrum, at 100 MHz, of the hexapentaene in [$^2H_6$]dimethyl sulfoxide contains, however, two sharp bands, at 1.25 and 1.29 ppm, which must be assigned to the two equivalent tert-butyl groups of the *cis* and the *trans*-form, respectively. When the solution is warmed these bands move closer together, and at 100 °C they coalesce to one broad band, which becomes sharp when the temperature is raised further. Cooling regenerates the original spectrum. From the coalesce temperature of the two bands the free energy of activation of the *cis-trans* isomerization in dimethyl sulfoxide can be calculated as $\Delta G^{\neq} = 20$ kcal/mole, whereas a value of 30 kcal/mole had been found[5] for the corresponding butatriene under the same conditions. The equilibrium constant is 1 in both cases. This is the first time that *cis-trans* isomerism has been demonstrated for a hexapentaene, albeit only in solution.

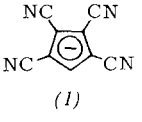
## Reactions of Cyano-Substituted Cyclopentadienyl Anions

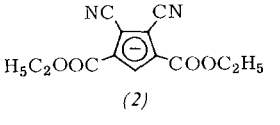
By Dr. K. Friedrich

Department of Chemistry, The University, Southampton (England) [*]

The tetracyanocyclopentadienyl anion *(1)*[1] and the 2,3-dicyano-1,4-diethoxycarbonylcyclopentadienyl anion *(2)* form stable salts. In distinction from the unsubstituted cyclopentadienyl anion, which yields dihydrosesquifulvalene with tropylium bromide in tetrahydrofuran[2], the tetramethylammonium salts of *(1)* and *(2)* give tropylium salts (m.p. 183 °C and 160 °C, respectively) when treated with tropylium fluoroborate in aqueous solution.

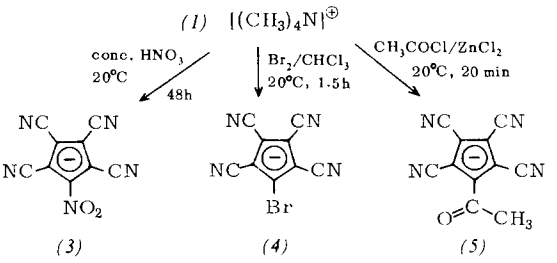


*(1)*



*(2)*

Electrophilic substitution can be effected on salts of *(1)* under mild conditions. The tetramethylammonium salt (m.p. 217–220 °C) with concentrated nitric acid gives the tetracyanonitrocyclopentadienyl anion *(3)* (m.p. of the tetramethylammonium salt >385 °C). With bromine in chloroform the bromo derivative *(4)* (m.p. of the tetramethylammonium salt 360–362 °C) is formed; and shaking a solution in acetyl chloride with zinc chloride gives the anion *(5)* (m.p. of the tetramethylammonium salt 335 °C).



(3) (4) (5)

The tetracyanocyclopentadienyl anion *(1)* described by *Webster*[1] can also be obtained from all-*trans*-1,2,3,4-cyclopentanetetracarboxylic acid[3]. With phosphorus pentachloride in benzene this acid yields the tetrachloride (b.p. 172–173 °C/4 mm Hg) which is converted by ammonia in benzene into the tetraamide (m.p. 335 °C). Dehydration with phosphorus oxide chloride in acetonitrile with addition of sodium chloride then yields all-*trans*-1,2,3,4-tetracyanocyclopentane (m.p. 221 °C), which is converted directly into tetracyanocyclopentadiene when heated with phosphorus pentachloride at 125–130 °C; addition of tetramethylammonium chloride to an aqueous solution of the reaction products precipitates the tetramethylammonium salt of *(1)*.

For preparation of the 2,3-dicyano-1,4-diethoxycarbonylcyclopentadienyl anion *(2)*, diethyl 2,3-dioxo-1,4-cyclopentanedicarboxylate[4] was converted by anhydrous hydrocyanic acid into the biscyanohydrin (m.p. 144 °C), whose diacetate (m.p. 120–121 °C) yields the potassium salt of *(2)* on addition of potassium t-butoxide; the tetramethylammonium salt precipitated from aqueous solution melts at 169 °C. An attempted extension of this reaction sequence to 3,5-dicyanocyclo-1,2-cyclopentadione (m.p. 225 °C), obtained from glutaronitrile and oxalic ester, was unsuccessful.

## Preparation and Properties of Tungsten Dioxide Diiodide, $WO_2I_2$

By Dr. J. Tillack and Dr. P. Eckerlin
Philips Zentrallaboratorium, Aachen (Germany)

and by J. H. Dettingmeijer
N. V. Philips, Hauptindustriegruppe Licht,
Forschungsabteilung, Eindhoven (The Netherlands)

When tungsten, tungsten trioxide, and an excess of iodine are subjected in a sealed quartz tube to a temperature gradient of 800/300 °C, previously unknown $WO_2I_2$ separates analytically pure in the cooler zone:

$$W + 2\,WO_3 + 3\,I_2 = 3\,WO_2I_2$$

$WO_2I_2$ decomposes above 200 °C in a vacuum with loss of iodine but can be sublimed unchanged under an iodine pressure of about 3 atm (equivalent to 14 mg of iodine per ml of tube volume) in a temperature gradient of 450/300 °C. Owing to the reversibility of the reactions, $WO_2I_2$ can also be obtained by reaction of iodine with tungsten and oxygen or with tungsten dioxide.

$WO_2I_2$ forms very thin platelets, several millimeters in size, with metallic luster, that gradually decompose in the air. It is insoluble in water, dilute mineral acids, or organic solvents (*e.g.* alcohol, ether, benzene, light peroleum, and chloroform). In dilute alkalis it gives colorless solutions from which acidification precipitates tungstic acid.

The properties of $WO_2I_2$ correspond to a considerable extent with those of a $WI_2$ described by *Roscoe*[1].

$WO_2I_2$ has a strongly disordered layer structure with a monoclinic unit cell: $d_{X\text{-ray}} = 6.40$; $d_{pyc} = 6.39$; $a = 17.095$ Å; $b = 3.899$ Å; $c = 7.492$ Å; $\beta = 102.66°$; probable space groups: C2/c and Cc.

$WO_2I_2$ plays an important part in the iodine lamp. The necessity for the presence of oxygen in quantitative re-transport of the evaporated tungsten to the filament can now be unambiguously explained.

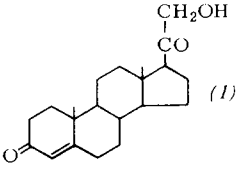
## A Vertebrate Hormone as Defensive Substance of the Water Beetle (Dytiscus marginalis) [1]

By Prof. Dr. H. Schildknecht, Dipl.-Chem. R. Siewerdt, and Dr. U. Maschwitz

Organisch-Chemisches Institut der Universität Heidelberg (Germany)

More attention has been paid to the defense glands in the pectoral section of dytiscids than to the function and contents of the pygidial vessels. In 1721 *Frisch* correctly assumed that the poisonous secretion of the water beetle constituted "foul drops that afford internal torment to a pike or other animal" that swallows it.

When merely firmly held, and certainly on application of slight pressure to the head, the beetle secretes the glandular liquid. When the secretion is taken up in a capillary the active ingredient (m.p. 135–140 °C) sometimes crystallizes; it is better isolated by thin-layer chromatography. Its ultraviolet absorption maximum at 241 mμ, its reaction with 2,4-dinitrophenylhydrazone[2], and its infrared absorption bands at 1613 $cm^{-1}$ (ν-C=C vibration) and 1668 $cm^{-1}$ (ν-C=O vibration) indicate an α,β-unsaturated ketone. A second keto group can be recognized from absorption at 1693 $cm^{-1}$. The active component was characterized as a steroid diketone by its optical circular dichroism, absorption having extrema at 283 and 321 mμ. By comparison with literature data[3] we concluded that the compound is a $\Delta^4$-3-keto steroid as well as a 20-keto steroid. However, the infrared absorption at 1693 $cm^{-1}$ indicated that the 20-keto group is hydrogen-bonded to an OH group that was disclosed by its absorption at 3475 $cm^{-1}$. All these findings pointed to 21-hydroxy-4-pregnene-3,20-dione (11-deoxycorticosterone, cortexone) *(1)*.



*(1)*

Commercial cortexone and its acetate agree in their physical properties with the natural product and its acetate. The physiological properties of cortexone explain the action of the *Dytiscus* toxin, for cortexone is a mineralocortical hormone of vertebrates. Since the beetle stores up to 0.4 mg of hormone – an amount that can be isolated from more than a thousand ox suprarenal glands[4] – it must strongly upset the sodium-potassium balance of vertebrates. Accordingly, and in agreement with *Blunck*'s results[5], we observed that pike and trout suffer deep narcosis, often within

a short time of being fed with *Dytiscus* secretion or cortexone solutions *per os*. Cortexone has no action on the beetle since it is a hormone foreign to the insects.

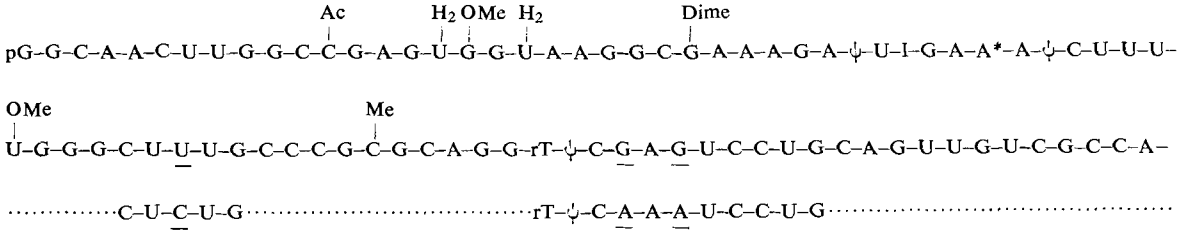
## Nucleotide Sequences of two Serine-Specific Transfer Ribonucleic Acids [1,2]

By Prof. H. G. Zachau, Dr. D. Dütting, and Dr. H. Feldmann

Institut für Genetik der Universität Köln (Germany)

Structural studies on transfer-ribonucleic acids (tRNA's [3]) recently entered a new phase when *Holley et al.* [4] established the primary structure of an alanine-specific tRNA. We have been able for the first time to elucidate the nucleotide sequences of two tRNA's specific for the same amino acid, *i.e.* of the two main serine-specific tRNA's from brewer's yeast. Thus the second complete nucleotide sequence of a nucleic acid can now be reported. In earlier stages of this work, *F. Melchers* [5] and *W. Karau* [6] made important contributions.

The serine-specific tRNA's were split with pancreatic RNase and $T_1$-RNase into oligonucleotides, the structures of which were determined by further enzymatic degradation. Sequences of up to 25 nucleotides could be constructed by comparing the two sets of oligonucleotides. In addition to the partial digestion with $T_1$-RNase [4], the elucidation of the complete sequences required partial digestion with pancreatic RNase, a second partial splitting of large oligonucleotide fragments, and sequential degradation with snake venom phosphodiesterase of oligonucleotides obtained by partial $T_1$-RNase digestion.



Serine-specific tRNA I and II from brewer's yeast.
Upper line: Nucleotide sequence common to both tRNA's.
Middle line: Continuation of the upper line for tRNA II.
Lower line: Continuation of the upper line for tRNA I.

The two serine-specific tRNA's differ only in three nucleotides (which are underlined in the formula). The differences may originate from transitions in the tRNA cistrons. The chain length (84 nucleotides) and the probable anticodon sequence I–G–A are the same in both tRNA's.

Thirteen odd nucleotides occur in the serine-specific tRNA's. *N*(6)-acetyl-Cp, A*p (the structure of which is not yet completely known [7]), and the two nucleotides methylated in the ribose have been found in tRNA-sequences for the first time. Models of the secondary structure of the two serine-specific tRNA's were constructed using only the principle of maximal base pairing. They show that *ca.* 60% of the nucleotides can be arranged in five paired regions. Almost all odd nucleotides appear in loops and unpaired regions. Probably the three nucleotides in which the two tRNA's differ are also located in loops.

The primary structures of the serine-specific tRNA's are very different from that of the alanine-specific tRNA. The distances, however, between I, DimeG, and one of the $UH_2$'s are the same. It is noteworthy that the distance between rT and the C–C–A-end is also the same in the three tRNA's. The sequence G–rT–ψ–C–G, however, which has been considered as a possible constituent of all tRNA's [4], is replaced by G–rT–ψ–C–A in serine-specific tRNA I.

Tsukanawa*, personal communication). Nuclear magnetic resonance studies in collaboration with *J. Sonnenbichler* showed that two methyl groups are located on C–3 and the double bond is between C–2 and C–3 of the side chain.

## Complex Formation between Copper and Organic Disulfides

By Doz. Dr. P. Hemmerich

Anorganisch-Chemisches Institut der Universität Basel (Switzerland) and

Prof. Dr. H. Beinert and Dr. T. Vänngard

Institute for Enzyme Research, University of Wisconsin Madison, Wisconsin (U.S.A.)

In general, mercaptide complexes of copper(II) are unstable, because of the reaction [1,2]

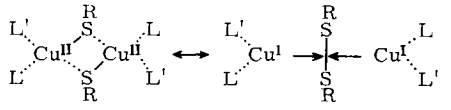
$$2Cu^{2+} + 2RS^- \overset{\alpha}{\rightleftharpoons} 2(Cu^{II}SR)^+ \overset{\beta}{\rightleftharpoons} 2Cu^+ + (RS)_2 \qquad (a)$$

Equilibrium β, however, can be displaced towards the right only in those cases where

a) the $Cu^+$ generated is stabilized by $Cu^I$-specific ligands, most easily by an excess of $RS^-$ (to form colorless $(Cu^ISR)_n$[3]), and where

b) the reaction is kinetically feasible, *i.e.* the hypothetical $(Cu^{II}SR)^+$ must either be able to dissociate into radicals ($\rightarrow Cu^+ + RS\cdot$) or to react with itself [$\rightarrow (CuSR)_2^{2+}$].

The formation of a binuclear complex *(1)*[4] is clearly the easiest way to fulfil condition b). In such a complex, $Cu^{II}$ mercaptide and $Cu^I$ disulfide are isoelectronic and chemically indistinguishable.



*(1)*

Of prime importance in this context is the affinity for $Cu^I$ of digonal sulfur, as found in the very stable, colorless $Cu^I$-methionine chelate[3]. In aqueous solution cystamine also forms a chelate with $Cu^+$ which, however, is deep violet in color and is maximally developed after liberation of one $H^+$ per Cu[3]. This complex may be formed according to Eq. (b) in agreement with structure *(1)* or according to Eq. (c) leading to structure *(2)*, which corresponds to the structure of a similar complex arising from thiomalic acid and $Cu^{2+}$ as found by *Klotz et al.*[5].

$$(RSSRH_2)^{2+} + 2\,Cu^+ \rightleftharpoons [Cu^I_2(RS) \leftrightarrow (Cu^{II}SR_2]^{2+} + 2\,H^+ \quad \text{(b)}$$

*(1)*

$$2(RSSRH_2)^{2+} + 8\,Cu^+ \rightarrow [(Cu^IRS)_4Cu^{II}]^{2+} + 3\,Cu^{2+} + 4\,H^+ \quad \text{(c)}$$

*(2)*

These equations differ essentially in the concomitant formation of $Cu^{2+}$. Hence we followed the formation of $Cu^{2+}$ during pH-titration of cystamine in the presence of $Cu^+$ by quantitative EPR spectroscopy in the solid (−170 °C) and liquid phase. In the pH-region 3–7 we found an increase in $Cu^{II}$ from 1 %[6] to not more than 7 % of total Cu. At pH 7, one mole of $H^+$ per mole Cu is liberated and the maximum color is reached with an extinction of *ca.* $5 \times 10^3$ $cm^{-1}$ per mole Cu[7]. The reaction, therefore, must follow Eq. (b) to more than 90 %, *i.e.* the contribution of a complex *(2)* cannot be more than 10 %. If the color were due to this complex exclusively, the molar extinction per $Cu^{II}$ would be as high as $10^5$ $cm^{-1}$, which is unlikely.

At pH 7, the violet complex disproportionates irreversibly with precipitation of $Cu(OH)_2$. If, on the other hand, a mercaptide-specific reagent, $ArHg^+$, is added, oxidoreduction ensues. In both cases the stoichiometric amount of $Cu^{2+}$ is found by EPR spectroscopy.

Hence, we take these results as strong evidence for the existence of copper mercaptides of type *(1)* with $R{-}L = CH_2CH_2NH_2$. Their strong color points to extensive electron delocalization in the – presumably diamagnetic – cluster $Cu\overset{S}{\underset{S}{}}Cu$. Their potential biological importance stems from the fact that certain Cu chromophores in redox enzymes, which may contain cyst(e)ine sulfur, are found to contain 2 or more Cu atoms (cytochrome oxidase, coeruloplasmine), which are redox-active, but not fully detectable by EPR spectroscopy[8]. Binuclear complexes of type *(1)* might explain this behavior when kinetically stabilized by a protein environment, whilst O- and N-ligands cannot be expected to allow for redox activity in Cu complexes unless accompanied by molecular rearrangements[3].

# CONFERENCE REPORTS

## Association of Aliphatic Hydroxy Compounds in n-Heptane

*G. Geiseler*, Leipzig (Germany)

Infrared-spectroscopic and thermodynamic studies of the association of isomeric alcohols, oximes, carboxylic acids, and hydroperoxides derived from n-heptane and n-octane have shown that chains and three-dimensional structures are preferably formed by monofunctionally associating isomers, but that only cyclic dimers and trimers are formed from bifunctionally associating isomers[1].

Indirect insight into the mode of association can also be obtained from the thermodynamic excess functions, as has been found in studies of binary mixtures of octanols or octanone oximes with n-heptane. The excess free energy determined from phase equilibria depends significantly on the position of the functional group in the chain. However, the excess enthalpy determined calorimetrically provides much more information: the excess enthalpy has a maximum at the same mole fraction ($x_{hept} \approx 0.55$) for all the oximes. From this it must be concluded that substantially the same type of order applies to all the (undiluted) oximes; structural differences have only slight effect.

The excess enthalpy has a maximum at $x_{hept} \approx 0.65$ for 1- and 2-octanol, but for 3- and 4-octanol the maximum is shifted to $x_{hept} \approx 0.75$. Clearly the type of order is different for the two alcohols (when undiluted or in concentrated solution). For the first two it is assumed that the molecules form linear associates, but for the second that they are joined in parallel.

The excess entropies, which pass through a minimum, show a completely analogous behavior. They indicate that in the region up to $x_{hept} \approx 0.95$ the associtates behave on the average as stoichiometrically uniform components and that on admixture with n-heptane they force a definite type of order on it. Only in highly dilute solution are the associates broken; this is particularly evident for the alcohols as the excess entropy then becomes positive.

German version: Angew. Chem. *78*, 395 (1966)

[1] *G. Geiseler*, Angew. Chem. *77*, 352 (1965); Angew. Chem. internat. Edit. *4*, 367 (1965); „Monofunctionally" and "bifunctionally" associating molecules differ by the number of atoms with acceptor effect in the associating group; the first type has one, the second two such atoms.

## Relations between Structural and Electrical Properties of Vanadium Spinels

*B. Reuter*, Berlin (Germany)

Mixed crystals of general composition $Mg(Mg_xV^{IV}_xV^{III}_{2-2x})O_4$ (ions in the octahedral positions are placed in parentheses) are obtained from the spinels $Mg(V^{III}_2)O_4$ and $Mg(MgV^{IV})O_4$ in the region $0 \leqslant x \leqslant 0.66$ [the vanadium(IV) spinel cannot be isolated pure because of partial disproportionation]. Since two $V^{3+}$ ions are replaced by $(Mg^{2+} + V^{4+})$ on increase of x, one has here a semiconductor system with controlled valence that is comparable with *e.g.* the system $Li_xNi^{III}_xNi^{II}_{1-2x}O$. By analogy with the views developed for this system in particular by *Jonker et al.*[1] the electronic properties of the system $Mg(Mg_xV_{2-x})O_4$ can be interpreted on a model for localized 3d-electron levels. The specific resistance $\rho$ is a minimum at $x = 0.15$. Consideration of the values of the thermoelectric power $\Theta$ indicates that part of the $V^{3+}$-ions may be replaced by two defect electrons.

The corresponding titanium system $Mg(Mg_xTi^{IV}_xTi^{III}_{2-2x})O_4$ can, however, be obtained phase-pure only in the region $x \geqslant 0.65$. Disproportionation of the $Ti^{4+}$ ion is excluded by its inert-gas configuration, as seen from the values of $\rho$ and $\Theta$.

The system $Mn(Mn_xV_{2-x})O_4$ behaves analogously to the Mg system, but the vanadium spinels of the iron group behave quite differently. The system $Fe(Fe_xV_{2-x})O_4$ includes a continuous range of solid solutions over the whole range $0 \leqslant x \leqslant 1$. The facts that in this case there is no disproportionation at high values of x, that $\rho$ is a minimum at $x = 1$, and that n-conduction occurs when $x > 0.65$, as well as the appearance of the products, show that $Fe_2VO_4$ contains $Fe^{2+}$, $Fe^{3+}$, and $V^{3+}$ ions, but no $V^{4+}$ ions. In the system $Co(Co_xV_{2-x})O_4$ ($0 \leqslant x \leqslant 0.9$) the minimum value of $\rho$ occurs at $x = 0$, which may be ascribed to separation of metallic cobalt. It is impossible to prepare a compound $NiV_2O_4$ because $Ni^{2+}$ ions do not occupy tetrahedral positions in the spinel lattice. However, $Ni^{2+}$ ions can be placed at octahedral positions in the spinel lattice of the systems $Mg(Ni_xV_{2-x})O_4$ ($x \leqslant 0.47$) and $Co(Ni_xV_{2-x})O_4$ ($x \leqslant 0.89$). The electrical properties of the system $Mg(Ni_xV_{2-x})O_4$ show considerable resemblance to those of the system $Mg(Mg_xV_{2-x})O_4$.

The octahedral positions of all these spinel systems are occupied not only by $V^{3+}$ and $V^{4+}$ ions, but also by ions other than vanadium, so that $\rho$ is increased and $\rho_{min}$ is shifted from $V^{3+}:V^{4+} = 1:1$ to smaller contents of $V^{4+}$ and foreign ions. The situation is different for $Li(V^{III}V^{IV})O_4$, which is almost as good a conductor as $Fe^{III}(Fe^{II}Fe^{III})O_4$. A continuous range of solid solutions $Li_xMg_{1-x}(V^{III}_{2-x}V^{IV}_x)O_4$ is formed; $\rho$ increases markedly in this series as x increases; $\Theta$ is almost zero at $x > 0.5$.

*Jaskowsky*[2] was able to describe the changes of $\Theta$ in the systems $Mg(Mg_xV_{2-x})O_4$ and $Li_xMg_{1-x}(V_2)O_4$ quantitatively by means of a model in which the influence of the non-vanadium ions was considered. By statistical analysis based on these considerations he deduced correctly the activation energy for hopping of the charge carriers and thus the value of $\rho$.

## Synthesis from Sugar Mercaptals

*H. Zinner*, Rostock (Germany)

*Hann* and *Hudson*'s rules[1] permit prediction of the tendency to formation of cyclic acetals from polyalcohols. The acetal rings are denoted as βC-, β-, αT-, α-, βT-, γT-, or αC-[2] according to the steric arrangement of the acetal-forming hydroxyl groups and according to the ring size. For benzylidene derivatives the tendency to ring formation decreases in the above order. These rules, set up first for benzylidene derivatives of glycitols, are valid also for extended (acyclic) structures, as is shown for the benzylidene derivatives of pentose mercaptals, pentose dialkyl acetals, and esters of pentonic acids. In the D-ribose, D-xylose, and D-lyxose series the 2,4:3,5- and in the D-arabinose series the 2,3:4,5-dibenzylidene derivatives are formed. The structures of the products are proved by synthesis and by oxidation of intermediates with lead tetraacetate.

2,3,4,5-Di-*O*-benzylidene derivatives of pentoses can be obtained by loss of thiol from the dibenzylidenepentose mercaptals and are oxidized by $CrO_3/H_2SO_4$ in dimethylformamide to the corresponding acids. The methyl esters of these acids are convertible into readily crystallizing dibenzylidene derivatives of the corresponding pentitols, pentonohydrazides, pentoamides, 1-amino-1-deoxypentitols, and 5-methyl-1,2,3,4,5-hexanepentols.

Treatment of acetates of aldose mercaptals with bromine gives acetates of 1-alkylthio-1-bromo-1-deoxyglycitols, which are reduced by $LiAlH_4$ to 1-alkylthio-1-deoxyglycitols and are converted by alcohols and silver carbonate into acetates of 1-alkoxy-1-alkylthio-1-deoxyglycitols. The last-named compounds afford 1-*O*-alkylglycitol acetates when boiled with Raney nickel in ether.

## Use of Tetrazolium Salts in the Early Diagnosis of Cardiac Infarcts

*F. Bölsing*, Hannover (Germany)

Ischemic damage to the heart muscle can be recognized by a reduced enzyme content resulting from changes in structure and permeability of the mitochondria in the necrotic region. Changes in the content of succinate dehydrogenase (SDH) can be detected by means of tetrazolium salts.

Detection of very small changes in SDH concentration requires a color test that is as intense as possible and gives a color tone different from that of the tissue as well as a strong contrast between sound and ischemically damaged areas. In place of the usual ditetrazolium salts one can use monotetrazolium salts, more simply and without the disadvantages of the former, if the red formazans formed are converted into intensely colored complexes of heavy-metal compounds. For this reason the complex-chemical behavior towards some heavy-metal salts was studied for triphenylformazan and its derivatives containing a nitro and a methoxy group (each in *para*-position in a phenyl residue) in the 27 possible arrangements. Only mercuriacetamide gave results suitable for tissue staining. Triphenylformazan itself with mercuriacetamide gives an intensely bluish-violet complex.

This method permitted detection of a 35 – minute – old experimental cardiac infarct (rat, ligature of the main stem of the left coronary artery).

For the human heart, residual blood is removed from the heart cavities and the coronary vessels with physiological Ringer solution, then the coronary vessels are washed out with a solution of triphenyltetrazolium bromide, and finally the whole heart is immersed in the solution. After incubation for 10 to 20 minutes at 37 °C, the heart is washed out and the process is repeated with the mercuriacetamide solution.

Triphenyltetrazolium bromide is obtained by oxidation of triphenylformazan with hypobromite solution.

## Structure and Magnetism of Ternary Fluorides

*D. Babel*, Tübingen (Germany)

The magnetic behavior of transition-metal ions $M^{2+}$ = $Mn^{2+}$, $Co^{2+}$, $Ni^{2+}$, and $Cu^{2+}$ in ternary fluorides $AMF_3$ and $A_2MF_4$ ($A^+$ = alkali-metal ion or $Tl^+$) is related to the structure of the compounds. Compounds $AMF_3$ crystallize in rhombic, cubic, or hexagonal perovskite lattices depending on the Goldschmidt tolerance factors. Hexagonal lattices are present, above all, in the Cs compounds $CsMnF_3$ (hexagonal $BaTiO_3$ type; also $RbNiF_3$), $CsCoF_3$ ($BaRuO_3$ type), and $CsNiF_3$ ($BaNiO_3$ type). The number of $MF_6$ octahedra sharing faces increases in the order given. Except for $Na_2CuF_4$ (monoclinic, individual type), compounds $A_2M_4$ are formed only when A = K, Rb, Tl, or Cs; they occur in the tetragonal $K_2MgF_4$ type, with the exception that cesium fluorides $Cs_2MF_4$ crystallize in a hexagonal structure, details of which are not known.

The magnetic properties range from antiferromagnetism ($KMF_3$) through normal paramagnetism ($CsMF_3$, $A_2CuF_4$) to strong ferrimagnetism ($RbNiF_3$), and can be explained by considering the distances and coordination relations in the lattices. In particular, consideration of superexchange [*] and its dependence on the electron configuration of the cation and the arrangement of ions in the crystal permits qualitative interpretation of the magnetic properties. Thus, cases of 3-, 2-, 1-, and 0-dimensional superexchange can be differentiated which, in conjunction with the dependence on M–F distances and M–F–M angles, account for the variations in magnetic behavior.

[Lecture at Erlangen (Germany), on February 10th, 1966]

[VB 982/289 IE]

German version: Angew. Chem. 78, 451 (1966)

[*] Superexchange is the magnetic interaction between paramagnetic cations by means of intermediary anions.

## Homopolar and Heteropolar Halogeno Esters of Phosphorus, Arsenic, and Antimony

*L. Kolditz*, Berlin (Germany)

Compounds of pentavalent phosphorus, arsenic, and antimony that carry both halogen and OR groups (R = alkyl or aryl) on the central atom, like the analogous simple pure and mixed halides, appear in homopolar and salt-like forms. In polar solvents equilibria are established between these two forms, the homopolar form undergoing association by means of halogen or OR bridges even in relatively dilute solution (*e.g.* 0.01 M in $CH_3CN$). The behavior of chloro(ethoxo)antimony compounds is typical, leading to equilibria according to (L = solvent):

$$2\,SbCln(OR)_{5-n}\cdot L \rightleftharpoons [SbCl_{n+1}(OR)_{5-n}L_2]^+ + [SbCl_{n+1}(OR)_{5-n}]^- \quad (a)$$

The situation is, however, complicated by exchange reactions between Cl and OR.

Alkoxofluorohydroxoarsenic compounds behave similarly; in the forms $HO(RO)_3AsF$ and $HO(RO)_2AsF_2$ they show a strong tendency to condense, with elimination of OH groups and formation of oligomers containing As–O–As linkages.

On reaction with $KOCH_3$ in $C_2Cl_3F_3$, arsenic pentafluoride gives the compound $AsF_4OCH_3$ as well as $K[AsF_6]$. The reaction mechanism is interpreted as:

$$2\,AsF_5 \rightleftharpoons AsF^+ + AsF^-$$
$$AsF_4^+ + KOCH_3 \rightarrow AsF_4OCH_3 + K^+ \quad (b)$$

Equilibrium (c) was found when $AsF_3$ was used as solvent:

$$(AsF_4OCH_3)_2 \rightleftharpoons [AsF_2(OCH_3)_2][AsF_6] \rightleftharpoons [AsF_2(OCH_3)_2]^+ + [AsF_6]^- \quad (c)$$

Compounds $P(OR)_2F_3$ and $[P(OR)_4][PF_6]$ are formed by exchange of Cl ligands in $PCl_2F_3$ (homopolar) and $[PCl_4][PF_6]$ (salt-like) for OR groups. In polar solvents (*e.g.* $CH_3CN$) the homopolar substance is transformed into the salt-like one in an equilibration of the above type. On decomposition of the salt-like compound the cation yields $OP(OR)_3$.

[Lecture at Mainz (Germany) on January 22nd, 1966]

[VB 979/286 IE]

German version: Angew. Chem. 78, 451 (1966)

## Chemistry of Phosphorus, Arsenic, and Antimony Halides

*L. Kolditz*, Berlin (Germany)

We have studied the reactions of phosphorus, arsenic, and antimony halides with polar solvents. $PF_5$, $AsF_5$, and $SbF_5$ form adducts with $CH_3CN$, and these dissociate in acetonitrile according to Eq. (a) (A = P, As, Sb):

$$2\,AF_5\cdot CH_3CN \rightarrow [AF_4(CH_3CN)_2]^+ + [AF_6]^- \quad (a)$$

An analogous formulation holds for $SbCl_5\cdot CH_3CN$. The dissociation can be demonstrated by conductivity measurements and hydrolysis experiments. Hydrolysis occurs only at the cation for A = P, As, the anions remaining unchanged. This is true also for the compound $PF_5\cdot N(CH_3)_3$, but $AsF_5\cdot N(CH_3)_3$ occurs only in the "homopolar" form and is unaffected by moisture; the arsenic compound is not even wetted by water.

A solution of chlorine in $AsCl_3$, which contains the solvate $AsCl_3–Cl_2$ but no $AsCl_5$, is a very strong chlorinating agent. Arsenic and antimony compounds that contain a $CF_3$ group as well as halogen (general formula $AX_2(CF_3)_3$) are more stable than the corresponding simple halides.

$[SbBr_6]^-$ ions decompose in $CH_3CN$ according to Eq. (b). The structure of $[SbBr_6]^-$ may thus be represented by the

$$[SbBr_6]^- \rightarrow SbBr_3 + Br\cdot Br_2^- \quad (b)$$

formula $[SbBr_4\cdot Br_2]^-$. Easy loss of bromine occurs also with $SbBr_5\cdot O(C_2H_5)_2$, which can be prepared only with an excess of antimony (*e.g.* Br:Sb = 4.7:1). $SbBr_5$, like $AsCl_5$, is not known in the pure form.

The system $SbCl_5/SbF_5$ contains associated apolar and also polar forms. The most stable compound is $SbCl_4F$, which is tetrameric in the solid state: distorted $SbCl_4$ tetrahedra are linked by asymmetrical fluorine bridges (varying Sb–F distances).

All the compounds mentioned tend to exchange halogen. The equilibria occurring in solution are dependent on solvent, concentration, and temperature, and the halogen-transferring action of the apolar substances differs from that of the salt-like forms, so that halogenation can be readily controlled.

[Lecture at Aachen and Frankfurt/Main (Germany), on January 21st and 27th, 1966] [VB 980/287 IE]

German version: Angew. Chem. 78, 452 (1966)

## Structures and Reactions of the Products of Reaction of Hydrogen Cyanide with Hydrogen Halides

*E. Allenstein, A. Schmidt*, and *V. Beyl*, Stuttgart (Germany)

Structural investigation of the "sesquihalides of hydrocyanic acid," $2\,HCN\cdot 3\,HX$ (X = Cl or Br), mostly by infrared spectroscopy but also by chemical methods, has shown that they are *N*-(dihalogenomethyl)formamidinium halides [2], $[HX_2C–NH–CH=NH_2]^+X^-$, in accordance with the view of *Gattermann* and *Schnitzspahn* [1].

On hydrolysis with an equivalent amount of water in ether, *N*-formylformamidinium bromide *(1)*[2] [obtainable by reaction of *N*-(dibromomethyl)formamidinium bromide with dimethyl sulfoxide] yields *N*-formylformamide *(2)* (m.p. 42 °C; b.p. 119 °C/12 mm Hg) in accord with Eq. (a).

$$[O{=}CH{-}NH{-}CH{=}NH_2]^+Br^- + H_2O \rightarrow$$
$$\underset{(1)}{} \qquad O{=}CH{-}NH{-}CH{=}O + NH_4Br \quad (a)$$
$$\underset{(2)}{}$$

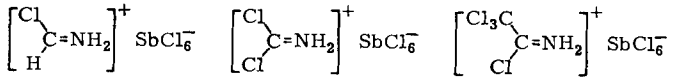
*N*-Formylformamide *(2)* can also be prepared by hydrolysis of *N*-(dichloromethyl)formamidinium chloride with traces of water in the presence of an excess of sodium hydrogen carbonate:

$$[Cl_2CH{-}NH{-}CH{=}NH_2]^+Cl^- + 2\,H_2O \rightarrow$$
$$O{=}CH{-}NH{-}CH{=}O + NH_4Cl + 2\,HCl \quad (b)$$

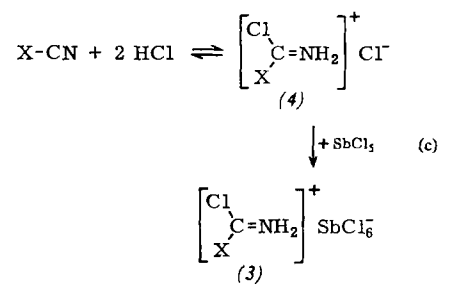
$$2\,HCl + 2\,NaHCO_3 \rightarrow 2\,NaCl + 2\,CO_2 + 2\,H_2O$$

The latter process is suitable also for the preparation of *N*-alkyl-*N*-formylformamides, starting with the *N,N'*-dialkyl-*N*-(dichloromethyl)formamidinium chlorides $[HCl_2C{-}NR{-}CH{=}NHR]^+Cl^-$ obtained by *Jentzsch*[3].

Hydrogen cyanide, chlorocyanogen, and trichloroacetonitrile, without or in the presence of hydrogen chloride, afford *N*-(dichloromethyl)formamidinium chloride[2], cyanuric chloride[4], and 2,4,6-tris(trichloromethyl)-*s*-triazine[5], respectively, by di- or trimerisation of the cyano compounds or of the hydrogen chloride adducts that are the primary products. However, we have shown that in the presence of antimony(V) chloride and hydrogen chloride, hexachloroantimonates *(3)* are produced. The antimony(V) chloride takes part in the reaction of the cyano compounds with hydrogen chloride according to Eq. (c):



*(3a)* [6] *(3b)* [7] *(3c)* [8]



The unstable imidium chlorides *(4)*, which are in equilibrium with the starting materials, are rapidly trapped as the stable hexachloroantimonates *(3)*; the slow dimerization or trimerization is thus prevented.

# SELECTED ABSTRACTS

**The synthesis of 2-aminoethylphosphines** $(C_2H_5)_2N{-}(CH_2)_2{-}PR_2$ by reactions (a) to (d) has been reported by *K. Issleib* and *R. Rieschel*.

$$(C_2H_5)_2N(CH_2)_2Br + KP(C_6H_5)_2 \xrightarrow[-KBr]{THF} (C_2H_5)_2N(CH_2)_2P(C_6H_5)_2 \quad (a)$$
$$\underset{(1)}{}$$

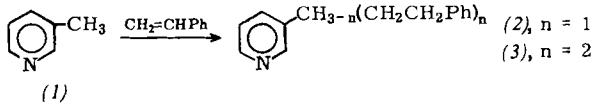
$$(C_2H_5)_2N(CH_2)_2Br + LiP(c\text{-}C_6H_{11})_2 \xrightarrow[-LiBr]{THF} (C_2H_5)_2N(CH_2)_2P(c\text{-}C_6H_{11})_2$$
$$\underset{(2)}{} \quad (b)$$

$$(C_2H_5)_2N(CH_2)_2Br{\cdot}HBr + HP(C_2H_5)_2$$
$$\rightarrow [(C_2H_5)_2HN(CH_2)_2PH(C_2H_5)_2]Br_2 \quad (c)$$
$$\underset{(3a)}{}$$

$$(3a) + 2\,Na \xrightarrow[-2\,NaBr]{-H_2} (C_2H_5)_2N(CH_2)_2P(C_2H_5)_2 \quad (d)$$
$$\underset{(3)}{}$$

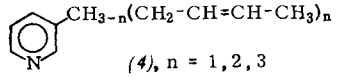
Reaction (c) is carried out in chlorobenzene, so that the phosphonium salt *(3a)* precipitates; after separation, *(3a)* is decomposed in ether in accordance with Equation (d). The products *(1)* to *(3)* can be isolated as colorless oils by vacuum distillation. They are soluble in ether, tetrahydrofuran, dioxane, benzene, and acetone, but not in water. The infrared spectra of *(1)* to *(3)* contain the triethylamine stretching bands, which are still present after the reaction with excess ethyl iodide. Thus only the phosphorus is quaternized. Oxidation of *(1)* to *(3)* with $H_2O_2$ in ether leads to the formation of the phosphine oxides. / Chem. Ber. *98*, 2086 (1965) / –Gn. [Rd 426/635 IE]

**The sodium-catalysed alkylation of 3-picoline** with styrene and butadiene has been achieved by *Y. I. Chumakov* and *V. M. Ledovskikh*. 3-Picoline *(1)* was boiled (145 °C) under $N_2$ with sodium [0.1 g-atom per mole of *(1)*]. An equimolar quantity of styrene was added dropwise over half an hour, and the mixture was refluxed for a further two hours. The products obtained included those resulting from monoalkylation [*(2)*, 23.2 % yield] and from dialkylation [*(3)*, 17.4 %].



*(1)* *(2)*, n = 1; *(3)*, n = 2

When butadiene was used instead of styrene, 2.4 % of the triply-substituted product was obtained, as well as 35.4 % of the mono-adduct and 16.4 % of the di-adduct. It was assumed that these adducts have the structure *(4)*. *(4)*, n = 1 could



*(4)*, n = 1, 2, 3

be reduced to n-amylpyridine, and yielded acetaldehyde on ozonolysis, indicating a 1,4-addition. A small quantity of the 1,2-addition product was also detected by infrared spectroscopy. The additions must take place on a derivative of *(1)* that has been metalated at the methyl group. The proton mobility was comparable to that of the 2- and 4-isomers. / Tetrahedron *21*, 937 (1965) / –Eb. [Rd 423/632 1E]

**The synthesis of substituted vinyl trialkylsilyl ethers** is described by *J. I. Baukov, G. S. Burlachenko,* and *I. F. Lutsenko.* Trimethylchlorosilane reacts with α-trialkylstannyl ketones to give excellent yields of α-alkylvinyl trimethylsilyl ethers *(1)*

$$(CH_3)_3SiCl + R_3Sn\text{-}CH_2\text{-}COR' \longrightarrow$$

$$(CH_3)_3Si\text{-}O\text{-}\underset{R'}{C}{=}CH_2 + R_3SnCl$$

*(1)*

[when R′ = $CH_3$, b.p. 92 to 94 °C/758 mm Hg, yield 80 %]. The infrared spectra of the products contain a band at 1652 $cm^{-1}$, which is assigned to the C=C double bond.

$$(C_2H_5)_3SiI + (C_3H_7)_3Sn\text{-}CH_2\text{-}COOCH_3 \longrightarrow$$

$$CH_2{=}C(OCH_3)(OSi(C_2H_5)_3) + (C_3H_7)_3SnI$$

*(2)*

1-Methoxy-1-triethylsiloxyethene *(2)*, b.p. 63 to 65 °C/7 mm Hg, is formed in the reaction of methyl tripropylstannylacetate with triethyliodosilane. / J. organomet. Chemistry *3*, 478 (1965) / –Sch. [Rd 431/640 IE]

**In the biosynthesis of insulin** the two peptide chains are formed separately and are then linked by the disulfide bridges. *R. E. Humber* has carried out labelling experiments using the Brockmann body of the anglerfish. The biosynthesis of insulin follows the general scheme of protein synthesis (it can be inhibited, *e.g.*, by puromycin) and proceeds from the amino end to the carboxyl end. Insulin obtained from the anglerfish contains three proline units, one roughly in the middle of the A chain ("A") and two in the B chain, in positions 2 and 28 ("$B_2$" and "$B_{28}$"). If the insulin synthesis is allowed to proceed for 8 hours in the presence of [$^{14}$C]-proline, the insulin is labelled to the same extent in all three proline residues. The synthesis is then allowed to continue for a further 15 to 30 min in the presence of [$^{3}$H]-proline; labelling of the proline units of the insulin with tritium increases with proximity to the carboxyl end. In the isolated insulin, the ratio $^{3}H/^{14}C$ was greatest in the $B_{28}$ proline unit, lower in the A proline, and lowest of all in the $B_2$ proline. If the insulin had been synthesized as a single peptide chain, which was subsequently cleaved (as is the case with chymotrypsin), the $^{3}H/^{14}C$ ratio should have decreased in the order $B_{28} > B_2 >$ A or A $> B_{28} > B_2$. / Proc. nat. Acad. Sci. USA *53*, 853 (1965) / –Hö. [Rd 411/620 IE]

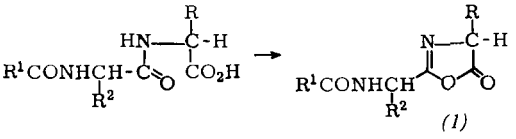
**Acetyl-CoA: D-amino acid α-*N*-acetyltransferase** has been concentrated by a factor of 2000 from baker's yeast by *M. H. Zenk* and *J. H. Schmitt.* The enzyme catalyses the reaction:

acetyl-CoA + D-amino acid → α-*N*-acetyl-D-amino acid + CoA

The reaction is irreversible, and cofactors are not required. D-Tryptophan was used as the substrate for the test, and acetyl-CoA was produced *in situ* from acetyl phosphate and CoA. The acetyl-D-tryptophan formed was extracted with ether and determined colorimetrically with *p*-dimethylaminobenzaldehyde. The reaction is specific for the D-amino acids, although D-proline and D-aspartic acids (in contrast to asparagine) react very poorly. The enzyme can be used for the preparative separation of D- and L-amino acids. Its biological function is probably to bind the D-amino acids and so render them non-toxic. / Biochem. Z. *342*, 54 (1965) / –Hö. [Rd 412/621 IE]

**Regulatory and functional sub-units in aspartate transcarbamylase** have been found by *J. C. Gerhart* and *H. K. Schachman.* With the aid of *p*-mercuribenzoate, these authors divided the enzyme (ATCase, MW = 310000) from *Escherichia coli* into two types of sub-units, two having a molecular weight of 96000 and four one of 30000. The larger sub-units carried the whole of the catalytic activity, but they were not inhibited by cytidine triphosphate, the feedback inhibitor for ATCase. The bonding sites for the inhibitor are located on the smaller sub-units, two to each sub-unit, as was shown by reaction with 5-bromocytidine triphosphate. On incubation in the presence of mercaptoethanol, the sub-units recombines to form the hexameric enzyme, which possesses the same catalytic and regulatory properties as the native allosteric enzyme. / Biochemistry *4*, 1054 (1965) / –Hö. [Rd 413/622 IE]

**A new method for the determination of C-terminal amino acids** in peptides and proteins is discussed by *H. Matsuo, Y. Fujimoto,* and *T. Tatsuno.* The C-terminal amino acid of an *N*-acetylpeptide is converted into the oxazolone *(1)* by boiling



*(1)*

$$R^1CONHCHCONH\text{-}\underset{D}{C}(R)\text{-}CO_2H \quad (2)$$

for a short time with acetic anhydride or dicyclohexylcarbodiimide in anhydrous dioxane. After the addition of a drop of pyridine, the compound *(1)* in dioxane is treated with $D_2O$ (or $T_2O$) to form the deuterated (or tritiated) compound *(2)*. The labelled amino acid can be determined after hydrolysis. / Tetrahedron Letters *1965*, 3465 / –Ma. [Rd 393/602 IE]

**A new method for the rapid cleavage of ethers** under mild conditions is described by *L. H. Long* and *G. F. Freeguard.* The method is based on the discovery that boranes or metal borohydrides and halogen (especially $I_2$) cleave O–C bonds with formation of O–B and C-halogen bonds. The resulting borates are completely hydrolysed within a few minutes at room temperature.

$$6\ PhOCH_3 + 3\ I_2 + B_2H_6 \rightarrow 2B(OPh)_3 + 6\ CH_3I + 3\ H_2$$

$$3\ PhOCH_3 + 2\ I_2 + NaBH_4 \rightarrow B(OPh)_3 + 3\ CH_3I + NaI + 2\ H_2$$

$$B(OPh)_3 + 3\ H_2O \rightarrow 3\ PhOH + H_3BO_3.$$

Boranes higher than diborane react more slowly. $NaBH_4$ is rather less reactive than $LiBH_4{\cdot}Br_2$, and interhalogen compounds such as ICl react more vigorously than $I_2$, but they are less convenient to use. The ethers may be symmetrical, unsymmetrical, aliphatic, aromatic, or cyclic. The cleavage can also be used for preparative purposes; for example, the cleavage of tetrahydrofuran with $B_2H_6$ and $I_2$ leads to the formation of 4-iodobutan-1-ol in a yield of more than 90 %. / Nature (London) *207*, 403 (1965) / –Ma. [Rd 394/603 IE]

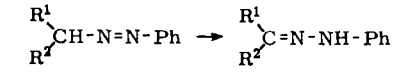
**The "trans effect" of ligands in square-planar palladium(II) and platinum(II) complexes,** *i.e.* the fact that the replacement of a ligand is more strongly promoted by a ligand *trans* to it than by a *cis* ligand, has been studied by *J. R. Durig, R. Layton, D. W. Sink,* and *B. R. Mitchell.* They examined the infrared spectra of *cis* and *trans* palladium(II) complexes $PdL_2Cl_2$ to find how the frequency of the Pd–Cl stretching vibration depends on the ligand L (see Table; of the two

Pd–Cl stretching vibrations of the *cis* complex, only the antisymmetric are given). The *trans* effect of L acts on the Pd–Cl bonds of the *cis* complex, but not on those of the *trans* complex. From the results given in the table, it is concluded that the *trans* effect of saturated compounds containing nitrogen is due simply to electrostatic weakening of the *trans* bond (the substitution of H by electron-donating alkyl groups causes a shift of $\nu_{Pd-Cl}$ towards longer wavelengths, corresponding to an increase in the *trans* effect).

| Ligand | $NH_3$ | $CH_3NH_2$ | $C_2H_5NH_2$ | Pyridine | $CH_3SC_2H_5$ | 3,6-Dithiaoctane |
|---|---|---|---|---|---|---|
| $\tilde{\nu}_{Pd-Cl}$ [cm$^{-1}$] (*trans*-compound) | 333 | 341 | 336 | 358 | 360 | |
| $\tilde{\nu}_{Pd-Cl}$ [cm$^{-1}$] (*cis*-compound) | 327 | 317 | 317 | 342 | | 323 |

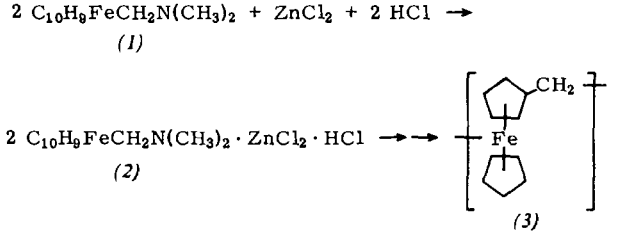
The shift to longer wavelengths does not occur in the case of ligands in which the nitrogen forms part of an aromatic system, or ligands containing sulfur. It may therefore be concluded that in ligands of this type, the *trans* effect is also due in part to $\pi$-bonding with the $d_\pi$-orbitals of the metal. / Spectrochim. Acta *21*, 1367 (1965) / –Hz. [Rd 395/604 IE]

**The rearrangement of phenylazoalkanes to phenylhydrazones** has been studied by *A. J. Bellamy* and *R. D. Guthei*, using free-radical, basic, and acidic catalysts.



The reverse reaction did not take place. Reaction of phenylazocyclohexane with catalytic quantities of benzoyl peroxide in $CHCl_3$ or hexane at 100 °C led to a 54 or 71 % yield, respectively, of cyclohexanone phenylhydrazone after 24 h. 1-Phenylazobutane refluxed for 1 h in $NaOCH_3/CH_3OH$ gave a 78 % yield of n-butyraldehyde phenylhydrazone. This last compound is obtained in 64 % yield after 5 min at 0 °C with concentrated $H_2SO_4$ in ethanol. All the reactions must be carried out in the absence of air to prevent autoxidation of the phenylhydrazones. Under the conditions used in the Fischer indole synthesis (anhydrous $ZnCl_2$ at 180 °C), the phenylazoalkanes react to form indoles. Thus 1-phenylazobutane gives 3-ethylindole (46 %), and 2-phenylazopropane gives 2-methylindole (27 %). / J. chem. Soc. (London) *1965*, 3528 / –Kü. [Rd 417/626 IE]

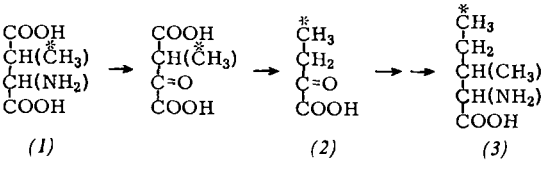
**The autocondensation of *N,N*-dimethylaminomethylferrocene** *(1)* in the presence of a $ZnCl_2$/HCl catalyst system, according to *E. W. Neuse* and *E. Quo*, leads to the formation of soluble polymers consisting of ferrocenylene units linked by methylene bridges. The crude condensation products prepared in the melt have a number-average molecular weights of 4000



to 8000. Elementary analysis and infrared spectroscopy, as well as viscometric data, indicate that the polymer has the formula *(3)*. The authors were able to isolate the intermediate *(2)* from the reaction mixture. / J. Polymer Sci. *3A*, 1499 (1965) / –Hl. [Rd 418/627 IE]

**Solutions of ethylmagnesium bromide in ether** have been studied by *E. C. Ashby*, who used triethylamine as a solvating agent. A solution of ethylmagnesium bromide was prepared from ethyl bromide and magnesium in ether, and was added to a large excess of triethylamine with vigorous stirring. This immediately resulted in the formation of crystals in a yield of more than 90 %; the molecular weight of the crystals, as found by the ebullioscopic method at 15 mm Hg, corresponded to the formula $C_2H_5-MgBr(C_2H_5)_3N$. Earlier ebulliscopic measurements had shown that in the absence of triethylamine, ethylmagnesium bromide in ether is largely dimerized, probably *via* symmetrical halogen bridges. The present work showed that ethylmagnesium bromide in ether cannot be decomposed to any great extent into diethylmagnesium and magnesium bromide (as had been suggested by *Schlenk* and *Schlenk*), and that the formation of the $C_2H_5MgBr(C_2H_5)_3N$ solvate is faster than this disproportionation. If this were not so, $MgBr_2(C_2H_5)_3N$ would precipitate as the least soluble component present. / J. Amer. chem. Soc. *87*, 2509 (1965) / –Eb. [Rd 422/631 IE]

**The preparation of isoleucine from β-methylaspartic acid with the aid of** *Escherichia coli* W has been reported by *T. Abramsky* and *D. Shemin*. These authors added DL-*threo*-β-methylaspartic acid *(1)* labelled with $^{14}C$ to growing bacteria cultures, and found that $^{14}C$ was incorporated into the baterial protein. Hydrolysis of the protein revealed that the only labelled amino acid present was isoleucine *(3)*. The same result was obtained on the addition of [4-$^{14}$C]-α-ketobutyric acid *(2)*. The following reaction scheme was assumed:



α-Ketobutyric acid is known to be an intermediate in the synthesis of isoleucine from threonine. The results are supported by the fact that during the growth of leucine-deficient mutants (*E. coli* IHM 544), isoleucine could be replaced by β-methylaspartic acid. The mutants lacked the threonine dehydrase required for the synthesis of isoleucine from threonine. / J. biol. Chemistry *240*, 2971 (1965) / –Hö. [Rd 404/613 IE]

**The preparation of iridium pentafluoride** from the elements has been described by *N. Bartlett* and *P. R. Rao*. Yellow, crystalline $IrF_5$ (m.p. 104.5 °C) separates at the cooler end of a monel reaction vessel containing a stoichiometric mixture of the elements at 350 to 380 °C. $IrF_5$ can also be obtained by the reaction of $IrF_5$ with glass powder. Earlier workers had assumed the formation of $IrF_4$[1]; however, the properties of the product are unlike those of other tetrahalides, but agree closely with those of the pentafluorides. The monoclinic $IrF_5$ is isomorphous with $RuF_5$ and $OsF_5$, and probably crystallizes with the $RuF_5$ structure. The magnetic behavior of $IrF_5$ is typical of the electronic configuration $d^4$ in octahedrally coordinated fluorides of the third transition series. / Chem. Commun. *1965*, 252 / –Gn. [Rd 427/636 IE]

[1] *G. J. Westland* and *P. L. Robinson*, J. chem. Soc. (London) *1956*, 4481.

**During the digestion of ribonuclease A from ox-pancreas by pancreas elastase,** *W. A. Klee* has isolated an enzymatically active degradation product. The reaction begins after an induction period, and ends with the decomposition of the ribonuclease into more than 20 fragments. In the course of the experiment, the reaction was stopped when roughly one peptide bond had been broken per ribonuclease molecule. Ribonuclease E was isolated by chromatography on Amberlite XE 64. Unlike ribonuclease A, ribonuclease E consists of two peptide chains with the N-terminal amino acids lysine and serine (A: lysine). Moreover, alanine is absent from position 20. Thus the primary attack of the elastase consists in the hydrolysis of two adjacent peptide linkages. The two fragments are held together by non-convalent bonds, and can be separated by trichloroacetic acid (the fragment consisting of 19 amino acids is soluble in trichloroacetic acid) with loss of enzyme activity. The equimolar mixture of the two fragments possesses 80 % of the original enzyme activity. In contrast to ribonuclease A, ribonuclease E is very sensitive to trypsin. Apart from the missing alanine, ribonuclease E is the same as the ribonuclease S obtained by the action of subtilisin. / J. biol. Chemistry *240*, 2900 (1965) / –Hö. [Rd 403/612 IE]

**Postasium dioxofluoroselenate(IV)** has been obtained by *R. Paetzold* and *K. Aurich* by the fusion of equimolar quantities of KF and $SeO_2$ and by reaction of $K_2SeO_3$ with $SeOF_2$.

$$KF + SeO_2 \rightarrow FSeO_2K \quad KSeO_2F$$

$$K_2SeO_3 + SeOF_2 \rightarrow 2\ SeO_2FK$$

Potassium fluoroselenate(IV) is a white crystalline substance which melts at 250 °C without decomposing, and which is very sensitive to water. Study of the hydrolysis by infrared spectroscopy showed that the products include potassium hydrogen selenite, potassium hydrogen fluoride, and selenous acid. The hydrolysis proper:

$$KSeO_2F + H_2O \rightarrow KSeO_2OH + HF$$

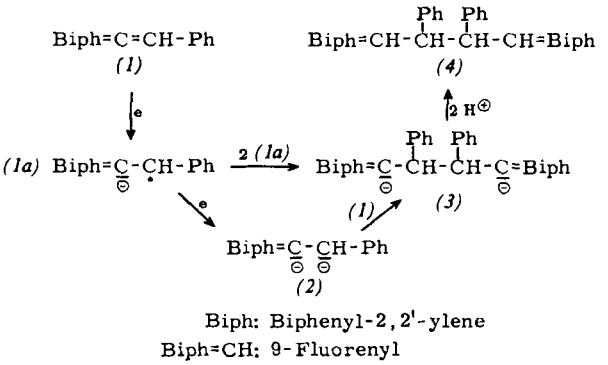
is followed by the reaction:

$$2\ HF + KSeO_2OH \rightarrow KHF_2 + (HO)_2SeO$$

which evidently takes place because of the high stability of $KHF_2 \cdot KSeO_2F$ reacts with methanol in the same way as with water. / Z. anorg. allg. Chem. *335*, 281 (1965 / –Sch. [Rd 434/643 IE]

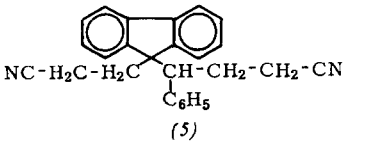
**The semiconducting properties of polymeric Schiff bases** synthesized by condensation of di-, tri-, and tetra-amino derivatives of benzene, fluorene, and anthraquinone with glyoxal or terephthalaldehyde have been studied by *J. Danhäuser* and *G. Manecke*. The polymers are light brown to black, insoluble, and infusible. The conductivities of these products are strongly dependent on the pressure (up to 8000 atm) used in the molding of the amorphous substances. There appears to be a relationship between the conductivity, color, and free-radical concentration, which points to an electronic conduction mechanism. The condensates with the best conductivities (*e.g.* glyoxal-triaminophenol, $\varkappa = 1.7 \times 10^{-10}\ \Omega^{-1}\ cm^{-1}$) are black. The relationship is probably similar to that prevailing in the case of the polyenes: the greater the number of delocalized π-electrons in the conjugated double bonds, the greater is the conductivity. / Makromolekulare Chem. *84*, 238 (1965) / –Hl. [Rd 420/629 IE]

**The electrolytic reductive dimerization of 9-benzylidenefluorene** *(1)* has been studied by *M. M. Baizer* and *J. D. Anderson*. 1,2-Diphenyl-1,2-bis-(9-fluorenyl)ethane *(4)* was obtained with an electrochemical yield of 66 % in DMF/water, the supporting electrolyte being tetraalkylammonium tosylate. In the course of the electrolysis, the Hg cathode became covered with a red film, which indicated the presence of carbanions. Two possible routes for the formation of the hydrodimer *(4)* are:



Biph: Biphenyl-2,2'-ylene
Biph=CH: 9-Fluorenyl

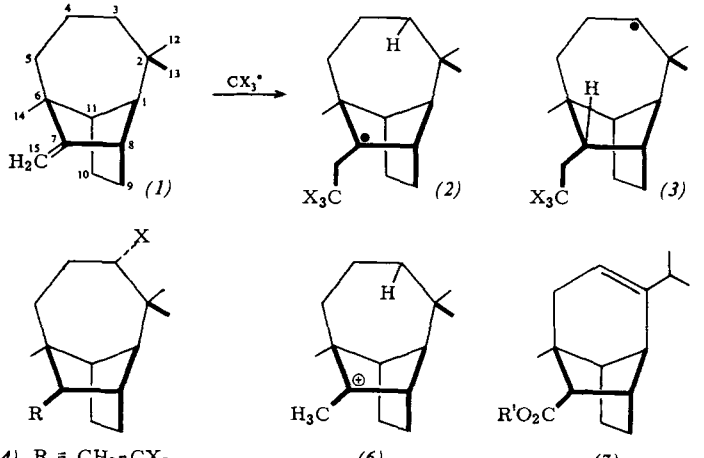
The dimeric dianion *(3)* is protonated to *(4)*. 8,8-Diphenylbenzofulvene gave a monomeric product, since dimerization is sterically hindered in this case.



*(5)*

In the presence of a ten-fold molar excess of acrylonitrile, *(1)* gave the product *(5)* of a double cyanoethylation in 76 % yield (Michael addition of *(2)* to two molecules of acrylonitrile). Compound *(2)* cannot be obtained by deprotonation of 9-benzylfluorene. / J. org. Chemistry *30*, 1348 (1965) / –Eb. [Rd 421/630 IE]

**Homolytic and heterolytic transannular 1,5-hydrogen shifts** occur in longifolene *(1)* and its derivatives. *D. Helmlinger* and *G. Ourisson* have obtained the adduct *(4)* by the free-radical reaction of *(1)* with tetrahalogenomethanes $CX_4$ ($CCl_4$, $CBrCl_3$, $CBr_4$), the reaction proceeding *via* the intermediates *(2)* and *(3)*. During the elucidation of the structure *(4)*, the compound *(5)* was isolated; on mild hydrolysis or slow chromatography on silica gel, *(5)* is converted quantitatively into pure *(1)*. If the carbonium ion *(6)* resulting from the



transannular 1,5-hydrogen shift is destabilized by the presence of electron-attracting groups on C-7, the solvolysis leads to a retro-pinacolone rearrangement, accompanied by ring contraction [*e.g.* to *(7)*]. / Liebigs Ann. Chem. *686*, 19 (1965) / –Bu. [Rd 436/645 IE]

**Rubredoxin, a new crystalline iron protein with a redox function,** has been isolated by *W. Lovenberg* and *B. E. Sobel* from *Clostridium pasteurianum*. It is red in the oxidized state ($\lambda_{max}$ = 490, 380, and 280 mμ) and colorless in the reduced state ($\lambda_{max}$ = 333, 311, and 275 mμ), has a molecular weight of approximately 6000, and contains one atom of iron (ferredoxin has 8) and four –SH groups per molecule. The

redox potential $E'_0$ at pH 7.0 and 25 °C is −0.057 V (ferredoxin: −0.41 V); only one electron is given up on oxidation (as in ferredoxin). Like ferredoxin and thioredoxin, rubredoxin contains many more acidic amino acids than basicones: 12 Asp, 6 Glu, compared with only 4 Lys. No specific reactions of rubredoxin have been found as yet. It catalyses the ferredoxin-catalysed reactions (*e.g.* the reduction of NADP by hydrogen and hydrogenase), but the reaction rates are only about 20 % of those obtainable with ferredoxin. / Proc. nat. Acad. Sci. USA *54*, 193 (1965) / −Hö. [Rd 414/623 IE]

**Fulvene containing less than 2 % of impurities** is formed in 74 % yield when a mixture of the acetoxymethylcyclopentadienes *(1)* and *(2)* is allowed to react with the equivalent quantity of triethylamine. *H. Schaltegger, M. Neuenschwander*, and *D. Meuche* prepared *(1)* and *(2)* from cyclopentadienylsodium and chloromethyl acetate in tetrahydrofuran

*(1)*, R = −CO−CH$_3$ *(2)*, R = −CO−CH$_3$
*(3)*, R = −CH$_3$ *(4)*, R = −CH$_3$

at −30 °C (yield 30 %). No fulvene is obtained from a mixture of *(3)* and *(4)* under the same conditions. / Helv. chim. Acta *48*, 955 (1965) / −Bu. [Rd 437/646 IE]

**The biosynthesis of the biotin enzymes from apoenzyme and biotin** has been studied by *Th. Höpner* and *J. Knappe*. They used the β-methylcrotonyl-CoA carboxylase from *Achromobacter* 1Vs-W. Even under oprimal growth conditions, this biotin-auxotrophic organism (grown with isovaleric acid as the only source of carbon) synthesizes a β-methylcrotonyl-CoA carboxylase in which only 80 to 90 % of the active centers are occupied by biotin. In the presence of a holocarboxylase synthetase which had been concentrated by a factor of 150, the remaining apo-centers could be saturated with biotin, this saturation being accompanied by stoichiometric regeneration of carboxyl reactivity. The course of the reaction [Equations (1) and (2)] was demonstrated by the following synthetase-catalysed reactions:

$$\text{biotin} + \text{ATP} \overset{\text{synthetase}}{\rightleftharpoons} \text{biotinyl-AMP} + \text{pyrophosphate} \quad (1)$$

$$\text{biotinyl-AMP} + \text{apoenzyme} \xrightarrow{\text{synthetase}} \text{holoenzyme} + \text{AMP} \quad (2)$$

a) ATP-dependent formation of biotin hydroxamate from biotin and hydroxylamine; b) biotin- and hydroxylamine-dependent formation of AMP from ATP; c) biotin-dependent exchange between ATP and $^{32}$P-pyrophosphate; d) synthesis of ATP from biotinyl-AMP and pyrophosphate; e) incorporation of biotin from biotinyl-AMP into β-methylcrotonyl-CoA carboxylase. / Biochem. Z. *342*, 190 (1965) −Hö. [Rd 415/624 IE]

# BOOK REVIEWS

**Cyclooctatetraen** (Cyclooctatetraene). By *G. Schröder*. Monograph No. 73 to "Angewandte Chemie" and "Chemie-Ingenieur-Technik". Verlag Chemie GmbH. Weinheim/Bergstr. 1965. 1st Edit., viii + 88 pp., many illustr., cardboard DM 23.– (about $6.–).

In recent years cyclooctatetraene has been the subject as well as the starting material of a large number of investigations, and these are comprehensively covered in this monograph. A description of the syntheses and a short chapter on the structure is followed by much the longest section, which is devoted to the chemical properties of cyclooctatetraene and its derivatives. The following are discussed in detail: reduction and oxidation products of cyclooctatetraene, its behavior towards acids, bases, and free radicals, the adducts formed with carbenes, halogens, and dienophiles, its organometallic complexes, valence-bond isomers, substitution products, and dimers with particular emph sis on bullvalene (obtainable from them). Finally there are selected recipes for preparation of 20 derivatives. The author restricts himself to short but clear restatement of the literature, which is considered up to the middle of 1964. Yet owing to the modernity of the subject, several sections already need expansion or correction (inversion of cyclooctatetraene, its bromination, and the structure of the dimer of m.p. 53 °C). Anyone interested in the unusually varied chemistry of cycloctatetraene will find this volume an ideal source of information. Unfortunately the price of this little book is not in proportion to its size.

*W. Roth* [NB 461/314 IE]

**Die komplexometrische Titration** (Complexometric Titration). Volume 45 of "Die chemische Analyse" (Chemical Analysis). By *G. Schwarzenbach* and *H. Flaschka*. Ferdinand Enke Verlag, Stuttgart 1965. 5th revised Edit., xvi + 339 pp., 42 figs., 12 tables, 48.– DM (about *fi* 12.–).

The present fifth edition of this part of "Die chemische Analyse" (Chemical Analysis) appears 20 years after the introduction of complexometric titration and 10 years after the first edition. Written in collaboration with *H. Flaschka* it has become a completely new book. The volumetric procedure established by *G. Schwarzenbach* is characterized by the use of specific complex-formers and indicators for metal ions, and its explosive development has necessitated an expansion of the text from 119 to 339 pages. Division of the text into two parts of equal length – one theoretical and the other practical – has been maintained. The first part contains general information about titration reagents, the theory of the course of the reactions and the mode of action of dye and fluorescent indicators in complexometry, the methods of visual and instrumental end-point determination and the various types of titration, their accuracy and selectivity. In the second part practical details are given, first for the preparation of volumetric and indicator solutions, then for complexometric determination of almost all the elements; in the last section is described the determination and masking of metals in a most imaginative way by manifold combinations of formation and fission of kinetically labile metal complexes. (The determination of non-metals, *e.g.* fluorine, should, however, be considered critically.) The literature up to the end of 1963 is cited in 1437 references, arranged alphabetically in groups according to the year of their appearance.

In its new expanded form this book has become the standard work for complexometric titrations. It is a valuable adviser for analytical practice and is exciting reading for all who are interested in the theoretical foundations of chemistry in aqueous solutions.

*F. Seel* [NB 463/316 IE]

**Boron-Nitrogen Compounds.** Vol. VI of the Series "Anorganische und allgemeine Chemie in Einzeldarstellungen". By *K. Niedenzu* and *J. W. Dawson*. Springer-Verlag, Berlin-Heidelberg-New York 1965. 1st Edit., viii + 176 pp., numerous figs., linen 27.– DM (about $ 7.–).

Several books have recently appeared on the chemistry of boron. The present one concerns boron-nitrogen compounds, which have been extensively studied during the last 10 years or so, and to which the authors have made numerous contributions. Six chapters are devoted to amine-boranes (borazanes), aminoboranes (borazenes), borazoles, BNC heterocycles, and boron nitrides. Additionally there is a short section on $^{11}$B nuclear magnetic resonance. Numerous tables

and recipes for the preparation of important starting materials complete the text. A useful author index (12 pp.) is to be contrasted with too short a subject index (5 pp.).

This readable book undoubtedly fulfils its object, as an introduction into the chemistry of boron-nitrogen compounds, and it provides stimulation for further development thereof. However, the chemistry of the borazoles and BNC heterocycles, *e.g.* the borazarenes deserves more detailed treatment, and so do the results obtained in the laboratories of *W. M. Michailow* and *V. I. Zacharkin*. It is mainly the work of the last five years that is discussed. The reviewer does not always agree with the authors' views, and study of the book makes it clear that more quantitative work is needed in order to provide a firm thermodynamic, kinetic, and structural basis for further discussions and to place the present plausible working hypotheses on a firmer basis.

*H. Nöth* [NB 465/318 IE]

**Die Bestandteile der Lebensmittel** (The Constituents of Foodstuffs). Volume I of the Series "Handbuch der Lebensmittelchemie" (Handbook of Foodstuffs Chemistry). Edited by *J. Schormüller*. Springer-Verlag, Berlin-Heidelberg-New York 1965. 1st Edit., xxviii + 1288 pp., 136 figs., linen DM 298.– (about $ 75.–). Subscription price DM 238.40 (about $ 60.–).

After 32 years the first volume of the new edition of the Handbuch der Lebensmittelchemie (Handbook of Foodstuffs Chemistry) has appeared, on the constituents of foodstuffs. This long interval has had the inevitable consequence that only the form of the old book is preserved, the text having been largely rewritten, yet strict control by the editor has ensured that the total number of pages is somewhat less than in the previous edition.

For treatment of the 24 chapters of this volume experts in specialized fields have been enlisted as well as specialists in general foodstuffs chemistry. References to the literature are given at the end of each chapter, and some of the authors have included references up to 1964.

Chapter 1 treats the history of food science from prehistory to the 20th century. This review is certainly comprehensive, including control and research, and has some very telling illustrations. In the next chapter *O. Högl* expounds the objectives of foodstuffs science. The most important aim is to disclose and evaluate the composition of foods; the recognition and removal of injurious components are recorded in further sections of this chapter, and in a very short space but quite comprehensively a further section treats the importance of water as a food constituent, including its place in fresh and preserved foods. Additionally *H. Langendorf* discusses inorganic cations and anions which are essential for the organism, sometimes in large quantities and sometimes in traces; their function in metabolism is also noted; and five tables give information about the content of essential ions in the most important foods.

The chapter on amino acids, peptides, and other nitrogen compounds seems to the reviewer to be too detailed: not only the chemical properties and physiological importance, but also the occurrence of rare amino acids, are reported, even for products that are not foods. The same applies to the discussion of peptides, but the treatment of proteins is better related to the main theme. There is, however, no reference to the manifold changes undergone by methionine or the unpleasant smell and taste that can result from its decomposition products.

The chapter on fats, lipids, waxes, and resins provides a short but very valuable review. The most important saturated and unsaturated fatty acids are described, and also glycerides, phosphatides, sphingolipids, and other possible secondary ingredients. It should, however, be noted that γ-sitosterol (pp. 338 and 345) has meanwhile been recognized as a 1:1 mixture of β-sitosterol and campesterol. Finally the author describes the natural and technological changes undergone by fats.

The isolation and composition of essential oils is treated by *K. Herrmann*. The most important mono- and sesqui-terpenes are mentioned, as well as other constituents such as acids, esters, ketones, and sulfur compounds that determine the taste.

In the chapter on carbohydrates and glycosides *Almut Klemer* describes the chemistry and analysis of sugars, and also sugar esters, amino sugars, pectins, algal products, and carbohydrate-protein compounds. The chapter concludes with seven tables giving the most important constants of these compounds. The authoress reports also on *O*-, *N*-, and *S*-glycosides. A few inaccuracies have crept in concerning saponins: α-amyrin is derived from ursane, and β-amyrin from oleanane (p. 527); aescin is an oleanane derivative, its structure having been determined in 1963 (p. 529); the triterpene acid of ursane type is named ursolic acid (pp. 530 and 1284).

*H. Endres* discusses the most important tannins. Unfortunately, except for passing mention of the catechins of tea and coffee beans, this chapter contains no reference to foodstuffs; but the omission is rectified to some extent in the next chapter where *K. Herrmann* treats plant phenolics in foodstuffs.

The following chapter, by *E. Beyer*, describes the isolation, constitution, and detection of natural dyes, in particular carotenoids, quinones, flavanoids, anthocyanins, and some porphyrins. It is expanded by *R. Hamm* in a good review of the chemistry of haemoglobin and myoglobin. The chapter on carboxylic acids, esters, carbonyl compounds, and alcohols shows a welcome orientation towards the requirements of foodstuffs chemistry. However, the formulae of the two optically active tartaric acids (p. 778) do not agree with the latest information: the formula described as D-(+)-tartaric acid is that of L-(+)-tartaric acid, and that described as L-(−)-tartaric acid is D-(−)-tartaric acid.

*K. Myrbäck* makes a valuable contribution to the general field of enzymes. It is supplemented by *H. Mohler*'s description of the importance of enzymes in foodstuffs technology and in the formation of aromatic ingredients, also by *H. Sommer*'s report on commercially prepared enzymes and their use in manufacture and analysis of foodstuffs. The chapter on vitamins deals first with their stabilization and with procedures for their analysis; it then treats the individual vitamins in alphabetical order, including their mode of action. There is, however, no mention of the artefact nature of cyanocobalamin in the discussion of vitamin $B_{12}$ or of the present-day preference of vitamin $D_3$ over vitamin $D_2$. The chapter on chemical additives treats preservatives very thoroughly, including their properties, uses, and modes of action. The discussion of dyes for foodstuffs records both the old use of saffrom and curcuma, and the toxic effects of certain azo dyes. There follows a list of permitted dyes in accordance with the data of the Farbstoffkommission of the Deutsche Forschungsgemeinschaft.

In the last chapter *S. W. Souci* and *E. Mergenthaler* report on all other chemical additives, such as antioxidants, synergists and complex-formers, color improvers and bleaching agents, thickening and gelling agents, surface-active materials and materials having a physical effect, coatings, insecticides, and herbicides. The list is comprehensive and provides a good orientation on the properties of the individual compounds. The book ends with a subject index running to 65 pages.

The publishers have produced the book to their usual high standard. The printing is almost free from error, and the formulae cannot be misinterpreted (with very few exceptions, *e.g.* gossypol, p. 351). The editor and the publishers are to be congratulated on a noteworthy achievement.

*C. H. Brieskorn* [NB 462/315 IE]

**Selected Papers on Molecular Genetics.** A Collection of Reprints with Introductory Material. Vol. 1 of the Series "Perspectives in Modern Biology – A Series of Reprint Collections". By *J. H. Taylor*. Academic Press Inc., New York 1965. 1st Edit., xii + 650 pp., bound $ 9.–, paper back $ 5.95.

In few parts of biochemistry has development been as lively during recent decades as in genetics with all its far-reaching

implications. It would be only too easy for those who take no direct part in this work to lose sight of the broad lines of the development, only too easy for interest in questions that are currently in the forefront to diminish attention to other problems. It was therefore a good idea to recall to memory the milestones of progress by republishing selected papers from the years 1913–1963 in their original form. It is, of course, not to be expected that a complete picture can be reconstructed from 46 publications. The editor was himself aware of this difficulty and has therefore written introductory prefaces to the five sections of the book (Biochemical Genetics, The Nature of Genetic Material, DNA Structure and Replication, Genetic Recombination, The Function of Genetic Material), these prefaces showing the relation between the papers that are reproduced and giving references to papers that have not been included.

Clearly no selection can be made entirely without arbitrariness. The editor has been at pains to find that paper – or at least a very early report – which has opened the door to each development: truly no light undertaking! Nevertheless, after reading this book, one is tempted to think, in periphrasis of a well-known phrase, that "la biochemie de l'hérédité est une science anglo-saxonne" – corresponds to the facts in many but not quite all respects.

Yet the book is to be recommended, in particular to the student seeking an introduction into biochemical genetics.

*H. Grünewald* [NB 450/303 IE]

**Biochemistry of Phenolic Compounds.** Edited by *J. B. Harborne*. Academic Press, London-New York 1964. 1st Edit. X + 618pp., 1 plate, several illustrations, 30 tables, £ 6.6.0d.

A combination of several factors, such as the improvement of physical methods of extraction, the isolation and elucidation of complex organic substances, the revival by *Birch* of *Collie*'s acetate theory, the introduction of labelling with $^{14}C$, and the development of enzymology and microbiology, has led in the past 20 years to an enormous growth of interest in phenolic compounds of natural origin. It is now recognized that the phenols and their derivatives are not insignificant end products of the natural processes, but sometimes play an important part in the animal or plant metabolism. There was therefore a real need for a review of the biochemistry of natural phenols.

The present book contains 14 chapters written by 17 experts of world-wide renown. The subjects discussed include: the structures and reactions of natural phenols (*Thomson*, 29 pp.), methods used for the isolation and identification of phenols from biological material (*Seikel*, 39 pp.), the occurrence of phenolic aglycones (*Harborne* and *Simmonds*, 45 pp.) and glycosides (*Harborne*, 36 pp.), the genetics of phenols (*Alston*, 30 pp.) and their metabolism in animals (*Williams*, 40 pp.) and plants (*Towers* 40 pp.), the biosynthesis of phenolic compounds (*Neish*, 50 pp.) and of lignin and the tannins (*Brown*, 33 pp.), the enzymology (*Conn*, 31 pp.) and physiology (*Siegelmann*, 16 pp.) of the biosynthesis of phenols, the physiology and pharmacology of phenols in animals (*Ramwell*, *Sherratt*, and *Leonard*, 48 pp.) and plants (*Cruikshank* and *Perrin*, 27 pp.), and finally the taste of phenol glycosides in citrus fruits (*Horowitz*, 24 pp.).

The literature up to the end of June 1962 has been taken into account in most cases. More than 2000 references and 2200 names in the index testify to the value of this book as a reference work. Almost 900 structural formulae, some 1150 entries in the subject index, and 950 names in the excellent class index will be very useful in searches for information. The scope of the book is possibly rather narrow. Many purely chemical model experiments in connection with biochemical problems would have merited some mention, and a detailed, separate chapter on phenolic alkaloids would have been welcome. No mention is made of the giberellins.

In its present form, however, the book must be recommended to the phytochemist, the taxonomist, and the plant physiologist, and in short, to all biochemists who are concerned with phenolic natural products. *J. M. Harkin* [NB 445/280 IE]

**The Oligosaccharides.** By *J. Staněk*, *H. Černý*, and *J. Pacák*. Academic Press, New York-London, and Publishing House of The Czechoslovak Academy of Science, Prague 1965. 1st Edit., 567 pp., numerous tables, linen $ 21.–.

"The Monosaccharides" [1] by *Staněk* and his collaborators, published in 1963, has now been followed by the second part of the comprehensive monograph, also in English. As is stated in the preface, this is not merely a translation of the Czechoslovak edition that appeared in 1962, but has been partly rewritten, with incorporation of publications up to the middle of 1964.

All who are interested in oligosaccharides, whether as chemists, biochemists, or biologists, will be glad that the authors have undertaken the tedious task of a general oversight of the oligosaccharide material that has accumulated over the years and have brought order into the myriad of results. The number of references – nearly 4500 – shows how thoroughly they have gone to work.

Division into many short chapters with their own lists of references greatly clarifies the text, and the very numerous formulae are a further help. Comprehensive tabulation of oligosaccharide classes, arranged according to molecular size, type of linkage, and type of derivative, made it possible to keep the text short and precise. Particularly noteworthy are a comprehensive table of oligosaccharides of natural origin and a collection of the oligosaccharides that have been obtained by enzymic degration and synthesis. Chemical syntheses and reactions of oligosaccharides and formation of derivatives of this class of compound are treated exhaustively, as are oligosaccharides with a basic or acidic function and even such a recondite class of compounds as the glycosylinositols. Moreover, several chapters are devoted to chromatographic and electrophoretic methods of analysis and separation.

However, the section on enzymatic synthesis could have been rather more detailed, for the benefit of the reader particularly interested in this field. The kinetics of interaction of enzymes and oligosaccharides are not mentioned, and it is only the kinetic study of these complex reactions that throws light on the simultaneous synthesis, hydrolysis, and resynthesis of the various combinations of reactants. Further, the titles "Transglycosylation of maltose, isomaltose, lactose, etc." are unhappily chosen; it would have been better to collect these sections under the titles "Transglucosylation, transgalactosylation, etc." The sections on the use of physical methods such as X-ray analysis and infrared spectroscopy for structure determination of oligosaccharides are also rather too short. However, these matters and a few erroneous references can be corrected in a new edition which will certainly be necessary within a few years.

Finally it can be stated that this book will be a welcome help to chemists and biologists. Together with "The Monosaccharides" it can be included among the most valuable reference works for carbohydrate chemistry.

**Advances in Physical Organic Chemistry.** Vol. 2. Edited by *V. Gold*. Academic Press. London-New York 1964. 1st Edit., xii + 288 pp., numerous illustr., £ 3.3.– (ca. $ 8.80).

The second volume of this series contains four sections: 1. *C. J. Collins*, Isotopes and Organic Reaction Mechanisms (84 pp.), 2. *W. E. Whalley*, Use of Volumes of Activation for Determining Isotope Reaction Mechanisms (65 pp.), 3. *H. Zollinger*, Hydrogen Isotope Effects in Aromatic Substitution (33 pp. , 4. *A. P. Wolf*, The Reaction of Energetic Tritium and Carbon Atoms with Organic Compounds (87 pp.). The first contribution describes in particular the less usual applications of isotopes, *e.g.* the use of compounds with two or more labels, the combination of isotope and kinetic experiments, and of isotope and stereochemical experiments. Fi-

[1] Cf. Angew. Chem. 77, 687 (1965); Angew. Chem. internat. Edit. 4, 723 (1965).

nally, kinetic isotope effects are discussed very critically, mainly from the experimental standpoint.

In the second contribution the experimental methods and theory are discussed in relation to a few types of reaction, and then the potentialities of the method are outlined. However, in this report little attention is paid to knowledge of reaction mechanism that was derived by other methods and recorded in the most recent literature. In the third section a narrower complex of questions is treated, in this case exhaustively. In the fourth contribution *A. P. Wolf* aimed at writing less a review article than a (most successful) introduction to a field that is highly interesting from a mechanistic point of view and in which few "experts" have hitherto worked.

The editor has been particularly successful in obtaining as contributors men who are leaders in their fields. They have been equal to the demands made on them.

*H. Simon* [NB 454/307 IE]

**A New German/English Dictionary for Chemists.** By *H. H. Neville, N. C. Johnston,* and *G. V. Boyd.* Blackie & Son Ltd., London-Glasgow 1964. 1st Edit., xviii + 330 pp., £ 2.15.0 (about $ 10.–).

**Elsevier's Dictionary of Industrial Chemistry in Six Languages:** English,American/French/Spanish/Italian/Dutch/German. Compiled and arranged by *A. F. Dorian.* Vol. 1: A–O and Vol. 2: P–Z. Elsevier Publishing Comp., Amsterdam-London-New York 1964. 1st Edit., 1220 pp., DM 130.– (about $ 33.–).

The first of the two works to be reviewed here is intended as a German-English dictionary for chemists "with little knowledge of German". It is adapted wholly to the needs of a user to whom English is the mother tongue or almost as familiar. Thus, for instance, the various English equivalents of the same German word are not differentiated; since such differences are known to an Anglo-Saxon that is justified in the authors' view, but it will be regarded as a serious deficiency by the user who does not come from an English-speaking country. Occasionally one gets the impression that the authors themselves have only "little knowledge of German", as, for in stance, when the first three of the four translations given for "abfüllen" – "to empty, to draw off, to decant, to bottle" do not correspond to the German word at all, but rather to ausgießen, abziehen, and abgießen, respectively; or when "Nachlaß" is ascribed the translations relaxation, remission, diminution, reduction", of which the first three mean Nachlassen. Apart from this, the choice of the about 20000 German entries can be considered successful.

The last remark can unfortunately not be applied to the six-language "Dictionary of Industrial Chemistry". Many-language dictionaries have their own problems and are so seldom satisfactory that it is difficult to understand why such lexicons continue to appear. In the present case the difficulties begin with the fact that a two-volume work of 1220 pages contains only 8426 entries. It cannot be considered that the vocabulary of "industrial chemistry" is even approximately exhausted thereby. Necessarily the choice has remained arbitrary. One might wish to know what an opacifier, a dialyser, or a centrifual pump is in one of the six languages, but must then turn to some other dictionary. The reviewer does not find that "enjoyable" (to use a word from the Preface). Some compensation for the small number of entries is provided by short explanations given with each entry. In this way the two volumes acquire the character of a reference work as well as that of a dictionary. *H. Grünewald* [NB 449/302 IE]

**Nobel Lectures, Physiology or Medicine** 1922–1941. Elsevier Publish. Comp., Amsterdam 1965. 1st Edit., xii + 548 pp., Dutch fl. 240.– (ca. $ 66.–) (3 vol.).

This middle volume[1] of the collection of Nobel lectures on physiological or medical subjects contains much that has already become history or a firm ingredient of our textbooks. Precisely that lends it a particular interest, because the laudations and the lectures of the prize winners lead us back to the early days, to the time when, for instance, the effect of insulin therapy on diabetes mellitus was not self-evident (the prize for the discovery of insulin was awarded to *Banting* and *Macleod* in 1923), or to a time when we did not know that typhus was carried from the sick to the healthy by lice and so were delivered helpless to an epidemic. It was in 1928 that the Frenchman *Charles Nicolle* received the Nobel prize for tracking down the route of typhus infection in Tunisian hospitals and prisons. In his Nobel lecture he said: "If in 1914 we had been unaware of the mode of transmission of typhus, and if infected lice had been imported into Europe, the war would not have ended by a bloody victory but in an unparalleled catastrophe, the most terrible in human history."

The history of science during the first half of the twentieth century is to be found in a nitshell among the Nobel lectures of this period; and it were hardly possible to relive this development more directly than by reading the lectures collected in this book. The volume is therefore most warmly recommended to all scientists (not only to physiologists or doctors), and particularly to the younger among us.

*H. Grünewald* [NB 448/301 IE]

[1] Review of 3rd volume: Angew. Chem. *77*, 632 (1965); Angew. Chem. internat. Edit. *4*, 617 (1965).

**Rodd's Chemistry of Carbon Compounds.** Edited by *S. Coffey.* Vol. I, Part A: General Introduction, Hydrocarbons, Halogen Derivatives. Elsevier Publishing Comp., Amsterdam-London-New York 1964. 2nd Edit., xix + 569 pp., numerous figs. and tables. Volume price Dutch fl. 80.– (about £ 8.0.0).

The first edition of this new version of Richter's "Chemie der Kohlenstoffverbindungen" established itself during the last decade as a valuable source for rapid, preliminary literature searches.

Now, only two years after appearance of the last volume of that work, we have the first three parts of the second edition. The new edition of this encyclopaedic work – itself a valiant effort in view of the rapid development of organic chemistry – is considerably larger than the first. Volume I, previously in two parts, is now issued in seven single volumes. It is questionable whether such a systematic treatment of organic chemistry, whose compilation necessarily takes several years, can in the future compete with the numerous up-to-date monographs and reviews.

The arrangement of subject matter in the new edition does not differ materially from that in the old. The present Part I, A (19 authors) is again divided into general and special chapters. Twelve short sections, some completely rewritten, include: theoretical organic chemistry (acid-base theory, *H. D. Springall*; stereochemistry, *I. G. M. Campbell*; reaction mechanism, *D. V. Banthorpe*; free radicals and homolytic reactions, *D. H. Hey* and *W. A. Waters*; wave mechanics, *W. Byers-Brown*) and methods (quantitative analysis, *R. Belcher*; physical properties, *H. D. Springall*; crystallography, *A. F. Wells*; spectroscopy, *I. E. Page*; labeled compounds, *H. R. V. Arnstein*). Although the literature is covered up to 1960 (partly up to 1963) the coverage of these important fields in barely 350 pages is unsatisfactory and gives only superficial informations; this applies especially to photochemistry (1 page), and ESR ($1^1/_2$ pages), NMR (2 pages), and mass spectrometry ($^1/_2$ page).

In the three following special chapters syntheses, properties, and reactions of the alkanes, alkenes, alkynes, and their halogen derivatives are handled briefly and clearly. Numerous references (up to 1962) and some short mechanistic indications make this part of the volume a welcome reference book which, if one is not looking for the completeness of Beilstein, will provide information rapidly on the most important new results in organic chemistry.

It is to be hoped that the individual volumes of the second edition will appear in rapid succession, for the "New Rodd" will doubtless be a valuable and much used reference work in every library. *K. Hafner* [NB 470a/323 IE]

**Rodd's Chemistry of Carbon Compounds,** Edited by *S. Coffey* Vol. I, Part B: Monohydric Alcohols, their Ethers and Esters, Sulphur Analogues, Nitrogen Derivatives, Organometallic Compounds. xvi + 313 pp., numerous figs. and tables. DM 56.– (about $ 11.–); Part C: Monocarbonyl Derivatives of Aliphatic Hydrocarbons, Analogues and Derivatives. xvi + 432 pp., numerous figs. and tables, DM 83.50 (about $ 20.50). Elsevier Publishing Comp., Amsterdam 1965, 2nd Edit.

The two most recent Parts B and C of Volume I concern simple functional derivatives of aliphatic hydrocarbons. Almost all the chapters contrast with those in the first edition in the fullness of information provided.

Part I, B comprises monohydric alcohols, their ethers and their esters with mineral acids, aliphatic sulfur and nitrogen compounds, and aliphatic organometallic compounds including transition-metal complexes of alkenes and alkynes. There are four sections giving clear accounts of their respective classes, but confined to synthesis, reactions and properties; the authors are *I. G. Buchanon, N. A. Hughes, G. A. Swan, H. Goldwhite, C. B. Milue,* and *A. N. Wright.*

Special attention should be paid to the much enlarged description (110 pp.; 40 pp. in the first edition) of organometallic compounds, whose importance has increased so greatly in recent decades. It is preceded by a short introduction into the theory of the metal-carbon bond. However, the detailed description of individual compounds often contains no reference to their preparative values (tertiary phosphines, ylides, Wittig reaction; olefin-nickel complexes, cyclooligomerization of dienes; *etc.*).

Part I, C concerns aliphatic monocarbonyl compounds (aldehydes and ketones) and their derivatives and oxidation products (carboxylic acids). The chapters on monocarboxylic acids and carbonic acid (174 pp. in the first edition) have been subdivided by the new authors (*M. F. Ansell, R. H. Gigg,* and *R. Howe*) into three large sections (300 pp.): monocarboxylic acids and their derivatives; carbon monoxide (metal carbonyls) isocyanides, and fulminic acid; carbonic acid derivatives. Although as in other chapters of these Parts there has been no attempt a theoretical explanation of the reactions, the clear presentation of the individual classes of compound will be of value to all those studying this field, even if, occasionally, important recent results (particularly those in the German literature) are not mentioned (*e.g.* reactions of isocyanides; acid amide acetals).

Both these Parts contain carefully compiled subject indexes and numerous references to original papers, reviews, and collected works (*e.g.* Houben-Weyl), the literature being partly covered up to 1963; they will be an essential reference book for every organic-chemical laboratory. *K. Hafner* [NB 470b/324 IE]

**Rubidium and Caesium.** By *F. M. Perelman.* Vol. 2 of the International Series of Monographs on Nuclear Energy, Division VIII, Materials. Pergamon Press 1965. 1st Engl. Edit., 144 pp., 17 illustr., 41 tables, linen, £3.–.– (*ca.* $ 7.40).

Since the appearance of the first (Russian) edition (1941) of *Perelman*'s monograph, caesium (besides other applications) has achieved greater technical importance in connection with the direct conversion of energy (heat/electricity). Further uses appear possible also in connection with propulsion in space by ion-beam engines. The 2nd edition, presented in English, has been reworked throughout; the additions needed have doubled the size.

Five sections treat the discovery and occurrence of rubidium and caesium (7 pp.), the properties of the two metals and their compounds (49 pp.), aqueous and non-aqueous systems (15 pp.), their analytical chemistry (27 pp.), the production of concentrates of the two elements from their ores (15 pp.), and finally their preparation in metallic form (15 pp.). Collections of data in tables and graphic presentations assist a survey of the material although, particularly in the section on "Properties", many numerical data remain scattered through the text and are thus not easily recoverable.

The book will provide welcome help to those who want a rapid introduction to rubidium and caesium or need to find the original papers concerning detail that specially interests them. 346 References are given to the literature up to 1949. 105 Further references for the period 1960–1964 are arranged according to subjects. The book contains few misprints, and the translation has introduced some incertainties.

*F. Endter* [NB 458/311 IE]

**Optical Rotatory Dispersion and Circular Dichroism in Organic Chemistry.** By *P. Crabbé.* Holden-Day, San Francisco-London-Amsterdam 1965. 1st Edit., xv + 378 pp., numerous figs. and tables, $ 12.95.

Although they were known already in the previous century, it is only recently that the two complementary methods of optical rotatory dispersion (ORD) and circular dichroism (CD) have found their way into the laboratories of organic chemists and biochemists. Whereas *Djerassi*'s classical book (1960) was based mainly on measurements by a single school, some 1000 publications have appeared in the meantime, and from many laboratories. A general review and introduction into this field was thus an urgent necessity, and *Crabbé* has provided this in a didactically excellent manner. Although the author has not attempted comprehensive coverage of the literature, all the important work published up to the end of 1964 is cited; and more than that, for many papers are included that were available only as manuscripts when the book went to the press. This monograph then like all the volumes in the Holden-Day series "Physical Techniques in Chemistry", is completely up to date.

A short introduction into theory and nomenclature, and a brief explanation of the principles involved in the measurements, are followed by a general review of the range of application of ORD and CD and their relative advantages and disadvantages. Next the chromophoric systems in compounds of low molecular weight are discussed, ketones naturally requiring most space here. A short review of the applications to polypeptides, proteins, and nucleic acids closes the descriptive section. An appendix contains a computer program for calculation of rotational strengths and thermodynamic data from low-temperature measurements of CD, and there is a bibliography which includes also papers that could not be discussed in detail in the special sections.

The text is made more readily intelligible by many carefully prepared diagrams, and the formulae are supplemented by stereoprojections where necessary. Misprints are very rare. The wealth of material presented and, above all, the skill with which it is presented, make "Crabbé" equally valuable for beginners and experts. This monograph is indispensible for all concerned with the use of ORD or CD in organic chemistry, and the author and publisher are to be congratulated on this outstanding aschievement.

# New Methods in Preparative Organic Chemistry VI[*]

## Ring Closures with Carbon Monoxide

BY DR. J. FALBE

SHELL GRUNDLAGENFORSCHUNG-GESELLSCHAFT M.B.H.,
SCHLOSS BIRLINGHOVEN, SIEGKREIS (GERMANY)

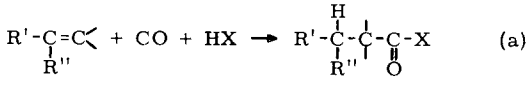
*Carbon monoxide undergoes catalytic reactions with unsaturated compounds to give heterocyclic carbonyl compounds. This cyclization has led to new syntheses of imides, lactams, lactones, phthalimidines, indazolones, and tetrahydroquinazolines.*

### A. Introduction

Around the middle of the 1920's, carbon monoxide started to become an important reactant for organic syntheses. It was used in the Fischer-Tropsch synthesis [1] for the production of synthetic gasoline and later for the synthesis of methanol with hydrogen [2,3], for *Roelen*'s oxo synthesis [4], and for Reppe syntheses [5]. These uses were followed by *Koch*'s carboxylic acid synthesis [6], which is being used to an increasing extent in industry.

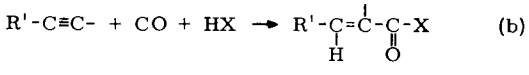
With a few exceptions, the reactions of carbon monoxide with organic compounds can be classified as three-component reactions and two-component insertion reactions.

The three-component reactions are those with unsaturated hydrocarbons and compounds containing reactive hydrogen atoms to form carbonyl compounds as indicated by Equations (a) and (b).



(a)

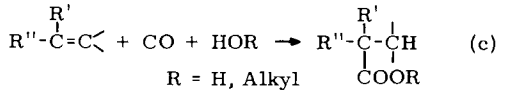
X = $OR^{[7]}$, $NHR^{[8]}$, $SR^{[9]}$, $H^{[4]}$



(b)

X = $OR^{[10]}$, $NHR^{[10]}$, $SR^{[10]}$

When this reaction is catalysed by transition-metal carbonyls, the carbon monoxide preferentially adds to the end of the carbon chain. If, on the other hand, olefins [6] or reactive cycloaliphatic compounds [11] are treated under mild conditions (room temperature and pressures below 100 atm) with carbon monoxide and water or alcohols in the presence of inorganic acids such as sulfuric acid, phosphoric acid, or $H_3PO_4/BF_3$, the reaction leads exclusively to secondary or tertiary carboxylic acids or their esters [see Equation (c)].



(c)

R = H, Alkyl

In two-component reactions [Equations (d) to (f)], a molecule of carbon monoxide is inserted into an existing bond.

[*] The papers in the preceding series have been published in three volumes by Verlag Chemie, Weinheim/Bergstr.; English edition: Academic Press, New York-London. Volumes IV and V are in preparation.

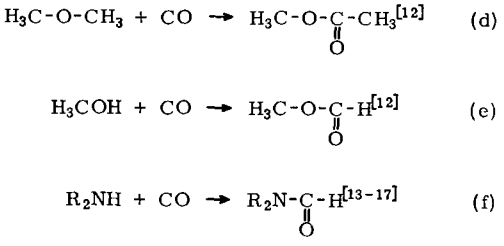
The mechanisms of both types of reactions have been studied in detail by numerous research groups. The reader is referred to a number of publications, which have also been of great assistance in the interpretation of the ring closures described below[18–29].



(d)

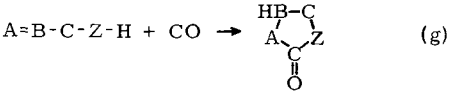
(e)

(f)

## B. General Remarks on Ring Closure with Carbon Monoxide

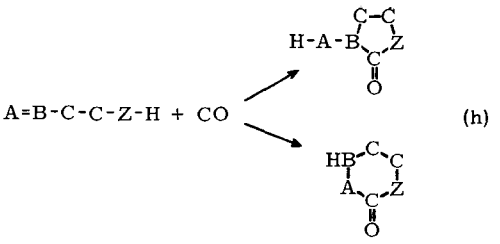
The present review deals with a third type of reaction of carbon monoxide, *viz.* two-component reactions leading to ring closure.

Unsaturated compounds containing a reactive hydrogen atom in a position that favors ring closure react with carbon monoxide in the presence of catalysts to give cyclic carbonyl compounds. If the starting compound is a four-atom chain, the product is a five-membered ring, as illustrated in Equation (g). If the chain in the starting



(g)

compound is five or more atoms long, six-membered rings may be formed as well as five-membered rings [see Scheme (h)].



(h)

For example, carbon monoxide reacts with unsaturated amides to give imides [30–33], with unsaturated amines [34] to give lactams [35], with unsaturated alcohols to give lactones [36], with Schiff bases [24, 37, 38], aromatic ketoximes [39], phenylhydrazones [28, 40], semicarbazones [41], azines [41], and nitriles [42] to give phthalimidines, and with azobenzenes [24, 43, 44] to give indazolones or 2,4-dioxo-1,2,3,4-tetrahydroquinazolines.

These reactions proceed at 170 to 280 °C under pressure (100 to 300 atm). The best catalysts are cobalt carbonyls [33, 35, 36, 38]; rhodium [36, 44] and iron carbonyls [38] also are active; however, nickel carbonyls [33, 38], which are active in Reppe syntheses, are inactive in this case. Some of the reactions can also be carried out with stoichiometric quantities of cobalt or rhodium carbonyls at normal pressure in the absence of free carbon monoxide [45]. Suitable solvents include benzene, toluene and inert hydrocarbons [36, 38]; tetrahydrofuran or dioxane may be used where the starting materials or the products are highly polar.

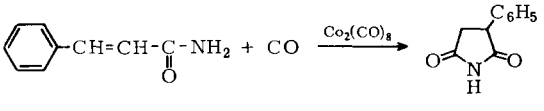
| *(i)* | 2,6-Dichloro-phenyl | *N*-(2,6-Dichlorophenyl)-succinimide | 44 | [33] |
| *(j)* | Benzyl | *N*-Benzylsuccinimide | 92 | [33] |
| *(k)* | Allyl | *N*-Allylsuccinimide | 55 | [35] |

substituted succinimides *(4)* (see Table 1). When the starting materials contain halogenated aromatic groups, no dehalogenation takes place. Similarly, methacrylamides and *N*-substituted methacrylamides *(5)* give α-methylsuccinimides *(6)* (see Table 2).

Table 2. Reaction of methacrylamide and *N*-substituted methacrylamides *(5)* with carbon monoxide in the presence of $Co_2(CO)_8$ [33].

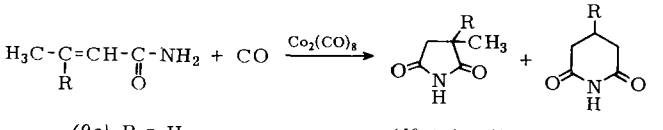
| *N*-Substituent in *(5)* | | Reaction product *(6)* | Yield [%] |
|---|---|---|---|
| *(a)* | H | α-Methylsuccinimide | 68 |
| *(b)* | Methyl | *N*-Methyl-α-methylsuccinimide | 70 |
| *(c)* | n-Butyl | *N*-n-Butyl-α-methylsuccinimide | 74 |
| *(d)* | Benzyl | *N*-Benzyl-α-methylsuccinimide | 76 |

β-Arylated acrylamides also react to give α-substituted succinimides. Thus α-phenylsuccinimide *(8)* is obtained from cinnamamide *(7)*.



*(7)* *(8)*

The reaction of β-alkylacrylamides leads not only to α-alkylsuccinimides, but also to glutarimides. For example, crotonamide *(9a)* reacts to form a mixture of α-methylsuccinimide *(10a)* and glutarimide *(11a)*, and β,β-dimethylacrylamide *(9b)* gives only β-methylglutarimide *(11b)*.

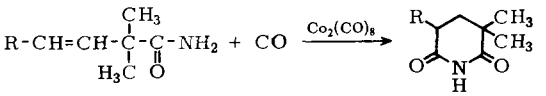


*(9a)*, R = H *(10a)*, (68%) *(11a)*, (19%)
*(9b)*, R = $CH_3$ *(11b)*, (67%)

The six-membered rings are formed by isomerization of intermediate complexes of olefinic starting material and the catalyst. Similar isomerizations were observed in other reactions with carbon monoxide in the presence of transition metal carbonyls [25,46–57] (see Section D).

The exclusive formation of the six-membered cyclic imide from β,β-dimethylacrylamide has a parallel in the oxo synthesis. *Keulemans* reported that no quaternary carbon atoms are formed during hydroformylations in the presence of cobalt catalysts [58]. Thus the hydroformylation of isobutene gives almost exclusively isopentanol, with only small quantities of neopentanol [59]; 2,6-dimethyl-5,6-dihydro-4*H*-pyran gives only 3-formyl products, whereas 5,6-dihydro-4*H*-pyran gives mainly 2-formyl products [60].

β,γ-Unsaturated amides such as *(12)* also react in accordance with the above scheme to give glutarimides *(13)*. Unsaturated alicyclic amides *(14)* and *(16)* yield



*(12a)*, R = H *(13a)*, (58%)
*(12b)*, R = $CH_3$ *(13b)*, (64%)

five-membered *(15)* or six-membered *(17)* bicyclic imides, depending on the position of the double bond. As expected, unsaturated *N*,*N*-dialkylamides and aromatic amides, such as benzamide, do not react in accordance with this scheme.

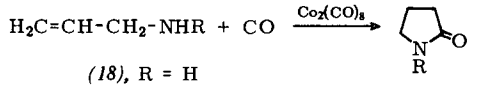
## 2. Lactams from Unsaturated Amines [35]

Allylamine *(18)* reacts with carbon monoxide to give 2-pyrrolidone [*(20)*, R = H]. The *N*-alkylallylamines



*(18)*, R = H
*(19)*, R ≠ H *(20)*

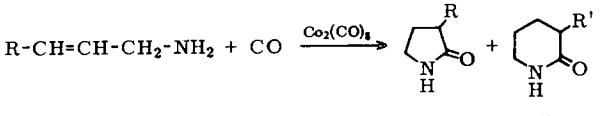
*(19)* [34], which are readily accessible from allyl chloride and primary amines or from allylamine and alkyl chlorides, react to form *N*-alkyl-2-pyrrolidones *(20)* (R ≠ H).

Table 3. Reactions of *N*-monosubstituted allylamines *(19)* with carbon monoxide in the presence of $Co_2(CO)_8$.

| | Substituent R in *(19)* | Reaction product *(20)* | Yield [%] | Ref. |
|---|---|---|---|---|
| *(a)* | Methyl | *N*-Methylpyrrolid-2-one | 78 | [35] |
| *(b)* | Ethyl | *N*-Ethylpyrrolid-2-one | 61 | [35] |
| *(c)* | Isobutyl | *N*-Isobutylpyrrolid-2-one | 61 | [35] |
| *(d)* | Octyl | *N*-Octylpyrrolid-2-one | 58 | [35] |
| *(e)* | Dodecyl | *N*-Dodecylpyrrolid-2-one | 47 | [35] |
| *(f)* | Phenyl | *N*-Phenylpyrrolid-2-one | 26 | [30] |

The carbonylation of diallylamine $HN(CH_2-CH=CH_2)_2$ leads to a mixture of *N*-allyl-2-pyrrolidone, *N*-propenyl-2-pyrrolidone, and 2-pyrrolidone. The principal product may be any one of the three lactams, depending on the reaction conditions. The migration of the double bond again is probably due to isomerization promoted by the metal carbonyl catalysts. The formation of 2-pyrrolidone, which becomes appreciable only at high temperatures, is accompanied by formation of propene. Under these conditions, the C–N bond evidently undergoes hydrogenolytic cleavage with hydrogen transfer.

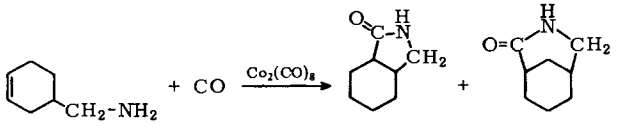
Carbonylation of *N*-alkylated β-methylallylamines yields 1-alkyl-4-methyl-2-pyrrolidones. γ-Alkylallylamines*(21)* give mixtures of 3-alkyl-2-pyrrolidones *(22)* and 2-piperidones *(23)*. As in the synthesis of imides, the



*(21)*, R = $CH_2R'$ *(22)* *(23)*

formation of six-membered lactam rings is attributed to the isomerization of intermediate complexes of the catalyst and the starting material.

Isomerizations also occur during the carbonylation of unsaturated alicyclic amines; for example, the carbonylation of (3-cyclohexenylmethyl)amine *(24)* leads to the bicyclic lactams *(25)* and *(26)*.

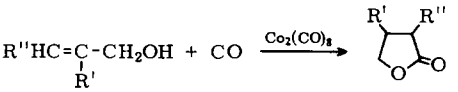


*(24)* *(25)* *(26)*

*N*-Alkenylformamides are formed only in small quantities in all the above reactions.

## 3. Lactones from Unsaturated Alcohols

Lactones *(28)* can be obtained by the reaction of primary unsaturated alcohols *(27)* with carbon monoxide. However, this is often accompanied by an un-

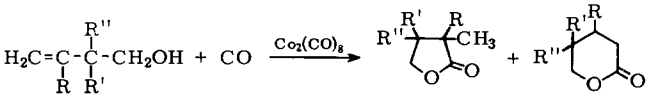


*(27a)*, R' = R'' = H *(28)*
*(27b)*, R' = $CH_3$, R'' = H
*(27c)*, R' = H, R'' = $CH_3$

desirable side-reaction (i), namely the carbonyl-catalysed isomerization of the unsaturated alcohols to saturated aldehydes. Thus allyl alcohol *(27a)*, β-methallyl alcohol *(27b)*, and crotyl alcohol *(27c)* give only about 2% of the γ-lactones, while about 50% of the starting compounds isomerize to the aldehydes. These undergo further reactions such as the aldol condensation or the Tischtschenko reaction, or polymerize at higher temperatures.

$$H_2C=CH-CH_2OH \rightarrow [CH_3-CH=CHOH] \rightarrow CH_3-CH_2-CHO \quad (i)$$

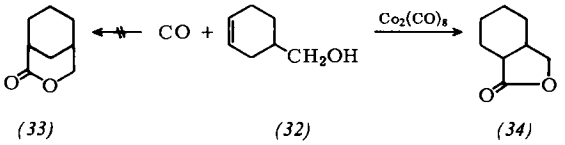
Higher yields of the lactones are obtained from unsaturated alcohols *(29)* that cannot undergo isomerizations of this type owing to the presence of substituents in position 2. As in the carbonylation of unsaturated



| | | |
|---|---|---|
| *(29a)*, R = H, R' = R'' = $CH_3$ | *(30a)*, (51%) | *(31a)*, (14%) |
| *(29b)*, R = R' = R'' = $CH_3$ | *(30b)*, (3%) | *(31b)*, (25%) |
| *(29c)*, R = H, R' = $CH_3$, R'' = $C_2H_5$ | *(30c)*, (40%) | *(31c)*, (13%) |

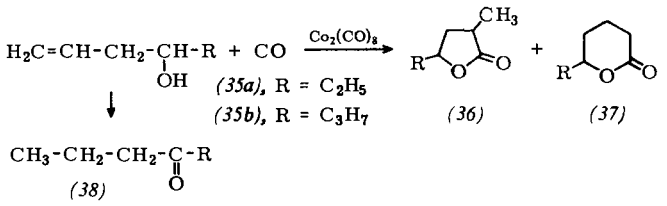
amines, formation of the six-membered ring is favored by an alkyl substituent in position 3.

Unsaturated alicyclic alcohols also give lactones. The reaction of 3-cyclohexenylmethanol *(32)* leads not to the expected bicyclic δ-lactone *(33)* but to the isomeric bicyclic γ-lactone *(34)*, probably again by isomerization of an intermediate cobalt complex.



*(33)* *(32)* *(34)*

γ-Unsaturated secondary alcohols *(35)* also form lactones *(36)* and *(37)*, but only in small yields, since the main reaction is isomerization to the ketones *(38)*.

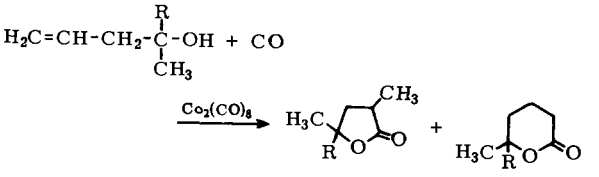


*(35a)*, R = $C_2H_5$
*(35b)*, R = $C_3H_7$

*(36)* *(37)*

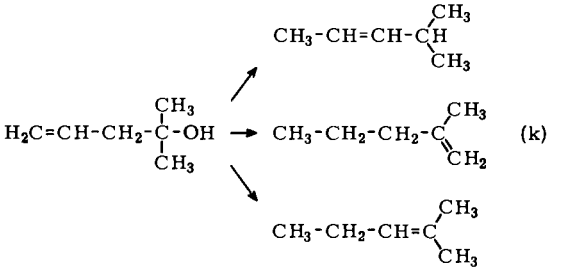
*(38)*

Since γ-unsaturated tertiary alcohols *(39)* cannot isomerize to carbonyl compounds, they generally give better yields of lactones.



| | | |
|---|---|---|
| *(39a)*, R = $CH_3$ | (10%) | (2%) |
| *(39b)*, R = $C_2H_5$ | (29%) | (6%) |
| *(39c)*, R = i-$C_4H_9$ | (10%) | (2%) |

The carbonylation of γ-unsaturated tertiary alcohols is accompanied by another side-reaction (k) leading to the formation of large quantities of mono-olefin. This can be

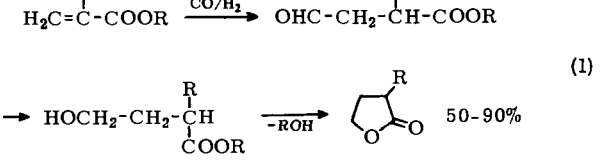


(k)

explained by elimination of water from the γ-unsaturated tertiary alcohols and hydrogenation of the resulting dienes by hydrogen transfer. The nature of the oxidation products formed in the hydrogen transfer has not been established. A related reaction was described by *Nicholson* and *Shaw*[61], who obtained propene when an aqueous solution of allyl alcohol was heated in the presence of catalytic amounts of $RuCl_3$. In this case the hydrogen was obtained by oxidation of allyl alcohol to acrolein.

[61] *J. K. Nicholson* and *B. L. Shaw*, Proc. chem. Soc. (London) *1963*, 282.

Many of the lactones that are difficult to obtain by the method described here can be prepared in good yields by a single-stage reaction (l) from esters of unsaturated carboxylic acids, carbon monoxide, and hydrogen[62,63].

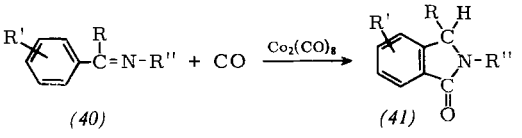


(l)

### 4. Phthalimidines from Schiff Bases[24,37,38] or Aromatic Nitriles[42]

The ring-closure reaction is not confined to compounds containing a C=C double bond, and the atom represented by Z in Equations (g) and (h) need not be a heteroatom.For example,Schiff bases,in which the unsaturated bond is a C=N double bond and Z is a carbon atom, react with carbon monoxide to give high yields of phthalimidines.

*N*-Benzylidenaniline *(40a)* gives 2-phenylphthalimidine *(41a)* in 84% yield. *N*-Benzylidenanilines with *o,p*-directing substituents also undergo this reaction. If, on the other hand, the starting compound contains a nitro group, the reaction fails. It appears that the nitro group is reduced, and the product then undergoes further reactions. Lower yields are obtained if the aromatic ring of the benzylidene group in *N*-benzylidenaniline carries an *o,p*-directing substituent such as a hydroxy or methoxy group in the *o*-position [see (n) in Table 4]. Schiff bases *(42)* of aliphatic amines also give phthalimidines, such as *(41q)* and *(41r)*.



*(40)* *(41)*

Table 4. Phthalimidines *(41)* obtained from Schiff bases *(40)* and carbon monoxide in the presence of $Co_2(CO)_8$.

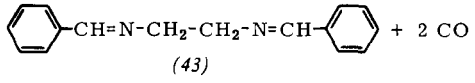
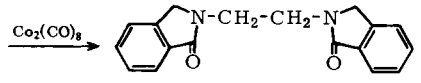
*(42q)*, R = $CH_3$ *(41q)*, (79%)
*(42r)*, R = $CH_2$-$C_6H_5$ *(41r)*, (82%)

Compounds containing two phthalimidine groups can also be prepared in this way; thus *N,N'*-dibenzylidenethylenediamine *(43)* gives *N,N'*-ethylenediphthalimidine *(44)*.

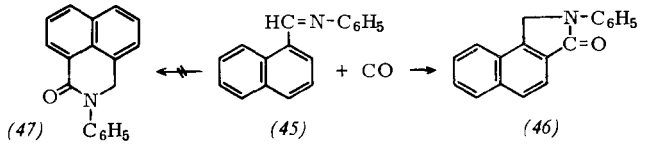


*(43)*



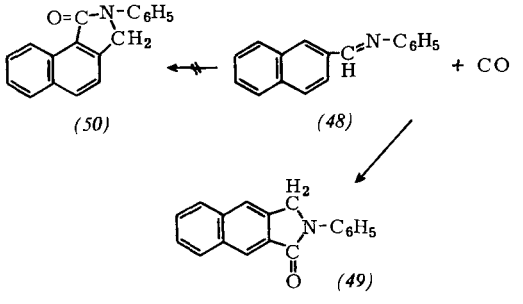
*(44)*, (49%)

Schiff bases from naphthaldehydes react in a similar manner. The reaction of 1-naphthaldehyde anil *(45)* leads to *N*-phenylbenzo[*e*]phthalimidine *(46)*; compound *(47)* was not observed among the products.



*(47)* *(45)* *(46)*

2-Naphthaldehyde anil *(48)* gives, not *N*-phenylbenzo[*g*]phthalimidine *(50)*, but only *N*-phenylbenzo[*f*]phthalimidine *(49)*. On the basis of the charge distribution, cyclization would be expected in position 1.



*(50)* *(48)* *(49)*

However, Stuart-Briegleb molecular models show that ring closure in this position is subject to strong steric hindrance, whereas ring closure in position 3 is unhindered.

The synthesis of *N*-benzylphthalimidine *(51)* by reaction of benzonitrile with carbon monoxide or synthesis gas in the presence of cobalt carbonyls may be regarded as a special case of the reaction with Schiff bases. It is known that nitriles can give Schiff bases as intermediates on hydrogenation [65]. From the products obtained in the carbonylation of nitriles, and from the fact that higher yields are obtained with synthesis gas than with pure carbon monoxide [29], as well as from the observation that the best yields are obtained when 1 mole of benzylamine is added per mole of benzonitrile [29], it is very probable that the formation of the phthalimidine in this case again proceeds *via* the Schiff base.

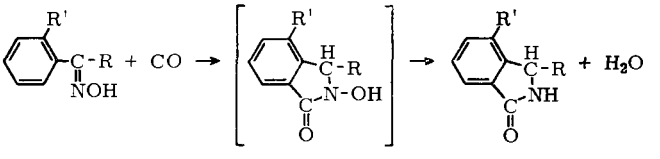
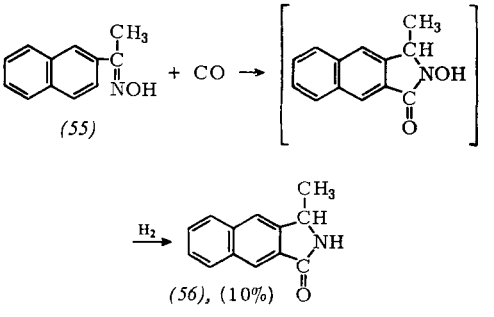
### 5. Phthalimidines from Aromatic Ketoximes [39], Phenylhydrazones [28,40], Semicarbazones [41], and Azines [41]

Aromatic ketoximes such as *(52)* react with a $CO/H_2$ mixture (98.5:1.5) to give phthalimidines. The initial products are probably *N*-hydroxyphthalimidines *(53)*, which are then hydrogenated to phthalimidines *(54)*. Reactions with alkyl aryl ketoximes such as *(52c)* and *(52d)* are less selective than reactions with diaryl



*(52a)*, R = $C_6H_5$, R' = H *(53)* *(54a)*, R = $C_6H_5$, R' = H, (80%)
*(52b)*, R = $C_6H_5$, R' = COOH *(54b)*, R = $C_6H_5$, R' = H, (86%)
*(52c)*, R = $CH_3$, R' = H *(54c)*, R = $CH_3$, R' = H
*(52d)*, R = $CH_2$-$C_6H_5$, R' = H *(54d)*, R = $CH_2$-$C_6H_5$, R' = H

ketoximes. Thus methyl 2-naphthyl ketoxime *(55)* gives the phthalimidine *(56)*, together with other products.



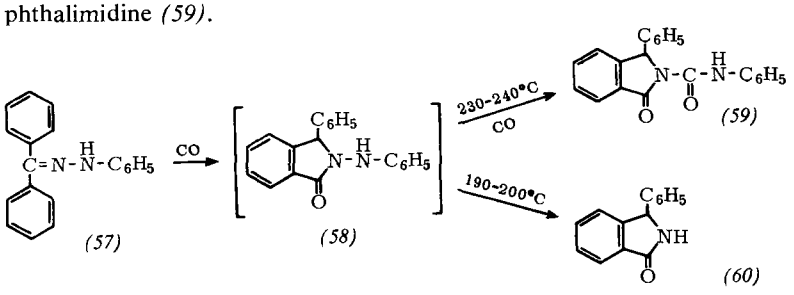
*(55)*

*(56)*, (10%)

As in the case of 2-naphthaldehyde anil, ring closure again takes place in position 3 because of steric hindrance. Attempts to prepare the *N*-hydroxy- or *N*-methoxy-methylphthalimidines were unsuccessful [39]; the products in every case were simply phthalimidines. The N–O bond appears to be very susceptible to hydrogenolysis by the hydrogen present (ratio CO:$H_2$ = 98.5:1.5).

Phenylhydrazones of aromatic ketones (see Table 5) also undergo ring closure with carbon monoxide [28,40]; however, the expected *N*-phenylaminophthalimidines, *e.g. (58)* from *(57)*, cannot be isolated. As in the

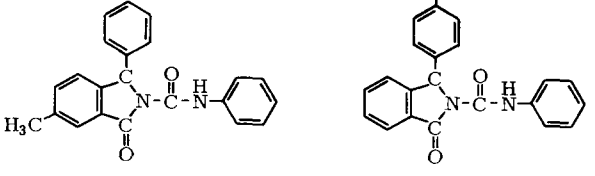
experiments with aromatic oximes, the N–N bond suffers hydrogenolysis at 190 to 200 °C. At higher temperatures, the hydrogenolysis gives way to the insertion of carbon monoxide into the N–N bond, leading to formation of *N*-(*N'*-phenylcarbamoyl)-phthalimidine *(59)*.



*(57)* *(58)* *(59)* *(60)*

Table 5. Carbonylation of phenylhydrazones of aromatic ketones in the presence of $Co_2(CO)_8$ [40].

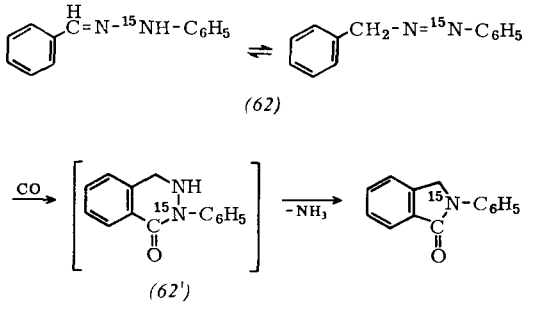
| Ketone | Reaction product | T [°C] | Yield [%] |
|---|---|---|---|
| Benzophenone | 3-Phenylphthalimidine *(60)* | 190–200 | 20 |
| Benzophenone | 3-Phenyl-(*N'*-phenylcarbamoyl)-phthalimidine | 210–220 | 12 |
| | 3-Phenylphthalimidine | | 50 |
| Benzophenone | 3-Phenyl-(*N'*-phenylcarbamoyl)-phthalimidine | 230–240 | 70 |
| 4-Methyl-benzophenone | *N'*-phenylcarbamoyl-3-(*p*-tolyl)phthalimidine *(61')* | 230 | 20 |
| | 6-Methyl-3-phenyl-(*N'*-phenyl-carbamoyl)phthalimidine *(61)* | | 20 |
| Acetophenone | 3-Methyl-(*N'*-phenylcarbamoyl)-phthalimidine | 230 | |
| | 3-Methyl-*N*-phenyl-phthalimidine | | |



*(61)*, (20%) *(61')*, (20%)

4-Methylbenzophenone phenylhydrazone gives two isomeric reaction products *(61)* and *(61')* [28]. Thus ring closure does not take place exclusively on the substituted ring, as in the case with Schiff bases and with the azo compounds described below, but proceeds to an equal extent on the unsubstituted ring.

Phenylhydrazones of aromatic aldehydes also give phthalimidines (cf. Table 6) [28,40]. With the use of compounds labelled with $^{15}N$ [*e.g. (62)*] it was shown that the nitrogen originally attached directly to the phenyl group of the phenylhydrazone is retained in the indazolone.



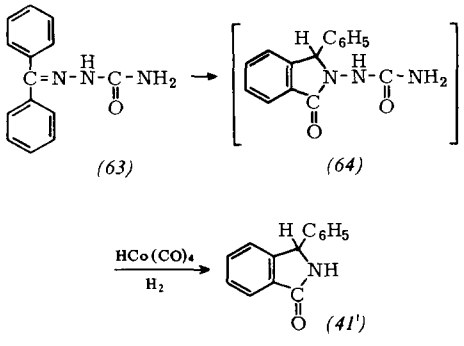
*(62)* *(62')*

Whereas the C=N double bond in the phenylhydrazones of aromatic ketones reacts in accordance with its original position, owing to conjugation with the two aromatic rings, the phenylhydrazones of aromatic aldehydes, like those of aliphatic aldehydes and ketones [66], exist partly in the tautomeric azo form. The phenylhydrazones of aromatic aldehydes evidently react in the azo form with carbon monoxide. However, the expected six-membered heterocycles, *e.g. (62')*, are not obtained; one nitrogen atom is eliminated as ammonia as a result of hydrogen transfer from the starting material or from the solvent.

Table 6. Carbonylation of phenylhydrazones of aromatic aldehydes in the presence of $Co_2(CO)_8$ [28].

| Phenylhydrazone | Reaction product | T [°C] | Yield [%] |
|---|---|---|---|
| Benzaldehyde phenyl-hydrazone | *N*-Phenylphthalimidine | 230–240 | 50 |
| Benzaldehyde (*m*-Tolyl)-hydrazone | *N*-(*m*-Tolyl)phthal-imidine | 230 | 20 |
| 1-Naphthaldehyde phenylhydrazon | 2-Phenylbenzo[*e*]-isoindol-1-one | 230–235 | |

Semicarbazones of aromatic ketones also react to form phthalimidines [41]. Once again, the expected *N*-ureidophthalimidines, *e.g. (64)*, cannot be isolated, evidently



*(63)* *(64)* *(41')*

because of hydrogenolysis. However, carbonylation probably does not take place exclusively on the unchanged semicarbazone, since benzophenone semicarbazones such as *(63)* decompose above their melting points to give benzophenone azines such as *(65)* [67]; according to *Rosenthal* [41] these react with carbon monoxide to give high yields of phthalimidines such as *(41')*. The formation of benzhydryl semicarbazones

[66] *R. O'Connor*, J. org. Chemistry *26*, 4375 (1961).

[67] *W. Borsche* and *C. Merkwitz*, Ber. dtsch. chem. Ges. *37*, 3180 (1904).

Table 8. Products obtained by reaction of azobenzenes with carbon monoxide at temperatures above 200 °C in the presence of $Co_2(CO)_8$.

| | (67) with R | R' | Substituted 2,4-dioxo-1,2,3,4-tetrahydroquinazolines (69) | Yield [%] | Ref. |

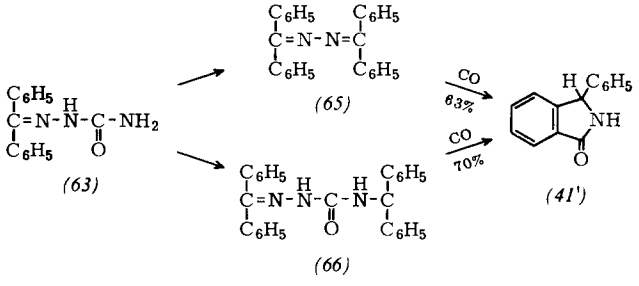
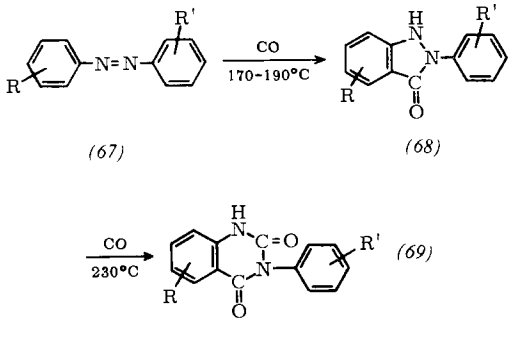
| (e) | m-$CH_3$ | H | 7-Methyl-3-phenyl- | 26 | [44] |
| (f) | p-$CH_3$ | p-$CH_3$—$C_6H_4$ | 6-Methyl-3-(p-toluyl)- | 40 | [44] |
| (g) | p-Cl | p-Cl—$C_6H_4$ | 6-Chloro-3-(p-chlorophenyl)- | 17 | [44] |
| (h) | p-$CH_3$ | p-$CH_3O$—$C_6H_4$ | 6-Methoxy-3-(p-methoxyphenyl)- | 28 | [44] |

[(66) in this case] has also been observed; these react further to phenylphthalimidines in high yields [41].



### 6. Indazolones and 2,4-Dioxo-1,2,3,4-tetrahydroquinazolines from Azobenzenes [43,44]

Aromatic azo compounds react with carbon monoxide to form indazolones. At higher temperatures, further reaction of the indazolones leads to insertion of CO to form 2,4-dioxo-1,2,3,4-tetrahydroquinazolines. Thus the reaction of azobenzenes *(67)* between 170 and 190 °C yields 2-phenylindazolones *(68)* (cf. Table 7), which react with further CO at 220 to 230 °C to form 2,4-dioxo-3-phenyl-1,2,3,4-tetrahydroquinazolines *(69)*. Azobenzenes containing *o,p*-directing substituents react in a



similar manner. If only one aromatic ring is substituted, cyclization always takes place on the substituted ring. Azobenzenes containing *m*-directing substituents do not

Table 7. Reaction of azobenzenes with carbon monoxide in the presence of $Co_2(CO)_8$.

| | (67) with R (R' = H) | Reaction product (68) | Yield [%] | Ref. |
|---|---|---|---|---|
| (a) | H | 2-Phenylindazolone | 55 | [43,44] |
| (b) | p-$CH_3$ | 5-Methyl-2-phenylindazolone | 35 | [44] |
| (c) | p-Cl | 5-Chloro-2-phenylindazolone | 24 | [44] |
| (d) | p-$(CH_3)_2N$ | 5-Dimethylamino-2-phenylindazolone | 80 | [44] |

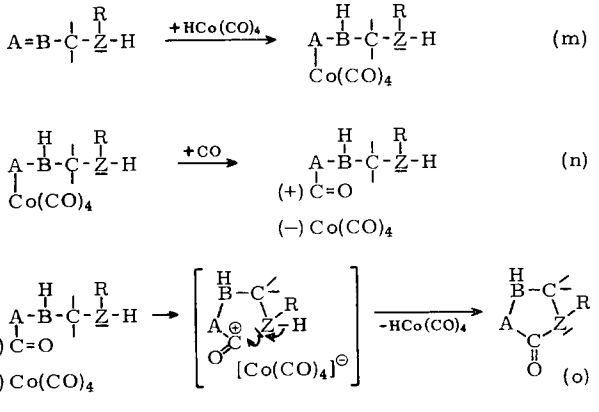
cyclize [38]. (An explanation for this is given in Section D).

The reaction of the indazolones *(68)* by CO insertion may be regarded as analogous to the formation of *N,N'*-dibenzylurea from hydrazobenzene and carbon monoxide [24]. The 2,4-dioxo-1,2,3,4-tetrahydroquinazolines *(69)* can be obtained in a single-stage reaction if the azobenzenes are allowed to react at temperatures above 200 °C [43,44] (see Table 8).

## D. The Mechanism of Ring Closure

It is reasonable to conclude, from the reactions described above, that the true catalysts are not the transition metal carbonyls, but the corresponding hydrogen metal carbonyls. On the one hand, the only metal carbonyls that are active as catalysts are those that can form hydrogen metal carbonyls, *e.g.* cobalt, rhodium, and iron [33,35,36,38], whereas nickel [33,38], for example, is inactive. Secondly, it is known that cobalt, rhodium, and iron carbonyls are able to abstract hydrogen from alcohols, amines, and even the much less reactive cycloparaffins under the reaction conditions used, to form hydrogen metal carbonyls [26,28,38,68]. Moreover, it has been shown that amides of unsaturated acids react with stoichiometric amounts of cobalt hydrogen tetracarbonyl, even at −30 to −20 °C, with ring closure to form imides; with $Co_2(CO)_8$, on the other hand, no reaction occurs under these conditions [45].

The three-step mechanism (m)–(n)–(o) agrees with the experimental results. The first step is the addition of the metal hydrogen carbonyl to the double bond of the starting compound (m).

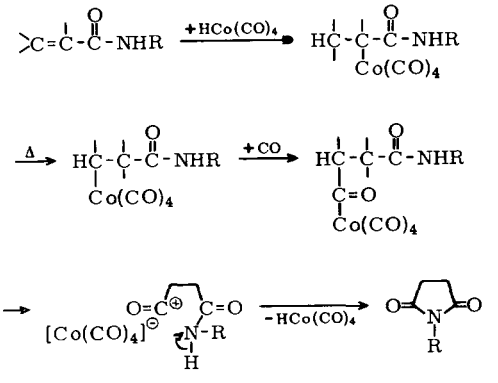


[68] *W. Hieber*, Angew. Chem. *55*, 7 (1942).

Although hydrogen tetracarbonylcobaltate gives a strongly acidic reaction in aqueous media [69–74], the hydrogen possesses hydride character in the gaseous substance [75–78]. The nature of the catalyst therefore also depends on the solvent. *Heck* and *Breslow* have already pointed out that the nature of the addition of the hydrogen carbonylmetallate is also largely dependent on the electron configuration of the substrate [25]. In the examples described, the hydrogen carbonylmetallates probably react preferentially in the hydride form. This explains the fact that their addition to the double bond of unsaturated amines and alcohols leads mainly to compounds with terminal metal.

The addition of hydrogen carbonylmetallates to Schiff bases, oximes, azo compounds, phenylhydrazones, semicarbazones, and azines can be explained on the basis of polar structures. If the electron density on the C atom of the C=N double bond in the Schiff bases is increased by a methyl substituent,the yields of cyclization products decrease, whereas the highest yields are obtained when the electron density is lowered by a phenyl substituent.

In unsaturated carboxamides, on the other hand, the electron-attracting carbamoyl group causes the hydride ion to be added to the β-carbon atom. The metal should therefore become attached in the α-position [top line in Equation (p)], as in unsaturated esters, which react at



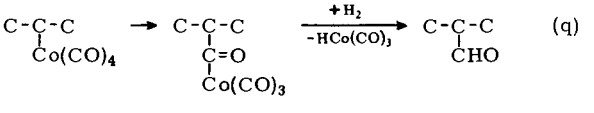
(p)

low temperatures (50 to 70 °C) to give products with Co attached in the α-position [25,63,79]; these products react with CO and then with hydrogen or alcohols to give the corresponding α-formyl esters of the carboxylic acid or diesters of malonic acid. At higher temperatures (110 to 150 °C), however, the reactions of the same starting materials lead to β-substituted esters of the carboxylic acids [62,63]. Compounds with longer chains give products containing even ω-substituted compounds, formed by isomerization of the intermediate cobalt compounds and migration of the metal substituent towards the end of the chain. An analogy to these results is the isomerization of alkylboron [80–85], alkylsilicon [86–88], and alkylaluminum compounds [89].

In compounds with longer chains the double bond can migrate already before the actual carbonylation. Various mechanisms [46–57,89a,89b] have been suggested for these isomerizations, including migration of an allyl hydrogen.

However, the alkyl-metal compound resulting from the addition of the hydrogen carbonylmetallate remains hypothetical. No such alkylcobalt compound has ever been detected with certainty in the addition of hydrogen tetracarbonylcobaltate to unsaturated compounds [25,27].

In the study of the hydroformylation mechanism, it has also been suggested that alkyltetracarbonylcobalt compounds may rearrange to acyltricarbonylcobalt compounds without taking up CO from the gas phase [25] [see Eq. (q)]. In the presence of hydrogen or alcohols, this should lead to the formation of $HCo(CO)_3$, which either catalyses the process as such, or takes up gaseous CO to re-form hydrogen tetracarbonylcobaltate [25,27].



(q)

Though this or a similar mechanism is not impossible, it is more likely, in view of the high CO pressures used, that the reaction proceeds *via* the hydrogen tetracarbonylcobaltate.

The last step in the reaction is the ring closure (with simultaneous regeneration of the hydrogen carbonylmetallate), the excess of electrons on the atom Z causing a nucleophilic attack on the acyl cation, while the hydrogen attached to Z is transferred as a proton to the $[Co(CO)_4]^{\ominus}$ anion.

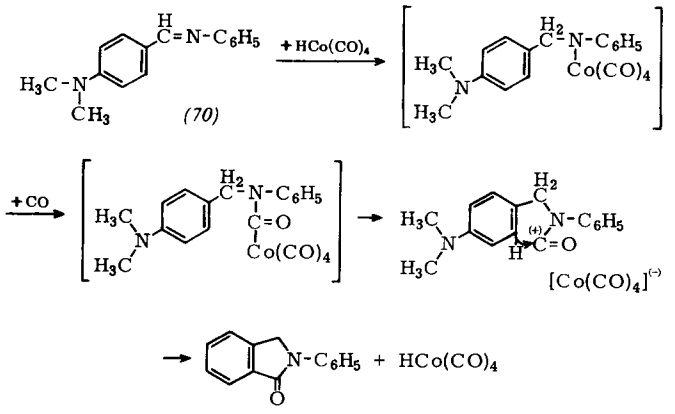
It is easy to see from the experimental results how the ring closure is affected by the electron density on the atom Z. For example, better yields are obtained with methylallylamine or *N*-methylacrylamide than with the phenyl homologues [33, 35].

Similarly, higher yields are obtained from the Schiff bases [*e.g. (70)*] derived from *p*- or *m*-dimethylaminobenzaldehyde and from *p*- or *m*-methoxybenzaldehyde, or the analogous azo compounds [38], than from the unsubstituted compounds; this is due to the inductive effect of the substituents and the resulting increased electron density in the aromatic system.



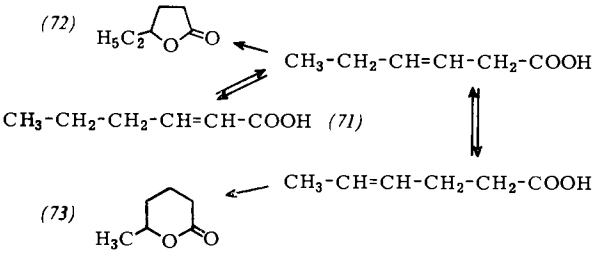
Only one result appears not to fit the proposed mechanism *viz.* the reaction of the Schiff base of 2-naphthaldehyde [38]. In this case the ring closure takes place, not on C-1, as expected, but on C-3; however, the special steric effects involved here have already been mentioned (Section C. 4).

A mechanism proposed by *Horiie* and *Murahashi* [24] for the carbonylation of Schiff bases and azo compounds, and later by *Rosenthal* [28] for the carbonylation of phenylhydrazones, has been shown to be incorrect. $Co_2(CO)_8$ was thought to react with the lone electron pair on the nitrogen atom to form a π-compound; insertion of CO then leads to an unsaturated Co-acyl compound containing 4-coordinate nitrogen, which subsequently undergoes ring closure in a multi-center reaction, the aromatic hydrogen in the *o*-position being simultaneously transferred to the C=N or C=C double bond. However, *Rosenthal*, and *Gervay* [29] later showed that in the reaction of nitriles with CO, $H_2$, and $D_2$, cyclization is not accompanied by simultaneous transfer of the *o*-hydrogen to the double bond.

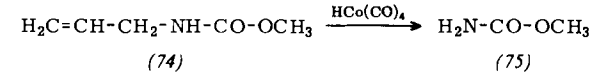
## E. Limitations of the Ring-Closure Reaction

A number of compounds having the structural formulae A=B–C–Z–H and A=B–C–C–Z–H do not react in accordance with Schemes (g) or (h). Thus unsaturated thiols give only traces of thiolactones, the principal products being polymers [90]. This is not surprising, since unsaturated thiols are well known for their thermal instability [91]. Moreover, thiols undergo a number of other reactions with carbon monoxide [92], and sulfur compounds also form complexes with the carbonyl catalyst [93–101a].

Acrylic acid and methacrylic acid polymerize under the conditions required for ring closure [90]; long-chain unsaturated acids such as *(71)* isomerize, and lactones such as *(72)* and *(73)* are then formed by intramolecular addition of the carboxyl groups to the double bond.



Unsaturated sulfonamides are recovered unchanged at the temperatures normally used for the ring closure, and decompose at temperatures above 300 °C [90]. Allylureas undergo thermal decomposition to give a large number of products [45]. Allylurethanes such as *(74)* react with hydrogenolysis of the C–N bond to form carbamates *(75)* and a number of unidentified products [45].



The reaction of aromatic aldoximes does not proceed in the same manner as that of the ketoximes, but leads by a Beckmann rearrangement to carboxamides. *Murahashi* [38] reported that this Beckmann rearrangement in the presence of hydrogen carbonylmetallates is confined to aromatic aldoximes, whereas aliphatic aldoximes are hydrogenated. It was later shown, however, that aliphatic aldoximes also undergo the Beckmann rearrangement. Thus the reaction of butyraldehyde oxime led to 38 % of butyramide and 23 % of 2-propyl-3,5-diethylpyridine [102].

Diethyl allylmalonate, ethyl allylacetoacetate, and ethyl allylcyanoacetate do not give cyclic ketones; the reactions of these compounds lead only to migration of the double bond and to hydrogenation by hydrogen transfer [90]. Whereas the failure of the reaction with unsaturated thiols, acids, urethanes, ureas, and aldoximes must be attributed to side-reactions, with the three allyl compounds mentioned above it is due rather to the

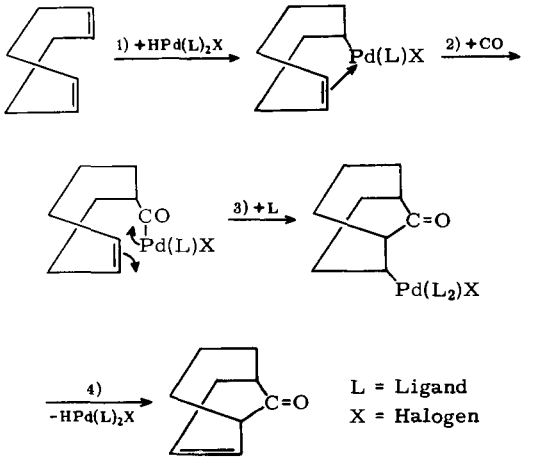
decrease in the electron density on the atom Z [see Equation (m)], with the result that the nucleophilic attack on the cobaltacylium cation is no longer possible.

## F. Appendix

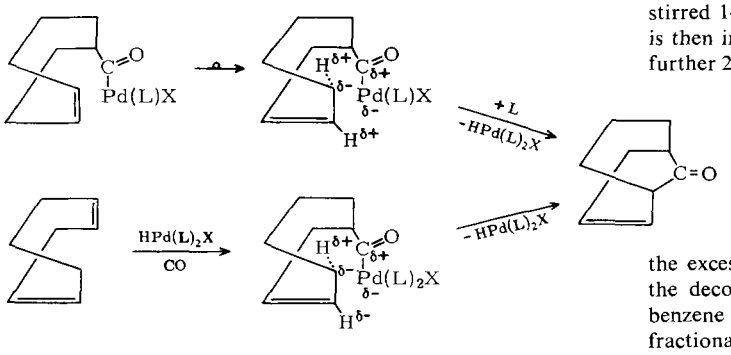
A few months after completion of this paper, *Brewis* and *Hughes*[103] described a related reaction.

1,5-Cyclooctadiene reacts in tetrahydrofuran at 180 °C and a CO pressure of 1000 atm in the presence of 1 % of diiodobis-(tributylphosphine)palladium(II) to give bicyclo[3.3.1]non-2-en-9-one in 40–45 % yield; 1,3-cyclooctadiene is also obtained in 45–50 % yield.

The authors propose the reaction sequence 1)–4). Steps 1) and 2) of this scheme correspond to the ring-closure mecha-



nism suggested in our own work. The formation of 1,3-cyclooctadiene shows the occurrence of isomerization, and it seems possible that instead of steps 3) and 4), the reaction proceeds by the mechanism indicated by Equations (m) to (o) (Section D) in accordance with step 5).



## G. Experimental Procedures

*Succinimide (2) from Acrylamide*[33]

Acrylamide (760 g, stabilized with 7 g of hydroquinone) and 60 g of $Co_2(CO)_8$ are dissolved in 5 *l* of tetrahydrofuran and heated to 200 °C over a period of 1 h in a magnetically stirred 10-*l* autoclave under 160 atm of CO. When the temperature reaches 200 °C, the CO pressure is increased to 300 atm and the mixture is stirred for a further 2 h. When the system has cooled to room temperature, the excess of CO is blown off; the mixture is refluxed for 1 h in a 10-*l* flask and nitrogen is constantly bubbled through to remove residual CO and to destroy the cobalt catalyst. The decomposition products of the catalyst are filtered off, the solvent is removed by distillation, and the crude product is fractionated in vacuum. Yield: 864 g (82 %); b.p.122–127 °C/0.6 mm Hg; m.p.125 °C.

*N-Methylsuccinimide (4a) from N-Methylacrylamide*[33]

A solution of 54 g of *N*-methylacrylamide in 250 g of thiophene-free benzene is carbonylated in the presence of 7.5 g of $Co_2(CO)_8$ in a magnetically stirred autoclave at 200 °C and under a CO pressure of 300 atm. After 4 h, the mixture is cooled to room temperature and the excess of carbon monoxide is blown off. The reaction mixture is then refluxed for 1 h in a current of nitrogen to ensure complete decomposition of the cobalt catalyst, and the decomposition products are filtered off. Benzene is distilled off in vacuum, and the crude product is distilled over a column. Yield: 67.5 g (94 %); b.p. 90–100 °C/1–2 mm Hg; m.p. 68–69 °C.

*2-Pyrrolidone from Allylamine*[35]

A solution of 50 g of allylamine and 2.9 g of $Co_2(CO)_8$ in 250 ml of benzene is heated to 280 °C under 150 atm of CO in a magnetically stirred 0.5-*l* autoclave. The CO pressure is increased to 300 atm, and the mixture is stirred for a further 2 h. When the system has cooled to room temperature, the excess CO is blown off. The mixture is refluxed for 30 min in a stream of nitrogen to destroy the cobalt catalyst, and benzene and unchanged allylamine are distilled off. The allylamine content of the benzene solution determined by gas chromatography corresponds to a conversion of 87 %. Distillation of the crude product yields 39 g of 2-pyrrolidone (52 %); m.p. 120–122 °C.

*N-Methyl-2-pyrrolidone from N-Methylallylamine*[35]

A mixture of 100 g of *N*-methylallylamine, 33 g of $Co_2(CO)_8$, and 500 g of benzene is heated to 250 °C in a magnetically stirred 1-*l* autoclave under 150 atm of CO. The CO pressure is then increased to 300 atm and the mixture is stirred for a further 2 h. When the system has cooled to room temperature, the excess of CO is blown off; the products resulting from the decomposition of the catalyst are filtered off, and the benzene is removed by distillation. The crude product is fractionated in vacuum. Yield: 109 g (78 %); b.p. 76–78 °C/10 mm Hg; $n_D^{20} = 1.4690$. 4 g (3 %) of *N*-methyl-*N*-allylformamide is obtained as a by-product.

*α,β,β-Trimethyl-γ-butyrolactone (30a) and γ,γ-Dimethyl-δ-valerolactone (31a) from 2,2-Dimethyl-3-buten-1-ol*[36]

A solution of 30 g of 2,2-dimethyl-3-buten-1-ol and 3.5 g of $Co_2(CO)_8$ in 130 ml of benzene is heated to 250 °C in a magnetically stirred autoclave under 150 atm of CO; the CO pressure is then increased to 300 atm. Samples are taken at 30 minute intervals by means of a steel capillary tube dipping into the liquid phase, and analysed by gas chromatography. When the starting material can no longer be detected in the sample, the autoclave is cooled to room temperature and the excess of CO is blown off. The reaction mixture is refluxed for 1 h in a current of nitrogen to decompose the catalyst,

[103] *S. Brewis* and *P. R. Hughes*, Chem. Commun. *1966*, 6.

and the decomposition products are filtered off. The benzene is removed by distillation, and the crude product left is vacuum distilled (b.p. 75–125 °C/10 mm Hg). Gas-chromatographic analysis shows that this fraction (29 g) contains α,β,β-trimethyl-γ-butyrolactone (51 % yield) and 18 % of γ,γ-dimethyl-δ-valerolactone (14 % yield). These lactones can be separated by preparative gas chromatography through Apiezon L on Chromosorb R (42/60 mesh).

*2-Phenylphthalimidine (41a) from Benzylidenaniline* [37]

A solution of 20 g of benzylidenaniline and 1.0 g of $Co_2(CO)_8$ in 100 g of benzene are heated for 1 h at 325 °C with constant stirring in a silvered 0.4-*l* autoclave under 200 atm of CO. The system is cooled to room temperature. Filtration of the product (total weight 111.5 g) yields 17.5 g of solid 2-phenylphthalimidine; a further 1.7 g is obtained by concentration of the benzene solution. Yield: 19.2 g (83 %); m.p. 163–164 °C.

*N-Phenylphthalimidine (41a) from Benzaldehyde Phenylhydrazone* [28]

Benzaldehyde phenylhydrazone (8 g) in benzene is carbonylated in a 0.28-*l* rocking autoclave for 2.2 h at 230 to 240 °C and under 250 atm of CO in the presence of $Co_2(CO)_8$. The decrease in pressure at 20 °C is 6.3 atm. When the reaction is complete, 1 g of a blue-black organocobalt complex is filtered off, and the catalyst is destroyed by heating to 70 °C. The solution is filtered once more, and the solvent is distilled off in vacuum. The residue is recrystallized twice from ethanol; the product is 4.2 g (50 %) of *N*-phenylphthalimidine (m.p. 166.5–167.5 °C).

*3-Phenylphthalimidine (54a) from Benzophenone Oxime* [39]

A $CO/H_2$ mixture (98.5:1.5) is introduced at a pressure of 145 atm into a glass-lined autoclave containing 14.1 g (0.07 mole) of benzophenone oxime, 7 g (0.02 mole) of $Co_2(CO)_8$, and 25 ml of thiophene-free benzene. When the autoclave is heated to 250 °C, the pressure increases to 285 atm. After 6 h, the system is cooled to room temperature. The cobalt catalyst is destroyed by refluxing (70 to 80 °C), and the benzene is distilled off in vacuum. The solid residue is extracted three times with 100 ml portions of ether. When the ether is distilled off, it leaves 2 g of a green syrupy substance, the melting point of which is about −10 °C. The ether-insoluble residue is extracted with hot chloroform, and gives 11.6 g (80 %) of 3-phenylphthalimidine. After recrystallization from ethanol, the product melts at 218–220 °C.

*3-Phenyl-2-(N'-phenylcarbamoyl)phthalimidine (59) from Benzophenone Phenylhydrazone* [40]

A solution of 7 g (0.023 mole) of benzophenone phenylhydrazone and 2 g (0.006 mole) of $Co_2(CO)_8$ in 50 ml of anhydrous benzene is subjected to a CO pressure of 140 atm. The solution is heated at 230 to 240 °C for 190 min, with constant stirring. The autoclave is allowed to cool (*e.g.* overnight), and the excess of gas is then blown off. The product consists of a dark brown solution and 6 g (71 %) of a yellow solid. When recrystallized twice from 75 % acetic acid, the solid gives 3-phenyl-(*N'*-phenylcarbamoyl)phthalimidine (white needles, m.p. 211–214 °C).

*2-Phenylindazolone (68a) from Azobenzene* [44]

A solution of 5 g of azobenzene and 1 g of $Co_2(CO)_8$ in 25 ml of benzene is heated in a 0.1-*l* stainless-steel autoclave to 180–190 °C under a CO pressure of 150 atm. The autoclave is shaken for 4 h and then cooled to room temperature. Approximately 3 g of a solid product precipitates from the benzene solution. After the catalyst has been decomposed and the benzene removed, 1.5 g of azobenzene is recovered. The solid product is treated with 5 % aqueous NaOH and the solution filtered. The component insoluble in NaOH consists mainly of diphenylurea (0.65 g, 16 %; m.p. 240 °C) and a little of the lactone of 2-(3-hydroxyindazol-2-yl)benzoic acid (m.p. 296 °C). The alkaline solution is acidified with HCl or $H_2SO_4$ or by the introduction of $CO_2$. The white crystalline product that precipitates is collected and recrystallized from alcohol. The alcohol-insoluble quinazolone (0.8 g, 17.5 %) remains behind. From the alcoholic solution 2.8 g (49.1 %) of 2-phenyl-indazolone crystallize as colorless needles (m.p. 204 °C).

*3-Phenyl-2,4-dioxo-1,2,3,4-tetrahydroquinazoline (69a) from Azobenzene* [44]

A mixture of 5 g of azobenzene, 2 g of $Co_2(CO)_8$, and 45 ml of benzene is heated for 30 min at 220–230 °C under 150 atm of CO. When the solution is cooled to room temperature, 5.2 g of a crystalline substance precipitates; this precipitate is filtered off. The filtrate is refluxed on a water bath to decompose the catalyst. The inorganic components are filtered off; the solution then contains 0.1 g of the lactone of 2-(3-hydroxyindazol-2-yl)benzoic acid. The crystals are treated with 5 % aqueous NaOH, in which 0.7 g (12.1 %) of the solid is insoluble (diphenylurea). The soluble material can be reprecipitated from the solution by acidification with $CO_2$, HCl, or $H_2SO_4$. The white crystalline product obtained in this way is 3-phenyl-2,4-dioxo-1,2,3,4-tetrahydroquinazoline (m.p. 275 °C).

*I am grateful to Prof. Dr. F. Korte for his encouragement and for helpful suggestions, and to Dr. H. Beecken, Dr. D. Scharf, and Dr. H. J. Schulze-Steinen for discussions during the preparation of the manuscript.*

# New Methods in Preparative Organic Chemistry VI[*]

## Syntheses of Thiocarboxamides

BY PROF. DR. W. WALTER AND DR. K.-D. BODE

CHEMISCHES STAATSINSTITUT,
INSTITUT FÜR ORGANISCHE CHEMIE DER UNIVERSITÄT HAMBURG (GERMANY)

*Methods for the preparation of thiocarboxamides are described with special reference to progress achieved in the last few years. The discussion is arranged according to the eight most important reaction types.*

1. Reaction of nitriles with hydrogen sulfide and thiols
2. Reaction of imidic acid derivatives with hydrogen sulfide and thiols
3. Sulfurization of amides
4. Addition of nucleophiles to isothiocyanates
5. The Willgerodt-Kindler reaction
6. Thioacylation of amines
7. Cleavage of heterocycles
8. Rearrangement of the benzenesulfonates of ketoximes
9. Procedures

The chemistry of thiocarboxamides has been developing rapidly for some 25 years. The compounds have many technical applications, *e.g.* as vulcanization promoters [1–3], as metal deactivators in petrochemistry [4], in pest control [5–7a], and as pharmacologically important substances [8–14]. The reader is referred to the reviews [15–18] for surveys of the earlier literature.

Departure from the division according to reaction types is occasionally made to refer to the preparation of individual thiocarboxamides when it seems appropriate in view of the nature of a reaction. The review is generally confined to syntheses in which a thioamide is formed or is directly involved. Thioureas and thiourethanes are not discussed.

### 1. Reaction of Nitriles with Hydrogen Sulfide and Thiols

The synthesis of thiocarboxamides from nitriles is one of the first known. *Völckel* [19] treated nitriles with hydrogen sulfide as early as 1841. The reaction requires high hydrogen sulfide concentrations; it is catalysed by bases, and is generally favored by the exclusion of water [20–20c].

Water-soluble sulfides or polysulfides can be used instead of hydrogen sulfide [20d]. The base-catalysed addition of hydrogen sulfide to nitriles could proceed in accordance with Equation (a).

Suitable catalysts, apart from ammonia, include aliphatic amines, pyridine, alkoxides, and potassium hydrogen sulfide[20–21a]. *Fairfull*, *Lowe*, and *Peak*[22] obtained very good yields by addition of hydrogen sulfide with hydrogen sulfide. *O*-Ethyl thioacetate *(5)* was identified by gas chromatography and mass spectrometry.

Some examples of thiocarboxamides prepared in accordance with Equation (a) are given in Table 1.

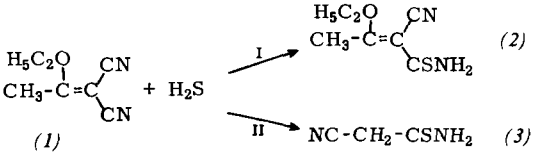
Table 1. Thiocarboxamides from nitriles and hydrogen sulfide, according to Equation (a).

| Compd. | Thiocarboxamide | M.p. [°C] | Yield [%] | Ref. |
|---|---|---|---|---|
| *(6)* | 3-$C_2H_5O$–$C_6H_4$–$CSNH_2$ | 75–77 | 100 | [28] |
| *(7)* | 1,4-$(CSNH_2)_2$–$C_6H_4$ | 263 | 94 | [29] |
| *(8)* | 4-$CH_3SO_2$–$C_6H_4$–$CSNH_2$ | 205–206 | 100 | [30] |
| *(9)* | 2-Cl–$C_6H_4$–$CSNH_2$ | 57 | 100 | [22] |
| *(10)* | $CF_3$–$CSNH_2$ | 42–43 | 37 | [31] |
| *(11)* | $H_2NCS$–$(CF_2)_2$–$CSNH_2$ | 112–114 | 40 | [32] |
| *(12)* | $C_6H_5$–$CH_2O$–CO–$CH_2$–$CSNH_2$ | 70–71 | 80 | [32a] |
| *(13)* | $(C_2H_5)_2C(CSNH_2)_2$ | 195 | 93 | [33] |
| *(14)* | $C_6H_5$–NH–N=C(CN)–$CSNH_2$ | 211–213 | 88 | [33a] |
| *(15)* | $(CH_3)_2N$–CH=C(CN)–$CSNH_2$ | 200–203 | 72 | [34] |
| *(16)* [a] | $H_2NCS$–$C_6H_4$–$O(CH_2)_x$–O–$C_6H_4$–$CSNH_2$ | – | 92–98 | [35] |
| *(17)* [b] | RCO–NH–CS–NH–$C_6H_4$–$CSNH_2$ | – | 87–98 | [36, 36a] |

[a] x = 3 to 10; [b] from the nitrile RCO–NH–CS–NH–$C_6H_4$–CN with R = $C_6H_5$, *p*-Cl–$C_6H_4$, *p*-$CH_3O$–$C_6H_4$, *p*-n-$C_4H_9O$–$C_6H_4$.

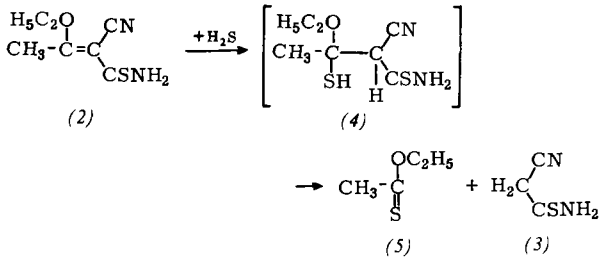
to aromatic nitriles in the presence of pyridine and triethylamine. *Kindler* measured the rates of reaction of several aromatic nitriles with hydrogen sulfide in the presence of sodium alkoxide[23].

Aliphatic nitriles often react very slowly and give poor yields unless the reaction is carried out at elevated temperatures and pressures[24–26a]. Aliphatic nitriles with several substituents exhibit interesting behavior[27]. 1-Ethoxyethylidenemalonodinitrile *(1)* can react with hydrogen sulfide to give different products, depending on the solvent. The product obtained in benzene (route I) is 2-cyano-3-ethoxythiocrotonamide *(2)*, whereas that obtained in ethanol (route II) is cyanothioacetamide *(3)*.



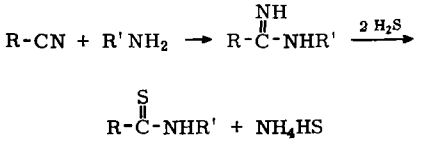
*(1)* *(2)* *(3)*

*McCall*'s explanation for this difference is that the same product *(2)* is initially formed in both solvents. This product is insoluble in benzene and precipitates; in hot ethanol, on the other hand, small quantities dissolve and react further



*(2)* *(4)* *(5)* *(3)*

This method was extended by *Kindler*[20] and *Hanford*[37] to permit the preparation of *N*-substituted thiocarboxamides by addition of hydrogen sulfide to nitriles in the presence of primary amines [Equation (b)].



(b)

Very good results are obtained by the addition of *O,O'*-diethyl dithiophosphate *(18)* (readily obtainable from ethanol and phosphorus pentasulfide) to nitriles[38]. The S–P bond in the adduct *(19)* is cleaved by hydrogen chloride.

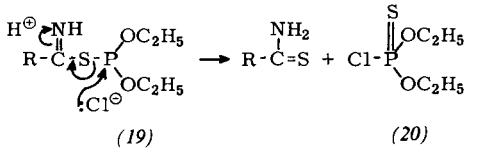
The cleavage of the S–P bond possibly is introduced by attack of the proton on the imino group[39]. This would explain the fact that acyl cyanides cannot be converted into α-oxothiocarboxamides by this method, as our own experiments have shown, since withdrawal of electrons by the α-keto group opposes the attack of the proton on the imino group. If this were the first step of the reaction, the scheme proposed in[38] could be modified in such a way that the thiocarboxamide is formed directly from *(19)*.



*(19)* *(20)*

Some thiocarboxamides can be prepared in very good yields in this way, as can be seen from Table 2. $CD_3$–$CSNH_2$ prepared by this method from $CD_3CN$ (D-content 99%) still contains 89% D attached to carbon[40a].

Table 2. Thiocarboxamides from nitriles and *O,O'*-diethyl dithiophosphate *(18)*.

| Compd. | Thiocarboxamide | M.p. [°C] | Yield [%] | Ref. |
|---|---|---|---|---|
| *(21)* | $CH_3$–$CSNH_2$ | 107.5–108.5 | 84 | [38] |
| *(22)* | $C_6H_5$–$CSNH_2$ | 115–116 | 90 | [38] |
| *(23)* | $C_6H_5CH_2$–$CSNH_2$ | 97.8–98 | 82 | [38] |
| *(24)* | $ClCH_2$–$CSNH_2$ | 78–79 | 80 | [38] |
| *(25)* | $Cl_3C$–$CSNH_2$ | 98–100 | 80 | [38] |
| *(26)* | $C_2H_5O$–CO–$CH_2$–$CSNH_2$ | 30–31 | 54 | [40] |
| *(27)* | $CH_3OCH_2$–$CSNH_2$ | 63–64 | 29 | [40] |
| *(28)* | 2,6-Cl,F–$C_6H_3$–$CSNH_2$ | – | 42 | [5] |
| *(29)* | 2,6-Cl,I–$C_6H_3$–$CSNH_2$ | 136–137 | 71 | [5] |
| *(30)* | 2,4-$Cl_2$–$C_6H_3$–$CSNH_2$ | 95–96 | 73 | [5] |
| *(31)* | 2,6-Cl($C_6H_5S$)–$C_6H_3$–$CSNH_2$ | 180–181 | 20 | [5] |

Preparation with the aid of *(18)* is at present the only method for the synthesis of chlorothioacetamide *(24)*, since the addition of hydrogen sulfide to chloroacetonitrile *(32)* leads first to a sulfide *(33)*, which then reacts further to the bis-thioamide *(34)*.

$$2\ ClCH_2CN + H_2S + 2\ NH_3 \longrightarrow S(CH_2CN)_2 + 2\ NH_4Cl$$

*(32)* *(33)*

$$S(CH_2CN)_2 + 2\ H_2S \longrightarrow H_2N\text{-}\underset{\underset{S}{\|}}{C}\text{-}CH_2\text{-}S\text{-}CH_2\text{-}\underset{\underset{S}{\|}}{C}\text{-}NH_2$$

*(33)* *(34)*

The reaction of nitriles with thioacetamide *(21)* instead of hydrogen sulfide has gained some importance; the thiocarboxamides are probably formed in accordance with Equation (c)[41–41b].

$$R\text{-}CN + CH_3\text{-}CSNH_2 \rightleftharpoons R\text{-}\underset{\underset{NH}{\|}}{C}\text{-}S\text{-}\underset{\underset{NH}{\|}}{C}\text{-}CH_3 \quad (c)$$

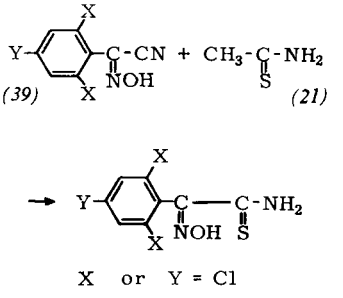
*(21)*

$$\rightleftharpoons R\text{-}\underset{\underset{S}{\|}}{C}\text{-}NH_2 + CH_3CN$$

The formation of the thiocarboxamide is favored by removal of acetonitrile from the equilibrium. The advantage of this method is that it can be used for the preparation of thiocarboxamides from nitriles and reducible substances. Some examples are given in Table 3. Halogenated α-cyanobenzaldoximes such as *(39)* can be converted into the α-thiocarbamoylbenzaldoximes by this method[7].

Table 3. Thiocarboxamides from nitriles and thioacetamide *(21)*, in accordance with Equation (c).

| Compd. | Thiocarboxamide | M.p. [°C] | Yield [%] | Ref. |
|---|---|---|---|---|
| *(35)* | *p*-$NO_2$–$C_6H_4$–$CSNH_2$ | 158.5–159.5 | 83 | [41] |
| *(36)* | *p*-$CH_3O$–$C_6H_4$–$CSNH_2$ | 148.5–149.5 | 87 | [41] |
| *(37)* | $CH_2(CSNH_2)_2$ | 211–212 | 63 | [41] |
| *(38)* | $H_2NCS$–$(CH_2)_4$–$CSNH_2$ | 178.5–179.5 (decomp.) | 78 | [41] |



*(39)* *(21)*

X or Y = Cl

On the other hand, for the reaction with hydrogen sulfide of nitriles containing hydroxyl groups, the OH groups must first be protected by acylation[42,43]. Keto groups such as that in *(40)* are readily converted into thioxo groups in acidic solution[44].

$$R\text{–}CO\text{–}CH_2\text{–}CONHR' + H_2S \xrightarrow{HCl}$$

*(40)* $R\text{–}CS\text{–}CH_2\text{–}CONHR + H_2O$

This reaction had previously been applied by *Mitra*[45] to acetoacetic ester.

The base-catalysed conversion of ketones into thiones by treatment with hydrogen sulfide was developed by *Mayer et al.* into a useful preparative method[46]. *Asinger* and *Gentz*[47] made the interesting observation that the previously unknown primary α-oxothiocarboxamides *(41)* are formed from acyl cyanides and hydrogen sulfide in ether in the presence of triethylamine. Some examples are given in Table 4.

Table 4. α-Oxothiocarboxamides of the type R–CO–CS–$NH_2$ *(41)*

| Compd. | R | M.p. [°C] | Yield [%] | Ref. |
|---|---|---|---|---|
| *(41a)* | $(CH_3)_3C-CH_2$ | 76 | 94 | [47] |
| *(41b)* | $(CH_3)_2CH-CH_2$ | 35 | 84 | [47] |
| *(41c)* | $(CH_3)_3C$ | 85.5–87 | 35 | [40] |
| *(41d)* | $C_6H_5$ | 97 | 94 | [47a] |
| *(41e)* | $p$-$CH_3O-C_6H_4$ | 93 | 75 | [40] |
| *(41f)* | $CH_3-(CH_2)_2$ | 56–57 | 5.4 | [47b] |

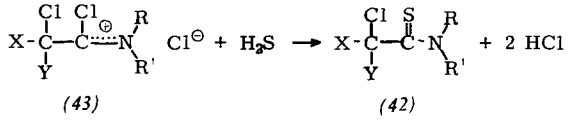
A possible reason for the different courses of the reactions observed by *Mayer* and by *Asinger* is that, owing to the polarization of the nitrile as shown in Equation (a), the carbonyl group cannot attain its normal polarization, so that the nitrile C-atom becomes the strongest electrophilic center in the molecule.

## 2. Reaction of Imidic Acid Derivatives with Hydrogen Sulfide and Thiols

The reaction of imidoyl chlorides with hydrogen sulfide was described almost simultaneously by *Bernthsen* [48], *Leo* [49], and *Wallach* [50].

$$R-C(NR)Cl + H_2S \rightarrow R-CS-NHR + HCl$$

This method has led to the preparation of many thiocarboxamides that could not previously be prepared. Thus *Speziale* and *Smith* [51] obtained a number of new α-chlorothioacetamides *(42)* by reaction of the immonium chloride *(43)* with hydrogen sulfide. Some examples are given in Table 5.

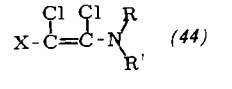


*(43)* *(42)*

Table 5. α-Chlorothioacetamides of the type *(42)* from the immonium chlorides *(43)* [51].

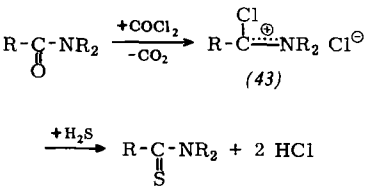
| Compd. | X | Y | R | R′ | M.p. [°C] | Yield [%] |
|---|---|---|---|---|---|---|
| *(42a)* | H | H | $C_6H_5$ | $C_6H_5$ | 140–147 (decomp.) | 88 |
| *(42b)* | H | H | $CH_3$ | $C_6H_5$ | 38–39.5 | 34 |
| *(42c)* | H | Cl | $CH_3$ | $C_6H_5$ | 103 | 60 |
| *(42d)* | H | Cl | $C_2H_5$ | $C_2H_5$ | *oil* | 73 |
| *(42e)* | Cl | Cl | $CH_3$ | $C_6H_5$ | 71–72 | 63 |
| *(42f)* | Cl | Cl | $C_2H_5$ | $C_2H_5$ | oil | 56 |

The immonium chlorides *(43)* were obtained by addition of hydrogen chloride to 1,2-dichloro- *(44a)* and 1,2,2-trichlorovinylamines *(44b)*.



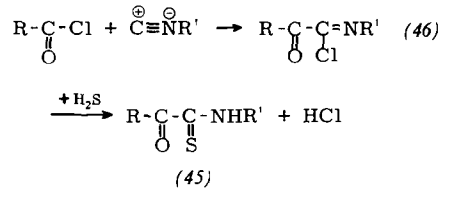
*(44)*

The immonium chlorides leading to the trichlorothioacetamides are obtained by addition of chlorine to *(44a)* or *(44b)*. *N,N*-disubstituted carboxamides and phosgene also give immonium chlorides *(43)*, which then react in the usual manner [52].



*(43)*

The *N*-substituted α-oxothiocarboxamides *(45)*, which could not previously be prepared, have been obtained by a similar method [53] (see Table 6) [*].

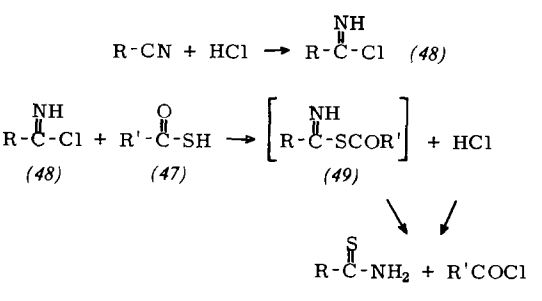


*(45)*

Table 6. *N*-Substituted α-oxothiocarboxamides *(45)* from *(46)*.

| Compd. | R | R′ | M.p. [°C] (B.p. [°C/mm Hg]) | Yield [%] | Ref. |
|---|---|---|---|---|---|
| *(45a)* | $p$-$NO_2-C_6H_4$ | $(CH_3)_2CH$ | 76–78 | 87 | [53] |
| *(45b)* | $CH_3$ | $(CH_3)_2CH$ | (104/11) | 85 | [53] |
| *(45c)* | $C_6H_5$ | $CH_3$ | (140/0.07) | 45 | [40] |
| *(45d)* | $CH(_3)_2CH$ | $(CH_3)_2CH$ | (40–41/11) | 75 | [40] |
| *(45e)* | $CH_3$ | $CH_3$ | (52/2) | 97 | [40] |
| *(45f)* | $p$-$NO_2-C_6H_4$ | c-$C_6H_{11}$ | 106–108 | 74 | [40] |

In *Ishikawa*'s method [54], nitriles are treated with thiocarboxylic *S*-acids *(47)* in the presence of hydrogen chloride. The initial product appears to be the imidoyl chloride *(48)*, which reacts with the thiocarboxylic acid *(47)*.



When thioacetic *S*-acid [*(47)*, R′ = $CH_3$] is used, an *N*-acetylthioamide may occur as a by-product, probably as a result of acetyl migration in *(19)* [55,56]. However, this rearrangement is avoided if the reaction is carried out at room temperature.

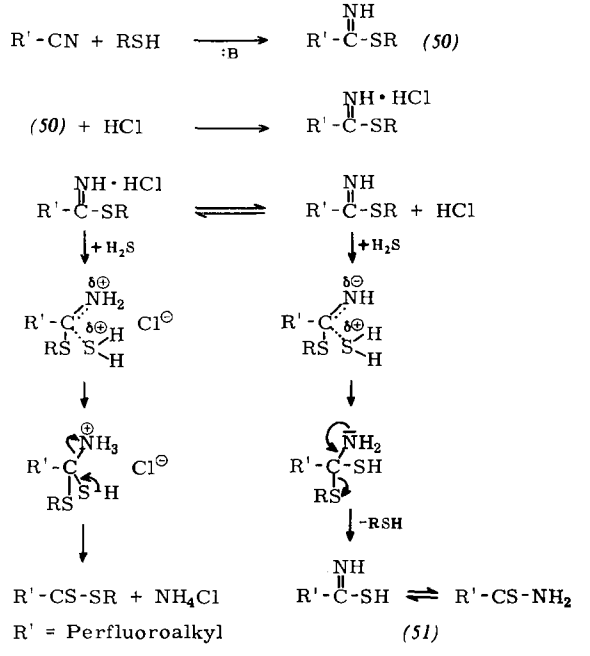
[*] Note added in proof: Oxo-α-dichloro compounds R–CO–$CCl_2$-R′ react with sulfur and primary amines to give monosubstituted α-oxothiocarboxamides in yields of 30–100%: *F. Asinger, A. Saus, H. Offermanns*, and *H.-D. Hahn*, Liebigs Ann. Chem. *691*, 92 (1966).

Amidines, also being imidic acid derivatives, give thiocarboxamides with hydrogen sulfide [48,57–60]. This reaction supports the proposed reaction scheme (a) for the base-catalysed addition of hydrogen sulfide to nitriles. If B is ammonia or an amine, the nitriles are first converted into amidines, which then add on hydrogen sulfide to form a thiocarboxamide. Amidines react with carbon disulfide at 100 °C to give thiocarboxamides [61–63].

$$R\text{–}C(NH)\text{–}NH_2 + CS_2 \rightarrow R\text{–}CS\text{–}NH_2 + HSCN$$

An interesting variant was discovered by *Brown* and *Pater* [64]. By addition of mercaptans to cyanoperfluoroalkanes, they obtained perfluoroalkylcarboximidic esters *(50)*, which react with hydrogen sulfide in acidic media to give perfluoroalkylthiocarboxamides *(51)*, together with dithio esters.



Finally, mention may be made of the esters of imidic acids, which also form thiocarboxamides on reaction with hydrogen sulfide. This method has not yet attained much importance, since imidic esters are generally prepared from the nitriles, which can themselves react with hydrogen sulfide. An interesting example, however, is the particularly useful laboratory preparation of dithiooxamide *(52)* from the ester *(53)*, which is easily accessible from cyanogen chloride and ethanol, and which reacts with hydrogen sulfide to give *(52)* in 90% yield [65].

$$C_2H_5O\text{–}C(=NH)\text{–}C(=NH)\text{–}OC_2H_5 \xrightarrow{+H_2S} H_2N\text{–}C(=S)\text{–}C(=S)\text{–}NH_2 + 2\ C_2H_5OH$$

*(53)* *(52)*

Substituted dithiooxamides are readily obtainable from *(52)* and amines, as is shown in Section 6.

### 3. Sulfurization of Amides

The replacement of the oxygen in carboxamides by sulfur is a general method for the preparation of thiocarboxamides, since it also permits the synthesis of *N*-monosubstituted and N-disubstituted compounds from the readily obtainable amides. The most useful reagent for this replacement is phosphorus pentasulfide, which reacts in accordance with Equation (d) [*].

$$10\ R\text{–}CO\text{–}NH_2 + P_4S_{10} \rightarrow 10\ R\text{–}CS\text{–}NH_2 + P_4O_{10} \qquad (d)$$

This method was first used by *A. W. Hofmann* [66]. Other sulfurizing agents are discussed at length in [15–18]. Little use is made of these nowadays; in special cases, *e.g.* in the synthesis of thiocaprolactam, carbon disulfide [67] and carboxylic *S*-acids have proved useful. The latter appear to add specifically to *cis*-amides [68]. Low yields are obtained on fusion of amides with phosphorus pentasulfide [69]. Better results are obtained in dry, inert solvents with sufficiently high boiling points. The reaction time is then reduced, and undesirable side reactions, such as the reaction of the phosphorus pentoxide produced with unsubstituted thiocarboxamides, are avoided.

Methods have been devised for sulfurization in benzene, toluene, xylene, tetrahydrofuran, dioxane, and diethylene glycol diethyl ether [70–75]. The sulfurization of liquid amides is also possible in an excess of the amide as solvent [76, 77].

A considerable improvement is obtained, however, by the use of pyridine[78,79]. In our experience, the pure thiocarboxamides are obtained in high yields in this solvent. Some examples are given in Table 7.

Table 7. Thiocarboxamides by sulfurization of amides with phosphorus pentasulfide in pyridine, in accordance with Equation (d).

| Compd. | Thiocarboxamide | M.p. [°C] | Yield [%] | Ref. |
|---|---|---|---|---|
| *(54)* | $C_6H_5$–CH=CH–$CSNH_2$ | 142 | 56 | [80] |
| *(55)* | $C_6H_5$–CH=CH–$CSNHCH_3$ | 119 | 93 | [80] |
| *(56)* | $C_6H_5$–CH=CH–$CSNHC_6H_5$ | 128 | 59 | [80] |
| *(57)* | $C_6H_5$–CH=CH–$CSN(C_2H_5)_2$ | 54–55 | 59 | [80] |
| *(58)* | $C_6H_5$–CH=CH–$CSN(C_6H_5)_2$ | 231 | 33 | [80] |

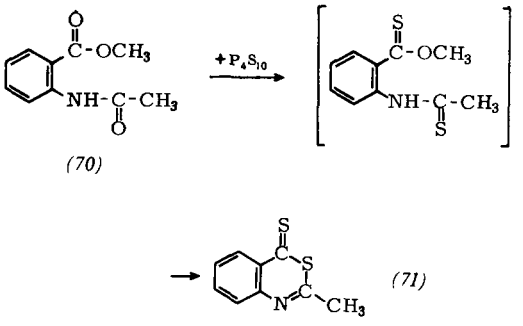
| *(69)* | 2-Furyl-$CSNHC_6H_5$ | 107–108 | 86 | [82a] |

[a] The compound was protected by benzyloxylation before sulfurization.

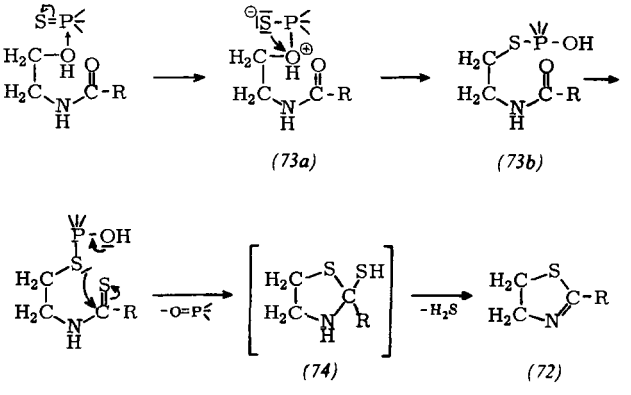
As in the preparation of thiocarboxamides from nitriles, the yields in the sulfurization of aromatic amines depend on the substituents. For example, 3- and 4-nitrobenzanilides give very good yields in the sulfurization, whereas the yields obtained with the corresponding aminobenzanilides are only moderate[83]. Unsubstituted amides often give very poor yields, because of further reaction to give nitriles, as mentioned above; in this case, however, the thiocarboxamides can often be obtained by the addition of hydrogen sulfide to the nitriles. The best yields are always obtained for *N*-monosubstituted thiocarboxamides. This reaction cannot be used with thermally unstable amides. Hydroxyl groups must be protected by acetylation before sulfurization[84,84a].

Ester groups generally are not attacked, as is shown by the sulfurization of the ethoxycarbonylthioformamides *(62)* and *(63)*[81,85]. An interesting exception to this rule was observed by *Legrand*[86] in the sulfurization of methyl *N*-acetylanthranilate *(70)*, in which sulfur is introduced into both the amide group and the ester group; the product cyclizes to give 2-methyl-4*H*-3,1-benzothiazine-4-thione *(71)*.



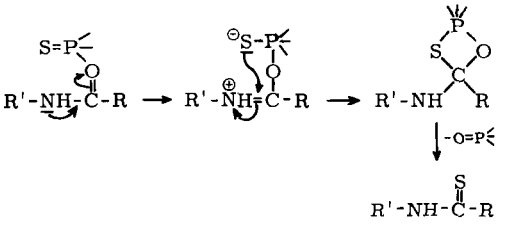
*(70)* *(71)*

Sulfurization of *N*-substituted amides with functional groups β to the nitrogen leads to 2-thiazolines *(72)*[87]. *Roggero* and *Metzger*[88] assume that the reaction proceeds by way of the intermediates *(73a)* and *(73b)*. The sulfurization of the amide group is followed by formation of *(74)*, which reacts further to form the thiazoline *(72)*.



*(73a)* *(73b)* *(74)* *(72)*

*Long* and *Tulley*[89] have proposed a similar scheme for the sulfurization of amides:



However, this mechanism has not yet been proved, since no intermediates have so far been isolated. The first attempts to elucidate the reaction mechanism were made by *Kindler*[20]; during the reaction of phosphorus pentachloride with *N*,*N*-dimethylbenzamide in cold carbon disulfide, this author isolated an oil, from which the amide is re-formed by hydrolysis, but which gives the thiocarboxamide when heated in an inert solvent. Thus the compound unites both reactants.

During an attempt to obtain 2-hydroxythiobenzamide by treatment of salicylamide in pyridine with phosphorus pentasulfide, we obtained a compound differing substantially from the desired product. It does not give the phenol color reaction with $FeCl_3$ solution, but after oxidation with hydro-

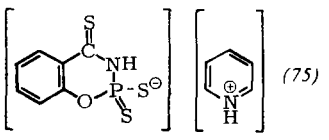
gen peroxide it gives an olive-green color with $FeCl_3$, indicating the presence of a thiocarboxamide grouping[90]. This substance is only sparingly soluble in many organic solvents, but dissolves readily in hot water, dimethylformamide, and dimethyl sulfoxide. After the addition of hydrochloric acid, the compound decomposes when heated. Treatment of the decomposition product with picric acid gives a picrate with a melting point similar to that of pyridine; however, the pyridine cannot be removed by vacuum distillation. Reaction with ammonium molybdate solution shows that the substance contains phosphorus.

These observations, together with the elemental analysis, can be explained by the formation of an intermediate *(75)*.



*(75)*

This assumption is supported by the mass spectrum of the substance, which is shown schematically in Fig. 1.

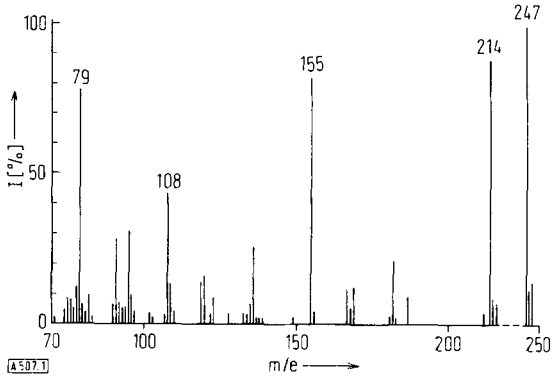


Fig. 1. Mass spectrum of substance *(75)*.

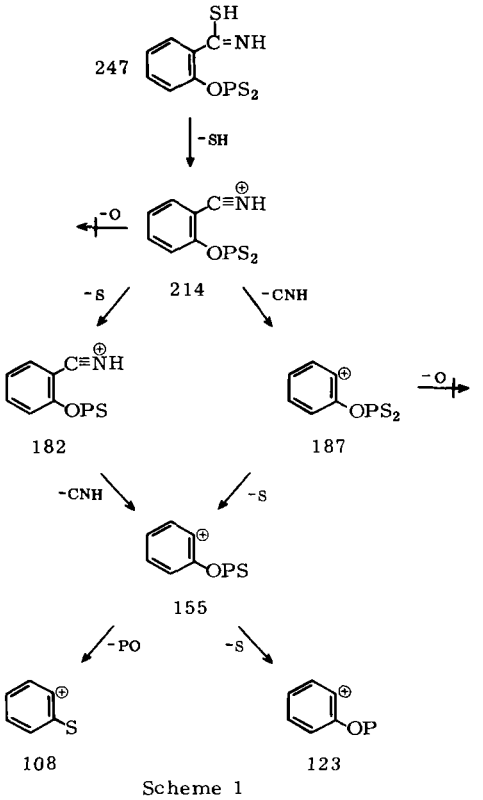

Scheme 1

[90] *W. Walter*, Liebigs Ann. Chem. *633*, 35 (1960).

The following decomposition sequence (Scheme 1) was constructed on the basis of the mass numbers: It must be assumed that the compound *(75)* first loses pyridine, with the result that the heterocyclic ring is opened. The compound formed in this way is assigned the mass number 274, so that further decomposition starts at this point.

The fragments corresponding to mass numbers 123 and 108 decompose further, with loss of OP and S, respectively, to form a fragment having the mass number 76. Other significant lines in the spectrum of Fig. 1 are that at mass number 95, due to the fragment $PS_2$, and that at mass number 79, due to pyridine. It can be concluded from these findings, and particularly from the presence of a line at mass number 123, that *(75)* contains a C–O–P linkage. The reaction therefore involves an intermediate such as *(73a)*, which may be stabilized by salt formation with pyridine. However, the line at mass number 108 also shows that the sulfurization has proceeded further under the conditions of measurement. Finally, further proof of the presence of a C–O–P linkage is provided by the infrared spectrum, in which an absorption band characteristic of this linkage appears at 1190 $cm^{-1}$ [92a].

## 4. Addition of Nucleophiles to Isothiocyanates

### a) Organometallic Compounds

Isothiocyanates react with Grignard compounds; subsequent hydrolysis under mild conditions leads to thiocarboxamides *(76)*.

$$RMgBr + R'NCS \rightarrow R{-}C(NR'){-}SMgBr \xrightarrow{H_2O} R{-}CS{-}NHR' + MgOHBr$$

*(76)*

This method was first used by *Sachs* and *Loevy*[91]. *Worrall*[92] later used it to prepare a large number of *N*-substituted thiovaleramides. In spite of the high yields and the relatively simple procedure, few publications deal with this reaction. A number of thiocarboxamides obtained by this method are given in Table 8 (in many of the earlier papers yields are not given).

Table 8. Thiocarboxamides *(76)* by addition of isothiocyanates to Grignard compounds.

| Compd. | R | R' | M.p. [°C] | Yield [%] | Ref. |
|---|---|---|---|---|---|
| *(76a)* | n-$C_4H_9$ | *p*-$CH_3$-$C_6H_4$ | 69–70 | 100 | [92] |

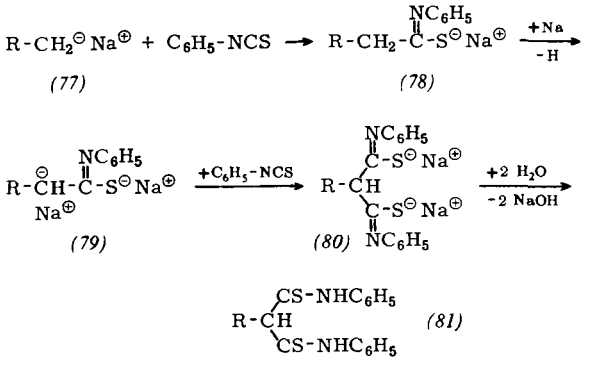
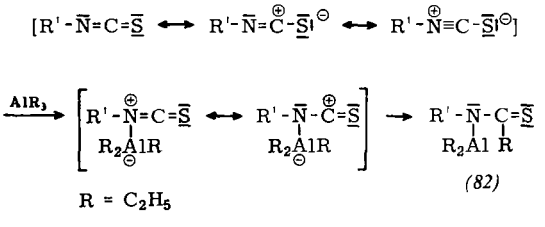
The reaction of alkylsodium compounds *(77)* with phenyl isothiocyanate leads to bifunctional thiocarboxamides *(81)* [96–99].

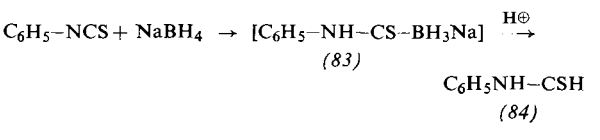


Thiobenzanilide *(60)* is obtained in a similar manner from phenyl-lithium and phenyl isothiocyanate [100].

*Reinheckel* and *Jahnke* [101] obtained a series of thiopropionamides by addition of $Al(C_2H_5)_3$ and $(C_2H_5)_{1.35}AlCl_{1.65}$ to aliphatic and aromatic isothiocyanates; these authors suggest the following mechanism [101a]:

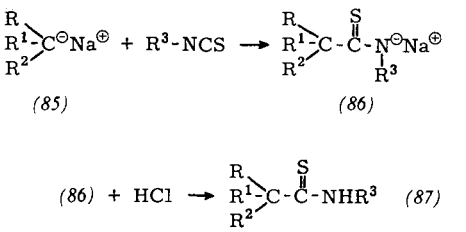


On hydrolysis of *(82)* with dilute acid, the thiocarboxamide is obtained in yields of 58 to 96%. An interesting reaction is that of phenyl isothiocyanate with sodium borohydride, which leads to the formation of thioformanilide *(84)* [102, 102a].



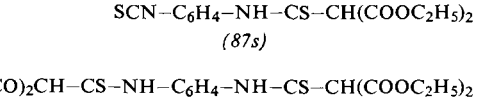
### b) CH Acids

The reaction of isothiocyanates with CH acids has become an important means of obtaining thiocarboxamides in very good yields. The CH acids are used in the form of their alkali-metal salts, as shown in Equation (e). Some examples are given in Table 9.

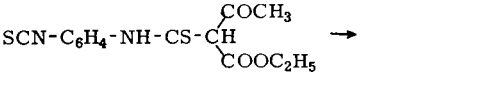


(e)

Sodiomalonic ester reacts with *p*-phenylene diisothiocyanate in anhydrous ethanol to give the sodium salts of the mono- and di-adducts; acidification of these yields diethyl *N*-(*p*-isothiocyanatophenyl)thiocarbomoylmalonate *(87s)* and diethyl *N,N'*-(*p*-phenylene)bis(thiocarbamoylmalonate) *(87t)*.



Sodioacetoacetic ester, on the other hand, gives only the mono-adduct, which decomposes in ethanol at room temperature to give ethyl acetate and ethyl *N*-(*p*-isothiocyanatophenyl)thiocarbamoylacetate *(87u)*. Ethyl *N*-arylmalonomonothioamides are readily obtainable in this way [113c].



The reaction of sodioacetylacetone with aryl isothiocyanates in absolute ethanol leads to *N,N'*-diaryldithiomalonodiamides [113d]. *Borisevich*, *Grabenko*, and *Pelkis* even obtained acetyldithiomalonodianilides *(87v)* by reaction of the sodium salts of acetylthioacetanilides with phenyl isothiocyanate [113e].

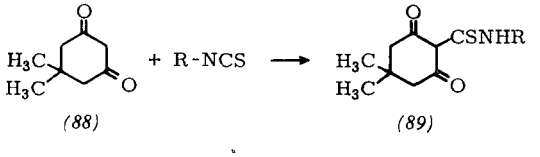
| *(87r)* | $CH_3CO$ | $CH_3NH-CH$ | | $C_6H_5$ | 138–139 | 71 | [113b] |

Cyclic CH acids have also been used. *Bullock* and *Abraham* [114] prepared various substituted pyrrolethiocarboxanilides, some in very high yields. The addition of isothiocyanates to dimedone *(88)* in acetonitrile proceeds in yields of about 60% in the presence of a little alkali [115], whereas no reaction occurs in ethanol with phenyl isothiocyanate [113a].



*(88)* *(89)*

*(89a)* R = $C_6H_5$
*(89b)* R = $p$-Cl–$C_6H_4$
*(89c)* R = $p$-$NO_2$–$C_6H_4$
*(89d)* R = α-Naphthyl [115a]

Alkali-metal cyanides react with isothiocyanates to give *N*-substituted cyanothioformamides *(90)*, which form *N*-substituted dithiooxamides on reaction with hydrogen sulfide [116]. Sodium cyanide gives poorer yields than potassium cyanide [for examples of *(90)*, see Table 10].

$$KCN + R-NCS \rightarrow \underset{(90)}{R-NH-CS-CN} \xrightarrow{H_2S} \underset{(91)}{R-NH-CS-CS-NH_2}$$

*Grabenko* and *Pelkis* treated alkoxyphenyl isothiocyanates with sodium or acetone cyanohydrin and obtained good yields of alkoxycyanothioformamides, which they converted into the alkoxyphenyldithiooxamides with hydrogen sulfide [117]. Some of the cyanothioformamides prepared in this way are listed in Table 10.

Table 10. Cyanothioformamides *(90)* by addition of isothiocyanates to cyanides.

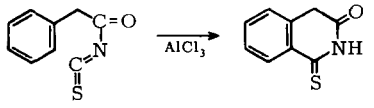
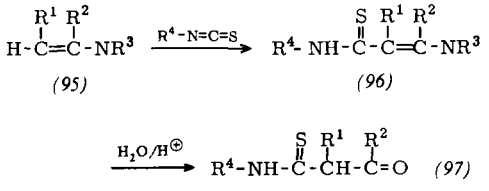
In analogy with the phenol ethers, phenyl ethyl sulfide was converted into a thiocarboxamide by treatment with phenyl isothiocyanate[122]. Aromatic hydrocarbons react under identical conditions[123]. In this way *Smith* and *Kan*[124] obtained homomonothiophthalimides such as *(94)* in yields of 40 to 70% by an intramolecular reaction of phenacetyl isothiocyanates such as *(93)*.



*(93)* *(94)*

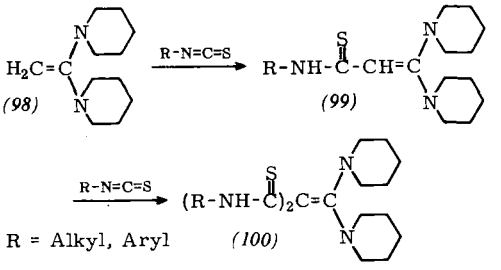
c) Enamines

Enamines of the type *(95)* react with aryl isothiocyanates to form β-aminoalkenethiocarboxamides *(96)*, which can be readily hydrolysed to β-oxothiocarboxamides *(97)*[125–126a].



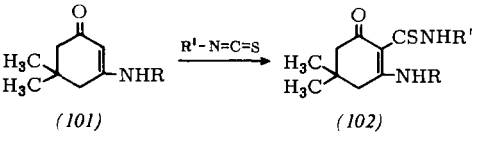
*(95)* *(96)* *(97)*

Some examples of β-aminoalkenethiocarboxamides *(96)* (which were prepared for the first time by this method) and β-oxothiocarboxamides *(97)* are given in Table 11.



*(98)* *(99)* *(100)*

*Goerdeler* and *Keuser*[115] obtained thiocarboxamides *(102)* in good yields by addition of tautomeric enamines of the type *(101)* to aryl isothiocyanates.



*(101)* *(102)*

Compounds containing a $\Delta^1$-triazoline ring, which can be prepared from cyclopentene and aryl azides, react with isothiocyanates only after thermal elimination of nitrogen to form cyclopentenylamines has taken place; the product is a thiocarboxamide (yields 50–99%)[127a, 127b].

Moreover, secondary enamines such as the esters of β-methylaminocrotonic acid can add to aryl and acyl isothiocyanates[113b]. Some examples are given in Table 9 [*(87j)–(87l), (87r)*].

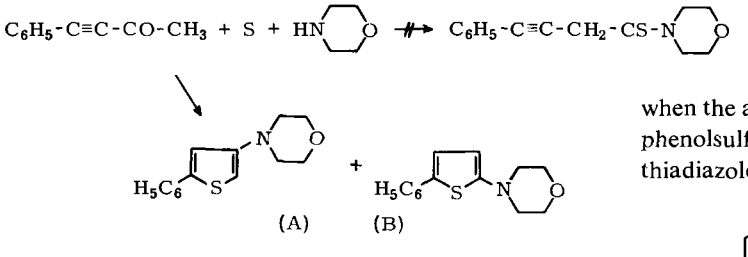
## 5. The Willgerodt-Kindler Reaction

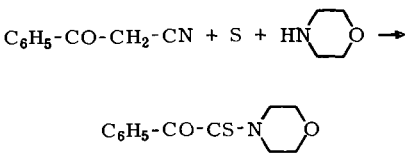
*Willgerodt* found that when aromatic-aliphatic ketones are heated with ammonium polysulfide to 150–200 °C under pressure, amides of aliphatic-aromatic carboxylic acids with the same number of carbon atoms are formed. The Willgerodt reaction [128] consists in the reduction of the keto group to a methylene group, accompanied by oxidation of the chain end by the sulfur. *Kindler* [20] improved the method by the use of primary or secondary amines and sulfur at high temperature. The course of this reaction is not yet certain [129,130]. Since there are several reviews [129–131] of the Willgerodt-Kindler reaction, only the most recent relevant papers will be discussed here.

According to *Asinger* [131], it appears impossible that the Willgerodt-Kindler reaction proceeds by a single mechanism, particularly since not only aromatic-aliphatic ketones, but *inter alia* also aromatic hydrocarbons [132], aromatic aldehydes [133], unsaturated aliphatic compounds [134], diazoketones [135], Schiff bases [136], and even amines themselves, react with sulfur [137]. The most important step is thought to be the initial thiolation and geminal dithiolation, which was also observed by *R. Mayer* [46] in the reaction of ketones with hydrogen sulfide in basic solution.

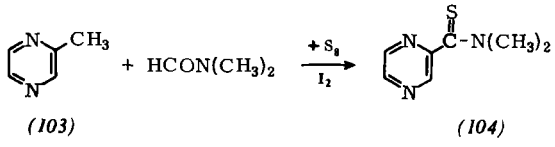
It has recently been shown that the reaction with acetylenic ketones leads not to the thiocarboxamides, as was previously believed, but to isomeric thiophene derivatives [138]. The isomers (A) and (B) are formed in the proportions 9:1.



Similar behavior was observed by *Asinger* and *A. Mayer* in the reaction of aliphatic-aromatic ketones [138a]. Diketones are reduced to monoketones, which then give thiocarboxamides [138b]. α-Cyanoketones give α-oxothiocarboxamides, with loss of a carbon atom [138c].



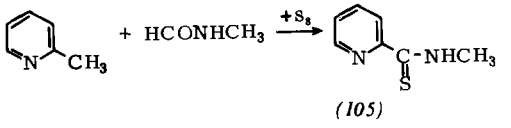
It is possible in principle to carry out the reaction at a much lower temperature by the use of a different solvent [131,139,140]. Another possibility is illustrated by the preparation of *N,N*-dimethylpyrazinethiocarboxamide *(104)* from methylpyrazine *(103)*, dimethylformamide, and sulfur in the presence of iodine. The iodine lowers the viscosity of the sulfur, and so permits the use of a lower reaction temperature. However, the yield is only about 14%, since the monomethylthiocarboxamide and other by-products are also formed [141].



*(103)* *(104)*

This synthesis is similar to the preparation of *N*-methylpyridine-2-thiocarboxamide *(105)* from α-picoline, sulfur, and methylformamide [142]. The yield in this case is about 50%.

Quinaldine can be converted in the same way into quinaldine-2-thiocarboxamides. However, the reaction fails when the amine component is anthranilic acid, *o*-aminophenolsulfanilic acid, 2-aminothiazole, 2-amino-1,3,4-thiadiazole, and 2-aminopyridine [142a].



*(105)*

A useful variant of the Willgerodt-Kindler reaction is the reaction of enamines with sulfur at room temperature in polar solvents such as dimethylformamide; thiocarboxamides are formed in yields of about 75% [143].

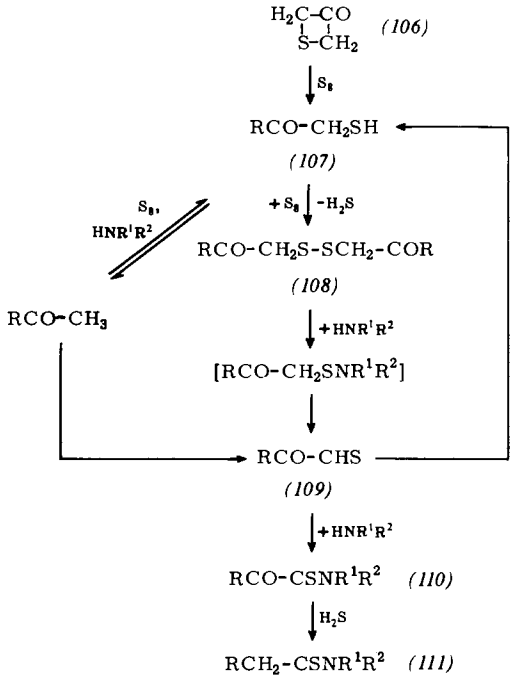
[143] *R. Mayer* and *J. Wehl*, Angew. Chem. *76*, 861 (1964); Angew. Chem. internat. Edit. *3*, 705 (1964).

As a result of studies on the reaction of thietan-3-one *(106)* with secondary amines, *Funk* and *R. Mayer*[144] recently proposed the reaction sequence shown in Scheme 2 for the Willgerodt-Kindler reaction.



Scheme 2. R = $CH_3$

According to this scheme, the reaction begins with the formation of the α-mercaptoketone *(107)*. This step requires vigorous conditions and is rate-determining. The formation of the disulfide *(108)* proceeds very readily. This compound is then converted, *via* the oxosulfenamide, into the oxothioaldehyde *(109)*, which undergoes a Cannizzaro disproportionation, the products in the presence of the amine being *(110)* and *(107)*. The α-oxothiocarboxamide *(110)* is then reduced to the thiocarboxamide *(111)*. A Cannizzaro reaction is thus regarded as the central event. However, this assumption is unnecessary for the reaction with ammonia, since *Asinger*, *Schäfer*, *Baumgarte*, and *Müting*[145] showed that unsubstituted oxosulfenamides *(112)* are dehydrogenated by sulfur at room temperature to give α-oxothiocarboxamides *(113)* (Equation f); for the mechanism see[145a].

$$\underset{(112)}{RCOCH_2-S-NH_2} \xrightarrow{+S} \underset{(113)}{RCOCS-NH_2} + H_2S \qquad (f)$$

This provides further confirmation of *R. Mayer*'s thesis that "this complex and variable reaction cannot be described by a single mechanism"[144].

## 6. Thioacylation of Amines

Thiocarboxamides can be prepared by thioacylation of amines with a wide variety of thioacylating agents. *Staudinger* and *Siegwart*[146] obtained thiobenzanilide *(60)* by reaction of thiobenzoyl chloride with aniline.

However, this method is of no importance, in view of the difficulty of preparing thioacyl chlorides (see[147]). Thiocarboxamides have also been obtained directly from dithiocarboxylic acids[148,149] and their salts[94, 150–154a] by reaction with aliphatic and aromatic amines. Sodium cyanodithioformate, which can be prepared from carbon disulfide and sodium cyanide, reacts with dimethylamine or diethylamine to form cyano-*N*,*N*-dialkylthioformamide[154b].

Esters of thiocarboxylic acids also act as thioacylating agents[152,155–156b]. Owing to their instability, however, these compounds are not generally suitable. Nevertheless, *R. Mayer* and *Orgis*[157] recently obtained thioformamide (which had previously been relatively difficult to prepare) in yields of more than 90% by reaction of ethyl *O*-thioformate with ammonia.

*Reynaud*, *Moreau* and *Samana*[157a] also obtained good results with this method in the preparation of monosubstituted and disubstituted aliphatic and aromatic thiocarboxamides. In some cases the reaction of the ester of the *O*-thiocarboxylic acid with substituted magnesium anilide bromides was found particularly useful[157a, 157b].

$$RO-C_6H_4-CS-OC_2H_5 + BrMgNH-C_6H_4-OR' \rightarrow RO-C_6H_4-CS-NH-C_6H_4-OR' + C_2H_5OMgBr$$

*Goerdeler* and *Horstmann*[157c] obtained high yields of thioacylimides, *e.g.* thioacylsuccinimides, by acylation of unsubstituted aromatic thiocarboxamides with dicarbonyl dichlorides, *e.g.* succinyl dichloride.

These products are very useful as thioacylating agents (yields between 60 and 95%).

According to *Walter* and *Maerten*[158], substituted thioformamides *(114)* can be obtained in good yields by the reaction of chloroform, amines, and hydrogen sulfide in alkaline solution. It is thought that the chloroform first undergoes α-elimination to form dichlorocarbene, which then reacts in accordance with Equation (g).

$$CCl_2 + R^1R^2NH + 2\,SH^{\ominus} \rightarrow R^1R^2N{-}CS{-}H + H_2S + 2\,Cl^{\ominus} \quad (g)$$

*(114)*

A number of thioformamides prepared by this method are listed in Table 12.

Table 12. Substituted thioformamides *(114)* by thioformylation of amines.

[a] m.p. 63–64 °C; [b] m.p. 50–50.5 °C; [c] two isomers with m.p. ≈ 7 and 67.5–68 °C; [d] two isomers with m.p. 59.5–60.5 and 67.5 to 68 °C; [e] m.p. 67–68 °C.

The carboxymethyl dithiocarboxylates *(115)*[148,159,160] have gained considerable importance for preparative work; they react not only with amines but also with amino acids.

$$R{-}CS{-}SCH_2COOH + H_2NR' \rightarrow R{-}CS{-}NHR' + HSCH_2COOH$$

*(115)*

A good survey of this method, with many examples of its application, has been published by *Kurzer*[161]. *Walter* and *Curts*[162] obtained alkylenebisthiobenzamides *(116)* in good yields by thiobenzoylation of diamines.

$$C_6H_5{-}CS{-}NH{-}(CH_2)_x{-}NH{-}CS{-}C_6H_5 \quad (116)$$

$x = 1-6$

The method fails with sterically hindered amines, and is unsuitable for the preparation of thioformamides.

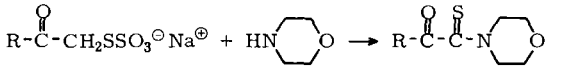
A variant of this method is the acylation of amines with ethyl dithiocarboxylates in accordance with Equation (h).

$$R{-}CH_2{-}NH_2 + R'{-}CS{-}SC_2H_5 \rightarrow R{-}CH_2{-}NH{-}CS{-}R' + C_2H_5SH \quad (h)$$

*(117)*

In this way, *N*-(2-arylethyl)thiocarboxamides [*(117)*, $R = ArCH_2$] have been obtained in yields of 86 to 99%[163].

The reaction of *S*-acylmethylthiosulfates (acyl Bunte salts) *(118)* with amines, which was discovered by *Milligan* and *Swan*[164,165], can also be regarded as thioacylation.



*(118)* R = $C_6H_5$, $CH_3$ *(119)*

This procedure, which leads to good yields of *N,N*-disubstituted α-oxothiocarboxamides, is regarded by the authors as a variant of the Willgerodt-Kindler reaction. However, there is some doubt about the mechanism proposed by *Milligan* and *Swan*[144], so that, despite the similarity of the reaction conditions to those of the Willgerodt-Kindler reaction, this method is dealt with in the present Section.

Finally, the unsubstituted thiocarboxamides are also stable thioacylating agents, since they react with primary aliphatic amines under mild conditions to give *N*-alkyl thiocarboxamides. This reaction is referred to in the literature[166] as the Wallach reaction. (However, it should not be confused with the reaction of the same name in which amines are alkylated with aldehydes or ketones and formic acid[167]). A detailed description of the reaction is given by *Hurd*[166], who used it to prepare a number of previously unknown dithiooxamide derivatives. An interesting reaction is that of monothiooxamide with aliphatic amines, since only the thioamide group reacts[81,168]. Two unsubstituted thioamide groups in the same molecule react one after the other. In the reaction of morpholine with dithiooxamide, for example, it was possible to obtain the previously unknown *N*-morpholinodithiooxamide[40]. *Persson* and *Sandström* recently used this method for the preparation of a number of thiooxamides[169]. Amino acids can also be acylated with dithiooxamide[170].

$$2\,R{-}CH_2{-}NH_2 + H_2N{-}CS{-}CS{-}NH_2 \rightarrow R{-}CH_2NH{-}CS{-}CS{-}NH{-}CH_2{-}R + 2\,NH_3$$

*(120)* R = COOH, $SO_3H$

The reaction of *N,N*-dimethylthioformamide with amines, on the other hand, leads to amidines[170a].

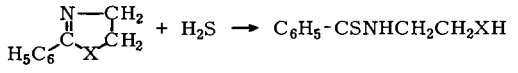
## 7. Cleavage of Heterocycles

Thiocarboxamides are often used as starting materials for the synthesis of sulfur heterocycles [171]. The reverse of this process, leading back to the thiocarboxamides, is therefore of no interest in this connection. However, some heterocyclic systems, obtained by another route, also give thiocarboxamides on cleavage.

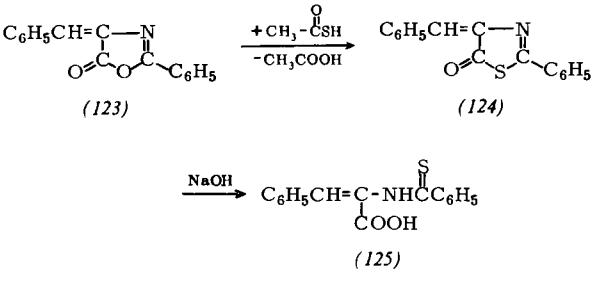
Thioamides are obtained when $\Delta^2$-oxazolines *(121a)* react with hydrogen sulfide in basic solutions [152].



*(121)* *(122)*

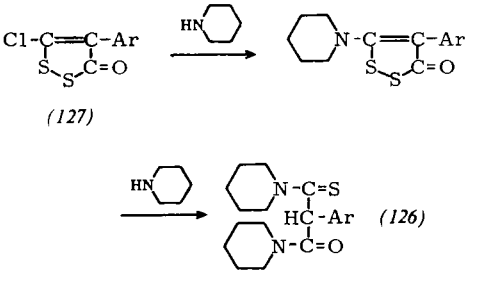
*a*: X = O, *b*: X = S

The corresponding reaction with 2-phenyl-$\Delta^2$-1,3-thiazoline *(121b)*, which could lead to *N*-(β-mercaptoethyl)-thiobenzamide *(122b)*, does not appear to have been studied as yet. The reaction of 4-benzylidene-2-phenyl-(4*H*)-oxazol-5-one *(123)* with thioacetic acid leads to a thiazolone *(124)*, which is cleaved by dilute sodium hydroxide to form the thioamide *(125)* [172].



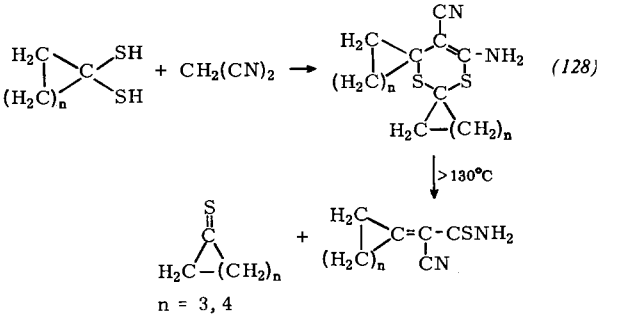
*(123)* *(124)* *(125)*

This reaction is reversed when *(125)* is heated in acetic anhydride. *Boberg* and *Marei* [173] recently observed the formation of arylmonothiomalonodiamides *(126)* in the reaction of 3-chloro-4-aryl-1,2-dithiolones *(127)* with amines.



*(127)* *(126)*

Geminal dithiols react almost quantitatively with malonodinitrile to form 1,3-dithiins *(128)*, which decompose into the thioketone and the thioamide when heated above their melting points [173a].

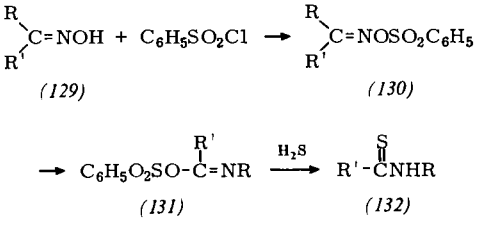


*(128)*

n = 3, 4

## 8. Rearrangement of the Benzenesulfonates of Ketoximes

An interesting preparation of *N*-substituted thiocarboxamides was discovered by *Huisgen* and *Witte* [174] and by *Kopecky* [175]. Ketoximes *(129)* are benzenesulfonated in pyridine, and the products are left to undergo spontaneous Beckmann rearrangement in the presence of hydrogen sulfide. The resulting imidosulfonates *(131)* react with the hydrogen sulfide to give thioamides *(132)* in yields of 50 to 90%.



*(129)* *(130)* *(131)* *(132)*

This method failed in only two of 21 open-chain, cyclic, aliphatic, aromatic, and mixed ketoximes (cf. Table 13). The process is similar to the synthesis of alkyl thioimidates by the reaction of imidosulfonates with alkylthiols [176].

Table 13. Thiocarboxamides *(132)* from ketoximes.

| Compd. | R | R' | M.p. [°C] | Yield [%] |

## 9. Procedures

a) *Cyanothioacetamide (3)* [27] (reaction type 1)

66 g of malonodinitrile is dissolved in 200 ml of ethanol, and 6 to 8 drops of triethylamine are added. Hydrogen sulfide is introduced into this solution with stirring. The cyanothio-

acetamide that precipitates is filtered off from time to time. Recrystallization gives 90 g (90% yield) of cyanothioacetamide of m.p. 116–117 °C.

b) *Chlorothioacetamide (24)* [38] (reaction type 1)

30 g of chloroacetonitrile is cooled to −15 °C, and 74 g of *O,O'*-diethyl dithiophosphate is added slowly with stirring, the temperature never rising above −10 °C. The mixture is stirred for 30 min at this temperature, and is then treated with HCl gas; this is accompanied by a temperature rise. When the evolution of heat has stopped, the mixture is stirred with 200 ml of petroleum ether. The yellow product is filtered off and extracted with petroleum ether. Chlorothioacetamide [yield 35 g (80%), m.p. 78–79 °C] is obtained as colorless needles.

c) *N-Isopropyl-C-(p-nitrobenzoyl)thioformamide (45a)* [53] (reaction type 2)

10 g of *N*-isopropyl-*p*-nitrobenzoylformimidoyl chloride is dissolved in 50 ml of dry benzene and 50 ml of dry chloroform. The solution is saturated with hydrogen sulfide, poured into water, and the organic phase is washed with $NaHCO_3$ solution and water and dried with sodium sulfate. When the solvent is evaporated, a red oil is left, which crystallizes on cooling. Compound *(45a)* forms orange-red crystals on recrystallization from petroleum ether [yield 8.7 g (87%), m.p. 76–78 °C].

d) *N,N-Dimethyl-C-ethoxycarbonylthioformamide (62)* [81] (reaction type 3)

72.5 g of *N,N*-dimethyl-*C*-ethoxycarbonylformamide is dissolved in 500 ml of dry pyridine and refluxed for 1 hour with 42 g of phosphorus pentasulfide. The mixture is concentrated to 1/3 of its original volume and poured into 1 l of water with vigorous stirring. The product that separates is filtered off, and the filtrate is extracted repeatedly with chloroform. The brown residue obtained when the chloroform is evaporated is combined with the main fraction and dissolved in ethanol, and the solution is boiled with activated charcoal. When the filtrate is concentrated, pale yellow crystals of *(62)* separate [yield 34 g (42%); m.p. 46–47 °C].

e) *2-Amido-2-cyanothioacetanilide (87a)* [115] (reaction type 4b)

1.95 g of potassium is dissolved in a mixture of 20 ml of anhydrous t-butyl alcohol and 10 ml of anhydrous tetrahydrofuran. 4.2 g of malonodinitrile is added to the suspension, and a solution of 6.75 g of phenyl isothiocyanate in 10 ml of anhydrous tetrahydrofuran is added dropwise over 30 min at 10 °C, with stirring. After 15 min, the clear yellow solution is concentrated *in vacuo* at 30 °C, and the residual syrup is dissolved in 300 ml of water and filtered. The yellowish filtrate is washed with water to remove residual isothiocyanate, and acidified to pH 3 with 2N HCl. 7.0 g (64%, based on $C_6H_5$–NCS) of almost colorless crystals of *(84a)* precipitate; these are recrystallized from ethanol with activated charcoal (m.p. 186–187 °C).

Many examples of reaction type 5 are given in [130].

f) *N-(p-Cyanobenzyl)thiobenzamide* [177] (reaction type 6)

19 g of *p*-cyanobenzylamine is dissolved in 90 ml of methanol and poured into a solution of 31 g of *S*-thiobenzoyl-2-thioglycolic acid *(115)* and 6 g of NaOH in 90 ml of water. The thiocarboxamide separates immediately with slight evolution of heat. After the solution is cooled, the product is filtered off, washed with 50% methanol, and dried. The crude product is recrystallized from ligroin (120–125 °C) [yield 29.5 g (81%), m.p. 143 °C].

g) *N,N-Di-n-propylthioformamide (114i)* [158] (reaction type 6)

23 g of sodium is dissolved in 350 ml of anhydrous ethanol. The resulting sodium ethoxide solution is cooled with ice water, and 34 g of hydrogen sulfide is introduced; some sodium hydrogen sulfide is precipitated. 25 g of di-n-propylamine and 59.5 g of chloroform are added to this suspension. The mixture is refluxed for about 25 hours, while a slow stream of nitrogen is continuously passed through the apparatus. When the reaction is complete, the NaCl that has precipitated is filtered off, and the filtrate is concentrated *in vacuo*. The residue is triturated with chloroform and filtered, and the filtrate is diluted with water and carefully acidified with concentrated HCl. The organic phase is washed three times with water and dried over calcium chloride. When the solvent is evaporated, it leaves behind a yellow oil, which is vacuum distilled [yield 28 g (77%), b.p. 129–130 °C/12 mm Hg].

h) *Thioacetanilide (61)* [174] (reaction type 8)

A solution of 13.5 g of acetophenone oxime in 50 ml of pyridine is treated with 19.5 g of benzenesulfonyl chloride at 0 °C, and the mixture is allowed to stand for 1 hour at room temperature. The introduction of hydrogen sulfide leads to an exothermic reaction; the temperature should not be allowed to rise above 50 °C. After being allowed to stand for 5 hours under $H_2S$ pressure, the solution is heated for 1 hour at 60 °C. The pyridine is evaporated off *in vacuo*, the residue is dissolved in dichloromethane, and the solution is extracted with 2N HCl and water. The organic layer is then shaken with 2N NaOH, and carbon dioxide is passed through to precipitate the thioacetanilide. After filtration, washing with water, and drying, 11.7 g of a bright yellow, crystalline crude product melting at 68–73 °C is obtained (77%). Recrystallization from petroleum ether/benzene yields 10.9 g (72%) of long, pale yellow needles (m.p. 75–76 °C).

# Reactions of Elementary Silicon

BY DR. E. BONITZ

BADISCHE ANILIN- & SODA-FABRIK AG., LUDWIGSHAFEN (GERMANY) [*]

*Dedicated to Professor Hans Kautsky on the occasion of his 75th birthday*

*Elementary silicon is normally treated "dry" with gaseous reactants in a fluidized bed. The apparent inertness of ordinary silicon is due to surface passivation. Non-passivated silicon reacts as a strongly electropositive element. Finely divided silicon is pyrophoric and forms surface compounds with many substances (e.g. alcohol, water, and metal or organic halides) even at room temperature. An alternative to the "dry" process is a new suspension process, in which finely divided activated silicon, preferably suspended in its liquid reaction products (possibly in the presence of soluble catalysts) reacts at elevated pressures, generally with liquids. The reactions in suspension can be easily controlled, and all the silicon is consumed. Polysilanes often are the only initial products, and these react further in the homogeneous liquid phase to give monosilanes. For example, dissolution of ordinary silicon in methanol leads smoothly to methoxysilanes, which can add to unsaturated hydrocarbons.*

## I. Reactions of Elementary Silicon with Gases

A silicon crystal formally is a giant polysilane molecule. Substitutive cleavage of Si–Si bonds thus is formally equivalent to the breaking of polysilane bonds. Two particularly important reactions of elementary silicon are the reaction (a) with methyl chloride and the reaction (b) with chlorobenzene.

$$Si + CH_3Cl \xrightarrow{290\,^\circ C} (CH_3)_2SiCl_2 + CH_3SiCl_3 + (CH_3)_3SiCl \quad (a)$$

(by-products: $CH_3SiHCl_2$, $(CH_3)_4Si$, $HSiCl_3$, $SiCl_4$, HCl, $H_2$, lower hydrocarbons, soot)

$$Si + C_6H_5Cl \xrightarrow{350\,^\circ C} C_6H_5SiCl_3 + (C_6H_5)_2SiCl_2 \quad (b)$$

(by-products: biphenyl, benzene, HCl, $SiCl_4$, $HSiCl_3$, chlorinated biphenyls).

These reactions (Rochow reactions [1]) are used in industry for the preparation of methyl- and phenylchlorosilanes. These react with water to form organosilanols, which are polycondensed to organosiloxanes and silicones. This subject is discussed in a number of reviews [2–5].

### 1. Passivation Phenomena

The reaction of "dry" silicon with gases requires temperatures above 250 °C, with the result that many of the primary products undergo disproportionation, rearrangement, or decomposition; reactions (a) and (b) cannot be formulated as equilibrium reactions.

Reactions of silicon in the heterogeneous system solid/gas are relatively sluggish owing to inhibition. The following types of inhibition can be distinguished:

a) passivation by oxide formation

b) passivation by formation of other surface compounds

c) passivation by decomposition products.

Passivation by oxide formation occurs already when dry silicon is ground (particle size 0.1 to 100 μ) in air. However, passivation of this type can also be caused by moisture and by oxygen-containing impurities in the gaseous reactants, particularly at high temperatures. To break open such passive oxide layers, reaction (a) generally is carried out at an initial temperature of about 340 °C, this being reduced to about 290 °C after the reaction has started. The lower the reaction temperature in the heterogeneous solid/gas system, the smaller is the number of Si–Cl bonds in the products; thus the highest yield of Si–C bonds is obtained at the lowest temperature at which the reaction still proceeds sufficiently fast.

If the reactants are not completely free from oxygen and its compounds, the passive oxide layer is continuously reformed. Particles of the silicon-copper alloy, particularly those in which the surface is already "swollen" by the reaction, act as gas purifiers. The gaseous reactant is highly purified and parts of the Si surface become passive. Experience has shown that very pure substances react only slowly with one another.

Further, as the reaction proceeds, the surface is passivated by surface compounds, which are precursors of the silanes that subsequently escape as gases. This passivation is characteristic of the gaseous reactant, and is particularly pronounced in reactions with aryl halides (large organic radical).

Passivation by decomposition products such as soot and silicon carbide is typical of "dry" reactions of Si

[*] Previous address: Institut für Silicium-Chemie der Universität Marburg (Germany).

with organic halides, and increases with increasing consumption of silicon [27]. The formation of solid decomposition products is due to local overheating (low specific heat of gases). Soot is formed from methyl chloride above about 400 °C. In addition to this effect, the silicon content of the surface of copper-alloyed silicon particles decreases steadily as the reaction proceeds.

All these phenomena are opposed by mechanical abrasion of the surfaces, *e.g.* by friction between the particles; this explains why better results are obtained in large-scale production.

## 2. Examples of "Dry" Reactions

### a) Methylchlorosilanes

Methylchlorosilanes are prepared in a "Rochow furnace", which is operated at from 1 to 6 atm (types: flying dust [79], stirrer [80], vibration [81], or fluidized-bed reactors [9]). The silicon-copper alloy may also contain Zn, Ag, and other metals [6–27,49–57] (see Tables 1 and 2).

*Table 1. Methylchlorosilanes from elementary silicon and methyl chloride.*

| Notes | Si-alloy with | T [°C] | Ref. |
|---|---|---|---|
| $CH_4$, $CH_2{=}CH_2$, $H_2$ also formed | Cu | 260–400 | [6] |

The reaction is carried out with methyl chloride or methyl chloride/hydrogen chloride mixtures, often with added hydrogen or nitrogen (for the technical scheme see [23]). The methylchlorosilane mixture, which is condensed by cooling when prepared at atmospheric pressure, is characterized by the ratio methyltrichlorosilane/dimethyldichlorosilane [25]. Since the subsequent preparation of polymethylsiloxanes requires more dimethyldichlorosilane than methyltrichlorosilane, the aim should be to obtain a $CH_3SiCl_3/(CH_3)_2SiCl_2$ ratio of about 0.25, and to stop the reaction when the ratio rises to about 0.4. In many cases only 40 to 50 % of the silicon has reacted when this stage is reached.

An important problem is to minimize or to find a use for the residues, which generally are pyrophoric. The relatively high cost of methylchlorosilanes is due partly to the fact that the silicon is not efficiently utilized. Thus a considerable part of the silicon simply serves to bind "excess" of halogen from organic halides whose organic groups have been lost by decomposition.

In order to increase the utilization of silicon to about 80 % at a $CH_3SiCl_3/(CH_3)_2SiCi_2$ ratio $\leq$ 0.4, it has been suggested that the silicon grains [which paradoxically become larger instead of smaller during the reaction in the fluidized bed, while the concentration of copper in the surface increases (> 10 %)] should be continuously removed, reground in a jet mill operated with liquid methyl chloride at the speed of sound, and then returned to the fluidized bed [25, 27]. The pyrophoric residues from the methyl chloride reaction can be made to react with chlorobenzene at 400 to 500 °C to form phenyltrichlorosilane [26]. A number of publications deal with methods of increasing the proportion of $CH_3SiHCl_2$ [12, 18–20, 22], which is a valuable intermediate in the production of organofunctional silanes and siloxanes, and which can at present be obtained only as a by-product in the Rochow synthesis.

### b) Ethylchlorosilanes

The "dry" reaction of silicon with ethyl chloride or ethyl chloride/hydrogen chloride mixtures [28–32] (see Table 3) is of little industrial importance. The reaction involves residence times of from 10 to 20 sec at temperatures between 320 and 380 °C. The silicon balance is even less favorable than in the reaction with methyl chloride. At a silicon consumption (Cu-content up to 20 wt-%) of 10 to 20 %, the $(C_2H_5)SiCl_3/(C_2H_5)_2SiCl_2$ ratio is found to be from 0.4 to 0.5. At higher silicon conversions, the amounts of $SiCl_4$ and $HSiCl_3$ in the product increase rapidly, and the yield of ethylchlorosilanes decreases. The only industrial product marketed is ethyltrichlorosilane; however, this is not produced directly, but *via* trichlorosilane by Pt-catalysed addition of ethylene.

Table 3. Ethylchlorosilanes from elementary silicon (alloyed with Cu) and ethyl chloride

| Notes | T [°C] | Ref. |
|---|---|---|
| Metal composition: 70.2 % Si, 21.2 % Cu, 1.8 % Fe; yield: 200–300 g of ethylchlorosilane mixture [$C_2H_5SiHCl_2$ 14 %, $C_2H_5SiCl_3$ 25 %, $(C_2H_5)_2SiCl_2$ 43 %] per kg of charge per hour in the fluidized-bed process | 270–300 | [28] |
| | 270–300 | [28] |
| Ethylchlorosilane synthesis in the flow reactor | 200–320 | [29] |
| Fluidized-bed reactor; Cu 17 wt-%; yield: $C_2H_5SiHCl_2$ 50–60 %; $C_2H_5SiCl_3$ 22–28 % | 370 | [30] |
| Reactions in the fixed bed with $C_2H_5Cl/CH_2{=}CH_2/HCl$ mixtures; yield: up to 50 % $C_2H_5SiHCl_2$, 30 % $C_2H_5SiCl_3$, 20 % $(C_2H_5)_2SiCl_2$ | 320 | [31] |
| Fluidized-bed reactor, $N_2$ as protective gas | 360–370 | [32] |

A process which, in view of the high reaction temperature used, should be regarded as a "dry" rather than as a suspension process (cf. Section II. 3a) has received little attention. This process permits the use of ethylene/HCl mixtures instead of ethyl chloride; when all the silicon has been consumed, the product consists of approximately equal quantities of diethyldichlorosilane and ethyltrichlorosilane, together with up to 20 % of ethyldichlorosilane ($C_2H_5SiHCl_2$). In this process, a slurry of silicon and copper powder in liquid paraffin is treated with ethyl chloride or ethylene/HCl at 270 to 320 °C [33]. Unfortunately, at temperatures above 300 °C, liquid paraffin generally is not inert in the presence of small quantities of $AlCl_3$, and the cleavage products interfere with the separation of the ethylchlorosilanes in the mixture. It has therefore been proposed that the reaction should be carried out in $ZnCl_2/KCl/NaCl$ melts [34].

### c) Phenylchlorosilanes

The production of phenylchlorosilanes from silicon and chlorobenzene by the Rochow process requires the use

of specially active silicon containing copper (up to 20 wt-%) together with silver, zinc, and aluminum (only low Al contents are permissible, since the aluminum trichloride formed cleaves Si–C bonds). However, if mixtures of chlorobenzene with hydrogen chloride are used, aluminum trichloride catalyses the reaction of Si–H compounds with chlorobenzene, *e.g.*:

$$Cl_3SiH + C_6H_5Cl \xrightarrow[-HCl]{} Cl_3Si{-}C_6H_5$$

From the point of view of silicon consumption, phenylchlorosilanes are more economically synthesized *via* mono-, di-, and trichlorosilane [35–40]. The majority of the processes operate (see Table 4) above the critical range (critical data for chlorobenzene: 359 °C, 44.6 atm).

The principal product at temperatures between 200 and about 350 °C is trichlorosilane, formed in accordance with the overall Equation (c). By-products include $SiCl_4$

$$Si + 3\ HCl \rightarrow HSiCl_3 + H_2\ (\Delta H = -40\ kcal/mole) \qquad (c)$$

and small quantities of dichlorosilane, together with polysilicon chlorides $Si_nCl_{2+n2}$ (mainly $Si_2Cl_6$). Reaction (d) cannot become the principal reaction under the conditions of the "dry" process, since dichlorosilane

$$Si + 2\ HCl \rightarrow H_2SiCl_2 \qquad (d)$$

undergoes a further relatively fast reaction with excess of hydrogen chloride in accordance with Eq. (e), which is catalysed by Friedel-Crafts catalysts, particularly aluminum trichloride.

$$H_2SiCl_2 + HCl \rightarrow HSiCl_3 + H_2 \qquad (e)$$

Table 4. Phenylchlorosilanes from elementary silicon and chlorobenzene.

## d) Chlorosilanes

Chlorosilanes $H_nSiCl_{4-n}$ (n = 1,2,3) are important intermediates for the synthesis of organosilicon compounds. Si–H compounds can be added catalytically or thermally to alkenes and alkynes [82]. Chlorosilanes are produced by the reaction of elementary silicon with hydrogen chloride in the presence of copper [42–47] (see Table 5) in a fluidized-bed process, laboratory preparations generally being carried out in silica fluidized-bed furnaces.

## e) Alkoxysilanes

Dimethoxy- and trimethoxysilanes are reported to be formed when a mixture of Si, CuCl, and $ZnCl_2$ reacts with methanol at about 300 °C in the presence of hydrogen as a fluidizing gas [48]. According to our

results, the reaction leads to about 2 % of trimethoxysilane [see Eq. (f)] together with 98 % of tetramethoxysilane (based on silicon used).

$$Si + 3\ CH_3OH \xrightarrow{300\,^\circ C/H_2} (CH_3O)_3SiH + H_2 \qquad (f)$$

No reaction occurs below 290 °C. The difficulties mentioned in connection with the control of the Rochow reaction are even greater here, since the heat of reaction is greater.

### 3. Mechanism of the Reaction between Silicon and Methyl Chloride

*Hurd* and *Rochow*[58] studied the mechanism of the reaction of gaseous methyl chloride with solid silicon and the catalytic action of copper, and the subject has been re-examined by *Müller* and *Gümbel*[59–61]. Methyl radicals probably are formed by the action of copper on methyl chloride [Eq. (g)]. Copper(I) chloride reacts with

$$Cu + CH_3Cl \xrightarrow{> 250\,^\circ C} CuCl + \cdot CH_3 \qquad (g)$$

silicon above 250 °C in accordance with Equation (h). Both reactions are catalysed by aluminum trichloride[59,60]. Unfortunately, however, aluminum

$$CuCl + -\overset{|}{\underset{|}{Si}}- \longrightarrow [SiCl] + Cu \qquad (h)$$

chloride also catalyses the decomposition of methyl radicals into methane, carbon, hydrogen, *etc.* Free methyl radicals presumably attack polysilane bonds in the surface of silicon crystals at the points where chlorine atoms are already attached.

$$-\overset{Cl}{\overset{|}{Si}}-\overset{Cl}{\overset{|}{Si}}- + \cdot CH_3 + CuCl \longrightarrow -\overset{CH_3}{\overset{|}{Si}}- + Cl\overset{|}{Si}- + Cu \qquad (i)$$

A surface reaction of the type (i) appears even more likely in that it has been shown that such "polysilane bonds" can react directly with olefins to give Si–(C–C)–Si linkages[62]. On the other hand, attempts to make elementary silicon react directly with methyl radicals produced by the action of heat on tetramethyl-lead were unsuccessful[58].

## II. Reactions of Elementary Silicon in Suspensions

The work described in Section I suggests that silicon is a relatively unreactive element. However, *Kautsky*[63–65] has described a particularly reactive form of elementary silicon, which is obtained in accordance with Equation (k).

$$3\ CaSi_2 + 2\ SbCl_3 \xrightarrow[\text{in } o\text{-}Cl_2C_6H_4]{140-180\,^\circ C} 6\ [Si] + 2\ Sb + 3\ CaCl_2 \qquad (k)$$

It seemed likely that ordinary silicon could be made reactive if the surface passivation, which appears to be caused mainly by atmospheric oxygen, were eliminated or prevented. This possibility was first suggested by *Kautsky*: "The fresh cleavage surface of a silicon crystal strives to saturate the free valences produced, and surface compounds may therefore be formed"[63].

### 1. A New Route to Active Silicon

In 1955, with *Kautsky*'s experience as a basis, the author began a search for a simpler method for the production of active silicon. It was found that a chlorine carrier such as antimony trichloride [see Equation (k)] is not required, and that it actually interferes with the separation of the reaction products. Chlorine gas reacts directly and quantitatively with calcium disilicide at room temperature to form active silicon[66], which is thus readily obtainable [Eq. (l)]. $CaSi_2$ is ground in

$$CaSi_2 + Cl_2 \xrightarrow{20-40\,^\circ C} 2\ [Si] + CaCl_2 \qquad (l)$$

$CCl_4$ or $SiCl_4$ under conditions such that the fresh fracture surfaces cannot be passivated by atmospheric oxygen. Calcium disilicide that has been ground in the presence of air does not undergo this smooth and stoichiometric reaction.

Reaction (l), *i.e.* the reaction of a completely insoluble solid with a gas at atmospheric pressure to form a second solid, is unusual in silicon chemistry.

### 2. Reactivity of Active Silicon

The silicon obtained by the action of chlorine on $CaSi_2$ is even more reactive than that produced with antimony trichloride. It is pyrophoric, and ignites in methanol or water, where it "burns" to give mainly $SiO_2$; the reaction is accompanied by vigorous evolution of hydrogen. If the reaction with methanol is carried out in a diluent such as tetraethoxysilane, a quantitative yield of tetramethoxysilane is obtained; the reaction (m) can be catalysed with sodium methoxide.

$$[Si] + 4\ CH_3OH \xrightarrow{20-60\,^\circ C} Si(OCH_3)_4 + 2\ H_2 \qquad (m)$$

Active silicon reacts quantitatively with a further mole of chlorine to give silicon monochloride [Eq. (n)]. This compound is a yellow-red to orange solid which, like active silicon, is insoluble in all solvents.

$$2\ [Si] + Cl_2 \xrightarrow{20-40\,^\circ C} 2\ [SiCl] \qquad (n)$$

[63] *H. Kautsky*, Z. Naturforsch. *7b*, 174 (1952).

[64] *H. Kautsky* and *L. Haase*, Z. Naturforsch. *8b*, 45 (1953).

[65] *H. Kautsky* and *L. Haase*, Chem. Ber. *86*, 1226 (1953).

[66] *E. Bonitz*, Chem. Ber. *94*, 220 (1961).

Silicon monochloride reacts with further chlorine to give the following succession of products[67]:

$$n\,[SiCl] + (n-4)/2\,Cl_2 \rightarrow Si_nCl_{2n-4}\ (M \approx 1000)\ [*] \quad (o)$$

$$n\,[SiCl] + (n-2)/2\,Cl_2 \rightarrow Si_nCl_{2n-2}\ (M = 850\text{–}950)\ [*] \quad (p)$$

$$n\,[SiCl] + n/2\,Cl_2 \rightarrow Si_nCl_{2n}\ (M = 670\text{–}690)\ [*] \quad (q)$$

$$n\,[SiCl] + (n+2)/2\,Cl_2 \rightarrow Si_nCl_{2n+2}\ (M = 170\text{–}700)\ [**] \quad (r)$$

Mixed halides can be obtained by reactions similar to (n) to (r) if mixtures of halogens are used, or if different halogens are used in succession (reaction conditions: atmospheric pressure; maximum temperature 60 °C; copper and iron halides have a catalytic effect).

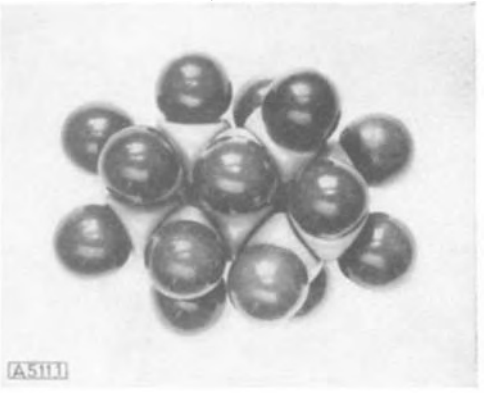
$$n\,[SiCl] + (n-2)/2\,Br_2 \rightarrow Si_nCl_nBr_{n-2} \quad (s)$$

Reaction (r) yields linear, colorless polysilicon chlorides, most of which can be distilled. The polysilicon chlorides obtained by reactions (o) to (q) become more intensely colored with increasing molecular weight, and fluoresce in ultraviolet light. Both properties had previously been observed only in cyclic silicon compounds. The cryoscopic molecular weights of compounds prepared by reactions (o) to (q) would also agree with cyclic structures. For example, $Si_{10}Cl_{18}$, a halide having the general formula $Si_nCl_{2n-2}$, is obtained in almost quantitative yield. It is a dark brown to yellow-red viscous liquid, which fluoresces yellow to orange-yellow in ultraviolet light, and crystallizes on prolonged standing under nitrogen.

Figs. 1 and 2 show Stuart-Briegleb molecular models of cyclic polysilicon chlorides. It is clear from these models that a silicon layer is enveloped by chlorine atoms, and they also show why the progressive chlorination of silicon crystals can stop with the formation of such polysilicon chlorides.

$Si_{10}Cl_{18}$ was discovered by *Schwarz* and *Köster*[68]. They obtained it by heating $Si_{10}Cl_{20}H_2$, prepared from $SiCl_4$ and silicon carbide in a current of $H_2$ in a quenching tube at 1000 °C[69]. Owing to the poor reproducibility of the experiments, the data published by these authors have repeatedly been questioned. However, we are able to confirm the properties described, particularly the solubility in benzene, the color, and the molecular weight.

In the active silicon obtained from the two-dimensional lattice of $CaSi_2$, practically all the polysilane bonds are accessible from the surface, owing to the lepidoidal structure[*]. On the other hand a compact silicon crystal can at first react only at its surface, and the reaction penetrates to deeper layers only when the products have been removed from the surface, either by mechanical means[70,71] or by a liquid reaction



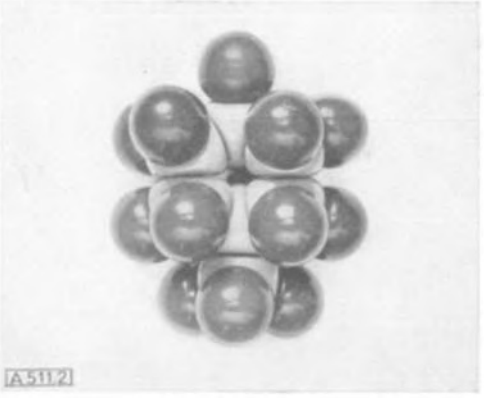


Fig. 2. $Si_7Cl_{14}$ ($M = 694$).

medium in which they are soluble[72]. There is no reason to believe that the active silicon obtained by the action of chlorine on $CaSi_2$ is fundamentally different from ordinary silicon[**] once the passive layer has been removed from the latter.

In any case, identical silicon compounds have been obtained from the two types under identical reaction conditions, and particularly at the same temperature[***]. This is also true in the case of ferrosilicon grades containing from 15 to 98 % of silicon. In continuous processes, the small quantity of impurities present in ordinary silicon makes it superior to active silicon, which contains about 66.5 wt-% of $CaCl_2$.

Active silicon produced from $CaSi_2$, as well as solid [SiCl], [SiBr] and [$SiOCH_3$], are excellently suited to the study of heterogeneous reactions of polysilane bonds. $Si_{10}Cl_{18}$ is very useful for the study of homogeneous reactions, owing to its ready solubility in hydrocarbons; it reacts in the same way as silicon dichloride (it formally contains 80 % of $SiCl_2$ groups).

Investigations on these test substances have led to the discovery of new reactions of the Si-Si bond. Thus ethylene reacts with polysilanes to form Si–(C–C)–Si linkages[62]; this reaction was first observed with [SiCl]. Polymerization of olefins in the presence of polysilanes, which may contain halogen or organic substituents, leads to polyolefins with silicon atoms in the polymer chains[73,74].

[71] German Pat. Appl. B 42296 IVb 120 (Oct. 17th, 1956), inventor: *E. Bonitz*

[72] German Pat. 1079607 (1958), BASF, inventor: *E. Bonitz*.

[**] Debye-Scherrer diagrams have also failed to provide evidence of the existence of another modification of silicon (*E. Hengge*, personal communication).

[***] The only difference is in the rates of the reactions. For example, the rate of reaction of a 98 % technical silicon with $Cl_2$ in tetrachloroethane suspension is generally from one fifth to one tenth of the rate for an active silicon obtained from $CaSi_2$.

### 3. Activation of Ordinary Silicon

#### a) Action of Ethyl Chloride on Silicon Suspended in Ethylchlorosilanes

Ethyl chloride is much less suitable for reaction with silicon than the thermally more stable methyl chloride. Ethyl chloride decomposes relatively quickly above 250 °C, giving ethylene and hydrogen chloride; consequently, satisfactory yields of ethylchlorosilanes cannot be obtained above this temperature. Thus the problem is to activate technical silicon to such an extent that the reaction can be carried out below 300 °C, and to maintain the activity throughout the reaction.

The best method is to produce fresh fracture surfaces by grinding the silicon in liquid alkylchlorosilanes, for example. Elementary silicon then becomes extremely reactive. Thus *Köster* [75] writes:

> If, after the pulverization of silicon in extremely pure argon, the vibratory mill is stopped and chlorine introduced, no reaction occurs. When the mill is switched on again, however, the reaction proceeds with explosive violence....

We offer the following explanation: The dry grinding of the silicon produces only a few active sites, on which silicon monochloride is formed instantaneously, so protecting underlying layers from further attack by chlorine at normal temperatures. However, if the surface chloride is rubbed off by further grinding, it reacts vigorously. Since the heat of reaction cannot be led away rapidly enough, the reaction leads mainly to silicon tetrachloride. If, on the other hand, activation by grinding is carried out in a liquid diluent (generally the products of an earlier reaction), the activity of the silicon in suspension is retained indefinitely.

An active silicon suspension is dark brown to brick and greasy, whereas an inactive suspension is graphite grey and hardly greasy. An active suspension of this type reacts with ethyl chloride at 90 °C in accordance with Equation (t) [76], with consumption of the silicon crystals and formation of polyethylchlorosilane as almost

$$n\,Si + n\,C_2H_5Cl \xrightarrow{90\text{-}150^\circ C} -\left[\begin{array}{c} C_2H_5 \\ | \\ -Si- \\ | \\ Cl \end{array}\right]_n- \qquad (t)$$

the only product. Reaction of the same starting materials at 180 to 220 °C leads quantitatively to ethylchloromonosilanes, possibly in accordance with Scheme (u).

$$-\left[\begin{array}{c} C_2H_5 \\ | \\ -Si- \\ | \\ Cl \end{array}\right]_n- + n\,C_2H_5Cl \xrightarrow{>150^\circ C}$$

$$\frac{n}{a}(C_2H_5)_2SiCl_2 + \frac{n}{b}C_2H_5SiCl_3 + \frac{n}{b}(C_2H_5)_3SiCl \qquad (u)$$

$(n/a + 2n/b = 1)$

No difficulties arise in connection with heat exchange, since the liquid and subsequently vaporizing alkyl halide can remove almost any amounts of heat produced in the reaction. It is preferable to use elevated pressures.

The smoothness of reactions (t) and (u) is reminiscent of the analogous reaction (v) of aluminum with ethyl chloride, which leads to the formation of "ethylaluminum sesquichloride" [77, 78].

$$2\,Al + 3\,C_2H_5Cl \xrightarrow{40\text{–}180\,^\circ C} Cl_3Al_2(C_2H_5)_3 \qquad (v)$$

#### b) Reaction of Silicon with Methyl and Ethyl Chlorides in Liquid Paraffin

In attempts to carry out the Rochow reaction "dry" in a tube with active silicon produced from calcium silicide, the silicon reacted spontaneously in the methyl chloride stream at about 200 °C. To avoid this spontaneous reaction, active silicon was slurried in liquid paraffin (b.p. 340–380 °C). If methyl chloride is introduced at 180 to 200 °C and normal pressure, methylchlorosilanes distil off after a time. The reaction does not require additional catalysts, but it is facilitated particularly by paraffin-soluble copper compounds, such as copper(II) acetylacetonate.

Though the technical calcium silicide [*] used contained about 10 % by weight of ordinary silicon, the solid reaction residue consisted entirely of calcium chloride. The ordinary silicon had evidently been activated in a mixture with "active" silicon and consumed. The silicon component of ferrosilicon (25 wt-% Si) suspended in liquid paraffin also reacted quantitatively with methyl chloride. The residue consisted of silicon-free, pyrophoric iron (a sort of "Raney iron") [70, 71] [**].

### 4. New "Halogen-Free" Syntheses

Organosilanols cannot generally be isolated as the primary products of the hydrolysis of organochlorosilanes, but immediately condense under the influence of the hydrochloric acid formed to give organic polysiloxanes.

There had previously been no industrially useful syntheses of silanes not involving halogen compounds. It was therefore desirable to seek for a "halogen-free" silane synthesis, and for a method for the synthesis of organosilanes, organosilanols, or organosiloxanes from

[**] These studies were carried out in 1956-1958 with a stainless steel agitator having a ball mill in the hemispherical bottom.

elementary silicon, unsaturated hydrocarbons (or their derivatives) and water [83,84].

Elementary silicon dissolves readily in lower alcohols, particularly methanol, to form alkoxysilanes. (The reaction conditions and methods are identical with those described earlier.)

Reactions (w) and (x) take place between 20 and about 220 °C (preferably between 150 and 200 °C) and at 1 atm or slightly higher pressures. The yields per unit volume and per unit time are higher than in any other reaction of elementary silicon, and no metal catalysts are required.

$$Si + 3\,CH_3OH \rightarrow (CH_3O)_3SiH + H_2 \quad (w)$$

$$Si + 2\,CH_3OH \rightarrow (CH_3O)_2SiH_2 \quad (x)$$

Compounds containing more than two Si–H bonds may be obtained by disproportionation, *e.g.* in accordance with Equation (y).

$$2\,(C_3H_7O)_2SiH_2 \rightarrow (C_3H_7O)_4Si + SiH_4 \quad (y)$$

An example is the production of propylsilanetriol from silicon (98 % Si, 1.8 % Fe, 0.1 % Al, 0.1 % Ca), propene, and water. The methanol required to dissolve the silicon is regenerated on hydrolysis of the propyltrimethoxysilane, and can be recycled to reaction (z) if desired.

$$Si + 3\,CH_3OH \xrightarrow[5-7\ atm]{180-190\,^\circ C} HSi(OCH_3)_3 + H_2 \quad (z)$$

$$HSi(OCH_3)_3 \xrightarrow[40-50\ atm]{150\,^\circ C,\ +\,CH_3-CH=CH_2,\ Fe(CO_5)\ [85]} C_3H_7Si(OCH_3)_3$$

$$C_3H_7Si(OCH_3)_3 \xrightarrow{+3H_2O} C_3H_7Si(OH)_3 + 3\,CH_3OH$$

If the temperature rises above 250 °C during the reaction of silicon with lower alcohols, the reaction may become explosive, with intense evolution of heat and formation of $SiO_2$, SiC, soot, $H_2$, and hydrocarbons as the only products.

## III. Comparison of the Two Processes

In the "dry" process, the gaseous reactant is always present in excess relative to the amount of silicon in the active part of the surface of the solid. The reaction products are therefore monosilanes. In the suspension process, the active silicon phase is present in excess, the other reactant being added as it is consumed. Consequently, the primary products are polysilanes, which are initially solid, and subsequently become liquid. Liquid polysilanes are autoxidizable, and so protect the active silicon phase against oxide passivation. Polysilanes formed have an autocatalytic effect. Liquid polysilanes react in solution with compounds that cleave Si–Si bonds (*e.g.* halogen compounds, metal alkyls, alkali metals, or bases), to give monosilanes.

The "dry" process never even approaches chemical equilibrium. The losses due to thermal decomposition are too great to allow recycling of unwanted reaction products. In the suspension process, on the other hand, equilibria can be established, and unwanted reaction products can be recycled.

The "dry" process requires temperatures of about 300 °C or higher, whereas a maximum temperature of 200 °C generally suffices in the suspension process. Heat exchange is difficult to control in the "dry" process. In the suspension process, on the other hand, the heat of reaction can be compensated by the heat of vaporization of liquid components (solvent, reactant).

Processes in which the grinding and the reaction are carried out in separate vessels are preferred. To avoid spontaneous reactions, it is recommended that the mill should be cooled. Dry silicon powdered in the presence of air and slurried in liquids may react suddenly when an attempt is made to start the reaction. Grinding and reaction in alcohols, ethers, esters, and ketones is particularly dangerous.

It appears that any substance that reacts with silicon can also form passive layers. Even pure halogens can passivate the surface of the silicon crystals against further attack by halogen. These thin passive layers can apparently be broken open when the temperature is raised, with the result that a spontaneous reaction takes place.

*Thanks are due to the Deutsche Forschungsgemeinschaft for support of the part of this work carried out at the Institut für Silicium-Chemie der Universität Marburg. Other parts of the work were performed at the Badische Anilin- & Soda-Fabrik, Ludwigshafen. I am especially grateful to Prof. Dr. H. Kautsky.*

# Syntheses and Reactions of O,N,N′-Trisubstituted Isoureas

BY DR. E. DÄBRITZ [*]

INSTITUT FÜR ORGANISCHE CHEMIE DER UNIVERSITÄT MÜNCHEN (GERMANY)

*The $CuCl_2$-catalysed addition of alcohols to aliphatic carbodiimides (particularly diisopropylcarbodiimide) to form O,N,N′-trialkylisoureas may, in the case of bifunctional hydroxy compounds (esters of α-hydroxycarboxylic acids, diols, halogeno alcohols, amino alcohols, and cyclic hydroxy ethers), continue to give 5-, 6-, and 7-membered 1,3-O,N or 1,3-N,N heterocycles. O,N,N′-Trialkylisoureas are selective alkylating agents. Thus alcohols with allyl structures can be etherified with diisopropylcarbodiimide; a new method of esterification via O,N,N′-trialkylisoureas has been applied to mesitylenecarboxylic acid.*

## Introduction

The addition of alcohols to carbodiimides has been known since the end of the last century [1]. The isourea ethers *(1)* were prepared from "carbodiphenylimide", di-(*o*-tolyl)-, or di-(*p*-tolyl)-carbodiimide under pressure and at elevated temperatures [2] or with the aid of sodium alkoxides [3,4], and until about 10 years ago these were the only known compounds of this class [5].

$$ROH + R'N{=}C{=}NR'' \longrightarrow R'N{=}\underset{\displaystyle OR}{\overset{\displaystyle |}{C}}{-}NHR'' \quad (1)$$

The lack of interest in this reaction probably was due to the fact that the carbodiimides available at that time were troublesome to prepare [1,6] and had a marked tendency to polymerize [1,7]. This is particularly true of the only aliphatic carbodiimides known in 1938 [8], *viz.* diethyl- [9] and di-(n-propyl)carbodiimides [10,11]. The first indication that dicyclohexylcarbodiimide is not attacked by alcohols came in 1939 [12]. During the preparation of a number of new *N,N′*-diarylisoureas by the alkoxide method, *Khorana* [13] found that dicyclohexylcarbodiimide does not react with alcohols (*e.g.* n-butanol) under these conditions. *Erich Schmidt*'s work on the stabilities [14,15] of aliphatic carbodiimides and economical methods for their preparation [16] laid the foundations for an investigation of the addition of alcohols to aliphatic carbodiimides. It is now possible to obtain most *O,N,N′*-trialkylisoureas by addition of alcohols to aliphatic carbodiimides.

### 1. O,N,N′-Trialkylisoureas from Monofunctional Alcohols

The only cases of spontaneous addition of hydroxy groups are found in the cyclization of *N*-(β-hydroxyethyl)-*N′*-alkylcarbodiimides *(2)* formed *in situ* from thioureas and mercuric oxide. The products are 2-iminooxazolidines *(3)*, which may be regarded as cyclic isourea ethers. Similarly, the product obtained from 3-(hydroxypropyl)allylcarbodiimide has been assumed to have the structure of a 2-allyliminotetrahydro-1,3-oxazine [14].

*(2a)*, R = $C_6H_5$; R' = Alkyl, Aryl [17] *(3)*
*(2b)*, R = H; R' = Allyl [8]

The addition of alcohols to aliphatic carbodiimides became possible with the discovery by *Schmidt* and *Moosmüller*[18] that the reaction is catalysed by copper salts. In the presence of copper(I) or copper(II) chloride (*e.g.* 0.075 mmole of $CuCl_2$ per 100 mmole of diisopropylcarbodiimide[19]), equimolar amounts of primary, secondary, or tertiary alcohols without solvents react at room temperature in a slightly exothermic reaction. The *O,N,N'*-trialkylisoureas *(1)* that have so far been prepared by this method are shown in Table 1.

Carbodiimides are weakly electrophilic. As shown by the reactivities of differently substituted carbodiimides in the addition of water[23], the electrophilic strength of the central carbodiimide carbon atom increases as the basicity of the adjacent N atoms decreases. This is taken into account in the use of diarylcarbodiimides, though the effect achieved with phenyl and tolyl groups is very small: high temperatures and pressures are required for the addition of alcohols[2].

Although the presence of alkoxide[3,4] increases the chance of nucleophilic attack by the alcohol, the tendency of the carbodiimide to undergo addition remains weak, so that aliphatic carbodiimides such as dicyclohexylcarbodiimide cannot react under these conditions.

Acid catalysis increases the electrophilic strength of the carbodiimide to such an extent that vigorous addition of water takes place; similarly, the many known additions of H-acids[1] are initiated by a proton addition[24]. The possibility of acid-catalysed addition of alcohol was noted by *Stieglitz*[2] in his first preparations of "isourea ethers".

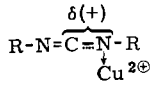
[24] *E. Vowinkel*, Chem. Ber. *96*, 1702 (1963), has studied the solvent-dependence of the addition of phenols to carbodiimides, and concluded that the reaction proceeds by simultaneous addition of the proton and the phenoxide ion.
[25] *H. G. Khorana*, Canad. J. Chem. *32*, 261 (1954).

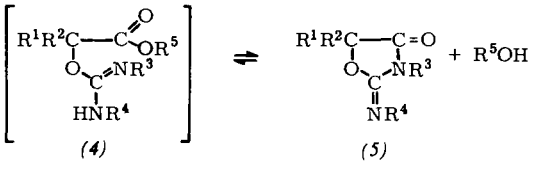
The catalytic action of metal halides such as copper(II) chloride and zinc chloride [26] presumably is due to coordination by nitrogen, with a consequent marked increase in the reactivity of the carbodiimide carbon towards nucleophiles.



## 2. O,N,N′-Trialkylisoureas Containing Another Functional Group

### 2.1. Esters of α-Hydroxycarboxylic Acids and Dialkylcarbodiimides

The first example of a secondary reaction following the $CuCl_2$-catalysed addition of alcohols was observed in the reaction of esters of α-hydroxycarboxylic acids with dialkylcarbodiimides to give 2-imino-4-oxazolidones *(5)* [22] (cf. Table 2); this reaction presumably proceeds *via* the initial product *(4)*, which cannot be isolated. The alcohol $R^5OH$ that is formed must be removed from the equilibrium by a second mole of carbodiimide.



*(4)* *(5)*

This cyclization was the first indication that the dominant chemical characteristic of *O,N,N′*-trisubstituted isoureas is the nucleophilic activity of the imino nitrogen. This nucleophilic activity is the basis of nearly all the reactions described in the present paper.

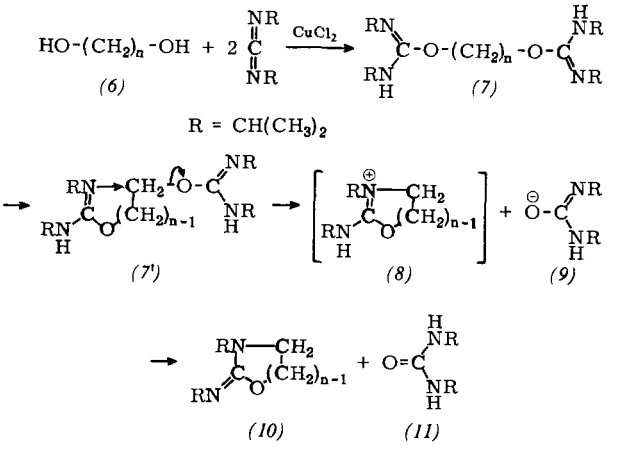
Table 2. 2-Imino-4-oxazolidones *(5)* prepared from methyl or ethyl α-hydroxycarboxylates and aliphatic carbodiimides [21,22].

| $R^1$ | $R^2$ | $R^3$ | $R^4$ | Yield [%] | B.p. [°C/mm Hg] | $n_D^{20}$ | $d_4^{20}$ |
|---|---|---|---|---|---|---|---|
| H | H | i-Pr | i-Pr | 91 | 96–98/10 | 1.4662 | 1.0161 |
| H | H | Me | t-Bu | 96 | 101–103/13 | 1.4755 | 1.0510 |
| $CH_3$ | H | i-Pr | i-Pr | 92 | 92–94/11 | 1.4569 | 0.9798 |
| $CH_3$ | H | Me | t-Bu | 90 | 89–91/10 | 1.4638 | 1.0061 |
| $CH_3$ | $CH_3$ | Me | t-Bu | 72 | 85–87/10 | 1.4560 | 0.9783 |

### 2.2. Bifunctional Alcohols and Dialkylcarbodiimides

The reactions of diols *(6)* with diisopropylcarbodiimide can be represented by the following sequence, which leads either to *O,O′*-alkylenebisisoureas *(7)* or 1,3-oxaza compounds *(10)* and *N,N′*-diisopropylurea *(11)*.

[26] *E. Schmidt, A. Reichle, M. Wandel*, and *W.-R. Carl*, German Published Pat. Appl. 1181202 (1962).



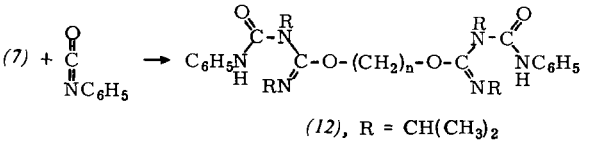
*(6)* *(7)*

R = $CH(CH_3)_2$

*(7′)* *(8)* *(9)*

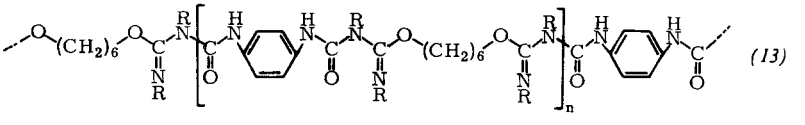
*(10)* *(11)*

The addition of the diol to two moles of carbodiimide leads to the acyclic product if the alcohol contains more than three methylene groups (n > 3). The *O,O′*-alkylenebis-(*N,N′*-diisopropylureas) *(7)* (n = 4,6) [19,19a], which are obtained in almost quantitative yields, react with phenyl isocyanate to form biuret-like adducts *(12)*, which may be regarded as derivatives of *N,N′*-diisopropyl-*N*-(*N*-phenylcarbamoyl)isourea.



*(12)*, R = $CH(CH_3)_2$

Diisocyanates such as n-hexylene diisocyanate or *p*-phenylene diisocyanate react with *O,O′*-alkylenebis-isoureas such as *(7)* (n = 6) to form linear macromolecules *(13)*.



*(13)*

The primary adducts of ethylene glycol and 1,3-propanediol with diisopropylcarbodiimide undergo spontaneous cyclization, initiated by an intramolecular $S_N2$ attack by the imino nitrogen. This step of the reaction can be followed by the color changes [19], which are probably due to the coordinated copper(II) ion in the activated carbodiimide.

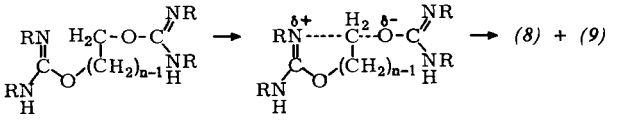
Proton transfer from the resonance-stabilized cyclic isouronium ion *(8)* to the strongly basic isourea anion *(9)* [27] leads to 3-isopropyl-2-(isopropylimino)oxazolidine *(10)* (n = 2) [28] or 3-isopropyl-2-(isopropylimino)tetrahydro-1,3-oxazine *(10)* (n = 3), together with *(11)* [19a].

[27] *D. V. Kashelikar* and *C. Ressler*, J. Amer. chem. Soc. *86*, 2467 (1964), have also proposed an intramolecular substitution with displacement of the isourea anion for the dehydration of carbobenzoxy-L-asparagine and carbobenzoxy-L-glutamine with dicyclohexylcarbodiimide to the nitriles of the corresponding ω-amino acids.

[28] 2-Arylimino-3-methyloxazolidines can be prepared from isocyanide dichlorides and *N*-methylethanolamine: *E. Kühle*, Angew. Chem. *74*, 861 (1962), Table 2; Angew. Chem. internat. Edit. *1*, 647 (1962).

The reaction with ethylene cglyol is so vigorous that cooling is necessary in order to avoid a reduction in yield. The formation of the sterically less favored tetrahydrooxazine ring requires longer reaction times and slight heating if good yields are to be obtained. *O,O'*-Butylenebisisourea *(7)* (n = 4) can be isolated, and must be heated for 15 hours at 120 °C to obtain *(11)* and the strained 7-membered ring system of 3-isopropyl-2-(isopropylimino)hexahydro-1,3-oxazepine *(10)* (n = 4)[19].

These reactions, like all the other $S_N2$ reactions described below, which are characterized by charge separation in the transition state *(8a)*, should be favored by polar solvents,

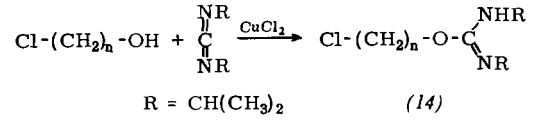


*(7)* *(8a)*

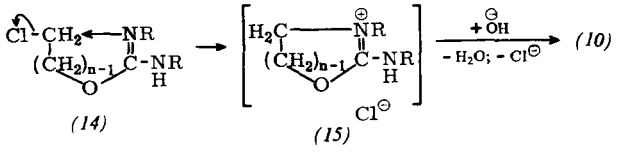
as has been found experimentally. The usual solvent is dimethylformamide, which also facilitates the removal of the *N,N'*-diisopropylurea, since this is only sparingly soluble in cold dimethylformamide. It has also been found advantageous to add dimethylformamide in some additions that proceed without secondary reactions.

### 2.3. Dialkylcarbodiimides and Halogeno Alcohols Containing Primary Hydroxy Groups

α,ω-Halogeno alcohols undergo ring closure, *e.g.* to form iminium chlorides *(15)*, from which the 2-imino 1,3-oxaza compound *(10)* is liberated by aqueous $K_2CO_3$, NaOH, or KOH.



R = $CH(CH_3)_2$ *(14)*



*(14)* *(15)*

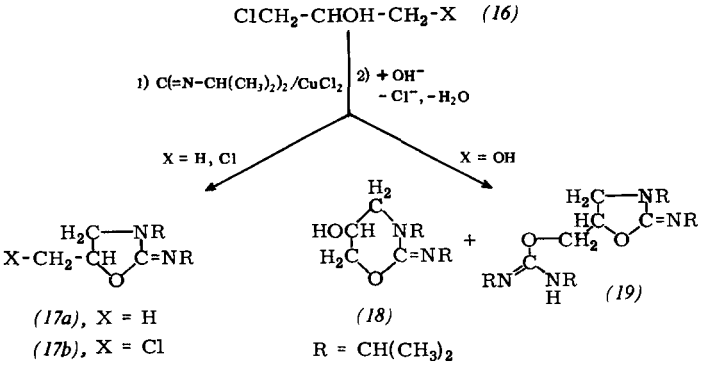
An exception is 4-chlorobutan-1-ol, from which the open-chain isourea *(14)* (n = 4) can be obtained; the 1,3-oxazepine *(10)*, n = 4, is formed only after prolonged heating.

Table 3. 2-Imino-1,3-oxaza compounds *(10)* synthesized from diisopropylcarbodiimide and diols (method I) or halogeno alcohols (method II).

| n | B.p. [°C/mm Hg] | $n_D^{20}$ | $d_4^{20}$ | Infrared C=N band [cm⁻¹] | Yield [%] method I | Yield [%] method II | Ref. |
|---|---|---|---|---|---|---|---|
| 2 | 86–87/9 | 1.4603 | 0.9398 | 1682 | 91 | 78 | [19, 19a] |
| 3 | 95/9 | 1.4709 | 0.9448 | 1642 | 91 | 74 | [19, 19a] |
| 4 | 96–97/10 | 1.4659 | 0.9247 | 1684 | 83 | 34 | [19] |

### 2.4. Dialkylcarbodiimides and Halogeno Alcohols Containing Secondary Hydroxy Groups

Alcohols of the type *(16)* react in accordance with the following scheme:



*(17a)*, X = H
*(17b)*, X = Cl

*(18)*
R = $CH(CH_3)_2$

*(19)*

1-Chloropropan-2-ol [*(16)*, X = H] and 1,3-dichloropropan-2-ol [*(16)*, X = Cl] give 5-methyl- and 5-chloromethyl-2-iminooxazolidines *(17a)* and *(17b)*; the yields of these products are lower than those obtained from primary halogeno alcohols.

Treatment of 1-chloropropane-2,3-diol [*(16)*, X = OH] with two moles of diisopropylcarbodiimide in dimethylformamide does not lead to the expected halogenated 5-membered cyclic bases and diisopropylurea. Instead, the product is a mixture of two compounds, to which the structures *(18)* and *(19)* have been assigned on the basis of their infrared spectra and elementary analyses.

Table 4. Products obtained by the reaction of halogeno alcohols Cl–$CH_2$–CH(OH)–$CH_2$X with diisopropylcarbodiimide.

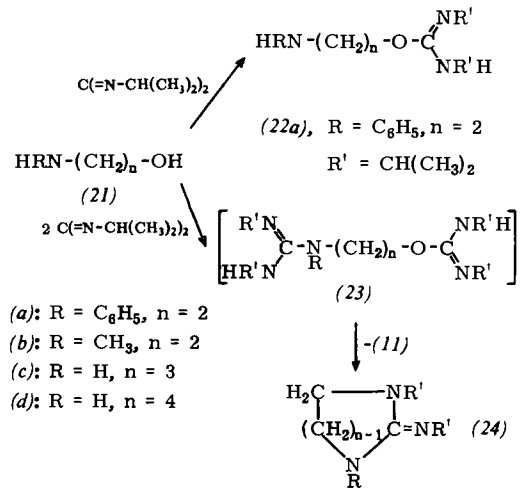
| X | End product | Yield [%] | B.p. [°C/mm Hg] | $n_D^{20}$ | $d_4^{20}$ | Infrared C=N band [cm⁻¹] |
|---|---|---|---|---|---|---|
| Cl | *(17b)* | 62 | 113–114/9 | 1.4791 | 1.0448 | 1682 |
| H | *(17a)* | 33 | 92–93/10 | 1.4597 | 0.9170 | 1685 |
| OH | *(18)* | (81) | 105–106/0.02 | 1.4788 | – | 1665 |
| | *(19)* | 74 (19) | 124–125/0.02 | 1.4755 | – | 1682 |

### 2.5. Dialkylcarbodiimides and Amino Alcohols Containing Primary or Secondary Amino Groups

Alcohols such as *(20)* containing tertiary amino groups react with diisopropylcarbodiimide almost quantitatively to give *O,N,N'*-trialkylisoureas or *O,O'*-al-

$R^1R^2N$–$CH_2$–$CH_2OH$ *(20a)* $R^1$, $R^2$=$C_2H_5$
*(20b)* $R^1$=$CH_3$, $R^2$=$C_6H_5$
*(20c)* $R^1$=$HOCH_2$–$CH_2$, $R_2$=$CH_3$

kylidenebis-*N,N'*-dialkylisoureas (cf. Table 1) without secondary reactions. On the other hand, primary or secondary amino groups in the β, γ, or δ positions with respect to the hydroxy group [as in the amino alcohols *(21)*] cause intramolecular substitutions in the diisopropylcarbodiimide adduct:



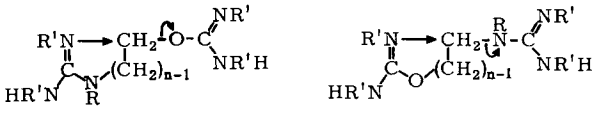
Whereas the amino alcohol *(21a)* reacts with diisopropylcarbodiimide (molar ratio 1:1) to give the *O,N,N'*-substituted isourea *(22a)* (yield 99%) [19,19a], the corresponding compound *(21b)* with aliphatic instead of aromatic substituents gives a number of products. For a stoichiometric reaction it is necessary to use two moles of carbodiimide per mole of *N*-methylethanolamine *(21b)*; cyclization to 2-isopropylimino-1-methylimidazolidine *(24a)* then occurs. Similarly, *(21c)* and *(21d)* react to form 3-isopropyl-2-(isopropylimino)hexahydropyrimidine *(24c)* and 3-isopropyl-2-(isopropylimino)heptahydro-1,3-diazepine *(24d)*, respectively.

Table 5. Cyclic guanidines *(24)* obtained from amino alcohols and diisopropylcarbodiimide.

| End product | Yield [%] | B.p. [°C/mm Hg] | $n_D^{20}$ | $d_4^{20}$ | Infrared C=N band [$cm^{-1}$] |
|---|---|---|---|---|---|
| *(24b)* | 84 | 93–94/9 | 1.4766 | 0.9133 | 1662 |
| *(24c)* | 82 | (m.p. 71 °C) | — | — | 1599 [*] |
| *(24d)* | 77 | 107–109/13 | 1.4741 | — | 1620 |

[*] In KBr.

The first step in the reaction of carbodiimides with the amino alcohols *(21b)* to *(21d)* probably is similar to the first step in the formation of bisisoureas *(7)* from diols. In the former case, however, instead of two hydroxy groups, one hydroxy group and an amino group add to two molecules of the carbodiimide to form the hypothetical adduct *(23)* in the primary step[29]. The subsequent ring closure is again induced by the influence of a neighboring group. In the diol cyclization, the imino nitrogen displaces an isourea group [see formula *(7')*]; in the asymmetric adduct *(23)*, on the other hand, the substitution can follow one of two courses, giving either cyclic guanidines [*via (25)*] or oxaza compounds [*via (26)*].



*(25)* *(26)*

R = $CH_3$, H; R' = $CH(CH_3)_2$; n = 2, 3, 4

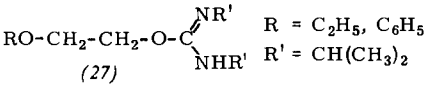
[29] The amino group is added more readily than the alcohol group; the preparation of substituted guanidines from carbodiimides has been known for a very long time, cf. *W. Weith*, Ber. dtsch. chem. Ges. *8*, 1530 (1875); Houben-Weyl: Methoden der organischen Chemie, 4th ed., Thieme, Stuttgart 1952, vol. 8, p. 182.

The products obtained [evidently *via* the complex *(25)*] are the 1,3-diaza compounds *(24b)* to *(24d)*, in agreement with theoretical expectations. The urea anion can leave the complex more easily than the guanidine anion. *Hammett* and *Pfluger*[30] showed, from the rates of displacement of other substituents by the trimethylamino group, that substituents that would react readily as entering groups are slow to leave the molecule. Thus the high nucleophilic activity of the guanidine group is in agreement with its reluctance to leave the molecule as a guanidyl anion in accordance with the model *(26)*.

Ring closures with acylated carbodiimides[31] probably are also based on intramolecular substitutions involving the guanidine group.

### 2.6. Hydroxy Ethers and Dialkylcarbodiimides

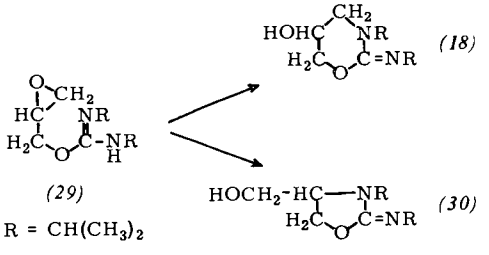
The carbodiimide adducts *(27)* of β-alkoxy alcohols do not enter into secondary reactions as shown by the



*(27)*

cases of the monoethyl[18] and monophenyl[19,19a] ethers of ethylene glycol (cf. also Table 1).

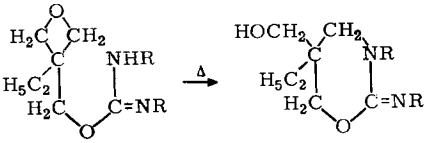
Strained cyclic ethers with β- or γ-hydroxy groups (cf. Table 6) can undergo ring cleavage following the addition step. 2,3-Epoxy-1-propanol *(28)* reacts first to form *(29)*, which then suffers spontaneous cleavage of the strained 3-membered ring. The strongly exothermic reaction leads to a mixture of two products, for which the structures *(18)* and *(19)* have been proposed[19].



*(29)* *(18)* *(30)*

R = $CH(CH_3)_2$

The oxetane *(31)* is less strained, so that the adduct *(32)* of 3-ethyl-3-hydroxymethyloxetane and diisopropylcarbodiimide is partially converted into the tetrahydro-1,3-oxazine *(33)* only on distillation; prolonged boiling in petroleum ether leads to *(33)* as the sole product. The ring cleavage can be followed by the disappearance of the characteristic oxetane band at 978 $cm^{-1}$ in the infrared spectrum[32].



*(32)* R = $CH(CH_3)_2$ *(33)*

[30] *L. P. Hammett* and *H. L. Pfluger*, J. Amer. chem. Soc. *55*, 4079 (1953).

[31] *K. Hartke* and *J. Bartulin*, Angew. Chem. *74*, 214 (1962), Angew. Chem. internat. Edit. *1*, 211 (1962).

[32] *L. J. Bellamy*: The Infrared Spectra of Complex Molecules. Methuen, London, 1958, p. 119.

As was shown for the adducts of carbodiimides with furfuryl and tetrahydrofurfuryl alcohols (see Table 1), the strainless 5-membered ring containing ether oxygen is stable towards the –N=C(OR)–NH grouping. Thus 1,4;3,6-dianhydro-D-sorbital *(34)* reacts with diisopropylcarbodiimide to form a crystalline monoadduct or a liquid diadduct, depending on the conditions [19].

Table 6. Products obtained by the reaction of cyclic hydroxy ethers with diisopropylcarbodiimide [19].

| Starting material | End products | Fraction of total [%] | Yield [%] | B.p. [°C/mm Hg] (m.p. [°C]) | $n_D^{20}$ | $d_4^{20}$ | Infrared C–N band [cm$^{-1}$] |

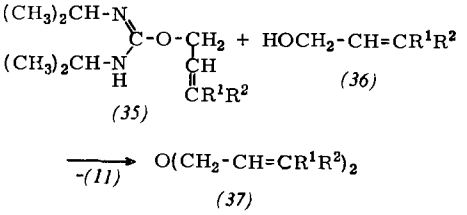
## 3. Alkylations and Condensations with O,N,N'-Trialkylisoureas

### 3.1. Etherification of Allyl Alcohols

The $CuCl_2$-catalysed reaction of equimolar amounts of diisopropylcarbodiimide with allyl alcohol leads to the isourea *(35a)*. Cinnamyl alcohol *(36b)*, and geraniol *(36c)* give mixtures of the ethers *(37b)* or *(37c)*, respectively, with diisopropylurea *(11)*. It appears that the carbodiimide adduct *(35b)* or *(35c)* initially formed alkylates unchanged alcohol *(36)*.



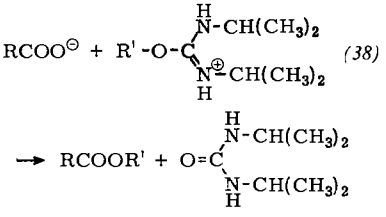
*(a)*: $R^1$, $R^2$ = H
*(b)*: $R^1$ = $C_6H_5$; $R^2$ = H
*(c)*: $R^1$ = $(CH_3)_2C{=}CH{-}CH_2{-}CH_2$; $R^2$ = $CH_3$

Allyl alcohol also can be etherified if the alcohol and the carbodiimide are used in a molar ratio of 2:1. The ethers *(37a)* to *(37c)* (yields 16, 37, and 60 %, respectively [19]) obtained when the alcohol is heated for 130 hours at 80 to 120 °C with diisopropylcarbodiimide are contaminated with allyl rearrangement products and resins.

[33] *M. S. Newman*, J. Amer. chem. Soc. *63*, 2431 (1941).

### 3.2. Esterifications

*O,N,N'*-Trialkylisoureas thus can act as alkylating agents. Carboxylic acids should be much more readily "alkylated" with these agents than are the allyl alcohols. The 1:1 combination of a monobasic carboxylic acid with the monoacid isourea ether should provide the carboxylate anion formed immediately with an electrophilic partner *(38)*, from which the preformed urea molecule can be easily displaced.



*(38)*

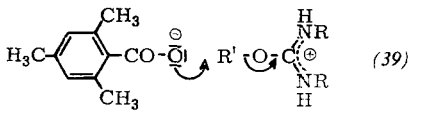
It was in fact found that ethyl acetate can be prepared in this way from *O*-ethyl-*N,N'*-diisopropylisourea and glacial acetic acid. The purified reactants were left to stand for 96 hours at room temperature, and the ethyl acetate was then separated from the diisopropylurea by distillation (yield 78 %) [19]. Probably the strongest evidence for reaction *via (38)* is the formation of esters of mesitylenecarboxylic acid (cf. Table 7). In this case the carboxylate anion makes a nucleophilic attack, as indicated in *(39)*, on the alkylating agent, *i.e.* the protonated isourea ether *(38)*. Since there is no transition state involving a tetrahedral carbonyl carbon,

Table 7. Esters of mesitylenecarboxylic acid obtained from *O*-alkyl-*N,N'*-diisopropylisourea (25 mmole in 10–20 ml of DMF).

| R | Conditions [hr/°C] | Yield [%] | B.p. [°C/mm] | $n_D^{20}$ | IR C=O band [cm$^{-1}$] |
|---|---|---|---|---|---|
| Ethyl | 140/75 | 80 | 120–121/10 | 1.5007 [*] | 1732 |
| *n*-Butyl | 50/50 | 94 | 144.5–145/10 | 1.4963 | 1728 |
| Benzyl | 15/50 | 89 | 127–128/0.01 | 1.5528 | 1725 |

[*] $n_D^{20}$ = 1.5008 [33].

this provides a new and simple method for the esterification of sterically hindered carboxylic acids.

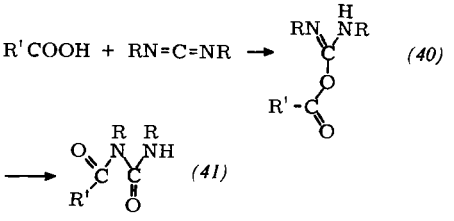


*(39)*

Phenol is alkylated similarly. As with carboxylic acids, a proton is first transferred to the isourea ether, which then alkylates the resulting phenoxide anion. n-Butyl phenyl ether was obtained in 91 % yield when phenol and *O*-n-butyl-*N,N'*-diisopropylisourea were heated at 120 °C for 15 hours [19]. *Vowinkel* [34] converted alcohols, phenols, and dicyclohexylcarbodiimide into aryl alkyl ethers by a similar method. The use of phenol labeled with $^{18}O$ recently showed that this "direct reaction" also involves the *O*-alkyl-*N,N'*-dicyclohexylisourea as an intermediate [35].

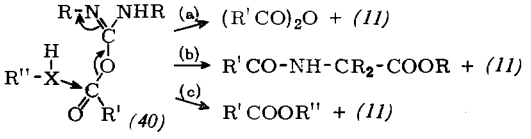
### 3.3. Dialkylcarbodiimides as Condensing Agents

A feature common to all known condensations involving carboxylic acids and carbodiimides is that these compounds first react to form the *O*-acylisourea *(40)*, which can either rearrange to give the *N*-acylurea *(41)* or react with a nucleophile R''XH [36–39].



*(40)* *(41)*

The nucleophile may be the carboxylic acid itself, which is acylated to give the anhydride by path (a). When aromatic carbodiimides are used, the reaction generally leads to *N*-acylureas *(41)* [37–41], whereas with aliphatic carbodiimides, the acid anhydride [39,41,42] or a mixture of the anhydride and *(41)* [41,42] generally are obtained.



*(40)* *(11)*

*(a)*: X = O; R'' = R'CO
*(b)*: X = NH; R'' = $CR_2COOR$
*(c)*: X = O; R'' = Alkyl

The *N*-acylureas *(41)* correspond to the trisubstituted ureas obtained by the reaction of phenols with diphenylcarbodiimide [43] or with dicyclohexylcarbodiimide [44]. Thus phenols, and particularly nitrophenols, also behave in the same way as carboxylic acids in the reaction with carbodiimides. However, no diaryl ethers were ever obtained in this reaction. The rearrangement of the initially formed *O*-phenylisourea to *N*-phenylisourea [43,44], which is analogous to the reaction *(40)* → *(41)*, may be classed as a Chapman rearrangement [45,46].

The formation of anhydrides with the aid of carbodiimides is of considerable importance in the preparation of esters of pyrophosphoric acid and of nucleotides [42,47,48]. Peptides can be obtained by route (b) if esters of amino acids are present to act as coupling components for *(40)* [16c,49].

For route (c), *i.e.* the alcoholysis of *(40)*, the results of previous esterification experiments with carbodiimide are summarized in Table 8.

Table 8. Reaction of carboxylic acids and hydroxy compounds in the presence of carbodiimides to form esters.

| Acid | Hydroxy compound | Yield of Ester [%] | Ref. | Remarks |
|---|---|---|---|---|

The suggested alcoholysis mechanism explains the large difference in the esterification yields or the complete failure of the reaction[56]: The competing reactions *(40)* → *(41)* and (a) are much more important in the esterification than in the peptide synthesis, since the alcoholic hydroxy group is much less nucleophilic than the amino group[57].

As an alternative to the aminolysis of *(40)*, another acylation mechanism has been suggested for the peptide synthesis[57a,58]. This mechanism is based on experiments in which, in the absence of the coupling component $H_2N-CR_2-COOR$, the symmetrical anhydrides of *N*-benzyloxycarbonyl and *N*-phthalylamino acids[59] and formic acid[60] were isolated with dicyclohexylcarbodiimide, and treated with esters $H_2N-CR_2-COOR$ of amino acids to form peptides. This acylation with anhydrides instead of *via* the intermediate *(40)* is possible not only for these peptide syntheses, but also for the esterifications described above.

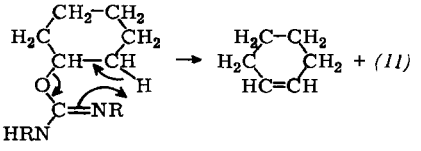
It is likely that both mechanisms are involved, depending on the reaction conditions and on the constitutions of the reactants.

The only experimental difference between the esterification *via* the *O,N,N'*-trisubstituted isoureas as intermediates with "activated alcohol", and the previous esterifications with carbodiimide is that in the method described here the carboxylic acid is added later. The new method[61] has two important advantages: The formation of *N*-acylthiourea and anhydride as by-products is avoided, and any steric hindrance of the carboxyl group is no longer troublesome, owing to the alkylation mechanism.

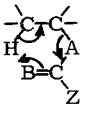
## 4. Thermal Cleavage of Isourea Ethers

The first indication of a new synthesis of olefins was obtained in the pyrolysis of isourea ethers. For example, if the *O*-cyclohexyl-*N,N'*-diisopropylisourea prepared from cyclohexanol and diisopropylcarbodiimide is heated for several hours at 204 to 213 °C, cyclohexene is formed in 35 % yield.

Formation of cyclohexene by 1,2-elimination would be comparable to the *Tschugaeff* dehydration [model



*(42a)*][62,63], the pyrolysis of esters [model *(42b)*][63–65], and the Cope-Mamlock-Wolffenstein reaction [model *(43)*][63,66,67], and like these syntheses, it should proceed as a *cis*-elimination[63].

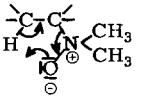


*(42)*

*(42a)*: A = O, B = S, Z = S-$CH_3$

*(42b)*: A, B = O, Z = Alkyl, Aryl

*(42c)*: A = O, B = N-Alkyl, Z = NH-Alkyl



*(43)*

Further experiments are in progress with the object of developing a stereospecific olefin synthesis *via* *O,N,N'*-trialkylisoureas *(42c)*.

*All the work described in this paper, except that based on the publications cited, was carried out under the guidance of Prof. Dr. Erich Schmidt, to whom I am indebted for his interest and for his generous support of this work.*

# Spectroscopy with Polarized Light

BY PROF. DR. F. DÖRR

PHYSIKALISCH-CHEMISCHES INSTITUT
DER TECHNISCHEN HOCHSCHULE MÜNCHEN (GERMANY)

*Polarized light is used in electronic spectroscopy not only to obtain information about the positions, intensities, and fine structures of absorption and luminescence bands, which can be obtained by normal electronic spectroscopy of solutions, but also to determine the orientation of the transition moments in relation to the molecular framework. The theoretical and experimental principles of molecular optical anisotropy are briefly described, and the three most successful methods (spectroscopy after mechanical alignment of the molecules on films and in crystals, or after electrical alignment in solution, and luminescence polarization of solid solutions) are discussed in detail and illustrated by typical examples. In connection with luminescence polarization, special emphasis is placed on triplet-singlet phosphorescence. Reference is made to the importance of polarization measurements on liquid solutions in biochemistry (study of intermolecular interactions of macromolecules by measurement of the rotational relaxation times).*

## A. Introduction

Methods for the determination of the orientation of optical transition moments in complex molecules with the aid of polarized light have been known for some time (for a review, see [1]). In molecules with some symmetry, the classification of excited electronic states is facilitated greatly by a knowledge of the transition directions. These methods of polarization spectroscopy have recently found increasingly wide application, mainly for the following reasons:

(a) The development of theoretical chemistry and the study of reaction mechanisms has led to increased interest in the electronic structures of excited molecules in general.

(b) The electronic states, energies, and density distributions of many molecules have recently been calculated by approximation methods. Polarization spectra can provide criteria for testing the theoretical conclusions, and hence also indications of how the calculation can be improved.

(c) The improvement of amplifier technology has led to an appreciable increase in the sensitivity of optical measurements, particularly those involving electrical orientation of the molecules.

(d) As a result of the development of efficient light sources and photoelectric detectors, high resolution can be obtained over a wide range of wavelengths in the study of luminescence polarization.

In the following survey of methods for the determination of the orientation of the transition moments, we place special emphasis on the method of luminescence polarization, which can be easily adapted for routine work. This method has recently been extended to the study of the mechanism of triplet-singlet phosphorescence.

## B. Molecular States and Energy Levels

The various stationary states of a molecule are described by functions $\Phi_i$ of the coordinates and spins of all electrons and nuclei. The energies $E_i$ corresponding to the various states are represented in an energy-level diagram (Fig. 1). To a close approximation [*], the energy can be expressed as the sum of the electronic energy and the vibrational energy of the nuclei, $E_i = E^i_{el} + E^i_v$, and the state functions $\Phi_i$ as the product of an electronic eigenfunction $\Theta_i$ and a vibrational eigenfunction $\chi_{iv}$ for a vibrational quantum number v:

$$\Phi_i = \Theta_i \cdot \chi_{iv} \qquad (1a$$

Molecular rotation is restricted in solution and will therefore not be taken into account. In organic molecules with even numbers of electrons, singlet states $^1\Theta$ in which the electron spins are paired to give a total spin $S = 0$ and triplet states $^3\Theta$ with two parallel electron spins giving a total spin $S = 1$ are known. Free radicals containing an unpaired electron exist in doublet states; higher multiplicities occur, for example, in complexes with transition elements.

Also to a good approximation, the electronic function $\Theta$ can be expressed as the product of a "space function" $\psi$, which depends only on the positions of the electrons, and a spin function $\Omega$. For two electrons, there are one singlet and three triplet spin functions. The spin-independent space component of the state function (1a) is then:

$$\Phi'_i = \psi_i \cdot \chi_{iv} \qquad (1b)$$

Fig. 1 is an energy-level diagram with singlet and triplet levels $S_i$ and $T_i$ and a number of superimposed vibrational levels. The absorption $T_1 \leftarrow S_0$ [**] is extremely weak, since the transition is forbidden by multiplicity. After an excitation to higher levels, the $S_1$ and $T_1$ levels

[*] Born-Oppenheimer approximation.

[**] According to *Herzberg*, the higher state is written first, and the direction of the transition is indicated by an arrow.

are reached by radiationless transitions; these are indicated by wavy arrows.

The arrows $A_S$ and $A_T$ denote allowed absorption transitions in the singlet and triplet systems, F denotes the fluorescence transitions, which generally take place from only one electronic level (usually $S_1$), and Ph denotes the slowly decaying triplet-singlet phosphorescence observed at low temperatures.

The various spectra of molecules having an energy-level diagram as shown in Fig. 1 are given schematically in Fig. 2. The absorptions $A_T$ can be observed only when excited molecules "accumulate" in the high energy state $T_1$ as a result of intense irradiation (see Section C). Below 300 °K, practically all molecules are in the ground state.

## C. Transition Moments and Selection Rules

### 1. Electric Dipole Transitions

All intense electronic transitions are electric dipole transitions. A molecule in the state $\Phi_a$ (*e.g.* $S_0$), having an energy $E_a$, can be excited to a state of energy $E_e$ by absorption of a quantum of wave number

$$\tilde{\nu}_{ae} = \frac{E_e - E_a}{hc} \text{ [cm}^{-1}\text{]} \quad (2)$$

The intensity (probability) of the transition is proportional to the square of the transition dipole moment $\mathbf{M}_{ae}$ [Equation (3)]

$$\mathbf{M}_{ae} = e\int \Phi_a^* \mathfrak{P}_M \Phi_e \cdot d\tau \quad (3)$$

where

$$\mathfrak{P}_M = \Sigma Z_i \mathbf{r}_i. \quad (3a)$$

$\mathfrak{P}_M$ is the dipole moment operator and $\Phi_a^*$ is the complex conjugate of $\Phi_a$; the functions are usually real in the case of molecules. $Z_i$ and $r_i$ are the charge number and position vector, respectively, of the i-th particle (electron or nucleus); the integration extends over the space and spin coordinates of all particles.

The vector $\mathbf{M}_{ae}$ has a definite orientation in relation to the molecular skeleton. The probability of absorption is highest for light quanta whose electric vectors vibrate parallel to $\mathbf{M}_{ae}$. The intensity of the light emission $\Phi_e \rightarrow \Phi_a$ (*e.g.* $S_1 \rightarrow S_0$) is proportional to $\tilde{\nu}_{ae}^3 |\mathbf{M}_{ae}|^2$.

If $\mathbf{M}_{ae}$ is zero, the dipole transition is forbidden. This is always the case when $\Phi_a$ and $\Phi_e$ have different total electron spins. If we assume that the initial and final states $\Phi_a$ and $\Phi_e$ have the same multiplicity, we can also operate with the pure space functions $\Phi_e'$ and $\Phi_a'$. It can now be decided, without knowing the exact eigenfunctions, whether $\mathbf{M}_{ae} = 0$. It is only necessary to know how the functions contributing to $\mathbf{M}_{ae}$ behave towards symmetry operations (rotations and reflections) that bring the molecule into coincidence with itself. In order that the component $M_x$ is not zero, the integrand in Equation (3) with $r_i = x_i$ must remain unchanged in relation to all possible coincidence operations of the molecule, *i.e.* it must be totally symmetric, or in other words, must belong to the totally symmetric representation of the symmetry group of the molecule. This is the case when the product of the irreducible representations $\Gamma_i$ of $\Phi_a'$, x, and $\Phi_e'$ is or contains the totally symmetric representation $A_1$.

$$\Gamma(\Phi_a') \times \Gamma(x) \times \Gamma(\Phi_e') = A_1 \quad (4)$$

The allowed transition is then polarized along the x-direction.

Similar rules apply to interactions of different molecular states, which are discussed in Section C.2; in this case, however, the dipole moment operator is replaced by the corresponding interaction operator. For this reason, it is very useful to classify the molecular states according to symmetry characteristics. If $\Phi_a'$ and $\Phi_e'$ are known, the fulfilment of condition (4) can easily be checked with the aid of a character table for the symmetry group of the molecule in question. If the functions $\Phi'$ are real, the so-called characters of the three irreducible representations $\Gamma_i$ in Equation (4) are simply multiplied with one another for every possible symmetry operation and to see whether the result obtained is +1. (Somewhat more effort is required for degenerate states[2,3].)

[3] *F. A. Cotton*: Chemical Applications of Group Theory. Interscience Publishers, New York 1964.

## 2. Weakening of Selection Rules for Dipole Transitions

### a) Vibronic Interactions

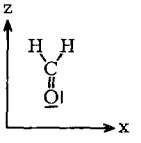
In the approximation (1b), the state function $\Phi_i'$ of a vibration-electronic ("vibronic") state belong to the representation

$$\Gamma(\Phi_i') = \Gamma(\psi_i) \times \Gamma(\chi_i) \tag{5}$$

The satisfaction of condition (4) therefore depends on the symmetry of the vibrational functions $\chi_a$ and $\chi_b$. It follows that a nuclear vibration that is not totally symmetric can make a forbidden electron transition allowed, or can even change the polarization direction of an allowed transition (see below). A simplification exists when one of the states involved is the vibrationless ground state $S_0$, which is always totally symmetric. To satisfy Equation (4) the other (higher) state need only belong to the same representation as the coordinate x.

For example, formaldehyde belongs to the symmetry group $C_{2v}$, which has the irreducible representations $A_1(z)$, $A_2$, $B_1(x)$, and $B_2(y)$; the direct products of these representations are shown in the following multiplication table.

| $C_{2v}$ | $A_1$ | $A_2$ | $B_1$ | $B_2$ |
|---|---|---|---|---|
| $A_1$ | $A_1$ | $A_2$ | $B_1$ | $B_2$ |
| $A_2$ | $A_2$ | $A_1$ | $B_2$ | $B_1$ |
| $B_1$ | $B_1$ | $B_2$ | $A_1$ | $A_2$ |
| $B_2$ | $B_2$ | $B_1$ | $A_2$ | $A_1$ |



A transition moment in the z direction leads from the vibrationless ground state $S_0(A_1)$ to another state of the same symmetry $A_1$ (*e.g.* the $\pi^* \leftarrow \pi$ transition to $S_2$). On the other hand the vibrationless excited state $S(n\pi^*) = S_1$, which is reached by excitation of a non-bonding (n)-electron on oxygen into an empty $\pi$-orbital ($\pi^*$), belongs to the representation $A_2$, which does not represent any coordinate of the molecule. If, however, a vibration of symmetry $b_2$ [*] (rocking vibration of the O atom out of the $CH_2$ plane) is superimposed on the $S_1$ electronic state, the transition $S_{1,1} \leftarrow S_0$ is polarized along x and is allowed, since $A_2 \times B_2 = B_1$ and x belongs to $B_1$.

Thus, owing to the coupling of an electronic state with a vibration that is not totally symmetric, a symmetry-forbidden electron transition becomes allowed. In other cases, a low-intensity transition that is allowed in accordance with Equation (4) is intensified by vibronic mixing. The validity of Equation (4) gives no information about the intensity of an allowed transition; this information is obtained by insertion of the explicit functions $\Phi_a$ and $\Phi_e$ in Equation (3).

The theoretical treatment of intensification by vibronic mixing is due to *Herzberg* and *Teller* [4], and was refined and applied to larger molecules (particularly benzene) whose state functions are approximately known by *Liehr* [5], *Murrell* and *Pople* [6], and *Kalantar* and *Albrecht* [7,8]. A displacement Q of the nuclei from the equilibrium position (Q = 0) also leads to a change in the electronic component $\psi$ of the state function (1b), since the electrons are light enough to immediately adjust themselves to the potential due to the nuclei. For a given electron function $\psi_K(Q)$ at a displacement Q of the nuclei from the equilibrium position corresponding to $\psi_K$, the deviation from the equilibrium function $\psi_K(0)$ is described by a series expansion in the other unperturbed electron eigenfunctions $\psi_S(0')$ of the molecule, which form a complete orthogonal set (S = 1, 2, ..., but S ≠ K). The equilibrium position corresponding to $\psi_S$ is generally different from that corresponding to $\psi_K$; this is expressed by the symbol 0′ in the case of $\psi_S$. Thus

$$\psi_K(Q) = \psi_K(0) + \sum_{S \neq K} c_{KS}(Q)\psi_S(0'). \tag{6}$$

The change in the Hamiltonian operator of the electrons for a displacement Q of the nuclei from the equilibrium position is described by the perturbation operator $\mathfrak{H}_e'$. Then [4–8]

$$c_{KS}(Q) = \frac{1}{E_S - E_K} \int \psi_K^*(0)\mathfrak{H}_e'(Q)\psi_S(0')d\tau \tag{7}$$

where $E_S$, $E_K$ are the energies of the corresponding molecular states.

The value of $c_{KS}$ is a measure of the extent of mixing of $\psi_S$ with $\psi_K$ as a function of the vibrational amplitude Q. Mixing of the ground state with higher states $\psi_S$ generally can be neglected, mainly because the denominator $(E_S - E_0)$ in Equation (7) is large, so that $c_{0S}$ becomes small, and because at normal temperatures vibrations in the ground state generally are not appreciably excited ($Q \approx 0$).

For a non-zero $c_{KS}$, a symmetry condition similar to (4) must be satisfied:

$$\Gamma(\psi_S(0')) \times \Gamma(\mathfrak{H}_e'(Q)) \times \Gamma(\psi_K(0)) = A_1 \tag{8}$$

in the simple non-degenerate case:

$$\Gamma(\psi_S(0')) \times \Gamma(\mathfrak{H}_e'(Q)) = \Gamma(\psi_K(0)) \tag{9}$$

$\mathfrak{H}_e'$ is approximated by the linear term in the expansion of the Hamiltonian operator for displacement Q (normal coordinates) [4]. For illustration, Fig. 3 shows an electronic state $\psi_K(0)$ to which a higher state $\psi_S(0')$ is added at time t by a vibration of suitable symmetry $Q = Q(t)$; the transition B to $\psi_S(0')$ is allowed. The transition A then "steals" intensity from the allowed transition B.

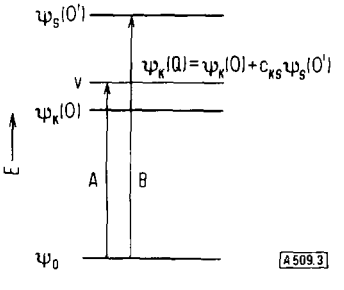


Fig. 3. Energy-level diagram for vibronic coupling.

Since several states $\psi_S$ of different symmetries can be mixed simultaneously with $\psi_K$ by means of vibrations of different types (*i.e.* with different symmetry behavior of

[*] Vibrations are denoted by lower-case letters to distinguish them from electronic states.

[4] *G. Herzberg* and *E. Teller*, Z. physik. Chem. B *21*, 410 (1933).

[5] *A. D. Liehr*, Z. Naturforsch. *13a*, 596 (1958).

[6] *J. N. Murrell* and *J. A. Pople*, Proc. physic. Soc. A *69*, 245 (1956).

[7] *A. H. Kalantar* and *A. C. Albrecht*, Ber. Bunsenges. physik. Chem. *68*, 377 (1964).

[8] *A. C. Albrecht*, J. molecular Spectroscopy *6*, 84 (1961).

the corresponding vibrational eigenfunctions $\chi_i$), the resulting transition may consist of several superimposed components with different polarization directions. In Fig. 3, for example, the transition A is intensified by a component with the polarization direction of the transition B. It is therefore desirable in polarization spectra to obtain such a high spectral resolution that vibrations of different types are separated as far as possible, thus enabling the polarization of the 0,0 transitions to be measured separately (cf. Section G).

Insertion of Eq. (7) into Eq. (6) gives the following equation for the transition (dipole) moment of the absorption $\psi_K(Q) \leftarrow \psi_0$ [Eq. (3)]:

$$\mathbf{M}_{0K}(Q) = \mathbf{M}_{0K}(0) + \int \sum_{S \neq K} \frac{\int \psi_K^*(0)\mathfrak{H}_e'(Q)\psi_S(0')d\tau_e \int \psi_S^* \mathfrak{H}_M \psi_0 d\tau}{E_S - E_K} \quad (10)$$

Thus the selection rules for mixing [(Eq. (8)] and for the optical transitions [(Eq. (4)] must both be satisfied before any enhancement is possible. (This can lead to an appreciable change in the intensity distribution of an electron-vibration band in relation to that given by the Franck-Condon principle alone.)

### b) Triplet-Singlet Transitions and Spin-Orbit Coupling

The long-lived phosphorescence of many compounds in vitreous solvents was interpreted by *Lewis* and *Kasha* [9] as a $T_1 \rightarrow S_0$ spin-forbidden transition. This interpretation has been confirmed by electron-spin resonance spectra of molecules in the metastable excited state [10, 11].

Intensification of spin-forbidden transitions can be explained in molecules, as in heavy atoms, by spin-orbit interaction. Owing to its orbital motion in the electric field of the molecular skeleton, an electron "sees" a magnetic field, which acts on its magnetic moment. The result is that it is no longer possible to rigorously distinguish between singlet and triplet states. To describe this case, we say that a small component of triplet states of suitable symmetry is "mixed" with a singlet state by spin-orbit coupling; similarly, singlet states can also be mixed with triplet states.

The theory and the selection rules for this mixing and for the resulting optical transitions have been formulated by various authors in terms of the usual approximation methods for unsaturated molecules [12–18]. Since the magnetic interaction energy is small in comparison with the electrostatic energy, a perturbation method can be used.

By analogy with Equation (6), the triplet state ${}^3\Theta_{Kj}$ perturbed by mixing with singlet states ${}^1\Theta_S$ is described by the expansion (11):

$${}^3\Theta'_{Kj} = {}^3\Theta_{Kj} + \sum_S c_{KjS}{}^1\Theta_S \quad (11)$$

($\Theta$ electron eigenfunctions including spin, cf. Eq. (1a); j = 1, 2, 3 denotes the three components of the triplet spin function).

The coefficients $c_{KjS}$ of the expansion are found by an equation similar to (7), *i.e.*

$$c_{KjS} = \frac{1}{E({}^1\Theta_S) - E({}^3\Theta_{Kj})} \cdot \int {}^3\Theta_{Kj}^* \mathfrak{H}'_{ls} {}^1\Theta_S d\tau \quad (12)$$

The spin-orbit operator $\mathfrak{H}'_{ls}$ causing the mixing consists of several (relativistic) components, but usually only one of these is retained in approximate calculations. For a system of n electrons and m nuclei with Cartesian coordinates:

$$\mathfrak{H}'_{ls} \approx \frac{e^2}{2m^2c^2} \sum^{n} \left[ \sum_{k=1}^{m} \frac{Z_k}{r_k^3} (l_{xk} \cdot s_x + l_{yk} \cdot s_y + l_{zk} \cdot s_z) \right] \quad (13)$$

$Z_k$: effective charge on the nucleus k;

$r_k$: distance from the electron in question to the nucleus k;

$l_{xk}$: x-component of the orbital angular momentum operator of an electron in relation to the nucleus k;

$s_x$: x-component of the spin operator of an electron; *etc.*

The summation in brackets extends over the nuclei, and that outside the brackets over the electrons.

The factor $Z/r^3$ is particularly large near heavy nuclei. Thus the intensification of singlet-triplet transitions by substituted heavy atoms (or by adjacent heavy atoms in the solvent) is explained as a result of the more pronounced mixing of S and T states in accordance with Equation (12) ("heavy-atom effect") [19]. The components of $\mathfrak{H}_{ls}$ have the same symmetry properties as the rotations $R_x$, $R_y$, and $R_z$ about the x, y, or z axes. If, as an approximation, the electron eigenfunctions $\Theta$ are written in the form (1a) as the product of a space function $\psi$ and a spin function $\Omega$, the integration in Equation (12) can be carried out separately over the space coordinates and the spin coordinates. The spin-dependent part gives one or two finite contributions for each component of s when ${}^3\Omega_{Kj}$ and ${}^1\Omega_S$ differ only in the spin of a single electron. Thus the selection rules for mixing depend only on the integral (14) over the space functions $\psi$.

$$\int {}^3\psi_K^* \mathfrak{H}'_{ls} {}^1\psi_S d\tau \quad (14)$$

${}^3\psi_K$: orbital function for the triplet state ${}^3\Theta_K$

${}^1\psi_S$: orbital function for the singlet state ${}^1\Theta_S$.

If the integral (14), and hence $c_{KjS}$ in Equation (11) are to be non-zero, a condition similar to Equation (8) must again be satisfied, except that in this case $\Gamma(\mathfrak{H}'_{ls})$ must be replaced by the irreducible representations of the rotations $R_x$, $R_y$, and $R_z$, which are obtained from character tables. Similarly, the singlet ground state

generally mixes with higher triplet states of suitable symmetry; the selection rules for mixing (15) are the same:

$$\Gamma(^3\psi_K) \times \Gamma(R_i) \times \Gamma(^1\psi_S) = A_1; \quad i = x, y, z \tag{15}$$

Thus the intensity of the dipole transition between the states $^1\Theta_0 \equiv S_0$ and $^3\Theta_1 = T_1$ ($T_1 \leftarrow S_0$ absorption, or $T_1 \rightarrow S_0$ phosphorescence), which are perturbed by spin-orbital interaction, contains contributions from several components, each generally differently polarized, with transition moments (16a) and (16b).

$$\mathbf{M}' = \underbrace{\int \frac{^3\Theta^*_{1j}\mathfrak{H}'_{ls}{}^1\Theta_S}{E(^1\Theta_S)-E(^3\Theta_{1j})}\,d\tau}_{c_{1js}} \cdot \int {}^1\Theta^*_0 \mathfrak{H}_M {}^1\Theta_S d\tau \tag{16a}$$

$$\mathbf{M}'' = \int \frac{^1\Theta^*_0\mathfrak{H}'_{ls}{}^3\Theta_{Kj}}{E(^3\Theta_{Kj})-E(^1\Theta_0)}\,d\tau \cdot \int {}^3\Theta^*_{1j}\mathfrak{H}_M {}^3\Theta_{Kj} d\tau \tag{16b}$$

The other terms vanish because the functions involved have different multiplicities. (The asterisks again denote complex conjugate functions.) Thus the transition $T_1 - S_0$ gains intensity from the allowed transitions between the singlet states $^1\Theta_S$ mixed with the $^3\Theta_{1j}$ states [see Eq. (16a)] and between the triplet states $^3\Theta_{Kj}$ mixed with the $^1\Theta_0$ state [see Eq. (16b)]. It is found in practice that, for organic molecules, a T–S transition is $10^6$ times weaker than a fully allowed S–S transition.

The above relationships are illustrated in Fig. 4 for the simple case in which only the singlet state $S_n$ mixes appreciably with $T_1$, only the triplet state $T_m$ mixes appreciably with the ground state $S_0$, and none of the states involved is degenerate. For simplicity, the symbols $S_0$, $S_m$, $T_1$, and $T_m$ represent the spin-independent space functions $\Phi'$ of Equation (1b), *i.e.* they are approximate functions which would be improved if interactions were taken into account. The irreducible representations are: $\Gamma(S_0) = A_1$ (totally symmetric); $\Gamma(\mathfrak{H}'_{ls}) = \Gamma(R_i)$, i = x, y, or z (the components of the spin-orbital operator have the symmetry of rotations about the coordinate axes [12]).

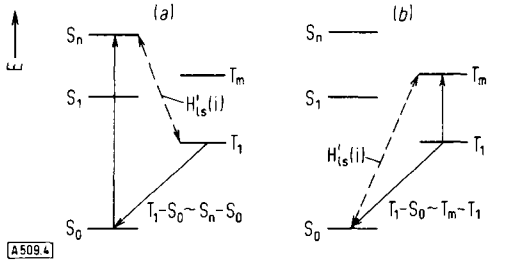

Fig. 4. Energy-level diagram for spin-orbit coupling.
(a) $T_1$ mixes with $S_n$; (b) $S_0$ mixes with $T_m$.

*Selection rules for the polarization of the $T_1 \rightarrow S_0$ phosphorescence*

I. State mixture, Eq. (15)

Fig. 4a:

a) $\Gamma(T_1) \times \Gamma(R_i) \times \Gamma(S_n) = A_1$
hence
b) $\Gamma(T_1) = \Gamma(R_i) \times \Gamma(S_n)$

Fig. 4b:

α) $\Gamma(S_0) \times \Gamma(R_i) \times \Gamma(T_m) = A_1$
hence, since $\Gamma(S_0) = A_1$
β) $\Gamma(T_m) = \Gamma(R_i)$

II. Optical transition, Eq. (4)

c) $\Gamma(S_n) \times \Gamma(x_j) \times \Gamma(S_0) = A_1$
hence since $\Gamma(S_0) = A_1$
d) $\Gamma(S_n) = \Gamma(x_j)$
inserted in b)

γ) $\Gamma(T_m) \times \Gamma(x_j) \times \Gamma(T_1) = A_1$
from β)
δ) $\Gamma(R_i) \times \Gamma(y_j) \times \Gamma(T_1) = A_1$
hence

$$\Gamma(R_i) \times \Gamma(x_j) = \Gamma(T_1); \; R_i = R_x, R_y, R_z; \; x_j = x, y, z \tag{17}$$

The transition $T_1 - S_0$ is then polarized along $x_j$.

*Example:* In formaldehyde (cf. Section C.2a) the triplet state $T_1 = T(n\pi^*)$ (a non-bonding electron raised to an empty π-orbital) belongs to the irreducible representation $A_2$. It can mix with an $A_1$ state, most probably with $S_2 = S(\pi\pi^*)$ (a π-electron raised from the double bond into an empty π-orbital) by means of the z-component of the spin-orbit operator [$\Gamma(R_z) = \Gamma(x) \times \Gamma(y) = B_1 \times B_2 = A_2$]. The $T_1 - S_0$ transition is then allowed with low intensity and with polarization direction $z(A_1)$, in accordance with Equation (17). This transition is in fact observed; the same mechanism is probably also responsible for the $T(n\pi^*)$–$S_0$ transitions of ketones having lower symmetries [20].

Spin-orbit coupling is influenced in a number of ways by vibration of the nuclei. For example, a singlet state $S_n$, which, according to condition (a) under Fig. 4, does not mix directly with the triplet state $T_1$, can be mixed by vibration coupling, in accordance with Equation (7), with a little of another singlet state $S_K$ with which $T_1$ has spin-orbital interaction. The spin-orbit operator [cf. Eq. (14)] itself can also be changed by vibration. The theory of triplet-singlet transitions was developed by *Albrecht* [21] with this effect in mind, and was applied by *El-Sayed* [22] to the symmetrical dihalogenonaphthalenes.

For extremely weak spin-orbit coupling, *Hameka* [23] has also discussed the direct interaction of the spin with the magnetic field of the light wave; this can cause a magnetic quadrupole transition between triplet and singlet states. The intensity of this transition was estimated to be $10^{-11}$ times the intensity of a fully allowed transition. In the case of benzene, which has a triplet lifetime $\tau > 10$ sec, this mechanism could be appreciable in addition to spin-orbit coupling. Finally, an S–T transition may be facilitated by external perturbation due to paramagnetic molecules, particularly oxygen, by two different mechanisms [24–26].

### 3. Magnetic Dipole Transitions

If the magnetic moment (which is related to the orbital angular momentum of the electrons) changes during the transition between the states $\Phi_a$ and $\Phi_e$, magnetic dipole radiation may be absorbed and emitted. The probability of this effect is about $10^6$ times smaller than for a normal electric dipole transition [27, 28]. However,

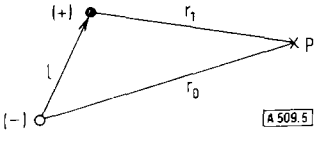
[28] *R. E. Ballard* and *S. F. Mason*, J. chem. Soc. (London) *1963*, 1624.

if the latter is forbidden, a magnetic dipole transition may be observed under certain circumstances.

It is very probable, for example, that in the spectrum of formaldehyde vapor a number of lines in the region of the forbidden $S_1(n\pi^*) \leftarrow S_0$ transition (see Section C.2a) are due to magnetic dipole transition [29]. In the plane of observation perpendicular to the orbital momentum vector **L**, the magnetic vector of this radiation is parallel to **L**. Relatively intense magnetic dipole radiation was found [30] in the spectral lines of rare earths, together with another type of radiation, which is produced by rotating electric and magnetic dipoles. Magnetic dipole transitions have not yet been definitely detected in the spectra of solutions of aromatic molecules.

### 4. Electric Quadrupole Transitions

In classical physics, a radiating quadrupole consists of two equal parallel dipoles vibrating with opposed phase, the distance between them being much smaller than the wavelength corresponding to their frequency. The intensity of optical quadrupole transitions is several orders of magnitude smaller, and the polarization relationships of the radiation are more complex than in electric dipole transitions. "Multipole transitions" are generally expected when the approximation $r_1 \approx r_2 = \text{const.}$ is replaced by the more accurate expression for $r_1$ in the calculation of the field of an oscillating dipole at a point P (cf. Fig. 5)



Several experimental methods distinguishing the various types of transitions are known. Typical distinguishing features are: (a) the intensity of the transition, (b) the distribution of the intensity in space, (c) the polarization of the radiation, (d) level splitting in the Zeeman effect (observed only in line spectra), and (e) circular dichroism.

### 5. Nature of the Oscillators in Organic Molecules

The spatial intensity distribution of the interference field of two wave trains emitted from an atomic system with a large angle between them is characteristically dependent on the multipole character of the emitting oscillator [31] ("wide angle interference"). It is not so easy to measure the intensity distribution as to measure the polarization of the luminescence radiation at various emission angles, on excitation with polarized light. According to *Feofilow* [30], the various multipole transitions also give characteristic "polarization diagrams", from which it is possible to establish the nature of both the absorbing and the emitting oscillators.

On the basis of wide-angle interference and polarization diagrams, it has been shown for a large number of organic compounds that all absorption transitions, as well as the $S_1 \rightarrow S_0$ fluorescence [32] and the $T_1 \rightarrow S_0$ phosphorescence [33, 34], are electric dipole transitions. It therefore seems reasonable to assume that this is true for all organic molecules, except certain complexes of transition metals and rare earths, in which magnetic dipole radiation is observed. Experimental methods for determining the orientation of the electric dipole transition moments in a molecule are discussed below.

## D. Mechanical Orientation of Molecules

### 1. Adsorption on Oriented Films

Natural fibers such as cotton, that have been dyed with substantive dyes, show distinct dichroism under the polarization microscope [35]. Quantitative studies can be carried out with clear films of cellulose hydrate, polyvinyl alcohol, polyethylene, *etc.*, which are dyed and then stretched to several times their original length [36]. In some cases it is better to stretch the film before it is dyed. Depending on the substrate and on the solvent, sufficiently strong adsorption is also observed with compounds that are not dyes in the technical sense. "Dyeing" may be assisted by gradual reduction of the solubility of the dye in the liquid phase (*e.g.* by addition of water). In favorable cases, orientation of the adsorbed dye molecules may be as high as 90 %. If the extinction of such a film is measured as a function of the wavelength of light polarized parallel ($E_p$) to and perpendicular ($E_s$) to the stretching direction, the spectra obtained are of the type shown in Fig. 6 (methylene blue [37]), which also shows the dichroic ratio DV defined as

$$DV \equiv \frac{E_p - E_s}{E_p + E_s} \qquad (18)$$

Maxima of the dichroic ratio correspond to oscillators with preferential orientation parallel to the stretching directions, and minima to those with transverse orientation. This method is confined to elongated molecules, and does not give very clear results, particularly in shorter-wavelength transitions. It is assumed that the molecules always orient themselves with their longitudinal axis parallel to the direction of stretching. The orientation of the long-wavelength oscillator of dyes is often known from quite reliable theoretical considerations, and the other bands can then be referred to this. It is more difficult to distinguish between the short axis in the molecular plane and in the direction perpendicular to the molecular plane. In a few cases the orienta-

tion on the film could be determined directly from the anisotropy of infrared bands of characteristic stretching vibrations of substituents (*e.g.* $-C\equiv N$) [38]. As expected, the longitudinal axis of the molecule was found to lie parallel to the stretching direction. By way of example, Fig. 7 shows the anisotropy of the ultraviolet absorption bands and of the $C\equiv N$ stretching band of *p*-dimethylaminobenzonitrile [38].

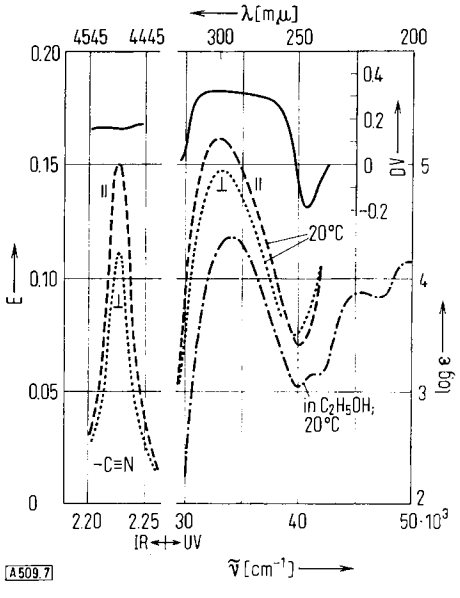

Fig. 7. Dichroism of the $C\equiv N$ stretching vibration and of the long-wavelength electronic band for *p*-dimethylaminobenzonitrile on stretched polyamide film (at 20 °C) [38].

A substantial refinement of the film method was recently introduced by *Eggers* and *Thulstrup* [39]. These authors studied large aromatic molecules and a number of aromatic hetero compounds embedded in stretched polyethylene.

[38] *J. Kern*, Z. Naturforsch. *17a*, 271 (1962).

[39] *J. H. Eggers* and *E. W. Thulstrup*, Lecture at the 8th European Congress on Molecular Spectroscopy, in Copenhagen (Denmark) on August 17th, 1965.

The luminescence of such films is also, of course, polarized to some extent. From their degree of polarization on excitation with natural light or with polarized light, information can be obtained about the orientation of the oscillators [40]. Other applications of the film technique are described by *Hanle* [41] and by *Eckert* and *Kuhn* [42]. When used in combination with a method developed by *Lewis* [43] and refined by *Zanker* and *Miethke* [44] for the measurement of triplet-triplet absorption transitions ($A_T$ in Fig. 1), dichroically dyed films permit determination of the polarization of these transitions [45, 46].

For this purpose, the films are placed in a Dewar cell (see Section G.2) cooled to the temperature of liquid air, and exposed to intense ultraviolet radiation (*e.g.* high pressure mercury lamp HBO 200 with filter UG 2 + $CuSO_4$ solution). This leads to a steady state in which up to 70 % of the adsorbed molecules are excited into the long-lived ($\tau \approx 1$ sec) triplet state $T_1$. These then give rise to the allowed, and therefore intense, absorption transitions $T_2 \leftarrow T_1$, $T_3 \rightarrow T_1$, *etc.*, which are situated in the red and near infrared regions of the spectrum. The dichroic ratio of these transitions can be determined from Eq. (18).

*Example* [46]: *The 3,6-diaminoacridinium cation on polyvinyl alcohol at 100 °K.* The $S_1 \leftarrow S_0$ transition occurs at 468 mμ; its polarization is parallel to the longitudinal axis of the molecule. The $T_2 \leftarrow T_1$ transition polarisation at 1100 mμ is oriented at 90° to the $S_1 \leftarrow S_0$ transition. However, this method does not show whether the $T_2 \leftarrow T_1$ transition is polarized in or perpendicular to the molecular plane; the former is expected on theoretical grounds.

## 2. Single Crystals and Mixed Crystals

At 4 °K, molecular single crystals often give very complex, sharp absorption and luminescence spectra with pronounced dichroism of the individual bands. However, these spectra are usually difficult to analyse, since interactions between the molecules in one unit cell lead to splitting of the electronic and vibrational levels, and so give numerous adjacent bands having different polarizations (crystal-field splitting, Davydow splitting).

Complete interpretation of the polarization measurements also requires knowledge of the crystal structure and of the interaction energies [47]. New eigenfunctions are formed for the unit cell as a whole by linear combination of the molecular states, and the selection rules for transitions between these eigenfunctions are determined. This is again best done on the basis of group theory, taking into account the symmetry of the individual molecule and that of the unit cell [47, 48].

Further complications are nearly always encountered in the luminescence spectra of single crystals. The absorbed energy migrates to a defect in the crystal, either a foreign molecule or an incorrectly situated or oriented molecule, where it is emitted. The polarization of the luminescence is then characteristic, not of the normally arranged molecules, but of the disturbed molecule. These difficulties are avoided if the molecules in question can be embedded in a host crystal at a high dilution and with defined orientation. The built-in molecules can, to a good approximation, be treated as an "oriented gas".

*Examples*: Naphthalene (1:$10^3$) is built into monoclinic 1,2,4,5-tetramethylbenzene with its long molecular axis parallel to the b-axis of the crystal. It was found that the longest-wavelength transition $S_1 \leftarrow S_0$ ($^1B_{3u} \leftarrow {}^1A_{1g}$) in naphthalene is polarized parallel to the long axis[49], whereas the triplet-triplet transition $T_2 \leftarrow T_1$ is polarized parallel to the short axis ($^3B_{3g} \leftarrow {}^3B_{1u}$)[50]. The long-wavelength $\pi^* \leftarrow n$ band of azobenzene built into stilbene has a transition moment that is rotated through approximately 36° from the N–C direction; the "forbidden" transition gains intensity by vibronic coupling (Section C.2a) with a $\pi^* \leftarrow \pi$ transition[51]. Mixed crystals with benzophenone[52] as the host crystal have not yet led to any definite conclusions since the crystal structure is not accurately known.

Mention should be made of some recent studies on pure single crystals (cf. also[48]). The polarization of the anthracene bands, which are split in the crystal field, indicates that in the free molecule the longest-wavelength transition is polarized parallel to the short axis ($^1B_{2u} \leftarrow {}^1A_{1g}$), and the next longest parallel to the long axis ($^1B_{3u} \leftarrow {}^1A_{1g}$); thus the order is the reverse of that found in naphthalene[53]. In azulene and phenanthrene, the first transition is polarized parallel to the short axis and the second parallel to the long axis[54]. In *p*-dimethoxybenzene, the long-wavelength transition occurs transverse to, and the next transition parallel to, the long axis[55]. In some purines and pyrimidines, the orientation of the transition at about 275 mμ was found to be approximately parallel to the N(1)–C(4) direction, and that of the transition at about 220 mμ to be perpendicular to this direction[56]. The ligand field splitting[57] of the energy levels of nickel was studied with polarized light in the complexes $Ni(NH_3)_4(NCS)_2$ and $Ni(NH_3)_4(NO_2)_2$, and was concluded to be affected by vibronic interaction[58]. A number of papers deal with the polarization of the characteristic absorption bands (CT bands)[*1] of electron donor-acceptor complexes (charge-transfer complexes). In anthracene/trinitrobenzene[59] and in quinhydrone[60], for example, the CT transition was found to be perpendicular to the plane of the molecule, as expected from the theory[61] of these transitions. In the pyrene/trichloroethylene complex, *Kuroda*[62] found two bands (510 and 830 mμ), which he interpreted as CT transitions on the basis of their polarization.

Attempts have also been made to assign the transitions in pyrene, phenanthrene, and benzil[63] on the basis of the luminescence polarization of single crystals. In the phenanthrene crystal, most of the emission occurs from molecules at lattice defects[64]. In the case of hexachlorobenzene, the polarization of the $T_1 \rightarrow S_0$ phosphorescence can be explained by assuming a threefold symmetry (in the crystal) and a spin-orbital interaction with the degenerate state $^1E_{1u}$ (components of the transition moment parallel to the plane of the molecule) and the state $^1A_{2u}$ (component of the transition moment perpendicular to the plane of the molecule)[65].

The pure vibrational transitions are also split in the crystal, owing to coupling between the molecules; the explanation of this is similar to that for splitting of the electronic levels[66]. Thus, in favorable cases, infrared bands can be assigned on the basis of their dichroic behavior[67, 68].

## E. Electric Orientation of Dipole Molecules

### 1. Electrically Induced Dichroism. Electric Fluorescence Polarization

The partial orientation by an electric field of molecules having a permanent electric dipole moment $\mu_g$ (in the ground state) was first used by *W. Kuhn*[69] to find the orientation of the transition moment in the long-wavelength absorption band, $S_1 \leftarrow S_0$. This author studied *p*-nitrosodimethylaniline ($\mu_g = 6.9$ D) in benzene solution (dielectric constant 2.28). The transition moment is parallel to $\mu_g$.

The orientation of dipolar molecules is opposed by their thermal motion. The potential energy of a permanent dipole $\mu_g$ in a field **F**, as a function of the angle $\Omega$ between $\mu_g$ and **F**, is given by Eq. (19).

$$\Delta E_g = -|\mu_g||\mathbf{F}|\cos\Omega = -\mu_g\mathbf{F} \qquad (19)$$

With Maxwell-Boltzmann statistics, the probability that a dipole will have the orientation $\Omega$ relative to the field direction is:

$$W(\Omega)d\Omega = \frac{\exp(-\Delta E_g(\Omega)/kT)}{\int \exp(-\Delta E_g(\Omega)/kT)d\Omega}\, d\Omega. \qquad (20)$$

The field strength is limited to a maximum of $10^5$ V/cm by the dielectric strength of the solvent, and $\mu_g$ is less than about 10 D. Thus $\Delta E_g/kT$ is about $10^{-2}$ and, for the solution, the

relative difference of the extinctions of light polarized parallel to and perpendicular to the field is about $10^{-4}$. The measurement of this electrically induced dichroism requires very sensitive methods. Present equipment (see *e.g.* [72]) permits the study of molecules having a dipole moment above about 2 D.

In many polar molecules, the dipole moment $\mu_a$ in the excited state $S_1$ is appreciably (up to 15 D) greater than $\mu_g$ in the ground state $S_0$ [70]. During the lifetime $\tau \approx 10^{-9}$ sec in the state $S_1$, therefore, the average degree of orientation in the field is increased according to Equations (19) and (20). The dipole moment $\mu_a$ in the excited state $S_1$ can be calculated from the degree of polarization P of the fluorescence of the solution in the electric field (electric fluorescence polarization). When observed perpendicular to the field, P is defined as

$$P = \frac{I_p - I_s}{I_p + I_s} \tag{21}$$

where $I_p$ (measured with an analyser) is the component of the light intensity polarized parallel to the field, and $I_s$ is the intensity of the component perpendicular to **F**. If the equilibrium distribution [Eq. (20)] is established in a "rotational relaxation time" shorter than about $\tau/4$, it is immaterial to the result whether the fluorescence is excited with natural or with polarized light. For P we obtain the approximation (22) [71].

$$P = \frac{1}{10} \cdot \frac{3\cos^2\alpha - 1}{2} \left(\frac{\mu_a}{kT}\right)^2 F^2 \tag{22}$$

From this equation, $\mu_a$ can be found if the angle $\alpha$ between $\mu_a$ and the transition moment corresponding to $S_1 \leftarrow S_0$ is known from symmetry considerations or from other measurements. (In most cases it can be assumed that the direction of $\mu_a$ is the same as that of $\mu_g$ for the ground state.)

The use of various electro-optical effects for the determination of molecular properties has been reviewed by *Labhart* [72].

## 2. Fundamentals of the Theory

A polar molecule in a non-polar solvent having a dielectric constant $\varepsilon_r$ is acted upon, not by the externally applied electric field $\mathbf{F}_0$, but by an internal (effective) field **F**, which may be considered to consist of two components: the field $\mathbf{F}_H$ in the cavity left in the dielectric solvent if the molecule in question were removed, and the field $\mathbf{F}_U$ produced by the polarization of solvent molecules by the polar molecule. Since the geometrical form of the polar molecule is generally irregular, and since its polarizability is anisotropic, the exact expressions for $\mathbf{F}_H$ and $\mathbf{F}_U$ are very complicated. In a first approximation $\mathbf{F}_U$ is neglected, and the field in a spherical cavity is used for $F_H$. The effective field **F** is then given by

$$\mathbf{F} \approx \frac{\varepsilon_r + 2}{3} \mathbf{F}_0 \tag{23}$$

If the polarizability of the polar molecule is taken into account by means of the tensor $(\alpha_g)$, its energy in the field is given, not by Equation (19), but by

$$\Delta E_g = -\mu_g \mathbf{F} - \frac{1}{2} \mathbf{F}(\alpha_g)\mathbf{F} \tag{24}$$

The same is true of the excited state (subscript a) [Equation (25)].

$$\Delta E_a = -\mu_a \mathbf{F} - \frac{1}{2} \mathbf{F}(\alpha_a)\mathbf{F} \tag{25}$$

A more accurate calculation should also consider the change in **F** on excitation, due to the change in the field component $\mathbf{F}_U$, produced by the change in the dipole moment.

From Equations (24) and (25), we see that the electric field causes a change $\Delta\tilde{\nu}$ in the wave number of the absorption [Eq. (26)].

$$\Delta\tilde{\nu} = \frac{1}{hc}(\Delta E_a - \Delta E_g) = \tilde{\nu}_o - \tilde{\nu}_F = \\ = \frac{1}{hc}\left\{\mathbf{F}(\mu_a - \mu_g) + \frac{1}{2}\mathbf{F}[(\alpha_a) - (\alpha_g)]\mathbf{F}\right\} \tag{26}$$

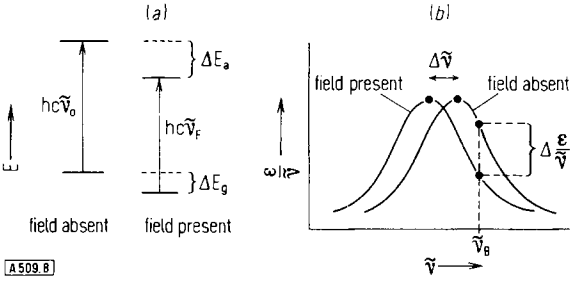

Fig. 8. Alteration of energy levels (a) and band shift (b) for the electronic excitation of a molecule in an electric field.

$\Delta E_a$ is generally greater than $\Delta E_g$ (cf. Fig. 8a). Consequently, an absorption band is displaced towards longer wavelengths in the field, with the result that the extinction coefficient $\varepsilon$ at a given observation frequency, $\tilde{\nu}_B$, changes when a field is applied, even in the case of natural light. If the field has no influence on the probability of the transition, *i.e.* on $|\mathbf{M}|^2$, then, since $|\mathbf{M}|^2 \propto \varepsilon/\tilde{\nu}$, the curve of $\varepsilon/\tilde{\nu}$ against $\tilde{\nu}$ is simply displaced parallel to itself when the field is applied (see Fig. 8b).

*Kuhn* [69] used the following assumptions in the evaluation of his measurements of electrically induced dichroism:

a) The orientation of the molecule is determined only by its permanent dipole moment $\mu_g$.

b) The anisotropy of the polarizability is neglected.

c) All transition moments are either parallel to or perpendicular to $\mu_g$.

d) The effective field is given by Equation (23).

e) The band shift of Equation (26) is not taken into account.

f) The transition probability, *i.e.* $\varepsilon/\tilde{\nu}$, is independent of the field strength.

On the basis of these restrictions, expressions were derived for the extinction coefficients $\varepsilon_p$ and $\varepsilon_s$, measured for light polarized parallel $(\varepsilon_p)$ to and perpendicular $(\varepsilon_s)$ to the field.

[70] *E. Lippert*, Z. Elektrochem., Ber. Bunsenges. physik. Chem. *61*, 962 (1957).

[71] *J. Czekalla*, Z. Elektrochem., Ber. Bunsenges. physik. Chem. *64*, 1221 (1960).

[72] *H. Labhart*, Tetrahedron *19*, Suppl. 2, 223 (1963).

The above simplifications can lead to large errors in the result (*e.g.* in the value of $\mu_a$ or in the angles between $\mu_g$ and the transition moments). *Labhart*[72–74] and *Liptay*[75–77] therefore extended the theory by a series expansion up to quadratic terms in **F**. *Liptay*[77] finally obtained very involved relationships (which cannot be discussed here) for the quantity $L_\chi$ defined in Equation (27), which can be determined experimentally.

$$L_\chi = -\frac{1}{2.303\ D_0 F^2} \cdot \frac{I_\chi - I_{\chi,0}}{I_{\chi,0}} \qquad (27)$$

In this equation, $D_0$ is the extinction at the observation frequency $\tilde{\nu}_B$ measured without an electric field; **F** is the effective field strength at the position of the molecule; $I_\chi$ is the intensity of the light having passed through the solution with an applied homogeneous field **F** when the incident light is polarized at an angle $\chi$ to the field direction; $I_{\chi,0}$ is the same quantity in the absence of the field. Depending on the symmetry of the molecules, $L_\chi$ can be used to find the angle between $\mu_g$ and the transition moments, the dipole moment $\mu_a$ in the excited state, the polarizability ($\alpha$), and other quantities.

### 3. Experimental Detection of Electric Fluorescence Polarization and Electrically Induced Dichroism

a) The degree of polarization of the luminescence of a solution in an electric field was determined by *Czekalla*[71] using the apparatus sketched in Fig. 9. The measuring cell Z is irradiated with monochromatic, unpolarized light perpendicular to the plane of the diagram. The emerging fluorescent light is partially polarized [cf. Eq. (22)]. It is modulated by a half-wave plate rotating with frequency $\omega$. An alternating current of frequency $4\omega$ is produced in the receiver, and this current vanishes when the polarization is compensated by rotation of the quartz plate compensator K. The position of K is then a measure of the degree of polarization P.

b) The double-beam arrangement described by *Labhart*[73] (see Fig. 10) has proved useful for the measurement of $L_\chi$ [Eq. (27)]. The electric field is sinusoidally modulated, but the polarity is not reversed; the angle $\chi$ is adjusted by means of the polarizer P. To obtain sufficient equations for the determination of the various quantities that are involved in $L_\chi$, the latter is measured as a function of the wave number $\tilde{\nu}$, the polarization angle $\chi$, and the temperature T.

### 4. Examples of Electric Orientation

In Fig. 11 (according to *Labhart*[72]), the total absorption $\varepsilon_{tot}$ (continuous curve) of nitrobenzene has been divided into the transitions I, II, and III by means of electrically

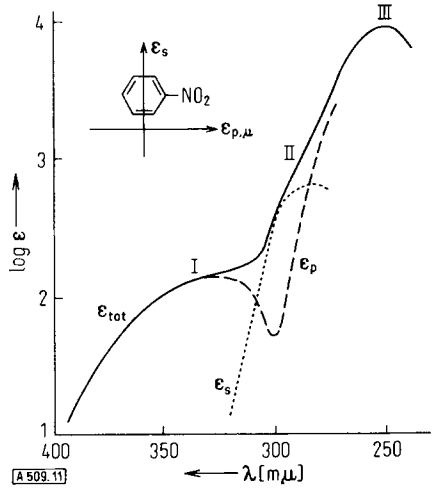

Fig. 11. Orientation of transition moments in nitrobenzene according to electrically induced dichroism [72].

$\varepsilon_p$ extinction coefficient for polarization parallel to the dipole moment; $\varepsilon_s$ that for transverse polarization.

induced dichroism. Transitions I and III are polarized parallel to the permanent dipole moment $\mu_g$ (broken curve $\varepsilon_p$), and II is polarized transverse to $\mu_g$ (dotted curve $\varepsilon_s$); $\mu_g$ is directed along the C–N axis. In spite of the transverse polarization of transition II, light absorption in this band leads to an increase of about 5 D in the dipole moment; thus the polarization of a transition may even be transverse to the net charge displacement.

In the same way *Labhart* analysed the spectra of 2,3-, 1,4-, and 1,8-dichloroanthraquinones, 2,3- and 1,4-dihydroxyanthraquinones, 2,3-, 1,4-, and 1,8-diaminoanthraquino-

[77] *W. Liptay*, Z. Naturforsch. *20a*, 272 (1965).

nes[73], nitrosobenzene, benzaldehyde, *p*-nitrodimethylaniline, *p*-nitrosodimethylaniline, and *p*-dimethylaminobenzaldehyde. The approximate direction of $\mu_g$ was determined theoretically for the unsymmetrical molecules[78].

According to *Czekalla*[79], the transition moments of the long-wavelength absorption bands for all the compounds listed below are parallel to $\mu_g$. The dipole moment $\mu_g$ (in debye units) in benzene solution is given alongside each compound; the dipole moment $\mu_a$ in the first excited state is shown in parentheses. In every case the polarity shows a marked increase on excitation:

4-dimethylamino-4′-nitrostilbene 7.15 (26.5); 4-amino-4′-nitrostilbene 6.50 (22); 4-dimethylamino-4′-cyanostilbene 6.95 (19); 2-amino-7-nitrofluorene 5.75 (23); 4-dimethylamino-4′-nitrobiphenyl 6.60 (24); 4-amino-4′-nitrobiphenyl 6.05 (23); *p*-dimethylamino-ω-nitrostyrene 7.65 (18), *p*-dimethylaminocinnamonitrile 6.90 (14, in hexane); *p*-nitrodimethylaniline 6.85 (15); *p*-nitroaniline 6.30 (14); *p*-nitrosodimethylaniline 6.90 (11.5).

## F. Photoselection

The electric light vector **E** vibrates perpendicular to the direction of propagation of the light. Thus the only molecules that can be optically excited are those whose transition moments have a component in the direction of **E**; *i.e.* in an isotropic solution, the light selects the suitably oriented molecules. Consequently, the excited molecules form an anisotropic entity with a definite degree of orientation, which is retained for some time after excitation in solid solution, *e.g.* in ethanol at 100 °K. The degree of orientation attainable with plane-polarized light is greater than with natural light. Fig. 12 illustrates this "photoselection" for some molecules of different orientation. The transition moment is assumed to lie along the longitudinal molecular axis[80].

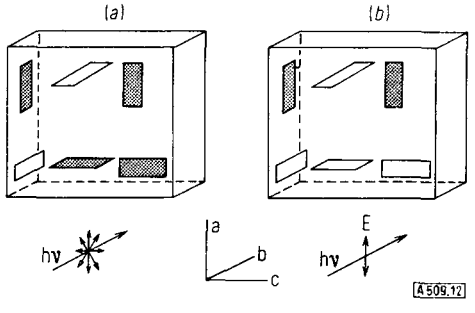

Fig. 12. Photoselection of differently oriented molecules with unpolarized (a) and with plane-polarized (b) light [80]. (The excited molecules are drawn in grey.)

If, after excitation, the molecules return to the metastable triplet state $T_1$, it is possible to measure the polarization of the $T_n \leftarrow T_1$ absorption transitions[81]. If, on the other hand, they undergo a photochemical reaction in the excited state to give a stable product, this product exhibits dichroic absorption[82–85]. The particularly important case in which the excited molecules re-emit partially polarized light ($S_1 \rightarrow S_0$ or $T_1 \rightarrow S_0$) is discussed in Section G.

### 1. Some Special Cases

By averaging over all orientations, *Albrecht* and *Simpson*[84] deduced general formulae for the dichroism, under various excitation and observation conditions, of a solid solution made anisotropic by a photochemical reaction. The most important special cases will be described below.

In Fig. 12b, letters a–c denote the axes of a coordinate system fixed in space. Suppose that the exciting light is propagated in direction b, and that it is plane-polarized along a. If the excited molecules undergo a photochemical change, but retain their positions in the solid solution, the extinctions $E_a$ and $E_b$ of the product of the photochemical reaction can be measured by means of light passing through the sample in direction c and plane-polarized along a and b, respectively. The ratio $E_a/E_b$ is characteristic of the relative orientation of the transition moment $\mathbf{M}_1$ causing the photochemical reaction in the original molecule, and of the transition moment $\mathbf{M}_2$ observed in the absorption of the reaction product.

If the excited molecules do not undergo photochemical reaction, but return to the ground state with emission of light, the emitted light is partially polarized. For observation in the b–c plane, *e.g.* in direction c, let $I_p$ be the intensity of the component of the emitted light polarized parallel to the exciting light, and $I_s$ the intensity of the perpendicularly polarized component.

For the first case above, a dichroic ratio corresponding to Equation (18) can be defined as

$$DV = \frac{E_a - E_b}{E_a + E_b} \qquad (28)$$

For the second case, the degree of polarization P is defined by Equation (21). Table 1 gives values for DV and P for a number of special positions of $\mathbf{M}_1$ and $\mathbf{M}_2$ under the experimental conditions described above.

Table 1. Limiting values of the dichroic ratio DV and the degree of polarization P for various orientations of the transition moment $\mathbf{M}_1$ corresponding to the initial absorption, and of the observed transition moment $\mathbf{M}_2$.

| Orientation of $\mathbf{M}_1$ | Orientation of $\mathbf{M}_2$ | $E_a/E_b$ or $I_a/I_b$ | DV or P |
|---|---|---|---|
| any | parallel to $\mathbf{M}_1$ | 3 | $^1/_2$ |
| any | perpendicular to $\mathbf{M}_1$ | $^1/_2$ | $-^1/_3$ |
| perpendicular to an axis of symmetry $C_n$ where $n > 2$ | parallel to $C_n$ | $^1/_2$ | $-^1/_3$ |
| perpendicular to an axis of symmetry $C_n$ where $n > 2$ | perpendicular to $C_n$ | $^4/_3$ | $^1/_7$ |

[78] *H. Labhart* and *G. Wagnière*, Helv. chim. Acta *46*, 1314 (1963).

[79] *J. Czekalla* and *G. Wick*, Z. Elektrochem., Ber. Bunsenges. physik. Chem. *65*, 727 (1961).

[80] *A. C. Albrecht*, J. molecular Spectroscopy *6*, 84 (1961).

[81] *M. A. ElSayed* and *T. Pavlopoulos*, J. chem. Physics *39*, 834 (1963).

[82] *G. N. Lewis* and *D. Lipkin*, J. Amer. chem. Soc. *64*, 2801 (1942).

[83] *G. N. Lewis* and *J. Bigeleisen*, J. Amer. chem. Soc. *66*, 520 (1943).

[84] *A. C. Albrecht* and *W. T. Simpson*, J. Amer. chem. Soc. *77*, 4454 (1955).

[85] *A. C. Albrecht*, J. Amer. chem. Soc. *82*, 3813 (1960).

It is assumed in the calculation of these values that the fraction of the molecules in the excited state is so small that the solution of the unexcited molecules can still be regarded as isotropic towards photons. This assumption is not valid under intense excitation, such as is required for the measurement of the $T_n \leftarrow T_1$ absorption, and only lower degrees of polarization are then reached [86]. It is also assumed that there is no overlapping of bands and no vibronic interaction.

The photoselection method (and hence the luminescence polarization described in Section G) gives information only about the relative orientation of the various transition moments in a molecule.

### 2. Examples

*El Sayed* and *Pavlopoulos* [77] studied the polarization of the $T_2 \leftarrow T_1$ absorption bands of perdeuterated naphthalene, phenanthrene, and chrysene by photoselection. In perdeuterated naphthalene and phenanthrene, the transition moment lies along the longitudinal molecular axis; it follows that the classification of $T_2$ for phenanthrene is $^3B_{3g}$ or $^3B_{2g}$.

*Albrecht* and *Simpson* [84] produced oriented molecules of Wurster's blue by photo-oxidation of *N,N,N',N'*-tetramethyl-*p*-phenylenediamine in solid solution. From the dichroic absorption of the dye, they deduced the positions of the transition moments: the weak band at 320 mμ, which corresponds to the long-wavelength benzene band, is polarized along the short molecular axis, and the intense band at 290 mμ along the long axis. In the short-wavelength part of the 320 mμ band, the vibrational interaction with the 290 mμ band can be recognized from the decreasing dichroism [85].

## G. Polarized Luminescence of Solid Isotropic Solutions

Of the methods mentioned so far for determining the orientation of transition moments in molecules, the measurement of luminescence polarization is the most general, since nearly all organic compounds have some symmetry and luminesce in solid solution, and since there are available polar, non-polar, acidic, and basic solvents that are transparent after solidification. The apparatus required is relatively simple, with the result that polarization spectroscopy can be developed into a routine method, which may also be of some analytical interest [87].

### 1. Definitions and Equations

Consider the absorption of monochromatic plane-polarized light of a wavelength corresponding to an isolated absorption band of the molecules in solid solution. Let the angle between the absorbing transition moment $\mathbf{M}_i$ and the emitting oscillator in the molecule be $\alpha_i$. The degree of polarization [88,89,113] of the luminescence is the same for every direction of observation in the b,c plane, which is perpendicular to the polarization direction a of the exciting light (see Fig. 12b), and is given by

$$P \equiv \frac{I_p - I_s}{I_p + I_s} = \frac{1-\rho}{1+\rho} = \frac{3\cos^2\alpha_i - 1}{\cos^2\alpha_i + 3} \qquad (29)$$

where $\rho = I_s/I_p$ is the depolarization; $I_p$ and $I_s$ are the intensities of the components polarized parallel and perpendicular to the exciting light, respectively. The limiting values are

$$-\frac{1}{3} \leqslant P \leqslant \frac{1}{2}; \quad 2 \geqslant \rho \geqslant \frac{1}{3}$$

It follows from Equation (29) that

$$\cos^2\alpha_i = \frac{3P+1}{3-P} = \frac{2I_p - I_s}{I_p + 2I_s} \qquad (30)$$

*Jablonski* calls the quantity r, defined by Equation (31), the degree of anisotropy.

$$r \equiv \frac{I_p - I_s}{I_p + 2I_s} = \frac{2P}{3-P} \qquad (31)$$

If several absorption transitions with extinction coefficients $\varepsilon_{i\lambda}$, whose oscillators include various angles $\alpha_i$ with the emitting oscillator, overlap at the exciting wavelength $\lambda$, then (still assuming excitation with plane-polarized light) we have

$$\left(\frac{2I_p - I_s}{I_p + 2I_s}\right)_\lambda \equiv B_\lambda = \frac{\sum_i \varepsilon_{i\lambda}\cos^2\alpha_i}{\sum_i \varepsilon_{i\lambda}} = \frac{\varepsilon_{1\lambda}}{\varepsilon_\lambda}\cos^2\alpha_1 + \frac{\varepsilon_{2\lambda}}{\varepsilon_\lambda}\cos^2\alpha_2 + \cdots \qquad (32)$$

The limiting values are $0 \leqslant B_\lambda \leqslant 1$.

$\sum_i \varepsilon_{i\lambda} = \varepsilon_\lambda$ is the total extinction coefficient measured at the wavelength $\lambda$.

In most cases, only two transitions overlap appreciably. If their polarizations relative to the emission are known (*e.g.* $\alpha_1 = 0°, \alpha_2 = 90°$), they can be separated according to Equation (32) if P is known. Thus for $\alpha_1 = 0°$ and $\alpha_2 = 90°$ we have:

$$\varepsilon_1 = \varepsilon\,\frac{3P+1}{3-P}; \quad \varepsilon_2 = \varepsilon - \varepsilon_1 \text{ [*]}. \qquad (33)$$

*Czekalla* and *Liptay* [90] developed the theory under very general assumptions: overlapping absorption bands, excitation and observation with high spectral bandwidths so that an average is obtained over various vibrational transitions, and no restrictions on the orientations of the oscillators. However, definite conclusions can be reached only if certain simplifications are introduced. The amount of information obtained is greatest for molecules of "medium" symmetry, particularly those of the symmetry groups $C_{2v}$, $D_2$, $D_{2h}$, $D_{3h}$, and $D_{6h}$, and for compounds whose π-electron systems

[88] *F. Perrin*, Ann. Phys. *12*, 169 (1929).
[89] *A. Jablonski*, Z. Physik *96*, 236 (1935).
[*] The formula given in the review [1] for this case is wrong, since the factor 2 in the case of $I_s$ is neglected.
[90] *J.Czekalla*, *W. Liptay*, and *E. Döllefeld*, Ber. Bunsenges. physik. Chem. *68*, 80 (1964).

approximately have such a symmetry despite unsymmetrical substitutions.

According to *Czekalla*[90], if the bandwidth of the exciting and measuring light is sufficiently small, the degree of anisotropy [Eq. (31)] of the $S_1 \rightarrow S_0$ fluorescence, $r_f$, is proportional to that of the $T_1 \rightarrow S_0$ phosphorescence, $r_{Ph}$, for all exciting wavelengths:

$$r_f = A \cdot r_{Ph} + B. \tag{34}$$

According to Section C.2b, the phosphorescence generally consists of several components. The components of the total phosphorescence intensity $I_{Ph}$ that are polarized in various directions in the molecule can be determined from the experimental values of A and B.

For molecules with three mutually perpendicular principal axes (x is chosen perpendicular to the plane of the molecule), we have[90]:

$$\begin{aligned} I_{Ph}(x) &= \frac{A - 1 + 10\,B}{3\,A} \\ I_{Ph}(y) &= \frac{A - 1 - 5\,B}{3\,A} + \frac{I_F(y)}{A} \\ I_{Ph}(z) &= \frac{A - 1 - 5\,B}{3\,A} + \frac{I_F(z)}{A} \end{aligned} \tag{35}$$

$I_{Ph}(i)$ phosphorescence components; $I_F(i)$ fluorescence components; i = x, y, z.

It was assumed above that absorption and fluorescence are both polarized in the plane of the molecule. This is frequently not the case, *e.g.* for $\pi^* \leftarrow n$ transitions or when there is pronounced coupling with out-of-plane deformation vibrations. In any case, it is desirable to obtain the greatest possible spectral resolution. Owing to the band overlap, more information can usually be obtained from the wavelength-dependent variation of the degree of polarization than from its absolute value.

A fundamental and as yet unsolved problem is that of how to differentiate between 0,0-transitions (whose polarization is characteristic of the pure electronic states involved) and vibronic transitions.

## 2. Experimental Technique

### a) Apparatus

Several recent publications describe methods for measuring one of the quantities ρ, P [Eq. (29)], r [Eq. (31)], or $B_\lambda$ [Eq. (32)][18,90–94].

*Ainsworth* and *Winter*[95] developed a recording instrument, which forms any function of the depolarization ρ using an analogue computer. The recording instrument described by *Dehler* and *Dörr*[96] for the degree of polarization P is particularly simple in operation; this instrument is shown in Fig. 13, together with an arrangement for separate measurements of $I_p$ and $I_s$.

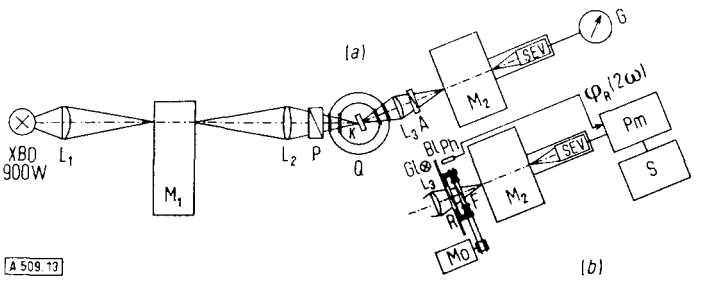

Fig. 13. Apparatus for the measurement of luminescence polarization (a) and accessory for automatic recording (b).

P Glan-Thomson-polarizer; electric vector of the transmitted light perpendicular to the plane of the drawing; K sample in a quartz Dewar vessel; A film polarizer, rotatable through 90°; $M_1$, $M_2$ monochromators; R rotating film polarizer; F fixed film polarizer, at 45° with respect to P; Gl, Bl, Ph incandescent lamp, rotating sector diaphragm, and photoresistor as phase standard; Mo motor; S pen recorder; Pm phase meter.

If the polarizer R rotates with a frequency ω, the photoelectric current consists of a direct component and two alternating components with frequencies 2ω and 4ω, respectively. The 2ω component is proportional to

$$(I_p - I_s)\cos 2\omega t + (I_p + I_s)\sin 2\omega t \approx \sin(2\omega t - \varphi)$$

where

$$\tan\varphi = \frac{I_p - I_s}{I_p + I_s} = P.$$

tan φ can be measured electrically with respect to the phase of a reference signal of frequency 2ω.

Observation at a small angle to the exciting light beam gives greater freedom in the choice of concentration than observation at right angles, since it is necessary in the latter case to match the concentration to the extinction (which depends on the wavelength), because of the strong dependence of the penetration depth on the wavelength. If ring cells or fused silica cells[96] with round bottoms and layer thicknesses of less than 3 mm are used, the stress birefringence in the sample is negligible. With high-pressure xenon lamps, the short-

[98] According to *M. Pestemer*: Anleitung zum Messen von Absorptionsspektren. G. Thieme Verlag, Stuttgart 1964.

wavelength excitation limit is about 220 mμ in favorable cases. The long-wavelength limit on the luminescence side is determined by the decrease in the sensitivity of the detector. A good film polarizer can be used in the range 310 to 700 mμ. Sheet polarizers for the short-wave ultraviolet have been described by *McDermott* [97]. In the polarization spectra of Fig. 14, the width at half-intensity of the exciting light and of the luminescence light is less than or equal to 2 mμ between 250 and 500 mμ.

The best solvents and solvent mixtures, which remain vitreous down to a temperature $t_G$, are listed in Table 2 [98]. The quantum yield in ethanol is generally higher than in non-polar solvents. To ensure accurate assignments, all the spectra to be compared must be recorded in the same solvent and at the same temperature.

### b) Corrections

When the measurements are carried out with an apparatus corresponding to Fig. 13a, the inherent polarization of the apparatus is included in the results. A λ-dependent correction factor is determined for the depolarization, $\rho = I_s/I_p$, by using translucent paper (instead of the sample) to produce non-polarized light. (The polarizer P is removed for these measurements). The values of P, r, or $B_\lambda$ corresponding to ρ are read off from a conversion table. The arrangement shown in Fig. 13b eliminates the polarization due to the apparatus, and is largely independent of variations in the intensity of the exciting light; it is used for the direct measurement of the degree of polarization P. Stray light causes a positive error in P. A check can be made for stray light by excitation at a slightly lower wavelength and examination of the region on the short-wavelength side of the luminescence spectrum with the receiver monochromator $M_2$; the intensity reading should then return to zero. If the transmission ranges of the two monochromators overlap then measurement becomes impossible, and for this reason single grating monochromators have not proved very useful. In practice, uncorrected P values are obtained only in the range $-0.32 \leqslant P \leqslant 0.47$; the limiting figures −0.33 and +0.5 are not reached. The main reason for this is probably the fact that depolarization due to passage through the various windows and lenses cannot be completely eliminated. In more concentrated solutions depolarization occurs as a result of energy migration (Section G.3.l); the magnitude of this effect is estimated by comparing the values obtained at various concentrations. The concentration limit at which depolarization due to energy migration becomes appreciable depends on the substance and on the solvent. It is greater than $10^{-3}$ M for aromatic compounds and ketones, and less than $10^{-4}$ M for dyes. It is often found that 1/P is linear in the concentration; cf. Section H and Fig. 21b.

## 3. Examples

The spectra in Figs. 14 to 20 were recorded using the arrangements shown in Fig. 13. In most cases it is possible to resolve the vibrational structure. Four types of polarization spectra can be recorded by the use of two monochromators:

(a) APF (absorption-polarization spectrum based on the fluorescence): the receiver is adjusted to one vibration fluorescence band (preferably the 0,0-band), and the wavelength of the exciting light is varied over the various absorption bands.

(b) APPh: as in (a), but based on the phosphorescence.

(c) FP (fluorescence polarization spectrum): A certain vibration band of the absorption spectrum (preferably the longest-wavelength 0,0-band) is excited, and the relative polarization of the various vibration bands in the fluorescence spectrum is determined.

(d) PhP: as in (c), but for the phosphorescence instead of the fluorescence.

All four types of polarization spectra are shown in Fig. 14 for phenanthrene, together with the normal absorption, fluorescence, and phosphorescence spectra.

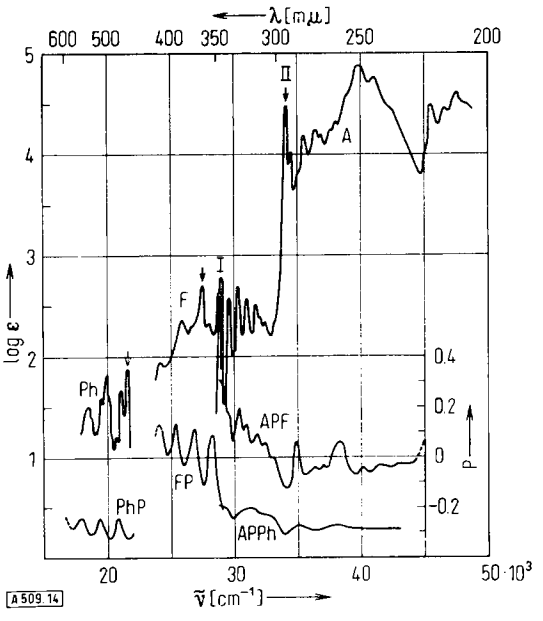

Fig. 14. Spectra of phenanthrene in $10^{-3}$ M ethanolic solution at 90 °K [96].

### a) A Simple Symmetrical Cyanine

In the simple pentamethinecyanine *(1)*, all the $S_n$–$S_0$ transition moments lie in the plane of the molecule. Theoretical considerations and measurements on stretched films indicate that the long-wavelength transition is polarized along the longitudinal axis.

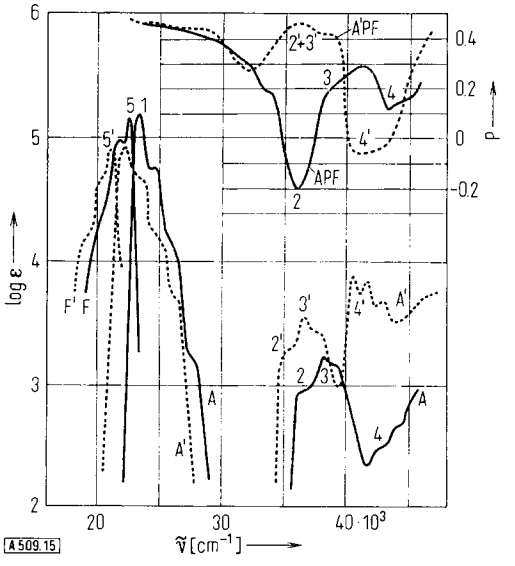

Fig. 15. Spectra of α,ω-di-(*N*-pyrrolidinyl)pentamethinecyanine in $10^{-4}$ M ethanolic solution at 90 °K [112]. *trans* (———); *cis* (– – – –); A,A′ absorption; F,F′ fluorescence.

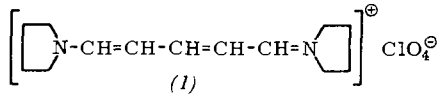
Fig. 15 shows the absorption spectrum (A) and the APF spectrum of the all-*trans* form of *(1)*. Since the symmetry is $C_{2v}$, all the transition moments are mutually parallel



*(1)*

or perpendicular. It can be concluded from the APF curve that transitions 1 and 3 are polarized along the longitudinal axis, and transitions 2 and 4 along the transverse axis. The curves A′ and A′PF are discussed in Section G.3k.

### b) Vibronic Interactions

The maxima and minima of the curves APF, FP, and PhP in Fig. 14 coincide with (partly masked) vibration bands in the absorption spectrum A. The degree of polarization, APF, decreases in the electron band I (29000–34000 $cm^{-1}$) with excitation of higher vibrational levels, since the increase in the vibration amplitude is accompanied by an increase in the vibronic coupling with the negatively polarized transition II. In the symmetry classification, I belongs to the representation $A_1$ (polarized parallel to the short axis), and II belongs to $B_1$ (polarized along the long axis); according to Equation (9) the coupled vibration of about 700 $cm^{-1}$, which causes the minima in APF, also has symmetry $b_1$ (in-plane deformation vibration) [93,99].

### c) $T_1 \rightarrow S_0$ Phosphorescence in Aromatic Compounds

The APPh spectrum in Fig. 14 shows that the $T_1 \rightarrow S_0$ phosphorescence of phenanthrene ($C_{2v}$) consists of a strong y-component [$\Gamma(y) = B_2$] perpendicular to the plane of the molecule, and a weak z-component [$\Gamma(z) = A_1$] parallel to transition I. Assuming that only the spin-orbital coupling of $T_1$, and not that of $S_0$, is important, and that the orbital function of $T_1$ belongs to the representation $B_1$, then the intense y-component results from the interaction of $T_1$, *via* $\mathfrak{H}'_{ls}(z)$ ($A_2$), with a $B_2$ state of the type $S(\sigma\pi^*)$ [93]. The maxima in the PhP spectrum may be due to $a_2$ or $b_1$ vibrations. The $T_1 - S_0$ oscillator is also perpendicular to the plane of the molecule in many other aromatic and N-heterocyclic compounds [100–103].

### d) The Heavy-Atom Effect in Spin-Orbit Coupling

The phosphorescence of naphthalene consists of a principal component perpendicular to the plane of the molecule, and a small component parallel to $^1L_b$ (the major axis). Halogenation in position 1 leads to an increase in the intensities of the components along the long and short axes, the effect increasing with the atomic number [cf. Eq. (13)]. Substitution in position 2, on the other hand, has very little effect (cf. Table 3) [90,104].

Table 3. Change in the APPh spectrum of naphthalene as a result of monohalogenation [104].

| $T_1 \rightarrow S_0$ | Naphthalene | 1-F | 1-Cl | 1-Br | 1-I | 2-F | 2-Cl | 2-Br | 2-I |
|---|---|---|---|---|---|---|---|---|---|
| P *vs.* $^1L_b$ [*] | −0.30 | −0.22 | −0.20 | −0.04 | +0.13 | −0.26 | −0.25 | −0.22 | −0.18 |
| P *vs.* $^1L_a$ [*] | −0.32 | −0.28 | −0.17 | +0.02 | +0.15 | −0.29 | −0.24 | −0.25 | −0.24 |

[*] 0,0-Band

### e) High Symmetry

Fig. 16 shows the fluorescence (F) and phosphorescence (Ph) spectra of triphenylene (symmetry group $D_{3h}$). Similar spectra are obtained with coronene ($D_{6h}$). The fluorescence is polarized in the plane perpendicular to the threefold (or sixfold, respectively) axis of symmetry; FP has the value $+1/7$ for all absorption transitions [105] (cf. Table 1). The phosphorescence is largely polarized perpendicular to the plane of the molecule; it is coupled with non-totally symmetric vibrations. (In the case of coronene, the fluorescence and phosphorescence spectra overlap to some extent.) The APF curve of crystal violet reaches values greater than 0.4 in the long-wavelength part of the "color band" [30,91]; this is consistent with the fact that the molecule does not possess threefold symmetry owing to steric hindrance.

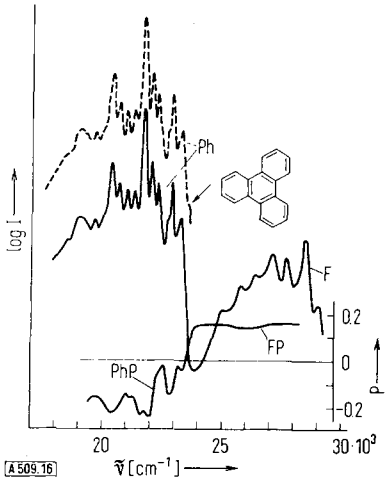


Fig. 16. Fluorescence (F) and phosphorescence (Ph) of triphenylene (example of a highly symmetrical molecule) in $10^{-3}$ M ethanolic solution at 90 °K [101].

### f) Aromatic Ketones

Aromatic ketones with long-wavelength $\pi^* \leftarrow n$ shoulders (cf. example in Section C.2a) do not fluoresce, but simply exhibit a $T_1(n\pi^*) \rightarrow S_0$ phosphorescence. This is probably parallel polarized to the C–O direction [20][cf. the example following Eq. (17)]. Fig. 17 shows the APPh spectrum of anthrone [106, 107]. The $\pi^* \leftarrow n$ absorption band is largely negatively polarized with respect to the C–O axis, probably in the plane of the molecule. The APF spectrum in the $\pi^* \leftarrow n$ band rises towards shorter wavelengths; the $S(n\pi^*) \leftarrow S_0$ transition can couple, by means of a non-planar $a_2$ vibration, with a $\pi^* \leftarrow \pi$ transition, resulting from the splitting of the transitions in the benzene rings, and lying in the C–O direction ($A_1$) [106–108].

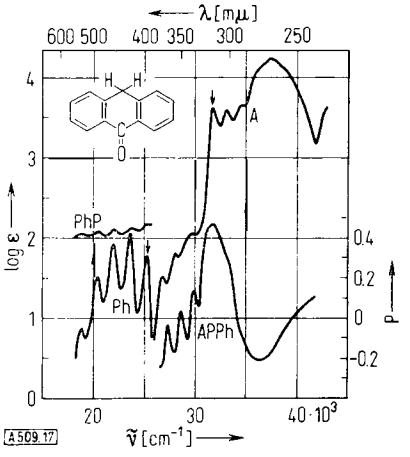

Fig. 17. Spectra of anthrone, $10^{-2}$ to $10^{-4}$ M in 2-methyltetrahydrofuran at 90 °K [108].

### g) N-Heterocycles

N-Heterocycles containing one or two rings give separate $\pi^* \leftarrow n$ transitions only if they contain two or three nitrogen atoms in the same ring. The $S(n\pi^*) \leftarrow S_0$ transition moment is perpendicular to the plane of the ring, and the $T_1 \rightarrow S_0$ emission from pyrazine and pyrimidine is polarized parallel to the N–N direction. In these compounds the $T_1$ state is of the ($n\pi^*$) type [18, 92].

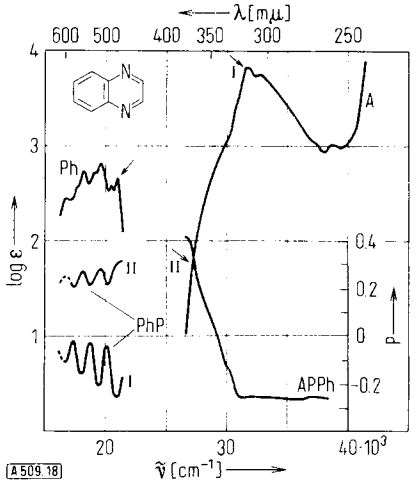

Fig. 18. Spectra of quinoxaline in $10^{-2}$ M ethanolic solution at 90 °K [110].

In quinoxaline, on the other hand, $T_1$ is of the ($\pi\pi^*$) type [109], and presumably (by analogy with the $^3L_a$ state of naphthalene) belongs to the representation $B_2$ (symmetry $C_{2v}$). The PhP and APPh spectra are positive on excitation in the $\pi^* \leftarrow n$ shoulder, and negative on irradiation in the strong $\pi^* \leftarrow \pi$ absorption bands (see Fig. 18) [92, 110].

### h) Masked Transitions

The $\pi^* \leftarrow n$ transition is not observed in the absorption spectrum of benzoquinoxaline since it is masked by the much stronger $\pi^* \leftarrow \pi$ bands. However, the $S(n\pi^*) \leftarrow S_0$ transition corresponds to the minimum in the APF spectrum and to the maximum in the APPh spectrum at 32000 $cm^{-1}$ [110]. *Zimmermann* and *Joop* [111] found an unexplained absorption band at 33900 $cm^{-1}$ in the polarization spectra of azulene. Calculation of the spectrum of azulene gives a corresponding excited state only if configuration interaction is taken into account.

### i) Hybridization State of a Heteroatom

Figs. 19 and 20 show the spectra of dibenzothiophene and its *S,S*-dioxide. These two compounds differ very markedly in their APF and APPh spectra. This must be due to the change in the hybridization of the sulfur atom.

### k) *cis-trans* Isomerism

The cyanine *(1)* (Fig. 15) undergoes a reversible photoisomerization. The absorption curve A′, the fluorescence spectrum F′, and the polarization spectrum A′PF are those of the product. The intensification of the short-axis polarized transition 4′ supports the proposed explanation, *i.e.* that light rearranges the compound to give an unstable mono-*cis* form [112].

### l) Concentration Depolarization

The radiationless transfer of excitation energy between identical molecules leads to a depolarization of the fluorescence, as can be seen from the FP spectrum, in which P tends towards zero. An example of this is shown in Fig. 21 [30]. The probability of energy migration increases with concentration [113]. The association of dye molecules is also clearly shown by the APF spectrum, sometimes at even lower concentrations than in the ab-

(a) Concentration depolarization (1) and concentration quenching (2) of the fluorescence; (b) linearity of 1/P with concentration; $I_{rel}$ relative fluorescence intensity.

sorption spectrum[114]. The phenomenon of association differs from depolarization due to energy migration in that the degree of polarization of the luminescence of the associates can even become negative.

### m) Polarization of Charge-Transfer Bands

*Mulliken*'s theory of electron donor-acceptor complexes (charge-transfer complexes) explains the long-wavelength, so-called CT absorption bands as resulting from electron transfer from the donor D to the acceptor A. The transition moment should lie along the line joining the electrical "centers of gravity" of A and D, *i.e.* for two planar molecules placed one above the other, the transition moment should be perpendicular to the planes of the molecules[*]. In solid solution, the $T_1 \rightarrow S_0$ phosphorescence of the donor molecule can be observed on excitation in this CT band[115].

In the cases of naphthalene (Table 3), phenanthrene (Fig. 14), and chrysene[101], the $T \rightarrow S_0$ transition is polarized perpendicular to the plane of the molecule. *Chowdhury* and *Goodman*[116] found that, in the complexes of tetrachlorophthalic anhydride with these aromatic compounds, the CT absorption band is polarized parallel to the phosphorescence band of the aromatic compound. This confirms the proposed "sandwich" structure.

### n) Fluorescence from Two Terms

Some compounds, *e.g.* indole, have a broad absorption band at long wavelengths, and a broad fluorescence band which is almost a mirror image of the absorption band. The polarization spectra show that both bands consist of two transitions, *i.e.* that two adjacent levels $S_1$ and $S_2$ with different symmetries are emitting simultaneously. The radiationless transition $S_2 \rightarrow S_1$ (cf. Fig. 1) is strongly hindered in this case[117,118].

## H. Polarization of the Luminescence of Liquid Solutions

*Perrin*[88] corrected for the depolarization in liquid solutions due to the rotation of the excited molecule (which was assumed to be spherical) by means of Equation (36). *Memming*[119] extended the theory to include non-spherical molecules.

$$\frac{1}{P} = \frac{1}{3} + \left(\frac{1}{P_0} - \frac{1}{3}\right)\left(1 + \frac{3\tau}{\rho_0}\right) \qquad (36)$$

with $\rho_0 = \eta V/kT$

[114] *V. Zanker, M. Held,* and *H. Rammensee,* Z. Naturforsch. *14b,* 789 (1959).

[115] *G. Briegleb, J. Czekalla, W. Herre,* and *R. Glier,* Z. Elektrochem., Ber. Bunsenges. physik. Chem. *61,* 537, 1053 (1957).

[116] *M. Chowdhuri* and *L. Goodman,* J. Amer. chem. Soc. *86,* 2777 (1964).

[*] From formal selection rules, transverse polarization should also be possible in special cases.

[117] *H. Zimmermann* and *N. Joop,* Z. Elektrochem., Ber. Bunsenges. physik. Chem. *65,* 61 (1961).

[118] *V. P. Klochkow* and *B. S. Neporent,* Optics and Spectroscopy *12,* 125 (1962) [Engl. transl. of Optika i Spektroskopiya].

[119] *R. Memming,* Z. physik. Chem. *68,* 80 (1964).

P: measured degree of polarization; $P_0$: limiting degree of polarization for the frozen solution; $\tau$: lifetime of the excited state; $\eta$: viscosity of the solvent at the temperature T; V: (effective) molecular volume.

It is found experimentally that 1/P is nearly linear in $T/\eta$, provided that there is no temperature-dependent quenching to shorten the lifetime $\tau$. If $\tau$ is appreciably reduced (this can also result from the concentration-dependent action of a fluorescence quencher), then according to Equation (36), P approaches the limiting value $P_0$ for the frozen solution. The degree of polarization can therefore also be used as an indicator for quenching effects (see [30]).

If the molecular volume V is known, *e.g.* from viscosity measurements, Equation (36) provides a means of determining the lifetime $\tau$. If, on the other hand, $\tau$ is measured independently, it is then possible to determine the molecular volume V. This may be of great practical importance especially for large molecules, for example, in biochemistry. Non-fluorescent macromolecules often interact with dye molecules to form fluorescent associates, which can be used for the measurement of rotational depolarization. Any change in the molecular volume as a function of temperature or of the concentration of other solutes (*e.g.* of the pH) can be detected from the variation of the degree of polarization.

[120] *G. Weber*, Advances in Protein Chemistry *8*, 415 (1953).

The quantity $\rho_0$ in Equation (36) has the significance of a rotational relaxation time. Only for spherical molecules is there a simple definition for it. For ellipsoids of revolution or for molecules in which two parts can rotate relative to each other, $\rho_0$ consists of two components $\rho_a$ and $\rho_b$:

$$\rho_0 = \frac{2(\rho_a + \rho_b)}{\rho_a \cdot \rho_b} \qquad (37)$$

Restriction or enhancement of such internal rotations by co-solutes also lead to a change in $\rho_0$, and hence in the degree of polarization.

The effects described in this section form the bases of some interesting applications of polarization spectrometry in biochemistry. *Weber*, who introduced this method to this field, published a survey of his results and an introduction to his extended theory [120]. He listed the following advantages: low concentrations (*e.g.* $10^{-2}$ % serum albumin) can be used; P is almost independent of the salt and protein concentrations; the temperature and pH can be varied within wide limits; in mixtures, a certain protein may be labelled; the procedure is relatively simple.

# Carbohydrates Containing Nitrogen or Sulfur in the "Hemiacetal" Ring

BY PRIV.-DOZ. DR. H. PAULSEN

CHEMISCHES STAATSINSTITUT, INSTITUT FÜR ORGANISCHE CHEMIE, UNIVERSITÄT HAMBURG (GERMANY)

*In 5-amino-5-deoxy- and 5-thioaldoses, a 6-membered hemiacetal ring can be formed by incorporation of a nitrogen or sulfur atom into the ring instead of the oxygen present in pyranoses. In the case of 5-(N-acylamido)-5-deoxyaldoses, the nucleophilic strength of the amide grouping is lowered, with the result that ring closure occurs only when sterically favored, or when a side reaction with formation of furanose is not possible. On the other hand, 5-amino-5-deoxyaldoses containing a free amino group readily form 6-membered "hemiacetal" rings. The resulting piperidinoses possess properties that are unusual in sugars, since they contain the 2-hydroxypiperidine ring system. Piperidinoses are stable to alkalis and labile to acids; they rearrange in the presence of acids to give Amadori compounds, or lose three molecules of water to give derivatives of β-hydroxypyridines. Owing to the high reactivity of the mercapto group, 5-thioaldoses form only sugars with rings containing sulfur, the behavior of which resembles that of the oxygen analogues. 4-Amino-4-deoxy- and 4-thioaldoses can form 5-membered rings containing nitrogen and sulfur.*

## I. Introduction

Free monosaccharides generally do not exist in the open-chain carbonyl form, but in the cyclic hemiacetal form, which results from the intramolecular reaction of the carbonyl group with a hydroxyl group. This reaction usually involves the hydroxyl group on C-5, and leads to the formation of a 6-membered pyranose ring. The 6-membered ring in the chair form is favored energetically, since in this form all the substituents assume the staggered position, particularly when the ring is fixed in one of the two chair forms, the C 1 or the 1 C form (see Fig. 1), by a sufficient number of bulky substituents.

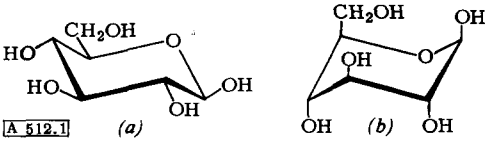

Fig. 1. β-D-Glucose: C 1 form (a) and 1 C form (b).

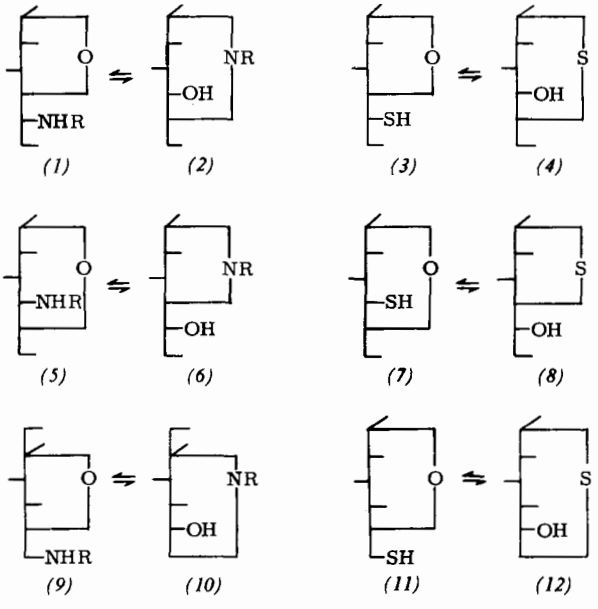
The hydroxyl group on C-4 can also react to give a 5-membered furanose ring. Owing to the presence of the substituents, however, the furanose ring is stereochemically unfavored and, therefore, is formed only in special cases (*e.g.* when position 5 is blocked).

It is interesting to replace the oxygen in the hemiacetal rings of sugars by other heteroatoms, particularly nitrogen and sulfur, and to study the properties and reactions of modified sugars of this type. We started with the synthesis of 5-amino-5-deoxy sugars, which were expected to form "hemiacetal" rings. In this way we obtained the first crystalline member of this class of substances, *N*-acetyl-α-D-xylopiperidinose [1]. Other sugars with rings containing sulfur or nitrogen have been prepared in recent years. These compounds are not only of chemical interest, but may also act as antimetabolites, particularly since many antibiotics contain aminodeoxy sugars with unusual structures [2].

Direct substitution of the ring oxygen, which is readily achieved in pyran chemistry, *e.g.* in the case of kojic acid [3], is not possible in the case of monosaccharides, since this is equivalent to *O*-alkyl cleavage on C-5, which does not occur in acetals. Thus the problem is to introduce a substituent containing the desired new heteroatom into position 5 of the monosaccharide, *i.e.* to synthesize a 5-amino-5-deoxy or a 5-thio sugar. Pyranose derivatives naturally cannot be used in this synthesis, which, therefore, must be carried out with furanose derivatives or derivatives of open chain forms.

Formulae *(1)* to *(12)* show a number of model schemes for the reaction of compounds substituted in this way. In the 5-amino-5-deoxy sugar *(1)* ⇌ *(2)*, the amino group competes with a hydroxyl group in the formation of the "hemiacetal" ring. If the amino group is sufficiently reactive with respect to acetal formation, a 6-membered ring *(2)* containing nitrogen is formed. If the amino group is not sufficiently reactive, the reaction leads to the formation of the energetically less favorable furanose form *(1)*. A similar situation occurs in the case of the 5-thio sugar *(3)* ⇌ *(4)*, in which there is competition between the mercapto group and a hydroxyl group.



In the compounds *(5)* ⇌ *(6)* and *(7)* ⇌ *(8)*, the positions of the substituents have been interchanged. A 5-membered ring *(6)* containing nitrogen will be formed only if the amino group is sufficiently reactive to overcome the preference for the 6-membered pyranose ring *(5)*. The same is true in the case of the derivatives *(7)* ⇌ *(8)* containing sulfur. Examples of other systems are the 6-amino-6-deoxy ketoses *(9)* ⇌ *(10)*, in which a 6-membered ring form *(10)* containing nitrogen is in equilibrium with a furanose form *(9)*. In very reactive aldoses with substituents in position 6, *e.g.* 6-thioaldose *(11)*, it is possible that a 7-membered ring *(12)* containing sulfur, which ordinarily would be energetically unfavorable, could enter into the equilibrium [3a].

The possibilities for tautomerism can be greatly increased if the positions of the heteroatoms O, N, and S (and possibly also Se) are interchanged. Though only some of these possibilities have so far been studied, it is already possible to recognize the fundamental modes of reaction of sugars containing nitrogen and sulfur in the ring.

There are two basic types of 5-amino-5-deoxy sugars, *i.e.* those containing *N*-acylated amino groups and those containing free amino groups. The amino group loses much of its basic character on acylation, owing to amide mesomerism, and it is, therefore, less able to compete with the hydroxyl group. Thus amides cannot form *N*-glycosides by direct reaction, except in the case of urea and glucose [4]. The Mannich condensation of amides [5] requires stronger acid catalysis than the corresponding reaction of amines [6]. 5-Acylamido-5-deoxy sugars, therefore, form 6-membered rings containing nitrogen only when ring formation is highly favored by steric factors, *e.g.* in the case of 5-acetamido-5-deoxy-D-xylose, or when this is the only ring that can be formed. Monosaccharides with an *N*-acylimino group in the ring behave in the same manner as the corresponding oxygen compounds, and react with alcohols to form glycosides.

5-Amino-5-deoxy sugars containing free amino groups behave quite differently. The more strongly nucleophilic amino group competes strongly with the hydroxyl group. This can be seen in the reaction of aldoses with amines, in which the glycosidic hydroxyl group readily can undergo nucleophilic substitution with formation of an *N*-glycoside. Thus 5-amino-5-deoxy sugars preferentially form a 6-membered ring containing nitrogen [*(2)*, R = H].

These piperidinoses *(2)*, R = H, exhibit properties not previously observed in carbohydrate chemistry. In contrast to all other monosaccharides, these sugar derivatives are stable only in alkaline solution; in the presence of acids they readily lose 3 moles of water to form derivatives of 3-hydroxypyridine. In alkaline media, the 2-hydroxypiperidine system is present; the sugar derivatives, therefore, possess some of the properties of this system, particularly the tendency to form piperideine. Thus it seems reasonable to name these sugar derivatives piperidinoses.

Owing to the high reactivity of the mercapto group, 5-thio sugars readily give the ring form *(4)*, in which the sulfur is built into the 6-membered ring. The mercapto group is more reactive than the amino group, since the reaction of aldoses with mercaptans always leads to cleavage of the hemiacetal ring and formation of the open-chain mercaptals; no thioglycosides are formed. The properties of the thiopyranoses [*] are similar to those of the corresponding oxygen compounds.

## II. Monosaccharides Containing Nitrogen in the Ring

### 1. Sugars with N-Acylimino Groups in the "Hemiacetal" Ring

#### a) 5-(*N*-Acylamido)-5-deoxy Sugars

The first sugar with nitrogen in the "hemiacetal" ring obtained in crystalline form was *N*-acetyl-D-xylopiperi-

[1] *H. Paulsen*, Angew. Chem. *74*, 901 (1962), Angew. Chem. internat. Edit. *1*, 597 (1962).

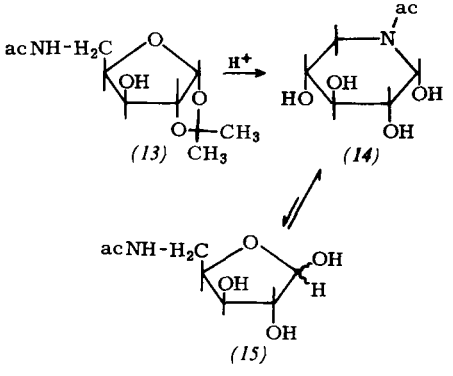
[*] The term "thiopyranose" is used in this paper for monothiopyranoses in which the oxygen in the hemiacetal ring is replaced by sulfur (cf. also Section IIIa).

dinose *(14)* [1,7–10]. Partial acid hydrolysis of the compound *(13)* leads to a mixture of piperidinose *(14)* and furanose *(15)* in the ratio 2:1, from which the crystalline piperidinose *(14)* is obtained directly[7]. Both forms *(14)* and *(15)* are stable in neutral solution and can, therefore, be separated by column chromatography without fear of interconversion due to readjustment of the equilibrium. Equilibration occurs only with catalysis by acids or bases. Thus with *(14)* or *(15)* in the presence of 0.1 N HCl at room temperature, equilibrium is reached after about 35 h [9]. In the presence of bases, equilibration takes only a few minutes; however, side reactions also occur in this case.

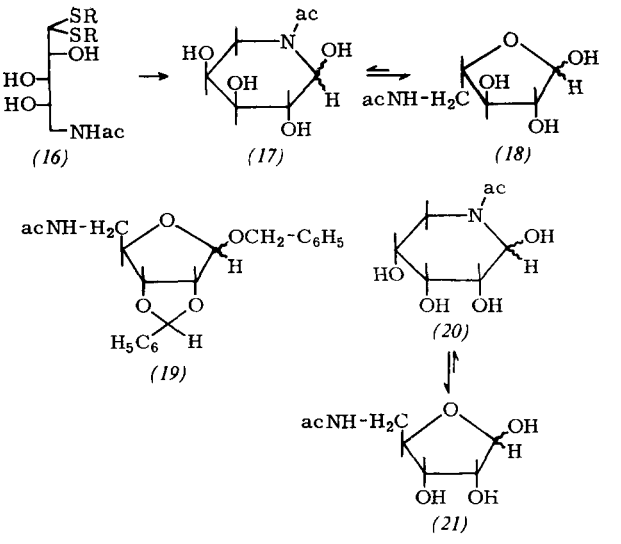


The 6-membered cyclic form of the piperidinose *(14)* is proved by the following results. The infrared spectrum of *(14)*, unlike that of *(15)*, does not contain an amide-II band due to an NH group. Peracetylation of *(14)* gives a tetraacetate, and that of *(15)* a triacetate[7]. The results obtained on cleavage of *(14)* with periodate indicate a 6-membered ring form[8], as do the differing NMR spectra of *(14)* and *(15)* [9].

The proportion of the piperidinose form can be increased by partial hydrolysis of 5-carbobenzoxyamino-5-deoxy-1,2-*O*-isopropylidene-D-xylofuranose. The product consists almost entirely of crystalline *N*-carbobenzoxy-D-xylopiperidinose, since the furanose concentration at equilibrium is small[11]. The carbobenzoxyamino group is evidently more strongly nucleophilic than the acetamido group, with the result that the 6-membered ring containing nitrogen is preferred. The behavior of *N*-benzoyl-D-xylopiperidinose is similar to that of the *N*-acetyl compound[11a].

The piperidinose *(14)* reacts readily with alcohol/hydrochloric acid to form the corresponding glycoside, in which the acetamido group is still built into the ring; this method has been used to prepare *e.g.* methyl- and benzylxylopiperidinosides[7,8], the properties of which are similar to those of the oxygen analogues.

5-Acetamido-5-deoxy-L-arabinose can be prepared, like *(14)*, by hydrolysis of a suitable 1,2-isopropylidene compound[12] or by elimination of RSH from *(16)*



with $HgCl_2$–$CdCO_3$ [9]. The product is again a mixture of the 6-membered and 5-membered ring forms *(17)* ⇌ *(18)*; the equilibrium ratio of *(18)* to *(17)* is approximately 2:1, *i.e.* in contrast to the *xylo* compound, the furanose form *(18)* appears to be favored in this case. In 5-acetamido-5-deoxy-D-ribose, which can be obtained by hydrogenolysis of *(19)* [9], the proportion of piperidinose *(20)* in the equilibrium mixture is even smaller, so that the isolation of *(20)* is not easy [9].

These results show that the weakly nucleophilic acetamido group cannot form a "hemiacetal" ring containing nitrogen except under the most favorable steric conditions. Such favorable conditions exist in the *xylo* configuration in the 6-membered ring, in which all the substituents are in the equatorial position, and where there is no steric hindrance by bulky substituents on C-5. This should, therefore, be the configuration assumed by most of the piperidinose form in the equilibrium *(14)* ⇌ *(15)*. Even in the case of the *arabino* configuration, containing one axial hydroxyl group, the proportion of the piperidinose form *(17)* is smaller. Ribose itself exhibits a complex mutarotation involving the furanose form or the open-chain form[13], and this explains to some extent the fact that the smallest contribution of piperidinose *(20)* and the largest of furanose *(21)* are found in 5-acetamido-5-deoxy-D-ribose.

4,5-Diacetamido-4,5-dideoxy-L-xylose can form either a 6-membered ring or a 5-membered ring containing nitrogen. It is obtained by hydrolysis of *(21a)* with

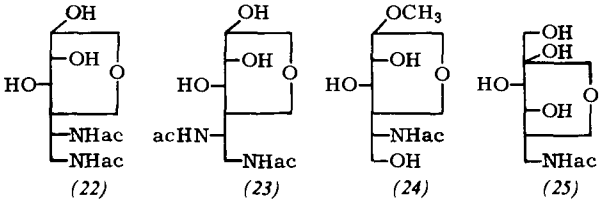
periodate followed by cleavage of *(21b)* [13a], or from *(21c)* by mercaptal cleavage [13b]. It exists in an equilibrium *(21d)* ⇌ *(21e)*, in which the piperidinose form *(21d)* greatly predominates [13a,13b]. 2,5-Diacetamido-2,5-dideoxy-D-xylose, surprisingly, forms only the furanose form [13c].

The tendency to form a 6-membered "hemiacetal" ring with an acetylimino group in the ring is even smaller in the case of 5-acetamido-5-deoxyaldohexoses. The compounds studied, *(22)* and *(23)*, when present as free sugars, always assume the furanose form [14]. Methanolysis of 5-acetamido-5-deoxy-1,2-*O*-isopropylidene-D-glucofuranose leads only to the methylfuranoside *(24)* [15]. 5-Acetamido-5-deoxy-L-idose is the only hexose with which a piperidinose form has been shown to exist. This is a special case, since the piperidinose cyclizes to give the bicyclic structure *(67)* [15a]. 6-Acetamido-6-deoxyketoses such as the *arabino* compound *(25)* also avoid forming 6-membered rings containing nitrogen, in favor of the furanose form *(25)* [16].

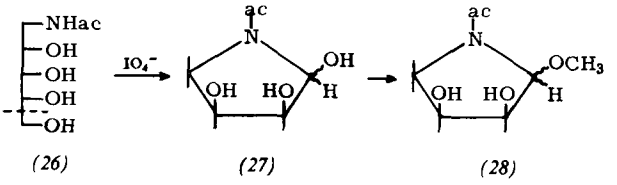


b) 4-(*N*-Acylamido)-4-deoxy Sugars

4-Acetamido-4-deoxyaldoses should be capable of forming a 5-membered "hemiacetal" ring, *i.e.* a sugar containing the pyrrolidine ring. Owing to the low reactivity of the acetamido group, a ring of this nature is to be expected mainly when no other ring can be formed, *i.e.* in 4-acetamido-4-deoxytetroses or 4-acetamido-4,5-dideoxypentoses.

Compounds of this class do, in fact, tend to form 5-membered rings. Thus, controlled cleavage of 1-acetamido-1-deoxy-D-ribitol *(26)* with periodate leads to an *erythro* compound *(27)* which, after treatment with methanol/HCl, was isolated as the methyl glycoside *(28)* of a pyrrolidine sugar [16]. As in the case of the 6-membered ring sugars, the fact that the acetamido group is built into the ring is shown by the infrared and NMR spectra and by the results obtained on cleavage with periodate [16].

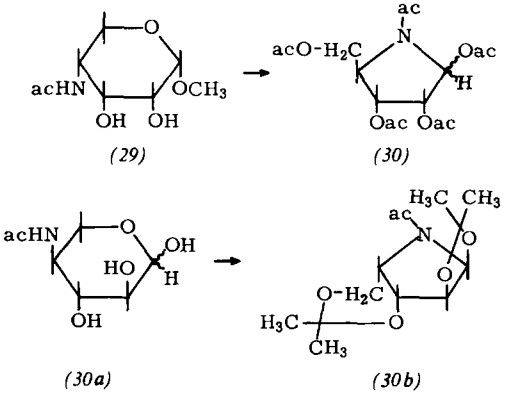
*(27)* can also be obtained by conversion of 5-acetamido-5-deoxy-D-arabinose mercaptal into the disulfone by oxidation with perpropionic acid, followed by degradation with ammonia [17]. Degradation of the sulfone of the corresponding *xylo* compound or the controlled cleavage of 6-acetamido-6-deoxy-D-galactopyranose with



*(26)* *(27)* *(28)*

periodate leads to the pyrrolidine sugar *(27)* with the *threo* configuration [18]. 4-Acetamido-4,5-dideoxy-L-xylose, too, forms only a pyrrolidine sugar, since the 6-membered cyclic form is not possible [13b, 18a].

A 4-acetamido-4-deoxypentose with a 5-membered ring containing nitrogen is most likely to occur in the *ribo* configuration, since ribose tends to form a furanose ring owing to its special configuration. Acetolysis of the ribopyranoside *(29)* does, in fact, lead surprisingly smoothly to ring contraction and formation of the peracetylated pyrrolidine sugar *(30)* [19]. It is not yet known whether free 4-acetamido-4-deoxy-D-ribose at equilibrium forms a 5-membered ring containing nitrogen. 4-Acetamido-4-deoxy-L-xylose occurs only in the pyranose form *(30a)*; it can be forced into the pyrrolidine form by conversion into the 1,2;3,5-diisopropylidene compound *(30b)* [19a].



A number of ketoses which possibly could give 5-membered "hemiacetal" rings containing nitrogen have been studied. The *xylo* compound *(31)* preferentially forms a 6-membered pyranose ring [20]. The ketoses *(32)* and *(33)*, in which ring formation would necessarily lead to a 5-membered ring containing nitrogen, exist in the open-chain keto form [21]. These examples show the low tendency for ring formation of the acetamido group in ketoses.

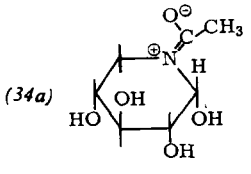
### c) Hindered Rotation in Sugars with Rings Containing an *N*-Acetylimino Group

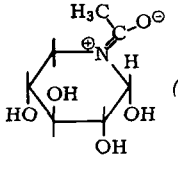
Carboxamides are generally stabilized by resonance $\rangle\overset{\oplus}{N}=\overset{|}{C}-O^{\ominus}$ in the planar form, so that rotation about the N–C bond is hindered. Thus unsymmetrically *N*-substituted carboxamides can exist in a *cis* and in a *trans* form. These forms have different NMR spectra and can, therefore, be generally detected in the presence of each other at room temperature by NMR spectroscopy [22]. At higher temperatures the rotation is generally no longer hindered. If the rotation (and hence the transition between the *cis* and *trans* forms) is sufficiently fast, an "average" NMR spectrum is obtained, the lines of which lie between those of the *cis* and the *trans* forms. Thus the spectrum of a carboxamide with restricted rotation will exhibit a characteristic temperature dependence [22].

Monosaccharides with an *N*-acetylimino group in the ring also exhibit hindered rotation. *N*-Acetyl-D-xylopiperidinose with a planar $\rangle\overset{\oplus}{N}=\overset{|}{C}-O^{\ominus}$ grouping can exist as the isomers *(34a)* and *(34b)* [23, 24].

The NMR spectrum of this compound at room temperature contains two doublets in the region of the anomeric protons.



(34a)



(34b)

The relationships are clearest in the NMR spectrum of the tetra-*O*-methyl compound of *(34a)* + *(34b)* (Fig. 2) [25]. The two widely separated signals due to the anomeric proton $H^1$ of the *trans* and *cis* forms ($\tau \approx 4.2$ and $\tau \approx 5.1$) can be seen at very low field. At 110 °C (upper curve), the lines converge because of rapid rotation of the amide group.

The signal due to the protons on C-5 also shows splitting. The left-hand quartet for the equatorial proton $H^5_e$ occurs at $\tau \approx 5.5$, while the corresponding right-hand quartet is masked by the multiplet between $\tau \approx 6$ and $\tau \approx 7$. At higher temperatures these quartets coalesce to give a single diffuse quartet ($H^5_e$ above). In the case of the axial proton $H^5_a$, only the right-hand quartet is visible ($\tau \approx 7.7$); this, too, migrates into the multiplet at higher temperatures. The signals due to the $OCH_3$ groups ($\tau \approx 6.6$ to 6.8) are also split at room temperature and coalesce at higher temperatures, as can be seen by comparison of the upper and lower spectra. Similar

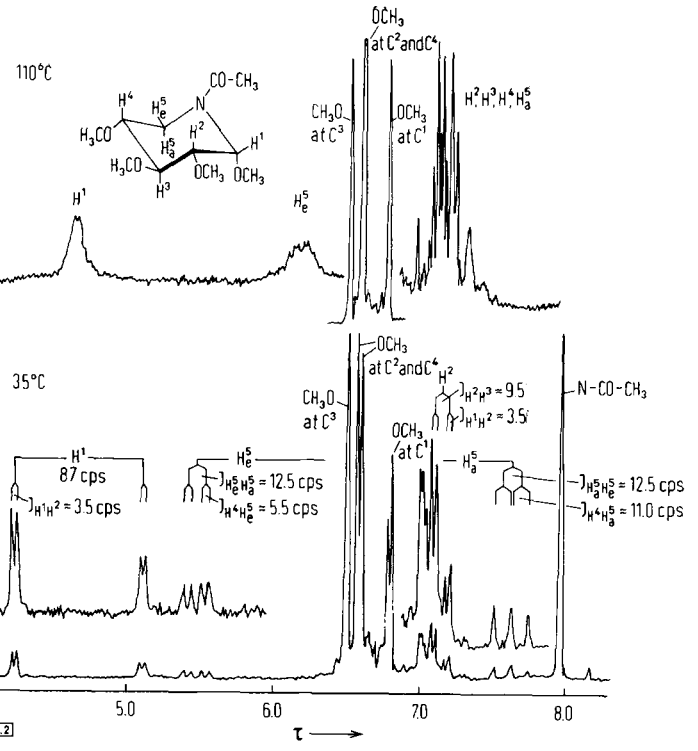


Fig. 2. NMR spectra of methyl 2,3,4-tri-*O*-methyl-*N*-acetyl-α-D-piperidinoside (100 Mc/s; in tetrachloroethylene, tetramethylsilane (TMS) as internal standard).

relationships are found with other *N*-acetylpiperidinoses and *N*-acetylpyrrolidine sugars [16, 18].

### d) Conformation of *N*-Acylpiperidinoses and their Configuration at C-1

The NMR spectrum of *N*-acetyl-D-xylopiperidinose shows slight splitting for the anomeric proton, giving a coupling constant $J_{H^1H^2} \approx 3.5$ cps. This small constant corresponds to an equatorial-axial coupling, and it was, therefore, concluded that the compound exists in the α-form, though this is contrary to the evidence of the negative optical rotation. No mutarotation is observed, so that only one anomeric form is present.

The configuration at C-1 can be found from the coupling constant $J_{H^1H^2}$ only if the conformation of the piperidinose ring is known. A complete conformational analysis was, therefore, carried out with the aid of NMR spectroscopy [25].

1,2,3,4-Tetra-*O*-acetyl-*N*-carbobenzoxy-D-xylopiperidinose *(35)* was found to be a suitable object for this study. This compound does not exhibit hindered rotation, so that there is no duplication of signals and the spectrum is consequently simplified. Accordingly, Fig. 3 contains only one line for the anomeric proton $H^1$. Fig. 3 shows a complete first-order analysis of the spectrum. The couplings were assigned by the double resonance technique. The oblique lines indicate that the irradiation frequencies used are the resonance frequencies of the protons $H^1$, $H^2$, and $H^4$. The upper series gives the corresponding signals which experience spin decoupling [25]. The results of this analysis are summarized in Fig. 4, which gives the positions of all the protons and their mutual coupling constants, together with the dihedral angle calculated from a modified Karplus relationship [25a]. The table

Fig. 4. Coupling constants J and the corresponding conformation of 1,2,3,4-tetra-*O*-acetyl-*N*-carbobenzoxy-α-D-xylopiperidinose *(35)* according to *Karplus* [*] ($J = 11 \cos^2 \Phi$) [25a].

shows definitely that the piperidinose must exist in the chair form. This is shown by the large diaxial couplings between $H^2$, $H^3$, $H^4$, and $H^5_a$. The small coupling constant $J_{H^1H^2}$, therefore, indicates the presence of the α form.

Comparison with the NMR spectra of other *N*-acylpiperidinoses and of the *N*-acylpiperidinosides shows that all known compounds of the *xylo* series exist only in the α form. The unfavorable steric situation in the β-anomer (the equatorial substituent in eclipsed position with respect to the amide group) is proposed as the cause of the pronounced anomeric effect.

[*] It should be emphasized that the Karplus equation gives only approximate values of the dihedral angle; critical appraisal shows, however, that these are suitable for comparison with the theoretically expected values for an ideal chair form. The vicinal coupling constants are influenced, apart from the dihedral angle, by factors such as electronegativities, bond distances, and bond angles, although to a lesser degree. These factors are not considered in the simple Karplus equation; they are not yet amenable to quantitative treatment.

For a discussion see *M. Karplus*, J. Amer. chem. Soc. *85*, 2870 (1963); *R. U. Lemieux* and *J. D. Stevens*, Canad. J. Chem. *44*, 249 (1966); *B. Coxon*, Tetrahedron *21*, 3481 (1965).

In an attempt to explain the anomalous optical rotation of the *N*-acylpiperidinoses, optical rotatory dispersion curves were recorded (Fig. 5) [25]. In normal monosaccharides of the D-series, in accordance with Hudson's rules, α-glycosides always give positive plain curves, β-glycosides always negative plain curves, as shown in Fig. 5b for the D-xylosides. The *N*-acyl-α-D-xylopiperidinoses and their α-glycosides, on the other hand, give negative plain curves, contrary to the predictions of Hudson's rule (Fig. 5).

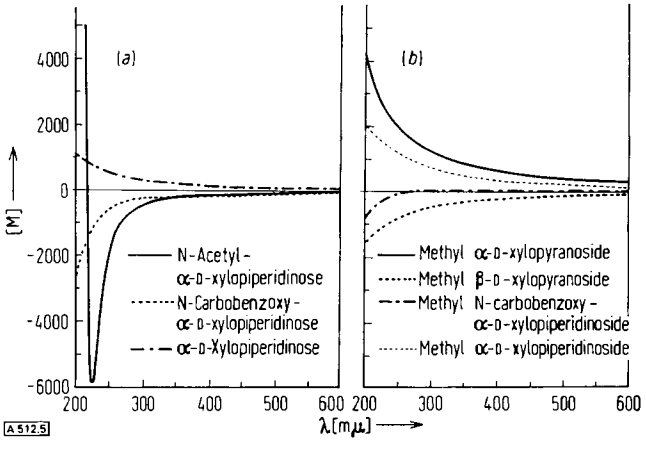

Fig. 5. Rotatory dispersion curves of some piperidinoses (a) and of some piperidinosides and pyranosides (b); [M] = molecular rotation.

## 2. Sugars Containing an Unsubstituted Imino Group in the "Hemiacetal" Ring

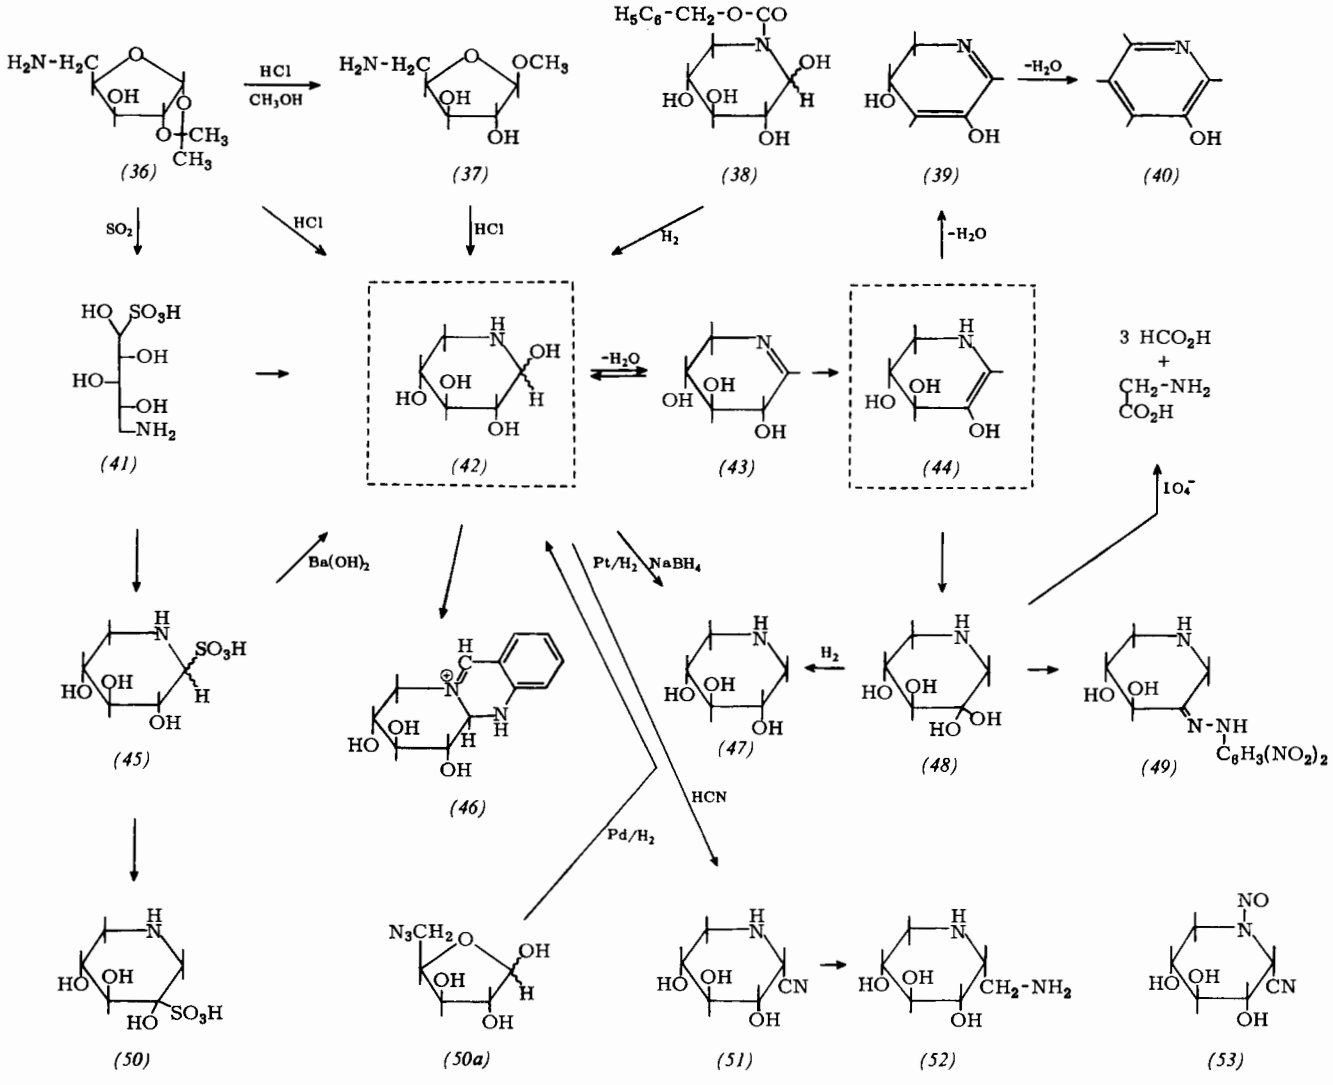
### a) 5-Amino-5-deoxypentoses

5-Amino-5-deoxy sugars with free amino groups are a more interesting class of compounds, since the reactivity of the free amino group in hemiacetal formation is sufficiently high to enable this group to compete successfully with the hydroxyl group. The resulting piperidinoses can enter into a series of fast secondary

reactions. The compound we have studied most is 5-amino-5-deoxy-D-xylose [26, 27], which will be used as a prototype for the detailed discussion.

The 1,2-*O*-isopropylidene *(36)* or cyclohexylidene derivative of 5-amino-5-deoxy-D-xylose was used as the starting material. Reaction of *(36)* with methanol/HCl in the absence of water leads to the methyl-β-furanoside *(37)*. Thus the furanose liberated on methanolysis reacts to form the furanoside before rearrangement of the 5-membered ring to the 6-membered ring can occur. Neither a methylpiperidinoside nor 3-hydroxypyridine (expected as a by-product) have been detected [27].

The compound *(48)* is a product of Amadori rearrangement of the assumed piperidinose intermediate *(42)*. The structure *(48)* is supported by NMR and mass spectroscopy [27]. In particular, the mass spectrum shows the expected fragments CO and $\cdot CH_2-\overset{\oplus}{N}H=CH_2$. Compound *(48)* gives all the color reactions of a strongly reducing Amadori compound; cleavage with periodate leads to glycine, and catalytic hydrogenation gives the optically inactive xylitol derivative *(47)*, the *N*-acetyl derivative of which again gives the expected fragments on reaction with periodate. Rather surprisingly, the Amadori compound *(48)* can only be



An entirely different course is followed by the hydrolysis of *(36)* with aqueous HCl. The products obtained are 3-hydroxypyridine *(40)* and 1,5-dideoxy-1,5-imino-D-threopentulose *(48)* in the form of the crystalline hydrochloride. The ratio of the two products depends on the reaction conditions, *(40)* being the main product of hydrolysis at 70 °C, while *(48)* is the main product at room temperature. The same products *(40)* and *(48)* are also obtained by acid cleavage of the furanoside *(37)*.

obtained as the hydrate. The water of hydration cannot be removed without decomposition of the compound; the carbonyl group can be detected by preparation of a dinitrophenylhydrazone *(49)*. The conversion of the piperidinose *(42)* into *(48)* is the first example of a cyclic Amadori rearrangement [27].

The formation of the Amadori compound *(48)* and of 3-hydroxypyridine *(40)* on hydrolysis of *(36)* demands some consideration. It appears that the 5-amino-5-deoxy-D-xylose liberated from *(36)* can readily assume a piperidinose form *(42)*, which spontaneously loses one mole of $H_2O$ in acidic solution to form the piperideine

[26] *H. Paulsen*, Tetrahedron Letters *1964*, 451.
[27] *H. Paulsen*, Liebigs Ann. Chem. *683*, 187 (1965).

*(43)*. A similar carbinolamine dehydration occurs in the case of the parent compound, α-hydroxypiperidine, and with many alkaloids [28].

The piperideine *(43)* is a cyclic Schiff's base of an α-ketol, and as such enolizes to give the enaminol *(44)* [29]; this latter compound is the central intermediate which can react further by one of two routes. Protonation of *(44)* on C-1 leads to completion of the Amadori rearrangement and formation of *(48)*; this rearrangement is irreversible, since *(48)* cannot be converted into 3-hydroxypyridine *(40)* by treatment with alkalis and subsequent acidification. The second route by which *(44)* can react leads to proton-catalysed elimination of $OH^{\ominus}$ from C-3 to form the dehydration product *(39)*, which then undergoes aromatization, with loss of a further mole of $H_2O$, to form 3-hydroxypyridine *(40)*. The formation of the aromatic pyridine system undoubtedly is an essential driving force for the second reaction route [27].

If cold sulfurous acid is used instead of hydrochloric acid for the hydrolysis of 5-amino-5-deoxy-1,2-*O*-isopropylidene-D-xylose *(36)*, the 5-amino-5-deoxy-D-xylose liberated is intercepted as the bisulfite adduct before the secondary reaction can occur; the product obtained is the open-chain sulfonic acid *(41)* [30]. When heated in water, *(41)* cyclizes to form D-xylopiperidinosyl-1-sulfonic acid *(45)*, which is a bisulfite adduct of the piperidinose *(42)* [11, 30a, 30a]

On prolonged heating, *(45)* is smoothly converted into the sulfonic acid *(50)*, which is a bisulfite adduct of the Amadori compound *(48)*. It is thought that *(45)* first loses $SO_2$, and that the resulting piperidinose *(42)* immediately rearranges *via (43)* and *(44)* to give *(48)*, which then adds sulfurous acid to form *(50)*. *(50)* can also be obtained by the reaction of the pure Amadori rearrangement product *(48)* with $SO_2$.

Cleavage of the sulfonic acids *(41)* or *(45)* with $Ba(OH)_2$ in alkaline solution gives D-xylopiperidinose *(42)*, the parent compound of this class [30a]. The piperidinose *(42)* is relatively stable in alkaline solution, but is extremely sensitive to acids, by which it is rearranged to *(48)* and *(40)*. Thus the behavior of piperidinoses is opposite to that of all other monosaccharides. Proof that *(42)* exists only in the form of a 6-membered ring containing nitrogen is found in the fact that *N*-acetylation of *(42)* leads to *(14)*, while hydrogenation leads to *(47)* [30a].

The piperideine *(43)* could also be detected as a further intermediate. This compound contains a C=N chromophore in an asymmetric environment. Its weak absorption due to the n → π* transition should, therefore, give a Cotton effect. Piperidinose solutions, in fact, give a negative Cotton effect at 300 mμ, which can be readily detected by measurement of the circular dichroism, and which must be assigned to the piperideine *(43)*, since *(42)* and *(48)* do not give a Cotton effect [30a].

Measurement of the circular dichroism is an excellent and extremely sensitive method for the study of the reactions of the piperidinose *(42)* [30a]. Freshly prepared solutions of *(42)* (pH 7.8) do not contain *(43)* or *(48)*; a Cotton effect is observed after a few hours and reaches a maximum after two days. An equilibrium piperidinose *(42)* ⇌ piperideine *(43)* is then established. This equilibrium is pH-dependent, the content of *(43)* being about 3 to 5 % at pH 7.8. On acidification with $CO_2$ to pH 6.8, the Cotton effect is immediately reduced, since the acid-catalysed Amadori rearrangement *(43)* → *(48)* is accelerated. However, the product *(48)* is a secondary amine and is, therefore, a stronger base than *(42)* and *(43)*, so that as *(48)* accumulates in the system, the pH rises once more. This retards the Amadori rearrangement *(43)* → *(48)* to such an extent that the equilibrium *(42)* ⇌ *(43)* with its high Cotton effect can be re-established. This reaction sequence can be repeated until all the *(42)* has been converted into *(48)*. When the solution of *(42)* is acidified to pH 5.8 with acetic acid, the Amadori rearrangement proceeds so rapidly that *(43)* cannot accumulate, and hence no Cotton effect occurs.

The sign of the Cotton effect is interesting. According to the theory [30c], C-3 and substituents on C-2 and C-5 in piperideines in the half-chair conformation *(53b)* do not contribute to the Cotton effect, the sign of which is determined by C-4; thus the Cotton effect should be positive if, C-4 lies above the plane of the ring, and negative if C-4 lies below the ring. The most favorable conformation for the piperideine formed from *(53a)* is undoubtedly *(53b)*; this should theoretically give a negative Cotton effect, as was actually found [30a].

*(53a)*  *(53b)*

A piperidinose with a free imino group, such as *(42)*, can generally also be prepared by hydrogenation of a 5-azido-5-deoxy sugar, *e.g. (50a)* [30d], or by hydrogenation of the *N*-carbobenzoxypiperidinose *(38)* [30a]. *(42)* cannot be isolated in pure form, since the product always contains *(43)* and *(48)*; it is, however stable enough in solution for derivatives to be isolated. Thus *(42)*, which is a 2-hydroxypiperidine, has the structure of a reactive Mannich base [5] and, therefore, can enter into condensations, provided that these are carried out in alkaline solution (rearrangement to *(48)* occurs in acidic solution). *(42)* reacts with *o*-aminobenzaldehyde and picric acid to form a red, crystalline 1,2-dihydroquinazolinium picrate *(46)*. *(42)* reacts particularly readily with HCN to form 2,6-dideoxy-2,6-imino-D-idononitrile *(51)*, which is an in-

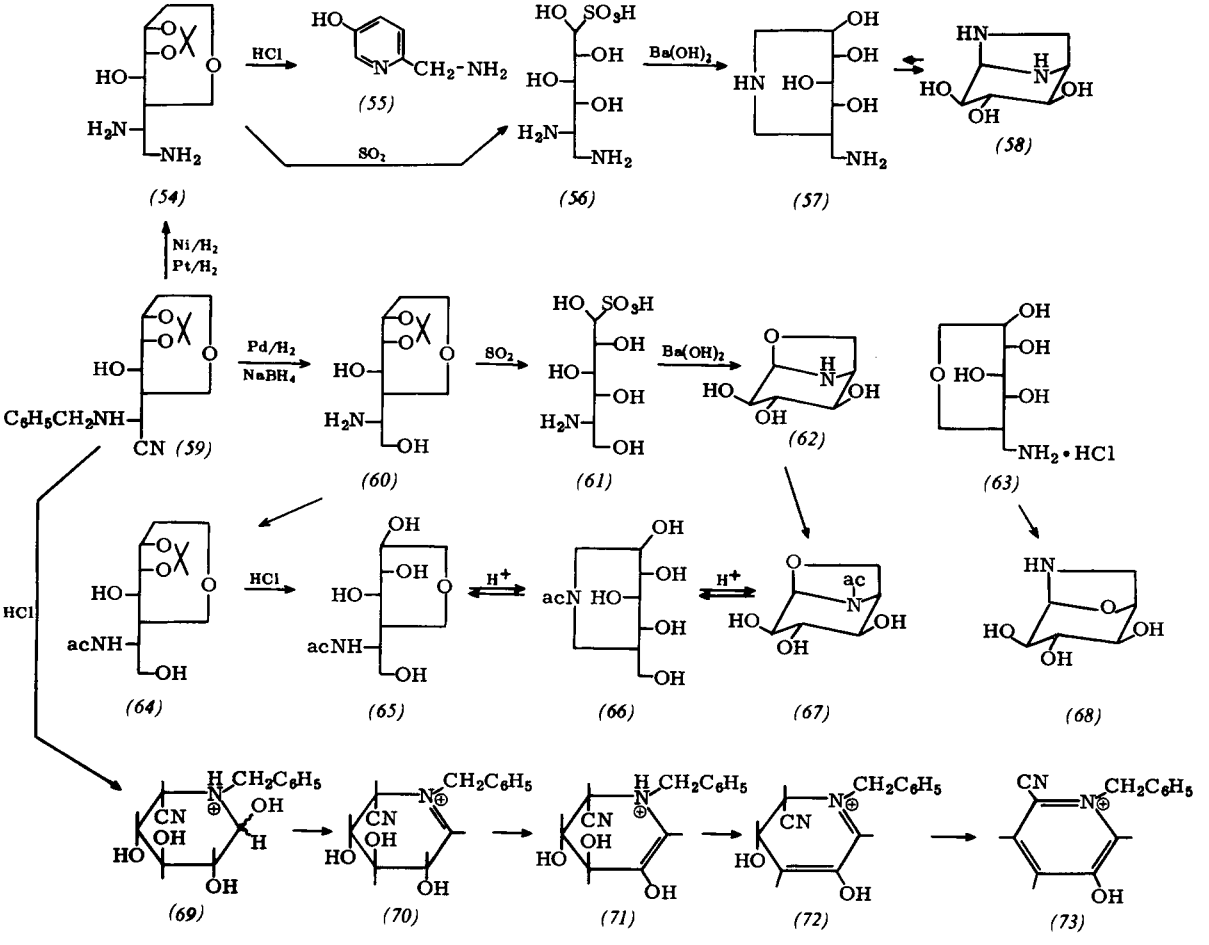
teresting starting material for further syntheses; for example, hydrogenation of *(51)* yields the amine *(52)*, and nitrosation leads to the nitroso compound *(53)* [31]. The methyl glycoside of *(42)* is very readily cleaved even by water. In methanol, it exists in equilibrium with the piperideine *(43)* formed by elimination of methanol [25].

### b) 5-Amino-5-deoxyhexoses

Hydrolysis of 5-amino-5-deoxyhexoses with aqueous hydrochloric acid also leads to elimination of three molecules of water to form hydroxypyridine derivatives. Thus the idose derivative *(54)*, which can be pyridinium salt *(73)* *via* the piperidinose *(69)* and *(70)* to *(72)*. Thus the pyridine formation is not blocked by *N*-alkylation of the 5-amino group. The reaction sequence *(69)* → *(73)* shows that protonation of the piperidinose *(69)* is essential, since the initial elimination of water to form the piperideine *(70)* otherwise cannot take place [34].

Hydrolysis of *(54)* with sulfurous acid leads to the sulfonic acid *(56)*. Alkaline cleavage of *(56)* leads immediately to the piperidinose *(57)*, which spontaneously loses water with quantitative conversion into *(58)* [15a, 34a]. The 1,6-anhydro compound *(58)* is an idosan derivative in which two oxygen atoms have been replaced by nitrogen; it can be obtained in crystalline



obtained by hydrogenation of the idurononitrile *(59)*, gives 2-aminomethyl-5-hydroxypyridine *(55)* [32]. Cleavage with methanol/hydrochloric acid generally leads to the methyl furanosides [33].

The dehydration in acidic solution proceeds particularly readily in the case of 5-*N*-alkylamino-5-deoxy sugars [34]. Thus on hydrolysis with HCl, the idurononitrile *(59)* is converted almost quantitatively into the *N*-benzyl-form and is the first known stable monosaccharide containing a free amino group in the ring.

Hydrogenation of *(59)* leads to the 5-amino-5-deoxyidose derivative *(60)*, which gives *(61)* on cleavage with $SO_2$. Alkaline hydrolysis of *(61)* again leads to cyclization of the intermediate piperidinose to give *(62)* [15a, 34a].

An interesting reaction in this connection is the selective hydrolysis of the 5-acetamido-5-deoxyidose derivative *(64)* with aqueous HCl. The crystalline bicyclic compound *(67)*, which can also be prepared from *(62)*, is obtained in 23 % yield from the reaction mixture [15a]. In this case there is, evidently, an equilibrium between

[31] *H. Paulsen* and *K. Todt*, unpublished work.

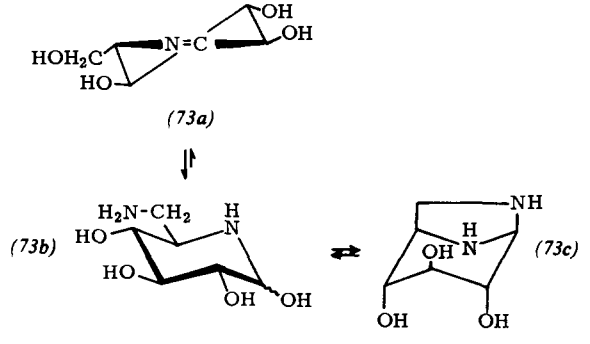
[34] *H. Paulsen*, *K. Todt*, and *K. Heyns*, Liebigs Ann. Chem. *679*, 168 (1964).

[34a] *H. Paulsen* and *K. Todt*, Angew. Chem. *77*, 589 (1965), Angew. Chem. internat. Edit. *4*, 592 (1965).

the furanose *(65)* and piperidinose *(66)* and the bicyclic form *(67)*. This is the only 5-acetamido-5-deoxyhexose in which a piperidinose form has been detected. The piperidinose formation is favored in this case by the secondary reaction to form the bicyclic compound *(67)*.

The third idosan derivative with nitrogen in the 5-membered ring, *i.e. (68)*, can be prepared from *(63)*. 6-Amino-6-deoxy-L-idose *(63)* has long been known as the hydrochloride [34b]; when this is converted into the free base, crystalline *(68)* is formed in quantitative yield [15a, 34a].

The tendency towards formation of the 1,6-anhydro compound is evidently greatly increased in the hexopiperidinoses. Thus *(62)* exists entirely in the anhydro form, while L-idose forms 75 % of the anhydro compound at equilibrium [35]. This becomes even clearer in the case of the glucopiperidinose *(73b)*, which can be obtained from the corresponding sulfonic acid. At equilibrium, this compound contains 20 to 40 % of the sterically highly unfavorable cyclic form *(73c)* [15a]. Glucose itself gives only 0.3 % of the 1,6-anhydro form on treatment with acid [35]. A small quantity of the piperideine *(73a)* is also present in equilibrium with *(73b)*, as is shown by the weak negative Cotton effect of the solution.



*(73a)* ⇌ *(73b)* ⇌ *(73c)*

The *N*-acetyl derivatives of *(58)*, *(62)*, and *(68)* all contain amido groupings with hindered rotation [15a]. The *N,N'*-diacetyl derivative of *(58)* is particularly interesting. It contains two amido groupings with hindered rotation in the same molecule, so that this compound can exist in four isomeric forms, the structures of which are shown in Fig. 6. In these formulae, which differ only in the conformation of the amido groups, the 6-membered ring is shown behind the 5-membered ring.

The NMR spectrum of the compound in Fig. 6 shows that all four isomeric forms are present at low temperatures, and that the two amido groups have quite different coalescence temperatures [15a]. Fig. 7 shows the NMR spectra at different temperatures. At 15 °C, three signals are found for the anomeric proton (top); the left-hand and right-hand signals are due to the *trans,trans* or *cis,cis*, and the strong middle signal to the *trans-cis* and *cis-trans* compounds. The splitting of all three signals is caused by slight spin coupling between $H^1$ and $H^2$. The *N*-acetyl signals (bottom) are more complicated.

At 35 °C the signals begin to coalesce. At 40 °C the amido group in the piperidinose ring exhibits free rotation, while rotation of the amido group in the 1,6-anhydro ring still

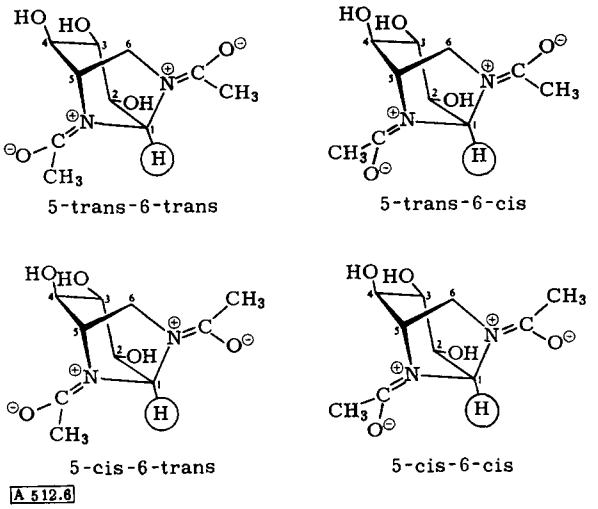


Fig. 6. Four isomeric forms of 1,6-acetylimino-*N*-acetyl-6-deoxy-L-idopiperidinose.

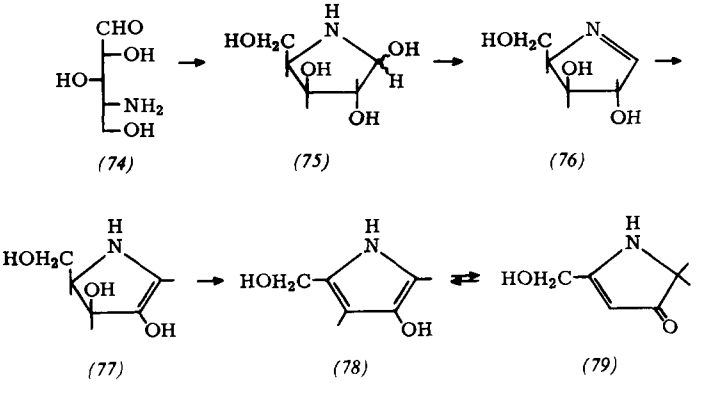
remains hindered. This is particularly obvious at 50 °C, when only two anomeric proton signals are obtained, corresponding to the remaining *cis* and *trans* forms. The corresponding *N*-acetyl signal (bottom) still shows the wide splitting corresponding to a 5-membered ring amide; the middle line is the signal of the amide in the 6-membered ring. At 65 °C the signals are closer together; at 96 °C the amide in the 5-membered ring also exhibits free rotation, and the anomeric proton and the *N*-acetyl groups now give only one signal each [15a].

### c) 4-Amino-4-deoxy Sugars

4-Amino-4-deoxy sugars with free amino groups, *e.g.(74)*, should be able to form 5-membered "hemiacetal" rings, in which the nitrogen is built into the ring to give sugars of the pyrrolidine type *(75)*. Since the tendency towards acetal formation is stronger for the amino group than for the hydroxyl group, the 5-membered pyrrolidine ring *(75)* should be favored; the 6-membered pyranose ring, on the other hand, is favored on steric grounds. Nevertheless, the amino group should compete successfully with the hydroxyl group.



*(74)* *(75)* *(76)*

*(77)* *(78)* *(79)*

The "pyrrolidine sugar" *(75)* is a carbinol base, and as such it should lose water in acidic solution to form the pyrroline *(76)*. This reaction is well known from model compounds, *e.g.* derivatives of γ-aminobutyraldehyde or of the 2-hydroxypyrrolidine present at equilibrium [36]. If a secondary reaction similar to that occuring in the conversion of piperidinoses into pyridine derivatives is

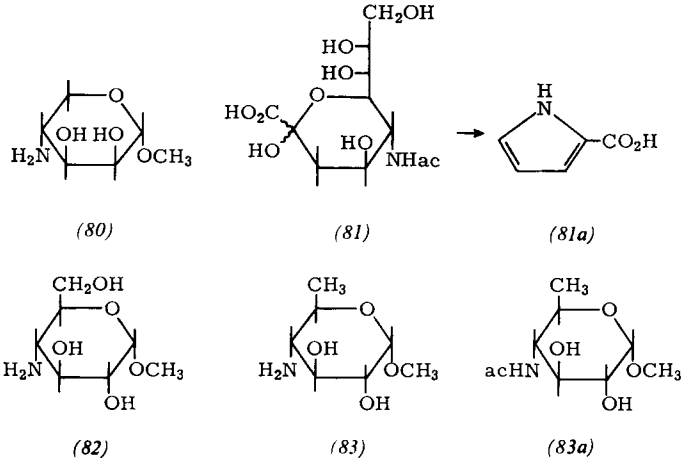
Bottom row: Signals due to the *N*-acetyl $CH_3$ groups.

assumed to take place, the pyrroline *(76)*, which is a cyclic Schiff's base of a ketol, should rearrange into the enaminol *(77)*; this in turn loses water, with formation of derivatives of 3-hydroxypyrrole *(78)* and of 4-oxo-$\Delta^2$-pyrroline *(79)* [37]. No derivatives of 3-hydroxypyrrole have so far been detected on hydrolysis of 4-amino-4-deoxy sugars, but certain observations suggest that the reaction sequence described is feasible. The derivatives of 3-hydroxypyrrole are unstable [38], and readily polymerize in a complex manner to give dark products [39]. When an attempt is made to obtain the free 4-amino-4-deoxy sugar by acid hydrolysis of methyl 4-amino-4-deoxy-α-D-lyxopyranoside *(80)*, the solution begins to darken within a few minutes, and black polymeric material separates out [40].



The long known *N*-acetylneuraminic acid *(81)* may be regarded as a 4-amino-4-deoxy-sugar, since the amino group is in position 4 with respect to the keto group. Under the action of mineral acids, *N*-acetylneuraminic acid *(81)* readily forms insoluble dark polymers of unknown structure [41]. Intensive alkali degradation of *(81)* gave pyrrol-2-carboxylic acid *(81a)* as a fragment [42].

Considerable difficulties were also encountered in attempts to obtain free 4-amino-4-deoxyhexoses by hydrolysis. The 4-amino-*gluco* compound *(82)* cannot be hydrolysed without decomposition [43]. Despite all efforts, attempts to liberate 4-amino-4-deoxy-D-glucose from other derivatives have so far been unsuccessful [44]. The 4-amino-4-deoxy sugar cannot be obtained by direct hydrolysis of the 6-deoxy-*gluco* compound *(83)* or of the corresponding *galacto* compound, since decomposition occurs instead [45]. However, hydrolysis of

methyl 4-acetamido-4-deoxyglucoside *(83a)* leads to the 4-amino-4-deoxy-*gluco*-pyranose hydrochloride, without formation of a "pyrrolidine sugar" [45].

### d) 6-Amino-6-deoxyketohexoses

In 6-amino-6-deoxyhexuloses, there is again competition between the 6-membered N-ring, and the 5-membered O-ring. On hydrolysis of the sorbose derivative *(87)* with strong aqueous hydrochloric acid, it is possible to isolate a crystalline furanose hydrochloride *(84)*, which is stable only in strongly acidic solutions. A solution of *(84)* in water (pH $\approx$ 6) leads quantitatively, in four days at room temperature, to 3-hydroxy-2-hydroxymethylpyridine *(89a)* [46].

In neutral solution, the salt *(84)* evidently is hydrolysed to such an extent that some of the base can change into the piperidinose *(85)*. Under the conditions of the reaction, *(85)* immediately loses one molecule of water to give *(88)*, which loses a further two molecules of water and is converted *via (88a)* and *(89b)* into the pyridine *(89a)*. On heating, this reaction is completed within a few minutes [46].

In alkaline solution, the furanose hydrochloride *(84)* is immediately converted into the free piperidinose *(85)*, which is so stable that it can be hydrogenated to the piperidine derivative *(86)* [46]. Thus 6-amino-6-deoxy-L-sorbose is a sugar that assumes the furanose form in acidic solution, and the piperidinose form in alkaline solution, while in neutral solution it spontaneously loses water with formation of *(89a)*.

only in alkaline solution. The most important secondary reactions in acidic solution are the cyclic Amadori rearrangement and the elimination of three molecules of water, under mild conditions, to form 3-hydroxypyridines. An interesting parallel to the latter reaction has been found in the fragmentations occurring in the mass spectrometer on ionization in the gas phase. Trihydroxypiperidine derivatives undergo a succession of cleavages which again lead to 3-hydroxypyridinium ions with mass number (MN) 96 as a principal fragment [27].

As an example, consider the mass spectrum of 1,5-(*N*-acetylimino)-2,3,4-tri-*O*-acetyl-1,5-dideoxyxylitol. This compound was obtained by hydrogenation and acetylation of the piperidinose *(42)*. Its mass spectrum is shown in Fig. 8; Fig. 9 shows reaction schemes for the various fragmentation processes.

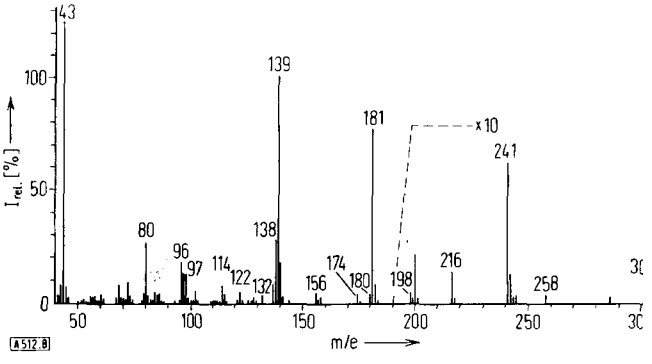

Fig. 8. Mass spectrum of 1,5-(*N*-acetylimino)-2,3,4-tri-*O*-acetyl-1,5-dideoxy-xylitol. (The relative intensity $I_{rel}$ of the ion with mass 139 was taken as 100 %).

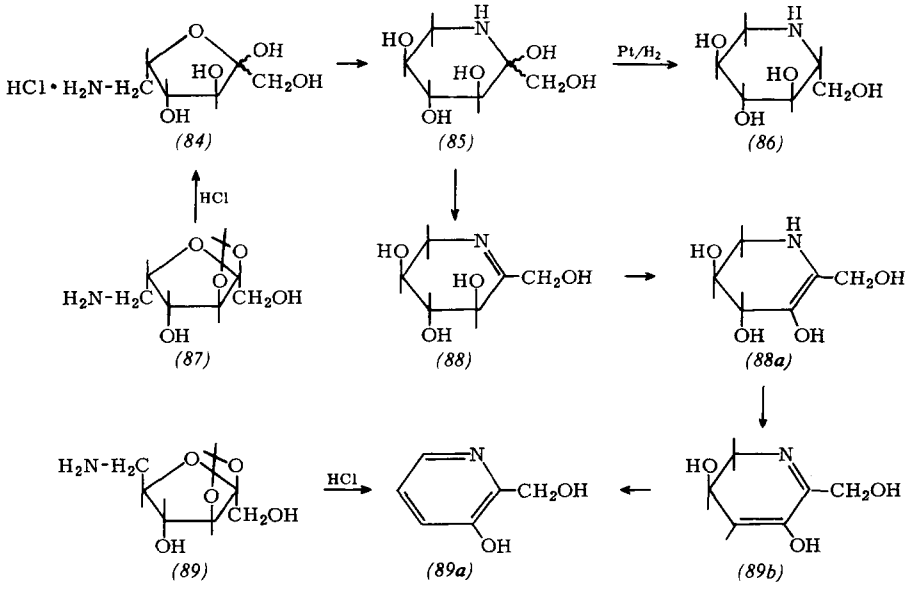

The fructose derivative *(89)* also forms *(89a)* on acid hydrolysis [46,46a]. 1,6-Diamino-1,6-dideoxy-2,3-*O*-isopropylidene-a-L-sorbofuranose reacts with aqueous hydrochloric acid in a similar reaction sequence to yield 2-aminomethyl-3-hydroxypyridine [46].

### e) Mass Spectra of 5-Amino-5-deoxy Sugars

As was shown in the case of the 5-amino-5-deoxyxyloses, piperidinose forms are readily formed, and are stable

The compound gives a molecule ion of MN 301. The principal route involves elimination of acetic acid to form the allyl radical ion with MN 241; this also loses acetic acid to form the ion with MN 181, which splits off ketene to give the ion with MN 139. This fragment is converted by two routes into the 3-hydroxypyridinium ion with MN 96, and also forms a pyridinium ion of MN 80 [27].

A second, less important route leads *via* the ion with MN 258, which loses several molecules of ketene and of water to give the 3-hydroxypyridinium ion with MN 96, as shown in Fig. 9 [27]. The formation of pyridine derivatives from piperidinoses and hydroxypiperidines, both in acidic solution and in the gas phase, illustrates the preference for eliminations leading to this aromatic ring system.

[46] *H. Paulsen, I. Sangster,* and *K. Heyns,* unpublished work.

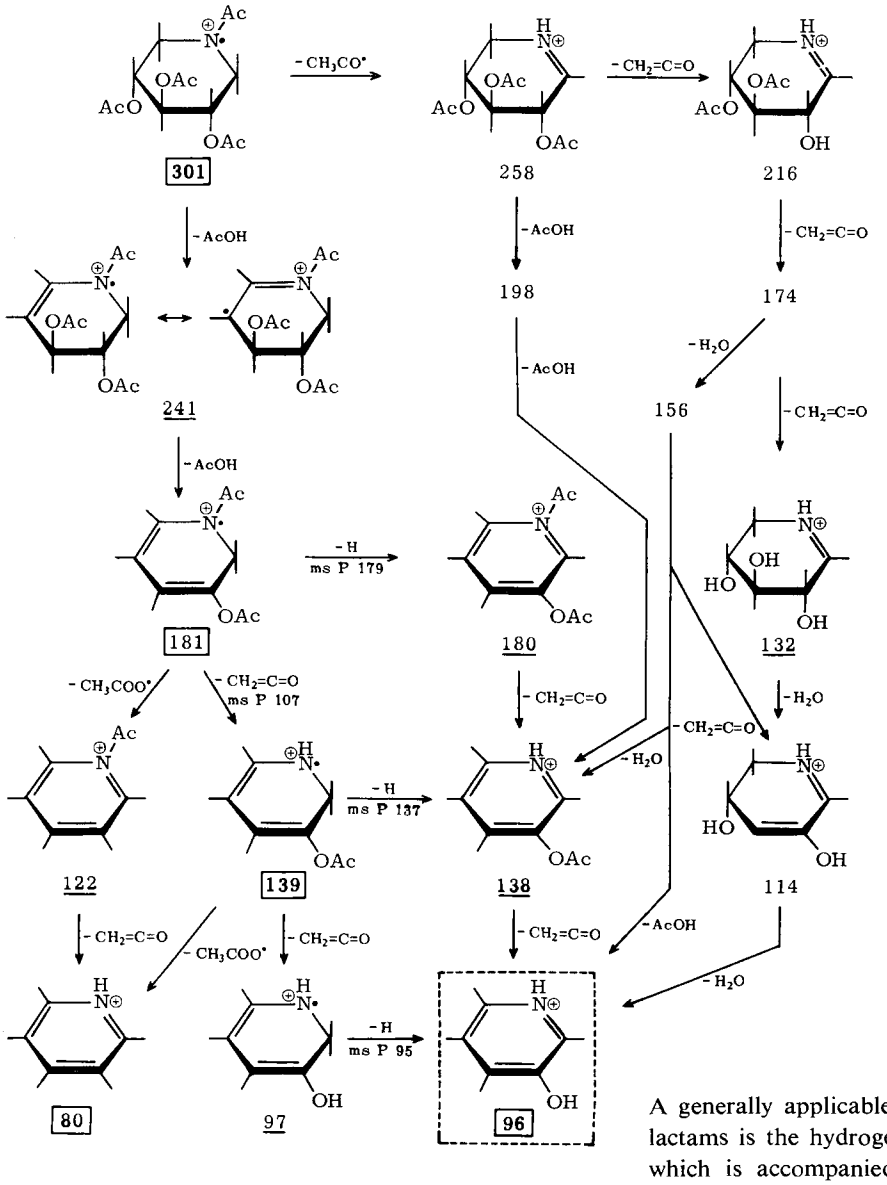

Fig. 9. Degradation routes for 1,5-(*N*-acetylimino)-2,3,4-tri-*O*-acetyl-1,5-dideoxyxylitol in mass-spectroscopic studies (ms P = metastable ion).

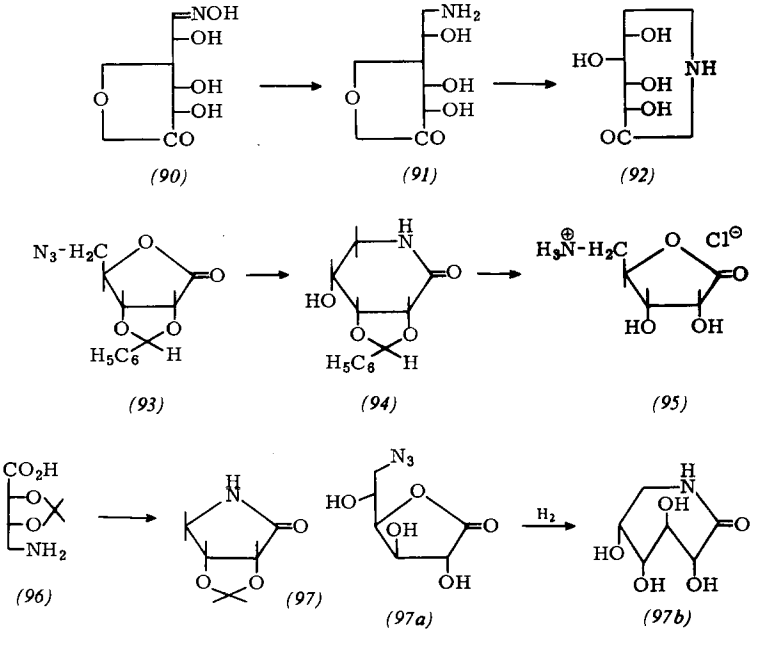
A detailed fragmentation scheme has also been published for methyl *N*-acetyl-2,3,4-tri-*O*-methyl-α-D-xylopiperidinoside [46b]. The so-called primary cleavage B in this case leads to the methoxypyridinium ion with MN 110. The precise fragmentation routes for the peracetylated bicyclic idosan derivatives *(58)*, *(62)*, and *(68)* have also been determined [46c].

## f) Sugars Containing a Lactam Ring

When carboxyl, hydroxyl, and amino groups are present simultaneously in sugar derivatives, competitive reactions can occur in the formation of cyclic ester and amide linkages. Since ester linkages can generally be cleaved by amines with formation of amides, the introduction of an amino group into an existing lactone will lead to rearrangement to the lactam, if this is sterically possible.

Thus hydrogenation of the lactone of D-glucuronic acid oxime *(90)* gives the amine *(91)*. This can be rearranged by treatment with alkali to give the gulonolactam *(92)*, a stable ε-lactam with a 7-membered ring [47].

A generally applicable method for the preparation of lactams is the hydrogenation of azido lactones *(93)*, which is accompanied by ring expansion. Thus the lactam *(97b)* is obtained from 6-azido-6-deoxygluconolactone *(97a)*. All the pentonolactams have been prepared in this way [46a]. Hydrogenation of the ribono-



[46b] *K. Heyns* and *D. Müller*, Tetrahedron *21*, 3151 (1965).

[46c] *K. Heyns* and *H. Scharmann*, Chem. Ber., in press.

[47] *H. Weidmann* and *E. Fauland*, Liebigs Ann. Chem. *679*, 192 (1964).

lactone azide *(93)*, for example, leads directly to a ribonolactam *(94)* [48]. However, acid hydrolysis of *(94)* leads to ring contraction, the product again being a ribonolactone *(95)* [48]. The 4-amino-4-deoxyerythronic acid *(96)* yields an erythronolactam *(97)* on sublimation at 150 °C [17].

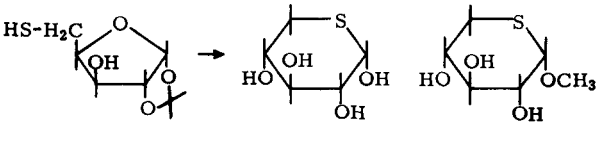
## III. Monosaccharides with "Hemiacetal" Rings Containing Sulfur

### a) 5-Thio Sugars

Mercaptans are much more reactive than alcohols in "acetal" formation. 5-Thio sugars therefore, should form only a 6-membered "hemiacetal" ring containing sulfur, since the furanose ring containing oxygen is also less favorable on steric grounds. Experimental results indicate, in fact, that free 5-thio sugars give only 6-membered S-rings and that no furanose form is detectable at equilibrium [49-51].

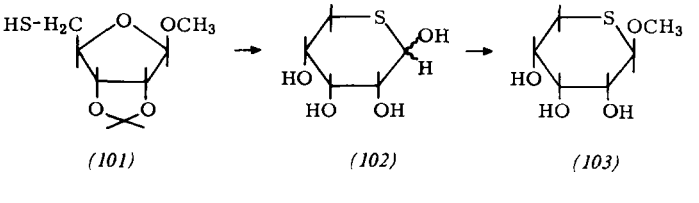
Thio sugars are usually prepared by nucleophilic displacement of *O*-tosyl groups with sodium benzyl mercaptide, sodium thioacetate, or sodium thiocyanate. Subsequent reductive cleavage or hydrolysis yields the desired sugar with a free SH group. Owing to the ease of oxidation to disulfides, strict exclusion of oxidizing agents is essential.

Acid hydrolysis of the 5-thioxylofuranose derivative *(98)* yields a free xylothiopyranose *(99)* as stable colorless crystals [49,50]. None of the reactions of free SH groups, such as oxidation with $I_2$ or dichloroindophenol, are given by *(99)*, making evident that the sulfur is stably bound in a mercaptal linkage in the 6-membered ring. The properties of the xylothiopyranose *(99)* are similar to those of normal xylose. The compound responds to the typical reduction tests for sugars, and exhibits a mutarotation of $[\alpha]_D = +202 \rightarrow [\alpha]_D = +178°$, which indicates the presence of the α form in the crystalline state [49,50]. Cleavage of *(98)* with methanol/HCl leads directly to methyl α-D-xylothiopyranoside *(100)* [51,52]. Thus in contrast to the behavior of compounds containing nitrogen, this methanolysis is accompanied by ring expansion to form the 6-membered S-ring.

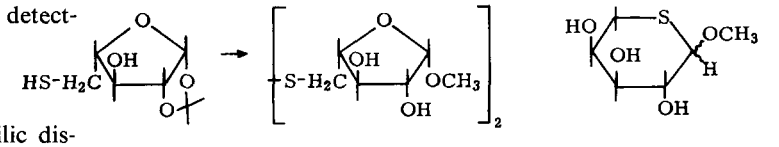


*(98)* *(99)* *(100)*

Acid hydrolysis of the *ribo* compound *(101)* leads to a syrupy ribothiopyranose *(102)*, which reacts only very slowly with $I_2$ and, therefore, must exist as the 6-membered ring [53]. Methanolysis of *(101)* proceeds with ring expansion and yields the stable methyl β-D-ribothiopyranoside *(103)* [52]. An interfering disulfide formation, which is noticeable even during the preparation of *(103)*, is particularly pronounced in the methanolysis of the *arabino* compound *(104)*, whereby, in addition to the methyl arabinothiopyranoside *(106)*, the principal product is the disulfide *(105)* [54].

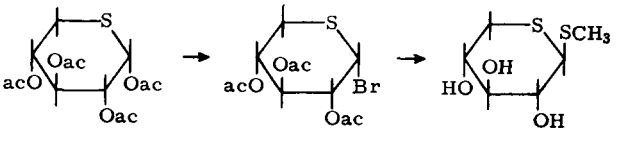


*(101)* *(102)* *(103)*



*(104)* *(105)* *(106)*

The properties and reactions of xylothiopyranose have been studied in detail by *Whistler*. It was found that the normal reactions of carbohydrate chemistry can be carried out, in the same manner, with sugars containing an S-ring. Thus the tetraacetate of the xylothiopyranose *(107)* reacts readily with HBr/glacial acetic acid to give the acetobromo compound *(108)* [55], from which methyl β-D-xylothiopyranoside [55], methyl-1-thio-β-D-xylothiopyranoside *(109)* [56], and *N*-glycosides [57] can be prepared by the Königs-Knorr synthesis.



*(107)* *(108)* *(109)*

Comparison of the NMR spectra of methyl-α-D-xylothiopyranosides and methyl-β-D-xylothiopyranosides with those of the corresponding α- and β-D-xylopyranosides shows that the sulfur compounds and the oxygen compounds scarcely differ in their conformations, and that all exist in the C 1 conformation. The same is true of free xylothiopyranose and xylopyranose [58].

The kinetics of hydrolysis of various xylothiopyranosides have been compared with those of the corresponding

[48] *S. Hanessian* and *T. H. Haskell*, J. heterocyclic Chem. *1*, 55 (1964).

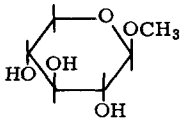
[56] *R. L. Whistler* and *R. M. Rowell*, J. org. Chemistry *29*, 3290 (1964).

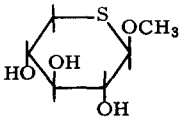
[57] *D. L. Ingles*, Chem. and Ind. *1963*, 1901.

[58] *V. S. R. Rao*, *J. F. Foster*, and *R. L. Whistler*, J. org. Chemistry *28*, 1730 (1963).

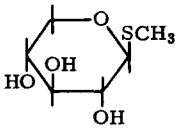
oxygen compounds[55,56]. It was found that glycosides containing S-rings generally are hydrolysed 10 to 20 times faster than their oxygen analogue[55].



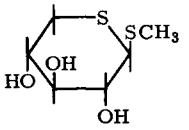
*(110)* $k = 1.8 \cdot 10^{-3}\ min^{-1}$



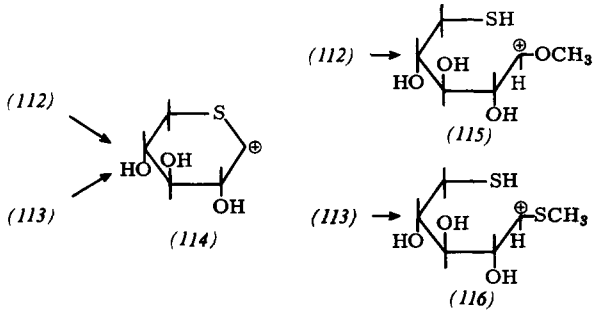
*(112)* $k = 26.1 \cdot 10^{-3}\ min^{-1}$



*(111)* $k = 0.9 \cdot 10^{-3}\ min^{-1}$



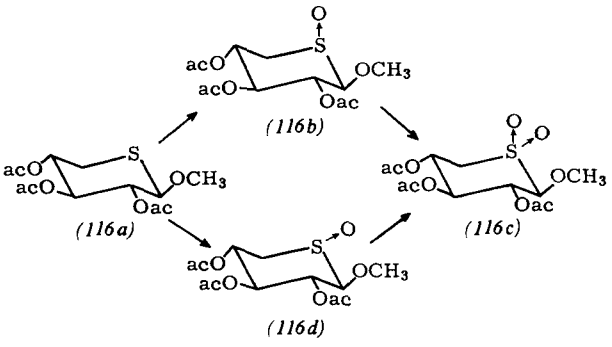
*(113)* $k = 18.3 \cdot 10^{-3}\ min^{-1}$



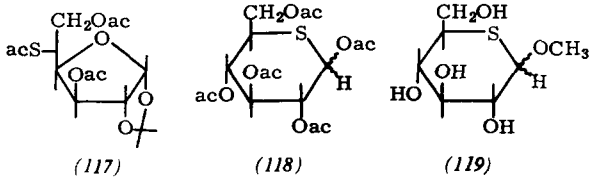
Of the compounds studied, *(110)* to *(113)*, two pairs with similar hydrolysis rates can be compared: *(110)* and *(111)* are hydrolysed slowly, while *(112)* and *(113)*, which contain S-rings, are hydrolysed 15 to 20 times faster[56]. It follows that the rate of hydrolysis is strongly affected by the heteroatom in the ring, but not by the glycosidic heteroatom. Thus the hydrolysis is assumed to proceed by a slow rate-determining initial step leading to a cyclic carbonium ion *(114)* since this is the only mechanism by which *(112)* and *(113)* would give the same transition state. If the mechanism were acyclic, *(112)* and *(113)* would give different transition states *(115)* and *(116)*, and this cannot easily be reconciled with the fact that the reaction rates are roughly the same[56].

Xylothiopyranose *(99)*, like normal sugars, reacts with aromatic amines to form *N*-glycosides, a large number of which have already been synthesized with various arylamines[57,59]. An attempt to rearrange *N*-*p*-tolyl-D-xylothiopyranosylamine yielded a substance with all the properties of an Amadori rearrangement product, but which is not crystalline and does not form crystalline derivatives[59].

The α-and β-xylothiopyranose tetraacetates *(107)* can be converted into sulfones by oxidation with $H_2O_2$[60]. Mild oxidation of methyl tri-*O*-acetyl-β-D-xylothiopyranoside *(116a)* with periodate yields a mixture of β-sulfoxide *(116b)* (sulfoxide group *endo* to the ring) and α-sulfoxide *(116d)* (*exo*)[60]. Both of these give the sulfone *(116c)* on further oxidation. Partial oxidation of methyl tri-*O*-acetyl-α-D-xylothiopyranoside gives only a β-sulfoxide, for steric reasons[60].



5-Thiohexoses, like 5-thiopentoses, preferentially form 6-membered rings, and the behavior of the two classes of compounds is similar. Acetolysis of the 5-thioglucofuranose derivative *(117)* gives a glucothiopyranose *(118)*; methanolysis of *(117)* gives a methyl glucothiopyranoside *(119)*[61]. A similar series of reactions has been carried out with 5-thioidose[50]. 6-Acetamido-6-deoxy-5-thio-L-idose also forms a 6-membered ring containing sulfur on acetylation[62].



b) 4-Thio Sugars

4-Thio sugars should also preferentially form a 5-membered S-ring, though the stability of this ring is expected to be lower than that of the 6-membered S-ring.

Methanolysis of the ribothiopyranose derivative *(120)* gives a methyl ribothiofuranoside *(121)*[63], while acetolysis leads to the tetraacetate *(122)*[64,65]. Neither *(121)* nor *(122)* gives the reactions of the SH group; the sulfur must, therefore, be stably bound in the 5-membered ring. Hydrolysis of *(122)* gives free ribothiofuranose *(123)*[65]. The spectroscopic data show that the free sugar is also almost entirely in the form of the thiofuranose *(123)*. This is supported by the fact that glycoside formation with *(123)* gives *(121)*, and acetylation of *(123)* gives *(122)*[65].

However, ribothiofuranose *(123)* gives positive reactions for SH groups. It is quickly and quantitatively oxidized by $I_2$ at room temperature to the disulfide *(125)*[65]. It must, therefore, be assumed that in contrast

[59] *T. van Es* and *R.L.Whistler*, J. org.Chemistry*29*, 1087 (1964).

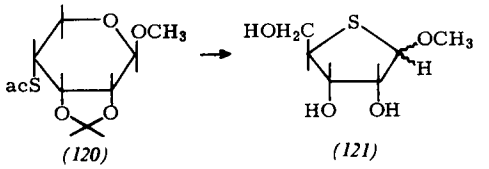
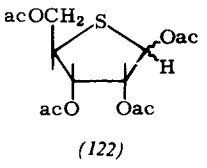
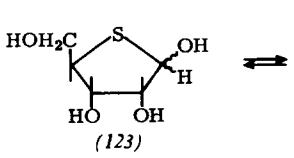
to the case of xylothiopyranose, an equilibrium is rapidly reached between ribothiofuranose *(123)* and 4-thiopyranose *(124)* The latter is readily oxidized to the disulfide *(125)* and is, therefore, continuously



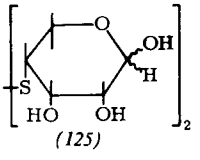
*(120)* *(121)*



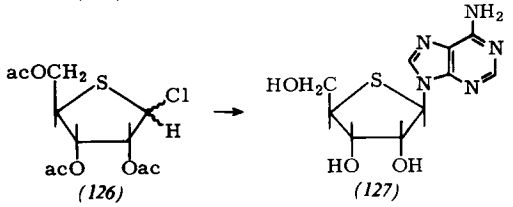
*(122)*



*(123)* *(124)*



*(125)*



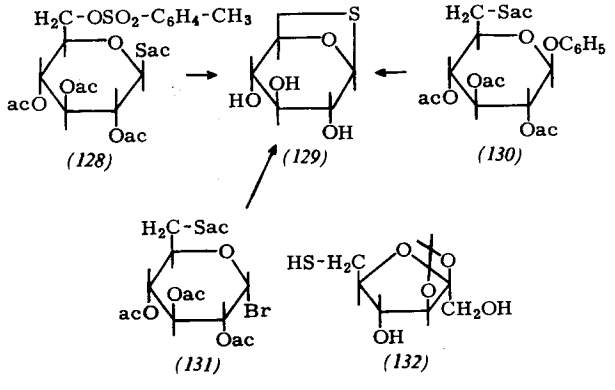
*(126)* *(127)*

removed from the equilibrium [65]. Thus the thiofuranose ring is much less stable than the thiopyranose ring.

The tetraacetate *(122)* reacts with HCl in ether to form the thiofuranosyl chloride *(126)*, from which the interesting modified nucleoside 4'-thioadenosine *(127)* has been prepared by condensation with 6-benzamido-9-(chloromercuri)purine [65].

### c) 6-Thio Sugars

1,6-Anhydropyranoses with sulfur in the 1,6-anhydro ring have been prepared in the form of the so-called "thiolaevoglucosan" *(129)*. The 1,6-anhydro ring can be closed from C-1 by treatment of *(128)* with alkali [66], while the ring is closed from C-6 by treatment of *(130)* and *(131)* with alkali [67].



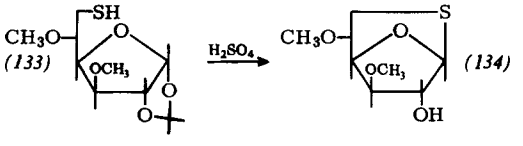
*(128)* *(129)* *(130)*

*(131)* *(132)*

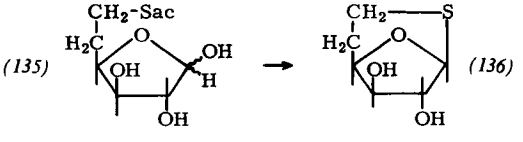
Attempts have also been made to detect a 6-thiopyranose form in 6-thiofructose [68]; however, the hydrolysis of the 6-thiofructofuranose derivative *(132)* did not yield conclusive results.

1,6-Anhydrofuranose derivatives with sulfur in the 1,6-anhydro ring have also been prepared from *(133)* and *(135)*. Position 5 is blocked by a methoxy group in *(133)*, and by the presence of the 5-deoxy group in *(135)*, so that cleavage of *(133)* and *(135)* [3a] yields *(134)* [3a] and *(136)* [69], respectively.

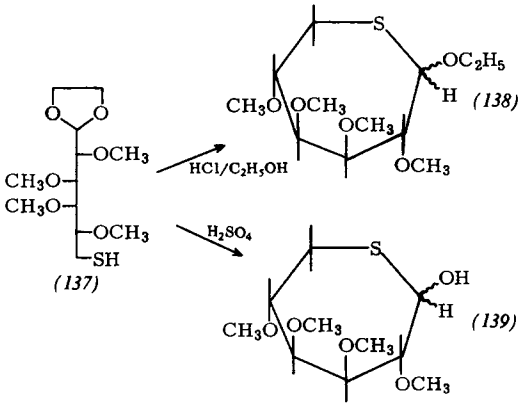
A heptanose derivative with sulfur in the 7-membered ring can be obtained by acetal cleavage of the 2,3,4,5-tetramethyl thiol *(137)* [3a]. Reaction with ethanol/hydrochloric acid gives the ethylthioheptanoside *(138)*, and hydrolysis with sulfuric acid yields the free thioheptanose *(139)*. The 7-membered S-ring is less stable than a thiopyranose ring [3a].



*(133)* *(134)*



*(135)* *(136)*



*(137)* *(138)* *(139)*

*I am grateful to my co-workers K. Todt, I. Sangster, D. Stoye, and F. Leupold for their enthusiastic assistance in the work on sugars containing N-rings. Thanks are also due to Prof. Dr. K. Heyns for his constant support of these investigations.*

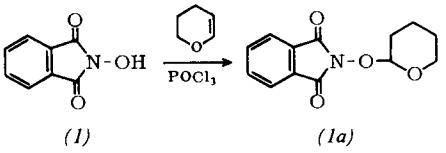
## Synthesis of 1-Hydroxy-2-thiouracil

By Dr. R. N. Warrener and E. N. Cain

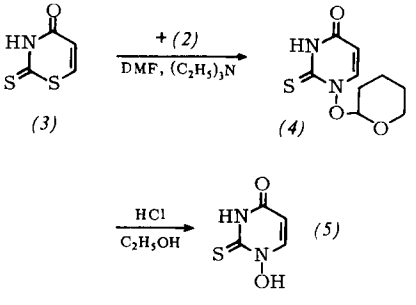
Department of Chemistry, Australian National University, Canberra, A.C.T. (Australia)

For the synthesis of 1-hydroxy-2-thiouracil, *O*-tetrahydropyran-2-ylhydroxylamine *(2)* was first prepared by the reaction:



Reaction of *(1)* [1] with 1.5 equivalents of 2,3-dihydro-4*H*-pyran and a few drops of phosphorus oxide chloride in tetrahydrofuran at 25 °C for 3 hours agave *(1a)*, m.p. 123 °C, which on heating with an equivalent of hydrazine hydrate in benzene for 3 hours, afforded *(2)* in 50% yield. It was obtained as a colorless liquid, b.p. 83 °C/23 mm (benzoyl derivatives: m.p. 150 °C, *(1a)*: m.p. 123 °C).

Reaction of *(2)* with the 1,3-thiazine *(3)* [2] in dimethylformamide containing one equivalent of triethylamine for 12 h at room temperature gives 1-tetrahydropyran-2-yloxy-2-thiouracil *(4)*, m.p. 208 °C (yield 21 %). The protecting group was readily removed by heating in ethanolic hydrochloric acid (10 %) to afford 1-hydroxy-2-thiouracil *(5)*, m.p. 203 °C and 275–277 °C, in 82 % yield. (Ultraviolet spectrum at pH 1: $\lambda_{max}$ = 217, 264, 297; log ε = 4.12, 4.08, 3.98; at pH 13: $\lambda_{max}$ = 244, 274, 320; log ε = 4.41, 4.15, 3.87).



Compound *(5)* gives an intense deep violet color with ferric chloride in ethanol, and like 1-hydroxy-uracil [3] liberates carbon dioxide from saturated sodium hydrogen carbonate solution.

Reaction between *O*-benzylhydroxylamine and *(3)* in boiling ethanol gives 1-benzyloxy-2-thiouracil *(6)*, m.p. 226 °C (yield 28 %). Removal of the *O*-benzyl group with hydrogen bromide in acetic acid is more difficult and gives inferior yields of *(5)*.

Treatment of *(6)* with alkaline dimethyl sulfate gives 1-benzyloxy-*S*-methyl-2-thiouracil *(7)*, m.p. 149 °C, yield 97 %, which on boiling with concentrated hydrochloric acid gives 1-hydroxyuracil *(8)* (50 %), m.p. 280–281 °C.

## Preparation of Saturated and Unsaturated Ketocarboxylic Acids from Dicarboxylic Anhydrides and Alkylaluminum Compounds [1]

By Dr. H. Reinheckel and Dr. K. Haage

Institut für Fettchemie der Deutschen Akademie der Wissenschaften, Berlin-Adlershof (Germany)

Reaction of organo-magnesium, -cadmium, and -zinc compounds with anhydrides of dicarboxylic acids to give keto acids occurs to a significant extent only when one of the reactants contains an aromatic group [2]. However, use of alkylaluminum compounds always leads to keto acids.

Succinic anhydride and $(C_2H_5)_3\,Al_2\,Cl_3$ (mole ratio 1:1) in methylene chloride at 40 °C give aluminum salts of 4-oxohexanoic acid, from which the free keto acid is obtained in 60 % yield on treatment with dilute $H_2SO_4$. Glutaric anhydride and $(C_2H_5)_3Al_2Cl_3$ (1:1) afford 5-oxoheptanoic acid in 44 % yield.

The reaction can be effected with higher alkylaluminum compounds, but it is then advantageous to use alkylaluminum dichlorides. The molar ratio of aluminum to anhydride should be 2:1 because of the resulting complex-formation.

The excess of alkylaluminum compound may be replaced by anhydrous $AlCl_3$. A solution of the anhydride and $AlCl_3$ in methylene chloride is allowed to react with the alkylaluminum compound, *e.g.* trialkylaluminum.

Maleic anhydride (as a suspension in methylene chloride) gives the corresponding α,β-unsaturated γ-keto acids, *e.g.* with $(C_2H_5)_3Al_2Cl_3$ (mole ratio 1:1) at −10 °C it gives 4-oxo-2-hexenoic acid in 47 % yield.

Lactones are by-products in all the reactions of cyclic anhydrides. Diketones and dicarboxylic acids are formed in addition to keto acids from acyclic anhydrides because of the statistical attack on the CO–O–CO group.

| Anhydride + alkylating agent | Molar ratio | Keto acid | Yield [%] |
|---|---|---|---|
| Succinic anhydride + $(C_2H_5)_3Al_2Cl_3$ | 1:1 | 4-Oxohexanoic | 60 |
| $AlCl_3$ + $(C_2H_5)_3Al$ | 1:1:0.4 | 4-Oxohexanoic | 69 |
| $C_6H_{13}AlCl_2$ | 1:1.7 | 4-Oxodecanoic | 49 |
| $AlCl_3$ + $C_8H_{17}AlCl_2$ | 1:1:1 | 4-Oxododecanoic | 56 |
| $AlCl_3$ + $C_{12}H_{25}AlCl_2$ | 1:1:1.3 | 4-Oxohexadecanoic | 38 |
| Glutaric anhydride + $(C_2H_5)_3Al_2Cl_3$ | 1:1 | 5-Oxoheptanoic | 44 |
| Maleic anhydride + $(C_2H_5)_3Al_2Cl_3$ | 1:1 | 4-Oxo-2-hexenoic | 47 |
| $AlCl_3$ + $C_8H_{17}AlCl_2$ | 1:1.5:1 | 4-Oxo-2-dodecenoic | 17 |
| Decanedioic anhydride + $(C_2H_5)_3Al_2Cl_3$ | 1:1.2 | 10-Oxododecanoic | 42 |
| Phthalic anhydride + $AlCl_3$ + $(C_2H_5)_3Al_2Cl_3$ | 1:1:0.5 | *o*-Propionylbenzoic | 95 |

a) *Saturated keto acids*: 89 g (0.36 mole) of $(C_2H_5)_3Al_2Cl_3$ is dropped, with stirring, into a solution of 35.6 g (0.36 mole) of succinic anhydride in 250 ml of $CH_2Cl_2$ at 20 °C. The mixture is boiled for 2 hours and then hydrolysed with 15 % $H_2SO_4$. Fractional distillation of the organic phase gives 28 g (60 %) of pure 4-oxohexanoic acid, b.p. 98–100 °C/0.1 mm, m.p. 34–36 °C.

b) *Unsaturated keto acids*: Reactions with maleic anhydride are carried out at −10 °C (suspension in $CH_2Cl_2$); hydrolysis is effected at −10 to −15 °C. 32.7 g (0.33 mole) of maleic anhydride and 83 g (0.33 mole) of $(C_2H_5)_3Al_2Cl_3$ afford 20 g (47 %) of 4-oxo-2-hexenoic acid, m.p. 110 °C, on evaporation of the solvent and recrystallization of the residue from light petroleum.

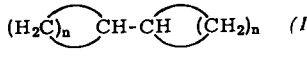
## Conformations of trans-1,2-Dicyclopropylethylene and Vinylcyclopropane

By Prof. Dr. W. Lüttke and Dipl.-Chem. A. de Meijere

Organisch-Chemisches Institut
der Universität Göttingen (Germany)

In the course of our systematic studies[1] of the rotational isomerism of 1,3-butadiene and the lower bicycloalkyls *(1)* we were interested in the conformational behavior of vinylcyclopropane, which is intermediate between 1,3-butadiene [*(1)*, n = 1] and bicyclopropyl [*(1)*, n = 2].



*(1)*, n = 1, 2 . . . 5

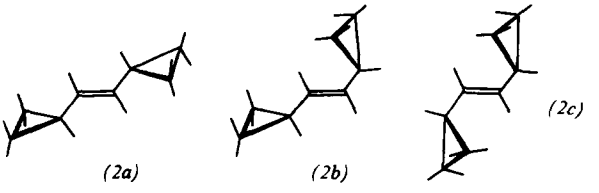
Vinylcyclopropane itself is not a suitable case for study of this problem by vibration spectroscopy since the conceivable conformers of this molecule (s-*trans*, s-*cis*, and *gauche* forms) do not differ sufficiently in symmetry and thus in the relevant selection rules (point groups: $C_s$, $C_s$, and $C_1$, respectively).

We have therefore measured the infrared spectrum of *trans*-1,2-dicyclopropylethylene *(2)* in the liquid and in the crystalline state; this compound may be considered to represent a vinylcyclopropane system with a potential symmetry center.

The most important result was the appearance of a C=C stretching vibration band at 1660 $cm^{-1}$ and two intense bands at 952 and 960 $cm^{-1}$ (C–H out-of-plane deformation of *trans*-1,2-substituted ethylenes[2]) in the spectrum of the liquid, whereas the bands at 1660 and 952 $cm^{-1}$ do not occur in the spectrum of the crystals.

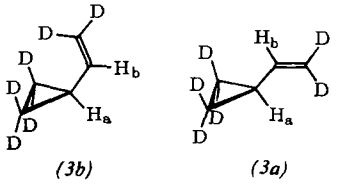
According both to experimental findings[3] and theoretical calculations[4] cyclopropanecarbaldehyde has a two-fold torsional potential, with minima at φ = 0 ° and φ = 180 ° (φ = torsion angle). It is thus to be assumed that only the s-*trans*- and the s-*cis*-conformation (φ = 180 and 0 °, respectively) of the isoelectronic vinylcyclopropane are stable, because only in these is the additional nonbonded interaction between hydrogen atoms minimal[5]. This fundamental difference from bicyclopropyl[1] follows from the differing geometry of the molecule.

On such considerations crystalline *trans*-1,2-dicyclopropylethylene consists exclusively of one of the two centrosymmetric conformers, s-*trans*-s-*trans* *(2a)* or s-*cis*-s-*cis*- *(2c)*, whereas the s-*cis*-s-*trans*-conformer *(2b)* also occurs in the equilibrium mixture in the liquid state.



*(2a)* *(2b)* *(2c)*

We have been able to prove, by NMR spectroscopy, that the s-*trans*-conformation of vinylcyclopropane is energetically more favored than the s-*cis*-conformation. For this purpose we measured the temperature-dependence of the vicinal H,H coupling constant $J_{ab}$ in hexadeuteriovinylcyclopropane *(3)*.



*(3b)* *(3a)*

Interconversion of the s-*trans*- *(3a)* and the s-*cis*-form *(3b)* is very fast in the temperature range studied. Thus a mean coupling constant (see table, second column) is observed, the following equation being valid ($x_{trans}$ and $x_{cis}$ = mole fractions of the s-*trans*- and the s-*cis*-form, respectively):

$$J_{ab}^{obs} = x_{trans} \cdot J_{ab}^{trans} + x_{cis} \cdot J_{ab}^{cis} \qquad (a)$$

$J_{ab}^{trans}$ is certainly larger than $J_{ab}^{cis}$[6]. It therefore follows from the fact that $J_{ab}^{obs}$ increases with decreasing temperature that the concentration of the *trans*-conformer increases. The s-*trans*-conformation is thus energy-poorer.

| Temp. [°C] | $J_{ab}^{obs}$ [cps] | $x_{trans}$ | $x_{cis}$ |
|---|---|---|---|
| −30 | 9.13 | 0.69 | 0.31 |
| −10 | 9.05 | 0.68 | 0.32 |
| +60 | 8.38 | 0.56 | 0.44 |
| +80 | 8.15 | 0.53 | 0.47 |

If we assume that $J_{ab}^{trans}$ lies between 11 and 12 cps[7] and $J_{ab}^{cis}$ between 4.5 and 6 cps[8], we can obtain the equilibrium concentrations $x_{trans}$ and $x_{cis}$ from Equation (a). (In the table, columns 3 and 4 give the values of $x_{trans}$ and $x_{cis}$ that result from the values $J_{ab}^{trans} = 11.0$ cps and $J_{ab}^{cis} = 5.0$ cps.

From the temperature-dependence of the equilibrium constants

$$K = x_{trans}/x_{cis}$$

the energy difference between the *trans*- and the *cis*-conformer has been estimated graphically to be 1.1 ± 0.2 kcal/mole.

[5] In a recent publication [Angew. Chem. *78*, 266 (1966); Angew. Chem. internat. Edit. *5*, 251 (1966)] *H. Günther* and *D. Wendisch* support the view that for vinylcyclopropane derivatives a *trans* ($\varphi = 180°$) and two *gauche* forms ($\varphi \approx 40°$) are the stable conformers. – Consideration of a molecular model of cyclopropane, like calculation of the sum of all the H···H interactions as a function of the torsion angle $\varphi$ [potential according to *L. S. Bartell*, J. chem. Physics, *32*, 827 (1960)], shows a narrow minimum at the *cis*-position ($\varphi = 0°$) and a broad minimum region for the *trans*-position ($\varphi = 180 \pm 100°$). The two maxima of the torsional potential curve lie at $\varphi \approx 40°$ and 320°.

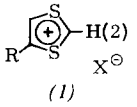
## Proton Activity in the 1,2-Dithiolium System

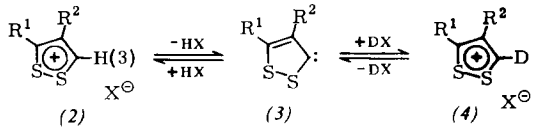
By Prof. Dr. H. Prinzbach, Dr. E. Futterer, and Prof. Dr. A. Lüttringhaus

Chemisches Laboratorium der Universität Freiburg (Germany)

As with analogous 1,3-dihetero cations, the acidity of the H atom at position 2 of 1,3-dithiolium salts *(1)* is considerable[1]. In concordance with the results of quantum-mechanical studies [2] and with the weak electronic shielding shown by low τ-values [3], the H atoms at positions 3 and 5 of the 1,2-dithiolium system *(2)*, $R^1{=}R^2{=}H$ (the C atoms to which they are attached have only one S atom as neighbor) undergo readily measurable H/D exchange even in 10% (v/v) $F_3CCOOD/D_2O$ (74 ± 2 °C; 0.5 mole/l). By NMR-spectroscopic measurements we have determined the effective exchange half-lives $t_{1/2}$ listed in the Table.



*(1)*

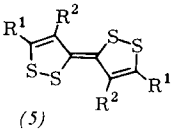


*(2)* *(3)* *(4)*

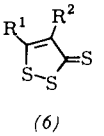
| | | | |
|---|---|---|---|
| *(a)*: | $R^1 = (CH_3)_3C$ | $R^2 = H$ | $X = ClO_4$ |
| *(b)*: | $R^1 = C_6H_5$ | $R^2 = H$ | $X = Br$ |
| *(c)*: | $R^1 = p\text{-}CH_3O\text{–}C_6H_4$ | $R^2 = H$ | $X = Cl$ |
| *(d)*: | $R^1 = H$ | $R^2 = C_6H_5$ | $X = Cl$ |

| | $t_{1/2}$ [min] | τH(3) ($F_3CCO_2D$) |
|---|---|---|
| *(2a)* | 522 ± 60 | −0.57 |
| *(2b)* | 120 ± 10 | −0.30 |
| *(2c)* | 200 ± 20 | 0.01 |
| *(2d)* | 11.6 ± 1 | −0.50 |

As expected from the acid-base equilibrium *(2)* ⇄ *(3)* the rate of H/D exchange decreases with increasing concentration of $F_3CCOOD$.



*(5)*



*(6)*

In contrast to 1,3-dithiolium salts *(1)*, the 1,2-dithiolium salts (in acetonitrile) do not give the dimers *(5)* when treated with *N*-ethyldiisopropylamine, but instead give the dithiole-3-thione *(6)* (yield *ca.* 50 %). In view of the easy scission of the disulfide linkage by carbenes[4], attack of the carbene *(3)* on the disulfide bridge in *(2)* or *(3)* is not excluded. The yields of *(6)* can be increased substantially (up to 97 %) by addition of elemental sulfur[5].

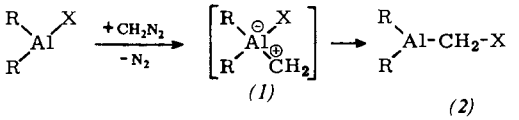
## Preparation and Rearrangement of Allylalanes

By Dr. H. Hoberg

Max-Planck-Institut für Kohlenforschung, Mülheim/Ruhr (Germany)

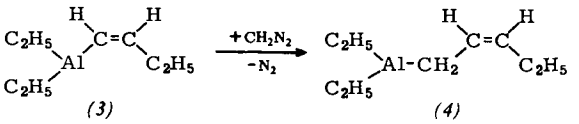
Diazomethane reacts with organic derivatives of aluminum hydrides in toluene at −78 °C, giving, by way of Al ylides *(1)*, products *(2)* in which a residue attached to the Al atom has been lengthened by a $CH_2$ group[1]. The $CH_2$ group is



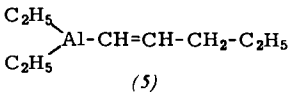
*(1)* *(2)*

X = Halogen, H, or organic group
R = $C_2H_5$

inserted preferentially between Al and the most electronegative ligand. Thus alkenyldialkylalanes *(3)* (prepared from triethylalane and acetylene[2]) reacts with equimolar amounts of diazomethane in toluene/anisole (4:1 v/v) at −78 °C predominantly at the Al–$C_{(alkenyl)}$bond, for hydrolysis of the product gives pentene as well as ethane. However,



*(3)* *(4)*

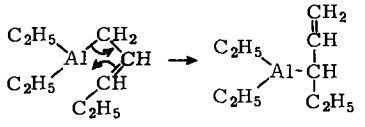


*(5)*

the product does not have the structure *(4)*, for the hydrolysis gives 1-pentene and not *cis*-2-pentene. This appears to indicate structure *(5)*, but hydrolysis with $D_2O$ gives a monodeuterio-1-pentene in which a saturated C atom has been deuterated, as is shown by the position of the C–D stretching vibration ($\tilde{\nu}$ = 2140 $cm^{-1}$) on comparison with the spectra of alkenes deuterated at known positions[3].

If an excess of diazomethane is used with compound *(3)*, insertion of a second $CH_2$ group per alane molecule occurs, so that subsequent hydrolysis gives propane and, above all, 3-methyl-1-pentene, but no hexene, as well as ethane and 1-pentene. Thus an isomerization *(4)* → *(5)* is excluded.

The formation of 3-methyl-1-pentene on alcoholysis after reaction of compound *(3)* with an excess of diazomethane throws light on the nature of the rearrangement. The 3-methyl group results from the second $CH_2$ insertion, so after the first insertion an allyl rearrangement onto aluminum according to *(4)* → *(6)* must have occurred.



*(4)* *(6)*

A recent paper on allyl rearrangements on addition of dialkylalanes to substituted 1,3-dienes[4] supports our formulations.

## New Synthesis of 1,2,5-Thiadiazole and Some of its Derivatives

By Dr. V. Bertini and Prof. Dr. P. Pino

Istituto di Chimica Organica, Facoltà di Scienze, Università di Pisa (Italy)

Hitherto the only synthesis of 1,2,5-thiadiazole has been a five-stage one affording poor yields[1].

In continuation of our study of the use of $S_4N_4$ for synthesis of thiadiazole derivatives we have prepared 1,2,5-thiadiazole (b.p. 94 °C, $n_D^{25}$ = 1.5151, ultraviolet spectrum: $\lambda_{max}$ = 254 mμ, log ε = 3.94) in 70 % yield by heating 0.0434 mole of ethylenediamine with 0.0109 mole of $S_4N_4$ in 45 ml of a mixture of *o*-, *m*-, and *p*-xylene for 2–3 hr[2,3]. The 1,2,5-thiadiazole was isolated and purified by distillation of the reaction mixture, followed by precipitation as Cd salt, decomposition of the latter in steam, and salting out of the aqueous solution with $Na_2SO_4$. Under similar conditions 0.0326 mole of propylenediamine and 0.0109 mole of $S_4N_4$ yielded 3-methyl-1,2,5-thiadiazole[4] (b.p. 121 °C; $n_D^{25}$ = 1.5053; $\lambda_{max}$ = 259 mμ, log ε = 3.94) in 97 % yield.

Synthesis of mono- and di-aryl derivatives of 1,2,5-thiadiazole, which can be obtained in low yield by reaction of $S_4N_4$ with alkylaromatic hydrocarbons of the type $R-CH_2-CH_2-R'$ (with R = $C_6H_5$, $C_{10}H_7$; R′ = H, $C_6H_5$)[5], is accomplished in much higher yield and more conveniently from the more readily accessible monoamines[6] $C_6H_5-CH_2-CH(NH_2)-R'$ (R′ = H or $C_6H_5$). In this way, boiling 0.0325 mole of phenethylamine with 0.0163 mole of $S_4N_4$ in the xylene mixture gives a 20 % yield of 3-phenyl-1,2,5-thiadiazole (m.p. and mixed m.p. 43–44 °C); and 0.0163 mole of α-phenylphenethylamine and 0.0165 mole of $S_4N_4$ give a 60 % yield of 3,4-diphenyl-1,2,5-thiadiazole (m.p. and mixed m.p. 85–86 °C)

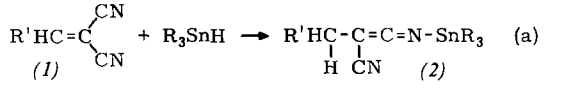
## Preparation of N-Stannylketenimines and Ketene Ethyl Stannyl Acetals by 1,4-Hydrostannation of Conjugated Systems

By Prof. Dr. W. P. Neumann, Dr. R. Sommer, and cand. chem. E. Müller

Institut für Organische Chemie der Universität Gießen (Germany)

In the presence of catalysts at 60–80 °C conjugated dienes, *e.g.* 1,3-butadiene, add organotin hydrides preponderatingly at the 1,4-positions in a radical reaction[1]. We now report a polar 1,4-hydrostannation of conjugated unsaturated systems whose C=C group is sufficiently polarized, *e.g.* of alkylidenemalononitriles *(1)*. *N*-Stannylketenimines *(2)* are thus formed, usually even at 20 °C and without a catalyst, in a strongly exothermic reaction. This is surprising because previous attempts to bring about reaction between organotin hydrides and CN groups failed[2] and cinnamonitrile and acrylnitrile react exclusively at their C=C groups[3].



*(1)* *(2)* (a)

R′ = *e.g.* $CH_3$, $C_2H_5O$, $C_6H_5$, *p*-$(CH_3)_2N-C_6H_4$, *p*-$CH_3O-C_6H_4$, *p*-$Cl-C_6H_4$, *p*-$O_2N-C_6H_4$, Furyl

R = $C_2H_5$, $C_4H_9$

Compounds $R'_2C=C(CN)_2$ (R′ = *e.g.* $CH_3$, $C_6H_5$) react analogously to *(1)*.

The *N*-stannylketenimines *(2)* are very reactive[4]. Their structure follows, *inter alia*, from the NMR spectra and the very intense ketene imine bands at 2060–2110 $cm^{-1}$ in their infrared spectra (C≡N absorption at 2180 $cm^{-1}$ is also present). They are readily soluble in hydrocarbons and ethers, sensitive to moisture, and stable only up to about 50 °C. The average molecular weight of these viscous, undistillable liquids in benzene increases rapidly with concentration, which indicates association by means of pentacoordinated tin.

Reaction is slower the less polarized is the C=C group. Electron-donating substituents R′ decrease the reaction velocity, as does replacement of CN by the more weakly electron-attracting ester group: alkylidenecyanoacetates *(3a)* and alkylidenemalonic esters *(3b)* also react with organotin hydrides by 1,4-addition, giving ketene ethyl stannyl acetals *(4)*, but sometimes so slowly that 1,2-hydrostannation of the C=C bond also occurs.

$$R^1HC{=}C(X)CO_2C_2H_5 + R_3SnH \longrightarrow R^1CH{-}C(X){=}C(OC_2H_5)(OSnR_3) \quad (b)$$

(3) (4)

*(3a)*, X = NC; R′ = $CH_3$, $C_6H_5$, *p*-$CH_3O$–$C_6H_4$, *p*-Cl–$C_6H_4$
*(3b)*, X = $C_2H_5CO_2$; R′ = $CH_3$, $C_6H_5$

The analogous vinyl ketones *(5)* [5] react exclusively by 1,4-addition, giving enol ethers *(6)* (characterized by, *inter alia*, NMR and infrared spectra). These are crystalline compounds, which in contrast to *(2)* and *(4)* are not sensitive to moisture.

$$R^1HC{=}C(CN){-}C(=O){-}R^2 + R_3SnH \longrightarrow R^1H_2C{-}C(CN){=}C(R^2)(OSnR_3) \quad (c)$$

(5) (6)

$R^1$ = *e.g.* *p*-$CH_3O$–$C_6H_4$, $C_6H_5$, *p*-$O_2N$–$C_6H_4$, Furyl
$R^2$ = *e.g.* $C_6H_5$

Reactions (a) and (b) also occur analogously and smoothly with dialkyltin dihydrides and organolead hydrides [6].

## Syntheses with N-Stannylketenimines and Ketene Ethyl Stannyl Acetals

By Dr. R. Sommer and Prof. Dr. W. P. Neumann

Institut für Organische Chemie
der Universität Gießen (Germany)

*N*-Stannylketenimines *(1)* and ketene ethyl stannyl acetals *(9)* have recently become known and easily accessible [1]. Some of the reactions of ketene imines and acetals [2] lead one to expect that compounds *(1)* and *(9)* would be particularly suitable for the synthesis of substituted malonic acid derivatives. This is in fact the case: compounds *(2)*–*(4)* are formed smoothly when the components are heated 6–10 hr to 60–80 °C, and compounds *(5)*–*(8)* are formed instantaneously at 0–20 °C, some of them exothermally. The by-product, trialkyltin halide or alkoxide, can be easily separated by destillation and reconverted into the organotin hydride from which compounds *(1)* and *(9)* are obtained.

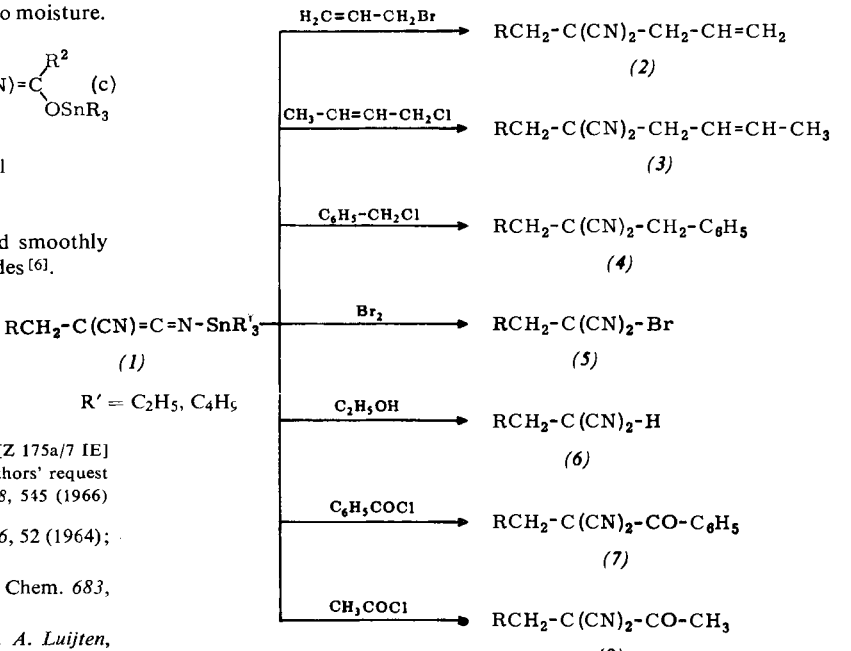
From the ketene stannyl acetals *(9)* [1]

$R{-}CH_2{-}C(X){=}C(OC_2H_5){-}OSnR'_3$ *(9a)*, X = CN
*(9b)*, X = $CO_2C_2H_5$

we obtained the following compounds similarly and in good yield:

$C_6H_5{-}CH_2{-}CH(CN){-}CO_2C_2H_5$ B.p. 160–165 °C/11 mm
$C_6H_5{-}CH_2{-}C(CN)(CO_2C_2H_5){-}CH_2{-}CH{=}CH_2$ B.p. 130–132 °C/$10^{-3}$ mm
*p*-$CH_3O$–$C_6H_4$–$CH_2$–$C(CN)(CO_2C_2H_5)$–Br B.p. 148–150 °C/$10^{-4}$ mm
*p*-Cl–$C_6H_4$–$CH_2$–$C(CN)(CO_2C_2H_5)$–$CH_2$–$CH{=}CH_2$ B.p. 135–136 °C/0.2 mm
$C_6H_5{-}CH_2{-}C(CO_2C_2H_5)_2{-}CO{-}C_6H_5$ B.p. 166–168 °C/$10^{-4}$ mm

Most of these compounds, like *(2)*–*(8)*, were previously unknown or were accessible only by complicated methods or in poor yields.



| | R | M.p. [°C] | B.p. [°C/mm Hg] | Yield [%] |
|---|---|---|---|---|
| *(2)* | $CH_3$ | | 85–86/10 | 82 |
| | $C_6H_5$ | 55 | 98–100/0.01 | 94 |
| | *m*-$NO_2$–$C_6H_4$ | 76 | | 81 |
| | 2-Furyl | 35 | 92–93/$10^{-4}$ | 86 |
| *(3)* | $C_6H_5$ | 78 | 116–118/$10^{-4}$ | 80 |
| | *p*-Cl–$C_6H_4$ | | 130–135/$10^{-4}$ | 81 |
| *(4)* | $C_6H_5$ | 131 | | 85 |
| | *p*-$CH_3O$–$C_6H_4$ | 110 | | 77 |
| | *p*-Cl–$C_6H_4$ | 127 | | 96 |
| | 2-Furyl | 104 | | 69 |
| *(5)* | $C_6H_5$ | 119 | | 90 |
| | *p*-$CH_3O$–$C_6H_4$ | 59 | | 73 |
| | *p*-$NO_2$–$C_6H_4$ | 138 | | 90 |
| | *p*-Cl–$C_6H_4$ | 124 | | 70 |
| *(6)* | $CH_3$ | | 96/21 | 83 |
| | $C_6H_5$ | 92 | | 68 |
| | *p*-$CH_3O$–$C_6H_4$ | 88 | | 96 |
| | *p*-$NO_2$–$C_6H_4$ | 154 | | 93 |
| | *m*-$NO_2$–$C_6H_4$ | 132 | | 87 |
| | *p*-Cl–$C_6H_4$ | 95 | | 67 |
| | 2-Furyl | | 88–90/$10^{-4}$ | 86 |
| *(7)* | $C_6H_5$ | 101 | 140–144/$10^{-4}$ | 58 |
| *(8)* | $C_6H_5$ | 102 | 115–120/0.6 | 66 |
| | 2-Furyl | 55 | 98–100/0.02 | 73 |

The acyl groups are removed from compounds *(7)* and *(8)*, with scission of the C–C bond, as acids by atmospheric moisture or faster as esters by means of alcohols.

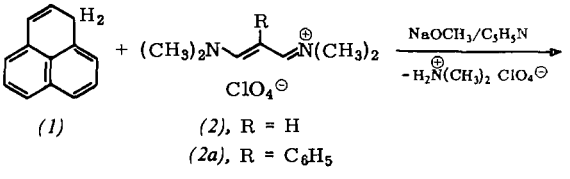
## Azuleno[5,6,7-cd]phenalene, a New Quasiaromatic System

By Doz. Dr. Ch. Jutz and Dipl.-Chem. R. Kirchlechner

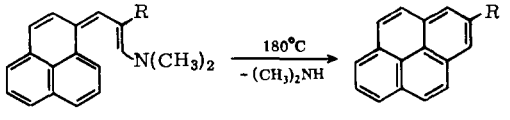
Organisch-Chemisches Institut
der Technischen Hochschule München (Germany)

Phenalene *(1)* [1] condenses with the azacyanine perchlorates *(2)* and *(2a)* in presence of sodium methoxide in pyridine under nitrogen, giving the deeply collred "phenafulvenes" *(3)* and *(3a)* in more than 90 % yield [*(3)*: lustrous green needles, m.p. 150–151 °C; $\lambda_{max}$ = 496 mμ (log ε = 4.53) in $CH_3CN$].

Compound *(3a)* undergoes ring closure to give 2-phenylpyrene *(4a)*, m.p. 166 °C, already during isolation; compound *(3)* affords pyrene *(4)* in 80 % yield, with loss of dimethylamine, when heated in quinoline or sublimed in the presence of copper powder.

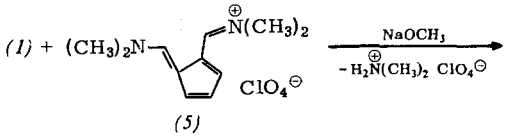


*(1)* *(2)*, R = H; *(2a)*, R = $C_6H_5$

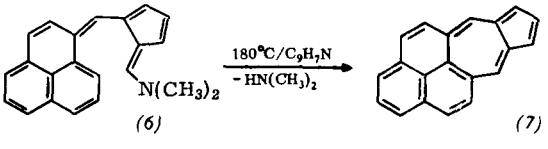


*(3)*, R = H; *(3a)*, R = $C_6H_5$ *(4)*, R = H; *(4a)*, R = $C_6H_5$

Reaction of phenalene *(1)* with *N,N*-dimethyl-(6-dimethylaminofulvenylmethylene)ammonium perchorate *(5)* [2] affords the violet "phenafulvalene" derivative *(6)*, which is converted into azuleno[5,6,7-*cd*]phenalene *(7)* (isomeric with 1,2-benzopyrene) in 60 % yield when heated in quinoline.



*(5)*



*(6)* *(7)*

The mass spectrum and elemental analysis confirm the composition. This compound *(7)* has a many-banded ultraviolet spectrum: $\lambda_{max}$ (in hexane) = 741 mμ (log ε = (3.21), 702 (3.04), 666 (3.08), 633 (2.87), 614 (2.77), 451 (5.10), 426 (4.60), 316 (5.29).

Maleic anhydride does not undergo Diels-Alder addition to compound *(7)*. Although significantly more basic, the green compound *(7)* (leaflets, m.p. 184 °C) shows many resemblances to azulene. Thus it is substituted at position 1 by dimethylformamide and phosphorus oxide chloride, affording a violet-red formimidium salt; with acetone in alcoholic mineral acid solution it forms a carmine-red carbonium ion having an intense green fluorescence.

## Preparation of Tetramethylzirconium, $Zr(CH_3)_4$

By Priv.-Doz. Dr. H. J. Berthold and Dipl.-Chem. G. Groh

Institut für Anorganische Chemie und Kernchemie
der Universität Mainz (Germany)

After having isolated crystalline tetramethyltitanium and trimethyltitanium iodide some time ago [1], we have now prepared tetramethylzirconium.

Sublimed $ZrCl_4$ was dissolved in boiling ether/toluene (2:3) under reflux in the absence of moisture. After the solution had been cooled to −78 °C an etheral solution of methyl-lithium in stoichiometric proportion was added under nitrogen. No reaction occurred at this stage. When the mixture was warmed with stirring to about −45 °C, the $ZrCl_4$-ether adduct that had partly crystallized at −78 °C, as well as any $LiCH_3$ that may have separated, dissolved. The beginning of the methylation could be recognized by appearance of a yellow color and separation of LiCl. Stirring for 4 hr at −45 °C led finally to a dark reddish-brown solution, from which a small yield of a red distillate was obtained by distillation in a closed vacuum at −30 to −15 °C. Sometimes red crystals separated during the distillation on the end of the condenser; they could be transferred to the collecting vessel without decomposition by aslight increase in the temperature of the coolant.

After hydrolysis of the chlorine-free distillate, analysis gave a Zr:$CH_4$ ratio of 1:3.998. It has not yet been established whether the red crystals are pure $Zr(CH_3)_4$ or an ether adduct thereof.

Solid $Zr(CH_3)_4$ as well as its solution is unstable and decomposes even below *ca.* −15 °C with blackening and loss of methane.

In experiments with a molar ratio $ZrCl_4$:$LiCH_3$ = 1:6, precipitation with hexane and redissolution in toluene gave chlorine-free, yellow solutions containing according to analysis the complex $Li_2[Zr(CH_3)_6]$. These solutions were thermally more stable than those of $Zr(CH_3)_4$; they decomposed at about 0 °C.

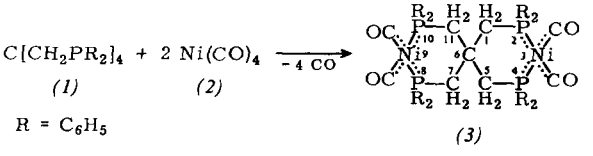
## A Spiroheterocyclic Nickel Carbonyl [1]

By Dr. J. Ellermann and Dipl.-Chem. K. Dorn

Institut für Anorganische Chemie
der Universität Erlangen (Germany)

The quadridentate complex ligand tetrakis(diphenylphosphinomethyl)methane *(1)* [2] usually reacts as a doubly bidentate reagent and is thus suitable for use in synthesis of spiroheterocyclic metal [1, 3] and non-metal compounds [4]. When the phosphine *(1)* is treated with tetracarbonylnickel *(2)* in the molar ratio 1:2 or with an excess of $Ni(CO)_4$ in benzene at room temperature with exclusion of air and moisture, then 3,3,9,9 - tetracarbonyl - 2,2,4,4,8,8,10,10 - octaphenyl-2,4,8,10-tetraphospha-3,9-dinickelaspiro[5.5]undecane *(3)* is formed, with elimination of 2 moles o CO per mole of $Ni(CO)_4$ in *ca.* 15 hours.



*(1)* *(2)* *(3)*

R = $C_6H_5$

Unchanged carbonyl *(2)* and benzene are distilled off in a high vacuum and the inhomogeneous dirty-white residue is

heated under reflux for 20 min with anhydrous, $N_2$-saturated ethanol. The ethanolic suspension is filtered and the small crystals of colorless residue are washed with a little alcohol and dried in a vacuum. Elemental analysis and molecular-weight determination confirm the constitution *(3)*. The compound is readily soluble in trichloroethylene, acetone, or benzene, less soluble in $CCl_4$, and almost insoluble in cyclohexane, light petroleum, ethanol, or ether. Decomposition occurs in $CS_2$. When heated, the compound discolors from 140 °C onwards and melts with decomposition at 205 °C. Its infrared spectrum (in $CCl_4$) shows, besides the bands of the spirocyclic ring system and the phenyl substituents, two intense CO stretching vibrations at 2008 ($A_1$) and 1952 ($B_2$) $cm^{-1}$ (point group $C_{2v}$), as are found also for other diphosphine-nickel carbonyl derivatives[5]. From the occurrence of only two CO stretching vibrations it follows that the two $P_2Ni(CO)_2$ groups do not couple with each other, which is to be expected for a non-planar spiroundecane system. The nickel is covalently bound in the rings; a considerable $\pi$-bond contribution is to be assumed for the N–P and Ni–C bonds[5,6].

## Mass Spectra of Weakly Excited Molecules [1]

By Prof. Dr. G. Spiteller and Dr. Margot Spiteller-Friedmann

Organisches Chemisches Institut
der Universität Göttingen (Germany)

We have recently shown[2] that mass-spectrometric fragmentations can be halted at the stage of primary or secondary degradation products by decrease of the electron energy and simultaneous limitation of the thermal excitation energy of the molecules to be analysed.

This procedure has now been applied to steroids (cf. Fig. 1). Whereas the spectra of steroids and terpenes, obtained with electron energies of 70 eV and hot ion sources (about 250 °C), are characterized by the formation of many, generally non-specific fragments, spectra obtained at 12–20 eV and with "cold" ion sources (about 70 °C) generally show only a few key fragments and often are as characteristic as those of alkaloids. During the determination of the mass spectra of such weakly excited molecules, the nonspecific hydrogen shifts otherwise frequently observed for steroids are absent or substantially reduced. Small hydrocarbon fragments that greatly complicate the interpretation of other spectra are not formed. The different rates of decrease in the intensities of various ions with decreasing electron energy in the range 20–12 eV yield valuable information on the energy requirements of the corresponding fragmentation.

## Reactions of α,α-Disubstituted Benzyl Anions with Carbonium Ions. Synthesis of p-Quinodimethanes

By Prof. Dr. R. Gompper, Dr. E. Kutter, and
Dipl.-Chem. H.-U. Wagner

Institut für Organische Chemie
der Universität München (Germany)

Benzyl anions are ambifunctional nucleophilic systems in which the exocyclic α-carbon atom and the nuclear *ortho*- and *para*-carbon atoms are reactive centers. According to MO calculations[1] the α-carbon atom carries most of the negative charge (see, *e.g.*, the deuteration of α,α-dimethylbenzylpotassium[2]).

With a view to obtaining thermodynamic control, and thus nuclear substitution, by the use of stable cations (cf. analogous reactions of phenols[3]), we studied the reaction of

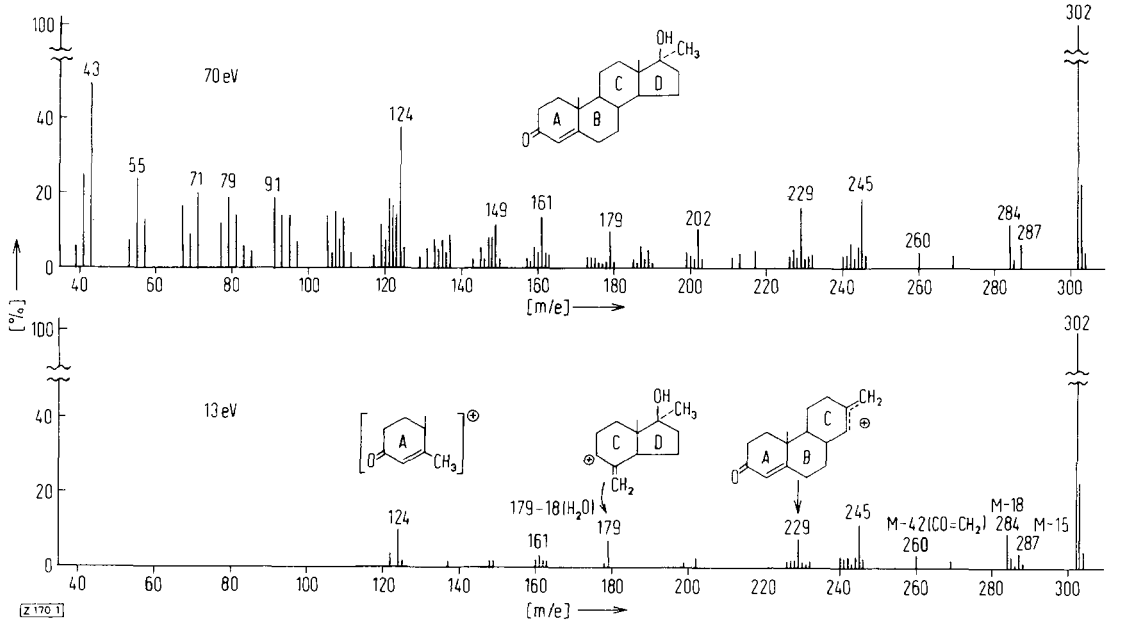

Fig. 1. Mass spectra of 17α-methyltestosterone at an ion-source temsperature of 70 °C (direct introduction of the sample into the ion source). Top: at 70 eV; bottom: at 13 eV. Increase in source temperature coniderably enhances fragmentation, making the spectra difficult to interpret. The fragment at m/e = 245 corresponds to loss of a 2-hydroxy-2-propenyl radical.

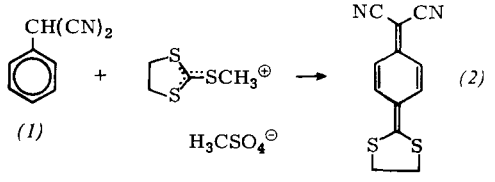
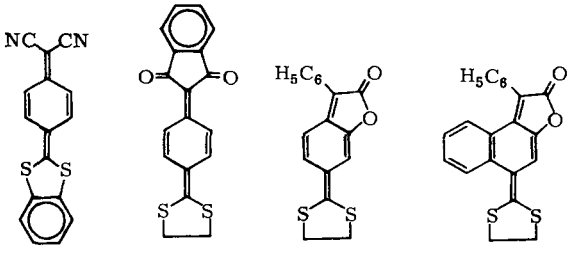
benzyl anions with carbonium ions and found that quinodimethanes can be synthesized in this way.

When benzylidene dicyanide *(1)* is heated with 2-methylthio-1,3-dithiolanium methyl sulfate in boiling glacial acetic acid/pyridine for *ca.* 112 hr, the deep blue, stable quinodimethane *(2)* results in approximately 50 % yield; it can be isolated by filtration. We have also obtained compounds *(3)* to *(6)* by analogous procedures; these products are also stable [compounds *(2)* to *(6)* decompose above 200 °C].



*(1)* *(2)*



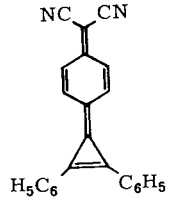
*(3)* *(4)* *(5)* *(6)*

The structure of compound *(2)* is derived from its NMR spectrum. The quinodimethanes *(2)*–*(4)* show a negative, and *(5)* and *(6)* a positive, halochromism (see Table).

| | Ultraviolet spectrum [a] in | | | |
|---|---|---|---|---|
| | $CHCl_3$ | | $CF_3CO_2H$ | |
| | $\lambda_{max}$ [mμ] | log ε | $\lambda_{max}$ [mμ] | log ε |
| *(2)* | 595 | 4.51 | 576 | 3.09 |
| | 550 | 4.69 | 535 | 3.02 |
| | 512 | 4.61 | 500 | 2.75 (S) |
| *(3)* | 638 | 4.75 | 612 | 1.70 |
| | 590 | 4.79 | 570 | 1.49 |
| | 547 | 4.57 | 540 | 1.18 (S) |
| *(4)* | 638 | 4.93 | 505 | 3.34 |
| | 585 | 4.89 | | |
| | 545 | 4.45 | | |
| | 512 | 4.22 (S) | | |
| *(5)* | 505 | 4.58 | 540 | 3.54 |
| *(6)* | 470 | 4.40 | 482 | 4.04 |

[a] Only the bands and groups of bands of longest wavelength are given. (S) = shoulder.

The generality of the reaction is illustrated by the preparation of the methylenecyclopropenes *(7)* by treatment of *(1)* with ethoxydiphenylcyclopropenylium tetrafluoroborate (in hot glacial acetic acid/pyridine). Infrared and NMR spectra are in accordance with the indicated structure. 2-Phenyl-1,3-indanedione appears to react analogously; however, we could isolate the corresponding quinodimethane only as a yellow perchlorate [$\lambda_{max}(CH_3CN)$ = 374, 320, 259 mμ; log ε = 4.50, 4.30, 4.21].



*(7)*

$\lambda_{max}(CHCl_3)$

509 mμ (log ε = 4.59)
309 mμ (log ε = 4.11)
294 mμ (log ε = 4.15)
282 mμ (log ε = 4.13)

Preliminary experiments have shown that *(1)* reacts also with amide acetals (which constitute potential carbonium ions) and related compounds.

## Tricarbonyl-(1,6-methanocyclodecapentaene)-chromium

By Prof. Dr. E. O. Fischer and Dipl.-Chem. H. Rühle

Anorganisch-Chemisches Laboratorium
der Technischen Hochschule München (Germany)

and

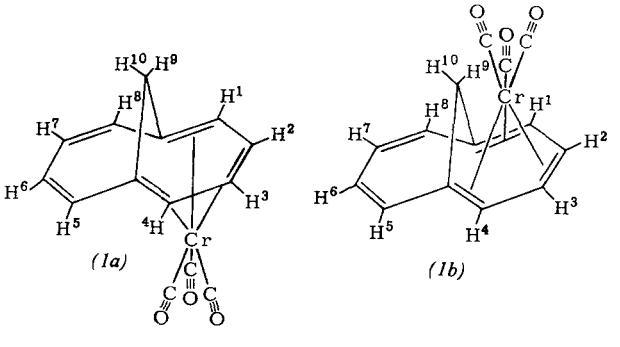
Prof. Dr. E. Vogel and Dr. W. Grimme

Institut für Organische Chemie
der Universität Köln (Germany)

Cyclodecapentaenes substituted by a 1,6-bridge ($CH_2$, O, or NH) have recently become known and it has been deduced, chiefly from NMR-spectroscopic investigations, that they contain a delocalized 10 π-electron system [1–3]. In agreement therewith, an X-ray structure analysis [4] of 1,6-methanocyclodecapentaene-2-carboxylic acid showed that this compound contains an approximately planar $C_{10}$ perimeter, and that, in contrast to those in cyclooctatetraene, the lengths of the C–C bonds do not appreciably alternate. We have, therefore, studied the π-complex formation by such systems.

Irradiation [*] of a solution of 1,6-methanocyclodecapentaene and hexacarbonylchromium in octane under purified nitrogen for 87 hours, filtration of the dark red solution obtained, and concentration led to a solid red residue that, on recrystallization from benzene/pentane (1:1), gave dark reddish-violet, monomeric tricarbonyl - (1,6 - methanocyclodecapentaene) - chromium *(1)* (sinters above 126 °C with decomposition; soluble in benzene) in 65 % yield.

The carbonyl region of the infrared spectrum (in hexane) includes three strong ν-CO bands at 1976, 1919, and 1892 $cm^{-1}$. The NMR spectrum [at 60 Mc working frequency, chemical shift positive towards lower fields, tetramethylsilane as internal standard] is particularly informative [5]: In agreement with studies of tricarbonylnaphthalenechromium complexes [6], the $A_2B_2$ system of the half-ring not bound to the metal is shifted, in comparison with that of the free ligand, only by 26 cps to higher field, at 410 cps (H–5, H–8) and 389 cps (H–6, H–7). The protons of the half-ring bound to the metal form an $A_2B_2$ system with its center shifted by 110 cps at 374 cps (H–1, H–4) and 262 cps (H–2, H–3).



*(1a)* *(1b)*

The complex formation is particularly evident in the shift and splitting of the signals of the methylene protons: in the free ligand they are equivalent and lie at −25 cps; the equivalence disappears on complex formation, so that two doublets appear at −66 cps (H–10) and −104 cps (H–9),

with a coupling constant J = 8.8 cps; *i.e.* the tricarbonylchromium group must be asymmetrically bound to the ligand. We consider structures *(1a)* and *(1b)* to be compatible with these findings.

However, particularly in view of the molecular structure of dicarbonylnorbornadienecyclopentadienylmanganese, $C_5H_5Mn(CO)_2C_7H_8$ [8], which was originally deduced from NMR data [7] and subsequently confirmed by X-ray studies, the very large shift of the methylene protons of compound *(1)* to higher field makes structure *(1b)* appear the more probable. An X-ray analysis is in progress.

Reaction of 1,6-methanocyclodecapantaene with hexacarbonylmolybdenum gave two pale red complexes, one of which is apparently analogous to compound *(1)*.

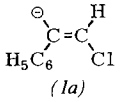
## β-Hetero-Substituted Lithium Alkyls and Alkenyls

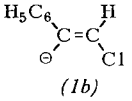
By Dr. M. Schlosser and Dr. V. Ladenberger [*]

Organisch-Chemisches Institut
der Universität Heidelberg (Germany)

Results of H–D exchange experiments with styryl chlorides [1] indicated that the carbanions *(1a)* and *(1b)* can exist.



*(1a)*



*(1b)*

Accordingly, organometallic compounds of the type 2-chlorovinyl- and 2-chloroethyl-lithium should also occur, at least transiently. However, in the only β-hetero-substituted organolithium compounds hitherto isolated the C–Li bond is part of a ring system, or is stabilized by an α-substituent capable of mesomerism or by an accumulation of neighboring fluorine atoms.

We have treated some β-hetero-substituted alkyl and alkenyl iodides with butyl-lithium in a solvent mixture of methylal, tetrahydrofuran, ether, and pentane (2:2:1:1) at −130 °C [2]. The "vicinal counter-polarized" compounds listed in the table were formed by iodine-lithium exchange; for characterization they were carboxylated, the resulting acids were esterified with diazomethane, and the methyl esters either separated and analysed or identified by gas-chromatography.

| β-Hetero-substituted lithium compound | Methyl ester, yield [%] |
|---|---|
| Cl–CH=CH–Li (*trans*) | 0 |
| Cl–CH=CH–Li (*cis*) | 0.2 |
| $Cl–CH_2–CH_2–Li$ | 5.0 |
| $F–CH_2–CH_2–Li$ | 8.0 |
| $H_3CO–CH_2–CH_2–Li$ | 5.3 |
| *(2)* | 42 |

At −50 °C 1,4,5,6-tetrachlorobicyclo[2.2.1]-5-hepten-2-yl-lithium *(2)* rearranges to the tricyclene derivative *(3)* [3]. On carboxylation and treatment with diazomethane the compounds *(2)* and *(3)* give methyl esters of m.p. 86–88 °C and 63–65 °C, respectively; hydrolysis leads to chlorinated hydrocarbons: from *(2)* to crystals of m.p. 38–40 °C [4]; from *(3)* to a colorless liquid. C–H analyses and infrared, NMR, and mass spectra prove the structures.

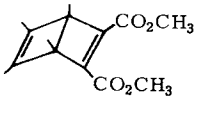
## Octamethyltetracyclo[2.2.0.0$^{2,6}$.0$^{3,5}$]hexane-1,4-dimethanol, a New Derivative of Prismane

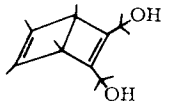
By Prof. Dr. R. Criegee and Dr. R. Askani

Institut für Organische Chemie
der Technischen Hochschule Karlsruhe (Germany)

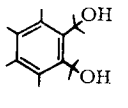
With an excess of methylmagnesium iodide at −30 °C, the dimethyl ester *(1)* [1] of "Dewar phthalic acid" (dimethyl 1,4,5,6 - tetramethylbicyclo[2.2.0]hexa - 2,5 - diene - 2,3-dicarboxylate) gives in 69% yield octamethylbicyclo[2.2.0]-hexa-2,5-diene-2,3-dimethanol *(2)*, m.p. 136–137 °C (on rapid heating). This product is almost unchanged when heated for 5 min at 200 °C; when heated for several hours at 200 °C it affords 1,3-dihydrooctamethylisobenzobenzofuran *(4)* by dehydration of the expected aromatic compound *(3)*. Only the less hindered double bond of compound *(2)* reacts on catalytic hydrogenation ($Pt/H_2$) in methanol or on treatment with ozone in methanol at −78 °C. On being boiled with *p*-toluenesulfonic acid in benzene, compound *(2)* is converted into heptamethylindene *(5)*.



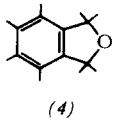
*(1)*



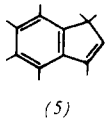
*(2)*



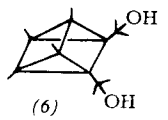
*(3)*



*(4)*



*(5)*

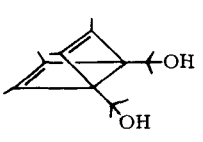


*(6)*

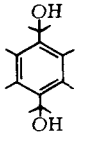
Irradiation (100 watt low-pressure mercury lamp; Messrs. Gräntzel, Karlsruhe) of a 1% solution of compound *(2)* in ether leads to at least three isomers: the aromatic compound *(3)* (20–25%; slightly soluble in ether), the prismane

derivative octamethyltetracyclo[2.2.0.0$^{2,6}$0$^{3,5}$]hexane-1,4-dimethanol *(6)* (22%), and octamethylbicyclo[2.2.0]hexa-2,5-diene-1,4-dimethanol *(7)* (6%).

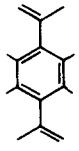
Compound *(6)* can be purified by recrystallization from ethyl acetate (m.p. ≈ 130 °C). It is extremely sensitive to acids, which reconvert it into *(2)* rapidly and exothermally even in the cold. However, when heated in pyridine at 100 °C it isomerizes predominantly to the diol *(7)* [isomeric with *(2)*], which is purified by recrystallization from ethyl acetate and itself isomerizes at 170 °C to the diol *(8)*. When *(7)* is boiled with *p*-toluenesulfonic acid in benzene, 1,4-diisopropenyl-2,3,5,6-tetramethylbenzene *(9)* is formed. Irradiation of *(7)*, under the conditions used for *(2)*, also leads to the prismane derivative *(6)*. The compound *(6)* is the second known example of this highly strained ring system, the first being 1,2,5-tri-t-butylprismane[2].



*(7)*



*(8)*



*(9)*

Appropriate elemental analyses have been obtained for compounds *(2)* to *(9)*; ultraviolet and infrared spectra agree with the structures assigned. The NMR data on which the structures are based are given in the table.

NMR spectra of compounds *(2)* to *(9)* in $CCl_4$ (tetramethylsilane as internal standard; τ values in ppm; d = doublet; q = quadruplet; m = multiplet; other signals are singlets).

## C-Azido-N-sulfonylformamidines and their Rearrangement to 5-(N-Sulfonylamino)tetrazoles

By Doz. Dr. R. Neidlein and E. Heukelbach

Pharmazeutisch-Chemisches Institut
der Universität Marburg (Germany)

We have obtained the (to our knowledge new) *C*-azido-*N*-sulfonylformamidines *(2)*[1] by addition of hydrazoic acid to *N*-sulfonylcarbodiimides *(1)*[2–4]. Equimolar amounts of

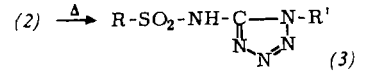
$$R\text{–}SO_2\text{–}N{=}C{=}N\text{–}R' \rightarrow R\text{–}SO_2\text{–}NH\text{–}C(N_3){=}N\text{–}R'$$
*(1)* *(2)*

the reactants are kept together for about 8 days in anhydrous benzene at room temperature with exclusion of moisture, and the solvent is then removed at not more than +5 °C. At higher temperatures there is a danger of the rearrangement *(2)* → *(3)*.

| | R | R' | M.p. (decomp.) [°C] | Yield [%] |
|---|---|---|---|---|
| *(2a)* | $C_6H_5$ | $(CH_3)_2CH$ | 69–71 | 69 |
| *(2b)* | $C_6H_5$ | $CH_3(CH_2)_3$ | 68–69 | 78 |
| *(2c)* | $C_6H_5$ | $CH_3(CH_2)_2$ | 70–71 | 75 |
| *(2d)* | $C_6H_5$ | $(CH_3)_2CH\text{–}CH_2$ | 65–66 | 79 |
| *(2e)* [*] | $C_6H_5$ | $C_6H_{11}$ | 110–111 | 54 |

[*] Compounds *(2f)* to *(2k)* (cf. the second table) were obtained only as oils. Distillation was not attempted because of the danger of explosion and rearrangement. The infrared spectra of the oils showed one intense azide band; the carbodiimide bands were absent.

*C*-Azido-*N*-sulfonylformamidines have infrared absorption bands between 2140 and 2160 $cm^{-1}$ characteristic of the $N_3$ group; bands due to the NH group occur between 3060 and 3200 and between 1590 and 1625 $cm^{-1}$.



*(3)*

When the formamidines *(2)* are heated in boiling anhydrous toluene for several hours they rearrange to substituted 5-(*N*-sulfonylamino)tetrazoles *(3)*. The structures of compounds *(3)* were proved by their infrared spectra. Thin-layer chromatography shows that they are single substances. The acidic hydrogen in compounds *(3)* can be titrated accurately with bases such as 0.1 N NaOH in ethanol.

| | R | R' | M.p. [°C] | Yield [%] |
|---|---|---|---|---|
| *(3a)* | $C_6H_5$ | $(CH_3)_2CH$ | 113–114 | 93 |
| *(3b)* | $C_6H_5$ | $CH_3(CH_2)_3$ | 96–97 | 90 |
| *(3c)* | $C_6H_5$ | $CH_3(CH_2)_2$ | 99–100 | 83 |
| *(3d)* | $C_6H_5$ | $(CH_3)_2CH\text{–}CH_2$ | 155–156 | 87 |
| *(3e)* | $C_6H_5$ | $C_6H_{11}$ | 197–198 | 88 |
| *(3f)* | $C_6H_5$ | $(CH_3)_3C$ | 165–166 | 64 |
| *(3g)* | $CH_3$ | $(CH_3)_2CH$ | 118–120 | 72 |
| *(3h)* | $CH_3$ | $CH_3(CH_2)_2$ | 72–73 | 68 |
| *(3i)* | $CH_3$ | $(CH_3)_2CH\text{–}CH_2$ | 74–76 | 60 |
| *(3k)* | $CH_3$ | $(CH_3)_3C$ | 132–133 | 75 |

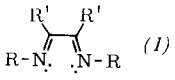
## 1,4-Diazabutadiene-Metal Carbonyls [1]

By Priv.-Doz. Dr. H. Bock and Dipl.-Chem. H. tom Dieck[2]

Institut für Anorganische Chemie
der Universität München (Germany)

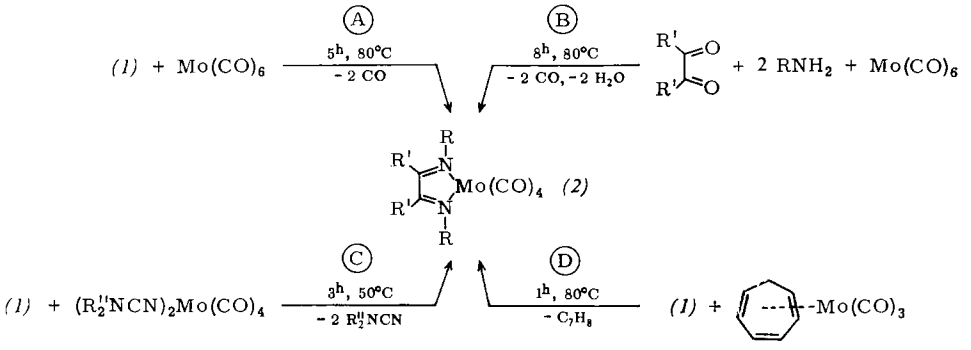
The n-orbitals of *cis-anti*-1,4-diaza-1,3-butadienes *(1)* are in positions that are geometrically favorable for formation of bidentate donor bonds. Since, moreover, the lowest unoccupied π*-level (symmetry $B_2$) of *(1)* has the symmetry

and energy required for π back-donation from metal d-functions, we expected [3] that these compounds would be suitable as metal(0) ligands.



*(1)*

Diazabutadienemolybdenum tetracarbonyls *(2)* are obtained as indicated in the scheme below, with benzene as solvent. The compounds have a metallic luster, are mostly stable to atmospheric oxygen, and give blue to orange-red solutions. The complexes are precipitated from the reaction solution either immediately or on concentration. They can be recrystallized from benzene when necessary.

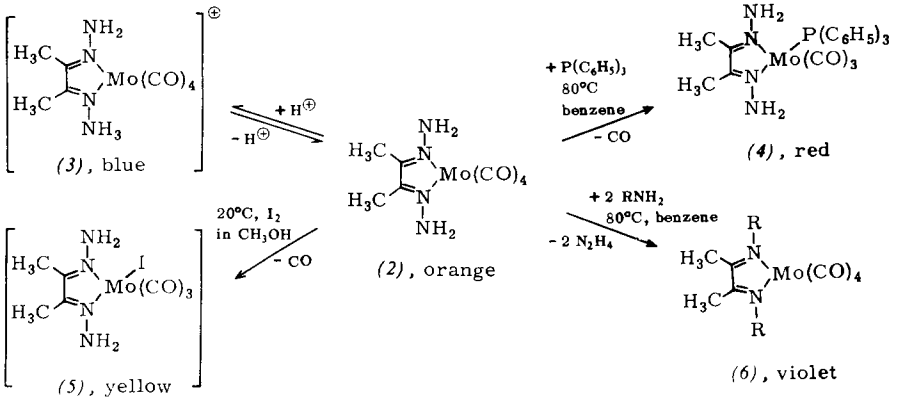


$R' = C_6H_5$; $R = OH$

$R' = CH_3$; $R = OH$, $OCH_3$, $NH_2$, $N(CH_3)_2$, Alkyl, Aryl

$R'' =$ Alkyl, Cyclopropyl, $C_6H_{11}$, Benzyl, $C_6H_5$, p-Cl-$C_6H_5$, etc.

Process A is generally applicable; process B, as a complex-induced synthesis, is the most elegant method for difficultly accessible ligands (*e.g.* R = alkyl [4]). Process C has proved advantageous for the preparation of thermally sensitive complexes *(2)* (*e.g.* R = OH or OH/$NH_2$) in a pure state.



*(3)*, blue

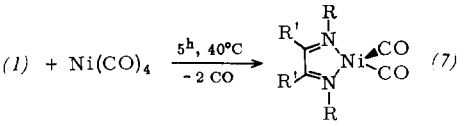
*(4)*, red

*(5)*, yellow

*(6)*, violet

All the complexes with R = $NH_2$ or $N(CH_3)_2$ are reversibly protonated by concentrated mineral acids, yielding *(3)*. The diazabutadiene ligand is not removed by triphenylphosphine, which, instead, replaces carbon monoxide, yielding the tricarbonyl derivative *(4)*. The complexes *(2)* are not oxidized by mercuric oxide or silver oxide; reaction with iodine in methanol gives presumably carbonyl iodides *(5)*. Remarkably, primary amines replace the hydrazone group by an imine group [see *(6)*].

Formation of diazabutadiene-metal carbonyls is not restricted to molybdenum. Analogous complexes are formed from chromium and tungsten hexacarbonyls by method A on additional ultraviolet irradiation. Nickel tetracarbonyl reacts with some ligands *(1)* even at room temperature, yielding diazabutadienenickel dicarbonyls *(7)* that are insensitive to air, have a metallic luster, and give wine-der solutions [5].



*(7)*

$C_{2v}$ symmetry and diamagnetism is demonstrated for the chromium, molybdenum, tungsten, and nickel compounds by their infrared and $^1$H-NMR spectra. An intense, long-wavelength absorption is characteristic of all the diazabutadiene-metal(0) complexes, largely independent of the nature of the central metal and the substituents R on the nitrogen; the maxima (in cyclohexane 18000–19000 $cm^{-1}$; in methanol 19000–21000 $cm^{-1}$) are more strongly influenced by solvatochromism ($\Delta\nu_m$ = 2000–3000 $cm^{-1}$) than by the substituents R on the nitrogen ($\Delta\nu_m$ = 1000–2000 $cm^{-1}$). The molar extinctions lie between 5000 and 12000 l $mole^{-1}$ $cm^{-1}$. These long-wavelength bands can be assigned to an allowed $A_2$–$B_2$ transition, which arises from an $A_2$ combination of metal d-orbitals into the lowest antibonding state of the system (interaction of the unoccupied ligand orbital $\Psi_3$ ($B_2$) with the $B_2$ combination of two d-orbitals).

## Germyl Compounds of Strontium, Barium, and Zinc

By Univ.-Doz. Dr. E. Amberger, Dipl.-Chem. W. Stoeger, and Dr. R. Hönigschmid-Grossich

Institut für Anorganische Chemie
der Universität München (Germany)

Whereas silyl, $M^{II}(SiR_3)_2$, and stannyl derivatives, $M^{II}(SnR_3)_2$, (R = $CH_3$, $C_6H_5$) of the elements of the second main group and sub-group have been extensively studied [1,2], analogous germyl compounds $M^{II}(GeR_3)_2$ have hitherto been unknown.

Hexaphenyldigermane reacts with strontium or barium in the molecular ratio 1:1 in liquid ammonia at −40°C, giving bis(triphenylgermyl)metal derivatives *(1)*.

$$(C_6H_5)_3Ge{-}Ge(C_6H_5)_3 + M^{II} \rightarrow M^{II}[Ge(C_6H_5)_3]_2$$
($M^{II}$ = Sr, Ba) *(1)*

After removal of the ammonia at −35 °C the products are extracted with tetrahydrofuran as yellow solutions, whence they are recovered by evaporation of the tetrahydrofuran and drying *in vacuo* (2 days at 40 °C) as THF adducts (1:1). They decompose with blackening without melting at 40 to 45 °C (Sr) and 60 to 70 °C (Ba). The adducts are sensitive to air and somewhat to light, reduce $AgNO_3$ to Ag, and are soluble in ammonia but insoluble in benzene and hydrocarbons; they are unstable in solution. Their compositions were proved by determination of the content of alkaline-earth metal and by C–H analysis. The THF-free compounds *(1)* could not be obtained.

Only small amounts of hydrogen are obtained on hydrolysis with moist methanol because of the stability of triphenylgermane against hydrolysis:

$$M^{II}[Ge(C_6H_5)_3]_2 + H_2O \xrightarrow{\text{Fast}} HGe(C_6H_5)_3 + M^{II}(OH)_2$$

$$(C_6H_5)_3GeH + H_2O \xrightarrow{\text{Slow}} (C_6H_5)_3GeOH + H_2$$

The triphenylgermane formed, and the tetrahydrofuran liberated from the THF adducts by heating *in vacuo*, were identified by infrared spectroscopy. Ammonolysis, as observed for the analogous silyl compounds [1], could not be established.

Preparation of bis(triphenylgermyl)zinc *(2)* was achieved by reaction of zinc chloride with triphenylgermyl-sodium or -potassium in liquid ammonia (molar ratio 1:2, −40 °C).

$$2\ M^{I}Ge(C_6H_5)_3 + ZnCl_2 \rightarrow Zn[Ge(C_6H_5)_3]_2 + 2\ M^{I}Cl$$
($M^{I}$ = K, Na) *(2)*

After removal of the ammonia *in vacuo* at −35 °C the product *(2)* was extracted into tetrahydrofuran (yellow solution). On evaporation of the solvent there remained a yellow adduct *(2)*·THF [reaction with $KGe(C_6H_5)_3$] or a pale yellow adduct $Zn[Ge(C_6H_5)_3]_2 \cdot 0.5THF \cdot 0.5NH_3$ [reaction with $NaGe(C_6H_5)_3$]. Both these adducts decomposed at 110 to 120 °C, resembled *(1)*·THF in properties, and were analogously identified.

## Correlation between Phosphorylation and Chlorophyll-b Dissociation in Photosynthesis

By Dr. B. Rumberg, Dipl.-Phys. P. Schmidt-Mende, Dipl.-Ing. U. Siggel, and Prof. Dr. H. T. Witt

Max-Volmer-Institut für Physikalische Chemie,
Technische Universität Berlin (Germany)

In the primary processes of photosynthesis, electrons are transferred from water to triphosphopyridine nucleotide. The rate of the electron transport is characterized by the rate of the oxygen production which takes place simultaneously; the intermediates can be identified by the wavelength of absorption changes on irradiation with flashes of light. The mechanism of the electron transport follows *inter alia* from the analysis of the kinetics of absorption changes [1]. A cyclic and a non-cyclic phosphorylation can be coupled with the electron transport [2].

The absorption changes at 478, 515, and 648 mμ are caused by a reaction of chlorophyll-b (Chl-b). This reaction, however, evidently does not participate directly in the electron transport [3]. Addition of ethanol eliminates the absorption changes of Chl-b without affecting those of Chl-$a_I$, Cyt-f, Cyt-b, and plastoquinone (PQ), or the oxygen production. We have now found that the reaction of Chl-b is related directly to phosphorylation coupled to electron transport: The electron transport is not affected when the phosphorylation is blocked by a specific poison, such as desaspidine [2,4]. Confirmation of these results is shown in Fig. 1.

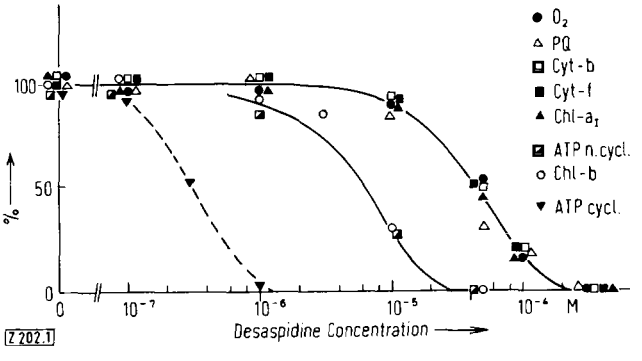

Fig. 1. Oxygen production, non-cyclic phosphorylation, cyclic phosphorylation, and absorption changes of plastoquinone (PQ) (at 254 mμ), cytochrome-b (Cyt-b) (at 405 mμ), cytochrome-f (Cyt-f) (at 405 mμ), chlorophyll-$a_I$ (Chl-$a_I$) (at 703 mμ), and chlorophyll-b (Chl-b) (at 515 mμ), as a function of the desaspidine concentration in illuminated spinach chloroplasts.

The 100% rates correspond to 38 μmole $O_2$/(h·mg Chl) for the $O_2$-production, to 116 μmole ATP/(h·mg Chl) for the non-cyclic, and to 240 μmole ATP/(h·mg Chl) for the cyclic phosphorylation. All measurements were performed 10 min after addition of desaspidine. Excitation time 5 min for $O_2$-production, 0.02 sec for absorption change; light intensity $3 \times 10^5$ ergs $cm^{-2}$ $sec^{-1}$. Temperature 20 °

Reaction volume 3 ml; chlorophyll content 0.1 mg. Additives (in μmole) for $O_2$-production: tris buffer 150 (≈ pH 7.2), $K_3Fe(CN)_6$ 10; for non-cyclic phosphorylation: tris buffer 80 (= pH 8), $MgCl_2$ 10, $K_2HPO_4$ 20, ADP 10, benzylviologen 0.1; for cyclic phosphorylation (anaerobic): tris buffer 80 (= pH 8), $MgCl_2$ 10, $K_2HPO_4$ 20, ADP 10, *N*-methylphenazonium methyl sulfate 0.1, *N*-(*p*-chlorophenyl)-*N'*,*N'*-dimethylurea 0.06; for absorption changes: as for $O_2$-production or non-cyclic phosphorylation. Oxygen determined manometrically, ATP with $^{32}P$ according to [6]. Separation of the absorption changes of cytochromes according to [7].

At desaspidine concentrations of $10^{-7}$ M the cyclic and the non-cyclic phosphorylation (measured by the formation of ATP) and the electron transport (measured by $O_2$-production) are unchanged. With $10^{-6}$ M desaspidine, cyclic phosphorylation is blocked, and only at $2\times10^{-5}$ M non-cyclic phosphorylation as well. The $O_2$-production, *i.e.* the electron transport, is not blocked at desaspidine concentrations below $2\times10^{-4}$ M. The absorption changes of the participants of electron transport such as Chl-aI, Cyt-f, Cyt-b, and PQ show the same dependence on the concentration of desaspidine as the $O_2$-production. However, the reaction of Chl-b parallels the behavior of the non-cyclic phosphorylation (Fig. 1). Addition of ethanol also blocks phosphorylation without interrupting the electron transport[5].

From the position of the absorption changes of chlorophyll-b it can be supposed that a dissociation of $H^+$-ions[8] from chlorophyll-b takes place. Obviously phosphorylation and this dissociation (pH-change) are related to each other.

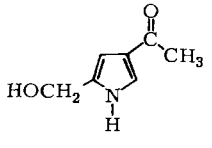
# CONFERENCE REPORTS

## Recent Results of Antibiotics Research

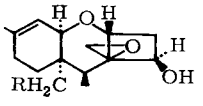
*Ch. Tamm*, Basel (Switzerland)

To date, 14 antibiotics termed verrucarines and roridines[1] have been isolated from *Myrothecium verrucaria* and *M. roridum*. The principal products are antifungal and, in particular, potent cytostatic agents; however, they are also very toxic

Verrucarine E, one of the minor N-containing metabolites, has been assigned the structure of the hitherto unknown 4-acetyl-2-hydroxymethylpyrrole *(1)*. On basic hydrolysis, verrucarines A, B, J, and H, and roridines A, D, and E, yield the same sesquiterpene alcohol, verrucarol ($C_{15}H_{22}O_4$), but they differ in the products of acidic hydrolysis. Verrucarine A ($C_{27}H_{34}O_9$) gives *cis,trans*-muconic acid and verrucarinolactone ($C_6H_{10}O_3$), verrucarine B ($C_{27}H_{32}O_9$) gives *cis,trans*-muconic acid and 2,3-epoxy-3-methyl-5-valerolactone ($C_6H_8O_2$); verrucarine J ($C_{27}H_{32}O_8$) gives *cis,trans*-muconic acid and the known 3-methyl-2-pentenolactone (anhydromevalolactone) ($C_6H_8O$); roridine A ($C_{29}H_{40}O_9$) gives roridinic acid ($C_{14}H_{22}O_7$), roridine D ($C_{29}H_{38}O_8$) gives anhydroepoxyroridinic acid ($C_{14}H_{20}O_7$); roridine E ($C_{29}H_{38}O_8$) gives anhydrororidinic acid ($C_{14}H_{20}O_6$); and verrucarine H ($C_{29}H_{36}O_8$) gives 3-methyl-2-pentenolactone and myrothecinic acid ($C_8H_{10}O_8$). The structures and stereochemistry of the new lactones and dicarboxylic acids have been elucidated. The constitutions of verrucarol *(2)* and roridine C (= trichodermol) *(3)* were derived by correlation with trichothecolone and trichodermine[2].



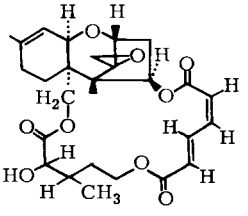
*(1)*



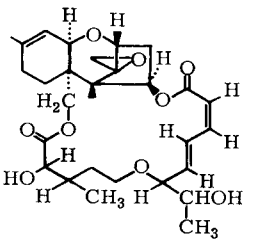
*(2)* R = OH; *(3)* R = H

Numerous rearrangements were observed with verrucarol and trichothecolone, some of which were discussed in detail. Oxidative degradations and partial hydrolyses showed that the above hydrolysis products are linked in the original antibiotics in the form of macrocyclic di- and tri-esters[3]. For instance, formulae *(4)* and *(5)* were derived for the two principal metabolites verrucarine A and roridine A, respectively. These many-membered cyclic esters present a new structural type.

Experiments on the biosynthesis of verrucarine A and roridine A with [2-$^{14}$C]mevalonate show that mevalonate is a biogenetic precursor of verrucarol and verrucarinic acid;



*(4)*



*(5)*

degradation experiments showed that the radioactivity of the verrucarinic acid was derived from C-2 of mevalonate.

## Synthesis and Decomposition of Organic Peroxides

*A. Rieche*, Berlin (Germany)

According to the "RH scheme"[1] of oxygen attack on organic compounds, the first products to be isolated are alkyl hydroperoxides, in accordance with reaction (a). The radicals initiating the chain reaction are formed, according to *Dulog*, by dehydrogenation [reaction (b)]. The hydroperoxides act autocatalytically by partial decomposition into radicals [reactions (c) and (d)].

$$RH + O_2 \rightarrow ROOH \quad (a)$$

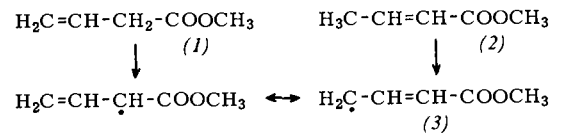
$$RH + O_2 \rightarrow R\cdot + \cdot OOH \quad (b)$$

$$ROOH \rightarrow RO\cdot + \cdot OH \quad (c)$$

$$2\,ROOH \rightarrow RO\cdot + ROO\cdot + H_2O \quad (d)$$

Decomposition of hydroperoxides and peroxidation are reactions of the same order: at very low concentrations they are usually of the first order, at higher concentrations of the second order (owing to dimerization). In ethers, hydroperoxides decompose at all concentrations by a reaction of the first order; here adducts ROOH·R′OR″ are present.

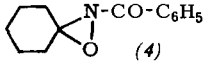
On peroxidation of unsaturated compounds, several isomeric alkyl hydroperoxides may arise, according to the number of double bonds. The cause of this is the mesomerism of allyl radicals formed by reaction (b), *e.g.* from methyl 3-butenoate *(1)* and crotonate *(2)*.



Although the butenoate *(1)* is more easily oxidized, the hydroperoxide derived from *(3)* is the main product obtained from the two esters. The formation of isomeric alkyl hydroperoxides makes it difficult to study the aerial oxidation of natural unsaturated oils and rubbers, so experiments to this end have been carried out with unsaturated model substances [2]. We were able to synthesize allyl hydroperoxide [3]; it proved to be surprisingly stable.

Ozonolysis of olefins in the presence of amines afforded geminal hydroperoxyamines $RHN-\overset{|}{\underset{|}{C}}-OOH$ (by way of the zwitterion $\rangle C^{+}-OO^{-}$), which are also obtained from Schiff bases and $H_2O_2$; they are precursors of 2-alkyloxaziridines. On treatment with ammonia and ozone, olefins give isooximes (3-substituted oxaziridines) ("ammozonization").

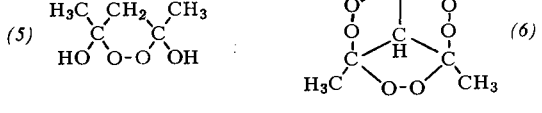
Cyclohexanone isooxime was isolated as its *N*-benzoyl derivative *(4)*, which is also formed on ozonization of bi-(cyclohexylidene) in the presence of benzamide.



*(4)*

Peroxidation of nitrogen compounds occurs at the carbon atom next to the nitrogen atom. Tetrahydroisoquinoline and azepine give peroxides ROOR directly, by way of hydroperoxides ROOH. Hydrazones and hexanolactam give hydroperoxides; pyrrolidone gives $H_2O_2$ and succinimide.

Cyclic peroxides such as *(5)* and *(6)* are obtained from β-diketones and "triacetylmethane" by means of $H_2O_2$. Like acetals, compounds of type *(5)* readily undergo exchange of OH groups for OOH or OOR by way of cations stablized by mesomerism. The symmetrical peroxide *(6)* has a high melting point and is chemically unusually stable, although explosive.



Preparative use of peroxides has received new impulses by the discovery of "fragmentable" peroxides. Polar cleavage and synchronous electron shifts lead, by reaction (e), to only a few fragments, whereas radical decomposition of peroxides yields a large number of products.

This method leads, for instance, to quantitative cleavage of 2,3,4,6-acetylated t-butyl glucosyl peroxide into arabinose, formic acid, and t-butyl alcohol (a new method of sugar degradation).

The so-called halogen-induced oxidation, hitherto incorrectly interpreted, has been clarified. β-Bromo hydroperoxides are obtained from olefins, HBr, and oxygen [4].

## Modern Methods for Electrical Indication of Titrations

*G. Kraft*, Frankfurt/Main (Germany)

Of the modern procedures for electrical determination of endpoint those involving noble-metal electrodes polarized by a few μA of direct current were discussed. These electrodes differ from the potentiometric ones (which respond to chemical events occurring during the titration without drawing current) in that their potential is determined only by their state of polarization, although this in thurn is a fuction of chemical events during the titration. Against this loss in specificity is to be set the advantage that polarized indicator electrodes are universally applicable – for redox titrations as well as for argentometric, complexometric, and even acidimetric titrations.

Platinum foil electrodes 10 to 100 $mm^2$ in size and polarized with currents between about 0.3 and 3 μA or potentials up to several hundred mV have proved valuable. Au, Ag, and Au-amalgam electrodes can also be used successfully. If polarization is effected with a constant current, the indication is described as voltametric, if with constant polarization potential as amperometric (or as dead-stop technique if only small polarization potentials are applied).

Details were discussed for the less well-known voltametry. The following two forms of indication technique are differentiated: A) Both electrodes are polarized and function simultaneously for potential measurement. B) Only one of the two polarized electrodes is a measuring electrode; it operates in conjunction with an additional, unpolarized electrode, such as a calomel electrode, also placed in the solution to be analysed.

For electrochemically reversible titration reactions the technique A gives a titration curve (potential/volume curve) characterized by a sharp peak; for irreversible systems it gives a steeply rising curve that somewhat resembles a potentiometric curve in appearance. The maximum or point of inflection corresponds to the equivalence point.

Independently of the reversibility of the chemical process, technique B leads to a steeply rising potential-volume curve; the point of inflection does not correspond exactly to the equivalence point. The deviation may be positive or negative according to whether the indication process occurs at the anode or the cathode, and increases with increasing dilution of the solution being analysed. This technique is thus useful for studying electrode reactions rather than for determination of endpoints.

Independently of which technique is used, voltametric indication involves a connection between polarization current density at the electrodes and concentration of the solution being analysed. Conditions are optimum at a polarization current density of about 0.05–0.1 $\mu A/mm^2$ in titration with 0.1 N solutions, or about 0.02–0.05 $\mu A/mm^2$ or 0.005 to 0.02 $\mu A/mm^2$ for titration with 0.01 N or 0.001 N solutions, respectively.

Voltametric indication (technique A) is usually superior to potentiometric indication, giving readily interpretable curves for titration of Ce(IV) or V(V) with Fe(II) even in 0.0001 N solutions. Complexometric titration of *e.g.* Cu, Pb, Zn, or Ca, which cannot be followed directly by the potentiometric method, can be carried out so precisely that the resulting accuracy of analysis exceeds that of the usual color-indicator methods.

## Rearrangements of α-Substituted Aldehydes

*A. Kirrmann*, Paris (France)

Attack of nucleophilic reagents on α-halogenated aldehydes takes place primarily at the carbonyl group. With the nucleophilic reagents $OH^-$, $OR^-$, $NH_2^-$, or $CN^-$, it can lead to the products of Favorski rearrangements or to stable epoxides, *e.g.* with alkoxides or, particularly, cyanides. The substituted aldehydes (substituent: SH, SR, SAr, or $NR_2$) that are first formed are often not very stable and rearrange to ketones, sometimes spontaneously, *e.g.* $RCH(NR_2)CHO \rightarrow R{-}CO{-}CH_2{-}NR_2$, or on acid (substituent: OH, OR, SR) or basic catalysis (substituent: OH, OAc), or on reaction with amines by way of enediamines in accordance with reaction (a):

$$C_6H_5{-}CH(NR_2){-}CHO \rightarrow C_6H_5{-}C(NR_2){=}CH{-}NR_2 \rightarrow C_6H_5{-}CO{-}CH_2{-}NH_2 \quad (a)$$

Correspondingly substituted epoxides are often very unstable and rearrange thermally to aldehydes (substituent: OAc, Cl), or catalytically[*] to ketones (substituent: OR, Cl) [see reaction (b)]. The catalytic rearrangement proceeds by way of enols.

$$R{-}CO{-}CH_2Cl \xleftarrow{\text{Catalysis}} R{-}CH\text{—}CH{-}Cl \xrightarrow{\Delta} R{-}CHCl{-}CHO \quad (b)$$

(O bridges the CH–CH)

The reaction with alkalis and amines is bimolecular only for branched chloro aldehydes. An intermediate formed from two molecules of aldehyde must be assumed in the case of unbranched α-halogeno aldehydes.

Use of epoxy nitriles permits the synthesis of *e.g.* α-fluoro aldehydes that are difficultly accessible by other routes [see reaction (c)].

$$R{-}CH\text{—}CH{-}CN + HF \rightarrow R{-}CHF{-}CH(OH){-}CN \rightarrow R{-}CHF{-}CHO \quad (c)$$

(O bridges the CH–CH)

## Heterogeneous Catalysis with Elemental Boron and with Nickel Borides

*H. J. Becher*, Münster (Germany)

In continuation of previous experiments[1], comparative measurements, at various streaming velocities, were made of catalytic dehydration of 2-propanol vapor on elemental boron (prepared by various methods[*]) and on technical $Al_2O_3$ catalysts. The most active catalyst was finely divided boron in the α-modification, with a surface area of 15 to 30 $m^2/g$; this was superior to the most active $Al_2O_3$ catalyst by a factor of two in respect of amount of catalyst and by a factor of 50 in respect of surface area.

Determination of the oxygen content and of the protons that are exchangeable with $D_2O$ indicates that an average of one OH group per boron atom is present in the surface of finely divided α-boron. On dehydration of $CD_3CH(OD)CD_3$ and $CH_3CD(OH)CH_3$ on α-boron hardly any of the hydrogen attached to secondary carbon is removed or exchanged, in contrast to the deuterium and hydrogen of $CD_3$ and $CH_3$ groups. Exchange experiments between $CH_3CH{=}CH_2$ and $D_2O$ at 300 °C also showed that the H atoms of $CH_2$ and $CH_3$ groups are exchanged preferentially in presence of the α-boron catalyst; in absence of α-boron there is no exchange under similar conditions. These observations accord with the representation for catalytic dehydration on metal oxides put forward by *Eucken* and *Wicke*[2]; according to this model, finely divided boron is a weakly acidic, oxidic dehydration catalyst by virtue of the BOH groups on the surface; the high activity of the BOH groups is to be emphasized. It seems to be intensified by the peculiar arrangement of boron atoms in the α-boron lattice[**] since boric acid itself does not dehydrate 2-propanol under these conditions but on the contrary converts it into an ester.

Nickel borides, $Ni_3B$, $Ni_2B$, and NiB, have a dehydrogenating action on alcohols. Their activities in heterogeneous gas catalysis are less than that of finely divided nickel (nickel carbonyl), but nickel boride electrodes have more favorable properties than nickel electrodes[3] for anodic oxidation of hydrogen and methanol in a fuel cell. Reaction of nickel borides with aluminum at 675 °C leads to nickel-aluminum phases and to nickel borides very rich in boron, one such ($NiB_{12}$) having been characterized. These alloys can be converted by NaOH solution into a mixture of Raney nickel and $NiB_{12}$, and electrodes prepared therefrom are superior to electrodes made from $NiB_{12}$-free Raney nickel for anodic oxidation of methanol in fuel cells.

[Lecture at Marl (Germany), March 9th, 1966]

[VB 989/291 IE]

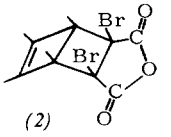
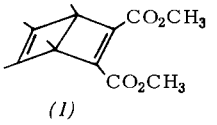
**Dimethyl 1,4,5,6 - tetramethylbicyclo[2.2.0]hexa - 2,5-diene-2,3-dicarboxylate** *(1)*, a derivative of "Dewar phthalic acid", was prepared by *R. Criegee* and *F. Zanker*. Reaction of 3,4-diiodotetramethylcyclobut-1-ene with dibromomaleic anhydride in the presence of mercury gives in 67% yield the anhydride *(2)*, which readily gives the dibromodimethyl ester *via* the dibromomonomethyl ester. Dehalogenation is achieved



*(2)*

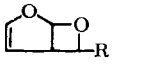


*(1)*

in 92% yield with copper-plated zinc in boiling ether. Compound *(1)*, m.p. 32–33 °C, shows no absorptions characteristic of aromatic systems. The bicyclohexadiene system in *(1)* is surprisingly stable. At 130 °C, dimethyl tetramethylphthalate is formed exothermically and quantitatively. / Chem. Ber. *98*, 3838 (1965) / –Ma. [Rd 453/662 IE]

**The bond lengths in non-aromatic hydrocarbons** depend only on the hybridization states of the C atoms involved and on the corresponding differences in electronegativity. They are not influenced by conjugation and hyperconjugation effects. As experimental evidence in support of this theory, *B. M. Mikhailov* showed that there is a linear relationship between the decrease in bond length ($\Delta d$) and the s-character of the C orbitals in ethylene, allene, and butatriene (length of the central C=C bond). Similarly, the lengths of the C≡C bonds in *e.g.* acetylene, propyne, 2-butynenitrile, and hexa-2,4-diyne are equal within the limits of experimental error. This theory also applies satisfactorily to O–H bond lengths, but the differences in electronegativity are more important in this case than in C–C bonds. It should be noted that, contrary to *Pauling*'s views, an increase in the electronegativity difference (and hence an increase in the ionic character) of a C–H bond should lead to a C–H bond longer than that expected from the sum of the covalent radii. However, this effect is outweighed by the decrease in the covalent radius of the carbon atom with increasing ionic character. / Tetrahedron *21*, 1277 (1965) / –Bu. [Rd 438/647 IE]

**Substituted dioxabicyclohexenes** *(1)* have been obtained by *S. Tobi*, *K. Shima*, and *H. Sakurai* in a photochemical reaction between aldehydes and furan. For example, exposure of furan and benzaldehyde to a 350 W high-pressure mercury vapor lamp for 6 h leads to the formation of 6-phenyl-2,7-dioxabicyclo[3.2.0]hept-3-ene *(1a)* (m.p. 49 to 50 °C) in 80% yield (based on the quantity of aldehyde consumed).



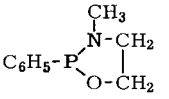
*(1a)* R = $C_6H_5$

*(1)*

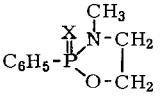
The structure of the product is confirmed by the infrared and NMR spectra. / Bull. chem. Soc. Japan *38*, 760 (1965) / –Bu. [Rd 439/648 IE]

**The partial fluorination of methane by an electrochemical method** is reported by *S. Nagase*, *K. Tanaka*, and *H. Baba*. These authors used a polyethylene gas inlet tube with a Teflon attachment, which produced very fine gas bubbles directly below the electrode. The electrolyte used was NaF in liquid hydrogen fluoride. As an example, a current density of 2.2 A/dm² (current yield 45 %) gave 45 % conversion, and the product consisted of 13 % $CF_4$, 26 % $CHF_3$, 15 % $CH_2F_2$, and 46 % $CH_3F$. Compounds such as $C_2F_6$ or $C_3F_8$, which are formed during the fluorination of $CH_4$ in the gas phase, could not be detected. / Bull. chem. Soc. Japan *38*, 834 (1965) / –Bu. [Rd 440/649 IE]

**A new method for the preparation of isocyanides** has been described by *T. Mukaiyama* and *Y. Yokota*. Isocyanates or isothiocyanates are allowed to react with 3-methyl-2-phenyl-1,3,2-oxazaphospholidine *(1)* under reflux in petroleum ether or ligroin.



*(1)*



*(2)*

For example, phenyl isothiocyanate reacts with *(1)* at 34 to 36 °C with loss of sulfur and formation of phenyl isocyanide (yield 93 %) and *(2)*, X = S. *(1)* is prepared from $C_6H_5PCl_2$ and *N*-methylaminoethanol in the presence of 2 moles of triethylamine (yield 41 %) or from phenylbisdiethylaminophosphine and *N*-methylaminoethanol at 120 °C (yield 83 %). / Bull. chem. Soc. Japan *38*, 858 (1956) / –Bu. [Rd 441/650 IE]

**Complex methylchromium compounds** have been prepared be *E. Kurras* and *J. Otto* in diethyl ether at –180 °C by thy reaction

$$CrCl_3 + 6\ LiCH_3 \rightarrow Li_3Cr(CH_3)_6\bullet + 3\ LiCl$$

$$\xrightarrow{C_4H_8O_2} Li_3Cr(CH_3)_6 \cdot 3\ C_4H_8O_2$$

*(1)*

The dioxane adduct *(1)* is formed in about 45 % yield as blood-red, rod-shaped crystals. Excess methyl-lithium and lithium chloride are precipitated as sparingly soluble adducts with dioxane. *(1)* is soluble in diethyl ether and dioxane, but insoluble in hexane; decomposition occurs in benzene at room temperature. The complex is extremely sensitive to oxidation and hydrolysis, and burns in air. Cryoscopic studies show that it is present in dioxane as the monomer. The magnetic moment of $\mu_{eff}$ = 3.75 B.M. indicates a spin-free complex with a $d^3$ configuration.

If the reaction mixture is heated to boiling, fractional precipitation with dioxane yields a finely crystalline yellow precipitate, which recrystallizes from tetrahydrofuran as the dimeric dilithium tetramethyl chromate(II)-tetrahydrofuran adduct *(2)*. Water and other protonic solvents hydrolyse this complex instantaneously.:

$$[Li_2Cr(CH_3)_4(THF)_2]_2 + 8\ H^+$$

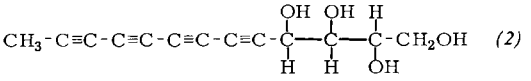
*(2)*

$$\rightarrow 4\ Li^+ + 2\ Cr^{2+} + 8\ CH_4 + 4\ THF$$

Molecular weight determinations in benzene showed that *(2)* is present as the dimer; the compound gives no ESR signals. / J. organomet. Chemistry *4*, 114 (1965) / –Sch. [Rd 430/639 IE]

**A naturally occurring tetrayne and tetrayne-tetraol** have been found for the first time by *E. R. H. Jones*, *G. Lowe*, and *P. V. R. Shannon* in ether extracts of fermented solutions of *Fistulina hepatica* (Huds.) The compounds are trideca-2,4,6,8-tetrayne *(1)*, translucent needles of m.p. 25–26 °C, and 2D; 3L;4L-trideca-5,7,9,11-tetrayne-1,2,3,4-tetraol *(2)*, silvery plates of m.p. 155 °C (decomp.), $[\alpha]_D^{24} = +1.8°$.

$$CH_3\text{-}C{\equiv}C\text{-}C{\equiv}C\text{-}C{\equiv}C\text{-}C{\equiv}C\text{-}(CH_2)_3\text{-}CH_3 \quad (1)$$



*(2)*

**Hexahalogenotitanates(III)** were prepared by *B. T. Russ* and *G. W. A. Fowles*. They obtained the orange-red tripyridinium salt $(C_5H_6N)_3[TiCl_6]$ from $TiCl_3$ and an excess of anhydrous pyridinium chloride. The latter was removed by extraction with chloroform at room temperature. The same product is obtained from pyridinium chloride and $(CH_3CN)_3TiCl_3$ in $CHCl_3/CH_3CN$. Tetraethylammonium chloride or bromide and $(CH_3CN)_3TiCl_3$ give $[(C_2H_5)_4N][TiCl_4(CH_3CN)_2]$ or the tribromochloro salt, respectively. The tetrabromo salt is obtained from $(CH_3CN)_3TiBr_3$ and $[(C_2H_5)_4N]Br$. Reaction of $(C_2H_5N)_3TiBr_3$ with anhydrous liquid HCl gives $(C_5H_6N)_3[TiCl_4Br_2]$. – Tripyridinium hexachlorotitanate(III) is orthorhombic with lattice parameters a = 16.0, b = 16.8, c = 20.8 Å. The compound is oxidized even by nitrobenzene. It gives a green solution in acetonitrile, from which it is recovered unchanged on evaporation of the solvent. Its diffuse reflection spectrum is almost identical to that of $[(C_2H_5)_4N][TiCl_4(CH_3CN_2)]$.

Evidently a reversible dissociation occurs:

$$(C_6H_5N)_3[TiCl_6] + 2\ CH_3CN \rightleftharpoons (C_6H_5N)\ [TiCl_4(CH_3CN)_2] + 2\ C_5H_6NCl$$

Chem. Commun. *1966*, 20 / –Kr. [Rd 458/667 IE]

**The primary process in the thiamine pyrophosphate catalysis of the decarboxylation of pyruvate is not enzyme-catalysed.** According to *J. Ullrich* and *A. Mannschreck*, the ionization at C-2 of the thiazole ring, which must precede the addition of the carbonyl group, has a half-life of 3 min at pH 5 and 38 °C. The half-life is shorter at higher pH. At pH 5, no catalysis by pyruvate decarboxylase from yeast could be detected by measurement of the H–D exchange, although the enzyme is capable of functioning at this pH (pH-optimum *ca.* pH 6). For the kinetic studies the change in intensity of the $^1H$–NMR signal at $\tau = 0.32$ of the thiazole proton (relative to the practically constant signal at $\tau = 2.06$ of the pyrimidine proton in $D_2O$) was measured. / Biochim. biophysica Acta *115*, 46 (1966) / –Hö. [Rd 460/669 IE]

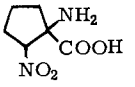
**The redox properties of ferredoxin** from *Clostridium pasteurianum* were studied by *E. Sobel* and *W. Lovenberg*. Contrary to previous views, two electrons are required for the reduction of oxidized ferredoxin. One mole of NADPH is required per mole of ferredoxin in the ferredoxin reductase-catalysed reduction of the latter. Conversely one mole of ferredoxin (after reduction with light and chloroplasts) reduces one mole of NADP. In the reaction with hydrogenase, one mole of $H_2$ per mole of oxidized ferredoxin is taken up. During the reduction two $Fe^{3+}$ ions are converted into $Fe^{2+}$. Neither in the reduced nor in the oxidized state do free thiol groups appear. The redox potential between pH 6 (–360 mV) and pH 9 (–496 mV) is a linear function of pH. / Biochemistry *5*, 6 (1966) / –Hö. [Rd 461/670 IE]

**Alkyl-substituted indenes** were synthesized independently in good yields from 1,1-dihalocyclopropanes by *J. Buddrus* and *F. Nerdel* and by *L. Skatteböl* and *B. Boulette*. The starting materials, easily accessible from olefins and trihalomethane, are treated with aromatic hydrocarbons under conditions of the Friedel-Crafts reaction. Examples: 1,1-dibromotetramethylcyclopropane *(1)* and benzene give 1,1,2,3-tetramethylindene (80% yield); *(1)* and toluene give a mixture of 1,1,2,3,5-pentamethylindene and 1,1,2,3,6-pentamethylindene (overall yield 81%). / Tetrahedron Letters *1965*, 3197; J. org. Chemistry *31*, 81 (1966) / –Bu. [Rd 463/672 IE]

**Solutions of toluenesulfonyl perchlorate** were prepared from *p*-toluenesulfonyl bromide and silver perchlorate by *F. Klages* and *F. Malecki*. The substance is preferably prepared, stored, and handled in nitromethane, in which it is stable up to –25 °C. Conductivity measurements in liquid $SO_2$ showed that *p*-sulfonyl perchlorate is ionized to a large extent. It has an extraordinary sulfonylating capacity, which makes accessible for the first time *N,N,N*-trialkylsulfonamidium salts from tertiary amines. These salts, *e.g.*

$[(C_2H_5)_3N{-}SO_2C_6H_4{-}CH_3]^+ClO_4^-$, can only be detected in solution. / Liebigs Ann. chem. *691*, 15 (1966) / –Bu. [Rd 464/673 IE]

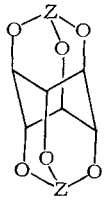
**1-Amino-2-nitrocyclopentanecarboxylic acid, a naturally occurring nitro compound,** has been isolated from culture filtrates of *Aspergillus wentii*. *B. F. Burrows* and *W. B. Turner* have elucidated the structure of the acid *(1)* (needles, decomp. above 150 °C) by degradation and by spectroscopy, and have synthesized it *via* 1-iodo-2-nitrocyclopentanecarboxylic acid.



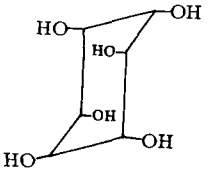
*(1)*

Only few nitro compounds are known in nature. Compound *(1)* has unusual growth-regulating and inhibiting properties and acts as L-leucine antagonist. / J. chem. Soc. (London) org. *C 1966*, 255 / –De. [Rd 457/666 IE]

**Hexaoxadiamantane** *(1)* **and hexaoxadiphosphadiamantane** *(2)*, heteroanalogues of diamantane (congressane), were synthesized by *O. Vogl* and *B. C. Anderson*. Compounds *(1)*, m.p. 303–305 °C, is obtained in 15% yield by heating scyllite



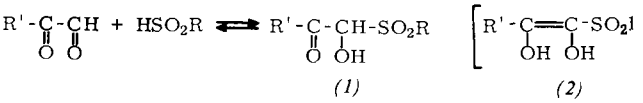
*(1)*, Z = CH
*(2)*, Z = P



*(3)*

*(3)* with an excess of triethyl orthoformate in dimethyl sulfoxide at 200 °C. Analogously *(2)*, m.p. 276–280 °C, is obtained from scyllite and trimethyl phosphite. / Tetrahedron Letters *1966*, 415 / –Ma. [Rd 448/657 IE]

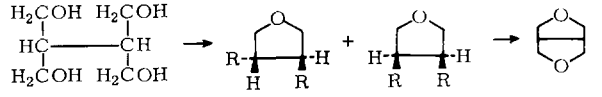
**α-Hydroxy-β-oxosulfones** *(1)* have been synthesized in good yields by *K. Schank* by the reaction of aliphatic or aromatic glyoxals with aliphatic or aromatic sulfinic acids. The colorless, crystalline compounds *(1)* tend to dissociate into the



*(1)* *(2)*

components on being heated or in solution, particularly in basic solvents. The free ene-diol form *(2)* probably does not exist. Examples: $R = R' = C_6H_5$, m.p. 104 °C, yield 82%; $R = p\text{-}CH_3{-}C_6H_4$, $R' = C(CH_3)_3$, m.p. 91–93 °C, yield 68%. Chem. Ber. *99*, 48 (1966) / –Ma. [Rd 449/658 IE]

**3,7-Dioxabicyclo[3.3.0]octane** *(1)*, of which pinoresinol, sesamin, and syringaresinol are naturally occurring derivatives, has been synthesized by *K. Weinges* and *R. Spänig*. Dehydration of the tetraol *(2)* gives *(1)*, b.p. 173 °C, yield 42%, probably *via* equimolar amounts of *cis*- and *trans*-3,4-bis(hydroxymethyl)tetrahydrofuran *(3a, 3b)*. Only *(3a)* can lead to *(1)*. / Chem. Commun. *1966*, 9 / –Ma.



*(2)* *trans (3b)* *cis (3a)* *(1)*

[Rd 450/659 IE]

**Houben-Weyl: Methoden der organischen Chemie** (Houben-Weyl: Methods of Organic Chemistry). Vol. 10, Part 3 "Stickstoffverbindungen I/3" ("Nitrogen Compounds I/3"). Georg Thieme Verlag, Stuttgart 1965. 4th Edit., edited by *Eugen Müller*. XLiii + 971 pp., 69 tables, subscription price before publication of the last volume DM 229.50 (about $57.–). Single volumes DM 255.– about $63.–).

The new edition of Houben-Weyl, having treated amines and quaternary ammonium compounds in volume 11/1–3, allots three volumes to the remaining nitrogen compounds, the third of these now being the first to appear. In this the well-tried method of presentation is used for the preparation and reactions of compounds containing multiply bonded nitrogen attached to at least one aromatic residue. The individual sections, except for the two chapters on azides and nitrile oxides (see below), are written by industrial chemists (Farbenfabriken Bayer) whose experience guarantees reliable reporting. It should, however, be emphasized that general scientific importance attaches to the azo compounds treated, as is particularly clear in the content and style of chapters 1, 4, and 5. In all sections the literature of the past 80 (!) years (modern authors please note) is carefully evaluated and it is good to see that this continues up to 1964.

1. Aromatic Diazonium Salts (200 pp., 35 tables, *R. Pütter*). This chapter conveys a lively impression of the numerous reactions available for the preparation of diazonium salts and of the influence of conditions and substituents. It includes heterocyclic diazonium salts. Direct introduction of the diazonium group, oxidation of arylhydrazines, and use of amine derivatives are described as well as methods of diazotization. Reactions involving loss of nitrogen are also described extensively. The article is enriched by inclusion of the most important theoretical results and of numerous tables.

2. Diaryl Azo Compounds (244 pp., 2 tables, *K. H. Schundehütte*). This unusually extensive field is made clear by means of skillfully chosen examples. First the tautomerism of hydroxy- and amino-azo compounds is described, and then the various coupling reactions of diazonium salts with hydrocarbons, derivatives of aromatic amines and phenols, reactions affording polyazo compounds, and the preparation of macromolecular azo compounds. Here one also finds reactions that are seldom considered, such as the $Cu^{\oplus}$-catalysed conversion $2\ ArN_2^{\oplus} \rightarrow Ar{-}N{=}N{-}Ar + N_2$ (*Vorländer*), as well as the preparation of azo compounds from reactive methylene compounds or phenols and active azides, and oxidative coupling. The section on alkylation and acylation of amino-azo compounds includes the preparation of reactive dyestuffs. The numerous methods for preparation of metal complexes of azo dyes occupy 22 pages. This chapter will appeal particularly to the technologically oriented chemist, not least because the patent literature is extensively evaluated.

3. Aromatic-Aliphatic Azo and Azoxy Compounds from Arylhydrazones by Coupling (73 pp., 6 tables, *E. Enders*). This scientifically interesting chapter describes the oxidative conversion of hydrazones into azo compounds, also their coupling with reactive methylene compounds (Japp-Klingemann reaction). Other relevant methods are also considered.

4. Other Arylazo Compounds (72 pp., 8 tables, *R. Pütter*). Under this heading are collected arene-diazotates, -diazo ethers, -diazosulfonates, -diazosulfones, -diazocarboxylates, *etc.* The original literature about this many-sided group of compounds, that is so troublesome to read, is here explained by means of characteristic examples.

5. Formazans (33 pp., 2 tables, *R. Pütter*). This class of compounds has long been known, but it has recently gained importance owing to the reversible conversion into tetrazolium salts and stable radicals. Views on the mechanism of the syntheses are critically examined.

6. Aromatic Triazenes and Higher Azo Homologues (44 pp., 8 tables, *C. Süling*). Aromatic-aliphatic as well as purely aromatic triazenes can be singled out on account of their technical importance as "protected" diazonium salts, and on account of the acid-catalysed fission. Surprisingly, triazatrimethinecyanines also occur in this section. Tetrazenes and pentazadienes are also treated.

7. Aromatic Azoxy Compounds (26 pp., 1 table, *K. H. Schündehütte*). This section describes the constitutional problem and then the synthesis from aromatic nitroso and hydroxyamino compounds, by reduction of nitro compounds, and by oxidation of azo compounds. Particular interest attaches to the Wallach rearrangement of azoxy compounds which takes different courses in light and in sulfuric acid.

The last two chapters depart from the form of the previous ones. *C. Grundmann* gives an excellent exposition of the importance of two functional groups in the whole field of organic chemistry:

8. Organic Azides (54 pp., 4 tables). First the preparation of hydrazoic acid and its salts is described and then introduction of the azido group into organic compounds by addition and substitution as well as by reactions of other nitrogen-containing groups. The reactions of azido compounds are of general importance: addition to multiple bonds, the Schmidt and the Curtius degradation, and the mode of reaction (described in detail) of the nitrenes that occur as intermediates.

9. Nitrile Oxides (29 pp., 3 tables). The very instructive description of this class of compounds, to which little attention is usually paid, includes not merely their preparation (with a review in tabular form) but also particularly their very numerous addition reactions to multiple bonds that lead, *e.g.*, to furoxans and isoxazole derivatives. This and the preceding chapter end with methods of detection of the two groups.

This short indication of content must suffice to show that this volume maintains the high standard of the complete work. In accordance with its aims the methodological aspect is in the foreground, and the experimental detail is intended as a help for analogous experiments.

The volume ends with an exhaustive author (42 pp.) and subject index (38 pp.), to which is added a special index of diazonium salts and the azo compounds treated (arranged according to their methods of preparation). A patent index would in this case have been useful.

A proposal for future volumes: preparative yields should be restricted to whole units percent. The extensive list of journals (37 pp.) would be better placed at the end, with the table of abbreviations on "fold-out" pages.

*S. Hünig* [NB 479 333 IE]

**Klassische und molekulare Genetik** (Classical and Molecular Genetics). By *C. Bresch*. Springer-Verlag, Berlin-Göttingen-Heidelberg 1964. 1st Edit., viii + 319 pp., numerous figs., 14 tables, cardboard DM 32.– (*ca.* $ 8.–).

Publication of this book is most welcome. The central position of genetics in biology, already recognized by far-sighted investigators at the turn of the century, is nowadays clearly acknowledged.

*C. Bresch*, the author of the present book is a representative of the modern "molecular" biologists; he came to biology through physics. He has reviewed the total content of mole-

cular genetics – up to date almost to the last minute – in a clear, readily intelligible, and "learnable" form, and, moreover, he has had the courage to place it in the framework of a brief presentation of the classical theory of heredity. In view of this grandly conceived attempt and the tremendous effort behind it, the reviewer hardly feels himself in a position to criticize. If criticism is at all justified, it applies almost entirely to the "classical" chapters of the book. Many topics have been dealt with in a rather aphoristic way, and it is to be hoped that the author finds the time to present them in a more thorough fashion in the next edition.

More serious, in the reviewer's opinion, is a general deficiency of the classical section: the chromosome theory forms the very kernel of classical genetics. It is true that to day only historical interest attaches to the stepwise logical derivation of this relation from experiments that have since become famous, yet it cannot be simply omitted – pushed out of sight – from a textbook of genetics, if only for didactic reasons. The reviewer would gladly receive a clear exposition of these relations in exchange for reductions in other parts of the book that have been included probably for the sake of completeness (*e.g.* tetraploid heredity, "Heredity and Culture"). The description of life cycles could also be shortened: information on these matters may be essential for the non-biologist, but it could equally well be given in a biological-technical appendix. Whether, in fact, the principles of Mendelism are better derived from haploid genetics than from *Mendel*'s experiment is in the reviewer's opinion, an open question. One should proceed from the known to the unknown: who, other than a botanist, knows what *Sphaerocarpus* is? And if haplonts, then why not unicellular organisms, such as *Chlamydomonas*?

As in many parts of its content, the book is unorthodox in arrangement and production. Short summaries and references at the end of each chapter, clear diagrams and schemes, and occasional naively drastic comparisons are reminiscent of American textbook make-up. All this admittedly is refreshing and in no way lessens the value of the book as a source of information. Nevertheless, the German reader would welcome a stylistic revision; in the long run it becomes annoying to stumble upon phrases such as "Sexuality can take place between any individuals of the species" (p. 86), and "Crosses between different species are seldom succesful and even then almost always lead to sterile bastards owing to the difficulty of meiosis" (p. 80 – incidentally, in this lapidary brevity the statement is untrue!).

All in all: a good and complete introduction into modern molecular genetics, *i.e.* into the principles of molecular transmission of information in viruses and bacteria, and their experimental derivation; further, a first introduction into the complexity of the phenomena of heredity in higher organisms that invites further quests. The low price of the book permits wide distribution, and this is certainly to be hoped for.

*W. Beermann* [NB 430/337 IE]

**Fortschritte der Chemie organischer Naturstoffe** (Progress in the Chemistry of Organic Natural Products). Vol. 22. Edited by *L. Zechmeister*. Springer-Verlag, Vienna-New York 1964. 1st edit., vii + 340 pp., 15 figs., linen DM 88.– (ca. $22.–).

Volume 22 of this progress series, which has been appearing for 27 years, contains the following contributions:

1. *K. Schaffner* (Zurich): Photochemical Transformations of Selected Natural Products (94 pp., 413 refs.). This treats fragmentation of carbonyl compounds (terpenes, usnic acid, and griseofulvin), skeletal rearrangement of alicyclic ketones (steroids, santonin, and related substances), and ring contraction of cyclic diazo-ketones (terpenoids); there are also examples of intramolecular substitution with hydrogen shift, transformation of double-bond systems (including suprasterin$_2$-II, homoannular dienes, tropolones, *etc.*), and the photochemical behavior of pyrimidines, riboflavine, and amino acids. Particular attention is paid to results obtained in the last 5 years.

2. *G. Billek* (Vienna): Stilbenes in the Plant Kingdom (29 pp., 129 refs.). Individual stilbene derivatives (including the glucosides) and 3,4-dihydroisocoumarins are recorded, as well as isolation, determination of constitution, syntheses, and biosyntheses of stilbenes; also data on their taxonomic importance and biological action.

3. *T. G. Halsall* and *R. T. Aplin* (Oxford): A Pattern of Development in the Chemistry of Pentacyclic Triterpenes (37 pp., 239 refs.). The article supplements earlier reports in this series (vols. 7 and 13). Results obtained in this field since 1949 are reported, the various systems and numerous physical data for 177 individual compounds are collected in tables, and facts concerning pentacyclic triterpenoids of unknown structure are included.

4. *J. F. Grove* (London): Griseofulvin and Some Analogues (55 pp., 121 refs.). This section treats the isolationsof grisans, their structure and stereochemistry, reactions of the various functional groups, optical properties, methods of detection and determination syntheses, biosyntheses, and behavior in metabolism of animals and plants.

5. *P. J. Scheuer* (Honolulu): The Chemistry of Toxins Isolated from Some Marine Organisms (84 pp., 53 refs.). This deals with an important field that has as yet been little worked on. Discoveries concerning the toxins of teleosteres (tetrodopahu-, and cigua-toxin), echinoderms (holothurins, starfish saponins), molluscs and protozoa (saxitoxin), annelids and coelenterates (nereis- and paly-toxin) are reported.

6. *W. Keller-Schierlein, V. Prelog*, and *H. Zähner* (Zurich): Siderochromes (37 pp., 123 refs.). After a description of the detection, isolation, and action, the authors present in detail the chemical and biological relations between the iron(III) trihydroxamato complexes (sideramines, sideromycins), isolated from microorganisms, and their chelating agents. The stability of the complexes and the uses of desferrioxamin B in human medicine are also described.

In sum, the present volume, whose use is made easier by an author- and a good subject index, deserves warm recommendation both as introduction and for further information of organic chemists, biochemists, and biologists.

*H.-J. Bielig* and *G. Rohns* [NB 436/343 IE]

**Synthetic Methods of Chemistry,** Vol. 19. By *W. Theilheimer*. Verlag S. Karger AG, Basel-New York 1965. 1st Edit., Vol. 19 xvi + 498 pp., numerous illustr., sFr/DM 170.– (about $ 43.–).

This book reaches the same high level of achievement as previous members of the well-known series. 996 Examples, chosen with skill mostly from the literature of 1962–1964, illustrate the newest advances in the synthetic field. In accord with their importance, hetero-organic compounds, particularly those of phosphorus, silicon, and boron, come increasingly into the foreground, either as intermediates (*e.g.* in the Wittig reaction) or as end products. Much weight is laid on the synthesis of the most varied heterocycles. A particular advantage of this book is that many of the reaction steps described can be used as patterns for other syntheses. The method of arrangement, which is not praticularly simple but is used consistently, is reinforced by a comprehensive index (43 pp.). Nevertheless the reviewer would ask again whether the treasures gathered here would not be made more useful by addition of an index on the peephole principle.

*S. Hünig* [NB 456/309 IE]

**Interaction of Metals and Gases.** Vol. 1 of the series „Thermodynamics and Phase Relations". By *J. D. Fast*. Philips' Technical Library, Eindhoven 1965. 1st Edit., 310 pp., numerous figs., Dutch fl. 36.– (about $10.–).

In this volume, the author discusses heterogeneous gas equilibria and the thermodynamics of solution of gases in

metals (a second volume "Kinetics and Mechanisms" has been announced).

A didactically elegant and very readable theoretical introduction is followed by chapters on reactions between carbon and oxygen in steel and on solutions of gases in metals and in alloys.

The author's particular interest lies in the technological aspect of the subjects treated; much space is thus devoted to the metallurgy of iron, while other systems are treated more cursorily. The wealth of empirical material is carefully related to a theoretical background, and numerical examples, presented in detail, help the student to find his way into this important field. In sum, this is a book that can be very warmly recommended to a wide circle of metallurgists and students of metallurgy.

*H. Brodowsky* [NB 477/331 IE]

**Advances in Inorganic Chemistry and Radiochemistry.** Vol. 6. Edited by *H. J. Emeléus* and *A. G. Sharpe*. Academic Press, New York 1964. 1st edit., 530 pp., numerous figs. and tables, bound, $ 16.–.

The latest volume of these "Advances" really needs no commendation since earlier issues of the series have long been accepted as required reading for all concerned with research or teaching. Once again the editors have obtained authors who are recognized masters of their material, some of them by virtue of their own contributions. The subjects of chapters 1, 2, 5, 7, and 8 are by no means at the end of their development, so that supplements will soon be necessary, yet the reader can rely on completeness of the presentation to date and on the critical judgement of the authors, which is a great advantage at a time rich in scattered publications. The individual subjects treated are:

1. *G. Booth*: Complexes of the Transition Metals with Phosphines, Arsines, and Stibines; 2. *C. C. Addison* and *N. Logan*: Anhydrous Metal Nitrates; 3. *A. S Kana'an* and *J. L. Margrave*: Chemical Reactions in Electric Discharges; 4. *A. H. W. Aten*: The Chemistry of Astatine; 5. *U. Wannagat*: The Chemistry of Silicon-Nitrogen Compounds; 6. *J. A. Connor* and *E. A. V. Ebsworth*: Peroxy Compounds of Transition Metals; 7. *J. J. Zuckerman*: The Direct Synthesis of Organosilicon Compounds; 8. *E. Fluck*: The Mössbauer Effect and its Application in Chemistry.

Chapters 5 and 7, in particular, treat areas where a review was urgently required. Unfortunately, because of the space that would otherwise have been required, the treatment in chapter 5 is in part only that of a summary, and detailed results are not given (*e.g.* for the use of catalysts). Chapter 3 shows most impressively the possibilities of reactions under extreme conditions – a field with a large future; and in chapter 8 a still very young type of spectroscopy comes into focus which, while certainly not expected to attain the importance of NMR and ESR spectroscopy, nevertheless is a most valuable extension of those methods. The particular value of this book lies in its stimulation to further work.

*W. Sundermeyer* [NB 431/338 IE]

**Bridged Aromatic Compounds.** By *B. H. Smith*. Vol. 2 of the Series: Organic Chemistry. A Series of Monographs. Edited by *A. T. Blomquist*. Academic Press, New York-London 1964. 1st edit., xi + 553 pp., numerous tables, bound, $ 14.–.

There has hitherto been no modern complete review of the field of macrocycles, although it has been intensively studied particularly in recent years. It is, therefore, extremely welcome that the author has undertaken the laborious task of reporting on the special topic of bridged aromatic compounds, including furans, thiophens, and ferrocenes. The various sections are concerned with methods for the preparation of these compounds, the chemistry of the aromatic nucleus and the bridge, and atropisomerism, as well as ultraviolet, infrared, and NMR spectroscopy, electron resonance, and *X*-ray structure investigations.

The older work, in which structures are often falsely interpreted, is generally discussed in detail and critically, great stress being laid on a historically accurate presentation of the developments. A new proposal is made for a consistent nomenclature of this class of compounds on the basis of the cyclophane nomenclature introduced by *Cram* and *Steinberg*.

Since the author is an expert in the field of compounds with multi-membered rings, his numerous critical remarks have particular importance. Only in his evaluation of the methods of ring-closure will one occasionally not agree entirely with him. For instance, very recently it has been shown that the Thorpe-Ziegler dinitrile ring closure is superior to the acyloin ring-closure procedure in its range of application.

Numerous hitherto unpublished results and notes of eminent authors make the work particularly valuable. All the relevant substances prepared up to 1963 are collected in a final table. This excellent book is essential for every chemist who works with macrocycles, for it provides rapid information concerning the work so far carried out.

*G. Schill* [NB 432/339 IE]

**Organometallic Synthesis.** Vol. I: Transition-Metal Compounds. Edited by *J. J. Eisch* and *R. B. King*. Academic Press, New York 1965. 1st Edit., viii + 186 pp., $ 6.50.

In view of the increasing importance that attaches to organometallic compounds in all branches of modern chemical research, there has been a general wish for a collection of recipes for the synthesis of these sometimes difficultly accessible substances. In this volume the authors, who are true experts, treat the laboratory preparation of complexes of transition metals with carbon monoxide, aromatic compounds, and olefins, and some of their halogen, nitrosyl, and substituted derivatives. The general methods and techniques for their isolation, identification, and handling are clearly set out in an introductory chapter. The specialized section contains recipes, carefully chosen and worked out down to the smallest detail, of synthesis of more than 60 key compounds, together with their most important properties and their spectroscopic characterization. Other methods of preparation, and syntheses of analogous complexe are outlined and provided with references to the original literature, which is taken into account up to 1964.

The book can be placed alongside the well-known and popular volumes of the series "Inorganic Syntheses" and "Organic Syntheses" and is most warmly recommended to all who are interested in this field.

*Th. Kruck* [NB 457/310 IE]

**Advances in Heterocyclic Chemistry,** Vol. 3. Edited by *A. R. Katritzky*, *A. J. Boulton*, and *J. M. Lagowski*. Academic Press, New York-London 1964. 1st Edit., xiii + 434 pp., numerous tables and figs., $ 15.–.

Like the two previous volumes [1], volume 3 contains reviews of current heterocyclic chemistry, in particular of some types of substance and reaction that have been closely studied only in recent years, and of new methods.

In the chapters about substances there are sections on carbolines (*R. A. Abramovitch* and *I. D. Spenser*), thiatriazoles (*K. A. Jensen* and *C. Pedersen*), and pentazoles (*I. Ugi*). These classes have not yet received up-to-date treatment in the systematic series of heterocyclic chemistry (*R. C. Elderfield*; *A. Weissberger*).

The carboline chapter summarizes about 500 original papers (up to the end of 1962) in 130 pages, with a wealth of easily

[1] Angew. Chem. *77*, 466 (1965); Angew. Chem. internat. Edit. *4*, 451 (1965).

legible formulae. In its succinct but clear style this chapter reminds the reviewer of *H.-G. Boit*'s book on alkaloids. Nevertheless, it is not only the β-carbolines important for the alkaloid chemist that are handled; the other isomers that have become readily accessible in recent years are also included. There is a welcome and not too short discussion of the anhydro-bases and of spectra; however, the data about biosynthesis of naturally occurring carbolines are in part already out of date. The chapter on thiatriazoles includes the iodine-azide reaction that was discovered by *Raschig* and was recognized by *Feigl* as suitable for analytical purposes. The chapter on pentazoles deals with their chemical and particularly their physicochemical properties.

The remaining chapters of volume 3 are concerned with characteristic reactions, for instance, quaternization of nitrogen bases (*G. F. Duffin*), and with selected reactions that have only recently been studied for heterocycles, such as nucleophilic substitution, and uses of the Hammett equation.

*G. Illuminati*'s discussion of nucleophilic substitution – the original papers are rarely more than 10 years old – clarifies the differences as well as the analogies in chemical behavior of nitro-activated aromatic hydrocarbons and nitrogen heterocycles. There are detailed discussions of catalytic and autocatalytic effects, and of the limits of "normal" nucleophilic substitution (reactions by way of aryne intermediates). Particular attention is paid to reaction mechanism and intermediate states. The author favors a two-stage mechanism with a true intermediate. The initial impression of a dearth of pertinent compounds is later weake by the detailed table at the end of the chapter.

There is unavoidable, but not disturbing overlap between the preceding chapter and one also by expert hands (*H. H. Jaffé* and *H. L. Jones*) on applications of the Hammett equation (in its simpler forms . Here the organic chemist working in preparative chemistry will also find much of value once he has become accustomed to the particularly wide interpretation given to "side chain". It was not originally self-evident that the Hammett equation would be applicable at all to heterocycles, although this might have been suspected from the similarity of benzene to thiophene. Actually it is just in the field of five-membered heterocycles that results are sparse, because the necessary compounds are not known. The experiments have therefore been carried out mainly in the pyridine and quinoline series, and there even dissociation constants disclose an influence of substituents. One section each is devoted to development of such effects throughout heterocyclic systems, and another to the position of tautomeric equilibria. Equilibria of this sort can often be quantitatively estimated by means of the Hammett equation, even in extreme cases.

Finally, the present volume contains a chapter on the reactions of heterocycles with carbenes (*C. W. Rees* and *C. E. Smithen*), dihalogeno and α-keto carbenes playing a main part; subsequent rearrangements are considered.

This volume, in which only one printer's error was found (p. 39, formula 99), is not merely a progress report; it can also be recommended as a textbook for the advanced student. When further volumes have been published a subject index will be valuable, *e.g.* as for "Zechmeister". One can only congratulate the editors and authors on a successful volume.

*H.-J. Teuber* [NB 464/317 IE]

**Friedel-Crafts and Related Reactions.** Edited by *G. Olah*. Vol. III. Acylation and Related Reactions. Parts 1 and 2. Interscience Publishers, a Division of John Wiley & Sons, New York-London-Sydney 1964. 1st edit., Parts 1 and 2 together 1606 pp., numerous tables, bound, £ 22.10.0

As in the previous volume II, which was concerned with alkylation, so in the present volume III on "Acylation and Related Reactions" the editor's intention is to bring systematizing principles into the field, now almost too wide for review, of reactions occurring under the influence of Lewis or Brønsted acids.

In Part 1 are successively discussed the synthesis of aromatic ketones (chapter XXXI, *P. H. Gore*), Houben-Hoesch syntheses and related reactions (chapter XXXII, *W. Ruske*), the Fries reaction (chapter XXXIII, *A. Gerecs*), and acylation by di- and poly-carboxylic acids and their derivatives (chapter XXXIV, *A. G. Peto*). Part 2 contains cyclizing acylations (chapter XXXV, *S. Sethna*), a summary on acylation mechanisms (chapter XXXVI, *F. R. Jensen* and *G. Goldman*), acylation of aliphatic compounds (chapter XXXVII, *C. D. Nenitzescu* and *A. T. Balaban*), aldehyde syntheses by formylation (chapter XXXVIII, *G. Olah* and *S. J. Kuhn*), acid syntheses by carboxylation (chapter XXXIX, *G. A. Olah* and *J. A. Olah*), sulfonylation (chapter XL, *F. R. Jensen* and *G. Goldman*), and a short section on the Fries reaction of aryl arenesulfonates (chapter XLI, *F. R. Jensen* and *G. Goldman*); then follow sulfonation (chapter XLII, *K. L. Nelson*), nitration (chapter XLIII, *G. A. Olah* and *S. J. Kuhn*), amination (chapter XLIV, *P. Kovacic*), perchlorylation (chapter XLV, *C. E. Inman, R. E. Oesterling*, and *F. L. Scott*), and, finally, halogenation (chapter XLVI, *H. P. Braendlin* and *E. T. McBee*).

Although treatment of the general problems pertaining to reactions of organic compounds in the presence of Lewis acids as catalysts is reserved for volume I of the complete work, the individual chapters contain shorter theoretical considerations that are well worth reading Nevertheless, the value of the book to the practical chemist is retained, particularly by the very numerous tables that account for about a third of the number of pages in both Parts. It would, however, have helped the reader to find his information still more easily if the individual reactions listen in the tables had been, so far as possible, provided not only with a reference to the original literature but also with the number of the page where the reaction is discussed in the text.

The book is a happy combination of monograph and handbook. It provides the reader with a complete presentation of the field with which at present no other work compares in clarity, modernity, and balance of content; moreover, subjective exaggeration of this or that aspect, that so often goes with the treatment outlined above, has been carefully avoided. Thus purchase of the two Parts – even without the complete work – can be recommended with conviction.

*J. Gosselck* [NB 433/340 IE]

**Progress in Inorganic Chemistry,** Vol. 6. Edited by *F. A. Cotton*. Interscience Publishers, a Division of John Wiley & Sons, Inc., New York-London-Sydney 1964. 1st Edit., 360 pp., numerous figs. and tables. £5/–/– (*ca.* $15.00).

The following subjects are treated in the present volume:

1. Reactions of metal halides with ammonia and aliphatic amines (*G. W. A. Fowles*).

2. Magnetic properties of transition-metal complexes (*B. N. Figgis* and *J. Lewis*).

3. Reactions of noble gases (*John H. Holloway*).

4. The coordination model for the behavior of non-aqueous solvents (*R. S. Drago* and *K. F. Purcel*).

1. This article describes reactions with liquid and gaseous $NH_3$ that lead to addition or ammonolysis products, and reactions with aliphatic amines. The phenomena observed are interpreted according to modern points of view (*e.g.* formation of anionic complexes on ammonolysis of $TiI_4$). The presentation is very clear.

2. The magnetic properties of complexes of the transition metals are discussed on the basis of ligand-field theory. It becomes clear how much superior this method of presentation is to the vector model of the atom used previously. A knowledge of group theory, representation theory, and quantum theory is assumed in the reader; but the reviewer believes that the symbols in the mathematical equations are not always sufficiently explained. The article provides a very good and complete review of present knowledge in the field (670 references).

3. The chemistry of xenon has developed at a remarkable speed since the discovery of $XePtF_6$ and the fluorides $XeF_4$ and $XeF_2$, so that a comprehensive presentation of the results is very welcome. This article provides an excellent review, including the use of molecular-orbital theory to explain the nature of the bond betweenXe and other elements.

4. The object of the fourth article is to show that interaction between a solute and a solvent can be interpreted much more comprehensively on the basis of coordination chemistry than by other theories, the former being also in better agreement with the experimental results. This is clear, for instance, for a solution of $FeCl_3$ in $OPCl_3$, where the primary product is $[Cl_3POFeCl_3]$ which dissociates with formation of the cation $[(Cl_3PO)_nFeCl_2]^+$; this is contrasted with the earlier theory whereby self-dissociation of the medium ($OPCl_3 \rightleftarrows OPCl_2^+ + Cl^-$) is placed in the foreground (formation of the ions $POCl_2^+$ and $[FCl_4]^-$).

All in all, the articles in the present volume can be regarded as highly successful and a useful addition to the literature of the field.

# Functional Groups on the Surfaces of Solids

BY PROF. DR. H.-P. BOEHM

ANORGANISCH-CHEMISCHES INSTITUT DER UNIVERSITÄT HEIDELBERG (GERMANY)

*Atoms or groups foreign to the structure of a solid are often bonded to its surface. On diamond, graphite, and even silicon dioxide, the foreign atoms are bonded covalently, whereas the bonding of the structural groups to titanium oxide and alumina is predominantly ionic. Oxides are normally covered with a monomolecular hydroxide layer. Changes in the valence of the metal atoms lead to changes in the acidity of the surface; for example, reduction of surface $Ti^{4+}$ ions gives the surface of $TiO_2$ an acidic nature.*

## 1. Introduction

The three-dimensional periodic arrangement of atoms in a crystalline solid is interrupted at the surface. The surface may therefore be regarded as an extreme lattice defect. Surfaces of molecular lattices contain entire molecules; the only forces acting at the surface are those that hold the molecules together in the crystal. These van der Waals forces can form only relatively loose bonds with molecules or atoms foreign to the crystal, *i.e.* only physical adsorption can occur on such surfaces.

In ionic lattices and lattices consisting of covalently bonded three-dimensional networks, on the other hand, the surface ions or atoms are coordinatively unsaturated, *i.e.* they possess "free valences". Thus foreign atoms, groups, or ions can be relatively firmly bound (chemisorption).

In most compounds the bonding is intermediate between ionic and covalent. Accurate measurement of the electron-density distribution [1] has shown that even in LiF, there are indications of the presence of "bonds", *i.e.* increased electron density, between the cations and anions.

The situation in amorphous solids is similar to that in crystals, since the former also contain small regions of quasi-crystalline short-range order due to the geometrical arrangement of the valence directions. For example, in amorphous silica, such as silica gel, the $sp^3$ hybridization of silicon gives rise to $SiO_4$ tetrahedra.

[1] *J. Krug, B. Wagner, H. Witte,* and *E. Wölfel,* Naturwissenschaften *40*, 599 (1953).

The strength of the bonds formed with the chemisorbed atoms can vary widely. A surface compound is formed when the bond corresponds in nature and strength to the bonds in the body of the solid or in ordinary chemical compounds.

Really "clean" surfaces are rare, since reactive substances, particularly oxygen and water, are present in the atmosphere. Under normal conditions, therefore, many substances are covered with surface oxides or hydroxides. This covering has a decisive influence on the character of the surface.

It is important for many technical applications to know how these surface coverings behave. Surface compounds play an important part, not only in heterogeneous catalysis, but also in friction and lubrication processes, in the reinforcement of rubber with fillers or of synthetic resins with glass fibers, in the behavior of pigments in lacquers and inks, in textile processing agents, in the adhesion of phosphors to television screens, and in many other processes. Nevertheless, very little work has been done with a unified approach to this field. This may be partly because only in substances with large specific surface areas does the number of foreign atoms bonded to the surface become analytically important. The usual chemical methods of analysis can only be used for substances with specific surface areas of several hundred square meters per gram. For smaller specific surface areas, down to values of the order of 1 $m^2/g$, specially adapted micromethods are required, while for still smaller specific surface areas, such as are found in coarse-grained material, the foreign atoms bound to the surface can be determined only by physical methods, if at all.

The structures and reactions of some typical surface compounds are described below. Chemisorption on metals, which is important in many catalytical processes, cannot be treated here.

## 2. Surface Compounds on Diamond-Like Structures

Diamond is a particularly suitable substance for the study of surface compounds. In the diamond lattice, which is also the lattice structure of silicon and germanium, the atoms are linked tetrahedrally because of their $sp^3$ hybridization. Diamond is the prime example of a crystal with purely covalent bonds. The most frequent cleavage plane is (111), *i.e.* the octahedral face, in which one bond is broken per C atom. It was observed as early as 1918 that diamond powder, which is normally hydrophobic, becomes hydrophilic on treatment with oxidizing agents [2]. Natural diamonds from volcanic pipes (*e.g.* at Kimberley) are hydrophobic; on the other hand diamonds from secondary deposits (placers) are hydrophilic.

This behavior is due to the formation of surface oxides [3]. Diamond powder with surface oxides has a higher heat of wetting in water than diamond powder without surface oxides. When diamond powders with surface oxides are treated with water, carboxyl groups are formed (Fig. 1a). Determination of the active hydrogen by the method of *Zerevitinoff* or by deuterium exchange shows that nearly all the hydrogen atoms present are in the form of carboxyl groups [4]. However, most of the oxygen is not bound in the carboxyl groups, but in a form that is not yet definitely known. No confirmation has been found for the conjecture that tertiary hydroxyl groups are bonded to the octahedral face (Fig. 1c). Other groups containing oxygen that could conceivably be attached to the surface of diamond are indicated in Figures 1b, 1d, and 1e.

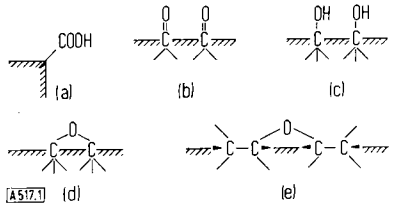

Fig. 1. Functional groups on the surface of diamond.

(b) Carbonyl groups on a (100) face (presumed);
(c) Tertiary hydroxyl groups on a (111) face (not detectable);
(d) Ether grouping on a (111) face (presumed);
(e) Ether grouping on a (110) face (presumed).

A surface oxide structure with unpaired electrons on the oxygen has also been ruled out. Electron-spin resonance measurements on a sample with an oxygen content of 320 μg-atom/g of diamond indicated only 7 μequiv of unpaired electrons/g of diamond [5]. Similar results were obtained when diamond powder was heated to remove surface oxides, and then treated with fluorine, chlorine, or hydrogen at elevated temperatures, whereby 200 μequiv of halogen per gram and 230 μequiv of hydrogen per gram were bound to the surface [3]. The infrared spectra of the substances contained corresponding absorption bands. Though the ESR signal showed only a small decrease in intensity during these reactions, its shape and width changed appreciably. It follows that the unpaired electrons are situated close to the surface.

Even diamond that had been freed from surface oxides in a high vacuum ($10^{-5}$ to $10^{-6}$ mm Hg) at 800 °C did not exhibit a much greater ESR absorption (11 μequiv of free radicals/g of diamond). A possible explanation is the rapid contamination of the surface by impurities such as vapor from the vacuum grease. Even at this low pressure, however, surface oxides are probably reformed on cooling. The coefficient of friction of diamond increases markedly when the surface oxides are removed in an ultrahigh vacuum ($5 \times 10^{-10}$ mm Hg). If the surface of this diamond is exposed to the residual gas pressure of $5 \times 10^{-10}$ mm Hg, the frictional coefficient decreases within 20 min to the value normally found in air [6]. However, chemical analysis revealed practically no bound oxygen on diamond that had been heated at 950 °C in a high vacuum and allowed to cool therein [4]. Confirmation of the formation of surface oxides under these conditions has been obtained in diffraction studies with low-energy electrons [7].

Low-energy electron diffraction [8] is particularly suitable for the investigation of the structures of surface compounds, as well as of the "bare" surface. The surface of a crystal with a diameter of a few millimeters is irradiated with an electron beam, the energy of which is varied between 20 and 200 eV. The corresponding wavelength (0.6 Å at 20 eV) is of the same order as the interatomic distances in the lattice. Since the penetration depth is small, amounting to only a few layers of atoms, the diffraction pattern represents the structure of the surface. Owing to the low energy of the electrons, the measurements must be carried out at $10^{-4}$ to $10^{-10}$ mm Hg, *i.e.* under conditions in which some surface compounds are not stable.

A pure, fault-free surface gives the diffraction pattern of the basic structure. If the foreign atoms or the surface atoms of the crystal have a periodic arrangement with unit cells larger than those of the crystal lattice, the reflections due to the latter are accompanied by others having fractional indices with respect to the "normal" reflections. A structure analysis of the surface layer is thus possible, but the difficulties involved are considerably greater than in normal X-ray analysis.

The principal results obtained by diffraction of slow electrons can be summarized as follows. Whereas "atomically pure" metal surfaces, *e.g.* the (100) face of nickel [9] or chromium [10], have the ideal face-centered and body-centered cubic lattices, respectively, "clean" silicon or germanium surfaces (diamond lattice) give reflections with fractional indices [11–13]. In a fresh (111)

cleavage surface, the Si tetrahedra are distorted to such an extent that the distance between pairs of surface Si atoms is only 2.6 Å compared to 3.84 Å within the crystal. Naturally, the Si atoms in the next two layers are also displaced from their normal positions. This structure is still unstable. When the crystal is annealed at 700 °C (300 °C for Ge), about 25% of the surface Si atoms diffuse to other positions. The result is a surface structure containing puckered six-membered rings [12]. Calculation of the Si–Si distance in the rings from the atomic coordinates gives a value of 2.2 Å, whereas the normal bond length is 2.35 Å. This indicates some double-bond character; *Lander* [8, 13] refers to the rings as "warped benzene rings". A structure consisting of Si chains with conjugated double bonds of length 2.2 Å has also been suggested [14].

In both of these structures, there is a regular pattern of vacancies in the topmost layer. However, it has been observed that surface structures with ideal periodicity are formed when oxygen [11] or iodine [13] is chemisorbed on these surfaces at low temperatures [15]. Moreover, compounds of silicon or germanium containing double bonds are unknown.

The free valences in the surface exhibit a marked tendency to saturate one another, and the energy liberated in this way is sufficient to cause severe distortion of the lattice. These results explain the observation that diamond does not exhibit strong electron spin resonance. It is apparently impossible to obtain a clean diamond surface with two-dimensional order. Diffraction patterns are observed only after treatments that lead to the formation of surface compounds, *e.g.* after treatment with aqua regia or hydrogen (at 700 °C) [7]. The normally very effective process in which clean surfaces are obtained by bombardment with $Ar^+$ ions leads to an "amorphous surface" with no periodic order [*].

After treatment of diamond powder with $H_2$ at 700 °C, the diffraction pattern of the surface contains strong reflections with integral number indices, and only weak reflections of half-integral order. Presumably this treatment generates C–H groups, as is also indicated by the low heat of wetting in water [3].

Significant effects were also observed on treatment of the diamond surface with oxygen at $2 \times 10^{-6}$ mm Hg [7]. The diffraction pattern changes only slowly at room temperature, and more rapidly at higher temperatures. Whereas chemisorption of oxygen on silicon leads to extinction of the reflections of half-integral order [11], these reflections occur frequently in surface oxides of diamond [7]. No structure analysis has been carried out, but it may be assumed that the free valences of the C atoms are saturated by oxygen bridges, again with distortion of the diamond lattice (Fig. 1d and 1e).

One atom of iodine or bromine per atom of Si (or Ge) is chemisorbed on the (111) face of silicon (or germanium). Contrary to expectations, the halogen atoms are not situated directly above the surface Si atoms, but above the centroid of a triangle formed by three Si atoms [12]. The bonding presumably involves the d-orbitals of the halogens.

Further peculiar surface structures are formed when phosphorus [12] or aluminum [16] is chemisorbed on the (111) surface of silicon.

The bonding of chlorine on diamond is different from that of oxygen or hydrogen. The infrared spectrum of diamond treated with hydrogen contains an absorption band at 2850 $cm^{-1}$ [4] (C–H bond). In diamond treated with chlorine, on the other hand, a weak absorption occurs at 1410 $cm^{-1}$, and not between 600 and 800 $cm^{-1}$ as expected. Diamond treated with oxygen absorbs at 1760 $cm^{-1}$, indicating the presence of carbonyl groups. These could easily be formed on the (100) surface of diamond (Fig. 1); on the (111) surface, however, their formation requires the cleavage of another C–C bond. Carbonyl groups on the (100) surface form part of a warped, rigid $C_6$ ring if the C atoms in the second and third layers are also considered. This would agree with the relatively high frequency of the absorption. A very broad absorption at 1000–1300 $cm^{-1}$ could be due to ether bridges on the (111) and (110) surfaces (Fig. 1d and 1e).

Microgravimetric and gas-analytical studies of the oxidation showed that diamond powder is not continuously oxidized below 360 °C [3]. The weight increases to a terminal value. Nevertheless $CO_2$ is formed, presumably by oxidation of exposed C atoms. The surface oxides are almost completely decomposed in a vacuum at 950 °C, with further formation of $CO_2$ in addition to CO. If it is assumed that one O atom is bonded to each surface C atom, isolated C atoms must remain on the surface after decomposition; when the surface is oxidized again, these atoms are removed as $CO_2$ before a new oxide layer is formed.

### 3. Surface Compounds on Black Carbon

Elementary carbon occurs as diamond, graphite, and graphite-like microcrystalline carbon. Whereas aliphatic carbon compounds are derived from the diamond lattice, the graphite layer lattice forms the basis of aromatic compounds. Each atom in these layers is linked by σ-bonds to three neighbors ($sp^2$ hybridization). The fourth valence electron is bound as a π-electron, which can easily migrate from one atom to another within the layer. The layers are relatively loosely held together by van der Waals forces (distance 3.35 Å). Microcrystalline carbon consists of packets of layers, in which some 3 to 30 aromatic layers about 10 to 1000 Å in diameter are stacked in an unordered manner (turbostratic order) [17]. The surface compounds correspond to the end groups

[14] *R. Seiwatz*, Surface Sci. *2*, 473 (1964).

[15] Cf. *N. R. Hansen* and *D. Haneman*, Surface Sci. *2*, 566 (1964).

[*] Note added in proof: *J. J. Lander* and *J. Morrison*, Surface Sci. *4*, 241 (1966), report a structure with puckered $C_6$ rings for a clean (111) face of diamond, similar to that of Si. After treatment with $H_2$ at 900–1000 °C, the ideal periodicity was observed, whereas $O_2$ did not produce an ordered surface structure.

[16] *J. J. Lander* and *J. Morrison*, Surface Sci. *2*, 553 (1964).

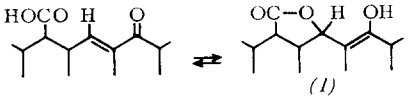
[17] *U. Hofmann* and *D. Wilm*, Z. Elektrochem. angew. physik. Chem. *42*, 504 (1936).

of polymers. It follows from the highly-condensed aromatic layer structure that surface compounds on graphite or microcrystalline carbon can be expected only at the layer edges (prism faces of graphite). Foreign atoms or molecules can be only weakly adsorbed on the basal faces by means of the π-electrons, except where they are bound at lattice defects.

When microcrystalline carbon is treated with oxygen just below its ignition temperature, surface oxides with acidic properties are formed. If, on the other hand, the carbon is heated to remove surface compounds, and cooled to room temperature in vacuum or in an inert gas, it can bind acids with simultaneous uptake of oxygen and formation of basic surface oxides. Thus depending on its pretreatment, the same sample may carry predominantly acidic groups or only basic groups [18]. The quantity of the basic surface oxides formed is always smaller than the quantity of acidic surface oxides; however, all charcoals with acidic surface oxides also carry basic surface oxides. Typical neutralization values are about 80–250 mequiv of NaOH/100 g and 10–15 mequiv of HCl/100 g.

The first attempts to elucidate the constitution of the acidic surface oxides by the methods of chemical analysis were made by *Villars* [19] and by *Hofmann* and *Ohlerich* [20].

The acidic surface oxides formed by the action of oxygen on microcrystalline carbon at about 400 °C contain four types of acidic groups. Carboxyl, phenolic hydroxyl, and carbonyl groups have been detected. One carboxyl and one carbonyl group probably combine to form a lactone *(1)* [21] or *(2)*.

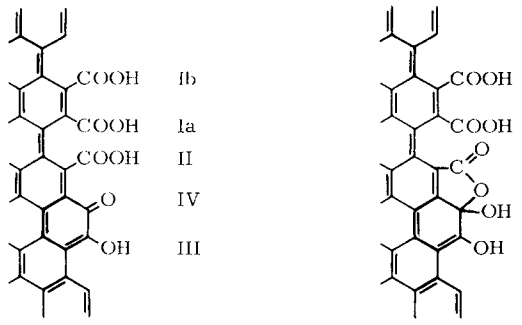


*(1)*

*(2)*

In fully oxidized samples, the four groups are present in equivalent amounts. When the carbon is treated with aqueous solutions of strong oxidizing agents (*e.g.* ammonium persulfate) at room temperature, two carboxyl groups are found for every one of the other groups, one of the two carboxyl groups decomposing at about 200 °C with liberation of $CO_2$. Fig. 2 shows a model containing all the functional groups that have been detected.

The acidic surface groups are most easily detected by neutralization with bases. Free carboxyl groups react with hydrogen carbonate ions, the lactone rings are opened by sodium carbonate, and the phenolic groups require sodium hydroxide for neutralization. The carbonyl group adds sodium ethoxide to form a salt of a hemiacetal, $C(OC_2H_5)O^-$



Open form Lactone form

Fig. 2. Model containing all the functional groups detected in acidic surface oxides of carbon. The arrangement of the groups in a closely spaced row has not been proved. Two carboxyl groups or two carbonyl groups often appear to be close together. The carboxyl groups can then form anhydrides [3].

Ia. Carboxyl group which is removed at about 200 °C (occurs only in products that have been oxidized at 20–150 °C);
Ib. Carboxyl group, removable only above 325 °C;
II. Carboxyl group that occurs as a lactone;
III. Phenolic hydroxyl groups;
IV. Carbonyl group that reacts with the carboxyl group II to form the lactone (or lactol).

$Na^+$ [22]. Moreover, unpaired electrons have also been detected in oxidized carbon [23].

The acidic surface groups are usually determined by neutralization with dilute sodium hydroxide solution. The samples are shaken with standard NaOH, and aliquots of the solution are back-titrated. It is important that shaking is continued to complete neutralization [3, 22, 24]. The time required for complete neutralization is 96 hours with 0.01N NaOH, or 12 hours with 0.05N NaOH [24a]. When concentrated sodium hydroxide solutions are used, more base is consumed, corresponding to the sodium ethoxide value; this value is reached after 96 hours with 0.25 N NaOH, and after 36 hours with 1 N NaOH. The use of barium hydroxide [24] has two disadvantages: 1. Porous charcoals nearly always contain adsorbed $CO_2$, which forms insoluble $BaCO_3$ ($Na_2CO_3$, on the other hand, is included in a back-titration, and so does not affect the result); 2. exchange of acidic hydrogen for bivalent cations may occur either between equivalent quantities or between equimolar quantities (Fig. 3). Equivalent ion exchange occurs when the charged surface groups are situated close together, *e.g.* in synthetic ion exchange resins. In equimolar ion exchange, a bivalent (or multivalent) cation, together with additional anions to preserve electrical neutrality, is bound instead of a monovalent cation; this occurs when the charges are relatively far apart. The possibility of equimolar ion exchange with multivalent ions must be borne in mind in all reactions used for the determination of surface groups. Charge compensation is better in this case than in

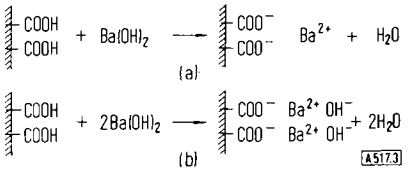


Fig. 3. Reaction schemes for equivalent (a) and equimolar (b) ion exchange. Example: neutralization of surface carboxyl groups.

equivalent exchange. *Pauling*[25] has pointed out that the positive ions in a crystal lattice occupy the positions at which the negative potential is greatest, and *vice versa*. The same is true on the surface[26]. The state adopted is that with the minimum potential and the smallest possible distance between opposite charges. The phenomenon of equimolar ion exchange was first observed in kaolinite by *Weiss*[26], and was subsequently also observed on the surface of $SiO_2$[27]. However, the more strongly acidic groups of the surface oxides of carbon appear to lie sufficiently close together to ensure equivalent exchange[3,24].

It has been shown[28] that oxygen is almost entirely chemisorbed on the prism faces of graphite crystals. Single crystals 2 mm in diameter and about 0.1 mm high were treated with $O_2$ at 700 °C. The oxides of carbon given off in vacuum at 900 °C were determined by mass spectrometry. The experiment was then repeated, but the crystals were first cleaved five times parallel to the layer planes, so that while the area of the prism faces remained the same, the area of the basal faces was increased by a factor of six. The quantity of gas given off was not affected by this treatment.

Carbon blacks that have been graphitized at 2400 to 3000 °C have a very homogeneous surface[29]. The surface of the isometric particles consists almost entirely of the basal surfaces of pyramidal graphite crystals, the apices of which are situated in the center of the particle[30]. Consequently, graphitized carbon blacks form practically no acidic surface oxides[31].

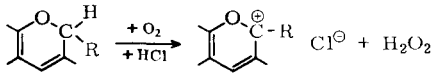
The functional groups on the carbon surface undergo the usual reactions of organic chemistry. The carboxyl groups react with diazomethane[3,20,22,31–33], alcohols[3], acetyl chloride[3], or $SOCl_2$[3,22,31]. Friedel-Crafts reactions and Curtius rearrangements can be carried out[3,22]. The phenols react with *p*-nitrobenzoyl chloride or with 2,4-dinitrofluorobenzene[3,22]. The carbonyl groups add ethoxide, and react with hydroxylamine to form oximes[22].

Although the basic surface oxides have been known longer[34] than the acidic ones, nothing definite is known as yet about the constitution of the former. Carbon binds mineral acids only in the presence of oxygen[35]. The extent of adsorption depends on the partial pressure of oxygen, at least below 20 mm Hg[36, 37]. Part of the bound acid is undoubtedly physically adsorbed, particularly at higher concentrations, since it can be displaced by solvents such as toluene[38,39]. This result indicates that a relatively weak interaction occurs with the π-electrons of the layers; perhaps proton complexes of the aromatic layers are formed[38,40].

According to *Burstein* and *Frumkin*[41], the reaction of basic surface oxides with acids yields $H_2O_2$:

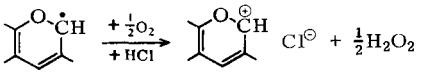
$$C_xO_2 + 2\,H^+ + 2\,X^- \rightarrow C_x^{2+}(X^-)_2 + H_2O_2$$

However, this product has never been detected in the expected quantities, possibly because of carbon-catalysed decomposition. A substance that oxidizes KI has been repeatedly observed[42]. More recent studies[43] have shown that the acid is adsorbed relatively slowly, and that the concentration of $H_2O_2$ in the surrounding solution passes through a maximum. The salts of the basic surface oxides decompose in vacuum above 60 °C[43]. *Garten* and *Weiss*[39] believe that the oxygen is present in chromene-like structures *(3)*, in which the positive charge is delocalized after the addition of acid as in benzopyrylium salts.



*(3)*

Free radicals such as *(4)* could also be responsible for the reaction[39].



*(4)*

On the other hand, carbonium and oxonium bases are normally very weak, and washing would be expected to lead to complete hydrolysis; the charcoals, however, cannot be completely freed from bound acids by washing with water [44, 45].

The anion must be ionically bound, since it is exchangeable[38,45]. Cationic sites have been detected in carbon blacks by hydride-transfer reactions[45]; thus isopropanol in 50% $H_2SO_4$ has been oxidized to acetone:

$$R^+X^- + CH_3\,CH(OH)\,CH_3 \rightarrow R{-}H + HX + CH_3COCH_3$$

The original carbon black, after oxidation with triphenylmethyl perchlorate, can also oxidize isopropanol:

$$R{-}H + (C_6H_5)_3C^+ClO_4^- \rightarrow R^+ClO_4^- + (C_6H_5)_3CH$$

The corresponding formate decomposes with evolution of $CO_2$[45]:

$$R^+HCOO^- \rightarrow R{-}H + CO_2$$

Since acids are bound only in the presence of oxygen, which can be detected in the reaction product[43], it is justifiable to speak of basic surface oxides. These prob-

ably play an important part in the transfer of oxygen by carbon in fuel cells using atmospheric oxygen or in the use of carbon as a depolarizer in other cells.

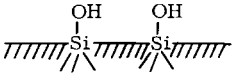
Hydrogen and halogens, as well as other elements, are bound on the surface of graphite and of microcrystalline carbon. In carbons (*e.g.* carbon black) obtained from hydrocarbons or other organic materials, most of the free valences at the edges of the carbon layers are saturated by hydrogen.

## 4. Surface Compounds on Silica

Silica occurs in many crystalline forms and in an amorphous form. Apart from stishovite, which has the rutile structure, and the very unstable fibrous silica, which has the $SiS_2$ structure [46], all the modifications have the well-known three-dimensional network of $SiO_4$ tetrahedra with common corners. The Si–O bond is partially ionic [47,48]. The bond angle at the oxygen atom in the siloxane bond Si–O–Si is close to 140° [49]. This value suggests that the electron pairs of oxygen that are not used in the $\sigma$-bonds are also involved in the bonding ($d_\pi$-$p_\pi$ bond).

The surface chemistry of silica appears at first sight to be much simpler than that of carbon. Under normal conditions, only two types of "end groups" are conceivable on the surface, namely siloxane groups *(5)* and silanol groups *(6)*.

*(5)*



*(6)*

By far the most investigations have been carried out with amorphous silica with a large specific surface area, mainly because this material has many industrial uses. Porous silica gel, for example, is used as an adsorbent and drying agent, while other types with spherical particles are used as fillers in rubbers and plastics. $SiO_2$ is also used as a powder base, as a toothpaste additive, and in the textile industry.

The very pure and non-porous "Aerosil" [*] and Cabosil [*], which are produced by flame hydrolysis of $SiCl_4$, have proved to be particularly suitable for many measurements.

*U. Hofmann et al.* [50] were the first to recognize that the free valences at the edges of the silicate layers in the clay minerals must be saturated by silanol groups. *Carman* [51] came to the same conclusion for colloidal amorphous $SiO_2$.

The number of surface silanol groups was at first determined from the loss on ignition at 1000–1100 °C. However, this method raises certain difficulties. Many products obtained by condensation of low molecular-weight silicic acids also contain silanol groups in the interior of the particles, since some of the silanol groups fail to find partners during the condensation. These groups are mostly, but not entirely, decomposed at 1000 °C. Small amounts of OH groups have even been detected in vitreous silica [52,53] and in rock crystal [54] by their infrared absorption. Water molecules may also be very strongly adsorbed, and they may fail to escape on drying at 150 to 200 °C [55]. This adsorbed water can be titrated by the Karl Fischer method. If a suitable correction is made to the loss on ignition, the resulting silanol contents agree satisfactorily [56] with the values obtained *e.g.* by reaction with thionyl chloride [27].

Calculation from the loss on ignition often gives a very high value for the packing density of the silanol groups on the surface. The maximum possible packing density can be estimated from the structure of the crystalline modifications of $SiO_2$. In this way *de Boer* [57] obtained a value of 4.55–4.85 OH/100 Å$^2$ for cristobalite and tridymite. The calculated values [58] for various crystal faces are listed in Table 1. If the lower density of amorphous $SiO_2$ is taken into account, averaging over all the crystal faces gives a packing density of about 5 OH/100 Å$^2$ for amorphous $SiO_2$. However, the values found by measurement are nearly always lower [59].

Table 1. Packing density of silanol groups on various crystal faces of silicon dioxide.

| Modification | Face | Packing density (OH/100 Å$^2$) | |
|---|---|---|---|
| | | [a] | [b] |
| Quartz | (001) | 9.6 | 8.5 |
| (d = 2.655) | (101) | 6.0 | 5.2 |
| Cristobalite | (100) | 7.9 | 7.6 |
| (d = 2.32) | (101) | 5.6 | 5.3 |
| | (111) | 4.5 | 4.4 |
| Tridymite | (001) | 4.5 | 4.5 |
| (d = 2.26) | (100) | 4.8 | 4.7 |

[a] for crystalline $SiO_2$.
[b] calculated value for amorphous $SiO_2$, based on density d = 2.20.

Hydroxyl groups on the $SiO_2$ surface have also been detected by infrared spectroscopy. Aerosil that had been degassed at 30 °C showed absorptions at 3750 cm$^{-1}$ (isolated silanol groups), 3660 cm$^{-1}$ (hydroxyl groups with weak hydrogen bonds), and 3520 cm$^{-1}$ (strong hydrogen bonds) [60]. When the sample was heated, the absorption at 3520 cm$^{-1}$ receded first; outgassing at 940 °C led to the disappearance of the peak at 3660 cm$^{-1}$, and the intensity of the absorption at 3750 cm$^{-1}$ increased at the same time. It can be concluded, therefore, that more than two hydroxyl groups must be present in the complexes that absorb at 3660 cm$^{-1}$, since no OH groups would otherwise remain after the removal of

water. The observation that the OH groups with the stronger hydrogen bonds are the first to be split off has been repeatedly confirmed [61,62]. Different reaction rates were also observed in the OH/OD exchange on the silanol groups [62]. The combination and overtone vibrations in the region between 1 and 3 μ [63–65] are particularly suitable for differentiation between silanol groups and water.

A silica particle may be regarded as very highly polymeric polysilicic acid. The silanol groups on the $SiO_2$ surface enter into many chemical reactions. They are weakly acidic, and can be titrated in concentrated NaCl solution with NaOH [66]. In our experience, all the silanol groups are neutralized at pH 9.0; further addition of NaOH leads to cleavage of siloxane bonds. On neutralization with $Ca(OH)_2$ an equimolar reaction occurs [27].

The reaction with thionyl chloride

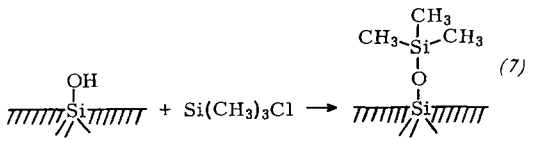
$$\equiv Si{-}OH + SOCl_2 \rightarrow \equiv Si{-}Cl + SO_2 + HCl$$

can also be used for the determination of silanol groups if the substance does not contain narrow pores [27,67,68]. The reagent and the reaction products are held so firmly in narrow pores that they cannot be completely removed by degassing at 200 °C.

However, the content of active hydrogen found by Zerevitinoff determinations was higher than that corresponding to the chloride uptake from $SOCl_2$ [69], but this may be due to very strongly adsorbed water (see below). The OH absorption in the infrared spectrum of porous Vycor glass (which is 96% $SiO_2$) disappeared when the glass was treated with $SOCl_2$, and after subsequent treatment of the glass with $NH_3$, the spectrum indicated the presence of $Si{-}NH_2$ groups [70].

Esterification with alcohols can be used for the analytical determination of silanol groups *via* the methoxy or carbon content. The silica is heated with the alcohol in an autoclave or, for higher alcohols, in a vessel fitted with a rectifying column, the water formed being distilled off as an azeotrope [71–73]. The silanol groups can also be methylated with diazomethane [27,74]. Esterification makes the surface hydrophobic, and leads to a finely divided silica which can be readily incorporated into oils or waxes [71].

Of the many other reactions of these surface hydroxides, we shall mention only those with $Si(CH_3)_3Cl$ [75,76], $BCl_3$ or $AlCl_3$ [67], with trialkylaluminum [77], and with $B_2H_6$ [78,79], in which the hydrogen of the silanol groups reacts to form HCl, alkane, and $H_2$ respectively. Coating as in *(7)* with trimethylsilyl groups leads to a marked decrease in the rate of dissolution of finely divided



(7)

silica in water [75]. Although some of the silanol groups remain unchanged, the surface is protected by the trimethylsilyl "umbrellas". Coating with a monoatomic layer of $Al^{3+}$ practically prevents the removal of $Si(OH)_4$ from the surface of Aerosil [67,77]. These ions are adsorbed hydrolytically on the $SiO_2$ surface from basic aluminum chloride solutions containing 1 to 2 hydroxide ions per $Al^{3+}$ ion [80]; one $Al^{3+}$ ion is firmly bound per silanol group [81]. During hydrolytic adsorption, the polynuclear complexes $[Al_x(OH)_y(H_2O)_z]^{(3x-y)+}$ in the basic aluminum chloride solution give up aluminum hydroxide to the $SiO_2$ surface.

The solubility of orthosilicic acid in water is about 1.67 mmole/l. In a solution of $NaCl/NaHCO_3$ buffered to pH 8.2, 123 μg of $SiO_2$ dissolves per ml of solution at 20 °C. When the solution is shaken with Aerosil (specific surface area about 150 $m^2/g$), this value is reached in about 24 hours. If the solvent is agitated under the same conditions with Aerosil coated with $Al^{3+}$ ions, only 6 μg/ml dissolves in three weeks [67]. The aluminum layer can be readily removed with mineral acids.

Many other ions are hydrolytically adsorbed on the silanol groups of the $SiO_2$ surface [82,83]. This behavior can be used for the analytical separation of ions on silica gel columns [84,85].

Table 2 summarizes results of many reactions on Aerosil. The packing density of the surface silanol groups can be calculated from the specific surface area and the conversion. Table 2 shows remarkable agreement between the results obtained by various methods, particularly in the experiments carried out with the same Aerosil sample of specific surface area 145 $m^2/g$.

Table 2. Amount and packing density of silanol groups on the surface of Aerosil.

| Reaction | Specific surface area ($m^2/g$) | Silanol groups: amount (meq/100 g) | Silanol groups: packing density (OH/100 Å$^2$) | Ref. |
|---|---|---|---|---|
| Weight loss at 1000 °C — free $H_2O$ (K. Fischer titration) | 180 | 103 | 3.45 | [56] |
| Reaction with $SOCl_2$ | 178 | 62 | 2.10 | [69] |
| Zerevitinoff method with $CH_3MgI$ or $CH_3Li$ | 178 | 122 | 4.12 | [69] |
| Reaction with $SOCl_2$ | 165 | 87 | 3.17 | [27] |
| Reaction with $SOCl_2$ | 145 | 55 | 2.30 | [59] |
| Titration with NaOH [66] | 145 | 57 | 2.38 | [86] |
| Reaction with $BCl_3$ | 145 | 56 | 2.34 | [67] |
| Sorption of $Al^{3+}$ from $Al(OH)_2Cl$ solution | 145 | 60 | 2.50 | [81] |
| Sorption of $UO_2^{2+}$ from $UO_2(CH_3COO)_2$ at pH 5.4 [82] | 145 | 52 | 2.17 | [87] |
| Methylation with $CH_3OH$ at 200–250 °C | 145 | 55 | 2.29 | [88] |
| $D_2O$ exchange after outgassing at 200 °C | 145 | 113 | 4.69 | [89] |
| Zerevitinoff method with $CH_3MgI$ after outgassing at 120–200 °C | 145 | 109 | 4.52 | [89] |
| Infrared spectra | 145 | 115 | 4.77 | [64] |

Values much smaller than 5 OH groups per 100 Å$^2$ were found by all methods except the Zerevitinoff active hydrogen determination and the $D_2O$ exchange method. The value found by the active hydrogen determinations was exactly twice as high. *Stöber* [55] attributed this result to the fact that for every two silanol groups, one molecule of water is adsorbed so strongly that it is not released even in a high vacuum at 100–200 °C. This argument is supported by the results of the reaction with $BCl_3$ or $AlCl_3$ [67]. However, the results of the Zerevitinoff determinations do not fit this explanation, since only one H atom of water reacts with $CH_3MgI$. The infrared spectrum of Aerosil treated with $SOCl_2$ still contains OH absorptions [89]. Aerosil deuterated with $D_2O$ was treated with $SOCl_2$; it then contained half as much exchangeable deuterium as before. Thus the OH groups that are stable towards $SOCl_2$ are situated at the surface.

It is difficult to see why only half of the silanol groups react with the other reagents, since it is very unlikely that the surface contains only silanediol groups $=Si(OH)_2$. These conflicting results require further experimental study. The packing density of silanol groups is influenced by the particle size of the $SiO_2$, and appears to decrease with increasingly fine division [90].

The existence of siloxane groups on the surface of silica has been inferred only from the observation that the number of silanol groups detected is not sufficient to cover the surface completely. Silica that has been heated to a high temperature contains practically no residual silanol groups. The dehydration is reversible if carried out below 450 °C. If, however, $SiO_2$ is heated to 800 to 1000 °C, no rehydroxylation occurs at room temperature on exposure to water vapor below saturation pressure [61,91,92], and the silanol groups are regenerated slowly over a period of several months in aqueous suspension [93,94]. This difference in behavior is ascribed to the stability and inertness of the siloxane grouping. Siloxane bridges formed at low temperatures are still strongly "strained". The strain can lead to distortion of the bond angles or bond lengths and to strongly polar bonds. Only above 450 °C is the thermal energy sufficient for rearrangement of the tetrahedra to such an extent as to remove the strain.

The inertness of the siloxane linkage is due to the $d_\pi$-$p_\pi$ component; it is the only reason for the resistance of silica vessels to many reagents at relatively low temperatures. The Lewis basicity of oxygen is greatly reduced in the siloxane group, and there is practically no tendency for the oxygen to form hydrogen bonds [95]. Consequently, the surface of silica that has been heated to high temperatures becomes hydrophobic. Water-vapor adsorption isotherms are of type III [61] in *Brunauer*'s classification [96], or type V for narrow-pored substances [91,92,97] (Fig. 4).

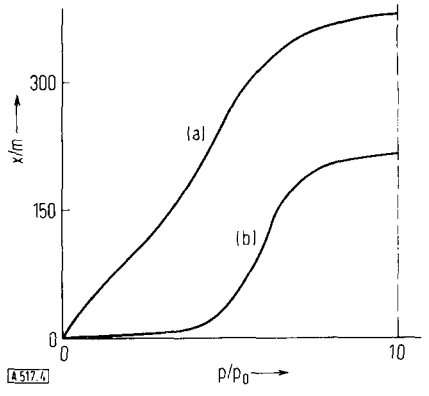

Fig. 4. Adsorption isotherms of water vapor on silica gel at 18 °C, after vacuum treatment at (a) 100 °C, (b) 1000 °C. The desorption branches are not shown (after [97]).

$p/p_0$ = equilibrium pressure/saturation pressure at 18 °C; x/m = quantity of water adsorbed in mm$^3$/g of silica gel.

Siloxane linkages are cleaved by nucleophilic attack on the silicon. The best-known example is the dissolution of $SiO_2$ in alkalis. Similarly, Aerosil is attacked by organolithium compounds [98]. The reaction with phenyl-lithium gives tetraphenylsilane, triphenylsilanol, diphenylsilanediol, and polymeric siloxanes. The $SiO_2$ surface contains phenyl groups bound to Si.

Silanol groups have been detected on the surface of crystalline quartz [55]. Chemical detection is difficult in this case owing to the small specific surface area. The $Na^+$ uptake from sodium hydroxide solution labelled with $^{22}Na$ gives a value of 4.25 OH/100 Å$^2$ for the packing density of the silanol groups [99]. OH groups have also been detected in the high-pressure modifications coesite and stishovite [100]. Stishovite, in which the silicon atoms have the coordination number 6, dissolves more rapidly in water than the other modifications of $SiO_2$, but is completely insoluble in hydrofluoric acid [100]. Its surface chemistry should resemble that of its structural analogue, rutile, *i.e.* it should point to the presence of strongly polar Si–O bonds.

## 5. Surface Compounds on Titanium Dioxide

Titanium dioxide has three naturally occurring modifications, rutile, anatase, and brookite, the first two of which are produced industrially as important white pigments. In all three crystal lattices, the $Ti^{4+}$ ions are surrounded by slightly distorted octahedra of six $O^{2-}$ ions, and the coordination number of the oxygen with respect to titanium is 3. The bonding may be regarded as essentially ionic. This leads to differences in behavior between the surfaces of titanium dioxide and of silica.

Hydroxyl groups have been detected on the surface of titanium dioxide by their infrared absorption [101, 102]. Whereas anatase still contained water molecules (bending vibration at 1605 cm$^{-1}$) after vacuum drying at 150 °C, two types of hydroxyl groups, which absorb at 3715 and 3675 cm$^{-1}$, remain at 350 °C. Under the same conditions, rutile gives only one band at 3680 cm$^{-1}$.

Water vapor adsorption and the heats of adsorption [103, 104], and the heat of wetting in water [105] also indicate that OH groups are still present on the surface of $TiO_2$ after evacuation at high temperatures. NMR measurements showed the presence of very firmly bound water in rutile after outgassing at 350 °C [106].

How can the presence of hydroxyl groups be explained? Figure 5 shows a section through an anatase crystal in the (100) plane. If the crystal is imagined to be cleaved along the (001) plane (broken line), it has the surface structure shown in Figure 5a: each $Ti^{4+}$ ion lacks one $O^{2-}$ ion in its coordination sphere, and each $O^{2-}$ ion has only two $Ti^{4+}$ neighbors. It may be assumed that in the

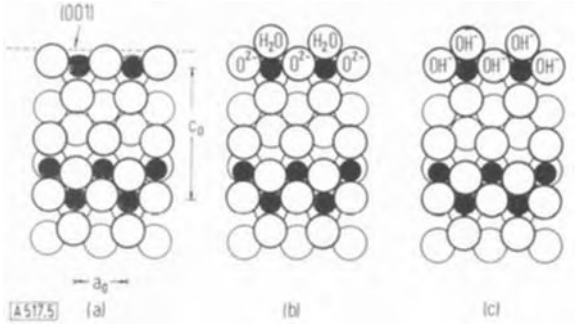

Fig. 5. Addition of water and formation of hydroxide ions on a fresh cleavage plane of anatase ( ●: Ti; O:O).

(a) Fresh cleavage plane along (001); (b) completion of coordination of the $Ti^{4+}$ ions by addition of water; (c) formation of hydroxide ions by proton transfer to the $O^{2-}$ ions on the surface.

presence of water vapor, the coordination gaps on the $Ti^{4+}$ ions are immediately filled by $H_2O$ molecules (Fig. 5b). The equilibrium vapor pressure of the water adsorbed in this way can be expected to be very low. However, even this state is not stable. Proton transfer from $H_2O$ to $O^{2-}$ (Fig. 5c) gives a surface covered with hydroxide ions, in which the charge distribution is much more favorable.

According to *Pauling*'s electrostatic valence rule [107], the negative charge on any anion in a stable ionic lattice is equal or nearly equal to the sum of the "strengths" of the electrostatic bonds joining the anion to the surrounding cations (and *vice versa*). The strength of a bond is defined as the quotient of the charge, z, and the coordination number, ν, of the cation. Thus the charge on the anion, ζ, is given by

$$\zeta = \sum_i z_i/\nu_i$$

Thus in anatase, the charge on the anion situated above the $Ti^{4+}$ ion should be −2/3, while the charge on the oxygen ion bound to two cations should be −4/3. This requirement is better satisfied by the charge −1 on the hydroxide ion than by the arrangement of Fig. 5b, in which the charge on the water is zero and that on the oxygen is −2. In other words, the stable state is that with the lowest potential, *i.e.* with the lowest free energy, and with the lowest possible charges and the minimum separation of opposite charges. Since the bonding forces on the surface OH groups act in only one direction, the distance from these groups to the $Ti^{4+}$ ions should be slightly shorter. A very similar situation is found on the other cleavage planes of anatase[(111) is the most common] and on those of rutile. This is also true of many other metal oxides.

In experiments with titanium dioxide, its sensitivity to reduction is important. When finely divided titanium dioxide is heated in vacuum, it turns gray to blue-gray, whereas it remains white when heated in air. This color change can be attributed to adsorbed organic impurities which are nearly always present [104, 108]. On decomposition these form carbon, which reduces $Ti^{4+}$ to $Ti^{3+}$.

Organic contamination of the surface is a very common phenomenon, and the contaminants can be determined analytically in substances with sufficiently large specific surface areas. Finely divided anatase ($TiO_2$ P 25 [*], specific surface area 56 m$^2$/g) was found to have a carbon content of 0.11%, and Aerosil ($SiO_2$, specific surface area 145 m$^2$/g) also to contain 0.11% of carbon [109]. The organic impurities are presumably derived from volatile constituents (*e.g.* antioxidants) of

[109] *M. Herrmann*, Dissertation, Universität Heidelberg 1965.

the plastic containers, from solvents in the laboratory atmosphere, from vacuum greases, and from respiration products of plants [110]. The carbon content of titanium dioxide could be reduced to 0.06% by extraction with petroleum ether followed by vacuum outgassing or by treatment with ozone at 100 °C [109]. The carbon remaining after this treatment was traced to $CO_2$, which is adsorbed on anatase even at low partial pressures. At 25 °C and a $CO_2$ pressure of 7 mm Hg (corresponding to a relative pressure $p/p_o = 1.4 \times 10^{-4}$), the product $TiO_2$ P 25 adsorbs 2 mg of $CO_2$ per g of $TiO_2$. The adsorbed $CO_2$ can be detected in the infrared spectrum [101].

The oxidizing power of $TiO_2$ is greatly increased by ultraviolet light [111]. Under these conditions, triphenylmethane derivatives can be oxidized to the leuco bases of the corresponding dyes [112]. Owing to this oxidizing power on irradiation, paints containing untreated $TiO_2$ rapidly deteriorate in light. To avoid this "chalking", the pigment particles are coated with thin layers of other oxides, such as alumina or silica.

The hydroxide ions on the surface of $TiO_2$ can be detected by their reactions, *e.g.* by esterification with alcohols [77, 113, 114]. Reactions with trimethylsilyl chloride and with triisopropylaluminum have also been described [77, 114] (see also Table 3).

Table 3. Reactions of OH groups on the surface of anatase ($TiO_2$ P 25), specific surface area 56.1 $m^2/g$ [109].

| Reaction | Conversion (mmole/100 g of $TiO_2$) |
|---|---|
| Deuterium exchange with $D_2O$ after outgassing at 100 °C | 38 |
| Sorption of $F^-$ from unbuffered NaF solution | 22 |
| Sorption of $F^-$ from NaF solution at pH 4.65 | 44 |
| $F^-$ content after washing with $H_2O$ | 16 |
| Sorption of $Na^+$ from NaOH | 36 |
| Sorption of $Ba^{2+}$ from $Ba(OH)_2$ | 42 |

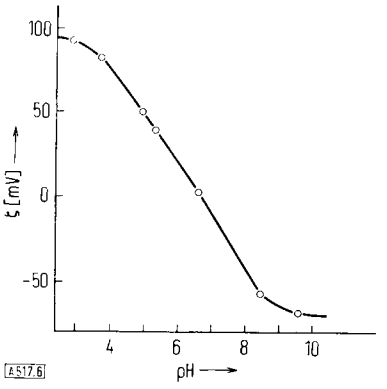

Fig. 6. Electrokinetic potential $\zeta$ of anatase ($TiO_2$ P 25) as a function of the pH, calculated from the electrophoretic mobility. Isoelectric point: pH 6.6.

The hydroxylated surfaces of anatase and of rutile are amphoteric [109, 115]. Figure 6 shows the relationship between the electrokinetic potential and pH for $TiO_2$ P 25. The isoelectric point is at pH 6.6. Consequently, $TiO_2$ can exchange hydrogen ions for cations in alkaline solutions, and the OH groups can be neutralized with alkali hydroxides [109]. Anions, and particularly fluoride, sulfate, and phosphate ions, are bound in acidic media. Industrial $TiO_2$ nearly always contains phosphate, most of which can be washed off with NaOH, and which must therefore be attached to the surface. The exchange of fluoride proceeds to completion even at low equilibrium concentrations (cf. Fig. 7). Unbuffered solutions are weakly alkaline.

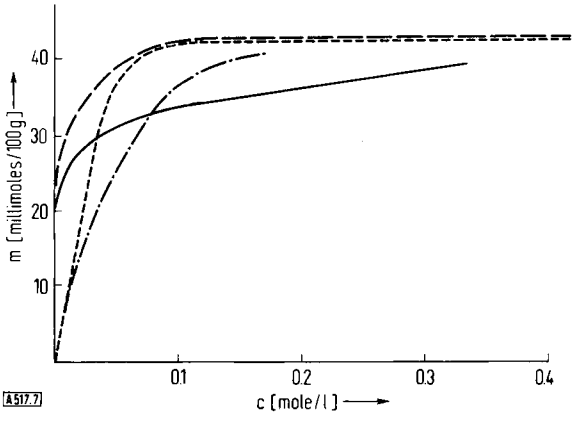

Fig. 7. Adsorption isotherms on anatase ($TiO_2$ P 25) at 23 °C.

An interesting observation was made in the adsorption of $F^-$ ions from NaF [109]: whereas finely divided $TiO_2$ (anatase) forms very stable suspensions in aqueous media, which separate only slowly even in a high-speed centrifuge, rapid flocculation occurs when fluoride is added. This is explained by the replacement of $OH^-$ ions on the surface by $F^-$ ions, so that dissociation to form $H^+$ is no longer possible. The surface charge of the $TiO_2$ particles in neutral or weakly alkaline media is then insufficient to stabilize the suspension.

The results of a number of reactions on an anatase sample are summarized in Table 3. Either 16–20 or about 40 milliequivalents of OH groups react per 100 g of $TiO_2$, in agreement with the presence of two infrared absorptions (3715 and 3675 $cm^{-1}$) [101]. 40 mequiv/100 g corresponds to a packing density of 4.3 OH/100 Å$^2$. The average packing density estimated from the structure of the various crystal surfaces is 14 OH/100 Å$^2$, and 7 OH/100 Å$^2$ in the outermost layer. As in $SiO_2$, fewer OH groups are found than expected. From the water loss on ignition of anatase, a value of 12 μmole of $H_2O/m^2$, corresponding to 14.4 OH/100 Å$^2$, was obtained [103]. When the sample was heated to high temperatures and rehydroxylated, the content of chemisorbed water decreased to 4.1 μmole/m$^2$, corresponding to 4.9 OH/100 Å$^2$.

Fig. 7 shows a number of adsorption isotherms for the same sample. In the presence of the alkalis, half of the hydroxyl groups are neutralized even at very low equilibrium concentrations (0.002 M). Further sorption involves less energy, as shown by the small slope of the isotherm, perhaps because half of the OH groups are much less acidic, or because additional $OH^-$ ions are adsorbed on the surface. In the reaction with $F^-$ ions, 20 mmole of $OH^-$ ions/100 g again react at very low equilibrium concentrations. The isotherms rise much more slowly in the sorption of phosphate ions ($Na^+$ ions are adsorbed at the same time) and in the hydrolytic adsorption of $Al^{3+}$.

The dye dimethylaminoazobenzene (butter yellow) is not adsorbed from benzene solutions on anatase, whereas methyl red is adsorbed as the red cation. Butter yellow ($pK_a = 3.3$) changes color at a lower pH than methyl red ($pK_a = 4.9$). When anatase is exposed to sunlight or ultraviolet radiation, however, butter yellow is also adsorbed to give a red color (18 mmole of butter yellow/100 g of anatase P 25). Evidently the surface becomes more strongly acidic on reduction, as is also shown by the increase in catalytic activity in the elimination of water from tert.-butyl alcohol [109]. Partially reduced $TiO_2$ also catalyses the Fischer-Tropsch synthesis [116]. Magnetic susceptibility and electrical conductivity measurements [116] show that the $Ti^{3+}$ ions formed on reduction are situated at the surface. It may therefore be assumed that protons are added to equalize the charge, and that these protons are responsible for the more strongly acidic reaction. The acidity of the reduced surfaces probably also contributes to the breakdown of paint binders, particularly in the case of esters such as alkyd resins.

## 6. Surface Compounds on Alumina and on Silica-Alumina

The surface of aluminum oxide is fundamentally similar to that of $TiO_2$. The number of crystalline modifications of $Al_2O_3$ is large. Apart from α-$Al_2O_3$ (corundum), there are at least eight other oxides, which are generally grouped together under the name γ-$Al_2O_3$ [117]. Some of these forms are probably non-stoichiometric oxide-hydroxides. Hydroxyl groups are present even in samples that have been heated to high temperatures, and can be detected by infrared spectroscopy [118, 119] and by proton magnetic resonance measurements [120]. The presence of hydroxyl groups on the surface was demonstrated by deuterium exchange [121] and by esterification with alcohols [114, 122]. The surface esters are very readily hydrolysed.

Interest in the surface chemistry of alumina and of the amorphous mixed oxides of silicon and aluminum is concentrated mainly on the strongly acidic groups formed when the samples are heated to 500–600 °C. Owing to these acidic properties, the oxides are used on a large scale as catalysts in petroleum chemistry. The question of whether the acidity is due to readily dissociable protons (Brønsted acids) or to electron acceptors in the surface (Lewis acids) is a subject of lively discussions.

A description of the many experimental arguments for and against the wo views would lead beyond the scope of the present paper. A dehydrated alumina catalyst is readily poisoned by water, whereas the catalytic activity of $SiO_2$–$Al_2O_3$ mixed oxides is impaired, but not inhibited completely. The spectrum of pyridine adsorbed on γ-$Al_2O_3$ dehydrated at 450 °C indicates that only Lewis acids are present [123]. On the other hand, both Lewis acids and Brønsted acids have been detected in $SiO_2$–$Al_2O_3$ mixed oxides [123, 124]. Accurate measurement of the wavelength of the X-ray fluorescence of the aluminum shows that up to relatively high $Al_2O_3$ contents, all the $Al^{3+}$ ions are tetrahedrally coordinated, *i.e.* they presumably replace $Si^{4+}$ in the three-dimensional $SiO_2$ lattice [125]. Electroneutrality is probably achieved by protons incorporated in the network. Chemical reactions have so far revealed only silanol groups, and no Al–OH groups [87].

Aromatic hydrocarbons such as perylene are oxidized to radical cations on adsorption on the surface of such a catalyst, as is shown by absorption spectra and electron spin resonance measurements [126–129]. This oxidation occurs even in the absence of oxygen [127]. Triphenylamine [130] and iodide anions [131] are also oxidized. The number of oxidation equivalents of a mixed-oxide catalyst of this type is much lower than the number of Lewis or Brønsted acid equivalents. For this reason, suggestions that these acidic centers are connected with

the oxidizing power [128-129] appear unlikely. The oxidizing power and the catalytic activity may be due to defects in the structure, *i.e.* in the coordination of the metal ions in the oxides [132]. Different types of reactions are evidently catalysed by different active sites; thus the addition of alkali, which suppresses the catalysis of one reaction, often has relatively little influence on another [87, 133]. Cracking processes may proceed *via* carbonium ions formed on acidic centers, as well as *via* free radicals formed at oxidizing centers [134]. The nature of the products depends on which of these routes is followed.

# The Structure of Glasses

BY PROF. DR. H. KREBS

LEHRSTUHL FÜR ANORGANISCHE UND ANALYTISCHE CHEMIE
DER TECHNISCHEN HOCHSCHULE STUTTGART (GERMANY)

*A melt can readily solidify to a glass with a three-dimensional or two-dimensional network, or a chain structure, provided that an irregular bonding system can be formed by virtue of free rotation about the bonds between a central atom and the ligands which function as bridging atoms. Such an irregular structure can arise when the system contains a sufficient amount of bridging atoms such as O, F, and S, or bridging groups such as $CH_2$, with bond angles less than 180°. When the network is formed predominantly by trivalent and tetravalent elements, such as As and Ge, the glasses – though they cannot be prepared by cooling of melts – can be obtained by other processes, e.g. by condensing the vaporized substances onto a surface (glasses in the wider sense of the word). As a result of extensive network formation, the bonding system and, therefore, the short-range order of the atomic arrangement in the melt differ from those in the glass or the crystal. A liquid mixture of substances having unlike molecular size and shape also can form a glass on solidification. Moreover, glasses can be formed even when the system contains only one component opposing regular packing into a crystal lattice.*

## I. Introduction [1a–1c]

In 1945, the American Society for Testing Materials (ASTM) defined glass as "an inorganic product of fusion which has cooled to a rigid condition without crystallizing". This definition is unsatisfactory, since it excludes transparent plastics and glasses prepared by a process other than fusion. Thus, vitreous selenium can also be obtained by the condensation of selenium vapor on a slightly warm surface. Furthermore, β- or γ-arsenic exhibiting a conchoidal fracture typical of glasses, and amorphous to X-rays like vitreous selenium, can be prepared only by condensation of arsenic vapor on a surface heated to about 100 °C [2], since it crystallizes at 270 °C (far below the softening point). Using the term in the wider sense, we can, therefore, define glass as a solid substance characterized by dense packing of the atoms and a lack of long-range order in the network. According to this definition, amorphous $Al(OH)_3$ and $Cr(OH)_3$, for example, are not regarded as glasses; they are loose powders containing empty spaces ranging in size down to atomic dimensions.

*Tammann* [3] was the first to carry out systematic investigations concerning the vitreous state by means of modern scientific techniques. *Goldschmidt* [4] correlated structural parameters with glass formation, and his pupil, *Zachariasen* [5], developed these concepts further and expressed them in the simple form which has since become well known.

## II. Causes of Glass Formation

### 1. Glasses Having a Three-Dimensional Network

*Zachariasen* has attributed glass formation to the possibility of the formation of a three-dimensional network differing from a crystalline lattice by the lack

[1] *J. D. Mackenzie*: Modern Aspects of the Vitrous State. Butterworth, London. a) Vol. I, 1960; b) Vol. II, 1962; c) Vol. III, 1964.

of the regular, periodic repetition of the structural unit. However, the ordered and the defect networks have the same basic structure, and their energy contents are, therefore, similar. In a two-dimensional representation, Fig. 1 shows the difference in the way the $SiO_4$-tetrahedra are joined to one another in vitreous and crystalline silica. In the former, ordered domains are interspersed with disordered ones [6]. According to *Zachariasen*, a pure oxide can form a glass if

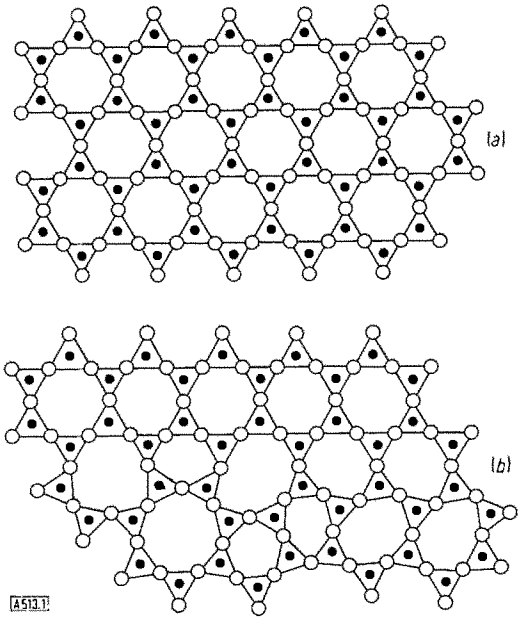

Fig. 1. Two-dimensional schematic representation of a crystalline (a) and a vitreous (b) $SiO_2$ network.
● network former (Si); ○ oxygen.

a) each oxygen atom is linked to not more than two central atoms (M);

b) the coordination number x of the $[MO_x]$ polyhedra is small;

c) these polyhedra share only corners, but not edges or faces;

d) in the case of a three-dimensional network, each polyhedron is joined to its neighbors by at least three corners.

Since glasses of the type of $M_2O$ and MO were unknown at that time, *Zachariasen* believed that only the oxides of elements having a coordination number (C.N.) of 3 or 4 can form glasses. Glass-forming oxides satisfying the above four conditions include $B_2O_3$, whose structural unit is the planar triangle $[MO_3]$; $As_2O_3$, whose structural unit is the trigonal pyramid $[MO_3]$; and $SiO_2$, $GeO_2$, $P_2O_5$, and $As_2O_5$ based on the $[MO_4]$ tetrahedra. Using the X-ray diffraction method, *Warren* [7] showed in 1933, within the accuracy then possible, that vitreous $SiO_2$ and $B_2O_3$ are in fact built of $SiO_4$ tetrahedra and $BO_3$ planar triangles, respectively.

[6] *A. E. Lebedev*: Stroenie stekla. Moskow-Leningrad, 1955. Cf. discussions in: The Structure of Glass. Proceedings of the Third All-Union-Conference on the Glassy State, Leningrad. Consultants Bureau, New York, Vol. I, 1958; Vol. II, 1960.

[7] *B. E. Warren*, Z. Kristallogr., Mineralog. Petrogr. *A 86*, 349 (1933).

In order to seek an explanation, the following reasons for irregular coupling of the coordination polyhedra, *i.e.* for glass formation, may be discussed:

a) Each M–O bond is capable of free rotation, though it is only when the oxygen has a coordination number of 2 that this free rotation effectively leads to the irregular linking of atoms. When oxygen has a coordination number of 3 or 4, fixing the position of two coordinated atoms automatically entails a complete or partial fixing of the direction of the third and fourth bonds. In such a case, therefore, disordered arrangement of the atoms is strongly opposed. We now understand not only the first, but also the second and the third of *Zachariasen*'s conditions, since a low coordination number of oxygen implies a low coordination number of the metal, owing to the fact that the ratio of the coordination numbers is inversely proportional to the stoichiometric ratio of the metal and oxygen atoms. Furthermore, if the coordination polyhedra share edges or faces, their mobility is again strongly restricted [8].

Oxygen also has a coordination number of 2 in the $ReO_3$ structure and in the perovskites ($CaTiO_3$ structure), which likewise are characterized by frequent lattice distortions, particularly well known in ferroelectrics with perovskite structure. It is thus understandable that for the preparation of optical glasses the oxides of Ca, Sr, Ba, and La, which readily occupy the calcium positions in the perovskite structure, are used in combination with the oxides of Al, Zr, Ta, and W [9], which are able to take up the titanium positions. However, glass formation is not very common for these structures, since the bond angle of the oxygen atom does not differ sufficiently from 180°. The perovskite structure of these glasses has not yet been confirmed experimentally.

b) Free rotation alone could hardly guarantee the saturation of valences and the formation of the typical $[MO_x]$ coordination polyhedra of all the atoms contained within a relatively large domain of an irregular network. In order to obtain irregular coupling, it must be possible to vary easily the valence angle of oxygen. Theoretically, this angle can lie between 90° (in a pure p-bond) and 180° (in a pure $sp^1$-hybrid bond); its value in crystalline silicates is between 130 and 180° [10].

c) In silicates, each oxygen atom invariably connects two $[SiO_4]$ tetrahedra, and only corners, but no edges and faces, are shared. There is only one unstable modification of silica in which the $[SiO_4]$ tetrahedra share edges and form chains [11] (Fig. 2). However, just as anomalous linkages arise on defect sites in crystal

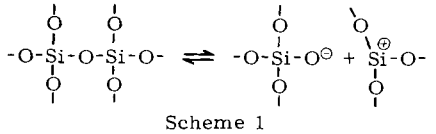
lattices, the [$SiO_4$] tetrahedra in silica glass will occasionally share edges whenever the requirements to neutralize all valences and to occupy the coordination sites cannot otherwise be fulfilled on steric grounds. Similarly, an oxygen atom is sometimes linked to three [$SiO_4$] tetrahedra [12]. At the same time either an equivalent number of oxygen atoms gives up its bridging function and remains linked to only one silicon atom, or the coordination number of Si must increase, *e.g.* to 6, as is the case in a modification of silica with rutile structure, formed at 1300 °C under pressures exceeding 160000 atm [13].

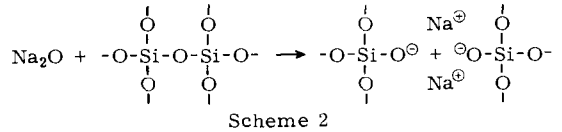
All the states mentioned in Section c), which are not normal for silicates, permit the continuation of the network in silicate glasses even when the disorder inhibits normal linking of the [$SiO_4$] tetrahedra. Such atom arrangments arise particularly in the softening of glasses, since local change of configuration results in a certain mobility of the atoms. The energy requirement involved is probably smaller than for the thermal dissociation shown in Scheme 1.



Scheme 1

The pronounced tendency of $GeO_2$ towards glass formation is connected with the fact that [$GeO_6$] octahedra of the rutile modification can easily arise, in addition to [$GeO_4$] tetrahedra of the quartz modification. *Kordes et al.* [14] have shown that in $BeP_2O_6$, $ZnP_2O_6$, and $MgP_2O_6$ glasses the central atom also has a tetrahedral configuration. When additional quantities of BeO, ZnO, and MgO are introduced, the extra Zn and Mg atoms become surrounded by six oxygens, but Be retains its coordination number of 4, which it can do only if a corresponding number of oxygen atoms becomes linked to three central atoms (P or Be).

The technically important silicate glasses contain, besides $SiO_2$, large amounts of basic oxides such as $Na_2O$, $K_2O$, MgO, CaO, and BaO, as well as more nearly neutral oxides such as $Al_2O_3$. In the melt the basic oxides contribute their oxygens to the network as shown in Scheme 2.



Scheme 2

The network is partially broken and becomes more mobile. Consequently, the softening point falls from about 1500 °C (pure $SiO_2$ glass) to 400–800 °C for technical grade silicate glasses.

Fig. 3 is a two-dimensional representation of a partially disrupted network. The central atoms M (*e.g.* Si) at the centers of the oxygen polyhedra are known as network formers, while the basic metal oxides (or in some cases

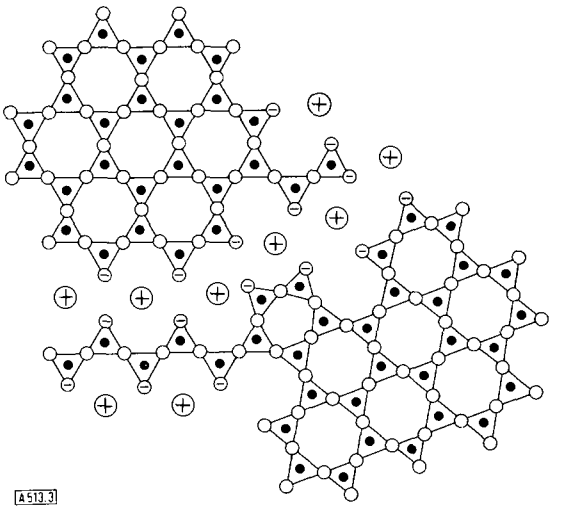


Fig. 3. Two-dimensional schematic representation of an $SiO_2$ glass containing network modifiers.

● network former (Si); ⊕ network modifier (cation); ○ bridging oxygen; ⊖ oxygen linked to network former and network modifier atoms.

the metals themselves) disrupting the network are called network modifiers. Fig. 3 shows that some of the oxygen atoms still act as bridges, while others are now linked to the network former atom only by one bond, the other valence being saturated ionically. Strongly basic metal oxides, such as $Cs_2O$, have a very pronounced tendency to contribute oxygen ions to the $SiO_2$ network, and are miscible in all proportions with $SiO_2$ in the silica-rich region. The depression caused in the melting point of silica (cristobalite) obeys Raoult's law [15] (see Fig. 4). When the melt is subjected to

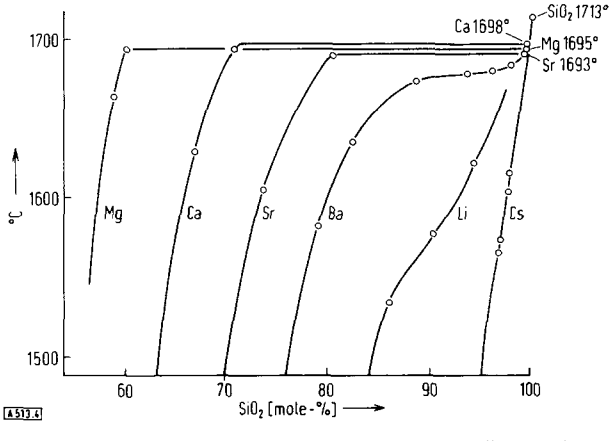

Fig. 4. Phase diagrams of the systems formed by cristobalite and the oxides of various alkali and alkaline earth metals [15].

moderately slow cooling, a glass is obtained. Substitution by a less basic oxide, such as $Li_2O$ or BaO, results in a deviation from the ideal behavior. With weakly basic oxides (*e.g.* MgO, CaO, and SrO), two melts are formed, each of which can solidify to a glass. One melt contains about 99 mole-% of $SiO_2$ and about 1 mole-% of MgO (or CaO or SrO), and the other about 60, 70, or 80 mole-% of $SiO_2$ and about 40, or 30, or 20 mole-% of the metal oxide. Cristobalite is in equilibrium with the melts at 1695, 1698, and 1693 °C.

[12] *E. D. Lacy*, Physics Chem. Glasses *4*, 234 (1963).

[13] *S. M. Stishow* and *S. V. Popova*, Geokhimiya *10*, 837 (1961); *A. Preisinger*, Naturwissenschaften *49*, 345 (1962).

[14] *E. Kordes, W. Vogel*, and *R. Feterowsky*, Z. Elektrochem., Ber. Bunsenges. physik. Chem. *57*, 282 (1953).

[15] *F. C. Kracek*, J. Amer. chem. Soc. *52*, 1436 (1930).

The reason for the formation of two melts is that less basic oxides, such as MgO, have a greater tendency towards formation of suitable oxygen polyhedra than strongly basic oxides[15a]. One can, therefore, assume that, just as in crystalline magnesium-oxygen compounds, each magnesium atom in the melt and the glass is surrounded octahedrally by six oxygen atoms. Apparently, the network of $SiO_2$ melts contains only few octahedral holes (about 1 %) of suitable size to accept the magnesium atoms. In order that a larger number of $[MgO_6]$ octahedra may be formed, the linkage of the $[SiO_4]$ tetrahedra must be altered completely. It is relevant in this connection to compare, for example, the tridymite-like structure of ice with the network of water molecules in the gas hydrates[16].

As in the series of crystalline silicates, there will be an abundance of short-range order in the glasses. However, it has not yet been possible to ascertain the ways in which the coordination polyhedra are connected. X-ray investigations, ESR-s and NMR-spectroscopic methods, and optical measurements normally give information only about the nearest neighbors, and only occasionally the next nearest. As a result, only the coordination polyhedra can be described, and not the manner in which they are interconnected.

For example, the absorption spectrum of a glass containing 16 wt-% of $Na_2O$, 10 wt-% of CaO, 74 wt-% of $SiO_2$, and traces of $Cr_2O_3$ corresponds fully to that of a solution of Cr(III) in 80 % sulfuric acid[17]. X-ray determination of short-range order in glasses containing $Cs_2O$ or BaO has revealed that, whatever their concentration, the distances between Cs or Ba atoms are only about 4 Å, indicating that the metal atoms they are connected by oxygen atoms into units containing at least two Cs or Ba atoms[18].

More recently, it became obvious that *Zachariasen*'s rules are only of limited validity. For example, the requirement that the coordination number of the network formers must not exceed 4 is not valid. Thus $TeO_2$, whose crystalline form (brookite lattice)[19] consists of $[TeO_6]$ octahedra interconnected in a complicated manner, forms a glass when a few mole-% of a metal oxide (*e.g.* 9 mole-% of $Li_2O$) is added. According to an X-ray determination of the atomic distribution curve[20], the glass, too, is composed of $[TeO_6]$ octahedra, these being also evidenced by infrared absorption measurements[21]. It should be borne in mind, however, that Te(IV) [like Se(IV)] tends to form distorted trigonal bipyramidal coordination polyhedra in which one apex is occupied by an electron pair. In this case, the coordination number is 4 for tellurium and 2 for oxygen. Tellurium can, therefore, easily change its configuration on sites where no $[TeO_6]$ octahedra can be formed. Being isoelectronic with trivalent bismuth, Te(IV) can possibly also form the same kind of coordination polyhedra as bismuth, with C.N. = 4 or 3. In oxide glasses containing $GeO_2$ and $Ga_2O_3$ and an alkali oxide, a maximum in density and refractive index is observed in the neighborhood of 10 mole-% of alkali oxide[20a]. The $O^{2-}$ ions introduced with the alkali oxide make it possible for the Ge and Ga atoms to increase their coordination number to 6 in some instances, without the bridging oxygen atoms having to increase their coordination number to 3.

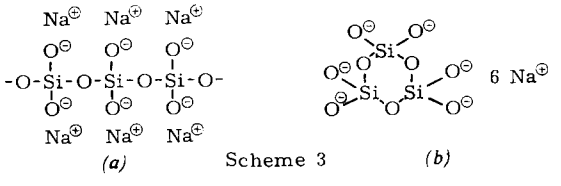
$$[GeO_{4/2}] + Na_2O \rightarrow Na_2^{+}[GeO_{6/2}]^{2-}$$

There are, furthermore, many glasses which do not have a three-dimensional network; the addition of a sufficient amount of network modifier oxides can break so many Si–O–Si bridges that a three-dimensional network can no longer exist.

### 2. Glasses Having a Chain Structure

In a glass having the composition $Na_2O{\cdot}2SiO_2$, each Si atom is linked to one negatively charged and three bridging oxygens. This gives rise to the possibility of formation of a two-dimensional lattice as in clay minerals, though it is not known yet whether such planar networks occur in silicate glasses.

It seems probable that at the composition of a metasilicate $Na_2O{\cdot}SiO_2$ the glass contains chains such as those in the pyroxenes (*e.g.* $MgCa(SiO_3)_2$; Scheme 3a), or rings such as those in benitoite ($BaTiSi_3O_9$; Scheme 3b). Glass formation can then be ascribed to the fact that these chains in the melt are no longer extended, but more or less coiled. Ordering to the long straight chains of a crystal is possible only with great difficulty.



*(a)* Scheme 3 *(b)*

Glasses with a chain structure include many organic high polymers such as polystyrene. The role of the bridging components of coordination number two (oxygen or methylene groups), frequently mentioned in the literature[22], is evident here.

### 3. Glasses Formed by Mixtures of Differently Shaped Molecules

A silica melt still solidifies into a glass when the $Na_2O$ content is increased beyond the equimolecular ratio, *e.g.* to 58 $Na_2O{\cdot}42\ SiO_2$, the long metasilicate chains being now shortened. Ignoring the rings, we find as a first approximation, on the basis of the chemical composition, that the mean chain length is 2.6 $[SiO_4]$ tetrahedra ($Na_{7.2}Si_{2.6}O_{8.8}$). The glass is probably formed from a mixture containing fairly short chains and small rings. In this case, glass formation depends not on

network formation, but on the inability of a mixture of differently formed anions to crystallize on solidifying [23].

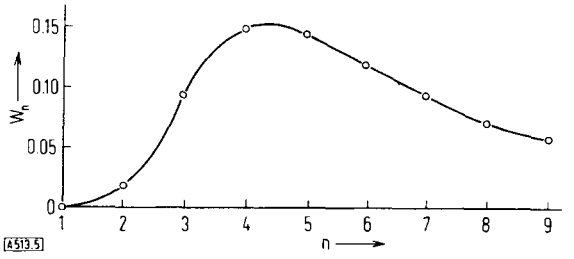

Fig. 5. Proportion $W_n$ of phosphorus present in chains of length n in a phosphate glass having the composition $Na_8P_6O_{20}$ [26] (cf. also [25] and [27]).

The structure of these silicate glasses cannot be elucidated by direct means, since, on being dissolved, these glasses react with the solvent. However, polyphosphate glasses may serve as models in an attempt to elucidate the structure of silicate glasses. Thus, *Thilo* and his school [23–26] have shown that alkali polyphosphates can be dissolved in water at room temperature without any change in their structure during the time required for chromatographic analysis (see Fig. 5).

### 4. Glasses from Single Compounds with Hindered Crystal Lattice Formation

Although the boiling point of toluene is higher (111 °C) than that of benzene (80 °C), which is to be expected on the basis of its higher molecular weight, the melting point of toluene (−95 °C) is surprisingly low in comparison with that of benzene (6 °C), indicating a hindered packing into a crystal lattice. When toluene is rapidly cooled, *e.g.* with liquid air, the time available is insufficient for the molecules to form an ordered arrangement, and therefore a glass is obtained. Similarly, it is easy to cool branched hydrocarbons to yield glasses, since thermal motion constantly changes the molecular configuration, and there is only one configuration which leads to the formation of a crystal lattice. As in the case of toluene, the asymmetry of these molecules opposes crystallization.

This group also includes nitrate mixtures whose melts readily solidify into glasses. Such a system is $KNO_3/Ca(NO_3)_2$ containing 53 to 70 mole-% of $KNO_3$ [28,29]. *Thilo* [30] has drawn attention to the fact that the transfer of the short-range order of cations from the melt to the crystal lattice of $KNO_3$ and $Ca(NO_3)_2$ is hindered in this system. Calcium nitrate crystallizes in a lattice related to that of fluorite [30a], while potassium nitrate can form a calcite lattice or an aragonite lattice; this dimorphism also facilitates glass formation.

### III. Microstructure of Glasses

In a number of cases the melting of glasses is accompanied by the appearance of opalescence due to the formation of small drop-shaped regions of a separate phase. This phenomenon depends on the composition and on the impurities (*e.g.* $SO_4^{2-}$) present in the glasses. It has been revealed by investigations based on small-angle X-ray diffraction [31,32] and electron microscopy [33,34] that many glasses which are clear to the naked eye actually contain such regions of inhomogeneity which may range in size down to the lower limit of detection (about 20 Å). Investigating the $Li_2O/SiO_2$ system, *Vogel* [35] has shown that these drop-shaped regions do not occur in pure $SiO_2$ glass and in the disilicate glass of composition $Li_2Si_2O_5$, but they do occur in the composition range between these two points, as well as in glasses containing a greater amount of $Li_2O$. The size of the droplets increases the more the composition deviates from pure $SiO_2$ and $Li_2Si_2O_5$. It has also been shown by chemical analysis that the composition of the droplets and the matrix in which they are embedded corresponds approximately to the limiting compositions $SiO_2$, $Li_2Si_2O_5$, and $Li_2SiO_3$.

Glasses are generally homogeneous, *i.e.* free from droplets, only within a narrow range of composition. As in the case of crystals (though not so critically) the short-range order in the glass lattice is apparently connected with certain fixed stoichiometric ratios. In a homogeneous glass, more ordered and less ordered regions alternate with one another (see Fig. 1), while in an inhomogeneous glass the phases are juxtaposed as in Fig. 3. This situation recalls the crystallite theory, developed in particular by Soviet authors [6].

The great variability in composition of a silicate glass appears, therefore, to rest not so much on the irregularity in atomic order, but rather on the mixing ratios of two finely divided phases. *Dietzel* [36] tried many years ago to trace some peculiarities of the variation in physical characteristics of glasses with composition to a heterogeneity in small regions. Furthermore, *Biltz et al.* [37] have shown that for many glasses the molar volume can be expressed as the sum of the molar volumes of suitably chosen components.

A two-phase glass may contain one component in the crystalline, and the other in the vitreous state. Thus, the glass with a composition of 58 $MgO \cdot 42\ P_2O_5$ clearly includes a crystalline phase, probably having the composition $Mg(PO_3)_2$ [38]. In a silicate glass containing a large amount of PbO, a PbO-rich phase melts first, and the silicarich phase floats in it in the form of an extremely finely divided glass.

The two-phase character of the microdomains of glasses greatly depends on the temperature [35, 39], the droplets being larger at low temperatures. In silicate glasses containing $B_2O_3$ and an alkali oxide (*e.g.* 70 % of $SiO_2$, 25 % of $B_2O_3$, and 5 % of $Na_2O$), the cooling after molding can be directed in such a way that a coherent and water-soluble phase rich in $B_2O_3$ and the alkali oxide separates, which can be dissolved out of the glass with acids [40,41], leaving behind a porous structure containing about 95 % of $SiO_2$. The latter can be sintered into a dense mass at about 1200 °C. This "Vycor" glass closely resembles a pure $SiO_2$ glass in many of its properties.

The two-phase nature of the microdomains of many glasses also accounts for the observation that the distance between heavy atoms, in the cases so far investigated, is independent of their concentration: when the composition of a glass is varied, the composition of the phase that contains most of the heavy atoms essentially remains unchanged, and only its amount changes.

Thus, the Cs-Cs distance in the glass with composition $xCs_2O \cdot (1\text{-}x)SiO_2$ remains 4.1 Å when x is varied between 0.029 and 0.107 [42,43]. Cesium oxide crystallizes in an anti-$CdI_2$ lattice characterized by a Cs-Cs distance of 4.26Å. In the above glass, therefore, the cesium atoms appear to be interconnected *via* oxygen atoms. In a glass having the composition $xBaO \cdot yNa_2O \cdot (1\text{-}x\text{-}y)SiO_2$, the Ba–Ba distance is 4.0 Å in the composition range of x = 0.39 to 0.273 and y = 0 to 0.069 (in NaO with an NaCl lattice, $d_{Ba\text{-}Ba}$ = 3.9 Å) [42,43]. The corresponding value is appreciably larger (6.6–6.9 Å) in borate glasses of the type $NaO \cdot xB_2O_3$ in the range x = 1.7 to 4 [44]. These data indicate that the barium atoms are connected by an O–B–O group forming part of a $[BO_3]$ triangle or a $[BO_4]$ tetrahedron.

## IV. Special Glasses

### 1. Halide Glasses

According to some authors [22,45], the formation of a glass results from the fact that the atoms of the network are linked by a mixture of covalent, ionic, and metallic bonds as well as van der Waals forces. In our opinion, this condition is not essential. It is the steric circumstances – in case of the network glasses through the presence of bridging atoms – which has to allow for a disorder. Thus, $BeF_2$, like $SiO_2$, is an excellent glass-former. Its crystalline form is characterized by a cristobalite lattice, while its vitreous form is completely analogous to the $SiO_2$ glass [4]. Just as silica forms glasses with alkaline earth metal oxides, beryllium fluoride forms glasses with alkali metal fluorides. The relationship is so close that the following glass analogues have practically the same composition ranges of phase homogeneity: $LiF–BeF_2$ and $MgO–SiO_2$; $NaF–BeF_2$ and $CaO–SiO_2$; $KF–BeF_2$ and $SrO–SiO_2$; and $RbF–BeF_2$ and $BaO–SiO_2$ [46]. This is because beryllium, like silicon, invariably has a coordination number of 4 with tetrahedral arrangement of the ligands. Furthermore, fluorine has here a coordination number of 2 and has the same bridging function as oxygen in the silicate glasses. The differences in the nature of the bonds are of no importance.

Zinc chloride forms a viscous melt which, like $BeF_2$, sets to a glass. This glass is rapidly hydrolysed in air [47]. The fluoride glasses developed by *Sun* and *Huggins* [48] seem to belong to the glasses whose short-range order is probably the same as that of the $ReO_3$ lattice or the perovskite lattice.

### 2. Borate Glasses

Boric oxide readily forms glasses by itself or with numerous other oxides. An important point in this connection is whether the structure is based on $[BO_3]$ triangles or on $[BO_4]$ tetrahedra. Only recent investigations based on infrared absorption [49] and NMR spectroscopy [50] have revealed that in $B_2O_3$-glass each boron atom is surrounded by three oxygen atoms forming an equilateral triangle, and that each oxygen atom connects two boron atoms. When an alkali oxide (up to 30 mole-%) is added, each $O^{2-}$ ion introduced is utilized to increase the coordination number of boron to 4. On further addition of alkali oxide

$$M_2O + B_2O_3 \rightarrow 2\ M[BO_2]$$

(up to 50 mole-%), the proportion of tetrahedra first remains practically unchanged, and then rapidly decreases. When the glass contains 70 mole-% of $M_2O$, *i.e.* somewhat more than corresponds to the formula $M_4[B_2O_5]$, all the boron atoms again have a coordination number of 3. However, this phenomenon cannot yet be explained. Furthermore, the line-width of the NMR spectra indicates that the environment of the $[BO_3]$-triangles is not always the same in these glasses containing alkali oxides.

### 3. Lead Glasses

As has already been mentioned, polyvalent cations such as $Mg^{2+}$, $Cr^{3+}$, $Be^{2+}$, $Zn^{2+}$, $Pb^{2+}$, $Bi^{3+}$, $Al^{3+}$, $Ti^{4+}$, and $Zr^{4+}$ in glasses develop coordination polyhedra cor-

responding to their own requirements. The greater their tendency towards formation of their own coordination sphere with oxygen atoms, the more closely do these network modifiers approximate to the role of network formers.

Glasses containing $Pb^{2+}$ and $Bi^{3+}$ deserve special mention. The amount of PbO in binary glasses can be very high, *e.g.* up to 67 mole-% in $SiO_2$, up to 77 mole-% in $B_2O_3$, and up to 62 mole-% in $P_2O_5$ [51]. This indicates that, despite the inability of pure PbO to form a glass, the lead atom in the above glasses must be able to form a network with oxygen. The ionization energy of the bivalent $Pb^{2+}$ ion (517 kcal/mole) is much higher than that of strontium (348 kcal/mole), which has the same atomic dimensions, indicating that the Pb–O bond is relatively strong. However, it is difficult to elucidate the exact nature of this bond, since bivalent lead forms a great variety of coordination polyhedra with oxygen, the coordination numbers of $Pb^{2+}$ being as follows: 12 in the perovskite-type lattice, 6 in magnetoplumbite; 4 in red tetragonal PbO; 3 in $Pb_3O_4$; and 2 in yellow rhombic PbO. It is, therefore, not surprising that lead can assume various functions in glasses.

Thus, recent NMR data indicate [52] that, similarly to alkali metal oxides, PbO acts at first as a network modifier in $PbO/B_2O_3$. The $Pb^{2+}$ ion here has a high coordination number and the oxygen is utilized for converting the $[BO_3]$ triangles into $[BO_4]$ tetrahedra, forming a network with the former. When the amount of PbO exceeds 15 mole-%, not all the oxygen atoms are used to form $[BO_4]$ tetrahedra. More specifically, in a glass containing 50 mole-% of PbO, *i.e.* having a composition of $Pb(BO_2)_2$, the proportion of the $[BO_4]$ tetrahedra is not 100 %, but only 50 %. This, in fact, is the highest attainable concentration of the $[BO_4]$ tetrahedra, since further addition of PbO is accompanied by a decrease in this concentration.

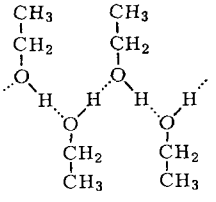
The NMR spectra show that when lead has a lower coordination number with respect to oxygen, it is linked only to $[BO_3]$ triangles and not to $[BO_4]$ tetrahedra [53]. This can be easily explained on the basis of *Pauling*'s electrostatic bond force [54], defined as the ratio of the oxidation number and the coordination number of the central atom (in this case B and Pb). In stable ionic lattices, the sum of the bonding forces of the bonds formed between the central atom and the anions (here oxygen) is numerically equal, or nearly equal, to the charge on the anions. In the case of $O_2B–O–Pb$, the charge on the oxygen is 2 (B–O, 3/3; Pb–O, 2/2). In the $[BO_4]$ tetrahedron and a non-linear $[PbO_2]$ group, however, oxygen has a charge of only 1.75 (B–O, 3/4; Pb–O, 2/2). Oxygen can have a charge of 2 if some of the O atoms assume a coordination number greater than 2. On the other hand, this is known to be unfavorable for glass formation.

This does not exclude that lead forms further weak bonds with other O atoms, as *e.g.* in yellow PbO. If, however, it is assumed that the lead atoms in $PbO–B_2O_3$ glasses with a high PbO content as in red PbO and $Pb_3O_4$ are surrounded by, respectively, four or three O atoms having a pyramidal configuration, the coordination number of the oxygen must again exceed 2. This is unfavorable for glass formation, but its occurrence cannot be excluded, provided that a sufficient number of Pb atoms with a coordination number of 2 is present in the glass.

The fact that lead easily can change its coordination number and the form of the coordination polyhedra permits the rearrangement of atoms, provided that oxygen can increase its coordination number. This may account for the ready softening of lead glasses. The glasses formed by $Bi_2O_3$ resemble lead glasses [51,55].

## 4. Glasses Containing Hydrogen Bonds

Molecules containing hydrogen bonds are good glass formers. Thus, on being cooled with solid $CO_2$, ethanol forms a glass which X-ray studies [56] suggest to contain long chains built up as follows:



This glass formation is due to the chain structure and the possibility of free rotation about the hydrogen bonds. In the case of water, each molecule is surrounded by four (sometimes three) neighbors. Water can form a glass only when it is subjected to sudden cooling with liquid air [57]. However, glass formation is facilitated by the addition of substances that can form hydrogen bonds with water, since this enhances the degree of disorder.

It is well-known that concentrated solutions of $H_2SO_4$, $H_3PO_4$, and sugar readily form glasses, as do also ethylene glycol, glycerol, and aqueous phenol.

## 5. Glasses Formed by Metals and Salts

In contrast to the above glasses, obtained by cooling of a melt, there are many similar substances – glasses in the wider sense of the word – which are prepared differently [58], *e.g.* by the condensation of vapors on cooled surfaces [59].

The condensation of vapors of pure metals or alkali halides onto a surface cooled to 20 °K leads, with the exception of a few metals, to a crystalline deposit. In the presence of impurity vapors (*e.g.* KI containing 10 % of KF, or Sn containing Cu) condensation in the vitreous state is obtained under the same conditions. Likewise, the condensation of a Bi vapor containing some Ga yields a glass which is stable at room temperature. Whereas CuCl, AgCl, and AgBr behave like the alkali

metal halides when deposited from the vapor phase, TlCl, TlBr, and TlI form amorphous deposits, the last two crystallizing only at 110 and 140 °K. This difference in behavior is probably connected with the fact that thallium halides tend to form complicated lattices (cf. the lamellar structure of TlI)[60].

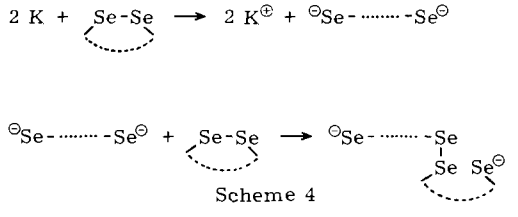
## 6. Chalcogenide Glasses

These glasses are formed when oxygen is replaced by S, Se, or Te. The name is not quite correct, since the chalcogens include oxygen.

### a) Vitreous Elements

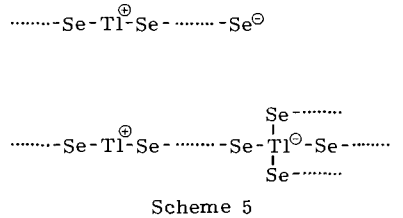
Vitreous selenium is formed when a selenium melt is subjected to moderately slow cooling. The formation of a state characterized by rubber-like elasticity at 70 °C is followed at 30 °C[61] by solidification to a glass which is usually thought to have a chain structure, though it contains about 40 wt-% of $Se_8$ rings which can be extracted with $CS_2$. The remainder consists of large rings containing on an average about 500 Se atoms. The presence of rings of different shape and size inhibits crystallization[62–64].

When traces of an alkali metal, particularly potassium, are added to the selenium melt, the latter assumes a highly mobile state because the large rings are broken up with formation of polyselenide ions, the extremely reactive ionic chain-ends of which attack neighboring selenium rings (Scheme 4).



Scheme 4

A potassium-containing selenium melt is so highly reactive that even quenching leads to well developed hexagonal selenium crystals. The effect of thallium is similar to that of potassium, but is much less pronounced. Scheme 5 shows the atomic arrangement presumably present in the melt[63,64].



Scheme 5

Owing to the fact that they rupture the network, alkali metals and thallium often lower the softening points of binary and ternary chalcogenide glasses.

Similarly to selenium, plastic sulfur also solidifies to a glass on cooling[65]. It consists of a mixture of smaller rings (predominantly $S_8$ and $S_6$ rings) and large rings with an average molecular size of 5000 atoms[64]. A mixture of rings containing 20 to 30 sulfur atoms has recently been isolated[66].

The glasses formed by $(PNF_2)_n$ and $(PNCl_2)_n$ are presumably built in a similar manner of rings of different sizes[63,67].

Vitreous tellurium cannot be obtained by cooling of a melt, but only by condensation of tellurium vapor on a surface[63].

The trivalent and the tetravalent elements adjacent to the chalcogens in the periodic table (*e.g.* As, Sb, C, Si, and Ge) do not form glasses in the strict sense of the word, since the cooling of their melts leads to the formation of crystals. However, they can be obtained in the vitreous state by condensation of their vapors. These glasses devitrify at the following temperatures: As, 270 °C[62]; Sb, 20 °C[62]; Si, 700 °C[62]; Ge, 400 °C[68]. Prolonged heating of molten white phosphorus leads to polymerization into glassy red phosphorus devitrifying at 550 °C. The crystallization temperature of P, As, Sb, Si, and Ge decreases with increasing atomic weight owing to the fact that the bond between the atoms becomes progressively weaker as the atomic number is increased.

The atoms in glassy phosphorus[69], arsenic[70], and antimony[70] form such an extensive network that they cannot be melted without basic structural changes, and cannot, therefore, be obtained from the melts.

Red phosphorus melts at about 600 °C, the process being accompanied by depolymerization into $P_4$ molecules. The structure of molten arsenic is not yet known[71]. The antimony melt is characterized by an octahedral arrangement of the atoms[72], as is molten germanium at 300 °C above its melting point, the Ge–Ge distance being 2.81 Å. In this case, however, the structure is so disordered that the maximum of the atomic distribution curve is hardly noticeable for next nearest neighbors, and the structural disorder is even stronger as the melting point is approached. Each atom is then surrounded by six neighbors, but four are situated at 2.70 Å and two at 3.15 Å[73].

As antimony and germanium are heated, the nature of the bonds is changed. This comes from the fact that the valence electrons are in pure p-quantum states (Sb, Ge at high temperatures), or in p-states which are slightly hybridized with s-states (Ge just above the melting point). Now, p-orbitals are known to be symmetrically disposed on either side of the nucleus; when the contribution of s-character increases on hybridization, one lobe of the orbital increases and the other decreases. In the case of pure p-orbitals, bonding is ensured in two opposite directions along each coordinate axis. When sp-hybridization takes place, on the other hand, bonding is possible in one direction only, while the other bond ceases to exist. The mobility of the atoms and their high reactivity in the melt are due to the ready hybridization in this sense [74]. As a result of this, structural ordering, *i.e.* crystallization, can occur even on rapid cooling.

In their stable modifications, As, Sb, Bi, Se, and Te have three or two nearest and, respectively, three or four more distant neighbors, all of which form a distorted octahedron (Fig. 6). This geometrical arrangement cannot be explained on the basis of the classical

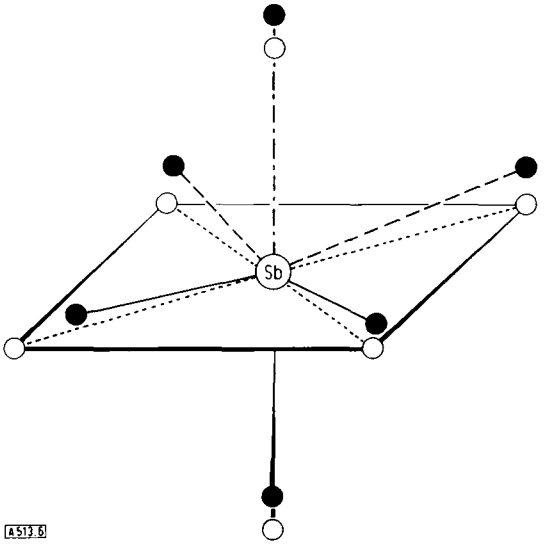

Fig. 6. Typical distortion of the coordination polyhedron incorporating As, Sb, or Bi.

Regular octahedron: ○ ligands; - - - bonds.
Distorted octahedron: ● ligands; ——— strong bonds; — — — weak bonds.

concept of bonding. According to the quantum-mechanical explanation, incomplete hybridization permits not only the preferred bond orientations (corresponding to the valence of the element), but also three or four weak and unfavored bonds [74,75]. Generally, the heavier the atom and the higher the temperature, the smaller is the difference between favored and unfavored bond orientations. In the case of heavy atoms, furthermore, these two types of bond orientation are present not only in the crystalline state and the melt, but also in the vitreous state. This has been confirmed by X-ray investigations on explosive antimony containing some chlorine. It has thus been found that each Sb atom is surrounded by three nearest neighbors situated at 2.90 Å and two more distant ones situated at 3.64 Å. This configuration appears to be similar to that in black phosphorus [70].

### b) Binary Chalcogenide Glasses

Table 1 shows the behavior of compositions of the type $M_2X_3$ on cooling at a rate of about 200 °C/sec (corresponding to quenching in water) [76,83].

Table 1. Solidification of compounds of the type $M_2X_3$.

| Sb | — | — | — |
| Bi | — | — | — |

+ glass formation.
— no glass formation.

Glass formation becomes progressively more difficult as the atomic weight increases. This has the following two reasons:

a) The bonds formed by the heavy atoms are weaker and can readily dissociate. The atoms can thus be arranged into a crystal lattice.

b) As mentioned before, the heavy atoms are able to bind loosely other atoms in addition to those bound closely according to the valence. At higher temperatures and, especially, in the melt the roles of closely and loosely bound atoms are readily interchanged as the atom of reference moves away from a close neighbor and approaches another one. Thus, rearrangement of the atoms and, thereby, crystallization is possible.

The cooling of a melt of $P_2S_3$ does not lead to a glass, since several definite compounds can arise in this system ($P_4S_3$, $P_4S_5$, $P_4S_7$, and $P_4S_{10}$). When a melt is heated to *e.g.* 900 °C, these compounds are formed to an extent of about 50 wt-%. When the melt is cooled, these compounds crystallize and can be extracted with $CS_2$. However, annealing for several hours at 270 °C promotes polymerization. In this case, cooling to room temperature leads to substances that can be drawn into threads, and glasses are formed on further cooling. Then only about 25 wt-% is soluble in $CS_2$ [77].

The composition of binary chalcogenide glasses can vary within wide limits [78,79]. Thus, in the As/Se and the As/S systems, the proportion of Se and S may be up to 100 and about 90 atom-%, respectively, but the As content cannot be increased to over 60 atom-%. As in the case of the oxide glasses, it is important here, too, that the coordination number of the chalcogen be 2 and the bond angle smaller than 180 °, since irregular linking is again due to free rotation and some flexibility of the bond angle of the bivalent bridging atoms.

## c) Ternary Chalcogenide Glasses

Since they have found technical importance, ternary chalcogenide glasses have recently been subjected to extensive investigations [80,81]. These glasses are generally obtained by melting together the components.

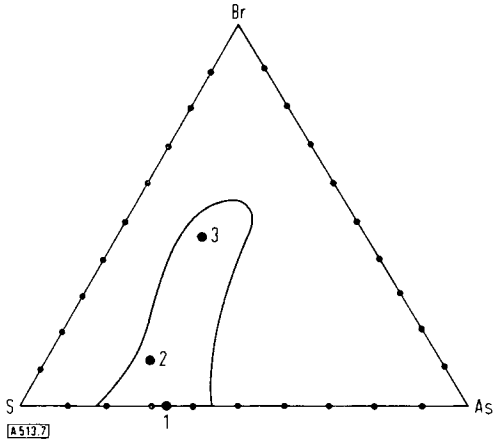

Fig. 7. Region of glass formation in the system As–S–Br [82].
1-$AsS_2$; 2-$AsS_{2.7}Br_{0.6}$; 3-$AsS_{1.8}Br_{2.5}$.

Fig. 7 shows the composition region in which glass formation occurs in the system As–S–Br [82]. Point 3 corresponds to the approximate composition $AsS_{1.8}Br_{2.5}$. This glass has a softening point of −60 °C and flows like water at room temperature. The glass formation is probably due to a mixture of small molecules whose composition is still unknown. When the bromine content is decreased and the sulfur content is raised, the molecules grow in size, since sulfur always links two atoms. As a result, the softening point increases: it is 90 °C for a glass with the approximate composition $AsS_{2.7}Br_{0.6}$ (point 2) and 200 °C for $AsS_2$ (point 1).

The region of glass formation of the chalcogenides of As, Sb, and Bi mixed with those of metals has been investigated by *Pearson* [82] and *Kolomiets* [83]. The addition of germanium and thallium chalcogenides results in large glass-forming regions. These regions generally decrease with increasing atomic weight, but thallium represents an exception. It appears that trivalent thallium can be incorporated in the network, in a state characterized by coordination numbers of 2 and 4. Thallium additions lead to decreased softening points of glasses.

*Hilton*, *Jones*, and *Brau* recently prepared some ternary chalcogenide glasses which are distinguished by relatively high softening points and, in some cases, transparency to infrared radiation [84,85]. Fig. 8 shows the glass-forming regions in the systems Ge-P-S, Ge-P-Se, and Ge-P-Te; the corresponding regions for the systems Si-As-Te, Ge-As-Te, Si-P-Te, and Ge-P-Te are shown in Fig. 9. The following deductions can be made from these figures:

a) Glass formation necessitates a relatively large proportion of the bivalent component (chalcogenide). The importance of the bridging atoms in the three-dimensional network of glasses in the strict sense of the word is again evident.

b) As the atomic weight increases along the series Si, Ge as well as in S, Se, and Te, the region of glass formation decreases. Systems containing Sn and Bi have only small glass-forming regions [86].

The relatively high softening points (up to 500 °C) indicate that the glasses included in Figs. 8 and 9 contain networks. It must also be born in mind, however,

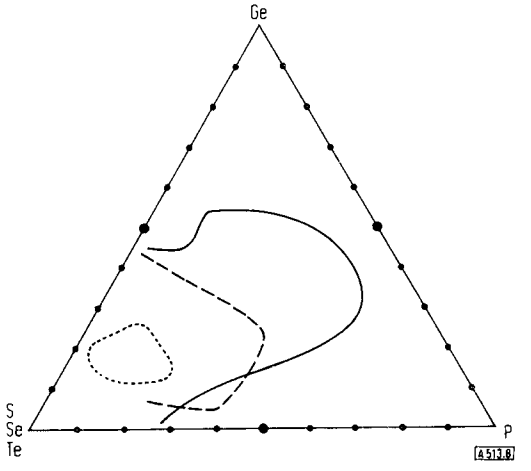

Fig. 8. Regions of glass formation in several systems.
——— Ge–P–S; – – – Ge–P–Se; · · · · Ge–P–Te [85,86].

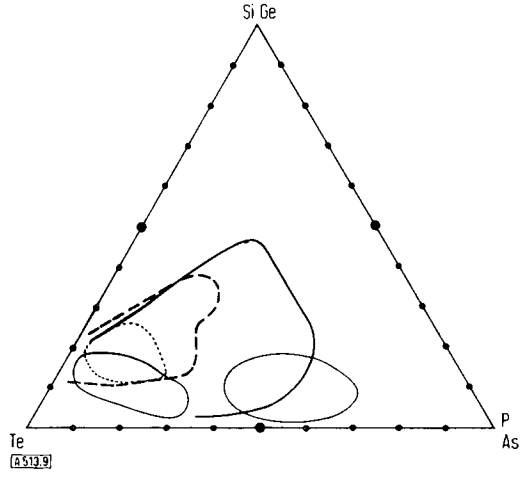

Fig. 9. Regions of glass formation in several systems.
▬▬ Si–As–Te; ——·—— Ge–As–Te; - - - - Si–P–Te;
····· Ge–P–Te [84,86].

that molecules such as $P_4S_{10}$ and $As_4S_4$ may be embedded in the networks of the systems containing P and S or As and S. Similarly to plasticizers in plastics, these molecules lower the softening point of the systems.

[86] *A. R. Hilton* and *M. J. Brau*, personal communication.

Glass formation in regions with high tellurium contents is surprising, since it does not occur in binary chalcogenide glasses. It can be calculated from the density of these glasses that, similarly to the Sb atoms in explosive antimony, the Te atoms are linked to two strongly-bound neighbors and several loosely-bound ones, so that the coordination polyhedron can assume the form of a distorted octahedron. The loosening effect of Te is counterbalanced by the formation of a stronger network with tetravelent elements (Si or Ge).

Fig. 9 shows that the regions of glass formation are smaller with phosphorus than with the heavier arsenic. This contradicts the observation that the ease of crystallization increases with increasing atomic weight, and is probably due to the fact that Si and Ge form definite compounds with As, but not with P and Sb [87]. It can be assumed, therefore, that Si and Ge do not form bonds with P in glasses either, and that they prefer instead chalcogenides as neighbors. This renders the formation of a three-dimensional network more difficult.

The chalcogenide glasses discussed above must have the same short-range order as their melts, since they can be easily obtained from the latter. If we ignore the additional weak bonds, we see that the bridging atoms permit mobility in the melt even when the molecules are larger. This mobility in the melt is greatly enhanced by the addition of halogens. In the absence of a sufficient number of monovalent or bivalent atoms in the melt, mobility can be ensured only by disruption of the network. This means that the atoms are forced to assume significantly higher coordination numbers. The difference between the preferred and the unfavored bond directions more or less disappears, as it does in the melting of Ge or Sb. Melts of a more highly metallic nature are thus formed, and this should be manifested in the electric conductivity. These atomic arrangements are unstable when the melts are cooled. In fact, extensive rearrangement must take place, which gives rise to the favored crystalline form.

*The investigations described above were carried out in the research laboratories of Texas Instruments Incorporated (Dallas, Texas, U.S.A.), and the author wishes to thank this firm for the hospitality extended to him, over a long period. # An Apparatus for Titrations in Liquid Ammonia

BY PROF. DR. P. W. SCHENK

INSTITUT FÜR ANORGANISCHE UND ANALYTISCHE CHEMIE,
TECHNISCHE UNIVERSITÄT BERLIN (GERMANY)

*To Prof. Dr. F. Patat on the occasion of his 60th birthday*

*An apparatus for titrations in liquid ammonia is described. The titrations can be carried out in the absence of air, and the utility of the apparatus is demonstrated for a number of conductometric and potentiometric titrations.*

The growing importance of water-like solvents has created the need of being able to follow reactions in these solvents quantitatively. In the case of low-boiling solvents of this type, such as liquid ammonia, the experimental requirements are greater since special care must be devoted to the exclusion of moisture, and sometimes also of air. As long as 30 years ago *E. Zintl, J. Goubeau,* and *W. Dullenkopf* [1], and more recently *G. W. Watt et al.* [2], described devices that permit titrations in liquid ammonia and other volatile solvents. A number of disadvantages associated with these devices led us to develop a new apparatus for our investigations, some of which are reported elsewhere [3]. Efficient cryostats that have recently become commercially available have made it possible to maintain a sufficiently constant low temperature (−50 to −60 °C) in the important parts of the apparatus over long periods with the aid of a circulating coolant (methanol).

## Description of the Apparatus

A reservoir *a* (Fig. 1) for liquid ammonia is connected *via* $b_{10}$ to the calibrated flask *c*, which has a capacity of 250 ml up to the mark *d*. The reagent used for the preparation of the titrant solution is introduced through $e_2$. Nitrogen is used to force the solution through *f* into the buret *g*. The buret tap $b_3$ is a standard ground-glass tap with a polished sleeve and interchangeable keys. In titrations with potassamide, an ungreased Teflon key is used. $KNH_2$ solution attacks Teflon, causing it to swell slightly with the result that the tap seizes if the sleeve is not polished. However, if the solution is not allowed to remain in contact with the tap longer than necessary, the Teflon key need only be renewed from time to time.

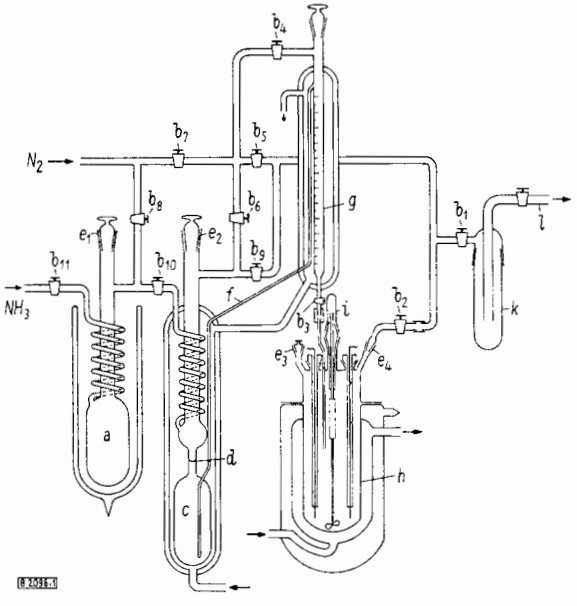

Fig. 1. Diagram of the apparatus for titration in liquid ammonia. *a* reservoir, $b_1$ *to* $b_{11}$ taps, *c* calibrated flask, *d* calibration mark, $e_1$ to $e_4$ ground-glass sockets, *f* tube, *g* buret, *h* titration vessel, *i* ground-glass cap, *k* cold trap, *l* line to mercury pump.

The titration vessel *h* is closed by a flat ground-glass cover fitted with six sleeve joints. Two of these accommodate the electrodes for the electrochemical indication. The middle joint carries the bronze sleeve bearing for the stirrer. This sleeve can be sealed with a glass cap *i* during evacuation of the apparatus. The cup is removed before the titration, and the steel stirrer shaft is connected to the motor by a flexible shaft. A glass sleeve with the spiral stirrer fused to its lower end is cemented over the stirrer shaft inside the vessel. Another socket in the cover holds the glass tube through which the titrant solution flows. This tube is connected to the buret by a length of plastic tubing or by a ball joint. The substance to be titrated is introduced through the joint $e_3$, and $e_4$ connects the titration vessel, *via* $b_2$, to the vacuum pump and the rest of the apparatus, so that it is possible to distil ammonia from *a* into *h*, if necessary. The calibrated flask *c*, the buret *g*, and the titration vessel *h* are insulated by evacuated jackets, and the cooling liquid from the cryostat circulates from one vessel to another between the jacket and the vessel.

The reservoir vessel *a* is separately cooled with acetone/dry ice. If the cryostat has two separate circulating pumps, this vessel may also be cooled by the cryostat. A small immersion heater introduced through the joint $e_1$ supplies the heat required for distillation of ammonia into *c* or *h*. The ammonia is preferably taken from a steel cylinder containing a little sodium [4]. If it is taken directly from the commercial cylinder, it is passed through drying tubes containing soda lime, barium oxide, and sodium wire. A little sodium is placed in *a* to ensure that the ammonia is really dry.

Before the titration, $b_3$ is fitted with a greased glass key, and the entire apparatus is evacuated for several hours with a mercury pump. Oxygen-free nitrogen from a Meyer-Ronge tower is then admitted. The required quantity of ammonia is distilled into *a*, and while a current of nitrogen is passed through, the glass key is removed from $b_3$, the grease is removed with an ether-soaked cotton pad, and a Teflon key is inserted. The cooling of *a* is stopped, and *c*, *g*, and *h* are cooled to cause ammonia to distil into *c* until it reaches the mark *d*. The weighed titrant reagent can then be introduced through $e_2$. The principal parts of the apparatus are shown in Figure 2.

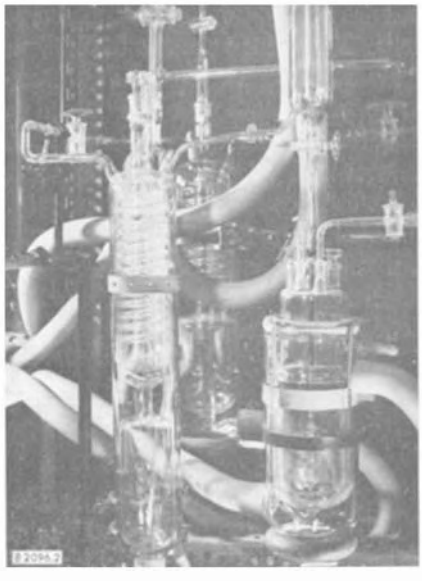

Fig. 2. Principal parts of the apparatus (rear: reservoir for liquid ammonia; front left: calibrated flask; front right: titration vessel with stirrer, electrodes removed).

## Preparation of Standard Potassamide Solutions

For titrations with potassamide solution, a weighed amount of oxide-free potassium is introduced. With the aid of the simple device shown in Fig. 3, a glass tube $n_1$ about 50 cm long and 6 to 7 mm in diameter is filled with oxide-free potassium by the following method.

The ampoule *m* is attached by the horizontal ground-glass joint *o* (which projects backwards) to a horizontal socket (not shown in Fig. 1) fitted to the main apparatus

[4] *F. Feher, J. Cremer,* and *W. Tromm,* Z. anorg. allg. Chem. *287,* 175 (1956).

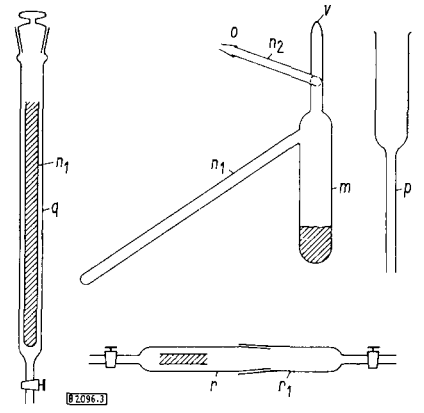

Fig. 3. Weighing accessories for oxide-free potassium.
*m* ampoule, $n_1$, $n_2$ glass tubes fused to the ampoule, *o* ground-glass cone, *p* funnel, *q* glass tube with tap and ground-glass stopper, *r* weighing tube.

between $b_1$ and $b_2$, and is thoroughly baked out in the mercury-pump vacuum. Nitrogen is then admitted, the tip *v* of the ampoule is cut open, and the funnel *p*, into which 8 to 10 g of pure potassium is placed, is inserted into the ampoule in a current of nitrogen. A loosely fitting stopper is inserted and the potassium is melted with a fan-shaped flame and allowed to run into *m*, still under nitrogen. The tip *v* of the ampoule is sealed, the ampoule is evacuated, *m* and $n_1$ are heated, and the ampoule is rotated about *o* to allow the potassium to run into the tube $n_1$. When the metal solidifies, nitrogen is admitted and the tube *q* is pushed over $n_1$, nitrogen being led in *via* the tap. The tube $n_1$ is then cut near the surface of the potassium and immediately pushed inside *q*, the top end of which is closed with a stopper. A suitable length of tube containing potassium is cut off in a "nitrogen bag" or dry box[5] and placed in the weighing tube *r*. Blank experiments have shown that if the joint of the weighing tube is only sparingly greased,

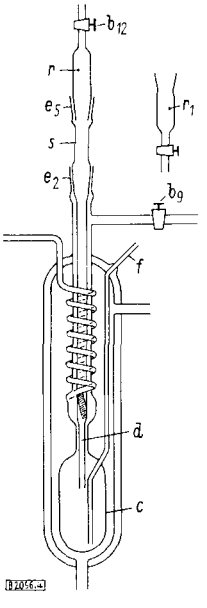

Fig. 4. Equipment for the introduction of a weighed sample of oxide free potassium into the calibrated flask.
*s* tube with ground-glass cone and socket, *r*, $r_1$ weighing tubes with ground-glass cap and tap $b_{12}$ (other symbols as in Fig. 1).

[5] Cf. *G. Brauer*: Handbuch der präparativen anorganischen Chemie. Enke, Stuttgart 1960, Vol. 1, p. 73.

weighing errors caused by the grease are negligible. After the nitrogen-filled weighing tube has been weighed, the ground glass cap $r_1$ is removed in a current of nitrogen and replaced by the tube *s* (Fig. 4). When *s* is full of nitrogen, the assembly is mounted in the socket $e_2$ of the main apparatus (Fig. 1) in a countercurrent of nitrogen ($e_5$ also is only sparingly greased). The pressure is now released at $b_{12}$ (Fig. 4), and *c* is placed under a slight pressure of nitrogen. The liquid ammonia rises in the tube *s* and dissolves the potassium out of the piece of tube, which is open at both ends. The operation must be repeated several times. When all the potassium has dissolved, the tube *s* is removed and placed in a glass tube of sufficient length and width, the lower end of which is closed. A few mg of $Fe_2O_3$ is added to catalyse the conversion of the blue potassium solution into $KNH_2$, and $e_2$ is immediately closed. A weak current of nitrogen is bubbled through the solution overnight *via f* to agitate the $Fe_2O_3$. The apparatus is sealed off from the outside air by a mercury relief valve, which prevents the entry of air and moisture. By the following day, the color of the solution is generally discharged. (The quality of the $Fe_2O_3$ appears to be important). By addition or removal of ammonia the meniscus in *c* is adjusted to the mark *d*. It should be ensured that the height in *f* is the same.

The potassium adhering to the tube *s* is washed down with alcohol and then with water, and the resulting solution is titrated. The length of glass tube is dried and weighed together with the weighing tube. The quantity of potassium titrated is added as a correction. Though the solubility of $KNH_2 \cdot 2NH_3$ (which is stable only below $-42\,^{\circ}C$) decreases rapidly with decreasing temperature[6], 1 N $KNH_2$ solutions can be used at temperatures down to $-60\,^{\circ}C$. As in aqueous systems it is advisable to use fairly dilute solutions. This is particularly desirable here, since after each addition of titrant, the solution between the tip of the buret and the tap runs out, so that dropwise titration as in aqueous systems is impossible, although this is no disadvantage when electrochemical indication is used.

For conductometric titrations we used two platinized platinum electrodes of the usual size, with a "Konduktoskop" (Metrohm AG., Herisau, Switzerland) as measuring instrument; in potentiometric titrations the indicator electrode was a platinum or silver electrode, while the reference electrode was a *gebremste Elektrode* as described by *Müller*[7]. The reference electrode was used in two forms. One of these, the usual form, has already been used in liquid ammonia by *Zintl*[1]. It consists of a glass tube about 3 mm wide, with a fine capillary about 2 cm long at the bottom. The tube is sealed about 2 cm above the capillary. A platinum wire projects into the resulting electrode compartment through the seal. For longer response times, the differential potentiometric method is recommended. In the reference electrode used in this case, the solution is drawn into the electrode compartment by means of a suction ball before each addition of reagent, and forced

[6] *P. W. Schenk* and *H. Tulhoff*, Angew. Chem. *74*, 943 (1962).

out again after the reading has been taken. The indicating instrument used was a "pH-Meter 260" (Knick, Berlin) with a titration attachment.

### Titration Procedure

The substance to be titrated is introduced into the titration vessel through $e_3$ (Fig. 1) in a stream of nitrogen, and rinsed down with a little ether. When a sufficiently large sample is used, a measured amount of titrant solution is run in as solvent, or alternatively, ammonia may be distilled over from *a*, so that the electrodes are covered. (The *gebremste Elektrode* must first be filled with ammonia gas to enable the liquid to enter). The stirrer is then switched on, and addition of the titrant is commenced. The portions added should not be too small. The reading generally becomes constant within 5 minutes.

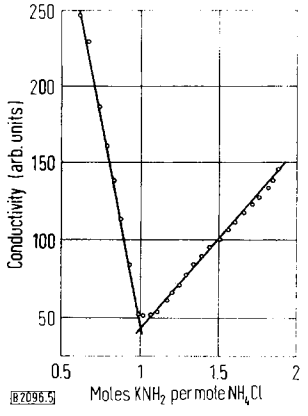

Fig. 5. Conductometric titration of $NH_4Cl$ with $KNH_2$.

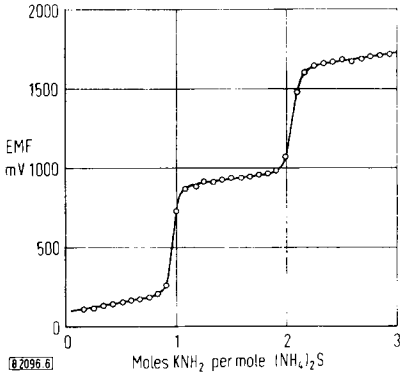

Fig. 6. Potentiometric titration of $(NH_4)_2S$ with 0.44 M $KNH_2$ (Pt indicator electrode, Pt *gebremste Elektrode* as reference electrode); temperature −51 °C, response time 5 min.

Figure 5 shows a conductometric titration curve of $NH_4Cl$ with $KNH_2$, and Figure 6 shows a potentiometric titration curve of $(NH_4)_2S$ with $KNH_2$. The latter clearly shows the two stages of dissociation of $H_2S$ in liquid ammonia. The titration of $(NH_4)_2S$ with

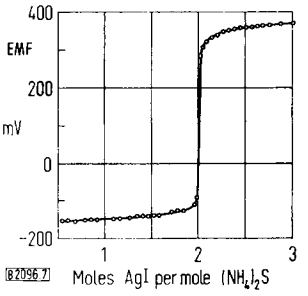

Fig. 7. Potentiometric titration of $(NH_4)_2S$ with 0.6 M AgI solution; indicator electrode Ag wire; reference electrode Pt *gebremste Elektrode*; temperature −50 °C; response time 5 min.

AgI solution (Fig. 7) naturally gives only one inflection, since this is a precipitation titration. The potential curve for the differential titration of $(NH_4)_2S$ with AgI solution is shown in Fig. 8. The apparatus has already

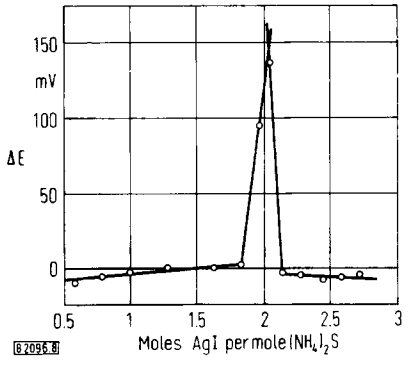

Fig. 8. Differential potentiometric titration of $(NH_4)_2S$ with 0.3 M AgI solution (ΔE EMF difference); Pt indicator electrode, Pt *gebremste* reference electrode.

proved its value in the hands of numerous workers. The results obtained were reported earlier [3]; further results will be published elsewhere.

*E. Krone, I. B. P. Tripathi, K. Huste, D. Gerlatzek, D. Lautenbach, and Frau E. Tulhoff contributed to the development of the apparatus. The author is grateful to the Senator für Wirtschaft des Landes Berlin and to the Fonds der Chemischen Industrie for their financial support.*

# Progress in the Chemistry of Casein

BY DR. P. JOLLÈS

LABORATOIRE DE CHIMIE BIOLOGIQUE, FACULTÉ DES SCIENCES, UNIVERSITÉ DE PARIS (FRANCE)

*Casein from cow's milk is not a single substance, but can be resolved into numerous components. These include κ-casein, which is the only fraction that contains appreciable quantities of sugars. This component plays a very important role in the clotting of milk by rennin, when it is split into an almost sugar-free fraction, para-κ-casein, and a fraction containing sugars, κ-caseinoglycopeptide. Caseinoglycopeptides have been isolated not only from the casein of cow's milk, but also from the caseins of sheep, goat, and human milk. The second part of the paper deals with the clotting of milk by rennin and the amino acid sequence in caseinoglycopeptides.*

## I. Caseins

The proteins in milk belong to two groups: phosphoproteins or caseins (78% in cow's milk), which are insoluble in acidic media, and milk serum proteins (17%), *i.e.* β-lactoglobulin, α-lactalbumin, globulins, serum albumins, *etc.* 5% of the substances are non protein nitrogen (NPN) containing components such as peptides. In this paper, the percentages indicated are percentages of the dry substances (by weight).

### A. Casein from Cow's Milk

#### 1. Number of Fractions and Their Names

Casein from cow's milk is one of the few substances isolated and studied as early as the first half of the 19th century [1–5]. It was later found [6–9] that casein is not a pure substance. Studies of solubility in dilute hydrochloric acid and in ethanol enabled *Linderstrøm-Lang* and *Kodama* [10] to characterize seven fractions in casein. These observations were confirmed by *Cherbuliez* and *Schneider* [11] by fractional salting out, and later by *Pedersen* [12] and in particular by *Mellander* [13] by physical investigations. Using electrophoresis, *Mellander* isolated three fractions, which he called α-, β-, and γ-casein, names that are still used.

New chromatographic and electrophoretic methods of separation and the use of buffers containing urea, which reduce the interactions between protein components, have made it possible to characterize up to 20 casein fractions. However, as *Waugh et al.* [14] have pointed out, it must be asked which of these fractions are synthesized directly by the cells in the mammary gland ("primary caseins"), and which are artefacts, produced, for example, by enzymatic breakdown of primary caseins. Some fractions might also be genetic variants, or complexes or mixtures of several proteins. The four principal fractions of casein ("primary caseins") are the $\alpha_{s1}$, $\alpha_{s2}$, β, and κ components. The main fractions of casein and the names of these encountered in the literature are listed in Table 1.

#### 2. Study of the Four Principal Fractions

##### a) $\alpha_{s1}$- *and* $\alpha_{s2}$-*Casein*

Nomenclature and Purification. Though α-casein initially appeared to be electrophoretically homogeneous (soluble in 6.6 M, insoluble in 4.6 M urea solution), it was later resolved into two main fractions: κ-casein, which is soluble in the presence of $Ca^{2+}$, and $\alpha_s$-casein, which is insoluble in the presence of $Ca^{2+}$ (0.03 M) at normal (20–40 °C) and low temperatures (1–5 °C). These fractions were named by *Waugh* and *v. Hippel* [15]. The $\alpha_s$ fraction is very similar to the $\alpha_1$ fraction reported by *McMeekin et al.* [16] and to the $\alpha_r$ fraction reported by *Long* [17].

$\alpha_s$-Casein can also be obtained by precipitation of casein with $CaCl_2$ [15]. Chromatography of $\alpha_s$-casein on

Table 1. The principal fractions of the casein complex.

| [13] | | [15] | | [14] | | [33] | Other names for similar fractions | Subsidiary fractions | Genetic variants |
|---|---|---|---|---|---|---|---|---|---|
| Name | [%] | Name | [%] | Name | [%] | Name | | | |
| $\alpha$ | 70 | | | | | | | | |
| | | $\alpha_s$ | 55 | $\alpha_{s1}$ $\alpha_{s1,2}$ $\alpha_{s2}$ | 38 | | $\alpha_1$ or $\alpha_r$ | "$\alpha_s$" (10%) | $\alpha_{s1}$-A, -B, -C, -BC, -D |
| | | $\varkappa$ | 15 | $\varkappa$ | 15 | | $\alpha_3$ | | $\varkappa$-A, -B |
| | | | | | | | $\alpha_2$, "m" ← | $\lambda$ (3%) | |
| $\beta$ | 27 | | | $\beta$ | 27 | $\beta_{slow}$ $\beta_{fast}$ [a] | | | $\beta$-A, -B, -C, recently -D, -E [39a] |
| $\gamma$ | 3 | | | | | | | | $\gamma$-A, -B |

[a] $\beta_{fast}$ is probably contained in $\lambda$.

DEAE-cellulose with a buffer containing 4.5 M urea yielded two fractions, both of which could be further purified by starch gel electrophoresis [14]. The first chromatographic fraction consists of a mixture of $\alpha_{s1}$- and $\alpha_{s2}$-casein (= $\alpha_{s1,2}$-caseins). The migration of the $\alpha_{s1}$ component at pH 8.4 is faster than that of the $\alpha_{s2}$ component. The second fraction was given the rather confusing name "$\alpha_s$-casein" (*i.e.* the fraction that contains other "$\alpha_s$-like" components).

Table 2. Properties of various casein fractions.

| Casein fraction | Molecular weight | $pH_i$ | Solubility in presence of 0.03 M $Ca^{2+}$ | | Sugar [%] | P [%] | Cys [%] | N [%] | Terminal amino acids or sequences | | Effect of rennin |

[a] Isoelectric point. [b] Value formerly accepted: 2 × 28000 [65].

Genetic Variants. Three genetic variants, $\alpha_{s1}$-A, $\alpha_{s1}$-B, and $\alpha_{s1}$-C, were identified by *Thompson et al.* [18–21, 27, 28]. The last two are probably very similar to or identical with *Waugh*'s $\alpha_{s1,2}$ fractions. *de Koning* [22] described the variants $\alpha_{s1}$-B, $\alpha_{s1}$-C, $\alpha_{s1}$-BC, and $\alpha_{s1}$-D.

Molecular Weight. $\alpha$-Casein forms aggregates in neutral media, but the size of these aggregates decreases with increasing pH; in molecular weight determinations by sedimentation and diffusion methods, *McKenzie* and *Wake* [23] obtained values of 27600 ± 1000 at pH 7.3 and 24800 ± 1000 at pH 11 in the presence of 6 M urea. The value found for $\alpha_{s1,2}$-caseins by *Waugh et al.* [14] was 27300, and that found by *Schmidt* and *Payens* [24] was 16500; *Manson* [25] found a molecular weight of at least 31000 for $\alpha$-casein (see Table 2), while *de Koning* [22] obtained a value of 30000.

Analyses (Amino Acids, Sugars, Phosphorus). The amino acid compositions of the $\alpha_{s1}$- and $\alpha_{s2}$-caseins were reported by *Hipp et al.* [26]. $\alpha_{s1,2}$-Caseins contain 14.7% N, 1.03% P, 2.3 tryptophan residues, and 11 tyrosine residues per molecule of molecular weight 27000 [14].

[28] *M. P. Thompson, L. Pepper, W. G. Gordon,* and *J. J. Basch,* J. Dairy Sci. *46,* 607 (1963).

α-Casein (mainly a mixture of $\alpha_{s1,2}$- and κ-casein) contains sugars, but these are confined to the κ component. *de Koning* [22] analysed the genetic variants $\alpha_{s1}$-B, -C, -BC, and -D and found that $\alpha_{s1}$-B contains one glutamic acid residue more and one glycine residue less than $\alpha_{s1}$-C-casein.

Structure studies. Arginine is the only *N*-terminal amino acid, not only in $\alpha_s$-casein (3.25 mole/$10^5$ g of protein) [25], but also in the variants $\alpha_{s1}$-A, -B, -C [29], and -D [22]. These components also have the same *C*-terminal sequence, *viz.* leucyltryptophan, provided they all consist of a single polypeptide chain (molecular weight *ca.* 31000); if on the other hand there are two peptide chains [24], one must have a *C*-terminal leucine and the other a *C*-terminal tryptophan residue. These results do not quite agree with those obtained by *Waugh et al.* [14], who found tryptophan, leucine, and tyrosine as *C*-terminal amino acids in $\alpha_{s1,2}$-caseins.

Many investigations have been carried out on peptides, particularly phosphopeptides, from α-casein. *Österberg* described a peptide containing 35 amino acids, and in this connection reviewed most of the phosphopeptides of casein studied up to that time [31]. The phosphorus in casein is mainly in the form of monoesters of phosphoric acid (phosphoserine, phosphothreonine).

b) *β-Casein*

Purification. In 1962, *Groves et al.* [32] described a purification method using chromatography on DEAE-cellulose, the starting material being the casein soluble at pH 4 and 2 °C. The product obtained seemed to be electrophoretically pure (soluble in 4.6 M, insoluble in 3.3 M urea solution at pH 4.6). However, *Gehrke et al.* [33] showed in 1964 by similar methods that β-casein of this kind consists of two components: "$\beta_{slow}$-casein", the principal component, which is soluble in water at 5 °C, and "$\beta_{fast}$-casein". *Garnier et al.* [34], also in 1964, published a process for the production of β-casein.

Genetic variants of β-casein have also been observed in milk samples [27,28,35–37], *viz.* β-A-, β-B-, and β-C-forms [39]. A new nomenclature based on variations of the histidine content was quite recently proposed [39a].

Molecular Weight. *McKenzie* and *Wake* [23] reported molecular weights of 17300 ± 800 at pH 11 and 19800 ± 1000 at pH 7 for slightly impure samples of β-casein in 6 M urea solution. *Groves et al.* [32] found a sedimentation constant of 1.17 S at pH 7 (0.05 M phosphate buffer, 0.1 M NaCl) and 0.8 °C, while *Gehrke* [33] obtained a value of 1.6 S at pH 8.6 (0.076 M tris buffer, 0.005 M citrate) for $\beta_{slow}$). Association and dissociation were observed in the presence of 0.1 M KCl.

Analyses. $\beta_{fast}$-Casein contains as much phosphorus as λ-casein and the two exhibit a similar electrophoretic behavior; $\beta_{fast}$-casein is probably a fraction of λ-casein (or of λ-caseins). The amino acid composition of β-casein was reported by *Gordon et al.* [38] and by *Pion et al.* [39]. Sugars were detected only in traces.

Structure studies. A number of investigations have been carried out on the isolation of phosphopeptides and on the products of trypsin hydrolysis of total β-casein [39–41]. The genetic variants β-B and β-C contain respectively one arginine and one lysine residue more, and one glutamic acid residue less than β-A [39].

β-Casein can be photo-oxidized at pH 8.6 and 37 °C; this leads in particular to the modification and/or destruction of the histidine, tryptophan, and tyrosine residues. Oxidized β-casein (18 moles of oxygen per 30000 g of casein) is not precipitated by a $CaCl_2$ solution [42].

c) *κ-Casein*

In the presence of 0.3 M $Ca^{2+}$, the complex between $\alpha_s$-, β-, and γ-caseins is broken down; only κ-casein remains in solution [15]. Another unusual property of κ-casein is its ability to stabilize other casein fractions; moreover, κ-casein is the only casein fraction that is attacked by rennin, and the only casein fraction that contains sugars.

Purification. κ-Casein, which forms part of *Mellander*'s α-casein, owes its name to *Waugh* and *v. Hippel* [15]; it is very closely related to the $\alpha_3$-component reported by *Hipp et al.* [26] and can be obtained by fractionation of total casein [43–55], *e.g.* with trichloroacetic acid and urea [44] or by chromatography [46].

The behavior of κ-casein in starch gel electrophoresis shows that it is not a single substance. *Woychik* [56,57], *Wake* [58], and *Schmidt* [59] found two main fractions and a number of subsidiary fractions following the reduction of κ-casein to "SCM-κ-casein". On chromatography on DEAE-cellulose with buffers containing 20% dimethylformamide, SCM-κ-casein was resolved into two (faster-moving) sugar-rich fractions and two sugar-free fractions. Since all these components are attacked by rennin, the sugar moiety seems to play no part in the clotting of milk by rennin. The heterogeneity of κ-casein (from the milk of several animals) is due to genetic variants (see below) and to the presence of more or less large quantities of sugars mainly in the caseinoglycopeptide part. Seasonal variations in the amino acid composition have also been observed [60].

Molecular Weight. At pH 7 (0.1 M phosphate buffer), the sedimentation constant $s_{20} = 12.9$ S (polymeric form; aggregates), while the value at pH 12.2 (0.19 M phosphate/KOH buffer) is $s_{20}^{c=o} = 1.4$ S (monomeric form) [43,44]. The values given in the literature for the molecular weight of κ-casein range from 26000 ± 3000 [23,61,66] to 160000 [62], even 280000 [47]. *Swaisgood* and *Brunner* [63] accepted a value between 50000 and 60000, while *Beeby* [64] postulated the presence of three sub-units with a molecular weight of 16000 that differ in their neuraminic acid and cystine contents. In 1964, *Swaisgood et al.* [65] concluded from studies on reduced κ-casein that it probably consists of two sub-units of molecular weight 28000. The same molecular weight was also deduced from its sulfur, phosphorus, and neuraminic acid contents. Very recent experiments by *Woychik* [56,57] (analysis of genetic variants, sedimentation constants of carbamoylmethyl-κ-casein) and by *Wake* [58] (investigation of fractions obtained from SCM-κ-casein) have shown that the molecular weight is very probably about 19000 ± 1000. This value is also in agreement with the first results obtained by *Jollès et al.* [67] in connection with the structure of κ-casein.

Genetic variants of κ-casein were detected by *Woychik* [56,68,69], *Neelin* [70], and *Schmidt* [59,71] with the aid of starch gel electrophoresis.

Analyses. The composition of κ-casein was studied by *Jollès et al.* [72] and *Swaisgood et al.* [63,65]. Special mention should be made of the high content of hydroxy-substituted amino acids, glutamic acid, and proline, as well as of the presence of cystine. The amino acid analyses of genetic variants (κ-A and κ-B) have been reported by *Woychik* [56] and *Schmidt* [59]. The two variants differ by one residue each of aspartic acid, threonine, alanine, and isoleucine.

κ-Casein is the only fraction of the total casein complex that contains appreciable quantities of sugars: galactose, galactosamine (not glucosamine, as was formerly believed), and *N*-acetylneuraminic acid were detected and assayed by *Alais* and *Jollès* [73]. The neuraminic acid contents reported differ very widely, either because some of this sugar is lost during the purification process, or because the milks contain κ-caseins with different sugar contents [48,49,73–79]. The phosphorus content (0.22%) is lower than in the other principal fractions.

Structure studies. During the clotting of milk by rennin the only significant alteration occurs in κ-casein. For this reason the structure of κ-casein will be reported in the second part of this article.

Biological Activity. *Yaguchi et al.* [80] found that several casein fractions containing the κ-component behave as lipases towards milk fat at pH 9.

κ-Casein as a Protective Colloid. – Interactions with Other Casein Fractions. – Micelle Formation. In the presence of calcium ions, $\alpha_S$-casein and β-casein are insoluble in water at room temperature, whereas κ-casein is soluble. κ-Casein stabilizes colloidal dispersions of calcium caseinate. According to *Waugh* [81] stable suspensions of micelles are formed when $\alpha_S$- and κ-caseins are present in the ratio of 4:1 by weight (0.03 M $Ca^{2+}$ at 37 °C). When this ratio is greater than 4:1, the excess $\alpha_S$-casein precipitates out, while if the ratio is smaller than 4:1, smaller micelles are formed. This association between κ- and $\alpha_S$-caseins has been studied in neutral solution [82]. Interactions can also occur between κ- and β-caseins [83] or κ-, $\alpha_S$-, and β-caseins [83–88]; β-

casein remains in solution at high temperatures in the presence of κ-casein. During the clotting of milk by rennin, part of the κ-casein is split off, and the κ-casein can then no longer act as a protective colloid (see Part II).

The chemical bonds in the micelles (*e.g.* ester linkages) and the behavior of calcium and phosphate ions towards the micelles have been studied by *Schipper* [87] and *Pyne* [89]. These authors found that colloidal calcium phosphate is either adsorbed on or chemically bonded to the casein.

Finally, it should be noted that interactions also occur between κ-casein and other proteins, *e.g.* β-lactoglobulin [90].

### 3. Study of Some Subsidiary Fractions

The $\alpha_s$ fraction that accompanies $\alpha_{s1,2}$-caseins was mentioned in Section IA2a [88,91]. The only other acidic phosphoprotein obtained from the casein complex is λ-casein [17] (or m-casein [87]), which often occurs together with κ-casein and which is also present in $\alpha_2$-casein [26]. λ-Casein has a high (1.2%) phosphorus content (see Table 2). A number of proteins with relatively high isoelectric points (6.4–8.0) have been isolated from the casein complex, but they contain very little or no phosphorus.

A new purification method was recently developed [32] for *Mellander*'s γ-casein [13]. The amino acid composition is known only for an earlier sample [92]. The sedimentation constant is 1.15 S at 1.3 °C for a 1% solution in 0.1 M phosphate buffer of pH 7, and the molecular weight is about 30000. *Aschaffenburg* detected two genetic variants [35].

When the pH of a solution of total casein is adjusted to 4, centrifugation gives a supernatant containing two proteins which are insoluble at pH 7–9. These are "red protein", which is a metalloglycoprotein belonging to the transferrin group [93], and a basic protein, lactollin [94].

Finally, it should also be mentioned that some enzymes, *e.g.* protease and lipase, are firmly bonded to casein [95].

None of the subsidiary fractions with relatively high isoelectric points are really caseins, since they are probably not synthesized in the mammary gland.

## B. Caseins from Sheep and Goat Milk. – Casein from Human Milk

Whereas casein from cow's milk and its fractions have been intensively studied, similar data for other caseins are almost completely lacking [97–99]. *Sloan et al.* [96] compared the caseins of 40 animals (eight species), though only by electrophoresis; three types of electropherograms were obtained.

It was shown by *Alais* and *Jollès* [73,99] that caseins from sheep, goat, and human milk contain galactose and galactosamine. While only *N*-acetylneuraminic acid (0.80% [99] or 2.1% [100]) was found in casein from human milk, the caseins from sheep and goat milk contain a mixture of *N*-acetylneuraminic and *N*-glycolylneuraminic acids (0.09 and 0.13%, respectively) [73].

Since the clotting of sheep milk by rennin follows a course similar to that of cow's milk (see Part II), it was assumed that a "κ-like" fraction was present. *Alais* and *Jollès* [98] tried to isolate this fraction and obtained a casein that remained soluble in the presence of 0.4M $CaCl_2$ and was attacked by rennin without added $Ca^{2+}$.

By electrophoretic studies with buffers containing urea, *Malpress* [100] and *Alais* and *Jollès* [101] showed that human casein consists of a very large number of fractions. It was not possible in each case to obtain preparations that could be digested with rennin [99]. *Malpress* and *Seid-Akhavan* [102] carried out chromatographic experiments on CM-C50 Sephadex with buffers containing urea and isolated a fration that has the same properties as the κ-casein of cow's milk.

It should be noted finally that the composition and properties of human casein do not appear to be constant. They are influenced by the composition of the milk from which the casein was obtained and by the changes in the activities of certain enzymes (*e.g.* protein-synthesizing enzymes) in the cells in which the milk is formed [103]. Human casein contains an alcohol-soluble fraction (25% of the total weight; only 5% in the casein from cow's milk), which has been resolved into five fractions by chromatography on DEAE-cellulose [104]. The alcohol-soluble fraction seems to consist mainly of lipids.

## II. The Clotting of Milk by Rennin

Two coagulation processes occur in nature: the clotting of blood, which involves the cleavage of an arginylglycine linkage, and the clotting of milk. *Hammarsten* [7] found that rennet contains an enzyme (rennin) [105–108] and that the treatment of casein with rennin leads to the liberation of peptide-like substances (substances containing non-protein nitrogen, *e.g.* peptides). It is now

believed that the interaction of casein with rennin includes three reactions [109–110]: A glycomacropeptide (caseinoglycopeptide [111]) is first split off ("primary reaction"), then coagulation takes place, and finally all the casein components are slowly broken down by rennin into smaller peptides [112].

According to *Waugh* [15], the substrate for the primary reaction is the κ-casein that stabilizes the colloidal dispersion of calcium caseinate. This was confirmed by *Jollès* and *Alais* [113], and simultaneously by *Nitschmann et al.* [114], who found that the glycopeptide obtained from a solution of κ-casein on treatment with rennin is the same as that obtained from solutions of total casein or α-casein. Following treatment with rennin, κ-casein gives a particularly high percentage of substances containing non-protein nitrogen, which are soluble in trichloroacetic acid [115]. The primary reaction can be represented as follows:

$$\kappa\text{-casein} \xrightarrow[\text{pH } 6.8]{\text{rennin}} \underset{\text{(insoluble)}}{\text{para-}\kappa\text{-casein}} + \underset{\text{(readily soluble)}}{\kappa\text{-caseinoglycopeptide}}$$

We shall first consider rennin and the structures of κ-casein and para-κ-casein and then deal in detail with the caseinoglycopeptide.

## A. Primary Reaction

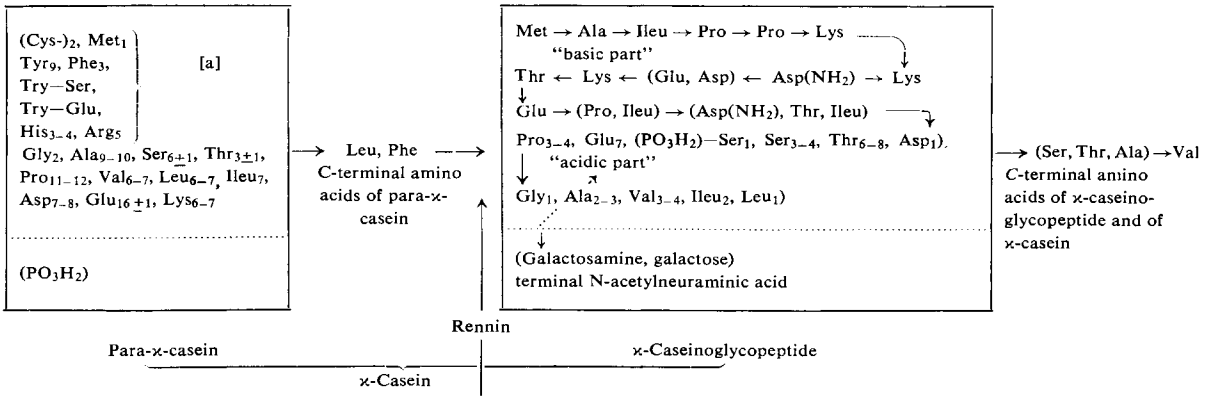
### 1. Rennin

Rennin is an enzyme which occurs in the fourth stomach of calves. It was first isolated and crystallized by *Berridge* [116]. Its specificity is similar to that of pepsin, but its optimum pH is much higher, at about 4 [117]. Rennin attacks not only casein, but also other proteins such as hemoglobin [116] or the B chain of oxidized insulin [118]. *Foltmann* [119,120] has recently studied the structure of rennin.

### 2. κ-Casein

It is now accepted that κ-casein has a molecular weight of 19000 ± 1000 [57,59,67] and that it has a homogeneous peptide skeleton of 165 ± 5 amino acid residues. A few changes are attributable to the genetic variants; these latter and the variations in the sugar composition are ultimately responsible for the heterogeneity observed on electrophoresis. The *N*-terminal amino acids have not yet been identified, but with the aid of carboxypeptidase, *Jollès et al.* [72] were able to liberate valine, together with some alanine, threonine and serine from the *C*-terminal end. Some data on the structure of κ-casein, which were mainly obtained in studies on para-κ-casein and on κ-caseinoglycopeptide, are summarized in Scheme 1 [67, 121,122,132]. Preliminary results obtained in the study of the tryptic units [67] are in agreement with Scheme 1. Clotting by rennin still occurs after treatment of κ-casein with neuraminidase [62], even when 50% of the galactose is subsequently oxidized [67]. Thus the sugar moiety does not appear to be essential to the action of rennin. A sugar-free fraction recently obtained by chromatography from a reduced κ-casein (*S*-carboxymethyl-κ-casein) [123] can also be digested with rennin. However, it is not yet known whether the soluble peptide obtained under these conditions is the same as the "normal" caseinoglycopeptide.

Scheme 1. Composition of cow's κ-casein (molecular weight 19000 ± 1000): cleavage by rennin into para-κ-casein and κ-caseinoglycopeptide.



[a] All the aromatic and basic amino acids (except lysine) and all the cystine of κ-casein are situated in this part of the molecule [67,72,121,122,132].

### 3. Para-κ-casein

Para-κ-casein is the insoluble fraction obtained after the action of rennin on κ-casein. It contains all the aromatic amino acids and all the arginine and cystine residues of κ-casein (see Scheme 1) but its sugar content is very low. The amino acid composition and the terminal amino acids were first reported by *Jollès et al.* [72, 121], who also showed that the sum of the amino acid residues in para-κ-casein and in κ-caseinglycopeptide is equal to the number of amino acids in κ-casein. *Kalan* and *Woychik* [57] recently also analysed para-κ-casein. As in the case of κ-casein, the *N*-terminal sequence has not yet been characterized. A *C*-terminal phenylalanine residue (together with a little leucine) was identified by digestion with carboxypeptidase [121]; this result has been confirmed by *Dennis* and *Wake* [124]. Casein is attacked not only by rennin, but also by other enzymes such as pepsin [125], chymotrypsin [124], and callicrein [126], as well as by chemicals (alkalis, reducing agents) [67, 121]; an insoluble "para-κ-casein-like" part, usually (but not always) with phenylalanine (together with a little leucine) in the *C*-terminal position, is obtained [67].

### 4. κ-Caseinoglycopeptide (from the κ-Casein of Cow's Milk)

Isolation and Molecular Weight. After treatment of κ-casein with rennin for a short time, paper electrophoresis of the soluble supernatant material revealed the presence of four fractions [127, 128]; the caseinoglycopeptide accounts for 80% of this soluble material, and one of the other fractions (10%) is probably a degradation product. The caseinoglycopeptide can be isolated either from the trichloroacetic acid extract of casein that has been treated with rennin, or by chromatography of the supernatant material on DEAE-cellulose [111, 114, 128]; it is very readily soluble, even in 12% trichloroacetic acid, and is non-dialysable. Electrophoresis and ultracentrifugation have shown that this is a single substance (molecular weight about 7500 ± 500 [129]).

Amino Acid Composition. Special mention should be made of the high contents of the hydroxy amino acids, glutamic acid, and proline, and of the absence of aromatic amino acids, cystine, histidine, and arginine [57, 111, 113, 130–132]. A methionine residue has recently been identified [122]. The peptide moiety of the caseinoglycopeptide amounts to about 65%, and the P content is 0.37% (phosphoserine residue [73]).

Sugar Composition. Galactosamine, galactose, and *N*-acetylneuraminic acid have been detected [73, 129, 133], the quantities present accounting for 75, 68 and 77%, respectively, of the quantities present in κ-casein; some authors even report that all the *N*-acetylneuraminic acid of κ-casein is contained in this part [62, 64]. The sugar moiety of κ-caseinoglycopeptide is approximately 30%. (As with many other substances with high sugar contents, some of the sugar escapes detection, probably because of imperfections in the methods used).

Structure Studies. *Jollès et al.* [111] showed by chemical and enzymatic methods that κ-caseinoglycopeptide contains a methionine residue as the *N*-terminal amino acid [122] and that this is followed by an alanine residue. The *C*-terminal sequence is the same as that of κ-casein [72], *viz.* (Ser, Thr, Ala)-Val; it may therefore be assumed that κ-caseinoglycopeptide is situated at the *C*-terminal end of κ-casein. The structure of the *N*-terminal octadecapeptide was elucidated by degradation with trypsin and chymotrypsin [132] (see Scheme 1).

Experiments with neuraminidase from *Vibrio cholerae* have shown that the *N*-acetylneuraminic acid occupies a terminal position in the sugar moiety [73, 134]; partial hydrolyses with $H_2SO_4$ led to the belief that the sugar directly attached to the peptide moiety (probably by an *N*-glycosidic linkage) is not galactose, but galactosamine [134]

Mention should also be made of a shorter but very similar glycopeptide from the colostrum of the cow [135].

### 5. The Linkage Cleaved in κ-Casein by Rennin

As mentioned above, after rennin has been allowed to act on κ-casein, no new *N*-terminal amino acids can be detected in the para-κ-casein produced [72] although a new *N*-terminal residue (methionine) is found in the caseinoglycopeptide [122]; a new *C*-terminal amino acid (phenylalanine), which comes from the para-κ-casein portion, has also been identified [121]. The question arises whether it can therefore be assumed that it is a Phe-Met linkage that has been cleaved.

*Garnier et al.* [137] followed the formation of the caseinoglycopeptide by titration of the carboxyl groups liberated at a constant pH, and found that one carboxyl group was liberated per 55000 molecular weight units (the molecular weight of κ-casein is now thought to be 19000 ± 1000). This and the following facts suggest the cleavage of an ester linkage. *Jollès et al.* [121] reduced κ-casein with $LiBH_4$ and then obtained an insoluble "para-κ-casein-like" part, which was found to contain a 2-amino-3-phenyl-1-propanol

[137] *J. Garnier, G. Mocquot*, and *G. Brignon*, C. R. hebd. Séances Acad. Sci. *254*, 372 (1962).

(phenylalaninol) residue; this also suggests an ester linkage between the *C*-terminal phenylalanine residue and a hydroxylated residue (a sugar, serine, or threonine); this experiment does not, however, rule out another kind of labile linkage, such as a labile peptide linkage [67].

*Cheeseman et al.* [138] disagreed with this "ester" hypothesis, since they were unable to observe any liberation of protons during the action of rennin. *Beeby* and *Nitschmann* [139] expressed the opinion that rennin first cleaves linkages like hydrogen bonds, with the result that part of the κ-casein dissolves afterwards; the rennin liberates the glycopeptide from the dissolved material.

Finally, *Dennis* and *Wake* [124] have shown that sugar-free reduced κ-casein is cleaved by rennin, so that an ester linkage between phenylalanine and a sugar can be ruled out.

Further investigation will be necessary in order to elucidate the nature of the linkage that is cleaved by the action of rennin (possibly a Phe-Met linkage as shown in Scheme 1; for earlier theories see [136]).

*N*-acetyl- and *N*-glycolylneuraminic acids, while the human glycopeptide contains only *N*-acetylneuraminic acid; the latter is the only glycopeptide in which fucose and glucosamine have been found [102].

*C*- and *N*-Terminal Amino Acids. The action of carboxypeptidase on sheep, goat, and human caseinoglycopeptides led to the liberation of valine [99, 111]. The *N*-terminal amino acid was studied only in the case of the sheep caseinoglycopeptide; as in cow's κ-caseinoglycopeptide, it was found to be methionine [122].

Structure Studies. The caseinoglycopeptide from total sheep casein consists of three parts: 1. an *N*-terminal sequence, which contains the three lysine residues of the peptide; 2. a decapeptide containing the only histidine unit of the peptide; and 3. an "acidic" part, which has not yet been completely purified by column chromatography. This last-named part contains the phosphorus and most of the sugar [122, 132, 140] (see Table 3).

Table 3. Data on the structure of sheep caseinoglycopeptide [122, 132, 140].

1. *N*-Terminal sequence containing the three lysine residues present in the molecule:
Met → Ala → Ileu → Pro → Pro → Lys → Lys → ($Asp_2$, Glu) → Lys → Thr → ($Ileu_2$, Ala, Pro, Glu, Asp)

2. Decapeptide containing the unic histidine residue in the molecule:
Thr → Ileu → Ala → Ser → Ala → Glu → Pro → Thr → Val → His

3. "Acidic" part:
phosphorus +
sugars +
*C*-terminal amino acid: Val
$Asp_5$, $Thr_8$, $Ser_6$, $Glu_7$, $Pro_3$, $Ala_6$, $Val_5$, $Ileu_1$.

## 6. Caseinoglycopeptides from Total Sheep, Goat, and Human Caseins

The total casein, α-casein, and κ-casein from cow's milk all give the same caseinoglycopeptide [113]. Since pure κ-casein fractions have not yet been isolated from sheep, goat, and human milk, *Alais* and *Jollès* [99, 111] used the total caseins for the preparation of caseinoglycopeptides.

Purification. The caseinoglycopeptides were isolated from the trichloroacetic acid extract of caseins that had been treated with rennin [111]; it was not always possible to obtain a glycopeptide from human total casein [99].

Amino Acid Composition. The three new caseinoglycopeptides contain large quantities of serine, threonine, glutamic acid, and proline, but no aromatic amino acids, cystine or arginine [111]. This composition appears to be characteristic of caseinoglycopeptides. The peptide contents are about 80% [73].

Sugar Composition. The sugar contents of caseinoglycopeptides from sheep, goat, and human milk are 7.1, 11.6, and 16%, respectively [73, 99]. All three substances contain galactosamine and galactose. The glycopeptides from sheep and goat milk contain a mixture of

The neuraminic acids occur in a terminal position in sheep and goat caseinoglycopeptides; galactosamine, but not galactose, appears to be directly attached to the peptide chain [134]. *Malpress* [102] believes that *O*-glycosidic linkages are formed between the sugars and the serine and threonine residues.

## 7. "Caseinoglycopeptide-like" Substances

As mentioned in Section II A 3, casein is attacked not only by rennin, but also by other enzymes [125, 126] and by chemical reagents [67, 121]. During the primary reaction between casein from cow's milk and pepsin, the peptide split off is the same as with rennin [125]; that split off by callicrein is slightly different [126]. A slightly different peptide is also obtained in good yields either with 0.1 N NaOH at 20 °C [67] or by reduction [121]. All these caseinoglycopeptide-like substances, such as the glycopeptide obtained by the action of rennin, are soluble in 12% trichloroacetic acid and are not dialysable; no aromatic amino acids or arginine are present.

When casein is heated to 100 °C not only neuraminic acid, but also "caseinoglycopeptide-like" substances are liberated [104, 141, 142] (regarding the action of heat on casein, see also [142, 143]).

## B. Secondary and Tertiary Reactions

The second phase in the clotting of milk involves several reactions (deaggregation, reaggregation, coagulation, syneresis of the gel), during which the degree of dispersion of the casein micelles changes. Coagulation is the easiest of these to be followed by physical methods (ultramicroscopy [144], ultrasonics [145], viscometry [146]). The clotting of milk can be represented by the following reactions [147] (see also Section IA2c):

$$\text{Micelles} \overset{Ca^{2+}}{\rightleftharpoons} \text{soluble complex } (\alpha_s, \varkappa, \beta, \ldots) \quad (1)$$

$$\text{Soluble complex } (\alpha_s, \varkappa, \beta, \ldots) \xrightarrow{\text{rennin}} \text{soluble complex } (\alpha_s, \text{para-}\varkappa, \beta, \ldots) + \text{caseinoglycopeptide} \quad (2)$$

$$\text{Soluble complex } (\alpha_s, \text{para-}\varkappa, \beta, \ldots) \xrightarrow{Ca^{2+}} \text{coagulum} \quad (3)$$

It is assumed that Reaction (1) is established very quickly, and does not affect Reaction (2). In the absence of $Ca^{2+}$, only Reaction (2) occurs, and no coagulation takes place. The rate of Reaction (3) increases rapidly with rising temperature; it is therefore possible to distinguish this reaction from Reaction (2) at low temperatures [148].

*Cheeseman* [149] showed that some substances can shorten or lengthen the coagulation time (*e.g.* $Ca^{2+}$ reduces the coagulation time, urea increases it). After coagulation, the syneresis of the casein gel is completed.

This reaction can be followed by the change in the weight of the gel or by measurement of the emerging liquid [149]. Syneresis according to Reaction (2) begins already during the hydrolysis of the $\varkappa$-casein. Hydrogen bonds are first formed between the casein aggregates, and bridges are finally also established between thiol groups [149, 150]. The rates of the second phase and of the clotting by rennin were recently studied [151, 152].

The existence of a tertiary phase was shown by *Alais et al.* [112]. The primary reaction involves aspecific digestion of casein by rennin, while the tertiary reaction involves a non-specific digestion. High molecular weight substances derived from the various casein components are formed first; the final products are a large number of polypeptides which are more or less resistant to rennin.

In conclusion, it should be mentioned that the digestion of casein by various enzymes (particularly pepsin) often leads to substances that are very similar to those obtained during the tertiary phase of the clotting by rennin [31, 153–157].

# Force Constants and Bond Orders of Nitrogen Bonds

BY PROF. DR. J. GOUBEAU

LABORATORIUM FÜR ANORGANISCHE CHEMIE
DER TECHNISCHEN HOCHSCHULE STUTTGART (GERMANY)

*The force constants and the corresponding bond orders of nitrogen bonds have been calculated from the vibrational spectra (infrared and Raman spectra) of a great number of nitrogen compounds. Plotting the maximum bond order of stable nitrogen bonds against the sum of Pauling's electronegativities of the bonding partners ($\Sigma x$) leads to one continuous curve for the N–X bonds where X represents elements of the first and the second short period of the periodic table. Furthermore, when the bonds formed between these elements are arranged in a coordinate system in such a way that the position of each bond is determined by the difference between the electronegativities of the bonding partners ($\Delta x$ along the ordinate) and the sum of the electronegativities of the bonding partners ($\Sigma x$ along the abscissa), the bonding partners capable of forming multiple bonds all lie within a closed domain, where their position can be correlated with their polymerizability and other reactivities of the multiple bonds. Also discussed are the orders of bonds between nitrogen and some transition elements. In an appendix, the present methods used to calculate force constants and bond orders are surveyed.*

## A. Introduction

The conditions for the formation of π-bonds have been previously summarized as follows [1]:

1) electron deficiency on both bonding partners;

2) the sum of the Pauling electronegativities of the partners must be at least 5;

3) the difference between the Pauling electronegativities of the bonding partners must be small.

We have endeavored in the past few years to verify these conditions on further examples and, in particular, to define more accurately condition 3). Condition 2) has recently been confirmed by *Herber* and *Stöckler* [2], who investigated the Mössbauer effect of tin compounds and showed that the isomeric shift is invariably proportional to the sum of the electronegativities of all bonding partners involved.

We have chosen nitrogen for our investigations, since it forms a great number of compounds and has the high electronegativity of 3,0, enabling it to form bonds with numerous elements in such a way that the sum of the electronegativities is at least 5. Unlike the halogens, and like oxygen, nitrogen can form π-bonds without the accumulation of high formal charges. The types of bonds that nitrogen can form are summarized in Table 1.

Table 1. Types of bond formed between nitrogen and a partner X.

| | |
|---|---|
| Ammines | $X \leftarrow NH_3$ |
| Amines, amides | $X-\ddot{N}H_2 \leftrightarrow X \leftarrow NH_2$ |
| Imines, imides | $X-\ddot{N}-H \leftrightarrow X=\ddot{N}H \leftrightarrow X \equiv NH$ |
| Nitrides | $X-\ddot{N}: \leftrightarrow X=\dot{N}: \leftrightarrow X \equiv N:$ |

In addition to the preferred bonds, in which the two atoms involved have a low formal charge (cf. Table 1), bonds in which the nitrogen carries a formal positive charge are also important. This formal positive charge is to some extent compensated by the fact that nitrogen is at the same time the negative end of the polar bonds which it forms in most cases.

## B. Calculation of Bond Order

The following discussion is based on vibrational spectra (infrared and Raman spectra) furnishing data for the force constants, which in turn are used for the calculation of the bond orders. In these calculations, the geometry of the molecule and the assignment of the observed frequencies to the fundamental vibrations is also accounted for. *Fadini*, *Sawodny*, and *Ballein* [3] have used a new method of calculation, enabling them to obtain the force constants and all interaction constants directly from the measured frequencies without a trial-and-error procedure [4]. The resulting valence bond constants, the only ones discussed below, have the advantage of being mutually comparable, since they are obatined by the same method. Deviations of more than 5–10 % correspond to actual changes in the nature of the bonding.

*Siebert*'s rule [4,5] has been used for the calculation of the force constants of single bonds. This rule gives good results, suitable for a general comparison of all force constants. *Siebert*'s values for single bonds correspond

[1] *J. Goubeau*, Angew. Chem. *69*, 77 (1957).

[2] *R. H. Herber* and *A. Stöckler*, Chem. Engng. News *42*, No. 28, 66 (1964).

[3] *A. Fadini*, Z. angew. Math. Mechan. *44*, 506 (1964); *W. Sawodny*, *A. Fadini*, and *K. Ballein*, Spectrochim. Acta *21*, 995 (1965).

[4] *J. Goubeau*, Angew. Chem. *73*, 305 (1961).

[5] *H. Siebert*, Z. anorg. allg. Chem. *273*, 170 (1953).

to $sp^3$ hybridization. Since differences in the hybridization can lead to large (up to 50 %) variations in the force constants of single bonds, it has been found necessary to introduce an empirical correction factor [11].

Using these theoretical force constants for single bonds, we can calculate the bond order, b. It is assumed that higher force constants are essentially due to $\pi$-bonds. *Siebert* has given two equations for the bond order. One is based on the assumption that the bond is proportional to the force constant up to about b = 1.5, the other being an empirical formula (giving good results) for b > 1.5 (see Appendix III). The calculations are generally based on direct proportionality even in the case of higher bond orders. It is further possible to correlate, on a theoretical basis, the bond orders of single and double bonds in certain compounds with the force constants, and then to find the bond orders corresponding to the other force constants, as has been done in Tables 3 and 5 (column $b_{II}$).

## C. Order of Bonds between Nitrogen and Elements of the First Period

The parameters of the N–O, N–N, and the N–C bonds are well known and need no further discussion. In all three cases, the bond order can be between 1 and 3 according to the force constants.

### I. The N—F Bond

Although, on the basis of the sum of electronegativities, the formation of multiple bonds should be possible in nitrogen trifluoride, this compound possesses no electron deficiency (condition 1 in Section A), and can, therefore, form no $\pi$-bonds. In the compounds $NF_2$ [6] and NF [7], which have recently been described together with their vibrational spectra, the nitrogen does not attain an electronic octet (*i.e.* it is electron deficient), and, therefore, it can form multiple bonds (at the most a three-electron bond in $NF_2$). Distributed over two N–F bonds, this leads to a maximum bond order of 1.25, while in NF the bond order may reach 2.0.

Table 2. Force constants f and bond orders b of the N–F bonds in various nitrogen fluorides.

| | $NF_3$ | $NF_2$ | NF |
|---|---|---|---|
| $f_{exp.}$ [mdyne/Å] | 4.38 | 4.85 | 5.90 [7] |
| $f_{calc.}$ (single bond) [mdyne/Å] | 4.26 | 4.05 [8] | 3.87 [8] |
| | | | 4.05 [8] |
| b | 1.03 | 1.20 | 1.45 [8a] |

The experimental force constants and bond orders increase in a parallel direction, which confirms the importance of electron deficiency for the formation of multiple bonds. Whereas the bond order in $NF_2$ is close to theoretical, it is appreciably lower than the theoretical value in NF. This is in agreement with the observation that the positive charge on fluorine in N=F opposes the formation of a $\pi$-bond:

### II. The N—B Bond

The most important results concerning force constants and bond orders of N–B bonds in various compounds are listed in Table 3 [9], together with the possible

Table 3. Force constants f and bond orders b of N–B bonds (X = H, $CH_3$, F, Cl; Y = H, $CH_3$)

| Formula | Ref. | Canonical forms | f [mdyne/Å] | $b_I$ | $b_{II}$ |
|---|---|---|---|---|---|
| $X_3BNY_3$ | [10] | $X_3B{\leftarrow}NY_3$ | 2.8 | 0.7 | 1.0 |
| $(O_3B_3NR_2)_3$ | [11] |  | 4.0 | 1.0 | 1.3 |
| $B(NR_2)_3$ | [12] | $(R_2N)_2B{-}\ddot{N}R_2{\leftrightarrow}(R_2N)_2{\leftarrow}NR_2B$ | 6.0 | 1.5 | 1.7 |
| $(HBNH)_3$ | [13] |  | 6.3 | 1.6 | 1.8 |
| $R_2BNCO$ | [3,14] | $R_2B{-}\ddot{N}{=}C{=}\dot{O}: \leftrightarrow R_2B{\leftarrow}N{=}C{=}\dot{O}:$ | 6.6 | 1.7 | 1.9 |
| $X_2BNY_2$ | [15] | $X_2B{-}\ddot{N}Y_2 \leftrightarrow X_2B{\leftarrow}NY_2$ | 7.0 | 1.8 | 2.0 |
| $BN_2^{3\ominus}$ | [16] | $[:\dot{N}{=}B{=}\dot{N}:]^{3\ominus}$ | 7.0 | 1.8 | 2.0 |
| BN | [17] | $B{-}\ddot{N} \leftrightarrow \overset{\ominus}{B}{=}\overset{\oplus}{N}: \leftrightarrow B{\equiv}N:$ | 8.3 | 2.1 | 2.3 |

mesomeric limiting structures. The bond orders $b_I$ are based on *Siebert*'s value for the single bond (f = 3.9 mdyne/Å). In calculating thebond order $b_{II}$, it was assumed that compounds of the type of $X_3BNY_3$ are characterized by a single bond, while $BN_2^{3-}$ contains a

[6] *F. A. Johnson* and *C. B. Colbuin*, Inorg. Chem. *1*, 431 (1962); *M. D. Harmony* and *R. J. Myers*, J. chem. Physics *37*, 636 (1962).

[7] *M. E. Jacox* and *D. E. Milligan*, J. chem. Physics *40*, 2457 (1964).

[8] In such a case, the value for the $\sigma$-bond represents an intermediate value, since the number of free electron pairs changes in the transition from single bond to double bond. For NF two values are obtained (3.87 and 4.05).

[8a] The bond orders were determined by a simple averaging method, the extreme values being b = 1.39 and b = 1.52.

[9] Cf. *J. Goubeau*, Advances Chem. Ser. *42*, 87 (1964). *H. Nöth*, *G. Schmid*, and *Y. Chung* (IUPAC Congress, Vienna, 1964) have found another example of a B–N bond with high bond order in the adduct $B(NR_2)_3{\cdot}TiCl_4$. However, since the force constant has not been calculated, this example could not be included in Table 3.

double bond. The intermediate bond orders were found on the basis of an assumed proportionality between the bond orders and the force constants. The difference between $b_I$ and $b_{II}$ (about 0.2) is of little significance for the subsequent discussion; the $b_I$ values are preferred for purposes of comparison. The maximum bond order has thus been found to be 1.8 for the N–B bond in compounds that are stable at room temperature.

### III. The N—Be Bond

Beryllium compounds, like boron compounds, form adducts with ammonia and amines [18]. The reaction between beryllium alkyls and amines leads to substituted beryllium amides [19] which could not be prepared from adducts of the type $BeCl_2 \cdot 2HN(CH_3)_3$ by the abstraction of HCl [20]. Unlike the boron compounds, these beryllium amides are known only in polymeric form.

The force constants have been calculated from the spectra of berylliumdi-[bis-(trimethylsilyl)] amide [13] and the adducts formed of ammonia, dimethylamine, and trimethylamine with $BeCl_2$ and $BeBr_2$ [21]. In the first case, the value f = 2.96 mdyne/Å has been obtained for the N–Be bond, while in the other cases, calculations on the basis of the antisymmetric vibrations of the $BeN_2$ group (600–785 $cm^{-1}$) led to f = 1.2 to 1.4 mdyne/Å. Using these values and taking, with *Siebert*, f = 3.1 mdyne/Å for the single bond, we obtain b = 0.95 and b = 0.39 to 0.45, respectively. Since the beryllium amides are polymeric, we cannot expect them to have appreciably higher force constants. In fact, there is no indication at the present of higher bond orders in N–Be compounds.

### IV. The N—Li Bond

Only one very broad infrared band has been observed for each of the simple compounds available, $LiNH_2$, LiNH, and $Li_3N$. These bands are situated, respectively, at 403, 465, and 430 $cm^{-1}$ and can be attributed to antisymmetric vibrations [22]. The resulting force constants (0.44, 0.61, and 0.55 mdyne/Å, respectively) are probably too high. On the assumption that the single bond has a force constant of 2.3 mdyne/Å, the average bond order for the N–Li bond is 0.23.

## D. Order of Bonds of Nitrogen with Elements of the Second Short Period

### I. The N—Cl Bond

Owing to the presence of vacant d-orbitals in elements of the second short period, electron deficiency exists here even when the electronic octet is reached. This means that double bonds can be formed, *e.g.* in $NCl_3$, unlike the case of $NF_3$:

The experimental data for the N–Cl bonds are listed in Table 4.

Table 4. Force constants and bond orders of N–Cl bonds in various compounds [*].

| | f [mdyne/Å] | b | Ref. |
|---|---|---|---|
| $H_2NCl$ | 3.1 | $1.2_6$ | [23] |
| $HNCl_2$ | 3.0 | $1.2_1$ | [23] |
| $NCl_3$ | 2.5–3.0 | $1.0_4$–$1.2_1$ | [23,24] |
| NCl | 4.0 | $1.7_2$ | [7] |
| $NClO_3^{2\ominus}$ | 8.9 | 2.2 | [25] |

In nitrogen trichloride, the calculated force constant varies with the Cl–N–Cl angle; the lower value corresponds to a tetrahedral angle, the higher to an angle somewhat smaller than 120°. However, the geometry of the molecule is not yet known. The bond orders in chloramine and dichloramine confirm the prediction based on the presence of vacant d-orbitals. These are also partly responsible for the fact that chlorine is the negative end in the N–Cl dipole [26]. The bond order in NCl is seen to be high; it is higher than in NF, probably because of the smaller difference between the electronegativities of the bonding partners. The highest force constant (f = 8.9 mdyne/Å) is exhibited by $NClO_3^{2-}$, this value being greater than that corresponding to a double bond.

### II. The N—S Bond

Out of the reliable data for the force constants of N–S bonds, some characteristic examples are listed in Table 5.

Table 5. Force constants and bond order of N–S bonds in various compounds.

| | f [mdyne/Å] | $b_I$ | $b_{II}$ | Ref. |
|---|---|---|---|---|
| $(CH_3)_3NSO_3$ | 3.0 | 0.8 | 0.8 | [27] |
| $H_3NSO_3$ | 3.1 | 0.8 | 0.8 | [28] |
| $(CH_3)_2NSCH_3$ | 3.1 | 1.2 | 1.1 | [29] |
| $H_3CN(SCH_3)_2$ | 4.3 | 1.5 | 1.3 | [29] |
| $(H_3CN)_2S$ | 8.1 | 2.5 | 1.9 | [30] |
| HNSO | 8.3 | 2.6 | 2.0 | [31] |
| NSF | 10.7 | 3.4 | 3.0 | [32] |
| $NSF_3$ | 12.5 | 3.4 | 3.0 | [32] |

With *Siebert*'s value of f = 3.7 mdyne/Å for the single bond, we obtain bond orders between 0.8 and 3.4, taking into account the hybridization and assuming a direct proportionality between f and b. However, since the bond order cannot exceed 3, it is better to ascribe the values b = 3 and b = 2 to $NSF_3$ and HNSO, respectively, and to recalculate the other values on this basis ($b_{II}$). The corrected *Siebert* formula gives b = 2.70 and b = 2.2 in these cases. The properties of these compounds confirm the presence of the double and triple bonds deduced from the bond orders.

## III. The N—P Bond

Only a few examples have been selected from the chemistry of N–P compounds [33] to illustrate the range of the force constants. Discounting the band spectrum of PN in the gaseous state, which would probably give b = 3, we find that the bond order for normal compounds varies between 0.8 and 2.0.

The force constants in $[Cl_3P{-}N{-}PCl_3]^+$ [*] depend on the P–N–P angle (which is again unknown):

| Angle | 120° | 140° | 160° | 180° |
|---|---|---|---|---|
| f [mdyne/Å] | 6.2 | 6.9 | 7.8 | 9.1 |

Table 6. Force constants and bond orders of N–P bonds in various compounds [**].

| | f [mdyne/Å] | b | Ref. |
|---|---|---|---|
| $H_3NPO_3^{\ominus}$ | 3.1 | 0.8 | [35] |
| $(CH_3)_2NPCl_2$ | 3.5 | 1.3 | [36] |
| $(NPCl_2)_3$ | 4.2 | 1.2 | [37] |
| $H_2NPO_3^{\ominus}$ | 4.3 | 1.2 | [35] |
| $HNP(CH_3)_3$ | 6.1 | 1.7 | [38] |
| $[N(PCl_3)_2]^{\oplus}$ | 6.9 | 2.0 | |
| NP | 10.6 | 3.4 | [39] |

On the basis of calculations [33], the most likely value for the angle is 140 °C; it is associated with the highest force constant known to us (f = 6.9). It should be added that compounds such as $RNPCl_3$, $RNPF_3$, $NPCl_2$, and $NPF_2$, for which high bond orders are expected, exist only in polymeric form at room temperature.

## IV. The N—Si Bond

The reported values of the force constants vary, probably because the bond angle exerts a strong influence on the value of f.

Table 7. Force constants and bond orders of N–Si bonds in various compounds.

| | f [mdyne/Å] | b | Ref. |
|---|---|---|---|
| Single bond | 3.3 | | *Siebert* |
| $HN[Si(CH_3)_3]_2$; 140° | 3.5 | 1.1 | [40] |
| $HN(SiCl_3)_2$; 140° | 4.0 | 1.2 | [41] |
| $N(SiH_3)_3$ | 4.1 | 1.2 | [42] |
| $N[Si(CH_3)_3]_2^{\ominus}$; 160° | 4.2 | 1.3 | [43] |
| NSi | 7.3 | 2.2 | [44] |

Discounting molecular SiN which exist only at high temperatures, we find that the maximum bond order is 1.3 for the N–Si bond in compounds stable at ordinary temperatures. The maximum value of f = 4.8 mdyne/Å reported for the compound $S{=}C{=}N{-}SiH_3$ [45] is not included in Table 7, since, on recalculation, we have obtained a considerably lower value. However, even for the published value the bond order would be only 1.45. In the case of silicon, compounds of the type >Si=NR, which are monomeric in the case of sulfur and phosphorus, exist here only in polymeric form. Although we have taken b = 1.3 as the maximum value, the bond order may be somewhat higher in certain compounds.

## V. The N—Al Bond

In this case and in the following ones, spectroscopic data that may be used for the calculations are relatively scarce, except perhaps for aluminum nitride [22] and the ammonia and amine adducts of aluminum com-

[**] *Siebert*'s value for the $sp^3$ single bond is f = 3.5.

pounds [10, 46]. The calculated force constants are between 1.9 and 2.5 mdyne/Å, to which correspond bond orders between 0.6 and 0.8 (*Siebert*'s force constant of the single bond is f = 3.0).

### VI. The N—Mg and the N—Na Bond

Infrared spectra have been recorded for $Mg_3N_2$, $Mg(NH_2)_2$, and $NaNH_2$ [22], and the force constants for the MgN (1.33 and 2.00) and NaN bonds (0.53) calculated only from antisymmetric vibrations on the basis of the two-body model now appear to represent upper limits. The resulting bond orders, b = 0.47 and 0.70 for MgN and b = 0.21 for NaN, are compatible with the high polarity of these bonds.

Basically the same curve is obtained by plotting b against $\Sigma x$ for the nitrogen bonds formed with elements of the first short period and elements of the second short period (Fig. 1; $\Sigma x$ denotes the sum of the electronegativities of the bonding partners, and the b values represent the maximum bond orders). Whenever $\Sigma x > 5$, double bonds can be formed (except in the case of F). Recalling condition 2 which states that, for the formation of double bonds, the sum of the electronegativities of the bonding partners must be at least 5, we note that, when this condition is not fulfilled (*i.e.* for the nitrogen bonds to Li, Be, B and Na, Mg, Al, and Si) the bond orders do in fact lie below b = 2 (b = 1 at $\Sigma x \approx 4.5$). Bond orders below 1 are due to the fact that the polarity of the bonds increases with decreasing value of $\Sigma x$ [3]. The bond orders of 0.42 and 0.72 for the "single bond" adducts of Be and B, respectively, fit in well with this series. The coincidence of the curves for the two short periods may be regarded as a confirmation of the second condition stated in Section A.

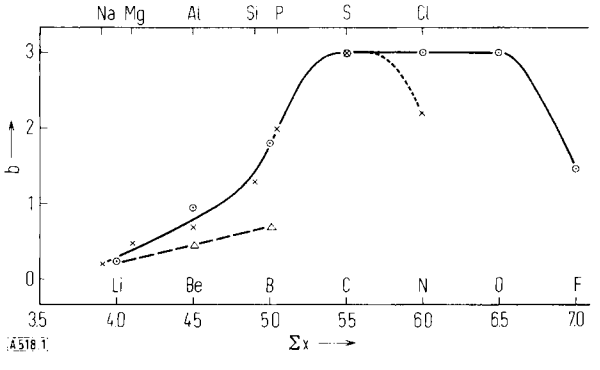

Fig. 1. Maximum bond order of the nitrogen bonds of elements of the first (○) and the second (×) short period and adducts (△), as a function of the sum of Pauling's electronegativities of the bonding partners ($\Sigma x$). The full curve refers to the maximum bond order.

### E. Order of Bonds between Nitrogen and Elements of Higher Periods Including Transition Elements

The bond order for NBr is 1.7 [7], and the bond is, therefore, similar to that in NCl. The compound RN=Se=O does not exist as a monomer and even its dimer (probably a four-membered ring) is stable only at temperatures below −10 °C [47], further polymerization occurring at higher temperatures. The N=Se bond is, therefore, less stable than the analogous N=S bond. Approximate calculations based on the assumption that the dimer forms a four-membered ring have given f = 3.4 and b = 1.3 for the N–Se bond.

In addition to insufficient experimental data on the nitrogen bonds of the transition elements, calculations are made difficult by the fact that the electronegativities are not accurately known and the electrons can occupy various orbitals. The force constants and the bond orders of the nitrogen bonds of the transition elements are listed in Table 8.

None of the elements has been subjected to exhaustive investigations concerning their bond parameters. Instead, ranges of single values are given in Table 8 for the force constants of azides, since the $N_3$ group was treated as a point mass in the simplified approximation. The lower limit corresponds to mass 14, the upper to mass *ca.* 30.

Table 8. Electronegativities (x), stretching frequencies (ν), force constants (f), and bond orders (b) of the nitrogen bonds of transition elements.

| | Ref. | x | ν [cm⁻¹] | | f acc. to *Siebert* | $f_{exp.}$ | b |
|---|---|---|---|---|---|---|---|
| (ClTiN)n | [48] | 1.6 | 406 | | 3.2 | 1.1 | 0.3 |
| $Cl_3TiN_3$ | [48] | | 565 | | | 2.0–3.1 | 0.6–1.0 |
| $Cl_4VN_3$ | [49] | 1.8 | 555 | | 3.7 | 2.0–3.1 | 0.5–0.8 |
| $Cl_2OVN_3$ | [48] | | 560 | | | 2.0–3.1 | 0.5–0.8 |
| VN | [22] | | 615 | | | 2.5 | 0.7 |
| $Cl_3VNCl$ | [49] | | | 1110 | | 8.0 | 2.2 |
| $Cl_2W(NH)_2$ | [50] | 1.9 | 475 | | 3.6 | 1.8 | 0.5 |
| $F_2W(NH)_2$ | [50] | | 470 | | | 2.1 | 0.6 |
| | | | 530 | | | | |
| $[Cl_2W(NH_3)_3]Na_2$ | [50] | | 715 | | | 4.8 | 1.3 |
| | | | 815 | | | | |
| $Cl_3WN$ | [49] | | | 1073 | | 8.8 | 2.4 |
| $Cl_4MoN_3$ | [49] | 2.0 | 552 | | 3.8 | 2.2–3.7 | 0.6–1.0 |
| $Cl_3MoN$ | [49] | | | 1045 | | 7.9 | 2.2 |
| $ClO_2CrN_3$ | [48] | 2.1 | 495 | | 4.1 | 1.6–2.5 | 0.4–0.6 |
| CrN | [22] | | 565 | | | 2.1 | 0.5 |
| $Cl_3ReNR{\cdot}PR_2R'$ | [51] | 2.1 | 780 | | 3.8 | 4.9 | 1.3 |
| $O_3ReN^{2\ominus}$ | [52] | | | 1025 | | 8.0 | 2.1 |
| $O_3OsN^{\ominus}$ | [53] | 2.2 | | 1023 | 3.9 | 8.0 | 2.1 |
| $Cl_5OsN^{2\ominus}$ | [53] | | | 1084 | | 9.0 | 2.4 |

The higher values, which are more probable, lead to bond orders of 0.6 and 1.0 in accordance with expectations. When the values of $b_{max}$ for Ti, V, Mo, W, Re and Os are plotted against $\Sigma x$ (Fig. 2), the points for Ti, Re, and Os lie on the curve, while Mo, and particularly W and V (the last two in their chloronitrides with b > 2) lie above the curve. The O-V bond in oxygen-containing compounds has a similar anomalous position.

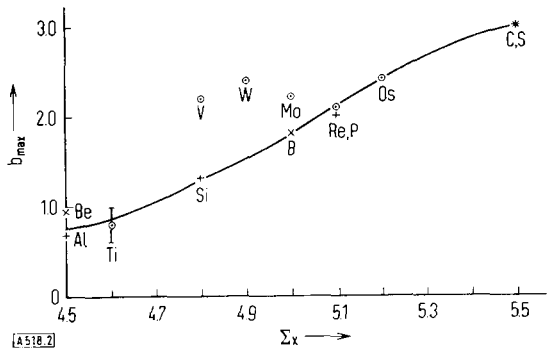

Fig. 2. Maximum bond order $b_{max}$ of the nitrogen bonds of transition and other elements as a function of the sum of *Pauling*'s electronegativities of the bonding partners (Σx).

It cannot yet be decided whether the electronegatitivies [*] and/or force constants belonging to the single bonds are incorrect, or whether the transition metal bonds are in fact different. A more accurate knowledge of the hybridization may throw some light on this problem.

## F. Comparison with Bonds Involving no Nitrogen

In order to compare the polarities of all possible bonds that may be formed within the first short period, we have constructed Fig. 3 by plotting the sum of the electronegativities against the difference of electronegativities of all such combinations. The three apexes of the triangle represent the three types of bond in pure form.

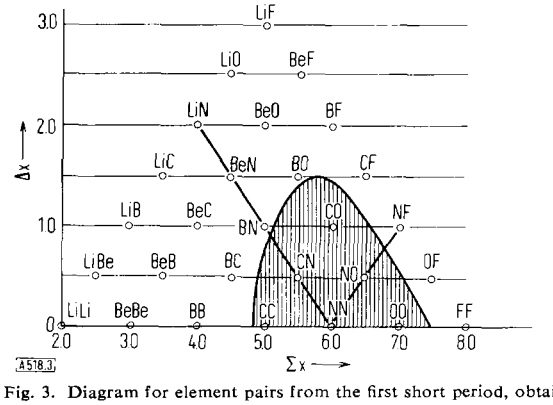

Fig. 3. Diagram for element pairs from the first short period, obtained by plotting the sum of the electronegativities (Σx) against the difference of electronegativities (Δx) of the bonding partners. The shaded area comprises bonds with b ≥ 2 in compounds stable at ordinary temperatures.

The shaded area contains the element-pairs that can form multiple bonds (b ≥ 2.0) in compounds stable at ordinary temperatures. The boundary to the top right is determined by the electron deficiency (condition 1), that to the top left by the difference, and to the left by the sum of the electronegativities (conditions 3 and 2, respectively).

Fig. 4 has been obtained in the same way for element pairs formed in the first and second short periods, the range being now set by Σx = 4.5 and 7.0 and by Δx = 0 and 2.0 comprising the more interesting combinations.

[*] The literature values of these electronegativities differ by 0.1 to 0.2 eV. We have taken the mean values, but the highest ones would bring V, W, and Mo nearer to the curve.

Most element pairs lying within the boundaries drawn for the first short period (shaded area) can similarly reach a bond order of 2, the exceptions being the chlorine bonds of P, S, and C [owing the polar bonding (halogen effect)] and the S–S bond. The latter, however, is clearly a limiting case, since S=S bonds do exist in $S_2$ molecules at 800 °C [54]. These anomalies indicate that, as expected, *Pauling*'s electronegativities represent only a rough approximation.

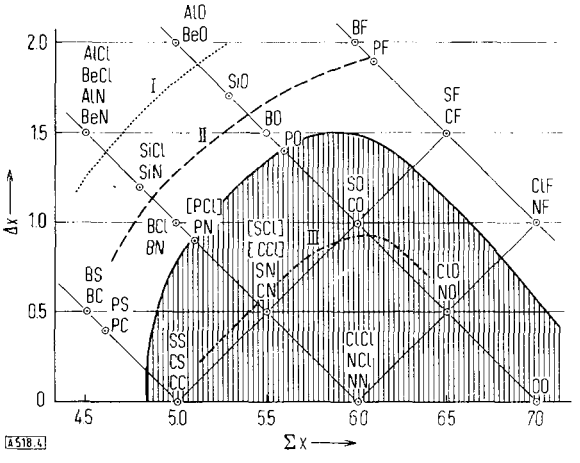

Fig. 4. Diagram for element pairs from the first and second short period, obtained by plotting Σx against Δx. The shaded area comprises bonds with b ≥ 2 in compounds stable at ordinary temperatures (curve I: b ≈ 1; curve II: b ≈ 1.5; curve III: b ≈ 3).

## G. Conclusions

Although it may seem like playing with numbers, the above treatment does lead to significant conclusions concerning the stability and the reactivity of multiple bonds. Thus, we can quote again the following examples (cf. Fig. 1):

| | |
|---|---|
| 3 :N≡N: ← $N_6$ | Σx = 6.0 |
| 3 HC≡N: ⇌ $H_3C_3N_3$ | Σx = 5.5 |
| 3 HB≡NH → $H_3B_3N_3H_3$ | Σx = 5.0 |

In the case of nitrogen with Σx = 6.0, the triple bond is so stable that no polymer is formed. In the case of HCN with Σx = 5.5, both monomeric and polymeric forms exist, while only the polymer is known for HBNH characterized by Σx = 5.0. In terms of the diagram in Fig. 4, the lower right element pairs form very stable multiple bonds with a small tendency to polymerize. The stability of the multiple bonds decreases, and the polymerizability increases, as one proceedes towards the top left, coming to bonds formed by carbon, phosphorus, and boron frequently encountered in polymer chemistry. The element pairs N–O, C–O, and B–O form similar rows, as do Cl–O, S–O, and P–O.

The N–O system affords a further example of the polymerizability increasing with decreasing Σx: having 10 valence electrons, $NO^{\oplus}$ shows no tendency to polymerize. Nitric oxide has 11 electrons, and its Σx value must be lower; accordingly, it dimerizes in the liquid

[54] *R. Maeder*, Helv. physica Acta *21*, 411 (1948).

state at a low temperature. The species $NO^{\ominus}$, having 12 electrons and being formed in the reaction of NO with alkali metals in liquid ammonia, exists only as a dimer [55]. This shows that the position of the element pairs in Fig. 4 is not fixed, but varies according to the type of bond and the other bonding partners. The polymerizability of C=S has recently been confirmed in the case of $F_2CS$ which polymerizes in the presence of fluorides [56].

Among the interesting bonds lying outside the shaded area in Fig. 4, whose boundary is not yet well defined in the low-$\Delta x$ region, we may mention the P–C and the P–S bonds, which have been studied with respect to their reactivities but which require further spectroscopic investigation.

## H. Appendix

### Calculation of Force Constants and Bond Orders (by Dr. W. Sawodny)

### I. Derivation of the Oscillation Equation [57–59]

The theoretical treatment of molecular vibrations starts with the assumption that the atoms can be considered as points of mass and the bonds between them as weightless springs, *i.e.* that we are faced with a mechanical system of coupled oscillators. It is further assumed that the very small motions of the mass points about their rest positions are harmonic vibrations and the potential curve can, therefore, be represented approximately by a parabola. The kinetic energy T and the potential energy V of the oscillating system are given by

$$2\,T = \sum_{ij} b_{ij}\dot{q}_i\dot{q}_j = \dot{\mathbf{q}}'\mathbf{B}\dot{\mathbf{q}} \quad (b_{ij} = b_{ji}) \tag{1a}$$

$$2\,V = \sum_{ij} f_{ij}q_iq_j = \mathbf{q}'\mathbf{F}\mathbf{q} \quad (f_{ij} = f_{ji}) \tag{1b}$$

where the $q_{i,j}$ are displacements of the mass points from their equilibrium positions. The potential energy coefficients $f_{ij}$ are described as force constants, and are a measure of the strength of the springs, *i.e.* of the forces acting between the atoms. For sufficiently small and slow vibrations, the coefficients $b_{ij}$ and $f_{ij}$ can be considered independent of $q_i$.

By substituting expressions (1a) and (1b) into the energy equation

$$T + V = \text{const.} \tag{2}$$

we obtain

$$^1/_2\,(\dot{\mathbf{q}}'\mathbf{B}\dot{\mathbf{q}} + \mathbf{q}'\mathbf{F}\mathbf{q}) = \text{const.} \tag{3}$$

Differentation with respect to time gives the equation of motion

$$\mathbf{B}\ddot{\mathbf{q}} + \mathbf{F}\mathbf{q} = 0, \tag{4}$$

a possible solution of which is

$$\mathbf{q} = \mathbf{a}\sin\omega t; \quad \ddot{\mathbf{q}} = -\omega^2\,\mathbf{a}\sin\omega t = -\omega^2\mathbf{q}. \tag{5}$$

Insertion of this result into Eq. (4) leads to a set of linear algebraic equations:

$$(\mathbf{F}-\lambda\mathbf{B})\mathbf{q} = 0; \quad \lambda = \omega^2, \tag{6}$$

which have non-vanishing solutions for $\mathbf{q}$ only at certain $\lambda$ values (eigenvalues). These eigenvalues are connected with the frequencies of the fundamental oscillations by the relationship $\lambda = 4\pi^2c^2\nu^2$, and they satisfy the secular equation:

$$\det(\mathbf{F}-\lambda\mathbf{B}) = 0. \tag{7a}$$

The substitution $\mathbf{G} = \mathbf{B}^{-1}$, carried out for convenience sake, leads to

$$\det(\mathbf{G}\mathbf{F}-\mathbf{E}\lambda) = 0 \tag{7b}$$

where $\mathbf{E}$ is the unit matrix.

Besides the eigenvalues $\lambda$ (fundamental vibrations) obtained from the vibrational spectra, the determinant contains the matrix $\mathbf{G}$, which is made up of the atomic masses, the bond angles, and the bond lengths of the molecule, and matrix $\mathbf{F}$, which is constructed of the desired force constants [*].

The derivation of the secular equation (7b) is independent of the choice of coordinates for the oscillator displacement, provided that they satisfy conditions (1a) and (1b). On the other hand, the coefficients $b_{ij}$ and $f_{ij}$ are determined by the coordinates used. Instead of Cartesian coordinates, linear transformations of these are generally used.

Most convenient are the internal valence coordinates, which embrace only the internal vibrations of the molecule without its translational and rotational motions (these have zero frequency). The movement of the atoms is thus described in terms of changes in either the bond angle or bond length. The force constants thus assume the following physical meaning: the diagonal elements of the $\mathbf{F}$ matrix represent the valence and the deformation constants, while the non-diagonal members denote the coupling constants between the valence and deformation modes. This is known as the General Valence Force Field (GVFF) model.

The mathematical effort rapidly increases as the order of the determinant (7b) increases, though it may be simplified by virtue of molecular symmetry. Within a symmetry class, the fundamental molecular vibrations are subdivided into various symmetry species. One can find linear combinations of the inner coordinates that correspond to the symmetry properties of the fundamental vibrations. These are called "symmetry coordinates". The overall secular determinant of the molecule can then be factorized into several smaller determinants whose orders are given by the number of fundamental vibrations of the corresponding symmetry species. These smaller determinants can then be solved separately.

Nevertheless, electronic computers generally must be employed in the treatment of the vibration problem, particularly for molecules of low symmetry or containing many atoms [60].

### II. Solution of the Secular Equation

Equation (7b) is termed the characteristic equation of the eigenvalue problem, and can be solved by various methods for the eigenvalues $\lambda$ [58]. This type of calculation presupposes a knowledge of the force constants and can be used to confirm the assignment of the fundamental vibrations for a given

[*] If there is only one fundamental vibration, the determinant reduces to one single equation $gf - \lambda = 0$ which, for a diatomic molecule, leads to $4\pi^2\nu^2 = f\left(\frac{1}{m_1} + \frac{1}{m_2}\right)$.

molecule by using the constants of compounds having a similar structure[61]. However, the problem is generally the reverse: we know the vibrational assignment and seek the coefficients of the F-matrix. The derivation of Eq. (7b) in the manner specified above involves the basic difficulty of having to calculate for each symmetry species n(n+1)/2 GVFF-force constants from n eigenvalues (in the case of a symmetric F-matrix); as a result, the system of equation is insufficiently defined for $n > 1$.

We can now attempt to find further defining equations by the use of additional experimental data, or to reduce the number of required force constants to n by use of simplifying assumptions concerning the force field, or else to employ mathematical approximation methods.

## 1. Additional Experimental Data

To obtain additional information, fundamental vibrations of isotope-substituted molecules can be used. The force field is considered to be independent of the masses of the system, *i.e.* the isotope substitution does not change the F-matrix, but the fundamental vibrations are changed and a new G-matrix results. Thus, additional equations for the force constants are obtained. However, the mass of the isotope-substituted molecule must differ sufficiently from that of the reference molecule, since otherwise the additional equations roughly duplicate the original ones, and the indeterminacy of the F-matrix is retained[62]. Furthermore, as the frequency shifts decrease, their measurement involves an increasing error. Therefore, H–D substitution is the most convenient for the calculation of force constants, although owing to the small masses, the anharmonicity cannot be neglected introducing a further uncertainty. In addition, there are some isotope rules, such as the product rule of *Teller* and *Redlich*[63], which represent relationships independent of the force constants, and decrease the number of independent equations available for the determination of the F-matrix.

The vibration-rotation interaction constants can also be utilized in the determination of the force constants. Both the centrifugal stretching constants $D_J$, $D_{JK}$, and $D_K$[64] and the Coriolis coupling constants $\zeta_i$[65] depend on the F-matrix, Although their relationship is a more complicated one, these constants can still be used successfully.

The force constants are also related to the mean vibration amplitudes obtained from electron diffraction studies[66] as well as to the intensities of Raman and infrared bands[67], although all these measurements are not yet sufficiently accurate for the application of the data in the calculation of the force constants.

Unfortunately, these additional data are at present available only for simple molecules. It may also happen that even the use of such information leads to no unique solution of the GVFF constants, and resort must then be taken to the application of simplified potential fields.

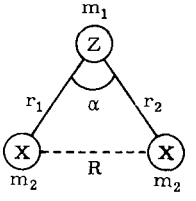
## 2. Simplified Potential Functions

To reduce the number of force constants, we can make certain assumptions concerning the magnitudes of some constants or the relationships between them. One possibility is to borrow some of the constants from other molecules. Particularly suited for this are constants obtained with the aid of the Urey-Bradley field[68]. However, this process becomes questionable when the changes in the bonds caused by the modified surroundings are to be investigated.

Simplification of the potential functions is best illustrated by means of an example: a symmetric non-linear three-body system $ZX_2$ of symmetry $C_{2v}$ executes three fundamental vibrations, two of the type $A_1$ and one of the type $B_1$. The potential energy is given, in accordance with Eq. (1), by

$$2V = f_r(\Delta r_1^2 + \Delta r_2^2) + 2f_{rr}\,\Delta r_1\,\Delta r_2 + f_\alpha\,\Delta\alpha^2 + 2f_{r\alpha}(\Delta r_1\alpha + \Delta r_2\alpha)$$

Therefore, the GVFF contains four constants to be determined.



The following two simplifying assumptions can be made. In one case, we assume that all interaction constants are negligibly small, so that they can be put equal to zero. The potential function then contains only two constants:

$$2V = f_r(\Delta r_1^2 + \Delta r_2^2) + f_\alpha\Delta\alpha^2$$

This model is known as the Simple Valence Force Field (SVFF). In the second case, we assume that the potential energy is a pure square function of all the internuclear distances, *i.e.* that the force acting on an atom is the sum of the attractive and the repulsive forces due to all the other atoms, these forces coinciding with the lines between the nuclei and depending on internuclear distances alone. This is the ionic model of the Simple Central Force Field (SCFF), in which the potential energy is given by:

$$2V = f_r(\Delta r_1^2 + \Delta r_2^2) + f_R\Delta R^2$$

Both the deformation constants and the coupling terms have thus been expressed in terms of the interaction between the two X atoms not bonded to each other. This postulate is inadequate in the case of linear and planar molecules, since it leads to a zero frequency for the out-of-plane vibrations. With certain molecular configurations, such as tetrahedral $ZX_4$ molecules, not only the squared, but also the linear potential energy terms must be taken into account. The rest position of the atoms is then described as a state of equilibrium between the attractive and repulsive forces.

Both the SVFF and SCFF system are characterized by a redundancy of parameters. Thus, in the given example, three fundamental vibrations are available for the determination of two force constants. The third equation can then be used to verify the results. The results reveal that both postulates involve oversimplifications[69]. It appears, therefore, that we cannot neglect all the coupling constants. The SVFF treatment gives the better result when the central atom is heavy in comparison to the ligands (weak coupling), whereas it is the SCFF treatment that leads to the better approximation when the central atom is light and the ligands are heavy (strong coupling).

The results can be improved by the introduction of additional interaction terms, so as to have the same number of force con-

stants to be calculated as the number of the available fundamental vibrations. These modified models have been used in most force-constant determinations. The above mentioned equalization may be achieved by the introduction of the required number of GVFF coupling terms into the SVFF model (Modified Valence Force Field, MVFF). Although the choice of the interaction terms is arbitrary, we can often rely on analogy and past experience. In many cases all interactions between identical internal coordinates are used, since this advantageously leads to a diagonal F-matrix in the derivation of the oscillator equation with symmetry coordinates. The potential energy of the non-linear $ZX_2$ molecule is then given by:

$$2V = f_r(\Delta r_1^2 + \Delta r_2^2) + f_{rr}\,\Delta r_1\,\Delta r_2 + f_\alpha \Delta\alpha^2$$

A model which combines the SVFF and the SCFF concepts is the Urey-Bradley Force Field model (UBFF)[70]. It contains the valence force constants and the deformation constants of the SVFF model and describes all couplings in terms of forces acting between the non-bonded atoms:

$$2V = f_r(\Delta r_1^2 + \Delta r_2^2) + f_\alpha\,\Delta\alpha^2 + f_R \Delta R^2$$

This treatment generally affords valence force and deformation constants that are appreciably smaller than those obtained by the valence force fields, but gives relatively large van der Waals terms. As mentioned above, the force constants can often be transferred from one molecule to another similar one, but in some cases the UBFF model must be further modified to obtain meaningful results[71]. For easy comparison with force constants obtained by other methods, the UBFF model is frequently employed to calculate the potential energy with symmetry coordinates, but the resulting constants are transformed into those of the valence force field.

Attempts have also been made to derive simplified potential fields by considering the coupling from the point of view of bond theory. Thus, *Heath* and *Linnett*[73] have used the change in hybridization that occurs during the vibration, and developed the Orbital Valence Force Field (OVFF). When an atom is displaced from its equilibrium position by a change of the bond angle, the overlap of the orbitals decreases. In certain deformation vibrations, the orbitals of the central atom can follow this motion either by a partial rotation of the system or a rehybridization with change of the s and p contributions. We thus arrive at a new definition of the deformation constants. The OVFF model resembles the UBFF model in describing the coupling forces by the interactions between the non-bonded atoms. Rehybridization of the orbitals of the central atom can give rise to yet another definition of the coupling between valence and deformation modes: an increase in s-character shortens the bond, while an increase in the p-component lengthens it. These considerations have been incorporated in a model by *Mills*[73] called the Hybrid Orbital Force Field (HOFF) model. This treatment has led to good results in force constant calculations[74], but is at present applicable only when d orbitals do not participate in the bond. A similar, though more complicated, model has been developed by *King*[75] for the $NH_3$ molecule; it is known as the Hybrid Bond Force Field (HBFF) model.

We must also mention an attempt at using the interactions of a $\pi$-electron system to describe relations between some of the GVFF force constants. This is called the $\pi$-bond Interaction Valence Force Field ($\pi$-IVFF) concept, and its use has made it possible to reduce the number of constants to be determined in the case of $Ni(CO)_4$ from 17 to 10[76].

## 3. Mathematical Approach

Mathematical approximation methods may be used to eliminate the indeterminacy of the secular equation (7b) caused by the fact that the number of force constants to be calculated exceeds the number of experimental data available. Thus, in one approach, the matrix product $\mathbf{A} = \mathbf{GF}$ is reduced to the Jacobian canonical form, *i.e.* the determinant $|\mathbf{A}|$ now consists only of the product of the diagonal elements. The eigenvalue $\lambda_k$ involving the fundamental vibration $\nu_k$ is considered as characteristic of the coordinate $q_k$, but corrected for the interaction with the rest of the molecule. The fundamental vibrations are first arranged in a series on the basis of their magnitudes, and the individual terms are then successively removed, so that the force constants $f_{ij}$ $(i > j)$ will depend only on eigenvalues between $\lambda_i$ and $\lambda_n$ [77].

A recent method [3] based on the Cayley-Hamilton theorem gives $n(n+1)/2$ equations for $n(n+1)/2$ force constants, but these equations are not mutually independent. However, this mutual dependence can be eliminated by systematic slight alterations of the equations and the use of an approximate solution. In practice, we start with fully uncoupled vibrations as a first approximation. For this case, a fully defined diagonal **F**-matrix from the diagonal **G**-matrix can be obtained. Using this **F**-matrix as a starting point, a complete **F**-matrix containing all the coupling terms can be calculated by the iterative and stepwise build-up of the known, complete **G**-matrix from the diagonal matrix.

The UBFF force constants have the following meaning:

K = stretching force constant

F = repulsive force constant between non bonded atoms

F' = repulsive force constant, linear term

H = bending force constant

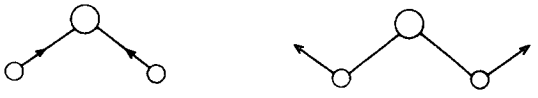
$\varkappa$ = internal tension

UBFF(V) denotes constants of valence force field calculated from UBFF.

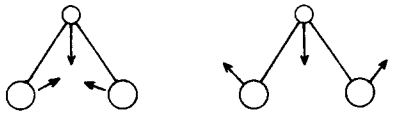
[77] *P. Torkington*, J. chem. Physics *17*, 1026 (1949).

[77a] *T. Shimanouchi, J. Nakagawa, J. Hireishi*, and *M. Ishii*, J. molecular Spectroscopy *19*, 78 (1966).

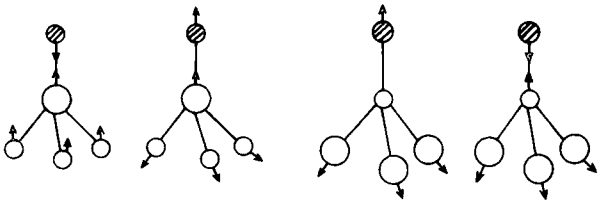
The results of calculations carried out for some simple molecules using various force fields are listed in Tables 9a and 9b, but their discussion must be preceded by brief mention of the concept of coupling. If, in the triangular $ZX_2$ molecule used earlier, the mass of the central atom $m_z$ is large in comparison to that of the ligands $m_x$, then the central atom will remain virtually static during the vibrations:



In this case, the vibrations are practically pure valence or deformation modes, owing to the lack of any coupling *via* the central atom. When, however, the mass relationship is the reverse (*i.e.* $m_z < m_x$), it is predominantly the central atom that oscillates; because of its similar motion in both vibrations, strong coupling between the two modes results.



Although the vibrations are no longer pure stretching and deformation vibrations, they still retain some of their original character, namely, the lower frequency is predominantly the deformation mode and the higher frequency, the valence vibration. On the other hand, in the case of strong coupling between two valence vibrations complete mixing can take place. When, for example, a tetrahedral molecule $YZX_3$ is characterized by the mass relationship of $m_z < m_x \approx m_y$, we can no longer describe the symmetrical valence vibrations as $\nu_{zy}$ and $\nu_{zx_3}$ sym., because these motions actually represent an in-phase and out-of-phase vibration $\nu_{yzx_3}$.



$\nu_{zy}$ $\nu_{zx_3}$ sym. $\nu_{yzx_3}$ sym. $\nu_{yzx_3}$ asym.

In addition to this coupling of masses, the coupling of vibrational energies also plays a part, as for example, in the $NO_2$ molecule. In this case, the relationship $m_z < m_x$ does hold, but the valence vibration of the N–O bond of bond order 1.5 and the deformation vibration differ in their energy so much that they can interact only to a small extent.

Weak coupling does not mean that the coupling constant will be very small. Calculations carried out on $H_2O$, $CH_4$, and $NO_2$ by the GVFF method have given by no means negligible values for the interaction constant $f_{r\alpha}$. However, the coupling constant can vary within wide limits without notable deviations in the valence and the deformation constants. As coupling increases, the system becomes more and more sensitive to changes in the interaction constants. It is, therefore, not surprising that the MVFF method gives poor results in the case of strong coupling. Quite often, no real solutions are obtained at all, as is the case with $F_2O$, $Cl_2O$, $CF_4$, and $CCl_4$; nor can the situation be remedied by neglecting $f_{rr}$, since its value cannot be neglected in most cases (*e.g.* $CF_4$).

By contrast, the UBFF method gives a better approximation for strongly coupled systems, but it leads to erroneous answers in the case of weak coupling. Whereas the constants obtained for $CF_4$ and $CCl_4$ are in good agreement (after transformation of the valence coordinates), the UBFF method

must be modified to result in reasonable values for $CH_4$. Similarly, additional interaction constants must be introduced in the calculations on silicon compounds and molecules with resonance structures (*e.g.* $NO_2$)[71]. The resulting modified model (MUBFF) gives good results, but generally contains more constants than the available number of vibration frequencies[77a].

The force constants obtained by the OVFF method are very similar to those of the UBFF method. The HOFF method on the other hand, represents a considerable improvement. In calculations on $YZX_3$ molecules[74], it was shown to be superior to the MVFF and the UBFF methods, although for tetrahedral $ZX_4$ molecules it again involves more constants than there are vibration frequencies available.

The mathematical method put forward by *Torkington*[77] generally leads to excessively high coupling constants. By contrast, the results obtained by the Cayley-Hamilton theorem[3] for intermediately coupled systems ($CF_4$, $SiF_4$, and $SiCl_4$) are in good agreement with those obtained by the GVFF method. For weak coupling, the resulting coupling constant is practically zero, but as mentioned earlier, this has only a small effect on the valence and deformation constants. The method is not applicable to strongly coupled valence vibrations, since a certain vibration character is a prerequisite for the validity of the first approximation (uncoupled vibrations).

Summing up, we may say that unambiguous answers concerning the coupling constants are available at the present only in very few cases, even with an exact knowledge of the vibrational frequencies and possible additional data as well as all the molecular dimensions (for the influence of the latter, see[78]). Thus, even the values obtained by the GVFF method, using various additional data, show considerable deviations, as for example in the case of $SiF_4$. As regards the valence and the deformation constants, on the other hand, the appropriate choice of the potential function ensures an accuracy of about 10%. Higher accuracy presumably is obtained by the application of a unified method.

Deformation force constants sometimes cannot been given in an explicit form, owing to the presence of "redundant coordinates" (*e.g.* in the case of $ZX_4$ tetrahedra, cf. Table 9a). For the time being, it is reasonable, therefore, to confine the discussion to valence force constants, which, incidentally, are also the most important parameters as regards the properties of bonds.

## III. Empirical Rules for Valence Force Constants

There have been attempts to correlate the valence force constants with other bond properties such as internuclear distance, dissociation energy, and the number of electrons in the bonding partners. The literature contains many such empirical correlations, though they are generally derived and verified only for diatomic molecules (Table 10).

The most important empirical rules are as follows:

*Badger*'s rule[79] correlates the force constant f with the internuclear distance r:

$$f(r-d_{ij})^3 = C_{ij}$$

where $d_{ij}$ and $C_{ij}$ are constants whose values are determined by the position of the bonding atoms in the periodic table.

A similar correlation is given by *Clark*'s formula[80]:

$$fr^6(z_A + z_B)^{1/2} = k_{ij} - k'$$

Table 10. Comparison of valence force constants calculated from empirical rules and from experimental data.

| Bond | Force constants according to: | | | | Group |
|---|---|---|---|---|---|

where $k_{ij}$ is a constant determined by the position of the bonding atoms in the periodic table, k′ is a correction factor for ions, and $z_A$ and $z_B$ denote the number of valence electrons of the two atoms.

Another relationship involving the number of valence electrons $z_i$ has been put forward by *Guggenheimer*[81] in the form:

$$f = R(z_A z_B)^{1/2}/r^t$$

where R and t are constants whose values depend on the polarity of the bond. *Gordy*'s relationship[82] involving the electronegativities

$$f = ab\left(\frac{x_A x_B}{r^2}\right)^{3/4} + c$$

is a special case of *Guggenheimer*'s formula[83]. The constants a and c here generally have the values of 1.67 and 0.30 (other values have to be assumed when one of atoms involved has only one valence electron); b denotes the bond order.

*Siebert*[5] has devised the particularly simple formula:

$$f_1 = P\,\frac{Z_A Z_B}{n_A^3 n_B^3}$$

where the constant P invariably has the value of 7.20, $Z_i$ is the nuclear charge and $n_i$ is the principal quantum number of the valence electrons of atom i. This formula enables us to calculate the single bond values $f_1$ without knowing any experimental data such as bond lengths. However, this formula is strictly valid only for bonds of $sp^3$ hybridization. It can be shown that the formation of free electron pairs at the bonding partners (*i.e.* the setting-up of overlapping p-orbitals) weakens the bond. This can be taken into account by the introduction of an empirical correction factor in *Siebert*'s formula[1]. Furthermore, the single bond value of the force constants increases with increasing s-character of the bond[84].

[86] *S. Bratoz* u. *M. Allavena*, J. chem. Physics *37*, 2138 (1962); J. Chim. physique *60*, 1199 (1963).

*Siebert* also gives a formula for the determination of the bond order b from the single-bond value $f_1$:

$$b = r_b f_b / r_1 f_1$$

Moreover, we can use an even simpler relationship

$$b = f_b / f_1$$

up to b = 1.5 whenever the distances $r_1$ and $r_b$ are not known. However, for bond orders over 1.5, we must use the formula

$$b = 0.29 + 0.71\, f_b / f_1$$

containing empirical correction factors; $f_b$ always is the experimental force constant.

Finally, it should be mentioned, that also attempts where made to find relations between quantum mechanical data, as the electron density, and force constants [85]. For small molecules ($H_2O$, $NH_3$) force constants have been calculated from energy values obtained from an approximative wave function [86].

## Acknowledgments

*The author wishes to thank his colleagues for their assistance in the syntheses and the spectroscopic investigations, and especially Dr. W. Sawodny for the calculation of numerous force constants. He also wishes to express his gratitude to the Deutsche Forschungsgemeinschaft, the Ministry of Scientific Research, and the Fonds der Chemischen Industrie for their financial support.*

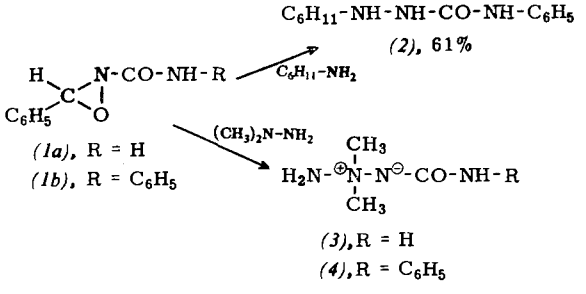
## Amination of Hydrazines to Yield Triazanes

By Prof. Dr. Ernst Schmitz, Dipl.-Chem. S. Schramm, and Dipl.-Chem. Heide Simon

Institut für Organische Chemie der Deutschen Akademie der Wissenschaften, Berlin-Adlershof (Germany)

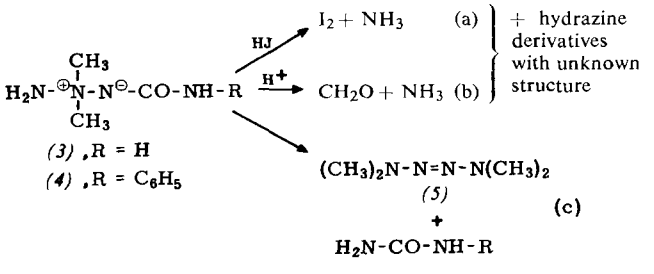
Experiments with $^{15}N$ have shown that hydrazine can be aminated by hydroxylamine-*O*-sulfonic acid, the reaction proceeding by way of triazane [1].

We have found 2-acyloxaziridines [2] to be extremely effective aminating agents. The compound *(1b)* aminates cyclohexylamine at room temperature within one minute, giving the hydrazine derivative *(2)* (m.p. and mixed m.p. [3] 141 °C). This reaction led to attempts to aminate hydrazines to triazanes.



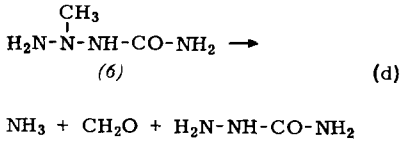
2-Acyloxaziridines, *(1a)* and *(1b)*, suspended in benzene, dissolved immediately on addition of *N,N*-dimethylhydrazine, and crystalline compounds separated in 70–80 % yield in 1–2 minutes at 5–10 °C.

Elemental analyses showed that products containing four N-atoms were formed with loss of benzaldehyde. These products liberated iodine from acidic iodide solution in the cold [reaction (a)]. As with peroxides, oxaziridines, and diaziridines, acid initiates an intramolecular redox reaction,

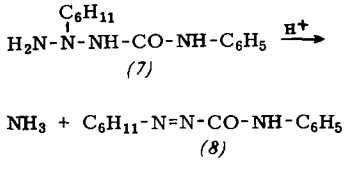


in which fission of the N-N bond is coupled with dealkylation. Dilute acid liberates ammonia (0.7 mol) and formaldehyde (0.5 mol) from compound *(3)* within a second [reaction (b)], and because of this competing reaction the yield of the iodide reaction amounts to only 70–75 %. Neutral aqueous solutions of compounds *(3)* and *(4)* decompose five minutes at room temperature with formation of tetramethyltetrazene *(5)* and urea or phenylurea, respectively [reaction (c)]. Compound *(5)* was identified by gas chromatography, phenylurea by melting point and mixed melting point, and urea by means of xanthydrol. The same products are formed when the crystalline compounds *(3)* and *(4)* are kept at room temperature for one hour. During a melting-point determination, compound *(4)* reacts at 80–85 °C and then shows the melting point of phenylurea.

Compounds *(3)* and *(4)* are formulated as triazanium betaines, in analogy to the 2,2-dialkyltriazanium salts obtained by *R. Gösl* [4] from *N,N*-dialkylhydrazines and hydroxylamine-*O*-sulfonic acid. Final proof of structure was provided for the triazanes prepared analogously from monoalkylhydrazines. A crystalline compound *(6)* (m.p. 63–65 °C) separates in 30 % yield from a solution of *(1a)* and methylhydrazine in tetrahydrofuran; *(6)*, too, oxidizes iodide to iodine. Its thermal or acid-catalysed decomposition leads to ammonia, formaldehyde, and semicarbazide [reaction (d)]; the semicarbazide contains the N–N bond obtained on formation of the triazane.



On reaction with cyclohexylhydrazine, compound *(1b)* affords the triazane *(7)* (yield 70 %). The position of the alkyl group, not rigidly proved for *(6)*, was made certain for this product *(7)*: the colorless crystals *(7)*, when brought into contact with acid, pass within seconds into yellow crystals (m.p. 89 °C), the azo compound *(8)* being formed with loss of ammonia. In *(8)* the cyclohexyl group has the position required by the triazane structure *(7)*.



The structure of product *(8)* follows from its cleavage by acid to cyclohexanone (2,4-dinitrophenylhydrazone, m.p. 162 °C) and 4-phenylsemicarbazide (benzylidene derivative, m.p. and mixed m.p. 180 °C).

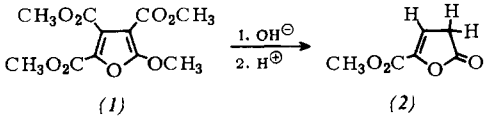
## Formation of Tetramethyl Furantetracarboxylate from Dimethyl Acetylenedicarboxylate

By Priv.-Doz. Dr. E. Winterfeldt and cand. chem. G. Giesler

Organisch-Chemisches Institut
der Technischen Universität Berlin (Germany)

In addition reactions of dimethyl acetylenedicarboxylate we isolated varying yields of the triester *(1)*. We have now found that this ester is also formed when dimethyl acetylenedicarboxylate is heated alone at 180 °C, and that the yield is increased to 25 % if the sealed tube is filled with oxygen and the reaction catalysed with copper powder. Support is thus withdrawn from the rather complicated mechanism proposed by *Huebner et al.*[1] when he isolated *(1)* in diene syntheses with acetylenedicarboxylic esters.

The structure of *(1)* was supported by, *inter alia*, formation of *(2)* on hydrolysis and by the spectral data.

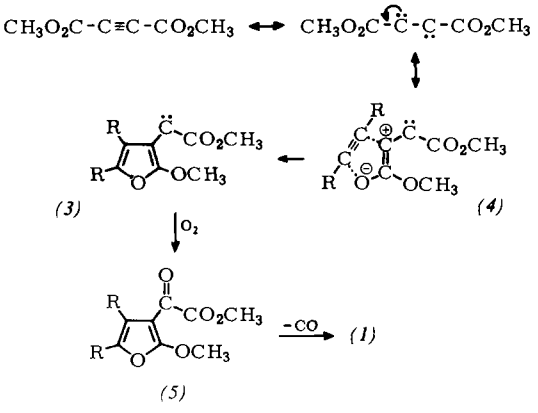


*(1)* *(2)*

*(1)*: M.p. 121 °C
IR: 1750, 1620, 1590, 1160, 1110, 1070 $cm^{-1}$
UV: 273 mμ (ε = 15400), shoulder at 248 mμ (ε = 10900) in ether
NMR: 5.72 τ (3 H), 6.02 (3 H), 6.12 (3 H), 6.17 (3 H).

*(2)*: M.p. 71 °C
IR: 1850, 1830, 1740, 1640 $cm^{-1}$
UV: 232 mμ (ε = 9850)
NMR: 6.22 τ (3 H); 6.60 (2 H), J = 2.5; 2.43 (1 H), J = 2.5

The formation of *(1)* can be understood if it is assumed that acetylenedicarboxylic ester reacts in the 1,3-dipolar form *(4)*.



The trapping reaction leading to the carbene *(3)* has parallels in the investigations of diazo derivatives by *R. Huisgen et al.*[2] The α-keto ester *(5)* can then pass into the triester *(1)* by decarbonylation. The following findings support this assumption: exclusion of oxygen reduces the yield of ester *(1)* to 0.01 %; the carbon monoxide liberated can be identified; the radical *(4)* can be trapped by other acetylenic compounds; and the carbene *(3)* can be trapped by sulfur. The correct order of the two steps is still open to question. The stability of tetramethyl furantetracarboxylate under the reaction conditions has been ascertained.

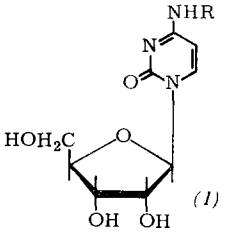
## A Simple Method for Selective Acylation of Cytidine on the 4-Amino Group [1]

By Dr. K. A. Watanabe and Prof. Dr. J. J. Fox

Division of Biological Chemistry, Sloan-Kettering Institute for Cancer Research, Sloan-Kettering Division of Cornell University Medical College, New York, N.Y. (U.S.A.)

To our knowledge, the only reported procedure[2] for the preparation of *N*(4)-acetylcytidine *(1a)* is the reaction of cytidine with 1-acetoxy-2(1*H*)-quinolones (65 % yield).



*(1)*

*(a)*: R = $CO-CH_3$,
*(b)*: R = $CO-C_6H_5$,
*(c)*: R = $CO-(CH_2)_2-CH_3$

A simple and direct synthesis, giving an almost quantitative yield of the selectively blocked nucleosides *(1)*, consists in treatment of cytidine with aliphatic or aromatic acid anhydrides in boiling methanol.

The structures of products were secured as follows: All gave ultraviolet spectra (details for pH 6.4 in the table) similar to those of poly-*O*-acetylated *N*(4)-acetylcytidine[3] and *N*(4)-acetyl-1-methylcytosine[4]. Elemental analyses agree with monoacetylated products. The compounds have sharp melting points and give only one spot on thin-layer chromatography in two solvent systems[5]. Their infrared spectra (KBr pellets) show no absorption bands in the region 1650 to 1800 $cm^{-1}$ that could be attributed to an ester-carbonyl group.

| | M.p.[°C] [a] | $\lambda_{max}$ [mμ] | $\varepsilon_{max}$ | $\lambda_{min}$ [mμ] | $\varepsilon_{min}$ |
|---|---|---|---|---|---|
| *(1a)* | 208–209 | 294 [b]<br>245<br>212 | (8600)<br>(15100)<br>(18200) | 268 [b]<br>225 | (4400)<br>(6100) |
| *(1c)* | 182–183 | 295<br>245<br>210 | (8500)<br>(17000)<br>(19300) | 278<br>225 | (7500)<br>(7600) |
| *(1b)* | 238–239 | 302<br>257 | (9900)<br>(18000) | 284<br>228 | (7900)<br>(8300) |

[a] Determined on a Thomas-Hoover melting-point apparatus; corrected.

[b] *Mizuno* [2] gives for neutral aqueous solution: $\lambda_{max}$ = 296, 247 mμ; $\lambda_{min}$ = 270, 227 mμ.

*Experimental*:

1 part of cytidine was heated with 1 part of acid anhydride for 5 hrs. under reflux in 100 parts of methanol. Further anhydride was added after 1, 2, and 3 hrs. (1 part each time). Compound *(1)* crystallized from the reaction mixture on cooling. After filtration, the crystals were washed with cold alcohol and then with ether; they were analytically pure (yields: 50 to 70 %). The mother-liquor was concentrated almost to dryness in a vacuum and the residue was rubbed with ether until a crystalline product was formed. The total yields were almost quantitative.

## Oxidation of Organoboranes with Amine Oxides

By Dr. R. Köster and Yoshiharu Morita

Max-Planck-Institut für Kohlenforschung,
Mülheim/Ruhr (Germany)

All B–C groups of organoboranes are smoothly converted into B–O–C groups by anhydrous *N*-oxides of tertiary amines (*e.g.* trimethylamine oxide, pyridine 1-oxide). Trialkyl- and triarylboranes afford the corresponding boric esters quantitatively.

$$BR_3 + 3 \text{ Amine oxide} \rightarrow B(OR)_3 + 3 \text{ Amine}$$

Aliphatic trisorganoboranes with $B-C_{primary}$ and $B-C_{secondary}$ groups (*e.g.* tricycloalkylboranes) are as readily oxidized as alkenyl (*e.g.* vinyl- or allylborane) and cycloalkenylboranes, but alkynyl groups on boron do not react. Dehydroboration, as in the reaction of trialkylboranes with triphenylphosphine oxide[1], does not occur.

Preparation of boric esters from organoboranes with trimethylamine oxide is superior to previously reported methods (*e.g.* those involving hydrogen peroxide, oxygen, or perbenzoic acid), because it is not complicated by protolysis (*e.g.* fission of $B-C_{aryl}$ or $B-C_{C=C}$ bonds) or homolysis of O–O bonds (*e.g.* on oxidation of arylboranes). The trimethylamine arising from trimethylamine oxide on oxidation of trialkyl- or triarylboranes is evolved and its acidimetric determination permits quantitative determination of the B–C bonds in organoboranes[2].

The B–C bonds of trialkylboranes react stepwise and exothermically with trimethylamine oxide, even at room temperature, so that partial oxidation leads to high yields of boric esters of the composition $R_2BOR$ and $RB(OR)_2$. Quantitative conversion of all the B–C bonds of trisorganoboranes is very rapid between 20 and 90 °C. If no solvent is used, it is advisable to add the *N*-oxide portionwise to the trialkylborane. The reactions are particularly smooth in solution (alcohols, chloroform) and when suspensions of trimethylamine oxide are used (*e.g.* in boiling benzene or toluene). Transesterification, *e.g.* with methanol, leads from the borates to the alcohols or phenols with nearly quantitative yields.

The B–C groups of saturated and unsaturated aliphatic as well as of aromatic boron heterocycles are also completely oxidized by *N*-oxides. Some particularly stable organoboranes (*e.g.* those with the $C_4B_2$ skeleton[3]) and organocarboranes[4] do not react in boiling toluene.

BH-containing organoboranes, *e.g.* tetraethyldiborane, react with amine oxides preferentially at the B–H linkages, in contradiction to the results of a spectroscopic study[5] of "borane-pyridine 1-oxide". Most of the BOH groups resulting from oxidation at room temperature react further with unchanged BH groups, with loss of hydrogen:

Relatively small amounts of hydrocarbons are also formed from BOH compounds containing $B-C_{aryl}$ and $B-C_{alkyl}$ linkages.

Further, all the B–C bonds of dialkylchloroboranes and dialkylfluoroboranes are oxidized by trimethylamine oxide. Not only each B–C bond of dialkyl(dialkylamino)boranes and similar compounds, but also each of their B–N bonds yields quantitatively 1 mole of trimethylamine. For example, piperidinodipropylborane consumes 3 moles of the *N*-oxide. BH groups of bis(dialkylamino)boranes and of some borazines also consume 1 mole of *N*-oxide. The B–N groups of some borazines (*e.g.* *N*,*N'*,*N''*-triphenylborazine, are however, not attacked in boiling toluene, though the B–N–B groups of acyclic compounds are completely oxidized. The latter is true also for the B–N bonds and the B–B groups of aminoboranes: tetrakis(dimethylamino)diboron with trimethylamine oxide affords 5 moles of trimethylamine.

*Oxidation of triphenylborane*:

A solution of 10.3 g (42 mmole) of triphenylborane in 150 ml of toluene is dropped into a boiling suspension of 9.6 g (128 mmole) of trimethylamine oxide in 50 ml of toluene. The liberated trimethylamine is led in a stream of inert gas into 1 N sulfuric acid and determined by titration. At the end of the reaction the mixture is filtered from small amounts of unchanged *N*-oxide and on distillation of the toluene affords 12 g (97 %) of triphenyl borate (m.p. 95 °C). 10 g of pure phenol (nearly quantitative yield) are obtained as residue after addition of 10 ml of anhydrous methanol, short heating, and distillation of the trimethyl borate.

## Preparation of Methyl- and Ethyl-Substituted Monocarbahexaboranes(9) and Dicarbaclovoheptaboranes(7)

By Dr. R. Köster and Dr. M. A. Grassberger

Max-Planck-Institut für Kohlenforschung,
Mülheim/Ruhr (Germany)

Organoboranes can be obtained on a preparative scale by dehalogenation of alkylhalogenoboranes with alkali metals[1]. If the dehalogenation is carried out in tetrahydrofuran with compounds containing more than one halogen atom on a boron atom, then organofluoroboranes are appreciably

better reactants than are the chlorinated compounds[1]. In this way ethyldifluoroborane and lithium in tetrahydrofuran at *ca.* 0 °C afford two types of carboranes, each containing five boron atoms per molecule and carrying alkyl groups on carbon as well as on boron. The total yield amounts to 7 to 8 g per 78 g of $C_2H_5BF_2$. About 25 % of the *B*-ethyl groups of the ethyldifluoroborane used are contained in the organocarboranes. More than 50 % of the *B*-ethyl groups can be recovered as triethylborane; the remaining 20–25 % are found in compounds with B–O bonds (cleavage of tetrahydrofuran) or in non-distillable high-molecular fractions of the product mixture.

*Preparation:*

A solution of 62.4 g (0.8 mole) of ethyldifluoroborane in 150 ml of THF is dropped at 0 to 5 °C into a well-stirred suspension of 11.2 g (1.6 g-atom) of finely divided lithium in 300 ml of THF. The metal is completely consumed in *ca.* 9 h. The LiF (42.6 g, containing 1.9 % of boron) is centrifuged off and washed with hexane. The THF solution is concentrated by distillation of 340 g (containing about 14 g of triethylborane) at 12 mm; the residual 70 ml, together with the hexane wash-liquor, is treated with ethylene at *ca.* 50 atm. for about 1 h at room temperature. Subsequent distillation afforded, first, 54 g of a fraction of b.p. 68–72 °C containing *ca.* 5 % of triethylborane, and then 18.7 g of a fraction of b.p. 41–91 °C/20 mm, which contained mainly compounds with BO bonds (ethylboroxine, cyclic boric esters[2]) and only small amounts of organocarboranes (molecular weights 174, 198). Further distillation gave 10.5 g of a colorless liquid (b.p. 65–106 °C/$10^{-2}$ mm), of which 60–70 % consisted of the alkylated $B_5$-carboranes detailed in the table.

Table 1. Carboranes obtained from $C_2H_5BF_2$ + Li in THF.

| Compound | Mol. wt. [a] | B.p. [°C/mm] | Yield [g] | Yield [%] calc. on $bC_2H_5$ consumed [b] |
|---|---|---|---|---|
| $C_{10}H_{23}B_5$ | 198 | — | little | 1 |
| $C_{12}H_{27}B_5$ | 226 | — | 1.23 | 8.2 |
| $C_{14}H_{31}B_5$ | 254 | 82/$10^{-3}$ | 2.48 | 17.0 |
| $C_{10}H_{27}B_5$ | 202 | — | 0.52 | 3.2 |
| $C_{12}H_{31}B_5$ | 230 | 84/$10^{-3}$ | 2.68 | 17.5 |

[a] Determined by mass spectrometry [3].
[b] b = $^1/_3$ B

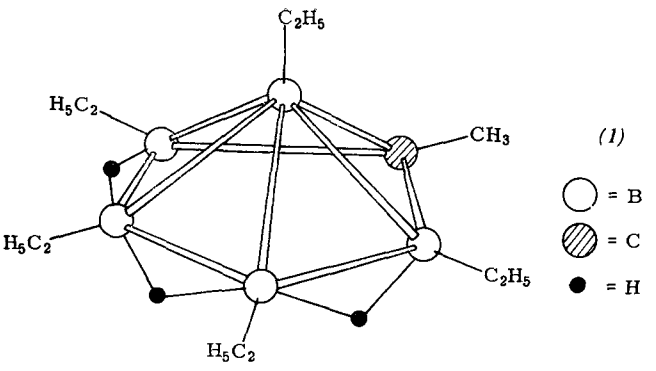
The individual carboranes could be enriched by fractional distillation and isolated in pure form by gas chromatography[4]. The non-distillable residue (17.2 g) also contained boron compounds (12.15 % B).

The compound of molecular weight 254 is considered from its spectroscopic properties ($^1$H- and $^{11}$B-NMR spectrum[5], infrared spectrum, and mass spectrum[3]) to be 1,3,5,6,7-pentaethyl-2,4-dimethyl-2,4-dicarbaclovoheptaborane(7) with the structure of a pentagonal bipyramid[6]. The carborane nuclei of the compounds with molecular weights 226 (three isomers) and 198 have the same structure.

The $^1$H- and $^{11}$B-NMR spectra[5] indicate that the compound with molecular weight 230 is an alkyl derivative of the unknown monocarbahexaborane(9), $CB_5H_9$. Structure *(1)*, a pentagonal pyramid with a boron atom at the apex, follows from consideration of the infrared spectrum and in analogy with hexaborane(10)[7] and dicarbahexaborane(8)[8].

Compound *(1)* is identical with the compound of molecular weight 230 obtained on hydroboration of acetylene with ethyldiboranes[9], the latter having been originally designated a derivative of a $C_2B_5H_{11}$ carborane because of its mode of formation.

The pure compound *(1)* is only slowly oxidized by 30 % $H_2O_2$ in acid solution at room temperature or by atmospheric oxygen. When heated to 200 °C it rearranges, with loss of $H_2$, $CH_4$, $C_2H_6$, and a small amount of triethylborane and



*(1)*

unidentified boron compounds of low molecular weight, into other carboranes among which 2,3,4-triethyl-1,5-dimethyl-1,5-dicarbaclovopentaborane(5)[10] and three isomeric *B*-tetraethyl-*C*-dimethyldicarbaclovoheptaboranes(7) (mass spectrometric molecular weights 226[3]) could be identified.

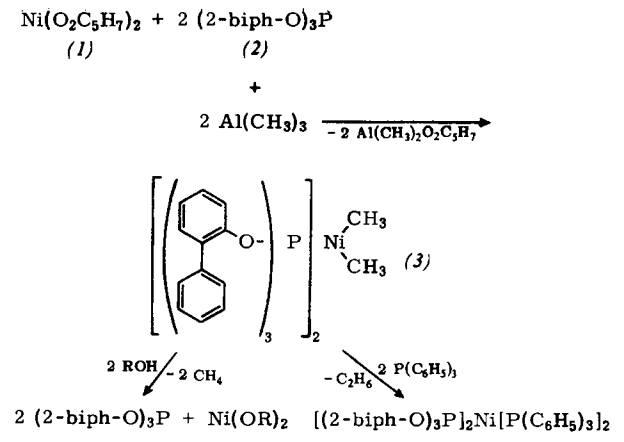
## Stabilized Dialkylnickel Compounds

By Prof. Dr. G. Wilke and Dr. G. Herrmann[1]

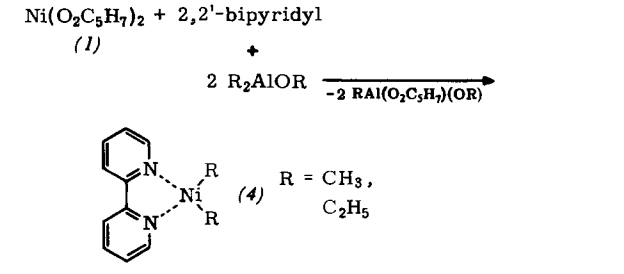
Max-Planck-Institut für Kohlenforschung, Mülheim/Ruhr (Germany)

The method[2] for preparation of transition metal complexes which depends on the reaction of transition-metal salts with organometallic compounds (*e.g.* organoaluminum) in the presence of electron donors fails if the usually unstable intermediate alkylmetal is stabilized by electron donors. Such a stabilization has hitherto been observed only with arylmetals such as bis(triethylphosphine)diphenylnickel[3]. Alkylnickel compounds, however, cannot be stabilized by triphenylphosphine; they decompose, and $Ni[P(C_6H_5)_3]_4$[4] is formed. If acetylacetonatonickel*(1)*is treated with trimethylaluminum in the presence of tri-(2-biphenylyl) phosphite *(2)* (molar ratio 1:2:2) in toluene at −45 °C and the mixture is warmed for 8–12 h to 20 °C, subsequent addition of ether precipitates a colorless product that, when redissolved in benzene, reprecipitated with ether, and dried, has the composition of a dimethylbis[tri-(2-biphenylyl phosphito)]nickel : $C_{74}H_{60}O_6P_2Ni$ (yield at least 30 %). The product is stable at 20 °C. Alcoholysis yields the calculated amount of methane. Heating the material with an excess of triphenylphosphine affords 1 mole of ethane per g-atom of nickel.

2,2′-Bipyridyl can also stabilize the Ni–C bond. However, trialkylaluminum compounds are less suitable for the preparation of dialkyl-(2,2′-bipyridyl)nickel compounds because they form adducts with 2,2′-bipyridyl, rendering it unavailable



for complex formation with nickel. The result is that elemental nickel is readily deposited. If alkoxy(dialkyl)aluminum[2] compounds, which do not form stable adducts with 2,2′-bipyridyl, are used for transfer of the alkyl groups dialkyl-(2,2′-bipyridyl)nickel *(4)* compounds are obtained in good yields (70–80 %).



The green compounds *(4)* are crystalline and can be recrystallized from boiling benzene; the solubility rises with increasing length of R[5]. The alkyl groups are quantitatively split off as RH by 5 N HCl or primary alcohols. (2,2′-Bipyridyl)diethylnickel reacts with phenol with liberation of only one ethyl group, and (2,2′-bipyridyl)Ni($OC_6H_5$)($C_2H_5$) is obtained in the form of deep violet crystals. On addition of trialkylaluminum compounds the complexes *(4)* are decomposed with separation of elemental nickel.

## π-Allylmethylnickel

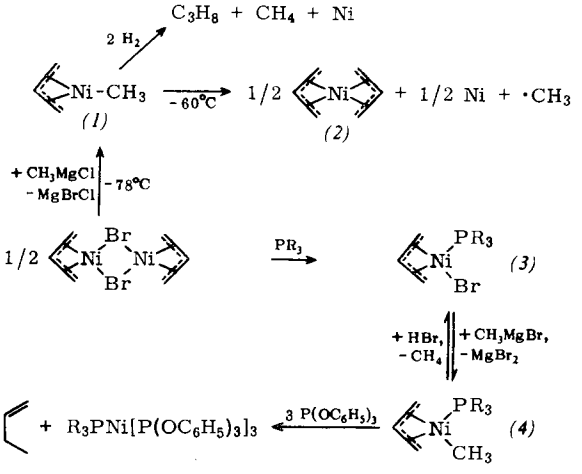
By Dr. B. Bogdanović[1], Dipl.-Chem. H. Bönnemann[2] and Prof. Dr. G. Wilke

Max-Planck-Institut für Kohlenforschung, Mülheim/Ruhr (Germany)

In a study of π-allylcompounds of transition metals[3] the stabilizing effect of a π-allyl group on a M–C bond linked to the same central atom appeared of interest.

π-Allylnickel bromide reacts with methylmagnesium chloride (molar ratio 1:1) in ether at −78 °C. The resulting deep violet solution is freed from MgBrCl by filtration at −78 °C. If the solvent is distilled off at −78 °C and $10^{-4}$ mm, violet crystals of composition $C_4H_8Ni$ are obtained (96 % yield). π-Allylmethylnickel *(1)* decomposes at −40 to −35 °C, even in an inert atmosphere, yielding a mixture of butenes, propene, ethane, and methane, together with elemental nickel. Compound *(1)* is somewhat volatile even at −78 °C, indicating that it is monomer; the molecular weight could not be determined mass-spectrometrically, owing to decomposition.

The following reactions, which also prove the constitution, characterize the π-allylmethylnickel *(1)*:



Hydrogenation of *(1)* at −40 °C yields, in addition to metallic nickel, methane and propane with small amounts of ethane and butane. Compound *(1)* disproportionates in solution at −60 to −50 °C quantitatively within a few hours, yielding bis-(π-allyl)nickel *(2)* and dimethylnickel, the latter at once decomposing into metallic nickel and methyl radicals. The coordinatively unsaturated compound *(1)* reacts with phosphines and phosphites, giving well defined, crystalline 1:1 adducts *(4)*. Adducts with R = ethyl, cyclohexyl, phenyl, phenoxy, and *o*-phenylphenoxy were isolated and, except for the $(C_6H_5O)_3P$ adduct, were stable at room temperature. The same compounds are obtained by treating the 1:1 adducts *(3)* of phosphines or phosphites and π-allylnickel bromide with methylmagnesium chloride. On reaction with HBr, methane is split off from compounds *(4)*, and π-allylnickel bromide·$PR_3$ *(3)* is again formed. Use of an excess of triphenyl phosphite leads to junction of the allyl and methyl radicals in *(4)*, affording butenes and, *e.g.* Ni[$P(OC_6H_5)_3$]$_4$.

The $^1$H-NMR spectrum of π-allylmethylnickel (at −60 °C in tetramethylsilane as solvent) shows four signals (relative intensities 1:2:2:3). Those of relative intensity 1:2:2 at 4.67, 7.24, and 7.75 τ are typical of the π-allyl group. The singlet at 12.1 τ arises from the methyl protons, and its unusually strong shielding is probably to be ascribed to interaction with the non-bonding d-electrons of the nickel. The low stability of compound *(1)* is apparently also connected to this effect[4]. The interaction is weakened by phosphines. Indeed, the signals of the $CH_3$ protons in the stable phosphine adducts *(4)* lie at lower field strengths (9.7 τ). In the spectrum of the triphenylphosphine adduct it can be seen that the *syn*- and *anti*-protons of the π-allyl group are no longer equivalent in pairs[5]: there are four signals, at 6.39 and 7.12 τ (*syn*), and 7.29 and 8.09 τ (*anti*). Thus the π-allyl group is not symmetrically bound to the central atom. The signal of the central allyl proton lies at 5.00 τ[*].

## Bistritylnickel and Tritylnickel Chloride

By Prof. Dr. G. Wilke and Dr. H. Schott[1]

Max-Planck-Institut für Kohlenforschung,
Mülheim/Ruhr (Germany)

According to all previous information, pure alkyl- and arylnickel compounds are stable only when stabilized by further ligands[2]. If, for instance, acetylacetonatonickel is treated with triethylaluminum in toluene at −78 °C, the diethylnickel formed as an intermediate decomposes rapidly with formation of elemental nickel. The nickel atoms can be trapped, *e.g.* by 1,5-cyclooctadiene, as bis-(1,5-cyclooctadiene)nickel(0)[3].

We have found that, for instance, bis-(1,5-cyclooctadiene)-nickel(0) *(2)* reacts with hexaphenylethane at 20 to 70 °C with loss of cyclooctadiene to yield stable bistritylnickel *(1)*, as deep violet crystals. This product can be recrystallized from benzene (solubility *ca.* 1 g/l at 20 °C). It is obtained in more than 90 % yield when acetylacetonatonickel is reduced with $(C_2H_5)_2AlOC_2H_5$ in benzene at about 0 °C in the presence of an excess of hexaphenylethane.

$$\underset{(2)}{Ni(C_8H_{12})_2} + (C_6H_5)_3C\text{-}C(C_6H_5)_3 \xrightarrow{-2\ C_8H_{12}} \underset{(1)}{(C_6H_5)_3C\text{-}Ni\text{-}C(C_6H_5)_3}$$

$$-2\ C_2H_5Al\begin{matrix}O_2C_5H_7\\OC_2H_5\end{matrix} \xrightarrow{-2\ \cdot C_2H_5}$$

$$Ni(O_2C_5H_7)_2 + 2\ (C_2H_5)_2AlOC_2H_5 + (C_6H_5)_3C\text{-}C(C_6H_5)_3$$
*(3)*

Compound *(1)* is also obtained by reaction of $NiBr_2$ with tritylsodium in ether at −78 °C (yield ≥ 40 %).

Pure bistritylnickel decomposes under argon at about 120 °C. If it is added to molten triphenylphosphine at 80 °C, a deep red color appears within a few minutes; addition of benzene precipitates $Ni[P(C_6H_5)_3]_4$ (yield 89 %):

$$Ni[C(C_6H_5)_3]_2 + 4\ P(C_6H_5)_3 \rightarrow Ni[P(C_6H_5)_3]_4 + (C_6H_5)_3C\text{–}C(C_6H_5)_3$$

Bistritylnickel *(1)* does not change visibly in air at 20 °C during several days, yet a slow oxidation occurs in solution. On treatment with pure oxygen, exactly 2 moles of $O_2$ are taken up per mole of *(1)*. Decomposition of the oxidation product is approximately described by the scheme:

$$(1) \xrightarrow{O_2} Ni[O\text{–}O\text{–}C(C_6H_5)_3]_2$$

10 mmoles

| $(C_6H_5)_2CO$ | $(C_6H_5)_3COH$ | $[(C_6H_5)_3C\text{–}O\text{–}]_2$ | $C_6H_5OH$ |
|---|---|---|---|
| 4.7 mmoles | 7.5 mmoles | 1.65 mmoles | 2.3 mmoles |

Bistritylnickel reacts only very slowly with non-oxidizing acids under argon, even in solution; *e.g.* in conc. HCl it takes ≥ 20h before tritylnickel chloride appears in the form of a blue insoluble product. Pure tritylnickel chloride *(4)* is obtained on treatment of 1,5,9-cyclododecatrienenickel(0) with triphenylmethyl chloride in ether at −78 °C:

$$Ni(1,5,9\text{-Cyclododecatriene}) + (C_6H_5)_3CCl \rightarrow \underset{(4)}{(C_6H_5)_3CNiCl} + 1,5,9\text{-Cyclododecatriene}$$

The product *(4)* is appreciably less stable than *(1)*. Suspensions in benzene decompose in a few hours:

$$2\ (C_6H_5)_3CNiCl \rightarrow (C_6H_5)_3C\text{–}C(C_6H_5)_3 + NiCl_2 + Ni$$
*(4)*

## Preparation of Carbonyl(chlorodifluorophosphine)nickel Complexes [1]

By Prof. Dr. O. Glemser, cand. chem. E. Niecke, and Dr. A. Müller

Anorganisch-Chemisches Institut
der Universität Göttingen (Germany)

The compounds $Ni(PF_2Cl)_4$ *(1)*, $Ni(CO)(PF_2Cl)_3$ *(2)*, $Ni(CO)_2(PF_2Cl)_2$ *(3)*, and $Ni(CO)_3(PF_2Cl)$ *(4)* can be prepared by direct reaction of nickel tetracarbonyl and $PF_2Cl$ in a Carius tube (molar ratio 1:4; about 80 hr at 30–90 °C)[*]. Mixtures of *(1)* to *(4)* are always obtained in this reaction, formation of products with higher phosphine content being favored by higher temperatures. The products *(1)* to *(4)* were separated by fractional distillation in a high vacuum. Except for *(1)*[2], they were all obtained pure and were characterized by mass spectra, elemental analyses, and infrared spectra between 4000 and 300 $cm^{-1}$.

In the region of ν(CO), ν(PF)[3], ν(PCl)[3], and ν(NiC) vibrations, the infrared spectra of the pure substances *(2)*, *(3)*, and *(4)* in the gaseous state showed the number of vibrations bands expected from group theory [$C_{3v}$ symmetry assumed for *(2)*, $C_{2v}$ for *(3)*, and $C_s$ for *(4)*]. The compounds are most easily characterized by their ν(CO) vibration frequencies:

$Ni(CO)(PF_2Cl)_3$: $\nu(A_1)$ at 2079 $cm^{-1}$

$Ni(CO)_2(PF_2Cl)_2$: $\nu(A_1)$ at 2097 and $\nu(B_1)$ at 2059 $cm^{-1}$

$Ni(CO)_3(PF_2Cl)$: $\nu(A_1)$ at 2114 and $\nu(E)$ at 2058 $cm^{-1}$ (assignment according to the symmetry of the $NiP_x(CO)_{4-x}$ skeleton)

The position of the ν(CO) frequency corresponds to experience in that the ν(CO) frequencies of substituted carbonyls are lowered when the ligands are not π-acceptors and are constant or even raised when the ligands are π-acceptors ($PF_2Cl$)[4]. In the present case the frequency of the symmetrical stretching vibration increases with increasing number of $PF_2Cl$ ligands as a result of the increased proportion of π-bonding in the CO linkage. Similar observations have been made for complexes of the type $Ni(CO)_x(PF_3)_{4-x}$[5].

## New Catalyst Systems for the Dimerization of Ethylene and Propene

By Dr. J. Ewers

Scholven Chemie AG, Gelsenkirchen-Buer (Germany)

According to *Wilke* and *Bogdanovic*[1], allylnickel halide systems catalyse the dimerization of ethylene and propene. These catalysts are particularly active if the halogen is bound in a complex by addition of Lewis acids, *e.g.* $AlCl_3$, and if phosphines are added to them.

We have found catalysts for the dimerization of ethylene and propene that are probably π-complexes of Ni(0) and substantially exceed the system named above in activity (based on nickel content).

The catalyst is formed when a nickel salt (*e.g.* bisacetylacetonatonickel) is reduced with a chlorine-containing organoaluminium compound in toluene. The most suitable reducing agent is $Al_2(C_2H_5)_3Cl_3$. Catalytic activity appears only when at least one mole of $Al_2(C_2H_5)_3Cl_3$ is added per mole of nickel salt. A yellow to orange solution is formed, which absorbs propene greedily. The activity of the catalyst is increased by electron-donors, *e.g.* triphenylphosphine.

The catalyst can be used over a wide temperature range and has a high activity even at −30 °C. A catalyst prepared from 1 mole of bisacetylacetonatonickel, 45 moles of $Al_2(C_2H_5)_3Cl_3$, and 16 moles of triphenylphosphine converts $5.7 \times 10^5$ moles of propene in 2 hours at 60 °C and 10 atm. 91 % of the product consists of:

2-Methyl-1-pentene 17.4 %

2-Methyl-2-pentene 26.5 %

4-Methyl-2-pentene 37.0 %

4-Methyl-1-pentene 1.6 %

2,3-Dimethyl-1-butene 6.0 %

2,3-Dimethyl-2-butene 0.5 %

2-Hexene 5.6 %

3-Hexene 5.3 %

Ethylene is dimerized even faster and with a higher conversion. A catalyst prepared from 1 mole of bisacetylacetonatonickel, 32 moles of $Al_2(C_2H_5)_3Cl_3$, and 8 moles of triphenylphosphine converts $8.3 \times 10^5$ moles of ethylene in 15 minutes and is still fully active at the end of this time. 94 % of the product consists of butenes, of which 95 % is 2-butene.

Catalysts for the dimerization of propene can also be obtained from:

1 Mole of di-(π-allyl)nickel + 32 moles of $Al_2(C_2H_5)_3Cl_3$

1 Mole of π-allylnickel chloride + 32 moles of $Al_2(C_2H_5)_3Cl_3$

1 Mole of di-(π-allyl)nickel + 32 moles of $Al_2(C_2H_5)_3Cl_3$ + 8 moles of triphenylphosphine

1 Mole of π-allylnickel chloride + 32 moles of $Al_2(C_2H_5)_3Cl_3$ + 8 moles of triphenylphosphine

1 Mole of di-(π-allyl)nickel + 32 moles of $AlCl_3$ + 8 moles of triphenylphosphine

These systems are, however, less active than those without the allyl group.

## Synthesis of Alkynylamines from α-Halogeno Iminium Salts and Ketene S,N-Acetals [1]

By Dr. R. Buijle, Dr. A. Halleux, and Dr. H. G. Viehe

Union Carbide European Research Associates, Brussels (Belgium)

Ynamines react with an excess of anhydrous hydrogen halide with formation of α-halogenoiminium salts[2]. The ynamines are regenerated therefrom by lithium dialkylamides. Ketene *N,N*-acetals, which can be separated by distillation, are also formed in this reaction, so that the total yields range between 50 and 75 %. An ethereal solution of the amide is dropped during 30 min into an ethereal solution of the iminium salt at 0 °C; the solution is then decanted from the precipitated salts and distilled.

α-Halogenoiminium salts are readily obtained from carboxamides and phosgene[3], so that this synthesis of ynamines has preparative interest. Pure *N,N*-diethyl-1-butynylamine is obtained from crude *N,N*-diethyl-1-chlorobutylideneiminium chloride in 77 % yield. A summary of the results is given in Table 1.

Table 1. Ynamines from α-halogenoiminium salts.

$$[R^1\text{-}CH_2\text{-}CCl{=}\overset{\oplus}{N}R^2_2]\ Cl^{\ominus} \underset{2\ HCl}{\overset{LiNR_2}{\rightleftharpoons}} R^1\text{-}C{\equiv}C\text{-}NR^2_2$$

| Ynamine | Base | B.p. [°C/mm Hg] | Yield [%] |
|---|---|---|---|
| $CH_3-C{\equiv}C-N(C_2H_5)_2$ | $LiN(C_2H_5)_2$ | 60–62/90 | 39 |
| | $LiN(C_6H_{11})_2$ | | 58 |
| $CH_3-C{\equiv}C-NC_5H_{10}$ | $LiN(CH_3)_2$ | 72–73/15 | 12 |
| | $LiN(C_2H_5)_2$ | | 39 |

| $n\text{-}C_4H_9-C{\equiv}C-N(C_2H_5)_2$ | $LiN(C_2H_5)_2$ | 77–78/15 | 29 |
| $HC{\equiv}C-N(C_2H_5)_2$ | $LiN(C_2H_5)_2$ | | [a] |

[a] Obtained only in solution and identified by infrared spectroscopy.

Ynamines can also be prepared from ketene S,N-acetals[4]. 4-Phenylethynylmorpholine is obtained by slow addition of β-methylthio-β-morpholinostyrene under nitrogen to lithium diethylamide in tetrahydrofuran at 20 °C or to sodium amide in boiling piperidine. After 3 hr the mixtures are fractionally distilled. The same ynamines arise when the ketene S,N-acetal is led over solid sodium amide at 150–165 °C and 1 mm.

Table 2. Ynamines from ketene S,N-acetals.

## Condensation of Alkynylamines with 1,3-Dipolar Compounds, Carbonyl Compounds, and Schiff Bases [1]

By Dr. R. Fuks, Dr. R. Buijle, and Dr. H. G. Viehe

Union Carbide European Research Associates, Brussels (Belgium)

Only two examples of cycloaddition to ynamines have so far been reported [2]. By 1,3-dipolar cycloaddition under the conditions described previously [3], ynamines readily afford dialkylamino-substituted heterocycles *(1)* (Table 1). The structure of the products follows from analytical data and in analogy to earlier results [3].

Table 1. Heterocycles from ynamines.

Ynamines condense surprisingly easily also with aldehydes and ketones. Although this addition occurs without catalysis when the components are heated [4], catalysis with 1 to 5 mole-% of boron trifluoride-ether is preferable.

Addition of this catalyst to an etheral solution of equivalent amounts of the reactants leads to exothermal condensation that is usually complete in a few minutes but at latest after refluxing for half an hour.

The four-membered ring system *(2)* probably formed as intermediate rearranges to the α,β-unsaturated carboxamides *(3)*.

$BF_3$-catalysed addition of Schiff bases to ynamines occurs less easily and gives lower yields. Reaction times are about 24 hr under the conditions described for the carbonyl compounds (heating under reflux). Acrylamidines *(5)*, whose structures are proved by independent syntheses, are obtained, probably by way of azetines *(4)*.

Table 2. α,β-Unsaturated carboxamides formed from ynamines.

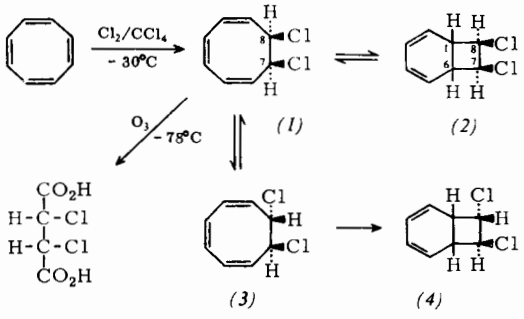
## Chlorination of Cyclooctatetraene

By Prof. Dr. R. Huisgen, Dr. G. Boche, Dipl.-Chem. W. Hechtl, and H. Huber

Institut für Organische Chemie der Universität München (Germany)

*W. Reppe et al.* [1] obtained the bicyclic *cis*-dichloride *(2)* from cyclooctatetraene and chlorine or sulfuryl chloride [2]. Studies on Diels-Alder adducts by *C. D. Nenitzescu et al.* [3] strongly suggest the *trans*-structure *(4)* for a dichloride formed from *(2)* under the influence of heat or acid catalysis.

This chlorination was found to follow a similar course as bromination [4]. Four isomeric dichlorides can be isolated in pure, crystalline form. Rapid stereospecific *cis*-addition of chlorine, yielding the isomer *(1)*, is observed in both polar (acetonitrile) and nonpolar solvents (hexane).



According to the NMR spectrum, *cis*-7,8-dichloro-1,3,5-cyclooctatriene *(1)* arises quantitatively as primary product on low-temperature chlorination and can be isolated by crystallization at 0 °C (m.p. 34 °C; 91 % yield). Ozonolysis in ethyl acetate gives 67 % of *meso*-dichlorosuccinic acid. The $^1$H-NMR spectrum of *(1)* in $CCl_4$ includes bands at 4.09 (s)

(vinyl-H) and 4.88 τ (s) (tert-H) with relative intensities of 3:1. When the solution is cooled to −54 °C the signal from H-7 and H-8 is split reversibly into a doublet plus a singlet, the areas of which indicate a 54:46 equilibrium of *endo-cis*- and *exo-cis*-dichlorides (boat form), the coalescence temperature being −30 °C.

*cis*-7,8-Dichlorobicyclo[4.2.0]octadiene *(2)*: The valence tautomerism *(1)* ⇄ *(2)* is mobile above 50 °C; at 70 °C there is 20 % of *(1)* and 80 % of *(2)* in the equilibrium mixture. Compound *(2)* (m.p. −7 °C) crystallizes from ether at −75 °C; its $^1$H-NMR spectrum shows 4 vinyl-H at 4.19 (s), H-7 and H-8 at 5.35 τ (d) with fine structure, and H-1 and H-6 at 6.67 τ (not resolved).

*trans*-7,8-Dichloro-1,3,5-cycloctatriene *(3)* can be obtained from *(1)* by stirring the $CCl_4$ solution with alumina at −30 °C; it is obtained pure, m.p. 24–25 °C, by crystallization from ether at −70 °C. The equilibrium, which can be attained from either side, corresponds to 66 % of *(3)* and 34 % of *(2)* at −30 °C. The $^1$H-NMR spectrum of isomer *(3)* (in $CCl_4$) shows vinyl-H and tert-H with relative intensities 3:1, and H-7 and H-8 at 5.37 τ (s). Ozonolysis in ethyl acetate at −78 °C gives racemic dichlorosuccinic acid.

*trans*-7,8-Dichlorobicyclo[4.2.0]octadiene *(4)* arises on tautomerization of *(3)* in $CCl_4$ at temperatures ≥ 0 °C. Compound *(3)* was not detectable in equilibrium with *(4)*. Compound *(4)* is formed also from *(1)* or *(2)* at 140 °C in $CCl_4$, at 75 °C in nitrobenzene, or at 70 °C in dioxane/HCl. It has m.p. −12 °C (from diethyl ether), and its $^1$H-NMR spectrum shows signals for 4 vinyl-H at *ca.* 4.2 τ (m), H-7 and H-8 at 5.36 (t) and 5.58 τ (t), and H-1 and H-6 at 6.2 to 7.3 (t).

Compounds *(2)* and *(4)* react with dienophiles, giving crystalline adducts. Reaction of *(1)* with maleic anhydride can be followed dilatometrically as described previously for 1,3,5-cyclooctatriene[5]. The rates and the activation energy of the tautomerization *(1)* → *(2)* can thus be measured.

## Addition of Trialkyl Methanetricarboxylates to 1-Alkenes Initiated by Peroxides

By Prof. Dr. F. Asinger, Dr. B. Fell,
Dipl.-Chem. H. H. Vogel, and Dr. H. Meuser

Institut für technische Chemie
der Technischen Hochschule Aachen (Germany)

Peroxide-initiated addition of trialkyl methanetricarboxylates to 1-alkenes affords high yields of the corresponding trialkyl 1,1,1-alkanetricarboxylates.

Of 625 mmoles of triethyl methanetricarboxylate (TEM) a quarter to a third is placed in a flask fitted with stirrer, reflux condenser, thermometer, and dropping funnel, saturated with argon in the cold, and warmed to 130–150 °C (thermostat containing silicone oil). 125 mmoles of 1-alkene and 12.5 mmoles of a peroxide[*] are dissolved in the remainder of the TEM and dropped into the flask with vigorous stirring during 2–5 hr. The excess of TEM is then distilled off through a column 1 m long with a mirrored vacuum jacket (internal diameter 25 mm; packed with glass spirals 5 mm long and 2 mm in diameter) (b.p. 76–78 °C/0.1 mm). The residue contains the addition product and is rectified through a 15-cm vacuum jacketed column (internal diameter 20 mm; filling as above). For the products see the Table.

The trialkyl 1,1,1-alkanetricarboxylates are converted by alkaline hydrolysis and subsequent acidification with concentrated HCl into the corresponding 1,1-alkanedicarboxylic acids, whence thermal decarboxylation affords monocarboxylic acids whose chains are by two carbon atoms longer than those of the 1-alkene.

Small amounts of 2:1 telomers are formed alongside the 1:1 adducts. Thus addition of TEM to 1-octene gave triethyl 3-hexyl-1,1,1-undecanetricarboxylate, b.p. 165–182 °C/0.15 mm Hg (yield 5–15 %), hydrolysis, decarboxylation, and re-esterification of which gave methyl 4-hexyldodecanoate, b.p. 115–116 °C/0.05 mm, $n_D^{20} = 1.4454$.

Attempted addition of TEM to open-chain alkenes with non-terminal double bonds always failed, but was successful with cyclic olefins in exceptional cases, *e.g.* bicyclo[2.2.1]-hept-2-ene (more than 60 % yield).

| Alkene | 1:1 Adduct | Yield [a] (%) |
|---|---|---|
| 1-Octene | $CH_3(CH_2)_7-C(CO_2C_2H_5)_3$ | 73 |
| 1-Dodecene | $CH_3(CH_2)_{11}-C(CO_2C_2H_5)_3$ | 70 |
| Methyl 1-undecenoate | $CH_3OOC(CH_2)_{10}-C(CO_2C_2H_5)_3$ | 51 |
| Vinyl acetate | $CH_3COO(CH_2)_2-C(CO_2C_2H_5)_3$ | 60 |
| β-Pinene | Triethyl 7,7-dimethyl-bicyclo-[3.1.1]heptan-2-yl-1,1,1-ethanetricarboxylate | 51 |

[a] Initiator: di-t-butyl peroxide (10 mole-%, based on alkene); 150 °C; reaction time 5 hr; molar ratio TEM: alkene = 5:1.

Allyl alcohol, allyl bromide, 4-vinylcyclohexene, and phenylacetylene do not undergo addition to TEM under the conditions described. Numerous attempts at radical-initiated addition of methanetri- and disulfonic esters to 1-alkenes were unsuccessful.

Received: April 23rd, 1963; revised April 13th, 1966 [Z 199 IE]
German version: Angew. Chem. *78*, 595 (1966)

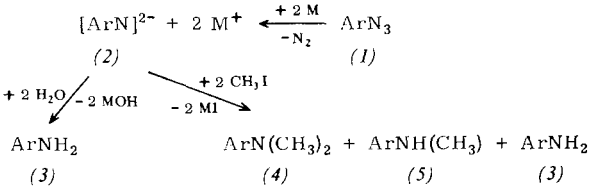
[*] The most favorable molar ratios are TEM: alkene = 5:1 to 10:1, peroxide 10 mole-% of alkene used. The peroxide used was di-t-butyl peroxide.

## Reaction of Aryl Azides with Alkali Metals

By Dr. W. Büchner[*] and R. Dufaux

Cyanamid European Research Institute,
Cologny/Geneva (Switzerland)

In a new type of reaction, aryl azides *(1)* react with sodium or potassium in liquid ammonia mainly (to the extent of *ca.* 96 %) according to Scheme I, whereby one mole of aryl azide consumes two gram-atoms of alkali metal with formation of the dianions *(2)* and evolution of one mole of $N_2$.



Ar = $C_6H_5$, o-$CH_3$-$C_6H_4$, p-$CH_3$-$C_6H_4$; M = Na, K

Scheme I

The nitrogen was determined by gas chromatography and volumetrically. The dianions *(2)* were identified indirectly,

in that the deep red solution in liquid ammonia gave arylamines *(3)* when treated with an excess of water, and dimethylarylamines *(4)*, methylarylamines *(5)*, and unsubstituted arylamines *(3)*, in a total yield of 90 % calculated on *(1)*, when treated with methyl iodide. The products *(3)* and *(5)* can have arisen only by protolysis of the ions *(2)* by ammonium iodide, the ammonolysis product of methyl iodide.

To a minor extent [*ca.* 4 % of *(1)* brought into reaction] there is also reductive cleavage of the N–C linkage of *(1)*, which leads to azide *(6)* and aryl anions *(7)* (see Scheme II).

$$\underset{(1)}{ArN_3} \xrightarrow{+\,2M} 2\,M^+ + \underset{(6)}{N_3^-} + \underset{(7)}{Ar^-} \xrightarrow{+\,NH_3} \underset{(8)}{ArH} + \underset{(9)}{MNH_2}$$

Scheme II

The intermediate formation of the aryl anions *(7)* is assumed because of the occurrence of alkali-metal amides *(9)* and of aromatic hydrocarbons *(8)*, which can arise only by ammonolysis of *(7)*. These anions are derived from the weak acids HAr and thus react readily with ammonia.

The reactions shown in Schemes I and II proved to be independent of the temperature (from −80 to −33 °C), of concentrations ($c_{ArN_3}$ from 0.01 to 0.5 moles/l; $c_M$ from 0.01 to 0.1 mole/l), and of the manner of mixing of the reactants.

*Experimental*: Ethereal solutions of phenyl or *o*- or *p*-tolyl azide were added from a dropping funnel, with stirring and equalization of pressure, to a solution of the alkali metal in liquid ammonia (0.05 M) at −80, −60, −48, or −33 °C [0.025 mole of *(1)* in 1 hr to 250 ml of solution; Hg seal; Hg-filled gas buret]. When the blue color of the metal solution had changed to red (dianion) the $NH_3$ was distilled off and the hydrocarbon was extracted with diethyl ether. The residue was cautiously dissolved in water at 0 °C. Extraction of the alkaline solutions with ether gave the arylamine $ArNH_2$; the aqueous phase was tested for alkali-metal azide.

For conversion of the dianions $ArN^{2-}$ into the *N*-methyl compounds the reaction mixture was treated with an excess of methyl iodide. The amines *(3)*, *(4)*, and *(5)* were extracted with ether after evaporation of the ammonia and separated by gas chromatography.

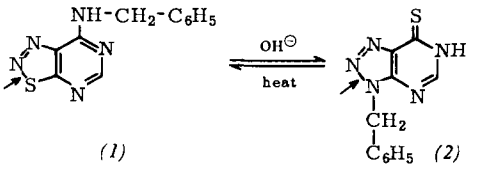
## The Rearrangement of Amino[1,2,3]thiadiazolo-[5,4-d]pyrimidines to Mercapto-8-azapurines, and its Retrogression

By Prof. A. Albert and K. Tratt

Department of Medical Chemistry, John Curtin School of Medical Research, Australian National University, Canberra (Australia)

9-Benzyl-6-hydroxy-8-azapurine[1], when heated with phosphorus pentasulphide in boiling pyridine for 1.5 hr gave the alkali-insoluble 7-benzylamino[1,2,3]thiadiazolo[5,4-*d*]pyrimidine *(1)* in 70 % yield, m.p. 140 °C, $\lambda_{max}$ = 325 mμ (log ε = 3.86 in $H_2O$), $\nu_{max}$ = 3310, 1615, 1530, 1330, and 1305 $cm^{-1}$, with absence of thiocarbonyl stretching frequency in the 1100–1200 $cm^{-1}$ region[1a]. The structure was confirmed by obtaining the same product (in 75 % yield) by refluxing 7-methoxy[1,2,3]thiadiazolo[5,4-*d*]pyrimidine[2] with benzylamine (1 hr in ethanol).

When *(1)* was refluxed with 1 N sodium hydroxide for 30 minutes, it was converted (90 % yield) to the alkali-soluble 6-mercapto-9-benzyl-8-azapurine *(2)*, m.p. 150 °C, $\lambda_{max}$ = 332 mμ (log ε = 4.26 in $H_2O$), $\nu_{max}$ (all strong) at 3030, 1590, 1345, and 1195 (C=S) $cm^{-1}$. This substance is re-isomerized to *(1)* when refluxed with alcohol for 3 hours (80 % yield).



*(1)* *(2)*

Rings open and close at arrow.

We prepared the mercapto-compound *(2)* also by refluxing 9-benzyl-6-chloro-8-azapurine[3] with thiourea in methanol for 15 min (90 % yield).

No record could be found of 6-mercaptopurine (which differs from *(2)* by having a CH group in position 8) rearranging to 7-aminothiazolo[5,4-*d*]pyrimidine, but the latter is known to be converted to the former by alkali[4].

Although earlier workers[5] claimed to have obtained 6-mercapto-8-azapurine (in 10 % yield) by the action of phosphorus pentasulphide on 6-hydroxy-8-azapurine[6] in boiling pyridine, the ultraviolet spectrum of their product resembled that of 7-amino[1,2,3]thiadiazolo[5,4-*d*]pyrimidine. In our hands, repetition of this work gave the alkali-insoluble thiadiazolopyrimidine in 60 % yield, but no 6-mercapto-8-azapurine. However, we obtained the latter (70 % yield) by refluxing the thiadiazolo-isomer in 1 N sodium hydroxide for 20 minutes; it begins to turn brown at 250 °C but is unmelted at 300 °, $\lambda_{max}$ = 330 mμ (log ε = 4.25 in $H_2O$ at pH 2.0), $\nu_{max}$ (all strong) at 3185, 1590, 1565, and 1180 (C=S) $cm^{-1}$, $pK_a$ 4.6 (*i.e.* about the same strength as acetic acid.) Re-isomerization of this substance to the thiadiazolopyrimidine was very slow in boiling water (10 % in 5 hours), and the mercapto-compound was rapidly destroyed by boiling 0.1 N hydrochloric acid.

## Triphenylcyclotriphosphinedipotassium, $K_2[P(C_6H_5)_3]$ [*]

By Prof. Dr. K. Issleib and Doz. Dr. E. Fluck

Anorganisch-Chemisches Institut, Universität Halle and Universität Heidelberg (Germany)

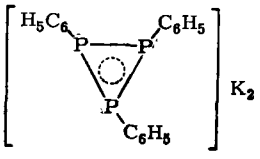
Depending on the relative quantities of the reactants, "phosphobenzene" $(C_6H_5P)_n$ and potassium in tetrahydrofuran afford not merely compounds KRP–PR–PR–PRK and KRP–PRK (R = $C_6H_5$)[1], whose analogues with aliphatic

groups R have long been known[2], but also the compound $K_2[P(C_6H_5)]_3$ *(1)*.

*Experimental*: 8 g of $(C_6H_5P)_n$ (m.p. 154–156 °C) and 1.9 g of potassium in 150 ml of THF are refluxed for 1 hr. A red solution is formed in an exothermic reaction, and after concentration and addition of light petroleum (b.p. 30–50 °C) the product *(1)* crystallizes. It is filtered off, washed with benzene, and vacuum dried; the yield is 12 g (90 %). Compound *(1)* crystallizes with 2 molecules of THF as an orange-red material. It is readily soluble in THF and dioxane, sparingly soluble in benzene and ether, and sensitive to air and hydrolysis.

The $^{31}P$-resonance spectrum of compound *(1)* in THF shows a single sharp line at $\delta = 49.8 \pm 0.5$ ppm, indicating chemical equivalence of the P atoms and thus a cyclic structure.

A $2\pi$-electron system is to be assumed for the anion of *(1)*, which is to some extent an analogue of the triphenylcyclopropenylium cation. Whereas in the cyclopropenylium cation[3] the $\pi$-electron system is composed of three $p_z$-orbitals, the two $\pi$-electrons in the $[PC_6H_5]_3^{2-}$ ion probably



*(1)*

occupy a molecular orbital composed of $d_z$-atomic orbitals. This $\pi$-electron system should have a stability similar to that of the cyclopropenylium cation[4].

Cleavage experiments with $[C_2H_5P]_n$ (n = 4 or 5) and potassium[5], and with "phosphobenzene" $(C_6H_5P)_n$ and lithium, as well as treatment of *(1)* with LiBr or water, show that not only the phenyl groups but also the potassium (which is more electropositive than lithium)are a prerequisite for stabilization of the cyclic anion of *(1)*. Thus, according to the NMR spectra, compound *(1)* and LiBr in THF give numerous phosphines $LiRP-(PR)_n-PRLi$ of different chain lengths as primary products, these phosphines being the same compounds that were found after treatment of $(C_6H_5P)_n$ with lithium (cf. Table, right-hand part). This exothermal reaction is signalled by a change in color of the solution from red-brown to yellow. If *(1)* is treated with two moles of LiBr, the principal product is 1,4-dilithio-1,2,3,4-tetraphenyltetraphosphine, which has sharp $^{31}P$–NMR lines at 3.4, 12.5, 80.0, and 88.9 ppm (Table, left-hand part; spectrum measured

Relative intensities $I_{rel}$ and positions of $^{31}P$–NMR signals (in THF; 22 °C) [*] on ring scission of:

| *(1)* with LiBr (molar ratio 1:2) | | | | $(C_6H_5P)_n$ with Li (molar ratio 3:8) | | | |

| – | – | 96.0 | 2 | 44.1 | 1 | – | – |
| – | – | 110.5 | 1 | 51.6 | 2 | – | – |

[*] Accuracy: ± 1.0 ppm; $I_{rel}$ is estimated.

several days after preparation. Dilithio-1,2,3-triphenyltriphosphine[1] is not found, probably owing to dismutation with formation of more stable lithium phosphides.

Hydrolysis of compound *(1)* in benzene with an excess of water at 20 °C leads to immediate decoloration of the solution and – analogously to the behavior of acyclic phosphines $HRP-(PR)_n-PRH$ (n = 0, 1, or 2) – to dismutation to "phosphobenzene" (m.p. 152 °C) and phenylphosphine $C_6H_5PH_2$, each arising in about 90 % yield.

Compound *(1)* behaves as an electron donor towards metal carbonyls. Thus ultraviolet irradiation of its mixture with $Ni(CO)_4$ and $Fe(CO)_5$ in THF leads to replacement of CO and formation of compounds *(2)* (decomp. from 95 °C) and

$$(1) + M(CO)_n \xrightarrow{-CO} K_2[M(CO)_{n-1}(PC_6H_5)_3]\cdot THF$$

*(2)*, M = Ni; *(3)*, M = Fe

*(3)* (decomp. from 195 °C), whose compositions are confirmed by elemental analyses. On concentration of the solutions, *(2)* and *(3)* are obtained as orange-red and brown crystals, respectively, in yields of about 90 %. They dissolve readily in THF and dioxane, are insoluble in light petroleum or n-hexane, and decompose in ethanol or water.

## Derivatives of Phospha-2,5-cyclohexadien-4-one and 4,4'-Diphosphabi-(2,5-cyclohexadienylidene)

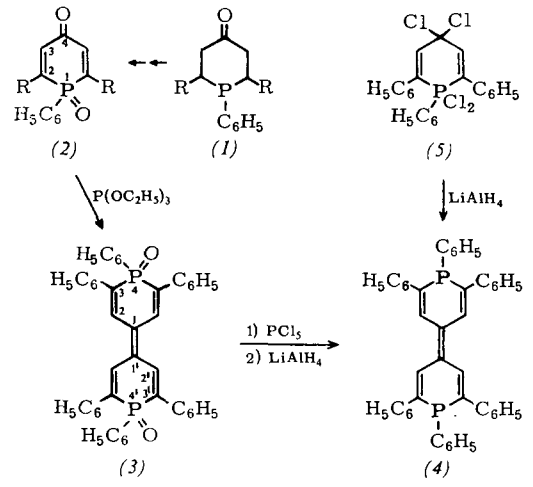
By Priv.-Doz. Dr. G. Märkl and H. Olbrich

Institut für Organische Chemie
der Universität Würzburg (Germany)

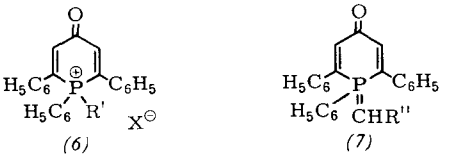
1-Phenylphosphacyclohexan-4-ones *(1)*, R = $C_6H_5$, m.p. 178 °C[1]; R = H, m.p. 44 °C[2], are dehydrogenated by treatment with $SeO_2$ for 36 hr in boiling ethanol by way of the *P*-oxides of their didehydro compounds (R = $C_6H_5$, m.p. 218–220 °C, $\tilde{\nu}_{CO}$ = 1662 $cm^{-1}$) to the 1-phenylphospha-2,5-cyclohexadien-4-one *P*-oxides *(2)* [R = $C_6H_5$, m.p. 162 °C, $\tilde{\nu}_{CO}$ = 1627 $cm^{-1}$, $\lambda_{max}$ = 323 and 342 mμ, 2 vinyl protons at τ = 3.28 (s), 67–80 % yield; R = H, m.p. 130–131 °C, $\tilde{\nu}_{CO}$ = 1650 $cm^{-1}$, 10 % yield).

The same products *(2)* are obtained by dehydrogenation of the 1-oxides or 1-sulfides of *(1)* with $SeO_2$. Neither silanes[3] nor strongly nucleophilic phosphines or phosphites reduce *(2)* to the phosphacyclo-2,5-cyclohexadien-4-ones although the latter correspond to γ-pyridones. Reduction of *(2)*, R = $C_6H_5$, in triethyl phosphite at 80–100 °C affords a quantitative yield of 3,3',4,4',5,5'-hexaphenyl-4,4'-diphosphabi-(2,5-cyclohexadienylidene)-4,4'-dioxide *(3)*, m.p. 425 to 428 °C, $\lambda_{max}$ = 324.5 and 437 mμ. The deep red *P,P,P',P'*-tetrachloro compound obtained from *(3)* and $PCl_5$ can be reduced smoothly by $LiAlH_4$ to 3,3',4,4',5,5'-hexaphenyl-4,4'-diphosphabi-(2,5-cyclohexadienylidene) *(4)* in 90 % yield. This product forms brownish-red crystals, m.p. 335–337 °C, $\lambda_{max}$ = 337 and 467 mμ, mol. wt. (mass spectrum) 648, is not autoxidizable in the solid state or in solution, and does not give phosphonium salts when treated even with strong alkylating agents (trialkyloxonium fluoroborates).

Sulfur reacts with *(4)* in boiling chloroform giving the bis-*P*-sulfide (m.p. 403–405 °C) corresponding to the oxide *(3)*; this product is also obtained by treating 1,1,4,4-tetrachloro-1,2,6-triphenylphospha-2,5-cyclohexadiene *(5)* with $H_2S$ or thioacetic acid in benzene at 25 °C. The latter reactions proceed by way of the dithio analogue of *(2)*, which is however not isolable. On reduction of *(5)* with $LiAlH_4$ direct dimerization to *(4)* intervenes.



The phosphonium salts *(1)*·R′X obtainable from *(1)*, R = $C_6H_5$, are dehydrogenated by $SeO_2$ in boiling ethanol within 24 h to phosphoniocyclohexadienones *(6)* [R′ = $CH_2C_6H_5$, X = $ClO_4^{\ominus}$, m.p. 218–220 °C, $\lambda_{max}$ = 317 and 342 mμ, $\tilde{\nu}_{CO}$ = 1650 $cm^{-1}$; R′ = $C_2H_5$, X = $ClO_4^{\ominus}$, m.p. 173–175 °C, $\tilde{\nu}_{CO}$ = 1648 $cm^{-1}$]. The salts *(6)* may also be prepared by brominating the salts *(1)*·R′X with $C_5H_5N$·HBr in acetic acid; the intermediate α,α′-dibromides need not be isolated. When R′ = $CH_2C_6H_5$, bromination leads immediately to *(6)*, R′ = $CHBrC_6H_5$; X = $ClO_4^{\ominus}$, m.p. 213 to 215 °C, $\tilde{\nu}_{CO}$ = 1659 $cm^{-1}$.



1,2,6-Triphenylphospha-2,5-cyclohexadien-4-one is formed as an intermediate on pyrolysis of *(6)* at 250–300 °C but under the reaction conditions is converted into the dioxide *(3)* and a small amount of the monoxide *(2)* by intra- or intermolecular transfer of the carbonyl oxygen to phosphine phosphorus. The alkylidenephosphoranes *(7)* formed from *(6)*, *e.g.* by "transylidation", are only very weakly basic.

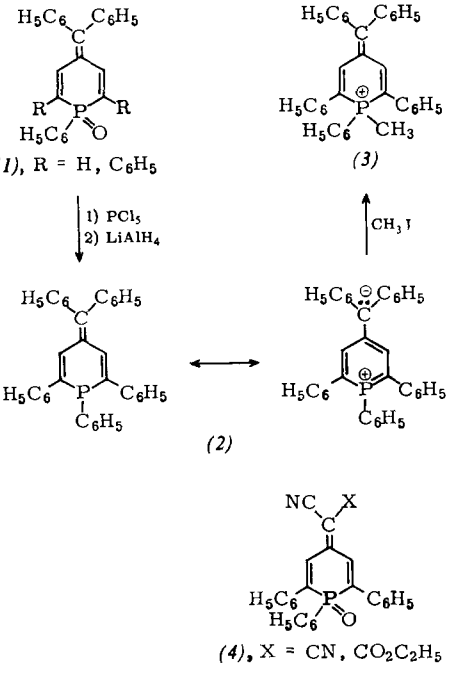
## 4-Methylenephospha-2,5-cyclohexadienes

By Priv.-Doz. Dr. G. Märkl and H. Olbrich

Institut für Organische Chemie
der Universität Würzburg (Germany)

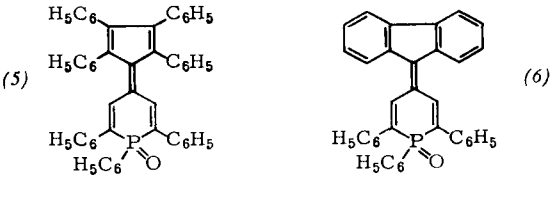
1-Phenylphospha-2,5-cyclohexadien-4-one *P*-oxides[1] react smoothly with the quinoline adduct of diphenylketene at 170 °C affording 4-(diphenylmethylene)-1-phenylphospha-2,5-cyclohexadiene *P*-oxides *(1)* [R = $C_6H_5$, lemon-yellow crystals, m.p. 319–321 °C, $\lambda_{max}$= 365.5 mμ, $^1$H-NMR band complex at 2.3–3.0 τ in $CDCl_3$, 80 % yield; R = H, m.p. 136–138 °C]. The phosphine dichloride obtained from *(1)* with $PCl_5$ can be converted by $LiAlH_4$ into 4-(diphenylmethylene)-1-phenylphospha-2,5-cyclohexadiene *(2)* (R = $C_6H_5$, m.p. 238–240 °C, yellow, non-autoxidizable crystals, $\lambda_{max}$ = 372 mμ, 76 %]. The dipolar limiting structure of *(2)* contains a phosphabenzene system comparable with aromatic pyrylium salts, but *C*-alkylation at the diphenylmethylene side-chain could not be observed alongside (kinetically controlled?) *P*-alkylation. Methyl iodide converts *(2)* smoothly into the quaternary salt *(3)* {m.p. 257–258 °C, orange-yellow needles, $\lambda_{max}$ = 376 mμ, 84 % yield, NMR: $CH_3$ signal in $CD_3NO_2$ at 7.42 τ (d), J = 13 cps $[(C_6H_5)_3\overset{\oplus}{P}-CH_3Br^{\ominus}$ (in $CDCl_3$) $CH_3$ doublet at 6,75 τ, J = 13 cps]}.

Under the conditions of the Knoevenagel condensation 1-phenylphospha-2,5-cyclohexadien-4-one *P*-oxides react with ethyl cyanoacetate or malononitrile in benzene or $CHCl_3$ in the presence of catalytic amounts of *N*-ethyldicyclohexylamine to the cyano derivatives *(4)* [R = $C_6H_5$, X = $COOC_2H_5$, m.p. 205–206 °C, $\lambda_{max}$ = 277 and 374 mμ, 54 % yield; X = CN, m.p. 259–260 °C, $\lambda_{max}$ = 285 and 388 mμ, 31 % yield]. Use of malononitrile leads in addition to a 40–60 % yield of the phosphorus analogue of a quinodimethane (deep red leaflets with a green metallic sheen, m.p. 185–187 °C, $\lambda_{max}$ = 361 and 533.5 mμ) by replacement of the P=O by a P=C(CN)$_2$ group in *(4)*, X = CN.



The 4,4-dichloro derivative (m.p. 128–131 °C) readily preparable in 70 % yield from 1,2,6-triphenylphospha-2,5-cyclohexadien-4-one *P*-oxide and $PCl_5$ can be condensed with cyclopentadienes, *e.g.* 1,2,3,4-tetraphenylcyclopentadiene or fluorene in a melt at 170–180 °C, leading directly to the fulvenoid 4-cyclopentadienylidene-1-phenylphospha-2,5-cyclohexadiene *P*-oxides *(5)* [m.p. 261–263 °C, $\lambda_{max}$ = 321 and 443.5 mμ, yellowish olive-green needles, 76 % yield] and *(6)* [m.p. 264–266 °C, $\lambda_{max}$ = 316 and 432 mμ, orange-red leaflets, 40 % yield)]; 3,3′,4,4′,5,5′-hexaphenyl-4,4′-diphosphabi-(2,5-cyclohexadienylidene)[1] is always formed as by-product.

Compound *(6)* can be reduced, after conversion into the *P*,*P*-dichloride, with $LiAlH_4$ to 4-(9-fluorenylidene)phospha-2,5-cyclohexadiene [m.p. 223–225 °C, $\lambda_{max}$ = 322 and 458 mμ].



Work is in progress to determine whether greater importance should be attached to the dipolar phosphabenzene limiting

structure – which is supported by the tendency of the cyclopentadienylidene residue to aromatize – in fulvenoid phosphacyclohexadienes than is indicated in structure *(2)*.

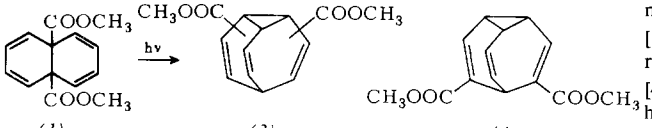
## A New Synthesis of the Bullvalene System

By Prof. E. Vogel, Dr. W. Grimme, Dr. W. Meckel, and H. J. Riebel
Institut für Organische Chemie, Universität Köln (Germany)

and Dr. J. F. M. Oth
Union Carbide European Research Associates, Brussels (Belgium)

Thermolysis at 80–90 °C of dimethyl *cis*-9,10-dihydronaphthalene-9,10-dicarboxylate *(1)* [1] produces a complex mixture of isomeric 9,10-dihydronaphthalenedicarboxylic esters, but so far there has been no reliable indication for the occurrence of a cyclodecapentaene intermediate during this reaction. We have now examined the photochemical behavior of *(1)* and of *cis*-9,10-dihydronaphthalene-9,10-dicarboxylic anhydride *(2)* [1].

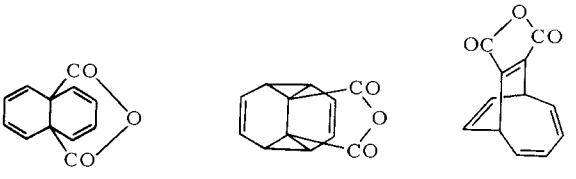
Irradiation of a solution of *(1)* in methanol with a low-pressure mercury vapor lamp [2] produced, in addition to dimethyl 2,6-naphthalenedicarboxylate and a few other products which could not be isolated in pure form, an isomer of m.p. 135–136 °C in 10 % yield. The ultraviolet spectrum of this compound contains only end absorptions with shoulders at 222 ($\varepsilon$ = 8800) and 245 m$\mu$ (6300) in $CH_3OH$. The NMR spectrum varies with temperature, indicating that the molecule has a fluctuating structure.



*(1)* *(3)* *(4)*

At 30 °C the NMR spectrum contains only a sharp singlet at $\tau$ = 6.3 and two very broad bands at $\tau$ = 4.3 and 6.4 (half-width about 100 cps each) in relative intensities of 6:4:4. For maximum resolution, cooling to −50 °C was necessary. Here, instead of the broad bands, a symmetrical signal at $\tau$ = 2.75 (two olefinic protons), a broadened doublet centered at $\tau$ = 4.08 (two more olefinic protons), a broadened doublet at $\tau$ = 5.78 (approx. 0.8 protons), a multiplet centered at $\tau$ = 6.60 (approx. 0.7 protons), and an only partially resolved signal centered at $\tau$ = 7.35 (approx. 2.5 protons) are observed. In addition, the sharp signal at $\tau$ = 6.20, which can be assigned to the six methyl protons of the ester groups, remains almost unaltered by cooling to −50 °C. At higher temperatures all of the signals coalesce, with the exception of the singlet for the methyl protons, first to give the two broad bands observed at room temperature and then (above 55 °C) to a single signal at $\tau$ = 5.25. The half-width of this signal at 100 °C is 4.5 cps. This dependence of the spectrum on temperature indicates the bullvalene structure *(3)* for this isomer. The intensities of the signals in the low-temperature spectrum reveal that of the twelve possible positional isomers of dimethyl bullvalenedicarboxylate, only those (at the most four) with the substituents on the unsaturated carbon atoms can be present in our product. By analogy to the analysis of the spectra of methyl bullvalenecarboxylate [3] and of two disubstituted bullvalene derivatives [4], it can be deduced that the isomer *(4)* predominates in the equilibrium mixture (minimum content 75 %).

On irradiation in ether with a low-pressure Hg lamp, *cis*-9,10-dihydronaphthalenedicarboxylic anhydride is transformed mainly into two isomeric anhydrides (A and B). Compound A has so far been isolated only in about 90 % purity. Its very simple NMR spectrum – a single signal at $\tau$ = 5.38 at 30 °C – proves it to be bullvalenedicarboxylic anhydride. This structure is also supported by the fact that reaction of A with methanolic hydrochloric acid and afterwards with diazomethane produces dimethyl bullvalenedicarboxylate *(3)*. The isomer B of m.p. 182–183 °C [ultraviolet spectrum with $\lambda_{max}$ at 255 m$\mu$ ($\varepsilon$ = 9100) and a shoulder at 310 m$\mu$ ($\varepsilon$ = 1400) in $CH_3OH$] gives an NMR spectrum with a doublet at $\tau$ = 2.47 (2 protons), a symmetrical multiplet centered at $\tau$ = 4.22 (4 protons), and a complex multiplet at $\tau$ = 6.35 (2 protons). Since the three absorptions can be ascribed to four sets of two equivalent protons, the molecular skeleton of B must be symmetrical. Judging from the multiplicity of the signals, B probably has the bicyclo-[4.2.2]decatetraene structure *(5)*; final proof of the constitution is yet to be obtained.



*(2)* *(6)* *(5)*

Compound *(5)* may be formed by a photochemically induced isomerization (4+4 cycloaddition [5]) of *(2)* to the tetracyclic system *(6)* followed by a retro-diene rearrangement of the latter [6].

## Structure of an Odd Nucleoside from Serine-Specific Transfer Ribonucleic Acid [1]

By Prof. K. Biemann and Dr. S. Tsunakawa
Massachusetts Institute of Technology, Cambridge, Mass. (U.S.A.)

Dr. J. Sonnenbichler
Max-Planck-Institut für Biochemie, München (Germany)

Dr. H. Feldmann, Dr. D. Dütting, and Prof. H. G. Zachau
Institut für Genetik der Universität Köln (Germany)

The odd nucleoside iPA [2] has been found immediately adjacent to the probable anticodon of the serine-specific tRNA, the nucleotide sequence of which has been elucidated recently [3]. In five solvent systems iPA has Rf = 0.8 to 0.9; it has an adenosine-like ultraviolet spectrum ($\lambda_{max}$ = 265 and 269 m$\mu$ at pH 2 and pH 7–12, respectively [4]. By treatment of iPA with acid (1 N HCl, 30 min, 100 °C) two compounds, A and B, are formed (Rf = 0.57 and 0.73, respectively, in n-butanol/$H_2O$/conc. $NH_4OH$, 86:14:5). In

the following, experiments are described which prove iPA to be *N*(6)-(γ,γ-dimethylallyl)adenosine *(1)*.

The high-resolution mass spectrum of iPA[5] showed its elemental composition to be $C_{15}H_{21}N_5O_4$. The abundance of ions containing five nitrogen atoms and no oxygen, particularly $C_5H_5N_5$ and $C_{10}H_{13}N_5$, indicated the presence of a substituted adenine pentoside. Nitrogen-free ions containing four oxygen atoms, particularly $C_5H_9O_4$, show that all of the oxygen atoms are in the sugar moiety. It follows that iPA is an adenosine derivative substituted by five carbon atoms. The presence of ions of the type $C_nH_mN$ up to $(C_5H_9NH)^+$ indicates an *N*(6)-$C_5$-alkenyl or cyclopentyl adenine derivative, which can eliminate all 5 carbon atoms on electron impact. A distinction between the two could be made by consideration of the fragments formed from the $C_{10}H_{13}N_5$ ion, which represents the free adenine derivative formed[6] on electron impact.

The low abundance of a $C_8H_{8\text{ or }9}N_5$ ion as contrasted to that of $N_5$-ions containing 6,7, or 9 carbon atoms implies that loss of two carbon atoms (as $C_2H_5$ or $C_2H_4$) from the side chain is much more difficult than the loss of one, three, or more carbon atoms. This behavior excludes a cyclopentyl substituent and suggests an isopentenyl group. The position of the double bond was clarified by NMR spectroscopy[7].

The spectrum shows the signals of the two aromatic adenosine hydrogens unchanged at 8.1 and 8.3 ppm (each of relative intensity 1). The signal at 8.1 ppm is superposed by the resonance of *one* amidine hydrogen, which exchanges slowly with deuterium (relative intensity 1). It therefore may be concluded that this nitrogen (at the 6-position) carries an additional substituent, *i.e.* the isopentenyl group. The signals of the 1′- and 5′-hydrogens of the ribose moiety appear at 5.94 ppm (intensity 1) and 3.84 ppm (intensity 2), respectively, as they do in adenosine. The region between 4.1 and 5.6 ppm cannot be analysed because of strong absorption by the solvent. A sharp signal at 1.73 ppm (intensity 6) proves the presence of a 2,2-dimethylvinyl group in the isopentenyl side chain.

The acid conversion product A has the composition $C_{10}H_{13}N_5$ according to mass spectrometry. The difference in abundance of the $C,H,N_5$ ions in this spectrum as compared to that of iPA, particularly the lower abundance of $(C_5H_5N_5)^+$ in the former, suggests the absence of an open-chain substituent attached to N(6) only. Acid-catalysed cyclization with the adenine ring would account for this product. The product B has an elemental composition $C_{10}H_{15}N_5O$ and thus contains one molecule of water more than the base of the iPA. The high abundance of a $C_3H_7O^-$ ion requires hydration of the double bond to produce a $C(OH)(CH_3)_2$ grouping; this is also corroborated by ions ($C_9H_{12}N_5O$ and $C_7H_8N_5$) representing the loss of a methyl- or dimethylcarbinol group.

Simultaneously with this work, iPA was isolated from unfractionated tRNA, elucidated, and synthesized[8].

It is interesting to note that the plant growth hormone zeatin is an *N*(6)-(γ-methyl-γ-hydroxymethylallyl)adenine[9] and that *N*(6)-(γ,γ-dimethylallyl)adenine also shows growth promoting activity[10].

## On the Secondary Structure of Soluble Ribonucleic Acids

By Dipl.-Chem. H. Doepner, Dr. H. Seidel, and Prof. Dr. F. Cramer

Max-Planck-Institut für Experimentelle Medizin, Göttingen (Germany)

*N*-Oxidation of adenosine units in polynucleotides with monoperoxyphthalic acid at pH 7.0 is inhibited by base pairing, a fact that can be used[1] to obtain information on the secondary structure of s-RNA[2]. We have applied this method to RNA from various sources isolated by different methods. s-RNA from brewer's yeast (AMP 19.8 %, UMP, 24.5 %, GMP 28.2 %, CMP 27.5 %, and terminal A 47 % of the theoretical value) and s-RNA from *Escherichia coli* B (AMP 20.5 %, UMP 18.2 %, GMP 30.2 %, CMP 31.1 %, and terminal A 34.0 % of the theoretical value) were examined in the native state and after heat denaturation and cooling. The results were interpreted as described previously[1]. The quotient $\varepsilon_{232\ m\mu}/\varepsilon_{259\ m\mu}$ served as a measure for the degree of oxidation. The average content of oxidized AMP units per molecule was determined from this quotient by means of a

| | s-RNA from brewer's yeast | | *E. coli* B | |
|---|---|---|---|---|
| | native | heated and cooled | native | heated and cooled |
| Final degree of oxidation ($\varepsilon_{232}/\varepsilon_{259}$) | 0.825 | 1.080 | 0.910 | 1.025 |
| Av. no. of AMP units oxidized per molecule | 2.68 | 4.93 | 3.41 | 4.44 |
| Av. no. of nucleotide units per molecule in single-strand regions | 13.54 (18 %) | 24.93 (32 %) | 16.64 (23 %) | 21.67 (30 %) |
| Av. no. of nucleotides per molecule | 77 | 77 | 73 | 73 |
| Av. no. of base pairs per molecule | 73–17<br>2<br>31.5 | 77–25<br>2<br>26 | 73–22<br>2<br>28 | 77–14<br>2<br>25.5 |
| Hyperchromicity of the untreated s-RNA (0.4 M phosphate; 0.01 M $Mg^{2+}$) | 35 % | 19 % | 25 % | 19 % |

calibration curve. By addition of the remainder of the bases in the ratios determined by analysis, the average total number of nucleotides present per molecule in single-strand regions was then derived.

The low oxidizability of s-RNA from brewer's yeast compared to that of the s-RNA from *E. coli* B is probably due to its higher content of UMP and is in accordance with its stronger hyperchromicity [2]. If s-RNA is heated for a prolonged period above its "melting temperature" $T_m$ [2] and then gradually cooled, the oxidizability of both preparations is significantly higher; the hyperchromicity also decreases with this treatment.

Subtraction of the average number of nucleotide units present per molecule in the single-strand regions from the average total number of nucleotides per molecule [3] gives the number of nucleotides occurring in double-strand regions (and hence the number of paired bases), which when plotted against the values for the hyperchromicity gives an almost linear dependence between about 15 and 40 % hyperchromicity.

Data for the *N*-oxidizability and hyperchromicity of s-RNA from baker's yeast obtained previously under different conditions [1] exhibit this same dependence within the limits of error. Thus, a direct relationship between the hyperchromicity of s-RNA and the degree of base pairing is established. The latter can be determined by means of *N*-oxidation.

s-RNA has presumably a variable secondary structure which depends strongly upon the $Mg^{2+}$ concentration and perhaps on other factors as well. A means is now available for determining the extent of base pairing even with minute amounts of substance by measurements of hyperchromicity.

## Protein Synthesis in Rat Liver Chromatin and Chromatin Fractions [1]

By Doz. C. E. Sekeris, W. Schmid, Dr. D. Gallwitz, and Dr. I. Lukacs

Physiologisch-Chemisches Institut,
Universität Marburg (Germany)

In addition to "classical" protein biosynthesis on messenger RNA and ribosomes, which also occurs in cell nuclei [2], another type of protein synthesis seems to take place in cell nuclei. We have found that chromatin isolated from rat liver cell nuclei can incorporate [$^{14}$C]leucine into protein. The new protein-synthesizing system has the following characteristics (cf. Table):

1. The incorporation of radioactively labelled amino acid into the protein is resistant to attack by ribonuclease.

2. The protein synthesis is independent of the addition of amino-acid activating enzymes.

3. The protein synthesis is not stimulated by messenger RNA.

4. The system loses some of its activity on incubation with deoxyribonuclease.

The chromatin was isolated from rat liver cell nuclei according to *Weiss* [4]. The preparation (aggregate enzyme [4]) incorporates ribonucleoside triphosphates into RNA; it consists of DNA, RNA, and protein in weight ratios of 1:2:10–15. The preparation could be freed from the major fraction (about 90 %) of its protein by treatment with 0.2 % sodium deoxycholate in 0.065 M tris buffer at pH 7.9. The sediment obtained after low-speed centrifugation contained the whole activity and had DNA:RNA:protein ratios of 1:0.4:1.5. It was suspended in 0.065 M tris buffer at pH 7.9 and shaken for 30 min at 37 °C with 100 µg/ml of deoxyribonuclease and 2 µM magnesium chloride. During this treatment, the clear glassy fibrous structure of the preparation disappears and a white powder is obtained. Centrifugation then separates the suspension into a white precipitate and a cloudy supernatant. The precipitate contains all of the activity; the supernatant, which contains liberated deoxynucleotide, RNA, and protein, inhibits protein synthesis, but the nature of the inhibitor is not yet known. It is thermally stable and has a molecular weight of 3000 to 15000. Treatment of the precipitate with ribonuclease (100 µg/ml) for 20 min at 37 °C removes proteins and RNA without loss of activity. The DNA:RNA:protein ratio after this treatment is 2:1.5:6.5. Partial digestion with trypsin solubilizes part of the enzyme in an active state; it occurs in the supernatant after centrifugation.

| | Incorporation of [$^{14}$C]leucine [counts/min × mg of protein] |
|---|---|
| Chromatin alone [a] | 1840 |
| Chromatin + ribonuclease (50 γ/ml) | 1945 |
| Chromatin + 105000 g supernatant (2 mg of protein) | 1795 |
| Chromatin + 50 γ of messenger RNA from rat liver | 1825 |
| Chromatin + deoxyribonuclease (100 γ/ml) | 525 |

[a] Chromatin (1 mg of protein, preparation obtained after treatment with deoxycholate, see below), 7.5 µmoles of KCl, 3 µmoles of $MgCl_2$, 80 µmoles of tris-(2-amino-2-hydroxymethyl-1,3-propanediol), 0.15 µmole of ATP, 150 µmoles of GTP, 0.5 µmole of creatine phosphate, 10 γ of creatine phosphokinase, 0.025 µmole each of 20 amino acids, and 0.1 µCi of [$^{14}$C]leucine with a specific activity of 150 mCi/mmole. Volume: 0.5 ml. Incubation time: 60 min at 37 °C. The degree of incorporation was measured as described in [3].

The protein synthesis is inhibited by histones from rat liver cell nuclei (up to 90 % inhibition with 1 mg/ml), by protamine sulfate (up to 98 % inhibition with 1 mg/ml), and by antibiotics such as chloromycetin (98 % with 1 mg/ml) and puromycin (80 % with 0.4 mg/ml). It was shown by the fingerprint method that leucine is incorporated into peptides. Between 10 and 15 % of the incorporated radioactivity is soluble in 0.2 N hydrochloric acid. The newly synthesized protein is not liberated from the enzyme complex. Only a small amount of the radioactive protein that is not extractable with HCl dissolves in 8 M urea.

The biological significance of this RNA-independent protein synthesis is still unknown. Part of the protein formed is probably structural protein of the chromatin, but the possibility of a regulatory function must also be considered. The fact that the protein synthesis on chromatin is influenced by hormonally active steroids and that it is promoted by partial hepatectomy support the latter suggestion.

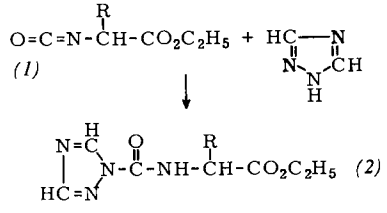
## Peptide and Azapeptide Syntheses with α-N-[1-(1,2,4-Triazolyl)carbonyl]amino Esters

By Dr. J. Gante[*]

Institut für Organische Chemie
der Freien Universität Berlin (Germany)

Equimolar amounts of 1,2,4-triazole and ethyl α-isocyanato esters *(1)*[1] react exothermally to give the previously unknown ethyl α-*N*-[1-(1,2,4-triazolyl)carbonyl]amino esters *(2)*. The reaction is induced with the less reactive isocyanates *(1c)* and *(1d)* by heating to 90 °C.

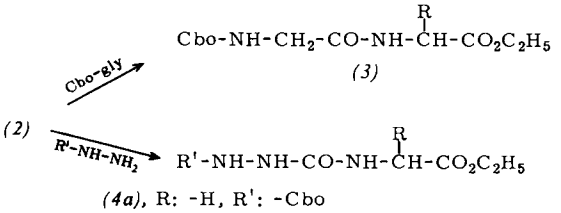


*(1)* *(2)*

| | R | Yield [%] | M.p. [°C] | $[\alpha]_D^{25}$ (in ethyl acetate) |
|---|---|---|---|---|
| *(2a)* | H | 84 | 109–111 | |
| *(2b)*, DL-form | $CH_3$ | 79 | 62 | |
| *(2c)*, L-form | $CH_2-C_6H_5$ | 95 | 103 | −15.0 ° (c = 1) |
| *(2d)*, L-form | $CH_2-CH(CH_3)_2$ | 75 | 65–67 | −6.1 ° (c = 1) |

Compounds *(2a)–(2d)* are colorless and crystallize well from dry ethyl acetate/petroleum ether or from dry ether/petroleum ether. The point of substitution in the triazole ring follows from the NMR spectra (measured in $CCl_4$) of *(2b)* and *(2d)*: in agreement with investigations of *Staab* with *N*-acetyl 1,2,4-triazole[2], the observation of two proton signals of equal intensities – at 2.13 and 1.17 τ for *(2b)* and at 2.15 and 1.20 τ for *(2d)* – established the unsymmetrical structure *(2)* with non-equivalent triazole protons.

Like the corresponding imidazole derivatives[3], *(2a)–(2d)* can be used for peptide syntheses. On heating them with equimolar amounts of carbobenzoxy(Cbo-)glycine for 9–12 h at 90–110 °C, carbon dioxide is evolved and triazole is liberated, producing the Cbo-dipeptide esters *(3a)–(3d)*, which can be purified by precipitation from ethanol/water.



*(3)*

*(4a)*, R: -H, R': -Cbo

*(4b)*, R: $-CH_2-CH(CH_3)_2$, R': Cbo-NH-$CH_2$-CO-

| | R | Yield [%] | M.p. [°C] |
|---|---|---|---|
| *(3a)* | H | 72 | 80–81 |
| *(3b)*, DL-form | $CH_3$ | 59 | 56–58 |
| *(3c)*, L-form | $CH_2-C_6H_5$ | 87 | oil |
| *(3d)*, L-form | $CH_2-CH(CH_3)_2$ | 76 | oil |

The triazole derivatives can also be used to prepare azapeptides[4] by their reaction with hydrazides. For example, when *(2a)* is refluxed for 3 hr with Cbo-hydrazine in anhydrous ethyl acetate and when *(2d)* is heated with Cbo-glycine hydrazide to 110 °C without solvent, each in equimolar amounts, aminolytic elimination of triazole occurs leading to the peptide analogues *(4a)*, m.p. 139–141 °C, and *(4b)*, m.p. 79–82 °C, in yields of 15 and 55 %, respectively.

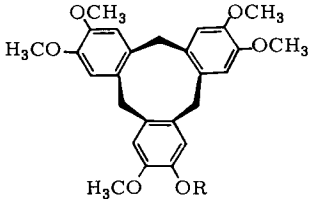
## Conformational Enantiomerism of a Derivative of Cyclotriveratrylene [1]

By Prof. Dr. A. Lüttringhaus and cand. chem. K. C. Peters

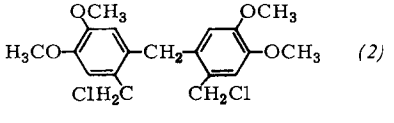
Chemisches Laboratorium
der Universität Freiburg (Germany)

The major product formed by acid-catalysed condensation of veratrole with formaldehyde was found by *Lindsey*[2] to be the nine-membered cyclic compound "cyclotriveratrylene" *(1)*. He also isolated the bischloromethyl derivative *(2)* as an intermediate of the condensation in hydrochloric acid. We have confirmed all of *Lindsey*'s results and also the findings of *Miller* and *Gesner*[3] on the constitution and conformation of *(1)*.

Replacement of one of the methoxy groups in *(1)* by a different substituent is expected to give a molecule, *e.g. (3)*, exhibiting conformational enantiomerism. We condensed *(2)* with *O*-benzylguaiacol in glacial acetic acid for 8 h at 120 °C and obtained *(3)* in 45 % yield.



*(1)*, R: $-CH_3$
*(3)*, R: $-CH_2-C_6H_5$



*(2)*

Compound *(3)*, purified by column chromatography on silica with a 1:1 mixture of benzene and ether, was homogeneous in thin-layer chromatography. 2-Benzyloxy-3,7,8,12,13-pentamethoxytribenzo[*a,d,g*]cyclo-1,4,7-nonatriene *(3)* crystallizes from benzene/petroleum ether (3:1 v/v) in clusters, m.p. 160–162 °C. Its ultraviolet absorption maxima lie at 232 (log ε = 4.51) and 291 mμ (4.01). Its NMR spectrum (0.3 M in $CDCl_3$; Varian A 60 instrument) shows aromatic proton signals at τ = 2.55 (m,5) and 3.02–3.14 (m,6), a benzyloxy methylene proton signal at 4.82 (s,2), methoxy proton signals at τ = 6.12 (s,12), and 6.26 (s,3); the methylene protons give rise to an AB quadruplet with doublets at τ = 5.26 and 6.48 of coupling constants J = 14 cps each. It has been possible partially to resolve *(3)* in benzene on "cellulose-$2^1/_2$-acetate"[4] into *stable* optical antipodes. A single passage through a column 120 cm long and 2 cm in

diameter afforded two fractions with specific optical rotations $[\alpha]_{405}^{22} = +4.3°$ and $-2.5°$. After a second passage the rotations were $[\alpha]_{405}^{22} = +7.5°$ and $-5°$ (1 % in $CHCl_3$).

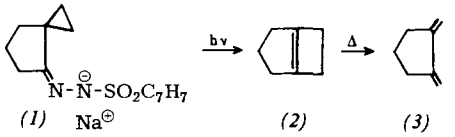
## Synthesis of $\Delta^{3a,5a}$-Bicyclo[3.2.0]heptene and $\Delta^{4a,6a}$-Bicyclo[4.2.0]octene

By Prof. Dr. W. Kirmse and Dipl.-Chem. K. H. Pook

Chemisches Institut der Universität Marburg (Germany)

We have applied the rearrangement of cyclopropylcarbenes – a reaction that has already been extensively examined[1] – to compounds with spiran structures.

The *p*-toluenesulfonylhydrazone (m.p. 159–160 °C) of spiro[2.4]heptan-4-one[2] was prepared. Photolysis[*] of the sodium salt *(1)* of the tosylhydrazone in diethylene glycol dimethyl ether (diglyme) produced in 70 % yield a hydrocarbon $C_7H_{10}$, b.p. 118–119 °C, $n_D^{21.5} = 1.4775$, which was ascribed the structure of $\Delta^{3a,5}{}_a$-bicyclo[3.2.0]heptene *(2)*. Thermolysis of *(1)* by addition to diglyme at 160 °C afforded an approximately equimolar mixture of *(2)* and 1,2-dimethylenecyclopentane *(3)*[3] in a total yield of 65 %. Control experiments showed that *(2)* is transformed into *(3)* under the conditions of the thermolysis.

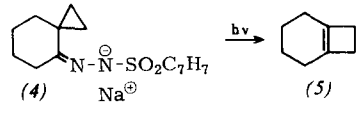


*(1)* *(2)* *(3)*

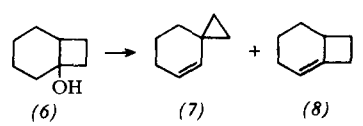
Compound *(2)* has no C=C absorption in the infrared; however, it does exhibit a Raman band at 1677 $cm^{-1}$[4] (1,2-dimethylcyclobutene: 1689 $cm^{-1}$). Its NMR spectrum contains multiplets at 7.48 τ (4 H) and 7.7–8.1 τ (6 H) [for comparison, cyclobutene $CH_2$: 7.46 τ; cyclopentene $CH_2$: 7.72 and 8.10 τ].

Treatment of *(2)* with NOCl in acetone produces a blue unstable nitrosochloride. Hydrogenation of *(2)* with Adams catalyst leads to bicyclo[3.2.0]heptane. Ozonolysis of *(2)* affords cycloheptane-1,4-dione.

$\Delta^{4a,6a}$-Bicyclo[4.2.0]octene *(5)* was obtained analogously in 65 % yield from spiro[2.5]octan-4-one[5] *via* the sodium salt *(4)* of its tosylhydrazone, m.p. 173–174 °C.



*(4)* *(5)*



*(6)* *(7)* *(8)*

The hydrocarbon *(5)* cannot be made from bicyclo[4.2.0]-octan-4a-ol *(6)*: pyrolysis of the acetate of *(6)* produces mainly spiro[2.5]hept-4-ene *(7)* together with a little $\Delta^{4,4a}$-bicyclo[4.2.0]octene *(8)* [5a].

The absence of spiro[2.4]hept-4-ene and spiro[2.5]oct-4-ene *(7)* respectively from the products of thermolysis of *(1)* and *(4)*[6] shows that the cyclopropylcarbene rearrangement is preferred to an intramolecular hydrogen shift[7]. The main products obtained from spiro[m.n]alkanone tosylhydrazones with m,n ≥ 3 were spiroalkenes[8].

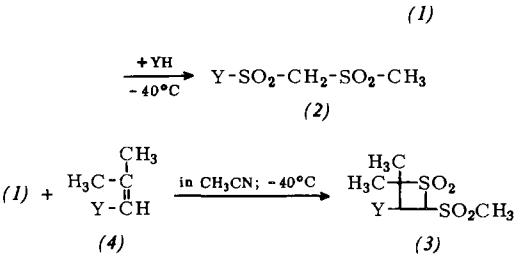
## A Sulfene Stable at −40 °C

By Prof. Dr. G. Opitz, Dr. M. Kleeman, cand.-chem. D. Bücher, Dipl.-Chem. G. Walz, and cand.-chem. K. Rieth

Chemisches Institut der Universität Tübingen (Germany)

If a solution of 0.15 mole of triethylamine in 150 ml of acetonitrile is treated with 0.10 mole of methanesulfonyl chloride at −40 °C within 30 min, pure triethylammonium chloride is precipitated (99 % after 60 min). If dimethylamine, pyrrolidine, aniline, or *p*-nitrophenol is added to the colorless filtrate, the corresponding methanesulfonylmethanesulfonic acid derivative *(2)* is obtained. The NMR spectrum of product *(2d)* in perdeuterioacetone shows 2 H (*ortho* to $NO_2$) as a doublet (J = 4.5 cps) at 1.6 τ, 2 H (*meta* to $NO_2$) as a doublet (J = 4.5 cps) at 2.3 τ, 2 H ($CH_2$) as a singlet at 4.5 τ, and 3 H ($CH_3$) as a singlet at 6.7 τ. Use of YH = *p*-$O_2N$-$C_6H_4$-OD leads to *p*-$O_2N$-$C_6H_4$-O-$SO_2$-CHD-$SO_2CH_3$ which undergoes rapid D/H exchange with $H_2O$. Thus a disulfene structure with two methylene groups, analogous to diketene, is excluded for the elimination product *(1)*.



| | Y | M.p. [°C] | Yield [%] |
|---|---|---|---|
| *(2a)* | $(CH_3)_2N$ | 113–114 | 60 |
| *(2b)* | $(CH_2)_4N$ | 176 | 62 |
| *(2c)* | $C_6H_5NH$ | 155–156 | 63 |
| *(2d)* | *p*-$O_2N$–$C_6H_4$–O | 123–124 | 61 |
| *(3a)* | $(CH_3)_2N$ | 114–116 | 61 |
| *(3b)* | $(CH_2)_4N$ | 138–139 | 63 [a] |

[a] 35 % yield on use of methanesulfonic anhydride instead of methanesulfonyl chloride.

In favor of the presence of the methanesulfonylsulfone *(1)* are the smooth 1,2-1′,2′-cycloadditions to enamines *(4)*, yielding compounds *(3)*, and the fact that products *(2)* and *(3)* are formed also on treatment of methanesulfonylmethanesulfonyl chloride[1]/triethylamine with YH or an enamine in tetrahydrofuran at 20 °C.

The H-NMR signal of compound *(3a)* in $CHCl_3$ shows signals at 4.6 τ (d, J = 8 cps, $SO_2CHSO_2$), 6.6 (d, J = 8 cps, NCH), 6.7 (s, $SO_2CH_3$), 7.6 [s, $N(CH_3)_2$], and 8.35 τ [s, $C(CH_3)_2$] in the ratio 1:1:3:6:6. The doublets for the ring protons in compound *(3b)* appear in acetone at 4.3 and 6.6 τ, but in pyridine the former signal is shifted to 3.3 τ; we have observed similar shifts to lower field for other 1,3-disulfones. Quaternization of *(3a)* with methyl iodide and heating of the salt with aqueous-alcoholic sodium hydroxide gives isopropyl methanesulfonylmethyl sulfone (m.p. 101–102 °C).

Capture experiments with *N*-isobutenylpyrrolidine show that compound *(1)* is stable for several days in acetonitrile at −40 °C [after 90 hr at −38 °C it gives *(3b)* in 52 % yield], but when warmed it decomposes above about −30 °C with formation of a reddish-brown color. On freeze-drying there remains a colorless powder composed of an adduct of triethylamine and *(1)*, elucidation of whose structure is in progress.

## Preparation of trans,trans- and cis,cis-1,6-Cyclodecadiene from cis,trans-1,5-Cyclodecadiene

By Dr. P. Heimbach

Max-Planck-Institut für Kohlenforschung,
Mülheim/Ruhr (Germany)

1,3-Cyclooctadiene is formed when 1,5-cyclooctadiene is heated with $Fe(CO)_5$ for 7 hr at 115 °C[1]. Under similar conditions *cis,trans*-1,5-cyclodecadiene *(1)*[2] yields almost exclusively *cis*-1,2-divinylcyclohexane *(2)*. This valence isomerization[3] is appreciably faster than isomerization of the double bonds in compound *(1)*. On ultraviolet irradiation $Fe(CO)_5$ is active as isomerization catalyst even at 20-50 °C[4]. We have therefore irradiated a solution of 3 ml of $Fe(CO)_5$ in 400 g of *(1)* at about 60 °C with a low-pressure Hg lamp (Messrs. Gräntzel, Karlsruhe). The products were *cis,cis-(3)* and *trans,trans*-1,6-cyclodecadiene *(4)*.

| Reaction time [hr] | Conversion [a] of *(1)* [%] | Yield [%] [a] *(3)* | *(4)* | other olefins |
|---|---|---|---|---|
| 0.5 | 21.4 | 84 | 16 | — |
| 1 | 36.3 | 84 | 16 | — |
| 4 | 65.7 | 85.9 | 13.8 | 0.3 |
| 21 | 86.5 | 90.3 | 9.4 | 0.3 [b] |
| 48 | 90.4 | 92.0 | 7.5 | 0.4 [b] |

[a] Conversions and yields determined by gas chromatography (50 m $V_2A$ capillary column, silicone oil DC 200, 120 °C, 1 atm of argon, retention time for *(3)* 12.3 min, for *(4)* 13.4 min).
[b] Two compounds in equimolar amounts.

*(3)*: B.p. 67 °C/11 mm, m.p. 28–28.5 °C (from ethanol) (lit.: 21–22 °C[5], 22 °C[6]), $n_D^{30} = 1.4964$ (lit.: $n_D^{25} = 1.4972$[5]); infrared bands of the *cis*-double bonds at 707 $cm^{-1}$ (s) and 1655 $cm^{-1}$ (m).

*(4)*: B.p. 65 °C/11 mm; $n_D^{30} = 1.4917$; infrared bands of the *trans*-double bonds at 952 and 977 $cm^{-1}$ (s) and 1667 $cm^{-1}$ (m).

The 1,6-position of the double bonds in compounds *(3)* and *(4)* was proved by ozonolysis and oxidation of the ozonide to glutaric acid. The ratio *(3)*:*(4)* was 5:1 after reaction for 1 hour and 12:1 after 48 hours, *i.e.* isomerization of *(4)* to *(3)* accompanies the shift of the double bond. Any *cis,trans*-1,6-cyclodecadiene – as intermediate in the conversion of *(4)* into *(3)* – can occur in the reaction mixture with a concentration of only *ca.* 0.3 %, if at all. This result does not agree with the report by *Dale et al.* that 8.0 % of *cis,trans*-1,6-cyclodecadiene was identified in the *cis,trans*-equilibrium mixture of 1,6-cyclodecadienes (7-hr irradiation of the *cis,cis*-isomer in the presence of diphenyl sulfide at 75 °C).

The isomerization *(1)* → *(3)* can also be effected by reduction of 1 g of an acetylacetonate of a group VIIIb metal in 10 g of diene *(1)* with $Al(C_2H_5)_3$ (1 mole per equivalent of metal acetylacetonate) and heating for 24 hr at about 60 °C.

| Acetylacetonate | Conversion of *(1)* [%] | Yield of *(3)* [%] |
|---|---|---|
| $Ni(C_5H_7O_2)_2$ | 61 | 98 |
| $Pd(C_5H_7O_2)_2$ | 90 | 98 |
| $Co(C_5H_7O_2)_2$ | 84 | 79 |
| $Fe(C_5H_7O_2)_2$ | 73 | 76 |

Isomerization of *(1)* to *(3)* was further observed on partial hydrogenation of *(1)* to cyclodecene (maximally 3 % of *trans*-cyclodecene was formed alongside *cis*-cyclodecene). When 1 mole of hydrogen had been absorbed in presence of Pd/$BaSO_4$ as catalyst, 65 % of cyclodecene, 19 % of cyclodecane, and 16 % of *(3)* (which is difficult to hydrogenate) were identified. Attempts to isomerize *(1)* with various hydrogenation catalysts in the presence of catalytic amounts of hydrogen did not give reproducible results.

## Hammett Constants of Substituents Containing Phosphorus [1]

By Dr. G. P. Schiemenz

Institut für Organische Chemie
der Universität Kiel (Germany)

Previously σ′-constants[2] for the groups $(C_6H_5)_2P-$, $(C_6H_5)_2P(O)-$, $(C_6H_5)_2P(S)-$, and $(C_6H_5)_2(CH_3)P^{\oplus}-$ were calculated from the half-neutralization potentials (HNP) of *p*-P-substituted dimethylanilines[3,4]. However, owing to lack of a reliable equation only approximate σ-values were obtained from the $pK'_a$ values of the corresponding *p*-P-substituted benzoic acids[5].

Equation (a) was obtained from the $pK'_a$ values of eight reference substances (see table), determined under the same conditions (67 % aq. $CH_3OH$; 0.02 N NaOH), together with the known substituent constants[2], by the method of least squares. With the parameters r = 0.996, s = 0.058, and ρ = 1.278, this is an "excellent"[2] Hammett equation. From it were obtained the σ-values of phosphorus-containing groups assembled in the table.

$$pK'_a = -1.278\,\sigma + 5.27 \quad (a)$$

$$\tilde{\nu} = 18.385\,\sigma + 1621.12 \quad (b)$$

A further method of determining σ is based on the fact that the frequency of the amide I infrared bands of *p*-substituted *N,N*-dimethylbenzamides depends linearly on the Hammett constants of the *para*-substituents. Wave numbers measured for seven reference substances in KBr lead to the "satis-

factory"[2] equation (b) (r = 0.965); of the three σ-values (see table) determined for phosphorus-containing substituents with this equation, those of the *p*-diphenylphosphino and diphenylphosphinyl groups agree well with the constants derived from the $pK'_a$ values of the acids.

Phosphorus behaves throughout as an electron acceptor, the order being phosphonium- > phosphinyl- ≈ thiophosphinyl- > phosphine-phosphorus. $(C_6H_5)_2P(O)$ has $\sigma_{para}$ only slightly greater than $\sigma_{meta}$ = +0.485 determined by alkaline cleavage of 3-(diphenylphosphinyl)benzyltrimethylsilane[6]; thus in this case 3d-orbital participation appears not to be significant. However, the fact that $\sigma_{(C_6H_5)_2P} < \sigma_{(C_6H_5)_2P(O)}$ – as in the phosphine $p$-$(C_6H_5)_2P$–$C_6H_4$-$N(CH_3)_2$[3] – indicates a certain amount of 3p-orbital participation by the phosphine-phosphorus.

## An Optically Active Carbodiimide

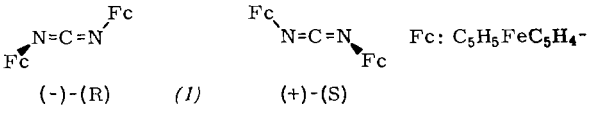
By Prof. K. Schlögl and H. Mechtler[1]

Organisch-Chemisches Institut, Universität Wien (Austria)

Carbodiimides (R–N=C=N–R) have as their sole element of symmetry a $C_2$ axis and therefore possess axial chirality; by analogy to allenes, they should therefore be resolvable into optical antipodes[2].

We have found that *N,N′*-diferrocenylcarbodiimide *(1)* is stable and is therefore suited to attempting racemate resolutions of compounds of this class. We have thus obtained the first sample of an optically active carbodiimide.

The racemic form of *(1)* was prepared from Fc–N=C=O[3] by the method of *Cambell et al.*[4] in 85 % yield in the form of crystals, m.p. 140–145 °C (decomp.). Elemental analyses, a sharp infrared band at 2120 $cm^{-1}$, and the mass spectrum are all in agreement with structure *(1)*. Addition of water to the compound gives *N,N′*-diferrocenylurea, Fc–NHCONH–Fc, m.p. 250 °C (decomp.)[3]; reaction with ethoxide in ethanol produces the isourea derivative Fc–NH–$C(OC_2H_5)$=N–Fc, m.p. 147–150 °C.



(−)-(R) *(1)* (+)-(S)

Partial resolution of the racemate *(1)* was effected by chromatography in benzene on a column (4 m long × 3 cm diam.) of partially acetylated cellulose[5]: 250 mg of *(1)* was passed through the column and seven fractions of approx. 50 ml each were collected. Subsequent purification by thin-layer chromatography on silica gel with benzene gave chemically unchanged (infrared spectrum) dextrorotatory *(1)*, which was enriched in the seventh (last) fraction: $[\alpha]_D^{20} = +4.1 \pm 0.2°$ (c = 0.4 in dry benzene). All the other fractions showed practically no optical activity.

Partial reaction of *(1)* with (+)-(*R*) or (−)-(*S*)-6,6′-dinitrodiphenic acid in anhydrous benzene at 25 °C to form the corresponding acylurea effected kinetic resolution of the racemate. The chemically unchanged carbodiimide *(1)* recovered by preparative thin-layer chromatography after the reactions was optically active: $[\alpha]_D^{20} = -4.8 \pm 0.2°$ (c = 0.3) and $+1.6 \pm 0.1°$ (c = 0.4 in benzene).

It follows from stereochemical considerations of the preferred transition state (stereoselective addition of the carboxyl group from the diphenic acid onto the –N=C= structure) that (+)-*(1)* should have the (*S*)-configuration. Application of a rule derived for allenes[6] leads to the same conclusion.

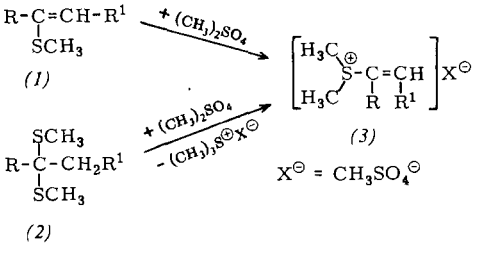
## Reaction of Substituted Vinylsulfonium Salts with CH-Acidic Compounds. – A New Route to Polysubstituted Cyclopropanes

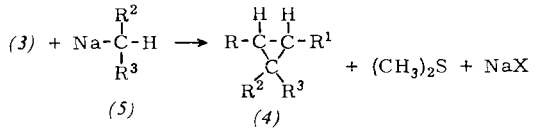
By Priv.-Doz. Dr. J. Gosselck, Dipl.-Chem. L. Béress, and Dipl.-Chem. H. Schenk

Institut für Organische Chemie
der Universität Gießen (Germany)

Dimethylvinylsulfonium salts *(3)* with a mono- or disubstituted vinyl group were obtained either by methylation of the corresponding methyl vinyl sulfides *(1)* with one equivalent of dimethyl sulfate or by heating dimethyl mercaptals *(2)* with excess of dimethyl sulfate[1].



If ethanolic solutions of *(3)* are added to the sodium salts of CH-acidic compounds *(5)* in ethanol, elimination of dimethyl sulfide occurs already at 0 °C to yield polysubstituted cyclopropanes *(4)*.



*(3)* + Na-C(R²)(R³)-H → R-C(H)(R²)-C(H)(R³)-R¹ + $(CH_3)_2S$ + NaX

*(5)* *(4)*

The products *(4)* are isolated by pouring the reaction mixture into ice/dilute sulfuric acid and extracting with ether; they are purified by fractional distillation or crystallization.

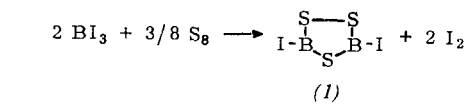
## A New Method for Preparing 1,3,4-Trithiadiborolanes and 1,3,5-Trithiatriboranes

By Prof. Dr. Max Schmidt and Dr. W. Siebert

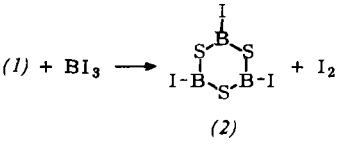
Institut für Anorganische Chemie
der Universität Würzburg (Germany)

Thiol groups are oxidized by iodine to disulfide groups in an aqueous medium. In an anhydrous medium this reaction is quantitatively reversible [1]. We have now found that boron triiodide and substituted boron iodides can cleave sulfur-sulfur bonds. Thus treatment of sulfur with boron triiodide in $CS_2$ (20 hr at 21 °C) leads to 2,5-diiodo-1,3,4-trithiadiborolane *(1)* [2] (colorless needles, m.p. 27 °C) in *ca.* 80 % yield.



$2\ BI_3 + 3/8\ S_8 \longrightarrow$ *(1)* $+ 2\ I_2$

Heating of the borolane *(1)* with $BI_3$ to *ca.* 90 °C (there is no reaction at room temperature) leads to formal introduction of "borene" IB: into the S–S linkage, with ring



*(1)* + $BI_3$ → *(2)* + $I_2$

expansion, leading to the known [3] 2,4,6-triiodo-1,3,5-trithiatriborane (m.p. 145 °C, lit. [3] 122 °C).

The B–I group can also cleave S–S bonds, as is shown by the formation of 2,5-bis(methylthio)- and 2,5-bis(phenylthio)-1,3,5-trithiadiborolane from compound *(1)* and R–S–S–R (R = $CH_3$, b.p. 74 °C/2 mm; R = $C_6H_5$, b.p. 207 °C/2 mm). Use of $BI_3$ in place of *(1)* affords smoothly the trithioboric esters $B(SR)_3$. $BI_3$ and diphenyl sulfide give, as expected, only a 1:1 adduct, m.p. 150 °C.

Since it is less electrophilic than $BI_3$, $BBr_3$ does not react with sulfur [2], although it does react with sulfanes [4, 5]. The stronger Lewis acid $C_6H_5BBr_2$ is reported to react with sulfur to yield the six-membered cyclic compound $(C_6H_5)_2B_2S_4$ [6]; we found this reaction to be exothermal and obtained, besides violet, polymeric B–S compounds, $BBr_3$ and a crystalline substance of m.p. 50 °C, as well as 2,5-dibromo-1,3,4-trithiadiborolane, which has already been prepared by another route [4]. Our product may have arisen from the primary product 2,5-diphenyl-1,3,4-trithiadiborolane by further reaction with bromine formed simulataneously (from $C_6H_5BBr_2$).

## Equilibria between Mono- and Di-bromoamines. Violet Bromoamine

By Prof. J. Jander and Dr. Chr. Lafrenz

Anorganisch-Chemisches Laboratorium,
Technische Hochschule München (Germany)

If the amount of methylamine required by Equation (1) is condensed into an ethereal bromine solution at −60 °C, a precipitate of $[CH_3NH_3]Br$ is at once formed and the resulting yellow solution has oxidizing properties. According

$$2\ CH_3NH_2 + Br_2 \rightarrow CH_3NHBr + [CH_3NH_3]Br \quad (1)$$

to analysis (N:Br = 1:1) it should contain $CH_3NHBr$[1]; free bromine cannot be detected. This solution shows three ultraviolet bands at 20 °C, namely, $\lambda_{max}$ = 370, 305, and 245 mμ. Of these, the second only is to be attributed to the $CH_3NHBr$, since solutions richer in $CH_3NH_2$ give only this band ($\varepsilon_{max}$ = 465) and the comparable $(CH_3)_2NBr$[2] in pentane gives a band at $\lambda_{max}$ = 318 mμ ($\varepsilon_{max}$ = 575). The first and the third band relate to $CH_3NBr_2$[3], which is obtained from $CH_3NH_2$ and bromine (molar ratio 3:4) in ether or pentane ($\varepsilon_{max}$ = 350 and 3380, respectively). The band of longer wavelength has not been previously recorded[4].

The equilibrium (2) is indicated by three isosbestic points at 340, 280, and 210 mμ. The spectra do not vary with time.

$$2\ CH_3NHBr \rightleftarrows CH_3NBr_2 + CH_3NH_2 \quad (2)$$

Analogously, the product from $NH_3$ and bromine (molar ratio 1:1) in dimethyl or diethyl ether at −78 °C (N:Br = 1:1 after removal of $NH_4Br$) is in equilibrium with $NHBr_2$ and $NH_3$ although it was previously held to be $NH_2Br$[5,6]. At −110 °C it gives shoulders at 350 and 288 mμ; the first of these is to be ascribed to $NHBr_2$, since solutions richer in $NH_3$ and solutions in liquid $NH_3$ give only a maximum at 288 mμ ($\varepsilon_{max}$ = 600). A corresponding equilibrium exists in aqueous solution[9].

The deviation from the N:Br ratio 1:1[6] observed on isolation of $NH_2Br$ by removal of the ether is thus explained, neglecting decomposition, by removal also of $NH_3$ from the equilibrium mixture, so that the material isolated contains $NHBr_2$.

The solvent-dependence of the UV spectrum of $NH_2Br$ ($\lambda_{max}$ in $H_2O$: 277[4]–278[7], in liquid $NH_3$: 280, in ether: 284[7] to 288 mμ) indicates varying degrees of solvation. If bromine is treated with $NH_3$ (molar ratio 1:1) in the non-solvating pentane at −120 °C, a dark-violet $NH_2Br$ is precipitated together with $NH_4Br$. If a yellow ethereal solution of "$NH_2Br$" (N:Br = 1:1) is poured into an approximately twenty-fold excess of pentane at −120 °C, dark-violet $NH_2Br$ (N:Br = 1:1) is again precepitated. Ethereal yellow "$NH_2Br$" solutions (N:Br = 1:1) reversibly assume a reddish-violet color when frozen[8]; in this case, however, it is not yet known whether the reddish-violet material is suspended in the solid ether or whether there is a true solid solution.

Addition of the strongly electron-donating $(CH_3)_3N$ to ethereal solutions of "$NH_2Br$" ($\lambda_{max}$ is then at 332 mμ) completely prevents precipitation of the violet material on pouring into pentane, as well as the violet coloration on freezing. Ethereal solutions of "$NHBr_2$" (N:Br = 1.9:1) and solutions of the methylbromoamines give neither precipitates nor violet colors whether or not this addition is made.

Thus it appears, contrary to previous interpretations[9], that the dark-violet color is due to association of the unsolvated $NH_2Br$. Reddish-violet colors can either be interpreted as before (as being due to $NH_2Br \cdot xNH_3$, not to $NBr_3 \cdot 6NH_3$[9]) or as a smaller degree of association of $NH_2Br$, owing to cleavage of the associates by solvent molecules. In favor of the latter possibility is that $\lambda_{max}$ varies from 520 to above 600 mμ, according to the "$NH_2Br$" concentration, for frozen reddish-violet etheral solutions; the dark-violet suspensions in pentane absorb at still longer wavelengths.

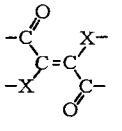
## Theoretically and Experimentally Determined Properties of the Fundamental Indigo Chromophore [1]

By Prof. Dr. W. Lüttke, Dipl.-Chem. H. Hermann, and Dr. M. Klessinger

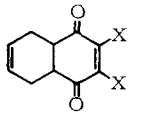
Organisch-Chemisches Institut
der Universität Göttingen (Germany)

According to Hückel molecular-orbital calculations, the structure *(1)* is to be regarded as the basic chromophore of indigo dyes[2]. Calculations by the Pople-Pariser-Parr method confirm these results and show that the spectroscopic properties of the grouping *(1)* depend on its configuration and conformation[1,2]. Our theoretically derived views were confirmed experimentally on compounds of type *(1)* with X = S, which we have now prepared[3].

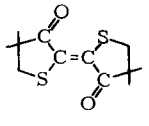


*(1)*
X = NH, S, Se, O

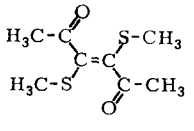
In Table 1 the experimental results for *trans- (3a)* and *cis*-$\Delta^{2,2'}$-bi-(4,4-dimethylthiolan-3-one) *(3b)*, *trans- (4a)* and *cis*-3,4-bis(methylthio)-3-hexene-2,5-dione *(4b)*, and 2,3-dianilino-4a,5,8,8a-tetrahydro- *(2a)*, 4a,5,8,8a-tetrahydro-2,3-bis(phenylthio)- *(2b)*, and 4a,5,8,8a-tetrahydro-2,3-bis(methylthio)-1,4-naphthoquinone *(2c)*[4] are compared with the



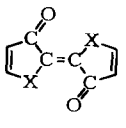
*(2a)*: X = NH-$C_6H_5$
*(2b)*: X = S-$C_6H_5$
*(2c)*: X = S-$CH_3$



*(3a)*



*(4a)*



*(5)*, X = S, NH

results of Pople-Pariser-Parr calculations on the structural isomers of *(1)*. Calculated values refer to systems with X = NH, but it was shown[5] that for indigoids the spectroscopic properties of the isolated molecule with X = NH agree very well with those of the corresponding molecule with X = S in the condensed phase.

Table 1. Comparison of the wavelengths $\lambda_{max}$ and intensities log ε of the longest-wavelength ultraviolet absorption maximum of compounds of type *(1)* (measured in cyclohexane), and of their stretching frequencies $\tilde{\nu}C{=}O$ (measured in KBr) with the wavelengths $\lambda_{max}$ and oscillator strengths f of the longest-wavelength $\pi\rightarrow\pi^*$ transition and the bond index $p_{C=O}$ of the C=O bond, determined by the Pople-Pariser-Parr method.

| Chromophore X = NH | Calculated | | | Observed | | | | |
|---|---|---|---|---|---|---|---|---|
| | $\lambda_{max}$ (mμ) | f | $p_{CO}$ | Compound | $\lambda_{max}$ (mμ) | log ε | $\nu C{=}O$ ($cm^{-1}$) | $\tilde{\nu}C{=}C$ ($cm^{-1}$) |
|  | 486 | 0.42 | 0.74 | *(5)*, X = S | 502 | — | 1639 | — |
|  | 453 | 0.34 | 0.81 | *(3b)* | 450 | 4.13 | 1674 | — |
| | | | | *(4a)* | 315 | 3.95 | 1654<br>1709 | 1484 |
|  | 398 | 0.27 | 0.85 | *(3b)* | 394 | 4.05 | 1692<br>1719 | 1520 |
| | | | | *(4b)* | 318 | 3.94 | 1668<br>1698 | 1485 |
|  | 415 | 0.55 | 0.83 | *(2a)* | 434 | 4.02 | 1642 | — |
| | | | | *(2b)* | 374 | 3.72 | 1677 | 1488 |
| | | | | *(2c)* | 386 | 3.83 | 1660<br>1693 | 1470 |
|  | 424 | 0.56 | 0.82 | | | | | |

If the calculated results for bispyrroleindigo *(5)* (X = NH) in Table 1 are compared with those for group *(1)* in the *trans-s-cis-s-cis*-orientation, or if the experimental values for the bisthiopheneindigo *(5)* (X = S) are compared with those for compound *(3a)*, then it is clear that *(3a)* — and thus *(1)* — can be regarded as the basic chromophore of the indigo dyes.

(a) Compound *(3a)* shows the unusually long-wavelength absorption predicted by the theory (in comparison with thioindigo the longest-wavelength absorption band is shifted by only 88 mμ to shorter wavelengths in spite of a reduction of the conjugated system from 22 to 10 π-electrons).

(b) Compound *(3a)* can be reduced reversibly to the leuco-form.

(c) Compound *(3a)* can, like thioindigo[6], be reversibly converted by irradiation to the *cis*-form; the hypsochromic shift $\Delta\lambda = -56$ mμ is in excellent agreement with the values for thioindigo ($\Delta\lambda = -53$ mμ) and the calculated values ($\Delta\lambda = -55$ mμ). Also the shift of the CO frequency from $\tilde{\nu}_{C=O} = 1674$ for *(3a)* to 1719 $cm^{-1}$ for *(3b)* is in agreement with the change in the CO bond index from $p_{CO} = 0.81$ to 0.85.

Thus the concepts developed by *Dähne*[7] to account for the color of indigo are experimentally disproved.

According to the calculations (Table 1) it is expected that compounds *(2b)* and *(2c)* absorb at a wavelength 17 mμ higher, and more intensely, than *(3b)*. However, only very broad bands of rather low intensity at 386 and 374 mμ, respectively, are observed; these undergo only a small hypsochromic shift in ethanol instead of the expected bathochromic shift [found for *(2c)*: $\Delta\lambda = -4$ mμ; *(2b)*: $\Delta\lambda = 3$ mμ; but *(2a)*: $\Delta\lambda = +13$ mμ]. Steric reasons are responsible for these discrepancies between predicted and observed results: The carbonyl groups on the six-membered ring and the SR groups cannot all be coplanar with the C=C double bond. For *(4a)*, which should have the same spectroscopic properties as *(3a)*, the deviation from coplanarity due to steric interaction of the CO—$CH_3$ with the S—$CH_3$ groups is so great that the indigoid character is completely lost; compounds *(4a)* and *(4b)* have similar infrared and ultraviolet spectra to α,β-unsaturated ketones having an alkylthio group at the β-position[8]. Since, owing to the distortion, compound *(4a)* has no symmetry center, both the $\tilde{\nu}_{C=O}$ and the $\tilde{\nu}_{C=C}$ vibrations are infrared-active.

Even the simplest Hückel molecular-orbital calculations (carbon approximation[2]) give the correct trend in spectroscopic properties in the series thioindigo, bisthiopheneindigo, *trans*-$\Delta^{2,2'}$-bi-(4,4-dimethylthiolan-3-one), as shown in Table 2. Hence it is concluded that important properties of the indigo dyes are determined by the topology of the grouping *(1)*.

Table 2. Comparison of Hückel molecular-orbital results (carbon approximation [2]) with spectroscopic data.

| | Calculated | | Observed (in $CHCl_3$) | |
|---|---|---|---|---|
| | ΔE | $p_{CO}$ | $\lambda_{max}$ ($cm^{-1}$) | $\tilde{\nu}CO$ ($cm^{-1}$) |
| Thioindigo (= *trans*) | 0.224 | 0.725 | 18300 | 1650 |
| Bisthiopheneindigo | 0.242 | 0.690 | 19800 | 1641 |
| *trans*-$\Delta^{2,2'}$-Bi-(4,4-dimethylthiolan-3-one) | 0.261 | 0.798 | 21800 | 1674 |

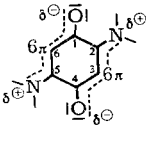
## Nature of the Bonding in Aminoquinones

By Dr. S. Kulpe, Dr. D. Leupold, and Dr. S. Dähne

Institut für Strukturforschung and Institut für Optik und Spektroskopie der Deutschen Akademie der Wissenschaften zu Berlin (Germany)

The physicochemical behavior of aminoquinones, *e.g.* of 2,5-diamino-1,4-benzoquinones *(1)*, is determined, in our opinion[1,2], by coupling of dipolar structural elements of merocyanine type. The compounds are, therefore, described as quadrupolar merocyanines. Crystal-structure analysis of 2,5-diamino-3,6-dichloro-1,4-benzoquinone (Fig. 1) con-



*(1)*

firms, in general, the bond lengths predicted [2] by a simple quantum-mechanical approximation on the basis of this concept. Interpretation of the properties of diaminoquinones on the basis of a quinone structure [3,4] is thus to be considered incorrect.

The coupling bonds $C^1-C^2$ and $C^4-C^5$ are much longer than an aromatic bond ($1.39_5$ Å). The polymethine chain shows clearly an averaging of the bond lengths. In comparison with the quinone structure [5,6] this amounts to lengthening of the $C^2-C^3$ and $C^5-C^6$ bonds and shortening of the $C^3-C^4$ and $C^6-C^1$ bonds. The C–N separation is appreciably less than the C–N single-bond distance (1.48 Å).

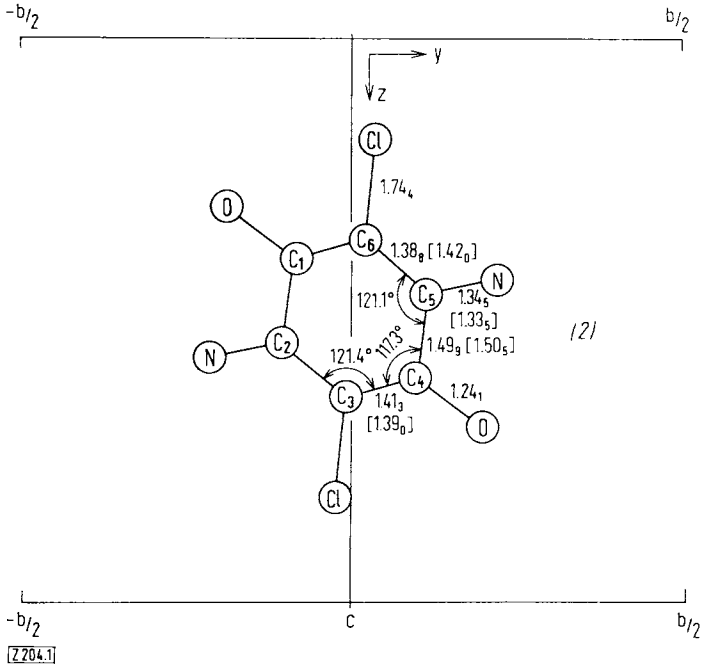


Fig. 1. A molecule of 2,5-diamino-3,6-dichloro-1,4-benzoquinone in (y,z)-projection about the center (x = 0, y = 0, z = 1/2). Distances in Å. Angles in degrees. Predicted values [2] in brackets.

The X-ray structure analysis was carried out on reddish-brown needle-shaped crystals of 2,5-diamino-3,6-dichloro-1,4-benzoquinone [X-ray density, 1.825 g/cm³; two molecules per unit cell; space group, $P2_1/c$ ($P2_1/n$ was used in the calculations); lattice constants, a = 3.787 ± 1 Å, b = 10.771 ± 3 Å, c = 9.305 ± 2 Å, β = 97.2 ± 1 °].

About 730 intensities, determined photometrically or estis mated, were used in the calculation. Patterson synthese-[$P_0$(u,w) and $P_0$ (v,w)] and $M_4$-minimum functions obtained therefrom gave first approximations for the x-, y-, and z-coordinates of the centers of gravity of the Cl, O, N, and C-atoms. Fourier and Fourier difference syntheses in two and three dimensions, as well as use of systems of linear structure factor equarions [6], led to refinement of the coordinates. The H atoms could be located approximately. The R factor for the space data (including $F_0 \approx 0$) is at present less than 14%. The mean error of the atomic distances given is estimated as 0.015 Å. The positions of the coordinates are being further refined.

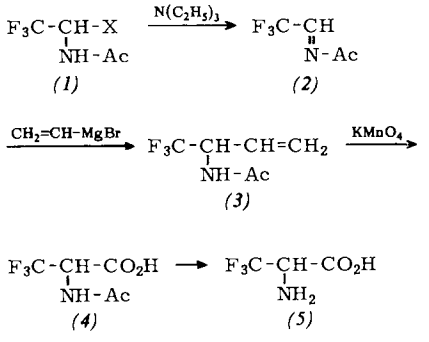
## Synthesis of 3,3,3-Trifluoroalanine and of 3,3,3-Trifluoroalanyl Peptides [1]

By Prof. F. Weygand, Doz. W. Steglich, W. Oettmeier, A. Maierhofer, and R. S. Loy

Organisch-Chemisches Institut, Technische Hochschule München (Germany)

The reaction of *N*-acyl-1-ethanesulfonyl-2,2,2-trifluoroethylamines *(1)*, X = $SO_2C_2H_5$ [2], or of *N*-acyl-1-halogeno-2,2,2-trifluoroethylamines *(1)*, X = Cl or Br [1], with triethylamine gives rise to *N*-acyl-2,2,2-trifluoroiminoethanes *(2)* [1], which react with vinylmagnesium bromide to give *N*-acyl-1-trifluoromethylprop-2-enylamines *(3)*. Oxidation of the latter with potassium permanganate in acetone/water (1:3) + 3 $NH_2SO_4$ (4.5 vol-%) affords high yields of *N*-acyl-3,3,3-trifluoroalanines *(4)* [Ac = $C_6H_5CO-$, 92%, m.p. 152 °C [2]; Ac = $C_6H_5-CH_2O-CO-$, 75%, m.p. 112 °C].

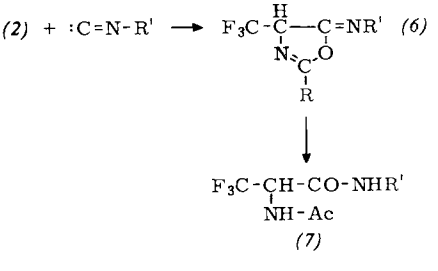


The *N*-benzoyl compound *(4)*, Ac = $C_6H_5CO-$, is transformed by heating with concentrated hydrochloric acid into 3,3,3-trifluoroalanine hydrochloride, which can be dissolved in chloroform by addition of triethylamine. Addition of acetic acid liberates trifluoroalanine *(5)* in 75% yield, which sublimes above 210 °C. Compound *(5)* is markedly acidic ($pK_1^* = 2.32$, $pK_2^* = 5.61$ [3]). In contrast to unsubstituted α-monoamino monocarboxylic acids it forms a crystalline dicyclohexylammonium salt (m.p. 152 °C) and dissolves on treatment with diazomethane in ether.

*N*-Benzyloxycarbonyl-3,3,3-trifluoroalanine can be used in the normal fashion to produce *N*-benzyloxycarbonyltrifluoroalanyl peptide esters, *e.g.* the methyl ester of benzyloxycarbonyl-3,3,3-trifluoroalanyl-L-phenylalanine, m.p. 158 °C, is obtained in 74% yield using *N*-ethynylmethyldiethylamine as condensing agent [4].

The method described can be adapted to prepare any α-amino acid with a perfluoroalkyl side-chain. *N*-Benzoyl-3,3,3-trichloroalanine, m.p. 163 °C, was made analogously.

Another synthesis of broad scope for the preparation of derivatives of 3,3,3-trifluoroalanine involves treatment of *(2)* with isonitriles. The adducts *(6)* initially formed [5] need not be isolated but are transformed by treatment with dilute acid into *N*-acyl-3,3,3-trifluoroalanine amides *(7)*; *e.g.* the cyclohexylamide of *N*-benzyloxycarbonyl-3,3,3-trifluoroalanine obtained in 80% yield is identical with that prepared from *N*-benzyloxycarbonyltrifluoroalanine itself.



This method can therefore be used to prepare trifluoroalanyl peptides directly, for the isonitriles are readily obtainable from *N*-formylamino esters[6]. For example, the methyl ester of *N*-benzyloxycarbonyl-3,3,3-trifluoroalanyl-L-leucine, m.p. 165 °C, was obtained in 64 % yield in this way. It was shown by conversion of the product into the *N*-trifluoroacetyl dipeptide methyl ester and separation of the diastereoisomers by gas chromatography[7] that an asymmetric induction takes place during the synthesis; the ratio of the diastereomers was 72:28.

The scope of these reactions is extended by using *N*-(*N* benzyloxycarbonylaminoacyl)-1-chloro-2,2,2-trifluoroethylamines *(1)*, X = Cl, Ac = $C_6H_5$–$CH_2O$–CO–NH–CHR–CO, which are obtained by reaction of *N*-benzyloxycarbonylamino acid amides with trifluoroacetaldehyde and subsequent treatment with phosphorus pentachloride. The reaction sequence described above then leads to *N*-benzyloxycarbonyl tripeptide esters with trifluoroalanine in the center; for example, the methyl ester of *N*-benzyloxycarbonylglycyl-3,3,3-trifluoroalanyl-L-leucine was obtained in the form of an oil, and the amino-acid sequence was confirmed by mass spectrometry[8] after conversion of the product into the *N*-trifluoroacetyl compound.

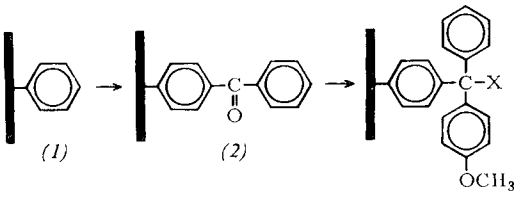
## Oligonucleotide Synthesis with a Soluble Polymer as Carrier

By Prof. Dr. F. Cramer, Dipl.-Chem. R. Helbig, Dr. H. Hettler, Dr. K. H. Scheit, and Dipl.-Chem. H. Seliger

Max-Planck-Institut für Experimentelle Medizin, Chemische Abteilung, Göttingen (Germany)

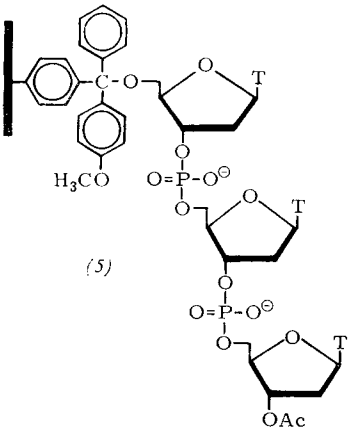
Stepwise synthesis of oligonucleotides requires column separations in aqueous systems after each step with consequent loss of time and material. By analogy with *Merrifield*'s method[1], we have tried to build oligonucleotides on a polymeric carrier[2], where use of a polystyrene derivative soluble in pyridine[3] proved expedient. In order to be able to link all four nucleotides to the polymers, we used a polystyrene containing *p*-methoxyphenylphenylmethyl chloride functional groups. Polystyrene *(1)* (mol. wt. 170000) was converted by benzoyl chloride/$AlCl_3$ into the polymeric ketone *(2)*, which was treated with *p*-methoxyphenylmagnesium bromide to give the tertiary alcohol *(3)*. This was converted into the chloride *(4)* with acetyl chloride. About 20 % of the phenyl groups of the polystyrene were thus transformed into functional groups.



*(1)* *(2)*

*(3)*, X : -OH
*(4)*, X : -Cl

The polymer *(4)* was treated with 3′-*O*-acetylthymidine in pyridine, wherupon 40 % of the functional groups reacted. The acetyl groups were then removed with 0.01 M sodium methoxide or ammonia in dioxane, and the polymeric residue was brought into reaction with 3′-*O*-acetyl-5′-thymidylic acid. Repetition of the procedure gave a polymer *(5)* containing a trinucleotide. After each reaction step the polymer can be precipitated by an nonpolar solvent or by water and freed from reagents and unchanged starting material by washing or reprecipitation.



*(5)*

After the last reaction the nucleotide mixture was split off by 1 ml of 50 % trifluoroacetic acid in 100 ml of dioxane (1 hr at room temperature), and the products were separated chromatographically and analysed. In this way thymidine and the nucleotides pT, TpT, and TpTpT were obtained in molar proportions of 28:7:25:40. The yield of TpTpT was 11 % calculated on thymidine.

Linear aminopolystyrenes can be loaded with nucleotides by formation of the (acid-labile) phosphoric amide linkage. The polymer used is one containing on an average one aromatic amino group on every fourth styrene unit. 9 % of the amino groups react with 5′-thymidylic acid (condensing agent: dicyclohexylcarbodiimide). Fission from the polymeric carrier is effected with 80 % acetic acid at 80 °C (24 hr).

## A Model for the Action of Chymotrypsin

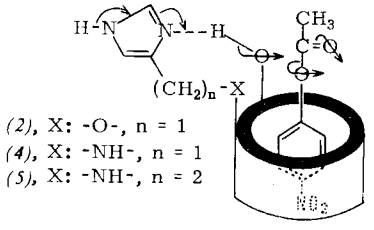
By Prof. Dr. F. Cramer and Dipl.-Chem. G. Mackensen

Max-Planck-Institut für Experimentelle Medizin, Chemische Abteilung, Göttingen (Germany)

Chymotrypsin catalysis consists in an acid-base catalysis by imidazole, in which a histidine imidazole group of the enzyme increases the nucleophilicity of a serine hydroxyl group of the protein to such an extent that at pH 7 to 9 ester transfer with subsequent splitting of the enzyme-product complex occurs[1]. In the first step of this reaction the substrate must be bound to the enzyme by a very specific, non-covalent bond

and must be presented to the catalytically active groups in the correct orientation; the "bonding" in inclusion compounds [2] resembles this lock and key relation of enzyme and substrate in many respects [3].

Cyclodextrins catalyse the fission of substituted pyrophosphates [4] and substituted phenyl acetates [5]; in both cases an acyl-catalyst intermediate complex is formed. The catalytically active groups are the hydroxyl groups of the cyclodextrin. We have now attached an imidazole residue to β-cyclodextrin *(1)* as additional catalytically active group. *(1)* was converted with 4-(or 5)-(chloromethyl)imidazole in the presence of base into the hydroxymethylimidazole ether *(2)*, whereby products with an average of two imidazole substituents per molecule of *(1)* were formed. A further possibility is treatment of hepta(6-*O*-tosyl)-β-cyclodextrin *(3)* with 4-(or 5)-(aminomethyl)imidazole or histamine, giving *(4)* and *(5)*, respectively. Finally, *(3)* was treated with imidazole to give derivatives *(6)* in which the imidazole nitrogen is linked to a C-6 atom of *(1)*.



*(2)*, X: -O-, n = 1
*(4)*, X: -NH-, n = 1
*(5)*, X: -NH-, n = 2

We determined the catalytic activity of substituted cyclodextrins from the rate of hydrolysis of *p*-nitrophenyl acetate ($0.3\times10^{-4}$ M) spectrophotometrically at 400 mμ, starting with the addition of the catalyst. Reaction conditions: 23 °C; $0.3\times10^{-2}$ M *(1)* or $0.3\times10^{-2}$ M free or bound imidazole in a mixture of 0.02 M tris buffer (pH 7.5) and dioxane (98:2 v/v). Our results are shown in the table.

| Catalyst | Imidazole groups per molecule of *(1)* | $10^4$k ($sec^{-1}$) |
|---|---|---|
| None (pH 7.5) | | 0.21 |
| α-Dextrin | | 0.32 |
| β-Dextrin (1) | | 0.59 |
| Imidazole | | 15 |
| *(1)* + Imidazole | | 17 |
| 4-(Hydroxymethyl)imidazole | | 3.3 |
| *(2)* | 2 | 41 |
| 4-(Aminomethyl)imidazole | | 2.1 |
| *(4)* | 3 | 3.6 |
| Histamine | | 4.0 |
| *(5)* | 3 | 6.1 |
| *(5)* | 4 | 13.0 |
| 1-Methylimidazole | | 8.8 |
| *(6)* | 2 | 12 |

## Synthesis and Properties of 5,6-Dimethyl-1,2,3,4-tetraphenylcalicene

By Prof. Dr. H. Prinzbach [1] and Dipl.-Chem. U. Fischer

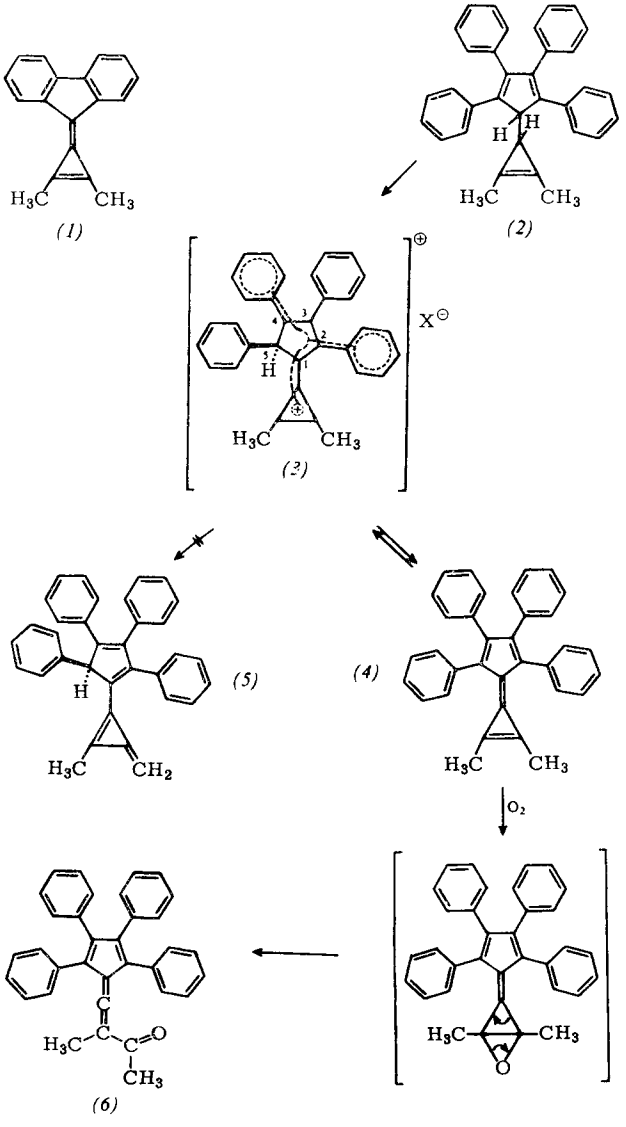
Chemisches Laboratorium
der Universität Freiburg (Germany)

We have prepared 5,6-dimethyl-1,2,3,4-tetraphenylcalicene *(4)* by way of the dihydro compound *(2)* in a synthesis analogous to that of 5,6-dimethyl-1,2;3,4-dibenzocalicene *(1)* [2]. Our product is a further stable derivative [3] of an evidently unstable parent that has not yet been isolated.

Tetraphenylcyclopentadienyl-lithium (32.4 mmole) and dimethylcyclopropenium fluoroborate (37.0 mmole) give the dihydro compound *(2)* in 40 % yield (in tetrahydrofuran at 0 °C under nitrogen).

The structure *(2)* is proved by, *inter alia*, the infrared spectrum ($\tilde{\nu}_{C=C}$ 1945 and 1876 $cm^{-1}$) and NMR spectrum ($CCl_4$) [2.5–3.1 τ (20H, m); 5.94 τ (1H, d; J = 5.5 cps); 8.5 τ (1H, d; J = 5.5 cps); 8.59 τ (6H, s)].

Removal of hydride from compound *(2)* by triphenylmethyl fluoroborate ($CHCl_3$, 20 °C, 15 min, 75–80 % yield) is accompanied by isomerization [5] to *(3)*. The salt *(3)* ($X^{\ominus}$ = $BF_4^{\ominus}$) forms lemon-yellow crystals, m.p. 202–206 °C, $\lambda_{max}$ (in $CF_3COOH$) = 418 mμ (ε = 17200) and 328 (7900), NMR spectrum (in $CF_3COOH$): 2.25–2.9 τ (20H, m), 4.31 τ (1H, s), and 7.76 τ (6H, s). In $CF_3COOD$, H-5 of the fluoroborate *(3)* is exchanged for D within a few minutes; there is no change in the relative intensity of the $CH_3$ signal when the substance is kept for several days in an 80 % (v/v) mixture of $CF_3COOD$ and $D_2O$. In agreement therewith, triethylamine in $CHCl_3$ or aqueous $NaHCO_3$ liberates the calicene *(4)* (65 % yield) selectively from the salt *(3)*. The isomeric triafulvene *(5)* is not formed in detectable amounts.



The calicene derivative *(4)* crystallizes from $O_2$-free benzene/cyclohexane as fine, yellow needles (m.p. 234.5–236 °C). In its infrared spectrum the bands of the endocyclic cyclopropene C=C linkage at 1852 $cm^{-1}$ are accompanied by further, very intense C=C bands at 1600, 1543, and 1499 $cm^{-1}$. Its NMR

spectrum ($CDCl_3$) shows a broad multiplet (2.45–2.8 τ) and a singlet (2.9 τ) for the 20 phenyl protons, and a singlet (8.29 τ) due to the two methyl groups. In $C_6D_6$ the $CH_3$ signal appears at appreciably higher field (8.84 τ), and the phenyl protons give two complex multiplets (2.3–2.6 τ; 2.6–3.0 τ; ratio of areas 8:12) which can be clearly differentiated. The diamagnetic shift of the $CH_3$ signal of *(4)*, which is remarkable in view of $\tau_{CH_3}$ for *(1)*, may perhaps indicate a considerable anisotropy effect for the phenyl substituents. The strongest peak in the mass spectrum[4] is that of the molecule ion at m/e = 434.

The ultraviolet spectrum of *(4)*, which shows only slight structure, is little influenced by the polarity of the solvent: $\lambda_{max}$ (acetonitrile) = 334 mμ (ε = 26500), 300 (26200), and 237 (15800); $\lambda_{max}$ (cyclohexane) = 336 mμ (ε = 23800), 298 (26000). As in the case of the vinylogous 7,8,9,10-tetraphenylsesquifulvalene[6] electrophilic attack in $CF_3COOH$ by the proton takes place exclusively at position 1, giving compound *(3)*, $X^{\ominus} = CF_3COO^{\ominus}$ (NMR analysis).

The calicene derivative *(4)* is thermally quite stable, but, like *(1)*[7], reacts rapidly with oxygen, giving the allene ketone *(6)* whose structure is proved by, *inter alia*, ultraviolet, infrared, NMR, and mass spectra: $\lambda_{max}$ ($CH_3CN$) = 420 mμ (ε = 2000), 308 (shoulder, 14200), 258 (shoulder, 34800), and 246 (37200); $\nu_{C=C}$ at 1927 $cm^{-1}$; $\nu_{C=C}$ at 1684 $cm^{-1}$; 2.6–2.1 τ (m), 7.84 τ (s), and 8.11 τ (s) ($CCl_4$; ratio of areas 20:3:3). The strongest peaks in the mass spectrum[4] a those of the molecule ion of *(6)* (m/e = 450), of *(6)*–tolan (272), and of tolan (178).

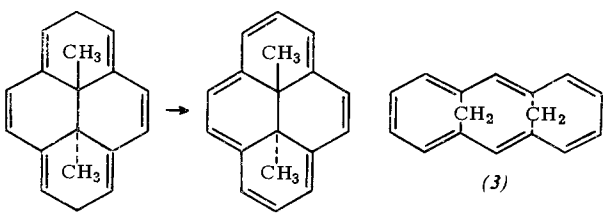
## Attempted Synthesis of anti-1,6:8,13-Bismethano[14]annulene

By Prof. Dr. E. Vogel, Dr. M. Biskup, cand. chem. A. Vogel, cand. chem. U. Haberland, and Dipl.-Chem. J. Eimer

Institut für Organische Chemie, Universität Köln (Germany)

2,7,15,16-Tetrahydro-*trans*-15,16-dimethylpyrene *(1)* can be readily dehydrogenated to 15,16-dihydro-*trans*-15,16-dimethylpyrene *(2)*, a [14]annulene with aromatic properties[1]. Whereas *(2)* has an almost planar $C_{14}$ perimeter, planarity of the outer $C_{14}$ skeleton of the analogous *anti*-1,6:8,13-bismethano[14]annulene *(3)* could be achieved only at the cost of appreciable bond-angle deformation, mainly of the

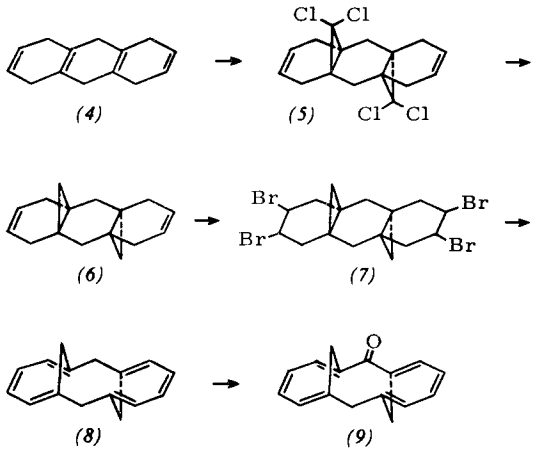


*(1)* *(2)* *(3)*

C–$CH_2$–C angles. Compound *(3)* might thus be an olefinic pendant to compound *(2)*.

We describe below the synthesis of 7,14-dihydro-*anti*-8,13-bismethano[14]annulene *(8)*, corresponding to *(1)*, and some of its reactions.

1,4,5,8,9,10-Hexahydroanthracene *(4)*[2] served as starting material. It was prepared by reduction of 9,10-dihydroanthracene with lithium in methylamine[3]. Addition of a



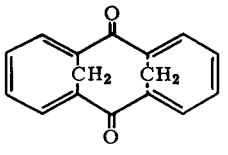
*(4)* *(5)* *(6)* *(7)* *(8)* *(9)*

cyclopropane ring to the skeleton of *(4)* by means of dichlorocarbene[4] (obtained by thermal decomposition of sodium trichloroacetate in 1,2-dimethoxyethane[5]) led, when the components were used in molar ratio 1:4, to the diadduct *(5)* (40 %), m.p. 262–263 °C, whose NMR spectrum showed a weakly split singlet at τ = 4.6, a multiplet at τ = 7.65, and a sharp singlet at τ = 7.75 (proton ratio 4:12). In favor of carbene addition in the *anti*-position is the finding that the resonances of the four middle $CH_2$ protons always appear as a singlet in the NMR spectra of compound *(5)* and the products *(6)* and *(8)* obtained therefrom (occurrence of a symmetry center)[6]. Compound *(5)* is converted by lithium and t-butyl alcohol in tetrahydrofuran[7] into the hydrocarbon *(6)* (90 %), m.p. 29 °C, which takes up two moles of bromine in methylene dichloride at −75 °C with formation of *(7)* (84 %), m.p. 129–130 °C (decomp.) (probably a mixture of isomers). When the tetrabromide is treated with methanolic KOH, the hexaene *(8)* (50–55 %), m.p. 147–148 °C, is formed directly with loss of four moles of HBr and opening of the three-membered ring. The structure of this hydrocarbon follows from its NMR spectrum: it consists of an AA'XX' system at $\tau_A \approx 3.6$ and $\tau_X \approx 4.0$, a broad singlet at τ = 6.6, and an AB system at $\tau_A = 7.27$ and $\tau_B = 8.54$ (J = 11.5 cps) (8:4:4). The ultraviolet spectrum contains maxima at λ = 221 mμ (ε = 41500) and 258 mμ (8400) in cyclohexane.

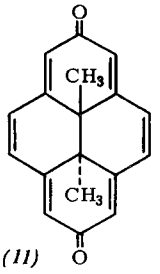
In remarkable contrast to the ready dehydrogenation of *(1)*, attempts to convert *(8)* into *(3)* by use of noble-metal dehydrogenation catalysts or 2,3-dichloro-5,6-dicyano-1,4-benzoquinone were unsuccessful. Selenium dioxide in dioxane / water oxidizes *(8)* at the allylic $CH_2$ groups of the peripheral ring, giving a mixture consisting in the main of a monohydroxy, a monooxo, and a hydroxyoxo compound. The colorless monoketone, m.p. 165–166 °C [ultraviolet spectrum: maxima at 213 (ε = 30500), 217 (31000), and 268 mμ (11900), with a shoulder at 315 mμ (4500), in cyclohexane], gives an NMR spectrum containing two complex groups of signals at τ = 3.2 and τ = 3.7, a broad singlet at τ = 6.4, and an AB system at $\tau_A = 7.26$ and $\tau_B = 8.55$ with J = 12.5 cps (6:2:2:4); it thus has structure *(9)*. This compound is a potential hydroxy derivative of the [14]annulene *(3)*; with potassium t-butoxide in dimethyl sulfoxide or tetrahydrofuran it gives intensely reddish-violet solutions, which are still under study.

Further oxidation, by chromium trioxide in pyridine, of the hydroxyketone obtained from *(8)* leads to a diketone, m.p.

299–300 °C [ultraviolet spectrum: $\lambda_{max}$ = 252 (ε = 25500) and 292 mμ (9200), in dioxane]; its NMR spectrum has only an AA'BB' system, centered at τ = 3.05, and an AB system at $\tau_A$ = 6.87 and $\tau_B$ = 8.43 (J = 13.5 cps) (8:4), so that structure *(10)* must be ascribed to it. Since this product is



*(10)*



*(11)*

colorless, and, as far as established, has no pronounced oxidizing capacity, it cannot be regarded as a quinone, in contrast to the yellow 15,16-dihydro-*trans*-15,16-dimethyl-2,7-pyrenedione *(11)* [8]. The main reason for this difference between *(11)* and *(10)* is doubtless to be sought in the steric hindrance to conjugation present in the latter.

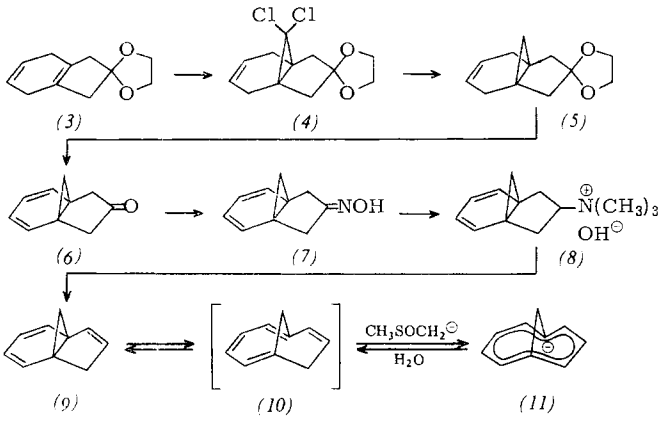
## Tricyclo[4.3.1.0$^{1,6}$]deca-2,4,7-triene, an Acidic Alicyclic Hydrocarbon

By Dr. W. Grimme, M. Kaufhold, U. Dettmeier, and Prof. E. Vogel

Institut für Organische Chemie, Universität Köln (Germany)

The existence and aromatic character of the neutral or positively charged 10π-electron systems 1,6-methanocyclodecapentaene *(1)* [1] and bicyclo[5.4.1]dodecapentaenylium cation *(2)* [2] suggested an attempt at synthesis of the bicyclo[4.3.1]decatrienyl anion *(11)* [3], the negatively charged analogue of compound *(1)* and cation *(2)*. If the anion is stable it should be produced by sufficiently strong bases from tricyclo[4.3.1.0$^{1,6}$]deca-2,4,7-triene *(9)*, which can be regarded as the stabilization product of 1,6-methano-1,3,5,7-cyclononatetraene *(10)*.

For the preparation of the hydrocarbon *(9)* we started from 4,7-dihydro-2-indanone ethylene ketal *(3)* [4]. This takes up dichlorocarbene (generated from chloroform and potassium t-butoxide) preferentially at the nucleophilic central double bond, whereby the product *(4)*, m.p. 97–98 °C, is formed (30 %). This can be nearly quantitatively reduced by sodium in liquid ammonia to compound *(5)*, b.p. 71–72 °C/0.4 mm, $n_D^{20}$ = 1.5085. Compound *(5)* is converted into the ketone *(6)* [56 %; m.p. 99–100 °C; NMR spectrum: $A_2B_2$ system



centered at τ = 4.0 (4); doublet at τ = 7.48 (4); and AB system at τ = 8.6 and 9.9 (2) with J = 5 cps], by reaction with bromine (0 °C, $CH_2Cl_2$), dehydrohalogenation of the dibromide with ethanolic $NaOC_2H_5$, and hydrolysis of the diene ketal produced by HCl in tetrahydrofuran, yields being increased if the intermediates are not isolated. The ketone is then converted into the oxime, m.p. 77–78 °C (80 %), which is reduced by $LiAlH_4$ to the corresponding amine (according to the NMR spectrum a mixture of the two stereoisomers) which is exhaustively methylated by methyl iodide and potassium carbonate in methanol; the yield of quaternary ammonium iodide calculated on *(7)* is 39 %. Hofmann degradation of the base *(8)* prepared from the iodide with silver oxide yields, finally, a 57 % yield of the norcaradiene hydrocarbon *(9)*, free from isomers, as a colorless liquid, b.p. 65–66 °C/14 mm, $n_D^{20}$ = 1.5470. The NMR spectrum of the hydrocarbon shows a multiplet at τ = 3.6–4.4 (5), a double triplet at τ = 4.8 (1), a quintuplet at τ = 7.4 (2), and an AB system at τ = 8.6 and 10.0 (2) with J = 3.0 cps. The ultraviolet-spectrum (in cyclohexane) has a double maximum at λ = 260 mμ (ε = 3100) and 270 mμ (ε = 3100), in excellent agreement with that of tricyclo[4.3.1.0$^{1,6}$] deca-2,4-diene [5]. Catalytic hydrogenation ($PtO_2$ in ethyl acetate) gives mainly tricyclo[4.3.1.0$^{1,6}$]decane [5]; the compound adds maleic anhydride even in the cold (m.p. of adduct 105–106 °C).

Compound *(9)* is not sufficiently acidic to exchange hydrogen for deuterium in $CH_3OD/CH_3ONa$ at room temperature. However, with sodium methylsulfinylmethylide ($CH_3SOCH_2^{\ominus}Na^{\oplus}$) [6] in [$D_6$]dimethyl sulfoxide a brownish-red solution is formed at once, in whose NMR spectrum the following signals appear: a double doublet at τ = 3.2 (2), a multiplet at τ = 4.0–4.6 (5), and an AB system at τ = 10.7 and 11.2 (2) with J = 7.5 cps. The changes from the spectrum of the hydrocarbon *(9)*, and in particular the shift of the signals for the bridgehead protons to higher field and the increase in the geminal coupling constant from 3.0 to 7.5 cps. indicate formation of the bridged cyclononatetraenyl anion *(11)* and the presence of a ring current in the $C_9$ perimeter. On addition of an excess of *(9)* to the solution of sodium methylsulfinylmethylide in [$D_6$]dimethyl sulfoxide the spectrum of the hydrocarbon appears together with that of the anion. It is thus shown that *(9)* is converted completely into *(11)* by the base, and that the NMR spectrum observed is not due to rapid proton exchange between *(9)* and *(11)*. Introduction of deuterium into *(11)* by [$D_6$]dimethyl sulfoxide at room temperature was not observed. If the solution of *(11)* in dimethyl sulfoxide is added to an excess of $D_2O$ a 45 % yield of compound *(9)*, which is 91 % deuterated at position 9, is obtained.

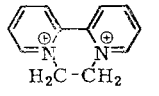
## Synthesis of a Dipyridothiadiazepine Derivative

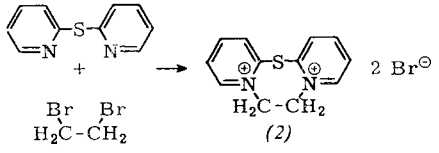
By Dr. L. A. Summers

University of Newcastle, New South Wales (Australia)

6,7-Dihydrodipyrido[1,2-*a*:2′,1′-*c*]pyrazinediium dibromide *(1)* is a herbicide[1]. We have now prepared the related, hitherto unknown 6,7-dihydrodipyrido[2,1-*b*:1′,2′-*f*][1,3,6]-thiadiazepinediium dibromide *(2)*.

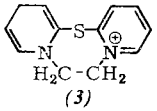


2 $Br^{\ominus}$ *(1)*



2 $Br^{\ominus}$

*(2)*



*(3)*

Treatment of 2,2′-dipyridyl sulfide (5g) with boiling ethylene dibromide (40 ml) for 1 hr gave a precipitate of *(2)*, which crystallized from aqueous ethanol as grey crystals of the monohydrate (65 % yield), m.p. 232 °C, $\lambda_{max}$ = 242 ($\varepsilon$ = 8600), 293 (12000), and 323 mμ (15000) in water. The structure was consistent with the elementary analyses (all bromine ionic) and with the NMR spectrum[2] in $D_2O$ with sodium 3-(trimethylsilyl)-1-propanesulfonate as internal reference. The NMR spectrum showed a singlet at $\delta$ = 5.7 ppm (four methylene protons) and a multiplet in the range $\delta$ = 8.1–9.2 (assigned to the eight aromatic protons) with an area ratio of 1:2.

An aqueous solution of compound *(2)* gave on treatment with zinc dust a yellow-green solution, the ESR spectrum[3] of which confirmed the presence of a comparatively stable radical, presumably the corresponding radical cation, one canonical form of which is represented by *(3)*. The complex ESR spectrum is difficult to interpret; it comprises 40 almost equally spaced lines with a total width of 33 gauss. No signal was obtained before treatment with zinc powder. Certain bipyridyl diquaternary salts, including *(1)*, are likewise readily reduced to the corresponding radical cations[4].

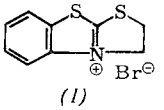
## Synthesis of Novel Heterocyclic Thiazolo Derivatives

By Doz. Dr. B. Stanovnik and Prof. Dr. M. Tišler

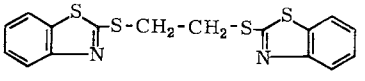
Organic Chemistry Institute,
University of Ljubljana (Yugoslavia)

Reaction of heterocyclic compounds containing a thioamide grouping as part of the ring system[1] with 1,2-dibromoethane gives heterocyclic systems which to our knowledge have not been previously synthesized.

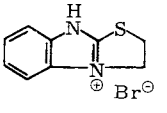
When equimolar amounts of benzothiazoline-2-thione, 1,2-dibromoethane, and potassium carbonate are left standing in dimethylformamide for 24 hr at room temperature, 2,3-dihydrothiazolo[2,3-*b*]benzothiazolium bromide *(1)*, m.p. 255–257 from dimethylformamide, is produced in 47 % yield. The yield of this product is not increased at higher temperatures (50 °C); instead 2,2′-ethylenedithiobis(benzothiazole) *(2)*, m.p. 150 °C from ethanol, is obtained in 42 % yield.



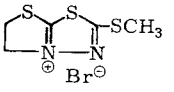
*(1)*



*(2)*



*(3)*



*(4)*

By applying the same method to benzimidazoline-2-thione, 2,3-dihydrothiazolo[2,3-*b*]benzimidazolium bromide *(3)*, m.p. 220–222 °C from ethanol, can be obtained in 43 % yield. Similarly, 2-methylthio-1,3,4-thiadiazoline-5-thione gives in 33 % yield 2-methylthio-5,6-dihydrothiazolo[2,3-*b*]-1,3,4-thiadiazol-4-ium bromide *(4)*, m.p. 225 °C (crystals separate from the melt which then melt at 280 °C).

The structures of compounds *(1)*, *(3)*, and *(4)* follow from their elemental compositions and infrared spectra. They are all soluble in water, their solutions forming a precipitate of AgBr immediately upon addition of silver nitrate; the iodoazide reaction[2] is negative.

## Inorganic Redox Ion Exchangers [1]

By Priv.-Doz. B. Sansoni[2], R. Winkler, and Prof. K. Starke

Institut für Kernchemie, Universität Marburg (Germany)

Redox ion exchangers can be made by loading commercial ion exchangers with redox ions. Previously only organic ion exchange resins had been used for this purpose. However, inorganic ion exchangers are more resistant to heat and radiation and are not irreversibly oxidized. We have therefore made and studied inorganic redox ion exchangers. The supports used were synthetic zirconium oxide hydrate and zirconium phosphate gels (BioRad HZO-1 and ZP-1, grains

of 50–100 mesh). Most silaceous ion exchangers are less suitable on account of their lower resistance to acids and bases.

Inorganic redox ion exchangers are obtained by loading either zirconium oxide hydrate gel with aqueous solutions of phosphite, dithionite, thiosulfate, sulfite, dichromate, permanganate, or oxalate, or zirconium phosphate gel with hydrazinium, hydroxylammonium, iron(II), iron(III), cerium(III), or cerium(IV) ions (see Table).

| Ion | Charging solution | | Capacity [a] | | |
|---|---|---|---|---|---|
| | | | | Time (min) | |
| | Concn. | pH | (meq/g) | half | totally charged |
| a) Zirconium oxide hydrate gel | | | | | |
| Dithionite | 1 N | 7.0 | 0.8 | 1.5 | 70 |
| Phosphite | 1 N | 6.2 | 1.2 | 2.5 | 90 |
| Sulfite | 1 N | 9.4 | 1.4 | 2.5 | 120 |
| Thiosulfate | 1 N | 6.2 | 0.75 | 0.5 | 35 |
| Dichromate | 0.1 N | 3.9 | 0.97 | 9 | 480 |
| | 0.8 N | 3.7 | 2.5 | — | — |
| Permanganate | 0.1 N | 6.3 | 0.36 | 1.0 | 12 |
| Oxalate | 1 N | 6.2 | 1.4 | 3 | 120 |
| b) Zirconium phosphate gel | | | | | |
| Hydrazinium | 1 N | 3.9 | 1.6 | 0.2 | 4 |
| Hydroxylammonium | 1 N | 2.8 | 1.1 | 0.2 | 4 |
| Iron(II) | 0.1 N | In 1N $H_2SO_4$ | 0.06 | 0.5 | 2 |
| | 1 N | In 1N $H_2SO_4$ | 0.13 | 0.5 | 2 |
| Iron(III) | 0.1 N | In 1N $H_2SO_4$ | 0.78 | 15 | 420 |
| | 1 N | In 1N $H_2SO_4$ | 2.1 | 60 | 600 |
| Cerium(III) | 0.1 N | In 1N $H_2SO_4$ | 0.06 | 0.5 | 2 |
| Cerium(IV) | 0.1 N | In 1N $H_2SO_4$ | 0.87 | 40 | 1800 |

[a] 0.5 g of support was shaken with 50 ml of charging solution until equilibrium was attained, and the bound ions were determined radiometrically or by redoxtitration.

The zirconium oxide hydrate gel is an amphoteric, the zirconium phosphate gel a weakly acidic, bifunctional ion exchanger. Sometimes the zirconium and phosphate ions in the support react irreversibly with ions in the charging solution. For this reason, the exchanger capacities found are much more dependent upon the experimental conditions than they are with organic ion exchangers. For example, zirconium oxide hydrate gel exhibits a strong pH dependence in its capacity for chromate and dichromate ions. At pH 1.0, the capacity is 1.4 meq/g but at pH 10.5 only 0.15 meq/g. Again, zirconium phosphate gel has a capacity of 7.5 meq/g for hydrazinium ions at pH 7.5 and a capacity of about 5 meq/g for hydroxylammonium ions at pH 5.5.

The high capacities, as well as the course of the loading reaction with time seem to indicate a precipitation of iron(III) on the zirconium phosphate matrix and complex formation of oxalate with the zirconium oxide hydrate support. Complex formation probably also occurs between hydrazinium and hydroxylammonium ions and zirconium phosphate supports.

Very strong oxidizing agents attack organic ion exchange resins. Consequently the cerium(IV)/zirconium phosphate and permanganate and dichromate/zirconium oxide hydrate systems are the first stable redox exchangers with extremely high redox potentials.

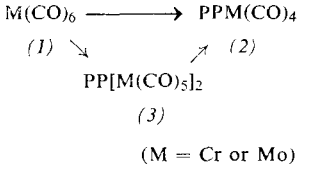
## Binuclear Complexes of Chromium and Molybdenum with Ethylenebis(diphenylphosphine) as Bridging Ligand [1]

By Dr. H. Werner, R. Prinz, E. Bundschuh, and K. Deckelmann

Anorganisch-Chemisches Laboratorium, Technische Hochschule München (Germany)

Chromium and molybdenum hexacarbonyls *(1)* react with ethylenebis(diphenylphosphine) (abbreviated PP) to give chelate complexes *(2)* in which the two phosphorus atoms of the diphosphine are coordinatively linked to the same metal atom [2]. Kinetic studies [3] show that these reactions occur by an $S_N1$ dissociation mechanism. If, however, a carbonyl *(1)* is treated with ethylenebis(diphenylphosphine) in a molar ratio 2:1 under mild conditions, binuclear complexes *(3)* are formed in which the diphosphine functions as bridging ligand and links two $M(CO)_5$ residues formed as primary dissociation products of *(1)*. After 20 hours in boiling dioxane, the yield of complex *(3)*, M = Cr, amounts to 55 %; for M = Mo it is 63 % after 4 hours' heating in a 1:1 mixture of dioxane and tetrahydrofuran. The complex *(3)* can be freed from the compounds *(2)* formed as by-product by chromatography on neutral alumina and recrystallization from toluene. Compound *(3)*, M = Cr forms pale yellow needles, m.p. 200–201 °C; compound *(3)*, M = Mo forms colorless crystals, m.p. 192–194 °C.



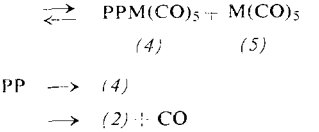
(M = Cr or Mo)

Proof of the structure of compounds *(3)* is based on elemental analyses, molecular-weight determinations (in $CHCl_3$ and $C_6H_6$), and infrared spectra. The $\nu_{CO}$ bands of *(3)* for M = Cr are at 2065, 1984, 1943, and 1933 $cm^{-1}$; those for M = Mo at 2073, 1990, 1952, and 1939 $cm^{-1}$ (in $CCl_4$).

The binuclear complexes *(3)* react with further ethylenebis(diphenylphosphine), giving the chelates *(2)*. The kinetics of these reactions can be followed by means of the infrared spectra. The results collected in the Table show that the reaction rate in toluene or dioxane is proportional to the concentration of *(3)* and independent of that of the diphosphine.

| | $PP[M(CO)_5]_2$:PP | $10^4 k_1$ (sec $^{-1}$) |
|---|---|---|
| M = Cr (in boiling toluene) | 1:2 | 1.08 |
| | 1:10 | 1.17 |
| | 1:20 | 1.05 |
| M = Mo (in boiling toluene) | 1:2 | 5.58 |
| | 1:10 | 5.42 |
| | 1:20 | 5.81 |
| M = Mo (in boiling dioxane) | 1:2 | 2.14 |
| | 1:20 | 2.23 |
| | 1:40 | 2.16 |

It follows that this substitution reaction is also governed by an $S_N1$ mechanism. The rate-determining step is probably the splitting of a metal-phosphorus bond. The coordinatively



unsaturated intermediate *(5)* reacts with the diphosphine in a second, rapid step, giving an intermediate *(4)* which forms the chelate with loss of CO.

## Free-Radical Initiated Addition of Bromotrichloromethane to Allyl Isocyanate

By Dr. W. J. Farrissey, Jr., F. P. Recchia, and Dr. A. A. R. Sayigh

The Upjohn Company, Carwin Research Laboratories, North Haven, Connecticut (U.S.A.)

The addition of radical species to allyl isocyanate has previously not been examined. We have now found that bromotrichloromethane undergoes rapid addition to the C=C double bond in the presence of azobisisobutyronitrile (AIBN) to form 2-bromo-4,4,4-trichlorobutyl isocyanate *(1)*.

A solution of allyl isocyanate (20 g) and AIBN (1 g) in bromotrichloromethane (200 g) is refluxed for 3 hr on a steam bath. Evaporation of the excess of $BrCCl_3$ gives crude product *(1)*, which is distilled at 92–94 °C/0.5 mm. Yield 80 %, colorless oil, $n_D^{22} = 1.5269$.

$$CH_2{=}CH{-}CH_2{-}NCO + BrCCl_3 \rightarrow Cl_3C{-}CH_2{-}CHBr{-}CH_2{\cdot}NCO$$

*(1)*

The NMR spectrum[1] of *(1)* comprises two doublets at 3.38 and 3.83 ppm (2 $CH_2$ groups) and a 5-peak multiplet at 4.45 ppm (CH group).

With methanol, *(1)* gives the urethane, m.p. 64–65.5 °C; with *p*-toluenesulfonamide in refluxing toluene it gives the urea derivative, m.p. 185–186 °C.

With stoichiometric quantities (or less) of $BrCCl_3$ in the synthesis of *(1)* the yield decreases and the amount of less volatile material increases. Presumably telomerization occurs, since the isocyanate function remains intact.

With $CCl_4$ in the presence of AIBN or benzoyl peroxide, allyl isocyanate reacts primarily at the isocyanate group.

# CONFERENCE REPORTS

## Macromolecular Colloquium

This colloquium was held on March 3rd–5th, 1966, at the Institut für Makromolekulare Chemie der Universität Freiburg (Germany).

### Studies of the Thermal Dehydrochlorination of Poly(vinyl chloride)

*D. Braun* and *M. Thallmaier*, Darmstadt (Germany)

In spite of numerous studies of the thermal removal of hydrogen chloride from poly(vinyl chloride) (PVC), the positions in the macromolecule responsible for initiation of this reaction have hitherto remained obscure. To test the effect of irregularities in structure of the PVC chains on thermal decomposition, we have investigated the dehydrohalogenation of copolymers of vinyl chloride with small amounts of diethyl fumarate (DEF), isobutene (IBu), vinyl bromide (VBr), and 2-chloropropene (2-CP). The rate of thermal dehydrohalogenation of the copolymers with VBr and 2-CP between about 100 and 140 °C is proportional to the square of the mole fraction of these units in the copolymers; it can thence be shown that the rate is proportional to the mole fraction of those VBr or 2-CP units which are present in sequences of two or more units. It follows that under the experimental conditions used the liberation of a molecule of hydrogen halide from an isolated, thermally labile structural unit does not initiate further loss by a "zip" mechanism. Longer polyene sequences arise only if loss of a second molecule of hydrogen halide is possible owing to the neighboring presence of a second labile unit, or on use of higher temperatures. The significance of these results for the mechanism of thermal removal of HCl from poly(vinyl chloride) and for the mode of action of heat stabilizers was discussed.

The polyene sequences arising on thermal decomposition can be analysed by means of their electronic spectra. The regularities in polyene spectra permit approximate establishment of the distribution of polyene sequence lengths in PVC and poly(vinyl bromide) (PVBr), and in vinyl chloride-DEF and -IBu copolymers. In degraded PVC, the frequency of occurrence of sequences decreases continously with increasing number of conjugated double bonds; in degraded PVBr, polyene sequences with a mean of 12 to 13 double bonds are commonest. For PVC, the ratio of the total number of polyene sequences to the amount of HCl liberated decreases with increasing time of degradation, *i.e.* with increasing removal of HCl; the frequency distribution is shifted in favor of shorter sequences, a result attributed to preferential disappearance of the longer polyene sequences by secondary reactions.

### Solution Properties of Polyvinylpyrrolidone

*W. Burchard*, Freiburg (Germany)

Light-scattering measurements on polyvinylpyrrolidone(PVP) in several solvents and in mixtures of solvent and precipitant show that the radius of gyration is clearly dependent on the composition of the Θ-solvent (change of conformation). The change of one conformation into another is, however, initiated far above the Θ-point by a relatively small amount of precipitant. The conformational change is particularly marked for aqueous solutions to which acetone or dioxane has been added. Acetone causes expansion of the coil, dioxane a contraction; these effects are not due to intermolecular interactions. The conformational change is explained as being due to preferential solvation of certain groups in the macromolecule.

Measurements with alcohols containing alkyl groups of various lengths also disclose a change of the unperturbed radii of gyration with growing length of the alkyl chain. Direct proof of this is, however, difficult because the unperturbed radius of gyration can no longer be taken as equal to the radius of gyration at the Θ-point.

### Determination of the Units in Homo- and Co-polymers of Trioxane by Pyrolysis Gas Chromatography

*K. Burg*, Frankfurt/Main-Höchst (Germany)

If homo- or co-polymers of trioxane are pyrolysed on a platinum spiral and the products are immediately separated by gas chromatography, the majority of the fragments obtained at a pyrolysis temperature of 1000 °C are very hard to identify. Pyrolysis gas chromatograms of various copolymers of trioxane show characteristic differences, so that the method can be used for differentiation of polymers. It is, however, not possible to draw conclusions about the structure of the polymers from the nature of the fragments.

If small amounts of acidic reagents are mixed with the polymers and pyrolysis is then carried out at 500 °C with subsequent gas-chromatographic analysis, considerably simpler chromatograms are obtained. Only a few fragments result which can be readily identified and correlated with the structure of the polymers. The most important pyrolysis products from polytrioxane are formaldehyde, trioxane, and tetroxane, whereas the copolymer of trioxane and ethylene oxide yields mainly formaldehyde, 1,3-dioxolane, trioxane, 1,3,5-trioxepane, diethylene glycol formal, and tetroxane. Thus acetal linkages are catalytically cleaved on pyrolysis in the presence of an acidic reagent, the ether linkages remaining intact. By quantitative evaluation of the chromatograms the ethylene oxide content can be determined for copolymers of trioxane with ethylene oxide, as well as the ratios of mono-, di-, and tri-oxyethylene units in the polymers.

### Determination of Molecular Heterogeneity of Polymers by Gel-Permeation Chromatography

*M. J. R. Cantow, R. S. Porter*, and *J. F. Johnson*, Richmond, California (U.S.A.)

Gel-permeation chromatography (GPC) permits rapid determination of the distribution of molecular size in polymers. It consists of column-chromatography in which the stationary phase is a heteroporous swollen network whose permeability varies over several orders of magnitude. A liquid phase containing dissolved polymer is passed through the gel, whereby the polymer molecules diffuse into all parts of the network not closed to them by virtue of their size. As a result, the smaller molecules of the solute penetrate further than the larger ones and are retained longer on the column.

A commerical GPC instrument (Waters), with a styrene-divinylbenzene copolymer as stationary phase, was used for the investigation of polyisobutenes with wide and narrow ranges of molecular weight. The average molecular weights of the preparations lay between 2000 and $10^6$. A computer program is described for rapid evaluation of the experimental results. The information fed in was the elution volume (as measure of molecular size) and data from the registering refractometer (as measure of the amount of polymer). These data are integrated numerically and the elution volumes are converted into molecular weights by means of a calibration curve. Two methods are described for setting up calibration curves. The computer output consists of cumulative and differential distributions of molecular weight and values for $M_n$, $M_v$, $M_w$, $M_z$, and $M_{z+1}$. By using these mean values, the conventional heterogeneities, as defined by *G. V. Schulz*, are calculated and tabulated. Standard deviations of the differential frequency and mass distribution are also obtained. The advantages of these values for the characterization of molecular-weight distributions by only one parameter are discussed. By using the standard deviation, a good correlation was obtained between non-Newtonian viscosity and the width of the molecular-weight distribution.

### Elasto-Osmometry

*J. van Dam*, Delft (Holland)

In elasto-osmometry changes in tension in a stretched and swollen strip of cross-linked silicone rubber are measured at constant length. The changes in tension result from deswelling of the strip when pure solvent is replaced by polymer solution. Swelling equilibrium is established in 10–15 minutes. The resulting change in tension is a function of the chemical potential of the solvent and thus of the number-average molecular weight and the concentration of dissolved polymer:

$$\left(\frac{\partial f}{\partial c}\right)_{c=0} = BRT/M_n$$

B is a constant dependent on the rubber used and on the solvent.

The method gives good results for polystyrene and poly(vinyl acetate) in toluene and for cellulose triacetate in dioxane, provided the molecular weight is above 5000. The upper limit is a molecular weight of about 150000 with 10 % accuracy.

### Kinetics and Molecular-Weight Distributions in Anionic Polymerizations in Weakly Solvating Solvents

*R. V. Figini*, Mainz (Germany)

Previous studies of the kinetics and the corresponding molecular-weight distributions in anionic polymerizations were carried out with naphthalenesodium as initiator and in relatively strongly solvating solvents[1–3]. In order to analyse the molecular-weight distributions more accurately, we have selected cumylsodium as initiator, because this compound gives only a monoactively growing chain on addition of the monomer; cumyl methyl ether was used as solvent, so that the influence of its dissociative properties on the reactivity of the ionic group could be studied simultaneously. The difference between the dielectric constant (3.7) of this ether and those of tetrahydrofuran and tetrahydropyran (7.4 and 5.5, respectively, at 25 °C) would be expected to result in less solvation.

The kinetic analysis showed addition of monomer in a reaction of first order, as in systems studied earlier, and, as expected, a smaller propagation constant of *ca.* 1 l·mole$^{-1}$ sec$^{-1}$ at −20.5 °C, which is only slightly dependent on the concentration of initiator. The dependence disappears entirely on addition of an electrolyte (sodium tetraphenyloborate). The mean molecular weight increases during polymerization in proportion to the monomer conversion. The molecular-weight distributions of polymers prepared without electrolyte diverge strongly from a Poisson function; on addition of electrolyte, the spread of the distribution decreases to such an extent that the deviation from a Poisson function becomes very small.

The results are interpreted by means of a reaction mechanism involving two routes[1–3], in which free anions or ion pairs

are considered to be propagators for the addition of monomer. On this hypothesis, molecular-weight distributions have been derived theoretically by the moment method[4]; they agree with the experimental results within the limits of error, providing independent evidence for the reaction scheme proposed.

## Characterization of Baker-Williams Fractions by Turbidimetric Titration

*G. Glöckner*, Dresden (Germany)

Analytical fractionation with a Baker-Williams column of 0.1–0.3 g of polymer gives many fractions containing only a few milligrams of material. The molecular weights of such small samples can be determined by turbidimetric titration. Plots of turbidity *vs.* volume fraction of precipitant are curves rising steeply from the abscissa. The corresponding curves of the samples used for calibration, which were obtained by fractional precipitation or "triangle" fractionation, rise only gradually and are S-shaped. It is therefore concluded that the Baker-Williams fractions are narrower than those used for calibration.

The effect of the rate of elution from the Baker-Williams column on the homogeneity of the fractions was studied. At a rate about four times that normally used, no broadening of the fractions could be detected turbidimetrically. S-shaped titration curves are obtained only at substantially higher rates of elution. This means that in the system studied [poly(butyl methacrylate) in acetone/methanol], and presumably in other systems as well, more rapid elution than previously thought permissible is possible.

## Investigation of Poly(vinyl dithioacetals) and their Use as Radiation-Protecting Substances

*K. Gollmer* and *H. Ringsdorf*, Marburg (Germany)

Vinyl dithioacetals (*S*-vinyl mercaptals, $CH_2=CH\text{-}S\text{-}CH_2\text{-}S\text{-}R$) have been prepared by dehydration of the corresponding 2-hydroxyethyl compounds and have been used for a kinetic study of their polymerization and for the synthesis of macromolecular compounds that might afford protection against ionizing radiation ($^{60}$Co-$\gamma$).

The over-all velocity ($V_p$, mole $l^{-1}$ $sec^{-1}$) of polymerization of the *S*-vinyl derivatives, initiated by radicals from azodiisobutyronitrile, is strongly dependent on the nature of the substituent R:

| R = | iso-$C_3H_7$ | $C_2H_5$ | $CH_3$ | $CH{=}CH_2$ | $C_6H_5$ | Styrene |
|---|---|---|---|---|---|---|
| $10^3$ $V_p$ = | 0.074 | 0.553 | 1.056 | 5.67 | 0.767 | 1.006 |

The assumption that there are overlapping inductive and steric effects is supported by the results of viscosity measurements and by the NMR spectra of the monomers.

Investigation of the protection of mice against irradiation[5] has shown that copolymers of the vinyl dithioacetals with vinylpyrrolidone are as effective as thiols of low molecular weight but remain active for longer periods. It is, moreover, characteristic of the polymers that they preferentially prevent damage to the intestinal tract and consequent disturbance of the electrolyte and water balance.

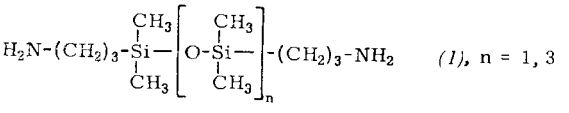
## Preparation and Polymerization of Difunctional Imide Derivatives

*G. Greber* and *R. Pense*, Freiburg (Germany)

The preparation of soluble and fusible macromolecules containing imide groups was attempted in two ways:

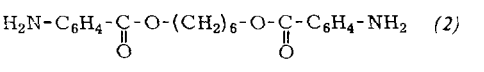
1. Pyromellitic dianhydride and trimellitic anhydride with *p*-aminophenol, ethanolamine, and *p*-aminobenzoic acid or its esters afford monomeric imides containing two reactive groups. These imides yield macromolecules by polycondensation with, or polyaddition to, suitable other reactants. Thus, for instance, reaction of *N,N'*-bis(2-hydroxyethyl)-pyromellitdiimide, the most soluble of these compounds, with adipic acid, phosgene, or hexamethylene diisocyanate leads to polyester-imides or polyurethane-imides, some of which are soluble and fusible.

2. Polyimide derivatives which also are soluble and fusible and which are stable up to more than 300 °C are obtained by polycondensation of pyromellitic dianhydride with $\omega,\omega'$-bis(3-aminopropyl)polysiloxanes *(1)*:



*(1)*, n = 1, 3

However, use of the ester diamine *(2)* as diamine component yields only insoluble and infusible products.



*(2)*

## Studies of Phase Equilibria as Basis for Fractionation of Polymers

*J. Klein*, München (Germany)

Fractionation of polymers is to be understood as a separation process, dependent on molecular weight, from a homogeneous system, with formation of a second phase. Analysis of the phases that are in equilibrium with each other – the dilute phase (sol phase) and the concentrated phase (gel phase) – with respect to polymer content, solvent, and precipitant shows that the phase equilibrium is univariant, as required by statistical thermodynamics.

Knowledge of the phase-equilibrium curve for the region of the dilute solution (sol phase) is important for a description of the fractionation, because this shows the maximum amount of soluble polymer that can be obtained under the respective conditions and, when the initial quantities in solution are known, permits the fraction of polymer precipitated in one fractionation step to be calculated.

The dependence of the equilibrium curve on concentration and molecular weight of the polymer, and on temperature, were determined for the system polystyrene/benzene/methanol, with the following results:

1. Concentration: The relation between content $\gamma^*$ of precipitant at the precipitation point (for constant M and T) and the logarithm of the polymer concentration c* gives a curve with a continuous curvature for measurements over a fairly large range of concentrations.

2. Molecular weight: The content $\gamma^*$ (for constant c and T) is a linear function of $1/M^\alpha$, where $\alpha < 0.5$, and varies with concentration.

3. Temperature: $\gamma^*$ is a linear function of the temperature T; the slope of the lines is independent of c and M.

Polydispersity must be considered as a fourth parameter. By using mixtures of samples of various molecular weights it was shown that species of low molecular weight (which change the number-average molecular weight) did not lead to higher solubility; the precipitation point is characteristic for the partial concentration of polymer which is responsible for the precipitation. Thence it can be concluded that the behavior of a polydisperse mixture can be described as the sum of the behaviors of the individual components in their respective partial concentrations. Thus the course of a fractionation can be predicted, and the most effective system chosen, from

[4] *R. V. Figini*, Makromolekulare Chem. *71*, 193 (1964); *R. V. Figini*, unpublished results.

[5] These investigations were carried out in collaboration with *W. Rüther* at the Institut für Strahlenbiologie und Isotopenforschung der Universität Marburg.

a knowledge of the analytically determined equilibrium curves.

The above argument assumes that equilibrium is in fact established in the fractionation process under consideration. Effects of coprecipitation (precipitation fractionation) or adsorption and transport phenomena (column fractionation) can have further influences and may distort the molecular-weight distribution predicted.

## Studies of Mucopolysaccharides of Normal and Sclerotic Human Aortas

*Almuth Klemer* and *D. Mempel*, Münster (Germany)

Normal and sclerotic human aortas, grouped according to degree of sclerosis and age, were degraded with papain. The contents of chondroitinsulfuric acid and heparitin sulfate were determined by preparative chromatography. Figure 1 shows the distribution pattern.

It is remarkable that aortas of patients with slight sclerosis show the highest content of chondroitinsulfuric acid.

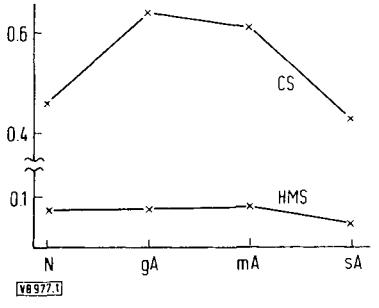


Fig. 1. Content of chondroitinsulfuric acid (CS) and heparitin sulfate (HMS) in human aortas.
Ordinate: % by weight of mucopolysaccharide.
Abscissae: Degree of sclerosis.
N = normal aortas (mean age of patients: 35 years).

mA = medium arteriosclerosis (63 years).
sA = severe arteriosclerosis (66 years)

## Relation between Synthesis of Antibodies and Metabolism of Nucleic Acids

*H. Kröger*, Freiburg (Germany)

After a second immunization, spleen cells were removed from rabbits that had been immunized with alcohol dehydrogenase. These cells continued to form antibodies to the enzyme *in vitro*. Puromycin and actinomycin D suppress this synthesis. Therefrom it can be concluded that the antibody protein is formed *de novo*, with the aid of an RNA that must originate at the DNA. In order to investigate how the information necessary for antibody synthesis is built up during the first immunization, the metabolism of DNA in rat spleen during this period was studied. This metabolism was considerably increased, but synthesis of RNA was only slightly greater than in the controls.

Endoxan and 6-mercaptopurine disturb the synthesis of antibodies. Both inhibit the synthesis of nucleic acids. Attempts to discover a relation between the first immunization and the induction of enzymes led to the conclusion that these processes have different mechanisms.

## Synthesis of Nylon Oligomers by the Merrifield Method of Peptide Synthesis on Synthetic Resins

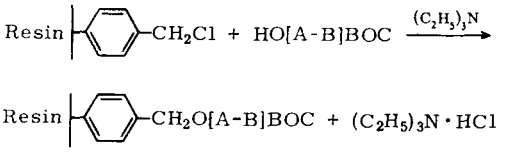
*P. Kusch*, Aachen (Germany) [*]

Stimulated by the work of *Merrifield*[1], we have prepared oligoamides of the type of Nylon 6 (H[Cap]$_n$OH, n = 2 to 4 and 8)[2], Nylon 11 (H[Und]$_n$OH, n = 2 to 5 and 10), and Nylon 6,6 (H[B–A]$_n$OH, n = 2 to 5 and 10).

[*] With collaboration by *G. Kalawrytinos*.

*Synthetic procedure*:

Step 1: The initial members of the above oligoamide series (n = 1) are converted into the readily soluble t-butoxycarbonyl derivatives and these are attached by ester bonds to chloromethylated polystyrene resin, *e.g.*:



Step 2: The amino group of the amino acid bound to the resin is unblocked and condensed with the corresponding BOC-amino acid by the DCC method[3] or by the mixed anhydride method[4], so that the chain is lengthened by one monomer unit.

Repetition of step 2 leads to further chain lengthening. At the end of the synthesis the ester bond between the resin and the oligomer is cleaved with HBr/glacial acetic acid. The oligomer set free is precipitated as oligoamide hydrobromide.

## Chemical Homogeneity of Binary Copolymers

*G. Markert*, Darmstadt (Germany)

The changes in chemical composition of mixtures of methyl methacrylate (MMA) and ethyl acrylate (EA) as a function of the conversion were calculated by an iteration method applied to the copolymerization equation. Extensive data obtained from eight initial mixtures permit integral and differential distribution curves to be drawn and regularities to be derived relating to the heterogeneity of the copolymers.

The distribution curves show that the chemical composition during polymerization changes the more the greater the difference between the chemical composition of the starting mixture and the polymer formed initially.

Some details can be deduced from the differential distribution curves, namely:

Starting mixtures with 15–70 % by weight of MMA give very heterogeneous polymers.

Of pairs mixed in reciprocal proportions the MMA-richer polymerizes more homogeneously.

Distribution curves have the highest symmetry when heterogeneity is large.

Units for characterization of the chemical heterogeneity proposed in the literature agree only partly with these results. In contrast, the frequency of the various over-all compositions provides a good measure of chemical homogeneity.

## Molecular Properties and Mode of Action of RNA Polymerase

*R. L. Millette*, *E. Fuchs*, and *W. Zillig*, München (Germany)

DNA-dependent RNA polymerase from *E. coli* has been prepared by a method that largely precludes changes in the

[1] *R. B. Merrifield*, Federat. Proc. *21*, 412 (1962).

[2] Abbreviations: [Cap] = $-NH(CH_2)_5CO-$, [Und] = $-NH(CH_2)_{10}CO-$; [B] = $-NH(CH_2)_6NH-$, [A]′ = $-OC(CH_2)_4CO-$, BOC = $(CH_3)_3C-O-CO-$.

[3] *J. C. Sheehan*, *G. P. Hess*, and *M. Goodman*, J. Amer. chem. Soc. *77*, 1067 (1955); *78*, 1367 (1956).

[4] *Th. Wieland* and *H. Bernhard*, Liebigs Ann. Chem. *572*, 190 (1951); *R. A. Boissonnas*, Helv. chim. Acta *34*, 874 (1951).

enzyme during isolation. It is based essentially on the high sedimentation coefficient of the enzyme. Together with differential centrifugation, chromatography on DEAE cellulose, precipitation with ammonium sulfate, and separation by zone electrophoresis in a sucrose gradient lead to a pure product that appears homogeneous in the analytical ultracentrifuge as well as on chromatography and electrophoresis. The physical and enzymatic properties of the purified enzyme are in accord with the properties established for the crude extract.

The Svedberg constant, $S_{20,w,c \to 0}$, is 24 S. The molecular weight is about 600000.

Electron micrographs (negative contrast) show the enzyme particles in two orientations. From these photographs a preliminary model can be derived in which six cylindrical subunits form the wall of a hollow cylinder whose internal "bore" has about the same cross-sectional area as a single subunit. The length of the enzyme particle is about 95 Å, the external diameter of the hollow cylinder is about 125 Å, and of the "bore" about 40 Å. Use of these dimensions and this model, and assuming a partial specific volume of 0.74, permit calculation of the molecular weight as about 600000 (cf. above).

When the ionic strength is increased, the enzyme particle dissociates reversibly into subunits of Svedberg constant $S_{20,w} = 12$ S and a molecular weight which is about one third of the molecular weight of the 24 S particle. These subunits no longer bind DNA and are thus enzymatically inactive. The enzymatic activity of the enzyme concerned with RNA synthesis is increased by raising the ionic strength. Enzyme particles that synthesize RNA are thus neither disintegrated nor separated from the DNA. Highly purified enzyme, when disintegrated in 6 M urea solution at pH 3.8, gives several bands on electrophoresis on starch gel, whence a complex composition involving various polypeptide chains appears probable.

The complex of DNA and polymerase can be recognized in the electron microscope. Analysis of such photographs provides information about the function of the enzyme.

In a cell-free DNA-dependent system from *E. coli*, synthesis of proteins commences already with nascent RNA. Synthesis of RNA and formation of protein thus proceed in the same direction.

## Phase Separation in Solutions of Polydisperse Polymers

*G. Rehage*, Aachen (Germany)

Isobaric phase-separation curves for binary systems are usually obtained from measurements of turbidity. The turbidity curve alone does not suffice for a description of phase separation in solutions of a polydisperse polymer. This was shown by diffusion measurements on the system polystyrene/cyclohexane, which shows a miscibility gap below 28 °C.

The phase-equilibrium curve varies with the initial concentration. The turbidity curve lies partly above and partly below the phase-equilibrium curve. Its maximum is shifted towards smaller polymer concentration and higher temperature with respect to the critical point. The position of the critical point can be determined directly from the course of the turbidity curve and the ratio of the phase volumes, and indirectly from the dependence of the chemical potential and the diffusion coefficient on concentration. The results are explained by means of a three-component system consisting of the solvent and two polymeric components of different molecular weights.

The effects observed are the stronger the higher the polydispersity of the macromolecular component. The difference between the point of maximum turbidity and the critical point is a sensitive criterion of polydispersity. This was demonstrated for polystyrenes prepared by anionic polymerization.

## Activity Changes of Ziegler-Natta Catalysts by Prepolymerization of Small Amounts of α-Olefins

*H. Schnecko, P. Freyberg, M. Reinmöller*, and *W. Kern*, Mainz (Germany)

Ageing of Ziegler-Natta catalysts, *i.e.* the action of the catalyst components on one another at the temperature of the subsequent polymerization, is usually carried out in absence of the monomer. This paper reports experiments in which ageing of the catalyst [mainly the system $Al(C_2H_5)_2Cl/TiCl_3$] was effected in the presence of small amounts of monomeric α-olefins (ethylene, propene, 1-butene, or 1s hexene). Partial polymerization of the olefins (prepolymerization) occurs during this time (usually 1 hour at 60 °C).

The rate of subsequent actual polymerization (main polymerization) of ethylene or propene with catalysts aged in this way is markedly different from the initial rate. It is lowered by preaddition of ethylene, but raised by preaddition of propene or higher α-olefins. The differences disappear with longer polymerization times. It is probable that copolymers are formed between the olefins used for prepolymerization and main polymerization.

The positive and negative changes in activity of the catalyst can in part be explained by the processes that occur in normal ageing. However, in addition, changes in solubility must be assumed to occur, caused by the products of the prepolymerization.

## The Formation of Oligomeric Amyloses by the Enzyme Amylomaltase

*G. V. Schulz, V. Häselbarth, H. E. Keller*, and *H. Schwinn*, Mainz (Germany)

The amylomaltase discovered by *Monod* in 1948 has been isolated in highly purified form. The enzyme has a sedimentation constant of 5.6 S and, on the basis of its elution volume from a Sephadex column, has a molecular weight of about 130000, in agreement with *Wiesmeyer* and *Cohn*'s results (M = 124000). The turnover number is about 10500 moles of maltose per mole of enzyme per minute, *i.e.* almost one order of magnitude higher than given by *Wiesmeyer* and *Cohn*.

Amylomaltase catalyses establishment of the equilibria

$$2\,G_2 \overset{K_1}{\rightleftharpoons} G_3 + G_1$$

$$G_3 + G_2 \overset{K_2}{\rightleftharpoons} G_4 + G_1$$

$$G_n + G_2 \overset{K_{n-1}}{\rightleftharpoons} G_{n+1} + G_1$$

($G_1$ = glucose, $G_2$ = maltose, *etc.*). The molar ratios of the oligomers were determined by thin-layer chromatography after the equilibria had been established, and the equilibrium constants were calculated therefrom. Since separations can be achieved up to maltopentaose, the constants $K_1$, $K_2$, and $K_3$ could be obtained and the mean equilibrium constant $\overline{K}$ could be calculated for the higher oligomers from their total amounts. At 23 °C the values $K_1 = 0.91$, $K_2 = 1.00$, $K_3 = 1.03$, and $\overline{K} = 1.04$ were found.

Further experiments showed that the enzyme is not specific for maltose but also catalyses establishment of the above equilibria with pure maltotriose or maltotetraose as substrate. Thus the general reaction is

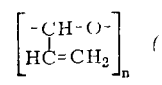
$$G_n + G_m \rightarrow G_{n+1} + G_{m-1}.$$

## Acid-Catalysed Degradation of Poly-3,4-acrolein

*R. C. Schulz, G. Wegner*, and *W. Kern*, Mainz (Germany)

Structurally homogeneous poly-3,4-acrolein *(1)* can be prepared by anionic polymerization of acrolein with sodium cyanide below 0 °C. Under these conditions, acrolein poly-

merizes exclusively at the C=O double bond. The polymers are colorless powders, dissolve in many organic solvents, and soften at 70 to 80 °C. In contrast to other polymeric



(1)

aldehydes, which often decompose spontaneously even at room temperature, poly-3,4-acrolein is remarkably stable, though it also is degraded by acids. This acid-catalysed degradation was followed viscometrically. The kinetic study showed that degradation proceeds almost exclusively by chain cleavage, which does not cause a "zip" reaction. The activation energy of chain cleavage amounts to 10.6 kcal/mole in dioxane and 12.8 kcal/mole in chloroform. Acid-catalysed depolymerization occurs only to a minor extent; it was followed by ultraviolet-spectroscopic determination of the monomeric acrolein formed on hydrolysis. The activation energy of depolymerization is 19.8 kcal/mole.

The stability of poly-3,4-acrolein towards acids is explained by formation of a resonance-stabilized cationic fragment, whereby the activation energy of depolymerization is greatly increased.

## Study of Structural Changes in Biopolymers by Chemical Relaxation

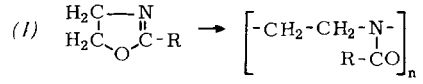
*G. Schwarz*, Göttingen (Germany)

Structural changes of biopolymers in solution generally comprise a very large number of individual steps. Use of chemical relaxation for study of the kinetics of such processes leads to relaxation curves with a complicated spectrum of relaxation times from which a mean relaxation time can be determined. A kinetic model of the structural change consisting of rapid growth steps and slow nucleation steps permits the mean value to be calculated theoretically. For certain conditions complete relaxation curves can also be calculated on this model. A mean relaxation time of the order of $10^{-7}$ second is obtained for the helix-coil transformation of polypeptides, and this is in agreement with current experimental results.

## Polymerization of 2-Oxazolines

*W. Seeliger* and *W. Thier*, Marl (Germany)

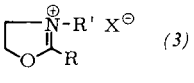
2-Oxazolines *(1)* can be converted into high-molecular poly-*N*-acylethyleneimines *(2)* by cationic catalysts.



(1) (2)

Polymerization of oxazolines is exothermal, the conversion of the imino ester into the amide structure being considered to provide the driving force.

A temperature of at least 110 °C is required for sufficiently rapid polymerization of the 2-oxazolines. Complete conversion is generally achieved within a few hours. Interruption of polymerization after incomplete conversion gives products with relatively low values of the reduced viscosity.



(3)

Compounds of formula *(3)* are suitable catalysts; they may be added as such or produced *in situ* by adding strong acids or their esters or anhydrides to the basic 2-oxazolines. R′ is then H, alkyl, or acyl, and $X^-$ is the weakly nucleophilic anion of a strong acid. Friedel-Crafts catalysts are also effective, and so are sulfuric acid and dialkyl sulfates, sulfonic acids and their alkyl esters, alkyl iodides, benzoyl *p*-toluenesulfonyl anhydride, iodine, crystalline salts of 2-oxazolines with *p*-toluenesulfonic or perchloric acid, $BF_3$ etherate, and *p*-nitrobenzenediazonium fluoroborate.

A mechanism for polymerization of 2-oxazolines is proposed in which the active end groups consist of oxazolinium cations that, formally from their oxonium limiting structures, alkylate the basic monomers and thus lead to the formation of new oxazolinium cations. According to this proposal, "living polymers" should be formed with stable end groups and narrow distributions of molecular weight.

Undiluted monomers are usually used for the polymerization, but solvents may also be added.

## Copolymerization in Systems with a Polymerization-Depolymerization Equilibrium

*P. Wittmer*, Ludwigshafen (Germany)

One of the conditions for validity of the well-known copolymerization equation [1] is irreversibility of all the growth reactions. If this condition is not fulfilled, the depolymerization reaction must be taken into account. The following copolymerization equation has been derived for the case where the propagation step in homopolymerization of one of the two monomers ($M_1$) is reversible:

$$\frac{d[M_1]}{d[M_2]} = \frac{1 + (r_1[M_1]/[M_2]) - (r_1K/[M_2])(1-x_1)}{1 + (r_2[M_2]/[M_1])}$$

Here K is the equilibrium constant between polymerization and depolymerization, and $x_1$ is the fraction of the active chains of the monomer $M_1$ with the sequence length 1. The following equation holds for $x_1$:

$$1-x_1 = \frac{r_1([M_1]+K)+[M_2]}{2r_1K} - \left[\left(\frac{[(r_1([M_1]+K)+[M_2]}{2r_1K}\right)^2 - \frac{[M_1]}{K}\right]^{1/2}$$

The equations contain three parameters, of which only two are freely disposable, namely, the two r values; the third (K) is determined by equilibrium measurements, carried out independently of the copolymerization system.

α-Methylstyrene was used as monomer whose polymerization reaches an equilibrium. The constants K for various polymerization temperatures (0–100 °C) were taken from the literature [2]. Methyl methacrylate and acrylonitrile were the comonomers; polymerizations were radical-induced in the absence of solvent. The new equations were found suitable to describe the copolymerization. The temperature-dependence of the r values can be represented by Arrhenius straight lines, as required by theory.

## Preparation of Star-Shaped Polymers by Anionic Polymerization

*J.-G. Zilliox*, *D. Decker*, and *P. Rempp*, Strasbourg (France)

The absence of spontaneous termination reactions in anionic polymerizations can be utilized for various syntheses. Star-shaped polystyrene molecules can be prepared by allowing "living" polystyrene to react with a polyfunctional deactivator, *e.g.* carbon tetrachloride, tribromomesitylene, or tetra(chloromethyl)siloxane [3]. The deactivation is, however,

[1] *L. Küchler*: Polymerisationskinetik. Springer, Berlin-Göttingen-Heidelberg 1951, p. 162.

[2] *H. W. McCormick*, J. Polymer. Sci. *25*, 488 (1957).

[3] See, *e.g.*, *S. P. Siao Yen*, Makromolekulare Chem. *81*, 152 (1965).

not always quantitative, and steric hindrance can also occur. In the best cases the number of polystyrene chains linked to each other is equal to the functionality of the deactivator.

A different method of preparing star-shaped molecules has been developed in the authors' laboratory: Divinylbenzene is treated with monofunctional "living" polystyrene and block-copolymerized. It is known that polymerization of divinylbenzene leads to a cross-linked insoluble polymer. However, in the present case the polymer remains completely soluble, provided that the amount of bifunctional monomer does not exceed 30 % of the tota amount of material. Solvated polystyrene branches are responsible for the solubility of the cross-linked stem which itself is insoluble.

The degree of branching depends on the experimental conditions and can reach high valucs. The polymeric products can be separated by fractional precipitation; successive fractions consist of star-shaped polymers with regularly decreasing degrees of branching.

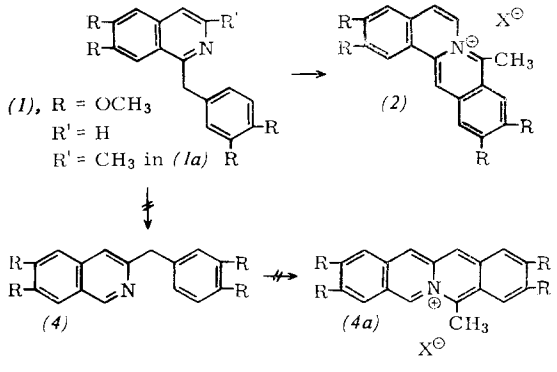
German version: Angew. Chem. *78*, 608 (1966)

## Acetylation of Benzylisoquinolines

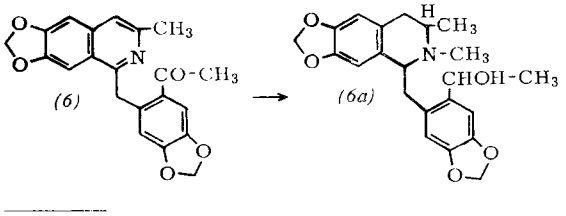
*W. Wiegrebe*, Brunswick (Germany)

According to *Awe*[1], the reaction of the 1-benzylisoquinoline alkaloid papaverine *(1)* with acetic anhydride and sulfuric acid that affords the berbine derivative "coralyn" *(2)* can be used to identify papaverine. However, 6,7-methylenedioxy-1-(3,4-methylenedioxybenzyl)-3-methylisoquinoline *(3)* cannot be converted into a coralyn derivative by acetylation. Several hypotheses have been forwarded to explain this failure of coralyn formation from *(3)*.

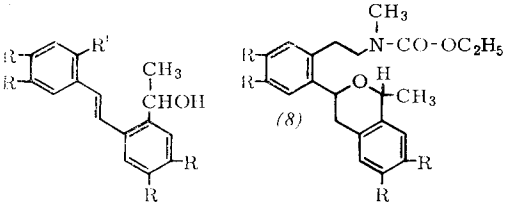
According to the paraberine hypothesis, coralyn has a paraberine and not a berbine structure. This hypothesis assumes, for example, that papaverine *(1)* rearranges to 6,7-dimethoxy-3-(3′,4′-dimethoxybenzyl)isoquinoline *(4)*, from which a paraberine *(4a)* is formed after acetylation. Compound *(4)* has been synthesized, but on acetylation does not give coralyn; this disproves the paraberine hypothesis.



Under the conditions of the acetylation, *(3)* gives 6,7-methylenedioxy-1-(3′,4′-diacetoxybenzyl)-3-methylisoquinoline *(5)* and 6,7-methylenedioxy-1-(2′-acetyl-4′,5′-methylenedioxybenzyl)-3-methylisoquinoline *(6)*; the structures of both these products have been demonstrated by chemical degradation and infrared and NMR spectroscopy and mass spectrometry[*]. For comparison with the tetrahydroisoquinolylalcohol *(6a)* formed from *(6)*, 1,2,3,4-tetrahydro-1-[2′-(1-hydroxyethyl)-4′,5′-dimethoxybenzyl]-6,7-dimethoxy-2-methylisoquinoline was prepared and subjected to degradation with ethyl chloroformate[2].

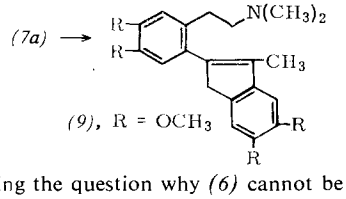


This produced mainly 3-[2′-(*N*-ethoxycarbonyl-*N*-methylamino)ethyl-4′,5′-dimethoxyphenyl]-6,7-dimethoxy-1-methylisochroman *(8)*, together with 2-[2-(*N*-ethoxycarbonyl-*N*-methylamino)ethyl]-2′-(1-hydroxyethyl)-4,4′,5,5′-tetramethoxy-*trans*-stilbene *(7)*. This stilbene is a by-product and not an intermediate in the formation of the isochroman *(8)*. The *N*,*N*-dimethylamino base *(7a)* corresponding to *(7)* is converted by acid into 2-[2-(2-dimethylaminoethyl)-4′,5′-dimethoxyphenyl]-5,6-dimethoxy-3-methylindene *(9)*.



(7), R' = $CH_2$-$CH_2$-$N(CH_3)$-CO-$OC_2H_5$

(7a) R' = $CH_2$-$CH_2$-$N(CH_3)_2$



Regarding the question why *(6)* cannot be converted into a coralyn analogue, *Halpaap*[1] suggested that the ring closure is prevented by the 3-methyl group, whereas *Hertel*[1] contended that it is hindered by the methylenedioxy substituents in the benzyl residue. The latter view is, however, contradicted by the fact that 6,7-methylenedioxy-1-(3′-methylbenzyl)isoquinoline *(10)* and its 1-(3′,4′-methylene-dioxybenzyl)-6,7-dimethoxyisoquinoline *(11)* yield coralyn analogues. On the other hand, although 3-methylpapaverine *(1a)* can be converted into its 2′-acetylbenzyl derivate *(12)*, it does not react further to give a coralyn derivative, thus confirming *Halpaap*'s view. The position of the acetyl group in *(12)* was elucidated mainly by NMR spectra[3]. The NMR spectra of the bases and cations from *(1)* and *(12)* show that these substances do not possess the benzylidene structures *(13)* that have been discussed as possible intermediates in coralyn formation, despite their theoretical unlikelihood Coralyn formation occurs by way of a (2′-acetylbenzyl)isoquinoline *(14)*, in a manner resembling the transformation of berberine aldehyde to the corresponding quaternary salt.

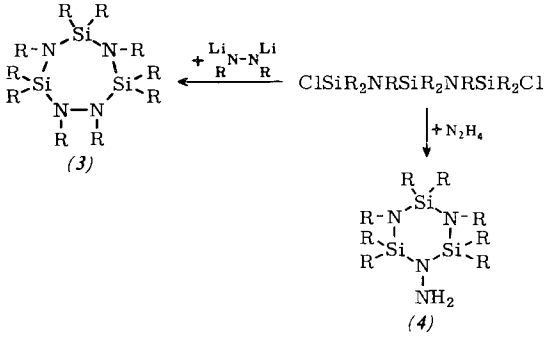
## Silyl Derivatives of Hydrazine and Hydroxylamine

*U. Wannagat*, Brunswick (Germany)

Pure 1,2-bis(trimethylsilyl)hydrazine *(1)* is obtained by reaction of hydrazine with chlorotrimethylsilane only below 20 °C and then only in moderate yield (ca. 25 %). Longer stirring and boiling under reflux lead to a mixture of the 1,2- and the 1,1-isomers *(2)*. The two products can be separated by gas chromatography and identified by infrared and Raman spectroscopy: *(2)*, $\nu_{as}$-SiNSi = 1005, $\nu_s$-SiNSi = 490, $\delta$-$NH_2$ = 1575 $cm^{-1}$. The two products are very similar in their physical properties, *e.g.* in melting point [*(1)* −64 °C, *(2)* −61 °C] and boiling point [*(1)* 149 °C, *(2)* 158 °C].

Analogous silylation of 1,1- and 1,2-dimethylhydrazine affords the monosilylated derivatives (R=$CH_3$),$R_2NNHSiR_3$, b.p.100 °C/721 mm, $\tau(SiCH_3)$=10.05 ppm,and $RHNNRSiR_3$, b.p. 109 °C/762 mm, $\tau(SiCH_3)$ = 9.96 ppm, which on further silylation by the above method yield the doubly silylated derivatives $R_2NN(SiR_3)_2$, b.p. 63 °C/13 mm, $\tau(SiCH_3)$ 9.99 ppm, and $R_3SiRNNRSiR_3$, b.p. 61 °C/13 mm, $\tau(SiCH_3)$ 9.87 ppm. Although the reaction of 1,5-dichlorooctamethyltrisilazane with the dilithium derivative of 1,2-dimethylhydrazine gives a seven-membered SiN ring compound, *viz.* decamethyl-1,2,4,6-tetraza-3,5,7-trisilacycloheptane *(3)* [R = $CH_3$, m.p. 42–43 °C, b.p. 67 °C/0.1 mm, $\tau(SiCH_3)$ 9.95 and 9.92 ppm in the ratio 2:1, $\tau(NCH_3)$ = 7.56 and 7.42 ppm in the ratio 1:1], the analogous reaction with hydrazine itself gives only the six-membered SiN ring compound, *N*-aminooctamethylcyclotrisilazane *(4)* [R = $CH_3$, m.p. 45 °C, b.p. 57 °C/0.05 mm] as is to be seen particularly from the infrared spectra.



Many of the silylated hydrazines show hypergolic behavior with fuming nitric acid (ignition time *ca.* 10 msec), inflame at once in fluorine, and explode when dropped into solutions of $O_3$ in liquid oxygen.

The following new silylated hydroxylamines have also been prepared: $(C_2H_5)_2NOSiR_3$. b.p. 35 °C/15 mm, from $(C_2H_5)_2NOH$; RO–NR–$SiR_3$, b.p. 98 °C/734 mm, from RO–NHR; and $(R_3Si)_2[NHO]$, b.p. 80 °C/97 mm, from $H_2NOH$; the last compound gives only one $R_3Si$ signal ($\tau$ = 9.94 ppm) in its $^1$H-NMR spectrum and is therefore presumably *N,N*-bis(trimethylsilyl)hydroxylamine. *O*-Silylated hydroxylamines are not cleaved at the Si–O bond by phenyl isocyanate.

[Lecture at Würzburg (Germany), Jan. 28th, 1966]

[VB 986 IE]

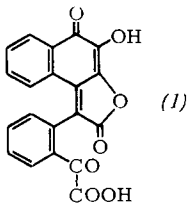
German version: Angew. Chem. *78*, 648 (1966)

## Constitution of the "Classical" 3-Hydroxy-1,2-naphthoquinone

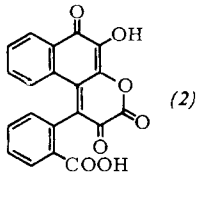
*H.-J. Teuber*, Frankfurt/Main (Germany)

*Zincke*[1] reported that autoxidation of naphthopyrogallol (1,2,3-naphthalenetriol) as well as oxidation of 1-amino-2,3-naphthalenediol[2] by iron(III) chloride gives a well-crystalline, ocher- or orange-colored compound which has hitherto been held to be 3-hydroxy-1,2-naphthoquinone[1–3].

This compound is best obtained from 2,3-naphthalenediol by oxidation with potassium nitrosobissulfate[4]. It is dimeric and has structure *(1)* or *(2)*.

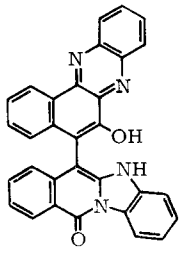


*(1)*

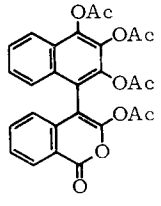


*(2)*

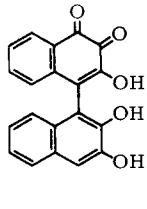
Since the compound is readily decarboxylated, like phenylglyoxylic acid, we prefer formula *(1)*. In agreement with this formulation are the spectra (the NMR spectrum, for instance, shows no aliphatic H), formation of naphthalene on distillation with zinc dust and of phthalic acid (not homophthalic acid!) on degradation with alkaline hydrogen peroxide, and absorption of only 1 mole of hydrogen on catalytic hydrogenation. Compound *(1)* – or *(2)* – condenses with 2 moles of *o*-phenylenediamine, giving *(3)*; with acetic anhydride it gives a tetraacetate, the isocoumarin derivative *(4)*, again with loss of one C atom; 1,2,3-triacetoxynaphthalene[5] is also formed in the latter reaction.



*(3)*



*(4)*



*(5)*

Compound *(1)* – or *(2)* – can be titrated as a dibasic acid (color change to purple); it is not obtained if the 4-position of 2,3-naphthalenediol is alkylated. Junction of the two naphthalene systems at positions 4′ and 1 in compounds *(1)* and *(2)* is indicated also by formation of compound *(1)* – or *(2)* – from the violet precursor *(5)* with potassium nitrosobissulfate or by disproportionation of the colorless dimeric 3-hydroxy-1,2-naphthoquinone[4].

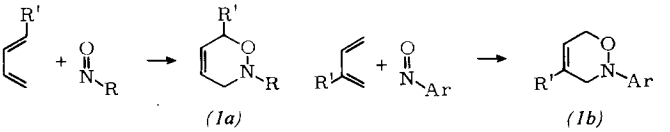
## Diene Syntheses of Heterocyclic Compounds

*G. Kresze*, Munich (Germany)

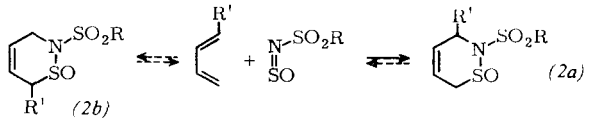
(2 + 4)-Cycloaddition is a particularly good method for the preparation of heterocyclic compounds when the dienophile contains hetero-atoms.

Nitroso compounds (aromatic nitroso and α-halogeno-nitroso compounds) react most readily. A monosubstituted diene affords mainly or exclusively the 3,6-dihydro-1,2-oxazine *(1a)* or *(1b)*.



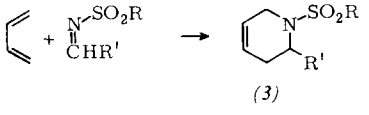
*(1a)* *(1b)*

Moreover, diene syntheses with *N*-sulfinyl compounds, and in particular *N*-sulfinylsulfonamides, lead to substituted 3,6-dihydro-1,2-thiazine 1-oxides when the reaction is under kinetic control. In some cases, however, an equilibrium mixture *(2a)* ⇄ *(2b)* results.



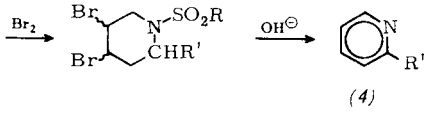
*(2b)* *(2a)*

*N*-Sulfonylimines, which can be obtained from *N*-sulfinylsulfonamides and a few aldehydes, are active as dienophiles if the carbon atom to which the imino group is attached carries a substituent that acts as an electron acceptor. The



*(3)*

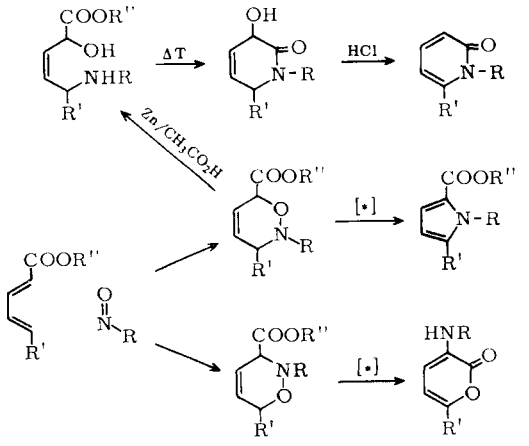
R' = $CCl_3$, COOR''



*(4)*

1,2,3,6-tetrahydropyridines obtained with dienes in good yield can be converted into pyridine derivatives *(4)* by bromination and subsequent removal of HBr and sulfinic acid.

Adducts of dienecarboxylic esters and nitroso compounds can be converted into other heterocyclic compounds:



The first step in the conversion of the oxazine derivatives involves an inverse β-fragmentation:

which appears to be a general reaction.

[Lecture at Aachen (Germany) on May 6th, 1966]

German version: Angew. Chem. *78*, 648 (1966)

[*] Chromatography on $Al_2O_3$ or treatment with bases in protic solvents.

# SELECTED ABSTRACTS

**A new synthesis of isocyanates under mild conditions,** from primary amines, carbon monoxide, and $PdCl_2$, is reported by *E. W. Stern* and *M. L. Spector*. The $PdCl_2$ is reduced to metal in the reaction. Aniline *e.g.*, afforded phenyl isocyanate in 68 % yield; n-butylamine afforded n-butyl isocyanate (49 % yield). Presumably a complex is formed among the amine, carbon monoxide, and the palladium compound, its decomposition leading to the observed products. / J. org. Chemistry *31*, 596 (1966) / –Bu. [Rd 486 IE]

**A solution of dichloroketene,** $Cl_2C{=}C{=}O$, was obtained for the first time by *W. T. Brady*, *H. G. Liddell*, and *W. L. Vaughn* when they treated trichloroacetyl chloride with zinc (activated with Cu) in anhydrous ether or ethyl acetate. Dichloroketene can be kept in these solvents for several days at 5 °C. It could not be isolated in substance because of its great tendency to polymerize, but it partially co-distils with octane or decane at reduced pressure. The infrared spectrum of the distillate shows a band at 1940 $cm^{-1}$, assigned to the C=C=O group. Chemical identification (and at the same time determination of the yield) of dichloroketene was achieved in reactions with ammonia, benzylamine, or aniline to give the corresponding dichloroacetamides in yields of up to 96 %. / J. org. Chemistry *31*, 626 (1966) / –Bu.

[Rd 485 IE]

**2,4,6-Triisopropylbenzenesulfonyl chloride was used to effect internucleotide linkages** by *R. Lohrmann* and *H. G. Khorana*. The $C_3'$–$C_5'$ internucleotide linkage was achieved with good yields. *R. Lohrmann*, *D. Söll*, *H. Hayatsu*, *E. Ohtsuka*, and *H. G. Khorana* synthesized the 64 possible ribotrinucleotides derivable from adenosine, cytidine, guanosine, and uridine, yields of trinucleoside diphosphates averaging 70–80 %. / J. Amer. chem. Soc. *88*, 819, 829 (1966) / –De.

[Rd 489 IE]

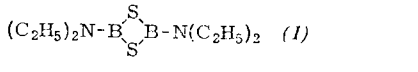
**Thiols can be selectively and irreversibly removed from aqueous solutions by poly[N-vinylphenylmaleic imide].** *E. G. Richards*, *D. L. Snow*, and *C. W. F. McClare* suggest using the polymer as column filling or adding it in portions to the solution, as a means of removing thiols and SH-proteins from biological preparations. The polymer is readily prepared from polyaminostyrene and maleic anhydride. The pale brown powder, when used as column filling at pH 7, has a capacity of *ca.* 1.3 mmole of SH per ml of column volume, measured with 2-mercaptoethanol. Nucleotides and transfer-RNA are not retained on the column; proteins are retained in accord with their SH content. / Biochemistry *5*, 485 (1966) / –Hö.

[Rd 472 IE]

**Twelve new buffers** for biochemical reactions in the pH range 6.1–8.3 are introduced by *N. E. Good et al.* There have hitherto been few suitable buffers available for this range. The substances proposed (with their $pK_a$ values at 30 °C) are: 1. 2-morpholinoethanesulfonic acid (6.15); 2. *N*-(carbamoylmethyl)iminodi(acetic acid) (6.6); 3. 1,4-piperazinedi(ethanesulfonic acid) (6.8); 4. 2-(carbamoylmethylamino)ethanesulfonic acid (6.9); 5. *N,N,N*-trimethyl-2-ammonioethylammonium dichloride (= cholamine) (7.1); 6. 2-[bis(2-hydroxyethyl)amino]ethanesulfonic acid (7.15); 7. 4-(2-hydroxyethyl)-1-piperazineethanesulfonic acid (7.55); 8. 2-*N*-[tris(hydroxymethyl)methyl]aminoethanesulfonic acid (7.5); 9. *N*-(carbamoylmethyl)glycine (7.7); 10. *N*-[tris-(hydroxymethyl)methyl]glycine (8.15); 11. Glycine amide hydrochloride (8.2); 12. *N,N*-bis(2-hydroxyethyl)glycine (8.35). Reduction of hexacyanoferrate(III) by illuminated chloroplasts was used as test reaction for biological suitability as well as oxidation of succinate by oxygen with help of plant mitochondria (followed manometrically), and protein biosynthesis in cell-free extracts of *Escherichia coli*. / Biochemistry *5*, 467 (1966) / –Hö. [Rd 473 IE]

**Lithium hydridotris-(t-butoxy)aluminate** is a selective reducing agent for the conversion of phenyl esters into aldehydes under mild conditions, as shown by *P. M. Weissman* and *H. C. Brown* for phenyl esters of aliphatic carboxylic acids. The yields are around 70%. The method is not applicable to aromatic, α,β-unsaturated, or cyclopropanecarboxylic acids. Examples: Phenyl cyclohexanecarboxylate → cyclohexanecarbaldehyde; phenyl hexanoate → hexanal / J. org. Chemistry *31*, 283 (1966) / –Bu. [Rd 462/671 1E]

**Cyclic boron-sulfur compounds** have been described by *J. A. Forstner* and *E. L. Muetterties*. Hydrogen, alkanes, and exclusively the dithiadiboretane derivative *(1)* are formed on treatment of hydrogen sulfide with triethylamine-borane at 200 °C.



*(1)*

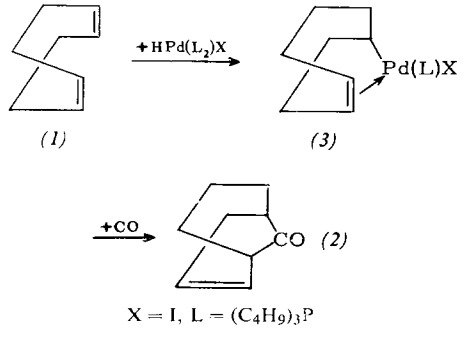
The product was resublimed and recrystallized from pentane. It is soluble in chloroform and carbon tetrachloride and melts at 70 °C in a vacuum. Molecular-weight determinations (cryoscopy in benzene and ebulliometry in $CCl_4$) confirm the molecular size proposed. The proton resonance spectrum shows a quartet at −3.3 ppm and a triplet at 1.2 ppm. Treatment of hydrogen sulfide with trimethylamine-borane gives the known compound $[(CH_3)_2NBS]_3$ containing a six-membered ring, instead of a compound with a four-membered ring. / Inorg. Chem. *5*, 164 (1966) / –Sch. [Rd 480 1E]

**Phenyldiimine** *(1)*, which has been assumed as intermediate *inter alia* in the oxidation of phenylhydrazine and the decarboxylation of phenylazoformic acid, has been detected in solution by *E. M. Kosower* and *Pih-kuei C. Huang*. On mixing of a degassed solution of the phenylazoformate ion *(2)* with phosphate buffer of pH 7.10, a new absorption spectrum, assigned to *(1)*, appears with maxima at 2140, 2700, and 4000 Å. The half-life of *(1)* at pH 7.3 is 80000 sec;

*(2)* *(1)*

at pH 13.7 compound *(1)* is completely destroyed in 100 sec, the main products being benzene, azobenzene, and hydrazobenzene. / J. Amer. chem. Soc. *87*, 4645 (1965) / –Ma. [Rd 454/663 1E]

**Transannular addition of carbon monoxide to cycloocta-1,5-diene** *(1)* was observed by *S. Brewis* and *P. R. Hughes*. Reaction of *(1)* with CO in tetrahydrofuran at 150 °C and 1000 atm in the presence of 1% of a palladium-containing catalyst



*(1)* *(3)* *(2)*

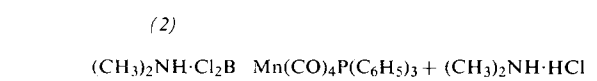
X = I, L = $(C_4H_9)_3P$

gave bicyclo[3.3.1]non-2-en-9-one *(2)* in 40–50% yield together with 45–50% of cycloocta-1,3-diene. Presumably *(2)* is formed *via* the adduct *(3)*. / Chem. Commun. *1966*, 6 / –Ma. [Rd 455/664 1E]

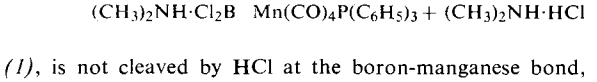
**Bis(dimethylamino)boron-pentacarbonylmanganese** *(1)* was obtained by *H. Nöth* and *G. Schmid* on treating sodium pentacarbonylmanganate with chlorobis(dimethylamino)-boron in tetrahydrofuran (yield 75%).

*(1)*

Compound *(1)* crystallizes as orange-red prisms, which, when fresh, decompose with melting from 60 °C. One mole of carbon monoxide is removed on treatment with triphenylphosphine, yielding bis(dimethylamino)boron-tetracarbonyl-(triphenylphosphine)manganese *(2)* as yellow crystals of m.p. 124 °C in 80% yield. Other reactions of compound *(1)* include cleavage of the boron-manganese bond with $Br_2$, $H_2$, or HCl, as well as hydrolysis. The complex *(2)*, in contrast to

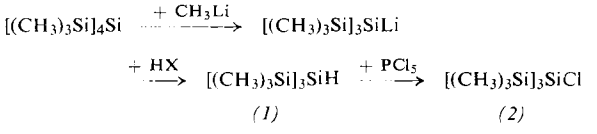


*(2)*



*(1)*, is not cleaved by HCl at the boron-manganese bond, but instead at the boron-nitrogen bond. / J. organomet. Chemistry *5*, 109 (1966) / –Sch. [Rd 478 1E]

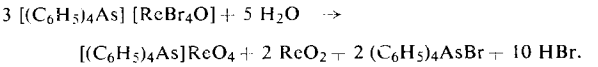
**Chlorotris(trimethylsilyl)silane** *(2)* is formed, according to *H. Gilman* and *R. Harrell*, in 50% yield in a three-stage synthesis.



*(1)* *(2)*

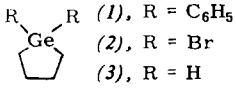
The chlorosilane *(2)*, b.p. 70–72 °C/0.5 mm Hg, m.p. 51–52 °C, can be obtained in 80–90% yield when *(1)* is treated with an excess of $CCl_4$. Chlorination of *(2)* at low temperatures leads to 2,2-dichlorohexamethyltrisilane, $[(CH_3)_3Si]_2SiCl_2$ *(3)* (yield 75%, b.p. 76–77 °C/10 mm); hydrolysis with aqueous tetrahydrofuran gives tris(trimethylsilyl)silanol, $[(CH_3)_3Si]_3SiOH$ (yield 68%; b.p. 81 °C/15mm). Compound *(3)* can be converted with methylmagnesium iodide into octamethyltrisilane and by $LiAlH_4$ into 1,1,1,3,3,3-hexamethyltrisilane (yield 60%; b.p. 65 °C/45 mm). / J. organomet. Chemistry *5*, 199 (1966) / –Sch. [Rd 479 1E]

**Oxotetrahalogenorhenates(V)** have been prepared by *F. A. Cotton* and *S. J. Lippard*. Reduction of potassium perrhenate with zinc in the presence of an excess of acid affords a new class of compound of general composition $L(ReX_4O)$, L being $(C_6H_5)_4As$, $(n\text{-}C_4H_9)N$, or $(C_2H_5)_4N$, and X being Cl, Br, or I. They probably contain a square-pyramidal ion $(ReX_4O)^-$ with strong π-bonding between oxygen and rhenium. $[(C_6H_5)_4As][ReBr_4O]$ *(1)* forms red prisms that are soluble in acetone, ethanol, acetonitrile, chloroform, or tetrahydrofuran but insoluble in diethyl ether or hydrocarbons. With $(C_6H_5)_3P$ in acetonitrile, *(1)* gives $ReBr_3(C_6H_5)_3P)_2O$, with HCl in acetone $[(C_6H_5)_4][ReCl_4O]$, with hot aqueous HBr $[(C_6H_5)_4As]_2[ReBr_6]$, and with sulfoxides in acetonitrile $[(C_6H_5)_4As]ReO_4$. The last-mentioned compound is also obtained by reaction with water:



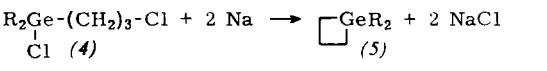
Compound *(1)* is diamagnetic. Its infrared spectrum indicates reversible addition of acetonitrile to form $[(C_6H_5)_4As][ReBr_4O(CH_3CN)]$. / Inorg. Chem. *5*, 9 (1966) / –Sch [Rd 474 1E]

**Germacyclopentanes and -butanes** have been prepared by *P. Mazerolles, J. Dubac,* and *M. Lesbre*. Treatment of dibromodiphenylgermane with Grignard compounds of 1,4-dibromobutane in benzene leads to compound *(1)* (70 % yield), and subsequent cleavage with bromine to *(2)* (80 % yield);



*(1)*, R = $C_6H_5$
*(2)*, R = Br
*(3)*, R = H

reduction with $LiAlH_4$ then gives germacyclopentane *(3)* (90 %) which is a liquid boiling at 91–92 °C. Chlorination of *(1)* with sulfuryl chloride affords 1,1-dichlorogermacyclopentane, b.p. 94 °C/64 mm Hg, in 90 % yield; by using $HgCl_2$, 1-chlorogermacyclopentane, b.p. 154 °C/745 mm, is obtained in 77 % yield. Synthesis of the cyclobutane derivatives *(5)* is achieved by treatment of chlorogermanium compounds *(4)* with sodium in boiling xylene.



$R_2Ge(Cl)-(CH_2)_3-Cl$ *(4)* + 2 Na → $GeR_2$ *(5)* + 2 NaCl

[*(5a)*, R = $C_4H_9$, yield 75 %, b.p. 111–112 °C/18 mm; *(5b)*, R = $C_2H_5$, yield 35 %, b.p. 77–78 °C/80 mm].

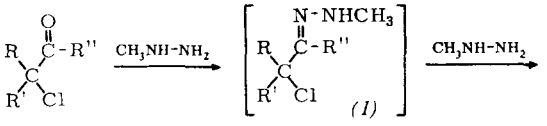
Ring scission of *(5a)* by HX affords compounds *(6)* quantitatively.

$(C_4H_9)_2GeX-CH_2-CH_2-CH_3$ (X = Cl, Br, or I)

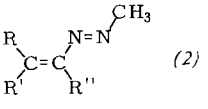
*(6)*

On reaction with sulfur, compound *(5a)* gives 2,2-dibutyl-1-thia-2-germacyclopentane, b.p. 130 °C 4 mm, in 84 % yield. / J. organomet. Chemistry *5*, 35 (1966) / –Sch. [Rd 475 IE]

**The synthesis of α,β-unsaturated aliphatic azo compounds,** previously unknown, is reported by *B. T. Gillis* and *G. D. Hagarty*. Reaction of α-chloroaldehydes or α-chloroketones with two equivalents of methylhydrazine (with or without solvent) leads by 1,4-dehydrochlorination of the intermediate hydrazone *(1)* to α,β-unsaturated methylazo compounds *(2)*, which have characteristic absorption spectra. Examples: 2-(methylazo)propene, b.p. 61–64 °C, yellow liquid, yield 31 %; 1-(methylazo)cyclohexene, b.p. 101–105 °C/80 mm Hg,



$CH_3NH-NH_2$ → [$R-C(=N-NHCH_3)-C(R')(Cl)-R''$] *(1)* → $CH_3NH-NH_2$



*(2)*

yellow, 61 %; 1-(methylazo)isobutene, b.p. 75–80 °C/200 mm, yellow, 35 %. / J. Amer. chem. Soc. *87*, 4576 (1965) / –Ma. [Rd 451/660 IE]

**Infrared spectra of cesium and tetraalkylammonium salts containing the anions $HCl_2^-$ and $DCl_2^-$** have been measured by *J. C. Evans* and *G. Y-S. Lo*. The salts were obtained by condensation of HCl or DCl onto the ordinary chlorides at −90 °C. The unstable Cs salts were studied at −78 °C, the ammonium salts at 25 °C. The spectra of the salts, dissolved in benzene, methylene dichloride, or acetonitrile, or suspended in Nujol, showed the structures of the anions to depend on the nature of the cations. The tetraethyl-, tetrapropyl-, and tetrapentyl-ammonium salts contain linear, symmetrical $HCl_2^-$ ions with a single potential minimum; for the cesium, tetramethylammonium, and trimethylhexadecylammonium salts the distances between the H or D atom and the two Cl atoms differ. / J. physic. Chem. *70*, 11 (1966) / –Hz. [Rd 467 IE]

**Kinetic data for irreversible electrochemical reductions** have been calculated from polarographic maxima by *A. Saraby-Reinjes* and *J. Th. G. Overbeek*. If these data are to be determined from the height of the diffusion-controlled polarographic steps, surface-active substance such as gelatin must be added to suppress the polarographic maxima; these, however, materially alter the kinetics of the reaction. The authors have found a simple empirical relation for the concentration polarization:

$$\log(c/{}^{\circ}c) \propto i_c$$

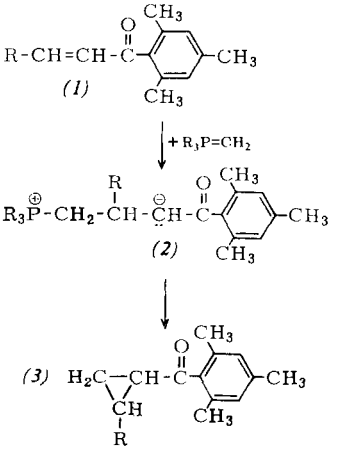
(c, °c concentrations of depolarizer in the bulk of the solution and at the electrode surface, respectively; $i_c$ cathode current).

which permits the current-potential curve to be evaluated up to currents double the value of the limiting diffusion current. In this way the following data for the reduction of bivalent cobalt and manganese in solutions containing lithium or magnesium perchlorate as supporting electrolyte were determined:

0.002M $Co(NO_3)_2$ in 0.02 M $LiClO_4$: $\alpha n_a = 0.753_5$; $\log k_o = 11.13$
0.02 M $Mg(ClO_4)_2$: $\alpha n_a = 0.730$; $\log k_o = 11.10$
0.002 M $MnSO_4$ in 0.04 M $LiClO_4$: $\alpha n_a = 1.783$; $\log k_o = 8.05$
0.02 M $Mg(ClO_4)_2$: $\alpha n_a = 1.744$; $\log k_o = 7.86$

where $k_o$ is the rate constant of the transfer reaction in cm/sec, α is transfer constant, $n_a$ the number of electrons involved in the rate-determining step. / Trans. Faraday Soc. *62*, 182 (1966) / –Hz. [Rd 465 IE]

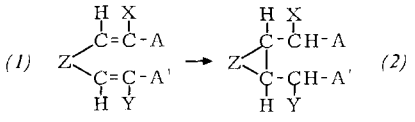
**The Wittig reaction with α,β-unsaturated ketones can involve also formation of a three-membered ring.** *J. P. Freeman*, carrying out this reaction with the ketone *(1)*, obtained the cyclic ketone *(3)*, R = $C_6H_5$, b. p. 150–155 °C/0.1 mm, $n_D^{20}$ = 1.5754, in 50 % yield by way of the betaine *(2)*.



*(1)* → (+ $R_3P=CH_2$) → *(2)* → *(3)*

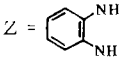
However, 1,3-diphenyl-2-propen-1-one (chalcone), which is sterically less hindered, reacts as expected to form 1,3-diphenylbutadiene, which dimerizes to 1,3,4-triphenyl-4-styrylcyclohexene. Compound *(3)* was also prepared from ethyl 2-phenylcyclopropanecarboxylate and mesitylmagnesium bromide in 56 % yield. / J. org. Chemistry *31*, 538 (1966) –Bu. [Rd 483 IE]

**Electrolytic-reductive cyclization of activated olefins** is a new route to cyclic compounds, according to *G. D. Anderson* and *M. M. Baizer*. For example, electrolysis of 40 g of diethyl deca-2,8-diene-1,10-dioate *(1a)* in a mixture of acetonitrile, tetramethylammonium *p*-toluenesulfonate, and water at 2 A and −1.91 to −1.96 V cathode potential gives 13.4 g of diethyl *trans*-cyclohexane-1,2-diacetate and 5.3 g of the *cis*-isomer. Analogously, from 40 g of the tetraethyl ester of *o*-bis(β-dicarboxyvinylamino)benzene *(1b)* was obtained 34.4 g



*(1)* *(2)*

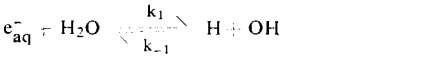
*(a)*: A = A' = $COOC_2H_5$, X = Y = H, Z = $(CH_2)_4$
*(b)*: A = A' = X = Y = $COOC_2H_5$,



of the tetraethyl ester of 2,3-bis-(dicarboxymethyl)-1,2,3,4-tetrahydroquinoxaline *(2b)*. Free-radical intermediates probably are not involved in the coupling reaction. (A,A' = electron-withdrawing groups; X,Y: electron-withdrawing groups or H). / Tetrahedron Letters *1966*, 511 / −Ma.

[Rd 452/661 IE]

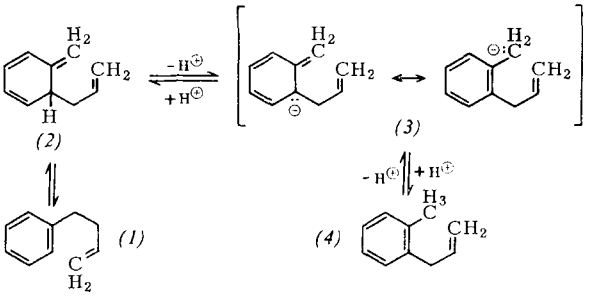
**The kinetics of reaction of the hydrated electron with water** at room temperature were studied by *E. J. Hart*, *S. Gordon*, and *E. M. Fielden* by means of electron pulse radiolysis. Reactions of $e^-_{aq}$ with, *e.g.*, $H_3O^+$, $O_2$, and $H_2O_2$ (which are about $10^9$ times faster than that with water) were suppressed by use of extremely pure, triple distilled water, adjustment of pH with carbonate-free KOH, and pre-irradiation. The rate constant $k_1$ of the reaction



in $H_2$-saturated solution of pH 8.3–9.0 at 25 °C is 16 ± 1 $mole^{-1}$ $sec^{-1}$ (concentration of impurities less than $5\times10^{-9}$ M); the constant of the reverse reaction, $k_{-1}$, is $2.3\times10^7$ $mole^{-1}$ $sec^{-1}$. / J. physic. Chem. *70*, 150 (1966) / −Hz.

[Rd 466 IE]

**Claisen rearrangement of compounds containing no heteroatoms** has been described by *W. von E. Doering* and *R. A. Bragole*. To explain why the Claisen rearrangement of C–H compounds has not been observed, it has generally been assumed that the necessary cleavage of a C–C bond would make the activation energy too high. The authors held that a more probable cause was the great difficulty of re-aromatization of compound *(2)* with shift of a hydrogen atom. Accordingly they carried out the rearrangement in a strongly basic medium (K t-butoxide in t-butyl alcohol) at 350 °C, since this difficulty should be overcome by deprotonation of *(2)* to *(3)*. Equilibria are set up between *(1)* and the four



*(2)* *(3)* *(1)* *(4)*

other possible phenylbutenes, and also between *(4)* and the two other *o*-tolylpropenes, so that eight compounds are involved in the equilibirum. However, a different mechanism, according to which the compound *(1)* is deprotonated at the *ortho*-position by the base, also explains the reaction route. / Tetrahedron *22*, 385 (1966) / − Bu.

# BOOK REVIEWS

**Ullmanns Encyklopädie der technischen Chemie** (Ullmann's Encyclopaedia of Technical Chemistry). Vol. 15: Saccharin to Silicones. Chief editor *W. Foerst*. Editor *Hertha Buchholz-Meisenheimer*. Verlag Urban und Schwarzenberg, Munich-Berlin 1964. 3rd, completely revised Edit., xii + 794 pp., 309 figs., DM 182.– (ca. $ 45.–) (sold only as the complete work).

The new volume of Ullmann contains 26 articles under main headings. Of these, the six largest account for as much as 72% of the volume. Such large articles, each heavily subdivided, have proved their value for the organisation of the work. Here they are on the following subjects: sulfur and sulfur compounds (Schwefel und Schwefelverbindungen) (193 pp.), lubricants (Schmiermittel) (139 pp.), pesticides (Schädlingsbekämpfung) (81 pp.), nitric acid (Salpetersäure) (65 pp.), silicon compounds (Siliciumverbindungen) (51 pp.), and silver (Silber) (40 pp.).

The article on sulfur and sulfur compounds gives a detailed review of the whole field. It is the result of collaboration between 19 authors from Farbwerke Hoechst, BASF, Farbenfabriken Bayer, Metallgesellschaft, Lurgi, the University of Heidelberg, Ruhrgas, Theo Goldschmidt A.G., Gewerkschaft Elwerath, and elsewhere. In spite of this variety the connections and unity within the article have not been lost – a sign of good collaboration and first-class editorial organisation.

For the paper on lubricants, Esso placed four authors from their research laboratory at Hamburg-Harburg at the disposal of the editor. Their contribution is both detailed and didactically instructive. Ten pages are devoted to theoretical ideas, which are brought completely up to date; further sections deal with details of this highly varied field, which stretches from lubrication by solids such as graphite and molybdenum sulfide to lubrication by gases, from oil for watches to oil for motors. The pressure of practical demands has made progress in this field very rapid and in part heterogeneous, and this article is very valuable because it gives the non-specialist an orderly technical perspective without sacrifice of material content

The third large article, on pesticides, is compiled by nine authors from Geigy A.G. It is in no sense confined to characterisation of substances used as pesticides; on the contrary, it goes deeply into the ramifications of biological relationships. Relevant problems are described; and legal requirements, questions of toxicology, and – with particular success – the technical evaluation and importance of pesticides are also treated. The subject is a new one; the most important advance, namely the discovery of synthetic contact insecticides, was made only 25 years ago; yet today pesticides are a determining factor in world nutrition and about one billion people are protected against malaria by means of contact insecticides.

Among the smaller articles, particular mention may be made of that on sera and vaccines (31 pp.), compiled by six authors of Behringwerke, Marburg, with Prof. *Günther* of the Paul-Ehrlich Institute in Frankfurt/M. This also is written in depth as well as in detail. The formation of antibodies is discussed, as well as, for instance, the isolation of sera from horses. Particular interest centers on the evaluation and control of sera and vaccines.

Of the small articles, all rich in content, the following deserve special mention: acid-base theories (Säure-Base-Theorien) (2 pp.) by Prof. *Seel*, Saarbrücken; shoe-polish (Schuhpflegemittel) (7 pp.); writing and drawing materials (Schreib- und Zeichenmaterialien) (15 pp.). The last two articles are also by experts from the appropriate industries. – Further titles include: hydrochloric acid (Salzsäure) (17 pp.), sapogenins (6 pp.), oxygen (Sauerstoff) (12 pp.), abrasion and abrasives (Schleifen und Schleifmittel) (7 pp.), welding and cutting (Schweißen und Schneiden) (15 pp.), and silk (Seide) (9 pp.).

It is good to see that industry is sufficiently convinced of the value of Ullmann for leading firms to feel obliged to place authoritative authors at the disposal of the editor and to present the results of their research in this frame. This has lead to a complete scientific account of industrial research which, incidentally, includes significant theoretical contributions from industrial sources. Of the total of 83 authors in the present volume, only 11 are from universities and only 4 (!) from technical colleges. In spite of this, the treatment does not lean unduly towards industrial practice: fundamental research is always fully considered. Neighboring fields, such as historical connections and legal requirements, are also well treated, the sections on toxicology by Prof. *Oettel* of BASF, which are appended to each article, being particularly noteworthy.

It should, however, be pointed out that, with a few exceptions, industry has been very reserved about financial and economic data. This can be understood where it concerns a firm's own new processes. But there are very many processes, *e.g.* most of the inorganic ones, that are traded on the world market with contractual guarantees of installation and running costs with regard to size and local conditions. Concrete comparison of the various processes could be drawn if the various advantages and disadvantages had been evaluated more actuarially.

Summing up, it can be said that in this volume, as in its predecessors, the purpose of Ullmann is excellently fulfilled, namely, to give an ordered and clear reference work for the growing wealth of practical research.

*H. Sachsse* [NB 429/336 IE]

**Kunststoffbestimmungsmöglichkeiten** (Characterization of Plastics). By *Anneliese Krause* and *A. Lange*. Carl Hanser Verlag, Munich 1965. 1st edit., 199 pp., 30 tables, linen, DM 34.– (ca. $ 8.50).

This is the first book to provide a collection of the methods and data needed for analysis of plastics in a way that is simple and intelligible to the non-specialist and yet substantially complete and easy to follow. A chapter giving general remarks on the types of plastics is followed by a review of the methods available for qualitative and quantitative analysis of individual plastics and their structural units; there follow chapters on additives and on quality control. Very valuable features are that each chapter includes the necessary characteristics, in tabular form, as well as detailed instructions for analysis and calculation of the results. – Listing benzene as a solvent for polyethylene (table 21) probable must be regarded as a typographical error. Unfortunately, infrared spectroscopy is not taken into account, although beyond doubt it permits rapid and sure identification of plastics. In spite of this shortcoming this book, which is adressed to the plastics industry as well as to experts and students, will be of great help in the analysis of plastics.

*G. Greber* [NB 435/342 IE]

**Grundriß der Technischen Organischen Chemie** (Fundamentals of Technical Organic Chemistry). By *A. Rieche*. S. Hirzel Verlag, Leipzig 1965. 3rd improved edit., xviii + 550 pp., 152 figs., 1 table, linen, DM 24.60 (ca. $ 8.–).

This new edition appears only three years after the previous one. The text has not been greatly changed, but the author has taken in the latest advances in chemistry and technology in many places.

The term "organic chemistry" is widely interpreted. It stretches from the technology of coal – beginning with its mining – over border areas such as manufacture of carbide, to the processing of agricultural raw materials. The term "technical chemistry" is also widely interpreted. Emphasis is on the materials. Numerous technical processes are described in detail with the aid of clear flow sheets, and summarising sections on chemical technology are scattered throughout the text. However, the weight placed on various fields and stages of development of chemical technology is very varied, and this makes it difficult for the beginner to obtain a balanced picture of the present chemical industry.

In its 530 pages of text the book presents an astonishing amount of material. It is remarkable how the author has remained master of such a wide field down to details. It is, however, questionable whether the student can work through such a book and retain much of its content in his memory. The reviewer, therefore, assesses the value of this book primarily as an easily accessible – and very cheap – reference work for a first introduction into a given field of work, the detailed and reliable index being of considerable help in this respect.

In preparation for his task in industry the student would, however, be better served if the book would present concrete examples of the problems met in industry and their solution. It is to be hoped that a textbook will soon be written which starts from the material and thus remains lively and yet illustrates the fundamentals of chemical processes in a deductive manner.

*H. Kindler* [NB 437/344 IE]

**Biochemistry of Quinones.** Edited by *R. A. Morton*. Academic Press Inc., New York-London 1965. 1st Edit., xvii + 585 pp., numerous figs., £5.17.6 (about $16.50).

Books are the only organized form in which the virtually limitless riches of biochemical information can be presented. In the absence of a better principle it is still customary to use the time-hallowed divisions of organic chemistry as a basis for assembling biochemical information.

An example of this is provided by the present volume where the chemistry and biological relations of some quinones are treated, in manifold variations, by 19 authors in 15 articles. Yet, when it comes to making a book out of these (sometimes excellent) articles, the greatest service has, in the reviewer's opinion, been provided by the printer who numbered the pages consecutively and by the binder who placed them between two covers.

There is, indeed, in this book an appreciable excess of the overlap, repetition, and omission – in comparison with what is promised by the title and the preface – to which one has become accustomed in modern multi-author monographs. Take, for instance, plastoquinone: there is a careful and completd account of it by *Langemann* and *Isler* in a chapter "Chemistry of Isoprenoid Quinones", and a still more detailed neighbouring article by *Redfearn* specially devoted to this quinone, then it occurs in a chapter on the biosynthesis of "biologically active quinones" (*i.e.* isoprenoid quinones), and finally it is presented comprehensively, yet again with its history, preparation, and function, in "Quinones in Photosynthetic Reactions" by *Arnon* and *Crane*. The same applies to ubiquinone, vitamin K, and vitamin E quinone. This is the result of dividing the contents both quasi-vertically into chapters on individual quinones, with general chemical and biological aspects as sub-headings,

and horizontally with general chemical and biological chapter headings, individual quinones occurring in subheadings.

Thus, in contrast to its title and pretty dust-cover, and in spite of its size, this book is restricted substantially to strongly lipophilic quinones with isoprenoid side chains. For these compounds, which are important as constituents of biologically functioning particles, it provides comprehensive and valuable documentation. -- The reader is advised to begin at page 89.

*K. Wallenfels* [NB 473/326 IE]

**Oligosaccharides.** A comprehensive account of all known sugars of the oligosaccharide class of compounds. By *R. W. Bailey*. Pergamon Press, Oxford-London-New York-Paris 1965. 1st edit., vi + 178 pp., bound $ 3.0.0.

The development of chromatographic methods for separation of oligosaccharide mixtures has led, particularly in recent years, to the isolation of numerous new compounds of this type. Since the results are recorded in journals appertaining to different disciplines the increasing number of new oligosaccharides makes it continually harder to determine whether a particular compound has or has not been described. The object of the present book is to ease this situation.

Nomenclature and the methods of isolation and determination of structure are first reviewed. The main part of the book contains a systematic list of all (about 480) the oligosaccharides that contain up to ten monosaccharide units and were known up to the end of 1962; this occupies some 100 pages. Short entries record the physical constants, source, isolation, and, as far as realized, the chemical synthesis. Each oligosaccharide is given a number which is used in the indexes.

An enormous amount of material (over 1000 references to original papers) has been brought together in this book, sifted, and splendidly handled The classification is clear and easy to follow, and the presentation intelligible despite its concise form. It affords a source of information that is rapid and fully sufficient for first orientation, this being aided by the excellent arrangement of the index. For instance, "Compound No 337" is found in the index of trivial names under raffinose, gossypose, and melitriose, and again in the general subject index as $6^G$-α-galactosylsucrose (the name being abbreviated according to *W. J. Whelan*'s proposal) among the oligosaccharides related to D-glucose, D-galactose, and D-fructose. This book is essential for the chemist working in the field and should be in every library. It only remains to be hoped that the classification and nomenclature used in it will be adopted, not only in the specialist journals, but also in textbooks.

*F. W. Lichtenthaler* [NB 434/341 IE]

**Oxidation Mechanisms.** By *T. A. Turney*. Butterworth & Co., Ltd. London 1965. 1 st Edit., viii + 207 pp., 35 s. (about $ 4.–).

The two recent monographs by *Waters* and *Stewart* dealing with oxidation mechanisms are now followed by a third, from a New Zealand author. It is similar in size to its predecessors but differs in that inorganic ions as well as organic compounds are treated.

The organic part is certainly too short. *Malaprade*, *Harries*, *Rieche*, *O. Dimroth*, *Hock*, *Bartlett*, *Roček*, *Swern*, *Prileshajew*, and *Teuber* are missing from the author index of about 600 names, entries such as cumene, decalin, peracids, and quinone from the subject index, and biological oxidation is not mentioned at all, the reaction of ozone with olefins is omitted, and the enormous influence of the configuration of a glycol on the velocity of its fission by periodate or lead tetra acetate is not mentioned; the reader is not told that the reaction with $OsO_4$ implies a *cis*-hydroxylation. This list could be expanded. One gets the impression that the author has confined himself almost entirely to the Anglo-Saxon and particularly the English literature.

On the other hand, oxidations occurring in inorganic chemistry are handled better and more completely. Even the division of the material, with its chapter headings "Cation,cation oxidations", "Cation,substrate oxidations", *etc.*, is better suited to inorganic than to organic oxidations since the latter often involve neutral molecules.

The claim on the dust-cover that "Without doubt, this is an exceptionally informative treatment of the suject for all chemistry students reading for Honours Ph. D. degrees. It will also be of value to industrial chemists concerned with oxidation processes" seems to the reviewer to be greatly exaggerated.

*R. Criegee* [NB 459/312 IE]

**High-Temperature Compounds of Rare Earth Metals with Nonmetals.** By *G. V. Samsonov*. Consultants Bureau Enterprises, Inc., New York 1965. 1st Edit., xiii + 280 pp., numerous figs., $ 17.50.

This monograph is an expanded and improved English translation of the Russian edition that appeared in 1964. The author, who is represented by many contributions to this field, deals with borides, carbides, nitrides, silicides, and sulfides of scandium, yttrium,lanthanum, and lanthanides. Each chapter is divided into sections: structure and properties, general methods of preparation, description of all the compounds, areas of use, literature citations. For example, in the chapter on carbides one finds:

(1) Crystal structure of compounds of the types $M_3C$, MC, $M_2C_3$, and $MC_2$; densities; specific electrical resistance; magnetic behavior. There are comparative observations on variation of the metallic component, and general viewpoints are brought out.

(2) Review of preparation from M + C or $M_2O_3$ + C.

(3) Reports on all the known carbides, from Sc to Lu; preparation and properties; phase diagram for La/C. Here the monograph takes on the character of a list of references.

(4) Short indications of possible uses.

The title "High-Temperature Compounds..." leads one to expect extensive applications in the high-temperature region. But this development peters out quite early. Often only laboratory experiments re reported and proposals mentioned. Information about the use of hexaborides ($LaB_6$) as cathode material is somewhat more extensive; and additionally the use of the substances described as semiconductors, neutron absorbers, and crucible materials is considered.

The book makes the impression of being complete (references up to 1964) and expertly compiled. It can afford valuable information to those interested in this field. Printing and production are good.

*H. Schäfer* [NB 467/320 IE]

**Stereochemistry, Mechanism and Silicon.** By *L. H. Sommer*. McGraw-Hill Book Comp., New York-St.Louis-San Francisco-Toronto-London-Sydney 1965. 1st Edit., xvi + 189 pp., 78 s. (ca. $ 9.50).

Monographs on organosilicon chemistry have hitherto been of the comprehensive, general type. The rapid growth of knowledge has, however, brought a further need for monographs on special problems and partial areas.

Therein lies the value of *L. H. Sommer*'s book on the relations between stereochemistry and reaction mechanism at the silicon center of organosilicon molecules. The author is Professor of Chemistry at Pennsylvania State University and has long been known for his valuable contributions to the preparative and theoretical chemistry of organosilicon com-

pounds, having worked in this field since 1958 with a large number of collaborators.

In this book the author begins with an account of the undamental experiments of his school on the preparation of optically active silicon compounds and then details the reactions in which Si–O, Si–halogen, and Si–H bonds play a part, finally discussing the stereochemistry and reaction mechanism at silicon centers. This leads up to a classification of all the reactions that can occur at a silicon atom.

The reader will be grateful for the concise and clear description of this field and for the collection of so many results. The book constitutes a valuable enrichment of the monograph literature of modern silicon chemistry.

# Classification and Analysis of NMR Spectra

BY DR. B. DISCHLER

INSTITUT FÜR ELEKTROWERKSTOFFE, FRAUNHOFER-GESELLSCHAFT, FREIBURG (GERMANY)

*The use of nuclear magnetic resonance as the basis of a spectroscopic method in organic analysis is steadily growing* [1]. *The object of the present article is to present a general picture of the classification and interpretation of the NMR spectra obtained at high resolutions. In simple cases complete interpretation is possible with the aid of only a few equations; otherwise it is often necessary to use a laborious mathematical procedure, which is discussed here. For a more profound study, the reader is referred to more detailed publications* [2–6].

## I. Introduction

Nuclear magnetic resonance arises as a result of transitions between the energy levels of a nuclear magnetic dipole in a static magnetic field. The existence of discrete states can be understood in terms of the quantum theory. The observation of nuclear magnetic resonance requires the presence of an external alternating magnetic field of suitable frequency, by which detectable transitions are induced.

When nuclear magnetic resonance signals were first observed, it was found that this "nuclear Zeeman effect" could be explained by the simple Equation (1):

$$1945: \quad h\nu_o = \frac{\mu}{I} H \qquad (1)$$

where h is Planck's constant; $\nu_o$ the resonance or Larmor frequency, $\mu$ the magnetic moment of the nucleus, I the nuclear spin, and H the strength of the external magnetic field.

With better resolution it became possible to recognize differences in the shielding of the external magnetic field by the electrons of atoms of identical species in different chemical environments. This "chemical shift" was taken into account by Equation (2).

$$1949: \quad h\nu_i = \frac{\mu}{I} H_o (1-\sigma_i) \qquad (2)$$

where i is a subscript for numbering the nuclei in a molecule, $H_o$ the field strength of the external magnetic field at resonance, and $\sigma$ a shielding parameter ($10^{-4}$–$10^{-5}$ for protons).

Later the indirect nuclear spin interaction caused by spin polarization of the electron cloud was discovered. A complete description of the spectrum therefore requires the introduction of a spin Hamiltonian operator, which is given by:

$$1951: \quad \mathbf{H} = \sum_{i=1}^{n} \nu_i \mathbf{I}_z(i) + \sum_{i=1}^{k-1} \sum_{k=z}^{n} J_{ik} \mathbf{I}(i) \mathbf{I}(k) \qquad (3)$$

where $\mathbf{I}(i)$ is the angular momentum operator for the nucleus i, $\mathbf{I}_z(i)$ the z component of $\mathbf{I}(i)$ [the negative z-direction is given by the direction of the static magnetic field], and $J_{ik}$ is the parameter for spin-spin coupling between the nuclei i and k.

This energy operator will be discussed further in Section III.

## II. Types of NMR Spectra

It is usual and convenient to divide nuclear resonance spectra into types. A short formula is used to characterize both the spectrum and the arrangement (the symmetry) of the nuclei in the molecule (see Figs. 1 and 2).

[1a] *K. H. Hauser*, Angew. Chem. *68*, 729 (1956).

[1b] *J. D. Roberts*, Angew. Chem. *75*, 20 (1963); Angew. Chem. internat. Edit. *2*, 53 (1963).

[2] *J. A. Pople, W. G. Schneider*, and *H. J. Bernstein*: High-resolution Nuclear Magnetic Resonance. McGraw Hill, New York 1959.

[3] *L. M. Jackmann*: Applications of Nuclear Magnetic Resonance Spectroscopiy in Organic Chemistry. Pergamon Press, London 1959.

[4] *P. L. Corio*, Chem. Reviews *60*, 363 (1960).

[5] *J. D. Roberts*: An Introduction to the Analysis of Spin-Spin Splitting in High-Resolution Nuclear Magnetic Resonance Spectra. Benjamin, New York 1961.

[6a] *J. Ranft*, Fortschr. Physik *9*, 149 (1961).

[6b] *H. Strehlow*: Magnetische Kernresonanz und chemische Struktur. Steinkopff, Darmstadt 1962.

The characterization requires that all the nuclei in the molecule should be reduced to the "spin system". This spin system consists of the nuclei having the spin $^1/_2$ (*e.g.* $^1$H, $^{19}$F, $^{31}$P) that interact with one another by indirect spin coupling [7].

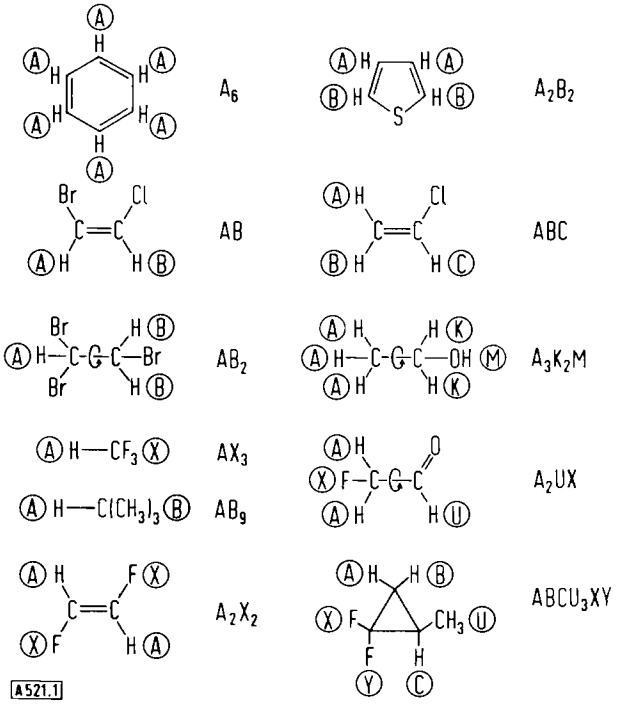

Fig. 1. Designation of NMR spin systems.

If the approximate values of the Larmor differences $\nu_o\delta_{ik}$ [8] and the coupling parameters $J_{ik}$ are known, the type to which a spectrum belongs can be given by two rules:

1. Chemically non-equivalent nuclei in a molecule are assigned different letters [9].

2. The choice of the letter is determined by the magnitude of the spin-spin coupling relative to the Larmor difference.

The first nucleus, *i.e.* that with the highest spin coupling (and any other equivalent nucleus), is always denoted by A and the other nuclei by

(a) a subsequent letter from the beginning of the alphabet (B, ...) if $J_{AB}$ is comparable in magnitude with $\nu_o\delta_{AB}$;

(b) a letter from the middle of the alphabet (M, ...) if $J_{AM}$ is approximately one order of magnitude smaller than $\nu_o\delta_{AM}$ [10];

(c) a letter from the end of the alphabet (X, ...) if $J_{AX}$ is two or more orders of magnitude smaller than $\nu_o\delta_{AX}$ [11].

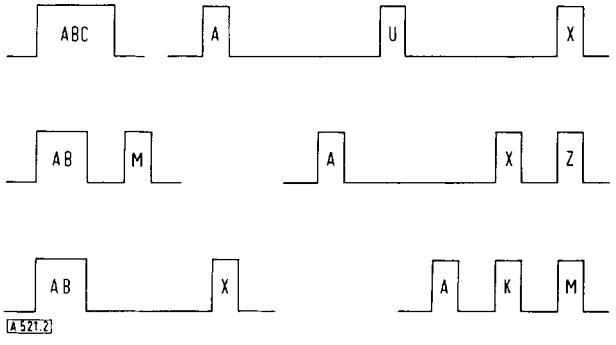

Fig. 2. Types of NMR spectra for three chemically non-equivalent nuclei, schematically represented by envelope curves.

Case (a) corresponds to the so-called complex spectra, in which the Larmor differences are important as well as the coupling parameters. In Case (b), the signals of the non-equivalent nuclei occur in separate groups, in which the line splitting and the line intensities depend only slightly on the Larmor differences. In Case (c), the resonance signals of the non-equivalent nuclei are so far apart that they are usually recorded as separate groups of lines; within these sub-spectra, the splittings and intensities of the lines are independent of the Larmor differences, *i.e.* they are determined only by the spin coupling. Thus the use of Rule 2 takes into account both the external appearance of the spectra and the various effects of the Larmor differences on the line splittings and intensities.

Rules 1 and 2 are sometimes not sufficient to give an unambiguous designation for more complex spin systems [12]; an extension of the rules is therefore desirable [13].

[7] The spin system does not include, for example, carbon and oxygen nuclei (spin = 0), except when the isotopes $^{13}$C and $^{17}$O are involved. Moreover, nuclei with spin $> ^1/_2$ (chlorine, bromine, *etc.*) are not normally included, since they have a quadrupole moment ($Q \neq 0$) and do not exhibit spin coupling because of quadrupole relaxation.

[8] The quantity known as the "Larmor difference" is defined by $\nu_i - \nu_k = \nu_o\delta_{ik}$.
($\nu_i$, $\nu_k$ = Larmor frequencies at constant magnetic field $H_o$ in the absence of any spin coupling; $\nu_o$ = the frequency of the radio-frequency transmitter; $\delta_{ik}$ = a dimensionless parameter related to the $\tau$ scale [22] by $\delta_{ik} = \tau_i - \tau_k$.)

[9] As a result of symmetries in the molecular structure, the nuclei in the spin system may have:
(a) equal Larmor frequencies, *i.e.* $\nu_i = \nu_k$,
(b) equal spin coupling parameters, *i.e.* $J_{ij} = J_{kj}$, for all i, k, and j with $\nu_j \neq \nu_i = \nu_k$.
If condition (a) is satisfied, the nuclei i and k are described as "chemically equivalent" or "isochronous". If condition (b) is also satisfied, the nuclei i and k are described as "magnetically equivalent". The special significance of this latter property will be seen in Section IIIe.
In the examples of the $AB_2$ type in Figures 1 and 7, the isochronous B protons are *magnetically* equivalent ($J_{AB} = J'_{AB}$), whereas in the examples of the $A_2B_2$ type in Figures 1 and 10, the A and B protons are *chemically*, but not *magnetically* equivalent ($J_{AB} \neq J'_{AB}$); see also [12].

[10] Rule 2b is a subsequent refinement, and has not yet been generally accepted. Some authors use the letter K instead of M.

[11] The condition for 2c is automatically satisfied when the nuclei present are different (*e.g.* $^1$H and $^{19}$F).

[12] Regarding nomenclature in $A_2B_2$ spin systems, it should be noted that notations such as $A_2'B'_2$, AA'BB', or AA*BB* are occasionally used in order to indicate that the nuclei are not magnetically equivalent [9]. However, the usual notations $A_2B_2$ and $A_2X_2$ are preferable. There is no danger of confusion, since there are very few $A_2B_2$ systems with magnetically equivalent nuclei. Two rare exceptions are cyclopropene and difluoromethane, which may be denoted by $A^*{}_2B^*{}_2$ or $A^*{}_2X^*{}_2$ [14b].

[13] The existing rules may be supplemented as follows. The omission of one or two letters in the alphabetic sequence should correspond to cases (b) and (c) of Rule 2. This suggestion is followed in the last three examples in Figures 1 and 2.

## III. Basic Principles for the Mathematical Treatment of NMR Spectra

In the quantum-mechanical picture, the lines of a nuclear magnetic resonance spectrum correspond to transitions between the stationary states of a spin system. The three fundamental equations are:

$$\mathbf{H}\Psi_p = E_p\Psi_p \tag{4}$$

$$f_{qp} = (E_p - E_q)/h \tag{5}$$

$$I_{qp} = \text{const.}\,|\Psi_p\,\mathbf{H}^{(x)}\,\Psi_p|^2 \tag{6}$$

The general equation of state [Equation (4)] is used to calculate the energy eigenvalues $E_p$ and the eigenfunctions $\Psi_p$ of the stationary states for a given Hamiltonian operator **H**. The line frequency $f_{qp}$ for a transition from the state $\Psi_q$ of energy $E_q$ to the state $\Psi_p$ with energy $E_p$ is given by the Bohr frequency condition [Equation (5)]. The corresponding intensity $I_{qp}$ is proportional to the matrix element with the operator of the transition probability $\mathbf{H}^{(x)}$ [Equation (6)].

### (a) The Spin Hamiltonian Operator

**H** in Equation (4) is replaced by the spin Hamiltonian operator from Equation (3). For nuclei with spin $^1/_2$, the complicated angular momentum operator is given by Equations (7), which together with Equation (3) give Equation (8).

$$\mathbf{I}_z(i)\,\Psi = m_i\Psi \tag{7a}$$

$$\mathbf{I}(i)\,\mathbf{I}(k)\,\Psi = \tfrac{1}{4}(2\mathbf{P}_{ik} - \mathbf{1})\,\Psi \tag{7b}$$

$$\mathbf{H} = \sum_{i=1}^{n} \nu_i\, m_i\, \mathbf{1} + \tfrac{1}{4}\sum_{i=1}^{k-1}\sum_{k=2}^{n} J_{ik}\,(2\mathbf{P}_{ik} - \mathbf{1}) \tag{8}$$

$m_i$ is the magnetic quantum number; $\mathbf{P}_{ik}$ the permutation operator, which permutes the subscripts of the nuclei i and k, and **1** the identity operator (without effect).

The first term in Equation (8) gives the "nuclear Zeeman energy" which is proportional to the resonance frequency $\nu_i$ [or the magnetic field strength H*, see Equation (1)]. The second term gives the energy due to indirect spin coupling, which is proportional to the coupling parameter $J_{ik}$.

### (b) The Spin Functions

The functions on which the Hamiltonian operator **H** is allowed to act are the product spin functions.

The spin functions corresponding to the two orientations of a single nucleus ($I = {}^1/_2$) are denoted by the symbols $\alpha$ and $\beta$ [15]. For a spin system consisting of two nuclei there are four product spin functions: $\alpha\alpha$, $\alpha\beta$, $\beta\alpha$, and $\beta\beta$. The first factor in the product spin function is then the spin function of the first nucleus, the second that of the second nucleus, and so on. Thus the permutation operator $\mathbf{P}_{12}$ [see Equation (8)] has the following effect:

$$\mathbf{P}_{12}\alpha\alpha = \alpha\alpha;\ \mathbf{P}_{12}\beta\alpha = \alpha\beta;\ \mathbf{P}_{12}\alpha\beta = \beta\alpha;\ \mathbf{P}_{12}\beta\beta = \beta\beta.$$

In general the stationary states are described by linear combinations of product functions. For example, the following functions occur in any $A_2$ spin system (cf. Fig. 3).

$$\frac{1}{\sqrt{2}}(\alpha\beta + \beta\alpha) \quad \text{and} \quad \frac{1}{\sqrt{2}}(\alpha\beta - \beta\alpha)$$

### (c) The Eigenvalue Problem

The entire calculations of nuclear magnetic resonance spectra have been programmed for electronic computers, so that now the theoretical spectrum corresponding to a given set of parameters can be obtained without effort (see Section V d, e). The course of the calculation is shown in Scheme (9).

$$\underset{\text{Parameter}}{\boxed{\nu_i,\ J_{ik}}} \overset{a}{\longleftrightarrow} ((H_{pq})) \overset{b}{\longrightarrow} (E_p, \Psi_q) \overset{c}{\longleftrightarrow} \underset{\text{Spectrum}}{\boxed{f_{qp},\ I_{qp}}} \tag{9}$$

Here the step a denotes the calculation of the complete energy matrix, $\mathbf{H}_{pq}$ being equal to $\varphi_p\mathbf{H}\varphi_q$,

b denotes reduction to the diagonal form by solution of the eigenvalue problem, and

c denotes calculation of the frequencies and intensities of the allowed transitions.

The values of the parameters $\nu_i$ and $J_{ik}$ are inserted in the Hamiltonian operator [Equation (8)]. The desired eigenvalues $E_p$ and eigenfunctions $\Psi_p$ that satisfy Equation (4) must then be calculated in the usual manner by means of secular equations, *i.e.* the energy matrix $((H_{pq}))$ is calculated with a set of starting functions and brought into the diagonal form by a unitary transformation. The diagonal elements are then the desired eigenvalues, and the transformation matrix consists of the eigenvectors that link the eigenfunctions with the starting functions.

### (d) Transition Probability and Selection Rules

The calculation of the line intensities by means of Equation (6) involves an operator $\mathbf{H}^{(x)}$, which is defined as follows for the resonance absorption of radio-frequency energy:

$$\mathbf{H}^{(x)} = \sum_{i=1}^{n} (1-\sigma_i)\,\mathbf{I}_{+(i)} \tag{10}$$

In Equation (10) $\mathbf{I}_+$ is a "shift operator" with the effect that

$$\mathbf{I}_+\,\alpha = 0 \tag{11a}$$

$$\text{and } \mathbf{I}_+\,\beta = \alpha \tag{11b}$$

Equation (11b) states that the nuclear spin is "flipped" from the $\beta$ into the $\alpha$ orientation [15]. No absorption can occur in the state $\alpha$ [Equation (11a)]. The transition $\beta \rightarrow \alpha$ leads to a change in the magnetic quantum number m from $-{}^1/_2$ to $+{}^1/_2$, *i.e.* $\Delta m = +1$. Equations (10) and (11) give the selection rule [Equation (12)]:

$$\sum_{i=1}^{n} \Delta m_i = +1 \tag{12}$$

$$\Delta m_i = 0 \text{ or } +1.$$

[14a] *J. A. Pople* and *T. Schaefer*, Molecular Physics *3*, 547 (1960).

[14b] *P. Diehl* and *J. A. Pople*, Molecular Physics *3*, 557 (1960).

[14c] *P. Diehl*, Helv. chim. Acta *48*, 567 (1965).

[15] It was assumed in Equations (3) and (8) that the vector of the static magnetic field points in the negative z direction; this is usually the case. In the state $\alpha$ ($m = +{}^1/_2$), the spin is then antiparallel to the magnetic field.

Equation (12) is applicable if the transition is between only two energy levels described by simple product spin functions. However, the eigenfunctions are mostly linear combinations, for which the less accurate selection rule of Equation (13) is used for the sake of simplicity [16]. A further condition for allowed transitions is given later [Equation (15)].

$$\Delta\left(\sum_{i=1}^{n} m_i\right) = \Delta F_z = +1 \qquad (13)$$

$F_z$ is the z-component of the total spin.

### (e) Some Important Rules

The signal due to isochronous nuclei [9] is usually split because of spin coupling. There are compounds, however, in which no splitting occurs in spite of spin coupling. For example, the "spectra" of unsubstituted benzene and methane consist of a single line each (see Rule 2). Moreover, it is a well-known fact that the spin coupling between the protons of a methyl group that can rotate is not detectable, but is by no means zero (see Rule 1).

The nuclei in these structures, are magnetically equivalent [9], and the following two rules are generally valid [17]:

**Rule 1.** The spin coupling between magnetically equivalent nuclei does not affect the spectrum.

**Rule 2.** If a spin system contains only one type of chemically equivalent (isochronous) nuclei, these are always magnetically equivalent [18a], and the "spectrum" consists of a single signal, irrespective of the couplings present.

An explanation for the peculiarities described in the two rules is found in the occurrence of "good" quantum numbers.

If two operators are commutable [Equation (14a)], their eigenvalues g are known as "good" quantum numbers [Equation (14b)]. The reason for their importance in quantum mechanics is the fact that they cause certain matrix elements to disappear [Equation (14c)].

$$\mathbf{GH}\Psi = \mathbf{HG}\Psi \qquad (14a)$$

$$\mathbf{G}\Psi_p = g_p\Psi_p;\ \mathbf{G}\Psi_q = g_q\Psi_q \qquad (14b)$$

$$\Psi_p\mathbf{H}\Psi_q = 0 \text{ when } g_p \neq g_q \qquad (14c)$$

If **H** in Equation (14c) is taken as the operator of the transition probability $\mathbf{H}^{(x)}$ from Equation (10), it follows from Equation (6) that all transitions in which at least one "good" quantum number changes are forbidden. For magnetically equivalent nuclei, the parameters for the mutual spin coupling occur only in the form of good quantum numbers. Thus owing to the substraction involved in the calculation of the allowed frequencies [Equation (5)], these coupling parameters cannot influence the spectrum.

The Hamiltonian operator can also commute with some other operators, *e.g.* the $\mathbf{F}_z$ operator of the total spin [see Equation (13)]. The energy matrix $((H_{pq}))$ therefore breaks down into independent sub-matrices for the various values of $F_z$.

The molecule under examination often possesses elements of symmetry, and the operators **H** and $\mathbf{H}^{(x)}$ can then commute with certain symmetry operators **S**. Symmetry eigenvalues s corresponding to these, *e.g.* with the values +1 and −1 for symmetric and antisymmetric functions, respectively, can then be defined as good quantum numbers.

Another good quantum number is the "particle spin" **I***, which is obtained when a group of magnetically equivalent [9] nuclei are considered together as a "spin particle" [18b]. In a freely rotating methyl group, for example, there are only states with $I^* = {}^3/_2$ or $I^* = {}^1/_2$. Thus in the magnetic field there are two molecular species, which cannot be interconverted by nuclear resonance. The situation is similar to that of ortho- and para-hydrogen in optical spectroscopy.

Owing to the ability of **S** and **I*** to commute with $\mathbf{H}^{(x)}$, another selection rule for allowed transitions in addition to Equations (12) and (13) results:

$$\Delta I^* = \Delta s = 0 \qquad (15)$$

Since **S** and **I*** may also commute with the Hamiltonian operator, the matrix elements $H_{pq}$ disappear whenever the condition of Equation (15) is not satisfied by the functions involved.

There is a simple, but very useful, summation rule [Equation (16)] for the line intensities. This rule is based on the energy-level diagram and requires that the total intensity for n nuclei of spin $= {}^1/_2$ be normalized to $n2^{n-1}$ [19].

**Rule 3.** The sum of the intensities of all transitions that terminate in the state $\Psi_t$ differs from the sum of the intensities of all transitions that start at $\Psi_t$ by exactly twice the value of the z component of the total spin in the state $\Psi_t$.

$$\sum_q I_{qt} = \sum_p I_{tp} + 2F_z(\Psi_t) \qquad (16)$$

The states p and q over which the sums are to be taken are given by the energy-level diagram; q passes through at most $\binom{n}{r+1}$ values and p through $\binom{n}{r-1}$ values, where $r = 2F_z(\Psi_t)$.

## IV. Examples of Simple Spin Systems

In the equipment used to record the following spectra, the magnetic field strength was varied and the radio frequency $\nu_0$ was kept constant.

### (a) The AB System

Figure 3 shows a number of calculated spectra for two coupled non-equivalent nuclei. The energy-level

[16] As an example of this, transition 9 in the $AX_2$ scheme in Figure 6 is forbidden according to Equation (12), though it appears to be allowed according to Equation (13).

[17] *H. S. Gutowsky, D. W. McCall,* and *C. P. Slichter,* J. chem. Physics *21,* 279 (1953).

[18a] In $A_n$, the spin coupling with all other (imaginary) nuclei is zero.

[18b] *D. R. Whitman, L. Onsager, M. Saunders,* and *H. E. Dubb,* J. chem. Physics *32,* 67 (1960).

[19] *G. Giomousis* and *J. D. Swalen,* J. chem. Physics *36,* 2077 (1962).

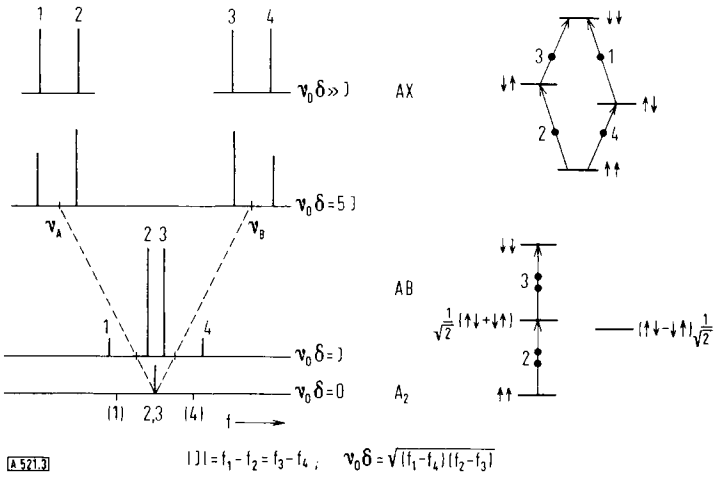

Fig. 3. Calculated spectra for the two-spin system AB, with energy-level diagrams and spectra for the limiting cases AX and $A_2$ [20].

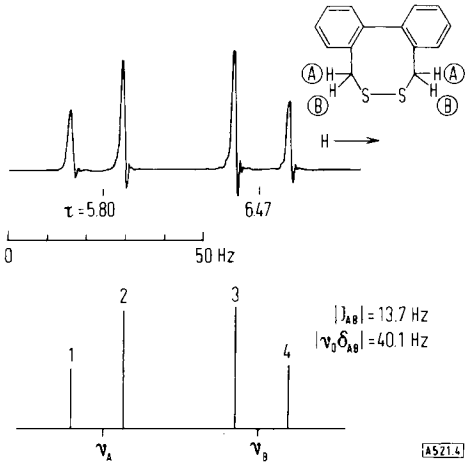

Fig. 4. Resonance of the methylene protons of 1,2-dibenzo[*d*, *f*,]dithiacyclooctadiene [21] in $CS_2$ at $\nu_0$ = 60 MHz and 24 °C ($\delta$ = 0.67 ppm.; J = 13.7 Hz).

In the rigid eight-membered ring, the protons are situated in sterically different positions, with a Larmor difference of 40.1 and a spin coupling of 13.7 Hz. These values were used for the calculation of the control spectrum (Fig. 4, bottom). The resonance of the protons of the *o*-phenylene residue is situated at a lower field strength, and is not shown [22].

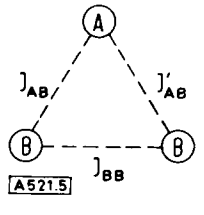

Fig. 5. Spin coupling in the $AB_2$ system (schematic).

diagram is given for the limiting cases AX and $A_2$. The forms of the spectra depend on the ratio $J_{AB}:\nu_0\delta_{AB}$. In the proton magnetic resonance spectrum of 1,2-dibenzo[*d*,*f*] dithiacyclooctadiene [21], the methylene protons in the eight-membered ring give rise to an AB spectrum (Fig. 4).

### (b) The $AB_2$ System

In the three-spin $AB_2$ system (Fig. 5), $J_{AB} = J'_{AB}$ because of symmetry. Consequently, the two B nuclei are magnetically equivalent [9] and form a spin particle with the possibilities $I^*_B = 1$ and $I^*_B = 0$. The BB coupling is not observed (cf. Section IIIe, Rule 1), and the energy-level diagram breaks down vertically into six and two states (cf. Fig. 6).

In the limiting case of an $A_3$ system ($\nu_0\delta_{AB} = 0$) there is a further vertical division. The good quantum numbers are then:

$I^*_A = 3/2$, $s_{23} = +1$ [Fig. 6, (a)];
$I^*_A = 1/2$, $s_{23} = +1$ [Fig. 6, (b)];
$I^*_A = 1/2$, $s_{23} = -1$ [Fig. 6, (c)] [23].

On this basis it is possible to deduce the following properties of the $AB_2$ spectrum:

1) Line 3 must remain invariant owing to the fact that it is isolated; its frequency is always $\nu_A$ and its intensity is 1;

2) as the limiting case $A_3$ is approached, Lines 1, 2, and 8 become weaker and weaker and are ultimately forbidden;

3) the "combination line" 9 is particularly weak, since it is forbidden in both limiting cases $AX_2$ and $A_3$.

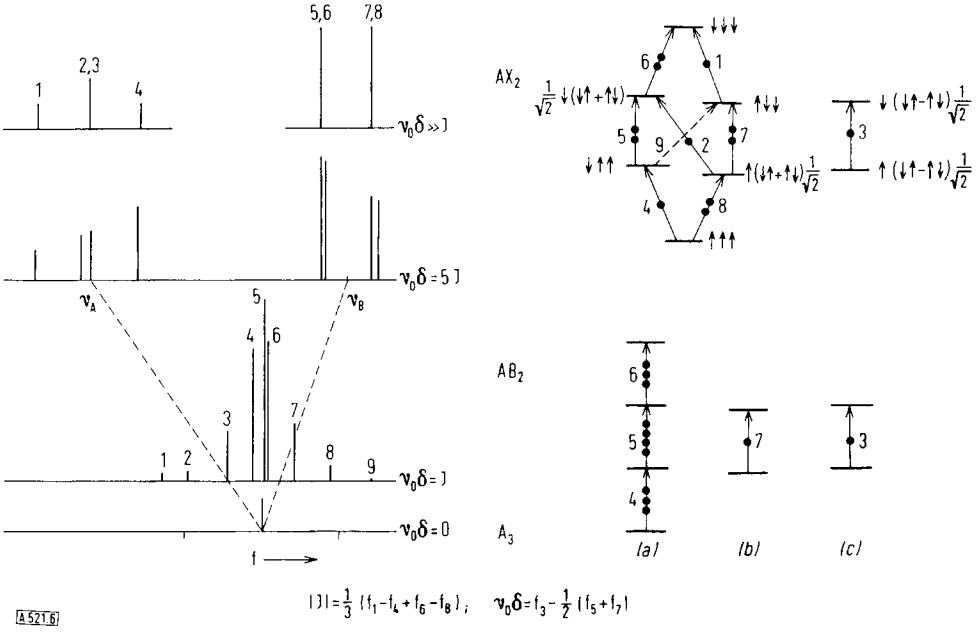

Fig. 6. Calculated spectra for the three-spin system $AB_2$ with the energy-level diagrams and spectra for the limiting cases $AX_2$ and $A_3$ [20].

[20] The arrows by the energy levels show the spin orientation, the static magnetic field being directed upward. The number of "beads" shown on the transitions corresponds to the intensity.

[21] *A. Lüttringhaus et al.*, Chem. Ber., in press.

[22] The Larmor frequencies in the spectrum are given relative to the tetramethylsilane signal on the dimensionless $\tau$ scale, where $\tau_i = 10 - 10^6(\nu_i - \nu_{TMS})/\nu_0$ ppm.

[23] The symmetry operation corresponding to the eigenvalue $s_{23}$ is $P_{23}$.

[24] *Corio* [4] gives Tables for AB, $AB_2$, $AB_3$, and $A_2B_3$, most of which are reproduced by *Strehlow* [6b].

Apart from the normalization factor, the $AB_2$ spectrum depends only on the ratio $J_{AB}:\nu_0\delta_{AB}$. Some calculated $AB_2$ spectra are to be found in the literature as a function of this ratio [24,25]. They show that there is no crossing of lines, *i.e.* the order of the lines always permits an unambiguous assignment.

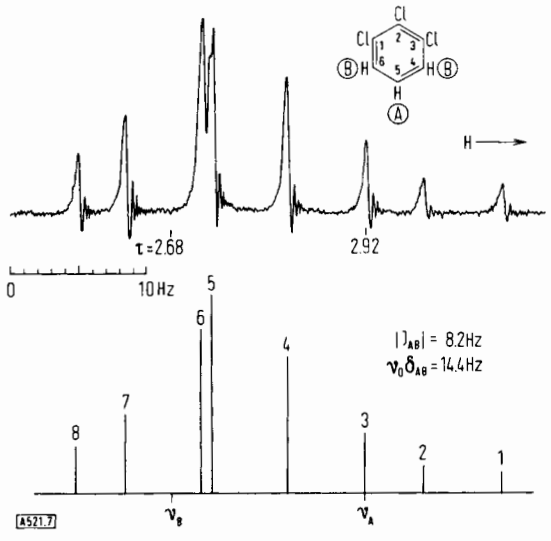

Fig. 7. Magnetic resonance of the protons of 1,2,3-trichlorobenzene in $CCl_4$ at $\nu_0 = 60$ MHz and 24 °C as an example of an $AB_2$ spectrum ($\delta = 0.24$ ppm.; $J = 8.2$ Hz).

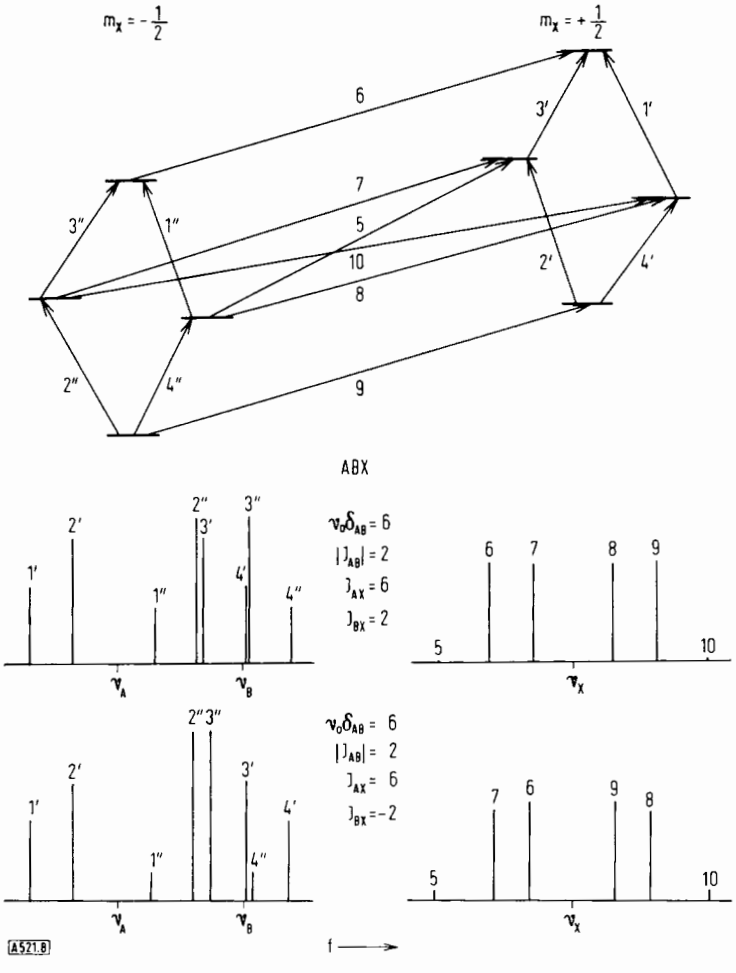

Fig. 8. Term diagram and two calculated spectra for the three-spin system ABX.
The influence of the signs of $J_{AX}$ and $J_{BX}$ can be recognized in the two calculated spectra.

Figure 7 shows the $AB_2$ spectrum of the protons in 1,2,3-trichlorobenzene.

### (c) The ABX System

New features of the ABX system in comparison with the above examples are first the dependence of the spectrum on the relative signs of the spin coupling parameters J, second the resulting problem of the assignment of the lines, and third the fact that the problem can be simplified [14] if the ABX system is broken down into two AB systems. The energy-level diagram can thus be subdivided into two parts with the magnetic quantum numbers $m_x = +1/2$ and $m_x = -1/2$ (see Fig. 8). The two subschemes are linked only by the transitions of the nucleus X; otherwise they represent two AB systems similar to that discussed in Section IVa. Here, however, the spectrum contains "effective" Larmor frequencies ($\nu'_A$, $\nu'_B$, $\nu''_A$, $\nu''_B$), which depend on the spin coupling with the X nucleus in the following manner:

Subsystem I ($m_X = +1/2$):

$$\nu'_A = \nu_A + \tfrac{1}{2}J_{AX};\quad \nu'_B = \nu_B + \tfrac{1}{2}J_{BX} \tag{17}$$

Subsystem II ($m_X = -1/2$):

$$\nu''_A = \nu_A - \tfrac{1}{2}J_{AX};\quad \nu''_A = \nu_B - \tfrac{1}{2}J_{BX} \tag{18}$$

In the analysis of the ABX spectrum, all the parameters can be found from the two AB subspectra. The defining equations are:

$$|J_{AB}| = f'_1 - f'_2 = f'_3 - f'_4 = f''_1 - f''_2 = f''_3 - f''_4 \tag{19}$$

$$\nu_0\delta_{AB} = \frac{1}{2}(D' + D'') \tag{20}$$

$$J_{AX} = f'_o - f''_o + \frac{1}{2}(D' - D'') \tag{21}$$

$$J_{BX} = f'_o - f''_o - \frac{1}{2}(D' - D'') \tag{22}$$

The symbols used have the following meanings:

$$D' = \nu'_A - \nu'_B = +\sqrt{(f'_1 - f'_4)(f'_2 - f'_3)} \tag{23}$$

$$D'' = \nu''_A - \nu''_B = +\sqrt{(f''_1 - f''_4)(f''_2 - f''_3)} \tag{24}$$

$$f'_o = \tfrac{1}{2}(\nu'_A + \nu'_B) = \tfrac{1}{2}(f'_1 + f'_4) = \tfrac{1}{2}(f'_2 + f'_3) \tag{25}$$

$$f''_o = \tfrac{1}{2}(\nu''_A + \nu''_B) = \tfrac{1}{2}(f''_1 + f''_4) = \tfrac{1}{2}(f''_2 + f''_3) \tag{26}$$

The resonance lines of the X nucleus permit the calculation of two additional quantities:

$$J_{AX} + J_{BX} = f_6 - f_9 \tag{27}$$

$$J_{AX} - J_{BX} = \frac{1}{2\nu_0\delta_{AB}}(f_5 - f_{10})(f_7 - f_8) \tag{28}$$

Whereas the spectrum is affected only by the magnitude of the coupling parameter $J_{AB}$, the relative signs of $J_{AX}$

[25] *K. B. Wiberg* and *B. J. Nist*: The Interpretation of NMR Spectra. Benjamin, New York, 1961. – This book contains tables and spectra for the AB, $AB_2$, $AB_3$, $AB_4$, and $A_2B_3$ system types and a collection of spectra whose form depends on more than one parameter (ABX, ABC, and $A_2B_2$ systems).

and $J_{BX}$ affect the frequencies and intensities throughout the spectrum (see Fig. 8).

The proton magnetic resonance spectrum of 1,2,4-trichlorobenzene (Fig. 9) appears to be an ABC spectrum, but is in fact of the ABM type ($\nu_0\delta_{AM} = 8.4\ J_{AM}$; $\nu_0\delta_{BM} = 14.2\ J_{BM}$; cf. Section II). In an ABM analysis, there are no simple defining equations similar to those that apply to ABX systems [Equations (19)–(28)]. However, it has been found that these equations can be used to good approximation, since the parameters obtained are practically the same as those obtained by precise ABM analysis [26].

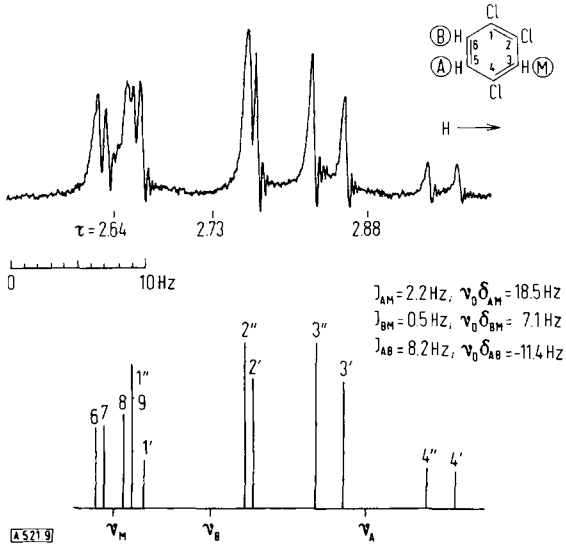

Fig. 9 Magnetic resonance of the protons of 1,2,4-trichlorobenzene in $CCl_4$ at $\nu_0$ = 60 MHz and 24 °C. The spectrum is of the ABM type and can be approximately analysed as an ABX type.

## V. Methods for the Analysis of NMR Spectra

The information about a molecule that can be obtained using nuclear magnetic resonance spectroscopy are usually based on the screening parameter $\sigma$ and the spin coupling constant J. Thus, analysis of an NMR spectrum, *i.e.* the determination of the numerical values of these quantities from the observed positions of the lines, is the reverse of the problem of calculating the spectrum corresponding to a given set of parameters (cf. Section IIIc). Scheme (9) should now be followed from right to left. This is possible for steps a and c, but there is no simple solution for the inversion of step b. Various approaches to the solution of this principal difficulty in the analysis of complex spectra have been suggested. The most important methods will de bescribed briefly in this section.

### (a) The Method of Moments

For any spectrum in which the line intensities and the distances of the frequencies from an arbitrary reference point $f_0$ have been determined, the "spectral moments" can be calculated by summation of simple products [27]. It has been shown by theory [28] that these moments can be equated to expressions containing the Larmor frequencies and coupling parameters. The advantage of this method is the fact that assignment of the lines is not necessary. It has the disadvantage that a complete analysis is impossible except for the simplest types of spectra, since it gives only the parameters that are explicitly contained in the spectral moments. However, the method is extremely useful, for example, when only the chemical shifts in $A_2B_2$ spectra are required (see Section VI, Table 2) or when the overlapping of the lines is too serious to permit the use of other methods, *e.g.* in broad-line NMR spectra of solids.

### (b) Direct Analyses

A very simple case is encountered with "multiplet spectra" (first-order spectra), *e.g.* of the type $A_rX_t$ with magnetically equivalent [9] nuclei. The coupling parameters can be read off directly from the multiplet splittings, and the Larmor frequencies from the multiplet centers. In other direct analyses, the parameters are obtained by substitution of the line frequencies in defining equations; this possibility exists for spectra of the types AB, $AB_2$, and ABX [see Figs. 3 and 6, and Eqs. (19) to (28)], or of the types $A_2X_2$, $A_2B_2$, $A_2B_2X$, and $AB_2X$ (see Table 4).

### (c) The Algebraic Method

In the algebraic method [29–31], the parameters are calculated from the solution of a system of equations. Such a system of equations is assigned to each eigenvalue problem or to its secular equation (Viéta's square root law). Other equations follow from the invariant rules for unitary transformations. The system of equations is solved numerically after insertion of the experimental energy eigenvalues. The observed line frequencies must first be converted into the eigenvalues with the aid of the energy-level diagram. Although explicit expressions have been derived even for complex systems such as $AB_2C_2$ [29], the practical use of this method is mainly confined to the type ABC [30, 31], since the experimental errors mount up too rapidly in the long equations obtained for larger systems.

[26] *G. Englert* and *W. Brügel*, unpublished results.

[27] The spectral moment of the n-th order with respect to a frequency $f_0$ is defined by

$$\langle f^n \rangle = \frac{\sum_k (f_k - f_0)^n I_k}{\sum_k I_k},$$

where $I_k$ = is the intensity. For example, for $A_2B_2$ spectra with $f_0$ in the center of symmetry[28]:

$$(\nu_0\delta_{AB})^2 = 4\langle f^2 \rangle;\ J_{AB}^2 + J_{AB}'^2 = \frac{\langle f^4 \rangle}{\langle f^2 \rangle} - \langle f^2 \rangle$$

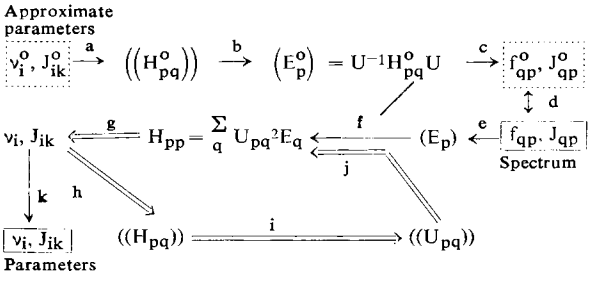
### (d) The Iteration Method

The principle of the iteration method is shown in the following scheme [32, 33]. An approximate set of parameters ($\nu_i^o$, $J_{ik}^o$) is established, *e.g.* by comparison with similar substances, from theoretical data, or by a preliminary analysis. These parameters are then used to calculate an approximate spectrum (Steps a, b, and c), and the assignment of the lines is transferred to the experimental spectrum (Step d). It is then possible to determine the eigenvalues $E_p$ from the experimental frequencies $f_{qp}$ (Step e). The crucial step now is the transformation of these eigenvalues back into the matrix elements $H_{pp}$ (Step f). This is carried out in approximation by means of the unitary transformation matrix U with which the eigenvalue problem was previously solved for the approximate parameters, *i.e.* U is given by the matrix of the approximate eigenvectors.



A set of parameters ($\nu_i$, $J_{ik}$) is then calculated from the diagonal elements $H_{pp}$ (Step g). This set is better than the approximate set ($\nu_i^o$, $J_{ik}^o$), since the experimental eigenvalues $E_p$ are more accurate than the approximation $E_p^o$. The eigenvalue problem is now solved with the new parameters (Steps h and i) and transformed back with the aid of the improved eigenvectors $U_{pq}$ (Step j). The cycle g-h-i-j-g is repeated until no further improvement of the parameters is obtained (Step k).

### (e) The Fitting Method

An attempt may be made to find a set of parameters to fit any spectrum by simple trial and error. The better the agreement between the frequencies and intensities calculated from the tentative parameters and the experimental spectrum, the closer is the set of parameters used to the correct values (trial and error fitting). This method can be regarded as an analytical procedure only if it is carried out systematically, *e.g.* by calculation of a succession of theoretically possible spectra and determination of the correct parameters by interpolation. It works well if only a few independent parameters are involved [4] or if a series of similar spectra are to be analysed [34, 35].

In another method [36], the correct set of parameters is calculated by the method of least squares. A set of approximate parameters is used as in Section Vd to calculate a theoretical spectrum, and partial derivatives of these approximate frequencies with respect to the individual parameters are determined numerically. The deviations of the calculated line frequencies from the experimental values and the partial derivatives give the corrections for the approximate parameter (minimum condition). As in Newton's approximation, the results converge towards the correct values if the starting values are reasonably good.

## VI. Comparison of Various Analytical Methods Using the $A_2B_2$ Spectrum of o-Dichlorobenzene

The proton magnetic resonance spectrum of *o*-dichlorobenzene (cf. Fig. 10) has been analysed several times by a number of different processes. It can be seen from Table 1 that the spin coupling parameters were obtained with an accuracy of only 0.1–0.2 Hz. The methods described in [34, 35, 38, 39] are exact analyses and would give accurate parameters for accurate line frequencies. Thus the deviations in the coupling constants are due only to the limited accuracy of the practical measurements. Since the measurements always involve some inaccuracy, the influence of these errors on the accuracy of the parameters must be taken into account in a comparison of the analytical methods.

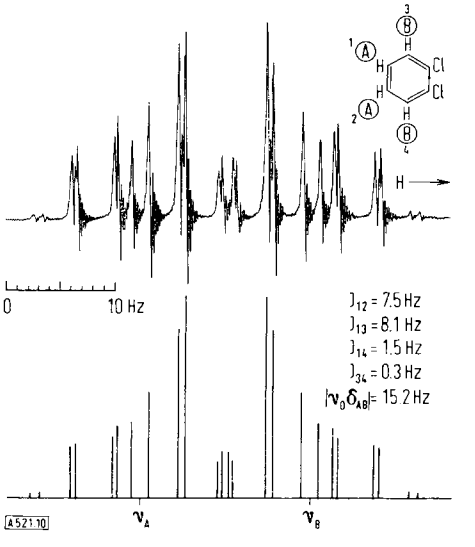


Fig. 10. Magnetic resonance of the protons of *o*-dichlorobenzene in $CCl_4$ at $\nu_0$ = 60 MHz and 24 °C [45b]. For the analysis of this $A_2B_2$ spectrum, see Part VI.

It can be seen from Table 2 that the various methods differ in this respect. The values in Table 2 all refer to

the same spectrum [40], and the same approximate parameters were used where necessary (in accordance with [37]). The quality of the analysis was assessed on the basis of the frequency deviation $\overline{\Delta f}$ [41] between the calculated spectrum and the experimental spectrum.

The analysis by the iteration process NMRIT [44] was carried out following the scheme in Section Vd. Divergence began after two iterations, though the approximate parameters (from [37]) had been distinctly improved. The analysis was repeated with these improved values, and the final set of parameters was obtained after seven iterations. The error limits were calculated from the program, with the assumption that the experimental eigenvalues are accurate to ± 0.1 Hz.

Table 1. Results of the analysis by various methods of independently recorded spectra of *o*-dichlorobenzene.

| Ref. | $\nu_o$ (MHz) | Concn. (%) | $J_{12}$ (Hz) | $J_{13}$ (Hz) | $J_{14}$ (Hz) | $J_{34}$ (Hz) | $\nu_o\delta$ (Hz) | $\delta$ (ppm) |
|---|---|---|---|---|---|---|---|---|
| [28] | 30 | 100 | — ± 1.0 | ≤ 8,1 [a] | — [a] | — | 7.8 ± 0.5 | 0.26 |

| Fitting [45a] | 9 | 0.076 | 7.53 ± 0.04 | 8.09 ± 0.10 | 1.52 ± 0.04 | 0.33 0.18 | 7.628 ± 0.002 | 7.606 ± 0.015 | 15.24 ± 0.02 |
| Average (lines 2 to 5) | | | 7.49 | 8.12 | 1.55 | 0.33 | — | — | 15.18 |

[a] $\sqrt{J_{13}^2 + J_{14}^2}$ = 8.4 Hz.

The following points should be mentioned in connection with the values given in Table 2:

The second moment of the spectrum gives a very reliable value for the Larmor difference $\nu_o\delta_{AB}$, and with the aid of the fourth moment [27] it is found that $J_{AB}^2 + J'^2_{AB} = 70.6$. It follows that $J_{AB} = J_{13} = 8.0$–$8.3$ cps if a value between 1.5 and 2.5 Hz is assumed for $J'_{AB} = J_{14}$. The moment method does not yield any information about the values of $J_{AA} = J_{12}$ and $J_{BB} = J_{34}$.

The direct analysis [38] was carried out using defining equations [42] but without the use of approximate parameters. The limits of error correspond to the maximum deviation between the frequencies of the experimental and calculated spectra.

In the algebraic analysis carried out by *Whitman* [39], summation rules [43] for frequencies and intensities were used in the assignment of the lines. The estimated accuracy value of ± 0.05 Hz [39] is very optimistic.

The analysis by the iteration process NMRIT [44] was carried out following the scheme in Section Vd. Divergence began after two iterations, though the approximate parameters (from [37]) had been distinctly improved. The analysis was repeated with these improved values, and the final set of parameters was obtained after seven iterations. The error limits were calculated from the program, with the assumption that the experimental eigenvalues are accurate to ± 0.1 Hz.

In the fitting method LAOCOON II [45], a comparison spectrum was first calculated from the approximate parameters. The correctly assigned experimental line positions were then introduced, but the expected convergence was not observed. In a second attempt, the four innermost lines, which showed particularly marked deviation from the comparison spectrum, were omitted. This gave a useful set of parameters in five steps, and these parameters were then used in four further steps using all the lines, in order to obtain the final values. The limits of error given by the program is the change in the parameters at which the mean frequency deviation $\overline{\Delta f}$ [41] would be exactly doubled. These "probable" errors are only indirectly connected with the inaccuracy of the parameters, which is, for example, about 10 times greater at $\nu_1$.

The fitting method gives the best results, both with regard to $\Delta f$ [41] and in relation to the average values in Tables 1 and 2, *i.e.* in this example at least, the errors in the measurements are best averaged out by LAOCOON II. This is as expected, since in this method the genuine information from the line positions is used exactly in accordance with their significance for the individual parameters. Though line positions are also used directly in the direct analysis method, the distribution of the weigths is rigid and unequal, as in any defining equation

[40] The spectrum published by *Whitman* [39] contains uncertainties of up to 0.2 Hz in the frequencies; this is desirable for the test of Table 2. Better accuracy can now be obtained if the spectrum is recorded several times and the results averaged.

[41] The root mean square error for t lines is:

$$\Delta f = \left[\frac{1}{t}\sum_{k=1}^{t}\left(f_k^{exp} - f_k^{calc}\right)^2\right]^{1/2}$$

[42] *B. Dischler* and *W. Maier*, Z. Naturforsch. *16a*, 318 (1961); *B. Dischler*, ibid. *20a*, 888 (1965).

[43] Cf. Rule 3 in Part IIIe. The following trivial rule applies to frequencies: The distance between two energy levels is independent of the transitions chosen. In Figure 3, for example, $f_1 + f_4 = f_2 + f_3$.

[44] Thanks are due to Dr. *W. Brügel*, Hauptlaboratorium BASF, Ludwigshafen, for the analysis by NMRIT [32].

[45a] The analysis with LAOCOON II (Least-squares Adjustment Of Calculated On Observed NMR spectra). [33] was kindly carried out by Dr. *H. Günther*, Institut für Organische Chemie, Universität Köln.

[45b] Dr. *H. Günther* also supplied the depicted spectrum of *o*-dichlorobenzene, which was recorded with a Varian A60 spectrometer.

of generally validity. With the analytical and iteration methods some of the original accuracy is lost in the conversion of frequencies into energies. In view of the uncertain convergence behavior encountered in the methods of[44] and [45a], it seems advisable to use two steps: for example, a set of parameters may be calculated by the simple direct method[42], and these may then be further improved, if necessary, by the fitting method[45a].

In order to make a general assessment of the efficiencies of the various analytical methods, it would naturally be necessary to work out a large number of examples.

## VII. Suggestions for the Analysis

### (a) Arrangement in Order of Difficulty

The very different mathematical requirements involved in the analysis of the individual spectra have here been arranged in order of difficulty. Table 3 shows the criteria used in the assessment, and Table 4 shows a selection of analyses that have been carried out.

Table 3. Classification of spectral analyses according to their difficulty.

| Difficulty grading | I | II | III | IV | V | VI |
|---|---|---|---|---|---|---|
| Without calculation | + | | | | | |
| Directly analysable | ∓ | + | + | + | | |
| Assignment required | | | + | + | + | + |
| Central spectrum required | | | | + | + | + |
| Difficult calculation | | | | | + | + |
| Good approximate parameters required | | | | | | + |

Table 4. Examples of investigated spectra, arranged to illustrate the various degrees of difficulty in accordance with Table 3.

| Type of spectrum | Difficulty grading | Method of analysis b) direct c) algebraic d) iteration e) fitting *) simplification by division into subspectra (cf. Sect. IVc) b) | c) | d) | e) |
|---|---|---|---|---|---|

### (b) Experimental Aids

Substitution by isotopes is useful in NMR spectroscopy. For instance proton magnetic resonance spectra can be simplified by partial deuteration of the substances, since the lines due to the hydrogen atoms that have been replaced by deuterium disappear, and the H–D spin coupling constants are smaller by a factor of 1/0.154 than the corresponding H–H coupling constants.

If the measuring frequency is increased from 60 to 100 MHz, the Larmor differences are almost doubled, whereas the spin couplings remain unchanged. Thus the spectrum approaches the multiplet type, which is easier to interpret and to analyse. Conversely, a change in frequency from 60 to 15 MHz leads to a more complex spectrum, owing to the smaller Larmor differences. Comparison of the spectra obtained with all three frequencies often makes it possible to decide between several combinations of signs in the spin couplings[49]. The Larmor differences can also be varied within certain limits by solvent effects[58]; this permits the unambiguous determination of the signs of the coupling parameters in systematic studies[59].

An important aid is nuclear magnetic double resonance (NMDR). In normal operation the spectrum is recorded in a radio-frequency field $H_1$, the strength of which is kept so small that the energy-level diagram remains stationary, so that the Dirac perturbation theory, on which the calculation of Equations (5), (6), (10), and (12) is based, is valid. In double resonance, a second radio-frequency field $H_2$ is applied parallel to $H_1$; the much greater field strength of $H_2$ leads to a change in the energy-level diagram whenever its frequency $\nu_2$ coincides exactly or approximately with a resonance line.

In "spin decoupling" experiments[60,61], the multiplet splitting caused by one or more X nuclei is caused to disappear by the application of the Larmor frequency $\nu_X$ with saturation field strength. In addition to simplifying the spectrum, spin decoupling yields information on the interrelationship between certain lines.

This interrelationship between lines is specially studied in "perturbation field experiments"[62], where the frequency of a single resonance line is applied permanently.

[58] *S. Clough*, Molecular Physics *2*, 349 (1959).

[59] *H. Dreeskamp* and *E. Sackmann*, Z. physik. Chem. N.F. *34*, 261 (1962).

[60] *A. L. Bloom* and *J. N. Shoolery*, Physic. Rev. *97*, 1261 (1955).

[61] *W. A. Anderson* and *R. Freeman*, J. chem. Physics *37*, 85 (1962).

[62] *R. Freeman* and *W. A. Anderson*, J. chem. Physics *37*, 2053 (1962).

The field strength must be large enough to perturb the energy levels involved in the resonance in question, the perturbation being either (a) energetic [62] or (b) in the occupation numbers [61,63], depending on the relaxation time. It is then found that for (a), the lines due to all transitions that begin or terminate at these two levels are split into two equally strong components [62] with a perturbation parameter that depends almost linearly on the field strength $H_2$, while for (b) these lines undergo characteristic intensity changes [64]. Since the lines in which the same levels are involved are known in perturbation field experiments, this method assists in obtaining a definite assignment of the lines.

The observation of multiple quantum transitions ($\Delta m = 2, 3 \ldots$) which occur near the saturation intensity of $H_1$ [65,66] yields additional information about the energy-level diagram, which may allow a particular choice in the signs of spin coupling parameters.

The proton magnetic resonance spectrum of gaseous 1,1-difluoroethylene (at 10–26 atm) contains both sharp and broad lines [51a]; this is in agreement with theoretical calculations which assume an interaction between the spin of the fluorine nuclei and the molecular rotation as the relaxation mechanism. The different line widths are of great assistance in the assignment of the lines, *i.e.* in the determination of the relative signs of coupling parameters [51].

## VIII. Outlook

For n nuclei of spin $^1/_2$, the number of energy levels increases with $2^n$, and the number of lines roughly with $n^3$ (see Table 5). As the size of the spin system becomes larger, the number of lines increases so rapidly that they can no longer be resolved. Moreover, the average intensity of the lines rapidly decreases. Analysis thus becomes very difficult or even impossible. It is therefore to be expected that the simpler spin systems studied so far (see Table 4) will still occupy the foreground in the future.

Table 5. Numerical data for increasingly complex spin systems with nuclear spin $^1/_2$.

| Example | A | AB | ABC | ABCD | – | – |
|---|---|---|---|---|---|---|
| Nuclei | 1 | 2 | 3 | 4 | 8 | n |
| Parameters ($\nu_i$, $J_{ik}$) [a] | 1 | 3 | 6 | 10 | 36 | $n+\binom{n}{2}$ |
| Matrix elements [b] | 2 | 6 | 20 | 70 | 12870 | $\sum_{i=0}^{n}\left[\binom{n}{2}\right]^2$ |
| Energy levels | 2 | 4 | 8 | 16 | 256 | $2^n$ |
| Allowed transitions [c] | | | | | | |
| max. | 1 | 4 | 15 | 56 | 11440 | $\sum_{i=0}^{n-1}\binom{n}{i}\binom{i+1}{n}$ |
| min. | 1 | 2 | 5 | 10 | 186 | $2^n-\binom{n}{g}$; $g=\frac{n}{2}$ or $\frac{n-1}{2}$ |
| Total intensity | | | | | | |
| normalized [d] | 1 | 4 | 12 | 32 | 1024 | $n^{2n-1}$ |
| experimental | 1 | 2 | 3 | 4 | 8 | n |

[a] For $n > 1$, the number of independent parameters is always two less, since the form of the spectrum depends only on the ratio of the Larmor differences to coupling parameters.

[b] These values take into account the breakdown into submatrices $F_z$.

[c] The number of these is variable, owing to the selection rule Equation (15). The minimum number is found, for example, in $A_n$ systems, and the maximum number in the above examples.

[d] The normalization is based on the summation rule (cf. Section IIIe, Rule 3).

*The author is grateful to the Director of this Institute, Prof. R. Mecke, for his support of this work. The experimental examples are taken from investigations carried out in the Institute. Thanks are due also to Dr. H. Friebolin and Dr. G. Englert for their valuable co-operation and for supplying the spectra (recorded with a Varian DP 60 spectrometer, Type V 4302), and to Dr. W. Brügel, Ludwigshafen, and Dr. H. Günther, Cologne, for carrying out the test calculations on the spectrum of o-dichlorobenzene.*

# Problems of Iron Metabolism with Special Reference to Biochemical, Physiological, and Clinical Aspects

BY PROF. W. KEIDERLING AND DR. H. P. WETZEL
MEDIZINISCHE UNIVERSITÄTSKLINIK, FREIBURG (GERMANY)

*A brief account of the functions and chemical structures of the principal iron compounds found in the human body is followed by a discussion of the physiology of iron metabolism, starting with its resorption, continuing with its transport and assimilation by the body cells, and concluding with its elimination. Special attention is paid to the problems of intracellular and extracellular transport of iron. A number of diseases with characteristic disturbances of the iron metabolism are also briefly described.*

Wherever respiration occurs, iron is present in some form. Iron is essential to the elementary metabolic processes in the cell. In the catalytic processes of the respiratory chain it acts as an electron carrier, and it is responsible for the transport of molecular oxygen in higher organisms. These important functions depend

on the ability of iron to exist in coordination compounds in different oxidation and bonding states [1].

The adult human body contains 4 to 5 g of iron. Several iron fractions, listed in Table 1, are distinguished according to the function of the iron.

Table 1. Body components containing iron.

| Occurrence | Iron bound as | Mode of linkage | Function | Iron content | |
|---|---|---|---|---|---|
| | | | | Total [a] | % of body iron |
| Blood system | Hemoglobin | Heme | $O_2$ transport | 3 g | 65.4 |
| | Plasma | Transferrin | Fe transport | 4 mg | 0.1 |
| Tissues | Functional iron (myoglobin, cell hemes) | Heme | Cell respiration | 650 mg | 13.9 |
| | Storage iron | Ferritin Hemosiderin | Iron pool Detoxication | 1 g | 21.5 |
| | | | | 4.65 g | 100.0 |

[a] Approximate values.

## A. Iron Compounds Present in the Human Body

### I. Hemoproteins

The compounds of this group (hemoglobin, myoglobin, *etc.*) all contain the iron(II)-protoporphyrin complex heme as specific prosthetic group. Their function involves the transport of oxygen and cell respiration.

The incorporation of metal atoms into the porphyrin ring system leads to extremely stable chelates. Biologically, the most important metal-porphyrin complexes are those of iron. Iron can bind six ligands in octahedral arrangement. In heme, the iron is situated in the center of the planar protoporphyrin ring; in hemoglobin, for example, the fifth coordination site is occupied by a nitrogen atom of a histidine residue of the globin, while the sixth is occupied by water. The hemoproteins can be divided into two groups according to function.

#### 1. Respiratory Enzymes

In cytochrome c, the protein component is bound by covalent sulfide linkages to side chains of the porphyrin-iron system. This linkage is much stronger than, for example, the protein linkage of the heme in hemoglobin. Moreover, the "heme" group in cytochrome c evidently is shielded by the protein chain to such an extent that the iron cannot react with oxygen. Cytochrome c is not autoxidable at physiological pH-values; further, the porphyrin component differs from that of hemoglobin in two of its side chains.

Many points concerning the structure and function of cytochrome b still remain unclear.

The respiratory enzymes also include catalase, which decomposes hydrogen peroxide into water and oxygen, and the peroxidases, which catalyse the oxidation of substrates by hydrogen peroxide.

#### 2. Hemoproteins that Store and/or Transport Molecular Oxygen

Hemoglobin (molecular weight 66000), the principal constituent of erythrocytes, consists of four subunits, each containing one heme molecule. The iron content of hemoglobin is 0.335 to 0.338 %. The four heme groups are situated on the surface of the peptide chains [2], the spatial arrangement of which was elucidated only a few years ago [2, 3].

Iron(II) myoglobin contains only a single peptide chain having a molecular weight of 17000. The structure of this protein was also established fairly recently [4]. Oxygen is bound as in hemoglobin, but myoglobin is saturated at considerably lower oxygen pressures. It stores oxygen in muscles and is particularly important in sea animals with lungs, when these animals remain submerged for long periods.

## II. Iron Proteins Responsible for the Storage and Transport of Iron

#### 1. Ferritin and Hemosiderin

Iron is stored in ferritin and hemosiderin in the liver, spleen, and bone marrow. Ferritin is a water-soluble, crystallizable iron protein built up from apoferritin and micelles of a colloidal iron(III) hydroxide-phosphate complex. According to *Granick* and *Michealis* [5], the iron content of ferritin isolated from horse spleen varies between 17 and 23 %. The iron micelles are situated within the protein envelope [6]. Electron microscopy gives a value of 55 to 60 Å for the diameter of the iron micelles, and 94 to 110 Å for that of the protein envelope [6–8]. The iron micelles are seen in the electron microscope to consist of four subunits with diameters of 27 to 30 Å. The values found for the molecular weight of the apoferritin from horse spleen vary from 327000 to 480000, depending on the method of determination [9–11]. The iron in ferritin is trivalent, but it is incorporated and released in the bivalent form [12].

The nature of hemosiderin is still a subject of controversy. Unlike ferritin, it is insoluble in water. In the optical microscope it can be observed in the form of granules, in which the iron is also trivalent. The iron

content according to most of the results reported is 30 to 40 %, *i.e.* much higher than in ferritin. The protein components of hemosiderin and ferritin show a number of similarities in their amino-acid composition [13].

### 2. Transferrin

Transferrin is the specific iron-transport protein of blood plasma. It is a glycoprotein; values of 90000 [14] and 86000 [15] have been reported for its molecular weight. Starch-gel electrophoresis after incubation of transferrin with neuraminidase leads, depending on the enzyme concentration, to the gradual formation of four slower bands. It has been concluded from this result that the transferrin molecule contains four neuraminic acid groups in addition to peptide chains [16].

Two atoms of iron can be reversibly bound by one molecule of transferrin, *i.e.* the binding capacity of 1 mg of transferrin is 1.30 µg of iron [15]. Magnetic measurements [17] have shown that the bound iron is present in the trivalent form. The nature of the bonding is not yet clear [18,19].

By the reversible binding of iron, transferrin is responsible for the transport of iron in the plasma and in the extracellular fluid, and for the transfer of iron between resorption, storage, and consumer organs [20]. It is therefore of the utmost importance to the correct functioning of the iron metabolism.

By starch-gel electrophoresis 15 genetically determined transferrin types [21] of different specific migration rates can be distinguished. These transferrin types are of special interest in human genetics.

## B. Physiology of Iron Metabolism

In view of the extent of the material available on the physiology of iron metabolism, a detailed description will not be given here. Instead, the most important principles will be discussed briefly with the aid of the scheme of iron metabolism in Fig. 1. Some hypotheses currently under discussion have also been included.

### I. Resorption

Tracer studies using $^{59}Fe$ (half-life 47 days) have shown that most of the iron ingested orally is resorbed in the cranial section of the duodenum [22,23]. However,

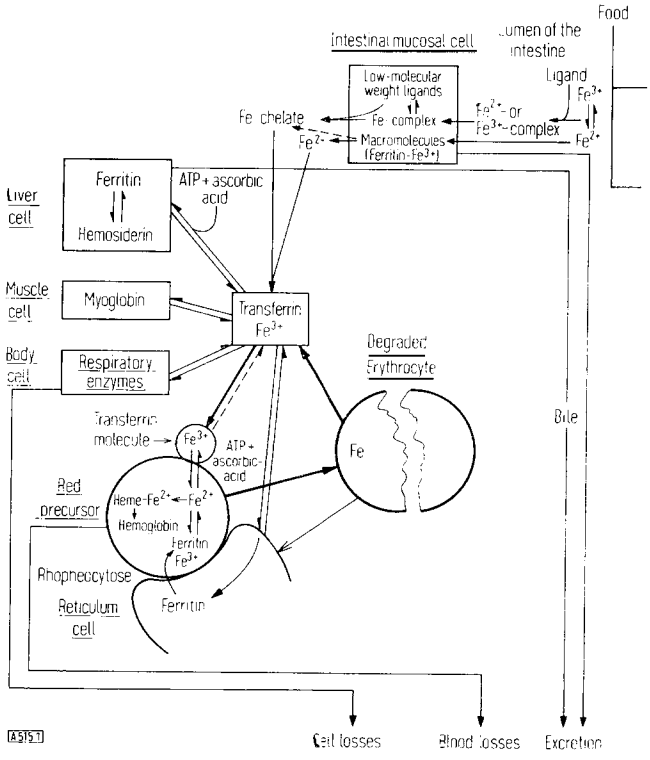

Fig. 1. Scheme of the physiology of iron metabolism.

other sections of the gastrointestinal tract, including the large intestine [24] are also able to absorb iron. Inorganic iron compounds are more readily absorbed than iron contained in the food. The iron present in various foods is absorbed to different extents.

Owing to experimental difficulties, no accurate quantitative data are available on the utilization of iron in the food. According to *Moore* [25], Europeans and North Americans absorb an average of 5 to 10 % of the iron in their diet. Thus from a daily iron intake of 12 to 15 mg in the food, 0.6 to 1.5 mg is absorbed. This does not include the iron consumed in water, beer, wine, and other beverages.

The general view is that iron is resorbed in the bivalent form [26]. Ascorbic acid [27] and substances containing thiol groups [28] increase resorption because of their ability to keep iron in the bivalent form. A number of organic acids is also claimed to promote resorption by increasing the acidity of the medium and the solubility of the iron [29]. Finally, resorption is also increased by amino acids [30] and by sorbitol [31]; however, this increase cannot be explained by increased acidity or by a reducing action.

These observations have recently led to the view that the iron passes through the intestinal epithelial cells [*] in a complex of low molecular weight. *Charley et al.* [32] have shown that not only bivalent, but also trivalent iron is rapidly resorbed if it is administered as the chelate with fructose. The experiments were carried out with 32 M fructose solutions containing a mixture of $^{59}FeCl_3$ with carrier $FeCl_3$, and with $FeSO_4$ in 0.9 % NaCl solution with $^{59}FeCl_3$ at iron concentrations of 0.5 mg/ml. The time taken for the iron to pass from the lumen of the intestine into the peripheral blood circulation was no longer than the time normally required by the bloodstream. Thus the passage through the epithelial cells appears to be very fast. The passage of low-molecular weight iron complexes through the cell membrane has been observed also in other biological systems such as liver slices and reticulocytes [33–35].

In addition to these views on the resorption path, there is the old mucosal block theory developed by *Hahn* [36] and *Granick* [37, 38], according to which the iron is passed through the mucosal cells with the aid of ferritin. The iron resorption is thought to cease when the ferritin in the mucosal cell is saturated, so that the organism is prevented from becoming overloaded with iron. However, this theory has been disproved [39]: by simultaneous determination of the quantity of iron offered and the quantity resorbed (with the aid of $^{59}Fe$) and of the ferritin content of the mucosal cells, it was shown that the iron resorption increases in proportion to the ferritin concentration in the intestinal mucosal cell even after the ferritin has been saturated. Nevertheless it is still believed that ferritin is involved in the resorption of iron.

Several authors [32,40,41] believe that the saturation of transferrin in the blood plasma with iron plays an important part in the resorption of iron. This view is based on experiments which show that $^{59}Fe$-fructose or $^{59}FeSO_4 \cdot 7H_2O$ administered enterally after saturation of the plasma transferrin with iron no longer pass into the peripheral blood. Other research groups [42,43], however, concluded from experimental evidence that the resorption of iron is independent of the degree of saturation of the plasma transferrin. According to this view, if the transferrin is saturated with iron, any further iron absorbed, which is probably not bound to the transferrin in the portal blood, is immediately intercepted and retained by the liver, so that it does not enter the peripheral blood. This interpretation agrees with the results of both groups of workers.

In studies on healthy persons, *Brown, Dubach,* and *Moore* [44] also came to the conclusion that the saturation of the transferrin has no influence on the resorption of iron. On the basis of our own investigations, particularly on a case of congenital atransferrinemia (which is discussed more fully in Section C.IV) we agree with this last interpretation.

The role of pancreatic secretion in iron resorption has only recently been re-examined, though a connection was mentioned by *Taylor, Stiven,* and *Reid* [45] as early as 1935. *Davies* and *Badenoch* [46] found increased iron resorption in severe cases of chronic pancreatitis. *Callender* [47] also observed increased iron resorption in chronic liver diseases; the resorption could be lowered by administration of pancreatin. It was concluded from these results that pancreatic juice contains a substance that inhibits iron resorption. It has recently been suggested that hemochromatosis may be caused by a genetic defect in the region of the pancreas, coupled with a deficiency or absence of iron resorption inhibitor.

## II. Iron Transport and Iron Turnover

Iron is transported by the specific transport protein, discovered by *Holmberg* and *Laurell* [48] in 1944, and independently by *Schade* and *Caroline* [49] in 1946, and named by these two groups transferrin and siderophilin, respectively. The reversible binding of iron by transferrin permits the rapid transfer of the metal between the resorption, storage, and consumer organs. The normal concentration of transferrin in plasma is 200 to 320 ppm. For practical reasons, the transferrin concentration usually is given as the total iron-binding capacity of the serum. This is the quantity of iron that is specifically bound by 100 ml of serum. The iron-binding capacity normally is only 0.25 to 0.30 ppm. Thus when the iron level in the serum is 0.1 ppm, the transferrin is only about one-third saturated with iron. Above the saturation limit, toxic reactions occur because of the presence of free iron ions.

Most of the iron transported in the plasma is derived from the degradation of hemoglobin. The economic control of the iron metabolism is particularly clear from the fact that the iron liberated by the breakdown of erythrocytes is largely re-used for the formation of fresh hemoglobin. For an erythrocyte life of 110–120 days, the daily iron requirement of the blood-forming tissue is 23 to 30 mg. Thus 8 to 10 times the quantity of iron present in the plasma (3 to 4 mg) would be needed to satisfy this requirement alone. This turnover is further increased by the exchange of stored iron, iron in myoglobin, and iron in cell hemin, as well as the iron that is absorbed and eliminated. The total iron turnover is calculated to be 0.36 to 0.52, and on an average [*] 0.42 mg of Fe per day per kg of body weight [50,51].

The rate of iron exchange in the plasma and the daily or hourly plasma iron turnover can be determined with the aid of $^{59}Fe$ (as $^{59}FeCl_3$ or $^{59}Fe$ citrate). The biological half-life[**] of iron bound by transferrin normally is 70 to 140 minutes.

Using $^{59}Fe$ samples with high specific activities, *Pollycove* studied the iron exchange among the iron fractions in the body[52]. He postulated the existence of a "labile iron pool"[53] (a labile, easily exchangeable iron reserve in the storage organs), and calculated its size from the rate of migration of the $^{59}Fe$ out of the plasma. No iron compound corresponding to this pool has so far been detected with certainty. *Pollycove* also calculated the quantity of ferritin (mobilizable stored iron) held in the storage organs together with the labile iron pool and hemosiderin, as well as the mean effective time for the hemoglobinization of the erythron[***] and the average life of the latter. Some important data are given in Figs. 2 to 4 and in Table 2[54].

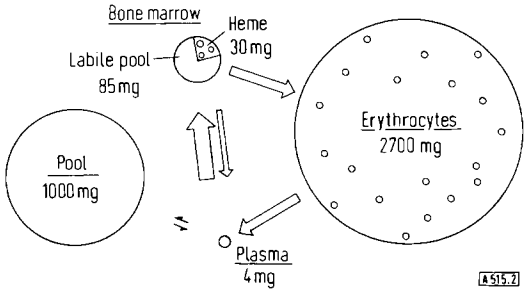

Fig. 2. Scheme of the iron exchange between the iron distribution sites [54]. The numerical values agree approximately with those of Table 1 (the erythrocyte iron is given here instead of hemoglobin iron; the two quantities are practically the same). The size of the circle is proportional to the component of the body iron fractions, and the area of the arrow to the rate of exchange.

The use of $^{59}Fe$ for the determination of the rate of migration of iron from the plasma, the daily or hourly iron turnover, the iron utilization by the erythrocytes, and the distribution of the iron in the organs is now applied in clinical diagnosis, and has led to valuable discoveries concerning disturbances of the iron metabolism.

## III. Assimilation of Iron by the Cells

Investigations on the uptake of iron by the body cells have so far been confined to red precursors[*] and liver cells. *Mazur* and *Carleton*[33] studied the incorporation

of plasma-bound iron into the ferritin of liver slices and liver cell homogenizates. They found that the incorporation of iron in this case involves the assistance of ATP and ascorbic acid, the liberation of the transferrin-bound iron being accompanied by the formation of a complex from two moles of ATP, one mole of ascorbic

[51] *W. Keiderling, H. A. E. Schmidt, M. Lee,* and *K. Th. Frank,* 5th Congress Europ. Hematology Soc. 1955. Springer, Heidelberg 1956, pp. 127, 779.

[**] The biological half-life in this case is half of the residence time of transferrin-bound iron circulating in the bloodstream.

[53] *M. Pollycove* and *M. Maqsood,* Nature (London) *194,* 152 (1962).

[***] The term "erythron" includes all stages in the development and aging of the erythrocyte. The time for the hemoglobinization of the erythron is the time required for the synthesis of the hemoglobin in the red precursors until the erythrocytes have reached maturity.

[54] *M. Pollycove* in [1], p. 148.

[*] Red precursors are nucleated red cells, which normally occur only in the bone marrow. Young red cells are found in the peripheral blood. These do not contain cell nuclei, but only nuclear detritus.

acid, and the transferrin molecule. A similar mechanism was proposed for the incorporation of iron into the red precursors [55]. It was assumed that following its release from the transferrin, the iron is coupled to ferritin before being used for the synthesis of hemoglobin.

The transfer of iron from transferrin to the hemoglobin-forming cells has recently been followed by tracer techniques. *Jandel*, *Katz*, and other workers [15,56–59] carried out incubation experiments with $^{131}$I-transferrin to which $^{59}$Fe was coupled. It was found that the transferrin becomes fixed specifically on the surface of young red cells [*]. The transferrin molecule adheres to the cell surface for about one minute. During this time, the iron is split off from the transferrin by an endothermic process and is then taken up by the cell. The affinity of the iron-containing transferrin molecule for the hypothetical receptors on the cell surface was found to be greater than that of iron-free molecules. This result explains the displacement of transferrin molecules that have given up their iron to the cell by iron-containing molecules reaching the cell surface later. The number of receptors has been calculated to be 50000 per reticulocyte. However, *Morgan* and *Laurell* [60] found that transferrin with or without iron is firmly bound to the reticulocyte surface, and that the iron resorption is proportional to the iron concentration, irrespective of the transferrin concentration.

The path followed by iron from its absorption by the red precursors to its incorporation into hemoglobin is largely unknown. It is not certain whether ferritin acts as an intermediate [55], possibly as the substrate of the labile iron pool postulated by *Pollycove* [55], or whether the iron undergoes further intracellular transport, possibly again *via* complexes of low molecular weight. *Goldberg et al.* [61,62] showed that the incorporation of iron into the protoporphyrin is catalysed by a specific enzyme, heme synthetase.

Another theory of the transfer of iron to the red precursors was developed by *Bessis* and *Breton-Gorius* [63,64] on the basis of impressive electron micrographs of "rhopheocytosis" [*]. Ferritin molecules are assumed to be transferred from the reticulocytes in the bone marrow directly to the erythroblasts. It is still uncertain whether the reticulocytes obtain their iron from the transferrin or directly from the hemoglobin of erythrocytes that have been broken down (erythrophagocytosis).

The course of the iron exchange between transferrin and the other body cells, particularly those of the reticuloendothelial system, has not yet been elucidated. As has been shown by our experiments, however, an essential function of transferrin appears to be the prevention of iron uptake by body cells that do not form hemoglobin and to protect the organism against siderosis.

#### IV. Elimination of Iron

According to *Finch* [65], the daily iron loss is approximately 0.6 mg for the human male, and about 2 to 3 times as much for the female after puberty. During pregnancy the iron loss increases to 3–4 mg per day owing to placental iron transport. The iron is generally lost as protein, bile and other secretions, and body cells. The loss of body cells accounts for the major part of the daily iron loss.

Assuming that the supply of iron is normal and that there is no disturbance of resorption, a negative iron balance can occur only as a result of bleeding. For a normal diet containing 12 to 15 mg of iron, 5 to 10 % of which are resorbed, adult males and non-menstruating females do not develop iron deficiency or hemochromatosis, and according to *Moore* [25], this is the best available evidence that the quantity of iron eliminated is between 1 and 1.5 mg per day.

### C. Pathology of Iron Metabolism

Though iron deficiency can be accompanied by many diseases, only a few outstanding forms can be described here.

#### I. Iron Metabolism in Infected Persons

The starting point for the ferrokinetic studies on infected persons was the observation that enterally or parenterally administered iron has little or no effect on the hyposideremia (lowering of the serum iron concentration) that accompanies the onset of inflammatory disease. Thus special conditions must prevail in infected persons.

The ferrokinetic studies consist of four parts: 1. Quantitative determination of the serum iron, and determination (by the isotope technique) of 2. the rate of migration of iron from the plasma, 3. the rate of incorporation of iron into the erythrocytes, and 4. the distribution of iron in the bone marrow, liver, spleen, and heart. From the iron concentration and the rate of migration of $^{59}$Fe from the plasma, it is possible to calculate the iron turnover per unit time, if the plasma volume is known. The tracer method can be used for the investigation, not only of the intermediate, but also of the exogenous processes of iron metabolism.

The resorption ratio and the rate of resorption were determined for guinea pigs after oral administration of

[*] The term "rhopheocytosis" refers to the supply of iron to the nucleated red precursor stages in bone marrow by transfer of ferritin molecules from the reticulocytes to the red precursors without cleavage of the ferritin-iron complex.

[65] *C. A. Finch* in [1], p. 452.

$^{59}FeSO_4$, first under normal conditions, and then after parenteral application of diphtheria toxin. The animals treated with the toxin absorbed more iron from the gastro-intestinal tract than the control animals [66–68]. We have recently confirmed this increase in iron resorption in humans by iron balance studies on 19 adult patients with florid infections [69]. Radical changes occur in the intermediate iron metabolism. The rate of migration of iron from the plasma is markedly increased, so that though the plasma iron concentration is generally much lower than normal, the iron turnover is increased, sometimes by a factor of more than four (see Table 3).

Table 3. Plasma iron turnover on infection (normal range 0.36 to 0.52 mg Fe per 24 h per kg body weight).

Cases 1–14: florid infections; cases 15–19: declining infections.

| Case | Disease | Iron turnover (mg/24h/kg) |
|---|---|---|
| 1 | Tuberculous meningitis | 1.78 |
| 2 | Pulmonary TB | 1.64 |

The migration rate and the iron turnover are normally determined by the erythropoietic activity of bone marrow. The increase in turnover on infection, on the other hand, is due less to the hemoglobin iron fraction than to the stored fraction (ferritin). Measurement of the radioactivity on the surface of the body showed that the $^{59}Fe$ administered does not travel to the hematopoiesis sites in the bone marrow, but to the reticuloendothelial tissues, especially in the liver and in the spleen. The incorporation of iron into hemoglobin is reduced in infected persons, whereas the rate of release is higher, since the life of erythrocytes is shorter.

The change in the iron metabolism on infection can be summarized as follows: The iron resorption from the gastro-intestinal tract is increased; the rate of migration and the turnover of plasma iron is increased; the rate and extent of utilization of iron for the formation of hemoglobin is reduced; and the rate of liberation of hemoglobin iron from the circulating erythrocytes, which have a shorter life, is increased. Most of the extra iron in infected persons travels into the reticuloendothelial system and accumulates as hemosiderin in the inflamed region [70].

As was shown by *Heilmeyer* and co-workers [71], iron salts, ferritin, and hemosiderin seem to have a protective action against various toxins. To all appearances, iron plays an important part in non-specific protection against infection. It therefore seems reasonable that the intermediate iron metabolism should change during an infection, in such a way that the iron is mobilized from the plasma, from the gastro-intestinal tract, and even from the erythropoiesis, and displaced into the protective cell system.

According to *Schäfer* [72], a single stimulation of the reticuloendothelial system, *e.g.* by injection of a storable substance (colloidal silver) leads to similar changes in the intermediate iron metabolism as an infection. Frequent repetition of injections of this type leads to blockage of the reticuloendothelial system, *i.e.* the system fails to respond to further stimuli. This is accompanied by the disappearance of the normal day-night rhythm of the serum iron level, which normally reaches its highest value during the morning and its lowest value in the late afternoon. In two children whose reticuloendothelial system was blocked by transfusion hemosiderosis, the day-night rhythm was found to have spontaneously disappeared. These findings indicate that the reticuloendothelial system does not greatly affect the intermediate iron metabolism even in normal circumstances. It has not yet been established whether the system is the sense organ of higher centers, or how the stimuli are transmitted.

## II. Iron Metabolism in Cases of Iron Deficiency

In cases of true iron deficiency, the total iron content of the body is reduced. This leads to a decrease, not only in the content of hemoglobin iron and stored iron, but also in the content of cell hemin iron, a fact that could explain a number of clinical symptoms. The principal causes of iron deficiency are malnutrition and loss of blood, an important factor in women being menstruation.

Iron resorption tests in cases of iron deficiency give high values. Though the plasma iron level is low, the rate of loss of iron from the plasma is increased, so that the iron turnover may in some cases be only slightly reduced, or may even be normal. The iron passing through the plasma is nearly all incorporated into hemoglobin. Thus the iron metabolism in cases of iron deficiency is characterized by displacement of nearly all the mobilizable iron into the erythropoietic tissue, where it is made available for the synthesis of hemoglobin.

Recent studies by *Heilmeyer* [73] have shown that interesting changes in the porphyrin metabolism occur during iron deficiency. The protoporphyrin and coproporphyrin concentrations in the erythrocytes increase, as do the concentrations of δ-aminolevulinic acid and coproporphyrin in the urine, but less porphobilinogen is eliminated. In incubation

experiments with hemolysates of erythrocytes from iron-deficient patients, the synthesis of porphyrins from δ-aminolevulinic acid was slower and less profuse than in normal hemolysates. However, if δ-aminolevulinic acid and protoporphyrin are added to a hemolysate from healthy erythrocytes, the rate of synthesis decreases in the same manner as in the iron-deficient hemolysate. Thus in cases of severe iron deficiency, where the quantity of iron available for the synthesis of heme is reduced, the synthesis of porphyrin also appears to be inhibited, in order to protect the organism from an accumulation of the toxic porphyrins.

### III. Iron Metabolism in Hemochromatosis

Idiopathic hemochromatosis is dominated by a very marked increase in the stored iron fraction. This leads to a series of characteristic changes in the exogenous and intermediate iron metabolism. The serum iron concentration is greatly increased, so that the transferrin, which is generally present only in small concentrations, is almost completely saturated with iron. The iron resorption is increased, as has also been shown by investigations with $^{59}Fe$ [74]. The loss of iron from the plasma is slower, but the higher serum iron level still gives a higher turnover. Most of the iron passing through the plasma goes to the storage organs (liver, spleen), as shown by radioactivity measurements at the surface of the body, and by the decreased incorporation into the erythrocytes [75]. However, the reduced iron utilization is due not to a decrease in the erythropoietic activity of the bone marrow, but to the marked increase in the iron pool.

The pathogenesis of hemochromatosis is still unknown, though interesting theories have been revived regarding the possibility that the pancreatic secretion [44] or the bile contributes in some way to the high iron resorption. Another possibility that has been discussed is that of disturbances in the regulation of ferritin synthesis, the excess of ferritin produced being subsequently converted into hemosiderin.

### IV. Iron Metabolism in Atransferrinemia

The case of congenital atransferrinemia studied in Freiburg [76] involved a girl aged seven years, who was retarded in her physical development and who had been found to have a severe anemia that did not respond to therapy at the age of only $3^1/_2$ months. Clinical observations included hepatosplenomegaly and megalocardia. Both the peripheral blood and the bone marrow punctate showed signs of severe iron deficiency, while the liver biopsy indicated severe siderocirrhosis.

The plasma iron concentration was only 0.014 ppm (normal range 0.08–0.13 ppm). As can be seen from Fig. 5, ferrokinetic investigation with $^{59}Fe$ showed extreme acceleration of iron loss from the plasma, an increased plasma iron turnover, and a very marked decrease in the uptake of iron by the erythrocytes. Determination of the $^{59}Fe$ distribution by measurements on the body surface showed a marked increase in activity above the liver, whereas very little $^{59}Fe$ was absorbed by the spleen, and none by the bone marrow. The iron resorption, as found in iron balance investigations with $^{59}Fe$, was higher than normal.

In the autopsy following the sudden death of the patient excessive iron deposits were found in the liver, heart, kidneys, pancreas, and thyroid gland.

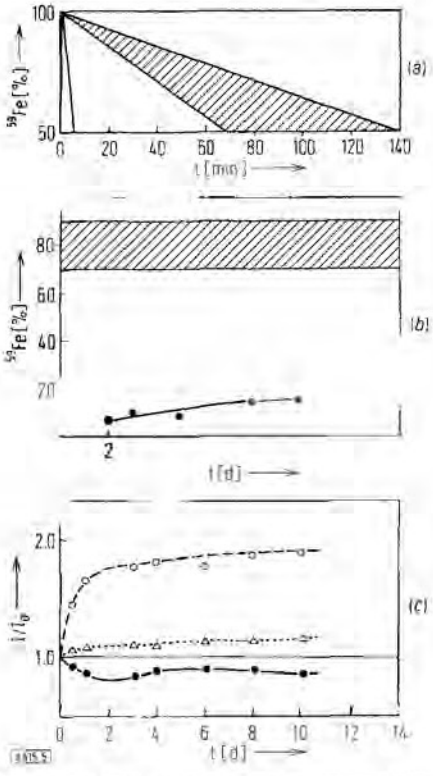

Fig. 5. Ferrokinetics in a girl aged 7 years suffering from transferrin deficiency.

(a) Migration of $^{59}Fe$ from the plasma.
Ordinate: $^{59}Fe$ remaining in plasma (%).
Abscissa: Time (min) after injection of autologous plasma incubated with $^{59}Fe$ citrate.

Ordinate: Relative radioactivity of the body surface.
Abscissa: Time (days) after injection of autologous plasma incubated with $^{59}Fe$ citrate.

This informative case shows clearly the importance of transferrin to the correct operation of the iron metabolism. When the iron transport system breaks down the iron evidently passes unhindered into the tissues, where it is stored as hemosiderin and leads to cirrhoses and brown induration. The supply of iron to the bone marrow, on the other hand, is insufficient, leading to the paradoxical situation of severe iron deficiency anemia and marked siderosis of the organs. The results also show that transferrin is of minor importance in iron resorption.

## V. Iron Metabolism in Sideroachrestic Anemias

The sideroachrestic anemias are divided into idiopathic forms, in which a congenital (hypochromic sideroachrestic hereditary anemia)[77,78] and an acquired type (refractory sideroblastic anemia)[79,80] are distinguished, and into symptomatic forms in lead poisoning and other types of poisoning, in pyridoxin deficiency, and occasionally in blood neoplasia and in the initial stages of myelosclerosis[81]. These diseases initially give the appearance of anemia; complications occur later as a result of abnormal deposition of iron in the liver.

A pathogenetic feature common to all forms is disturbance of the utilization of iron in the synthesis of hemoglobin. The development of the diseases was studied by determination of the heme precursors (uroporphyrin, coproporphyrin, protoporphyrin) in the erythrocytes, and by incubation experiments with hemolysates of bone marrow and peripheral blood with added heme precursors and δ-aminolevulinic acid or porphobilinogen[81,82].

The combination of iron, protoporphyrin, and globulin in the red precursors normally is preceded by the formation of these three substances in approximately stoichiometric amounts. After the synthesis in the erythrocytes all but very small quantities of the substances are consumed. In refractory sideroblastic anemia and in many symptomatic forms, the combination of iron and protoporphyrin is upset, so that porphyrin and iron accumulate in the erythrocytes. It is not certain whether the disturbance is due to iron deficiency, damage to the structure of the mitochondria, or disturbance of the intracellular iron metabolism. In pyridoxin deficiency and in hypochromic sideroachrestic hereditary anemia, the supply of protoporphyrin is retarded as a result of disturbance of the porphyrin synthesis, the disturbance in the case of hypochromic sideroachrestic hereditary anemia probably being mainly in the transition from coproporphyrin to protoporphyrin.

However, the disturbance of hemoglobin synthesis leads to an accumulation of iron, not only in the erythropoietic system, but also in the reticular cells of the bone marrow and in the liver. After the disease has lasted for some years, other organs such as the pancreas, lymph nodes, and heart muscle become overloaded with iron, and this can give rise to the symptoms of a secondary hemochromatosis.

Ferrokinetic investigation with $^{59}Fe$ shows normal loss of iron from the plasma, increased iron turnover, and a marked decrease in the rate of incorporation of iron into the erythrocytes. Most of the injected $^{59}Fe$ accumulates in the liver, and very little iron is taken up by the spleen and the bone marrow[78,80].

## Closing Remarks

Recent research on iron metabolism has yielded new and impressive results. Particularly interesting work has been done on the intracellular transport of iron, which may involve complexes of low molecular weight, and which is evidently very important in the resorption, of iron by the intestinal mucosal cells and in the absorption of iron by the hemoglobin-forming cells. Special attention is also due to the synthetic routes taken by the individual iron fractions in the body. Though we are still far from knowing the nature of the reaction sequences involved, the results obtained so far have helped towards a better understanding of iron metabolism and its disturbances.

# Acrylonitrile from Propylene, Ammonia, and Atmospheric Oxygen

BY DR. R. SCHÖNBECK, DR.-ING. H. KÖNIG, K. KRZEMICKI, AND DR. L. KAHOFER

CHEMISCHE FORSCHUNGSABTEILUNG, ÖSTERREICHISCHE STICKSTOFFWERKE AG., LINZ (AUSTRIA)

*Acrylonitrile was produced in a pilot plant from propylene, ammonia, and atmospheric oxygen in a fixed-bed reactor in the presence of a Bi/Mo/Si oxide shell catalyst. The propylene conversion, which can amount to about 70% under optimal conditions, was studied as a function of structural properties and the chemical composition of the catalyst, and of the composition of the starting mixture. Acrylonitrile of adequate purity for use in polymerizations could be obtained by multi-stage processing of the crude product.*

Acrylonitrile attained a certain importance in Germany during the second world war owing to its use as a raw material for the polyacrylonitrile fiber produced by the former I.G. Farbenindustrie and as an additive in the production of Buna N. It was originally synthesized from ethylene oxide and hydrocyanic acid and later, more economically, from acetylene and hydrocyanic acid. A few years ago the production of acrylonitrile from acetaldehyde and hydrocyanic acid, *via* lactonitrile, also gained some importance.

The production of acrylonitrile by the direct reaction of propylene, ammonia, and oxygen in accordance with the equation

$$CH_3{-}CH{=}CH_2 + NH_3 + {}^3/_2O_2 \rightarrow CH_2{=}CH{-}CN + 3\,H_2O$$

was described as early as 1949 in a patent application by Allied Chemical and Dye Corp., New York (USA)[1]. A few years later, the Distillers Company, Edinburgh (UK), published a process for the reaction of acrolein with ammonia and oxygen, the acrolein being obtained by the air oxidation of propylene[2]. In this case, the same reactants as are used in the Allied Chemical and Dye Corp. process are converted into acrylonitrile by a two-step reaction. However, the yields obtained in both cases were low, so that the processes could not yet be used economically.

At the beginning of 1959, Standard Oil of Ohio (SOHIO), Cleveland (Ohio, USA) published a process in which acrylonitrile is produced from the same raw materials, *i.e.* propylene, ammonia, and oxygen, in a conversion of about 50%[3]. A new feature of this process was the use of a bismuth/molybdenum catalyst with silica as a porous support. It thus became feasible to use this synthesis on an industrial scale, and experience gained over the next five years showed that it is economically far superior to all other processes. Fifteen plants using the SOHIO process are already in operation, and after completion of all plants currently under construction, it is expected that this process is used for 75% of the acrylonitrile production of the western world.

[1] U.S. Pat. 2481826 (1949).

[2] Brit. Pat. 709337 (1954); German Pat. 897560 (1953).

[3] U.S. Pat. 2904580 (1959).

Since ammonia is a cheap industrial product, and propylene is formed in the cracking of nearly all petroleum products, acrylonitrile has become a cheap organic base chemical. This has led to the development of many new applications, as is illustrated *e.g.* by the recent increase in production of copolymers of acrylonitrile. It is probable that in addition to polymerization and copolymerization, other reactions of acrylonitrile, leading to products of low molecular weight, will also become important.

## Laboratory Experiments

Following the publication of the SOHIO process, the examples of the synthesis of acrylonitrile in a fluidized bed described in Belgian Patent No. 571200 were repeated in our laboratory at the beginning of 1960. Since we also wished to study the ammonoxidation of propylene at low throughputs, and since the fluidized-bed process appeared to be difficult to use for small reaction units, we used fixed-bed reactors with which a great deal of experience had already been gained at our works in the production of phthalic acid.

The fixed-bed reactors each had one reaction tube with an internal diameter of 25 mm; a thermocouple shield tube (outside diameter 6 mm) with adjustable temperature measuring position was inserted axially from the top. The depth of the catalyst bed was 160 cm. The reaction tube was surrounded by a salt-bath jacket, in which the salt melt was circulated by means of an airlift pump driven by compressed air. The reaction gas leaving the reactor was washed with dilute sulfuric acid, whereupon an aqueous solution of acrylonitrile was obtained.

### Catalyst Composition

When granular catalysts of homogeneous composition (cf. [4]) were used the reaction was subject to heat build-ups which were difficult to control, to blockages due to catalyst dust, and to formation of large quantities of undesirable by-products (acrolein, oxides of carbon).

[4] Belg. Pat. 571200 (1958).

Since these difficulties were due mainly to poor heat removal from overheated microscopic regions on the catalyst core, we achieved a decisive improvement by the use of catalysts the particles of which consisted of a thermally conducting core and a catalytically active shell. The reaction could be controlled in this way to such an extent that it was possible, by using stoichiometric quantities of oxygen, propylene, and ammonia, to obtain conversions into acrylonitrile of more than 70% under optimal conditions. This process, the results of which represented a considerable improvement over existing data, was patented [5].

If the catalyst core is to possess a high thermal conductance, its crystallinity must be high and its porosity low. The relationship between these properties of the catalyst and the conversion of propylene into acrylonitrile is shown in Table 1, which is based on a series of runs with Bi/Mo/Si oxide shell catalysts.

Table 1. Conversion of propylene into acrylonitrile [mole-%] with various shell catalysts having a Bi/Mo/Si oxide coat 0.05 mm thick; particle size 3 to 4 mm; starting mixture, 1 $C_3H_6$:1 $NH_3$:2 $H_2O$: 8 air; residence time, based on the empty tube, 5 sec; highest temperature measured 470 °C.

| Core material | Porosity [vol-%] | Propylene conversion [mole-%] |
|---|---|---|
| Fused corundum, crushed | 2 | 62 |
| Sintered corundum, crushed | 6 | 60 |
| Granite, crushed | 1 | 64 |
| Quartz, crushed | 1 | 60 |
| Clay clinker, crushed | 8 | 62 |
| Alumina spheres (I) | 12 | 53 |
| Alumina spheres (II) | 25 | 45 |
| Alundum catalyst support | 44 | 31 |
| Aluminum silicate catalyst support | 50 | 30 |
| Glass spheres (amorphous) | 0 | 35 |

Table 2 contains the results of a series of experiments with catalyst systems consisting of two oxide components together with a silica support, coated on fused corundum having a particle size of 3 to 4 mm. The highest propylene conversion in this series was obtained with the binary oxide system $3Bi_2O_3 \cdot 8MoO_3$. The activity of this catalyst can be increased further by structural and chemical modifications.

## Composition of the Original Gas Mixture

The yield of acrylonitrile is strongly influenced, not only by the form of the catalyst, but also by the composition of the original synthesis gas. In addition to the principal components, *i.e.* propylene, ammonia, and air, the mixture must also contain a diluent if the reaction is to proceed smoothly. Water vapor, propane, carbon dioxide, and nitrogen were used in the present work, the best propylene conversion being obtained with water vapor (cf. Table 3).

## Purification of Acrylonitrile

The acrylonitrile produced must be obtained, not only in high yields, but also in a very pure state. For example, the tolerance for interfering impurities (*e.g.* hydrocyanic acid or acrolein) in polymerizations, the principal use of acrylonitrile, is only a few milligrams per kg of pure product. Attempts were made to use a combination of distillation processes, without the addition of foreign substances, for the purification of the crude acrylonitrile containing acetonitrile, hydrocyanic acid, and acrolein as impurities, and at the same time to obtain the by-products as pure substances where this was economically justifiable. The small quantities of acrolein and other carbonyl compounds present are made to

[5] Austrian Pat. 226672 (1962).

Table 2. Conversion of propylene into acrylonitrile [mole-%] in a series of experiments with shell catalysts consisting of silica and oxides of the elements A and B, coated to a thickness of 0.05 mm on fused corundum; particle size 3 to 4 mm; gas composition, $1C_3H_6$:$1NH_3$:$3H_2O$:8 air; residence time, based on the empty tube, 5 sec; highest temperature measured 470 °C; ΔT = difference between maximum temperature and salt-bath temperature.

react with the excess hydrocyanic acid to form cyanohydrins which are eliminated by distillation. Acetonitrile is obtained as a pure anhydrous product, without loss of acrylonitrile, by extractive distillation with water as the extracting agent, followed by two fractionations [6].

## Pilot Plant Experiments

### Synthesis

The synthesis was carried out in a tube furnace containing 60 tubes 2 m long and having an internal diameter of 25 mm (Fig. 1). The heat of the reaction was removed

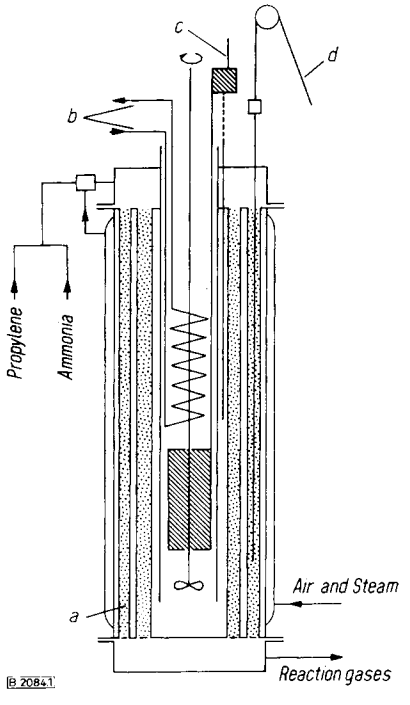

Fig. 1. Experimental reactor for the production of acrylonitrile; *a* catalyst packing, *b* air cooling, *c* electric heater (controlled), *d* temperature measuring position (vertically adjustable).

by a salt bath. The catalyst was arranged in two layers. The gas mixture first passed through a 60 cm bed of a corundum catalyst having a particle size of 3 to 4 mm and a coating thickness of about 0.05 mm, and then through a 100 cm bed having a particle size of 4 to 5 mm and a coating thickness of 0.3 mm. The residence time in the contact zone (based on the empty tube) was about 4 sec. The highest temperature measured in the reaction zone was 480 °C. The temperature of the salt bath used to dissipate the heat of reaction was 455 °C. 1.5 mole of oxygen (as air) and 3 moles of water vapor were used per mole of propylene (95%) and per mole of ammonia.

The gas mixture formed in the reactor was washed at about 80 °C with an aqueous ammonium hydrogen sulfate solution to remove ammonia. The water-soluble components were absorbed in an excess of water. The organic components were concentrated from the aqueous solution by distillation, and were determined mainly by gas chromatography. The exhaust gases from the water wash were determined by gas analysis.

The overall reactions shown in Table 4 were deduced from the analytical results. Some of these reactions are coupled with one another. For example, one molecule of propylene gives one molecule of acetonitrile and one molecule of $CO_2$. Table 4 also shows that about 20% each of propylene and ammonia pass through the reaction zone unchanged.

The proportions of the various reaction products in relation to the starting materials propylene, ammonia, and oxygen are shown graphically in Figure 2.

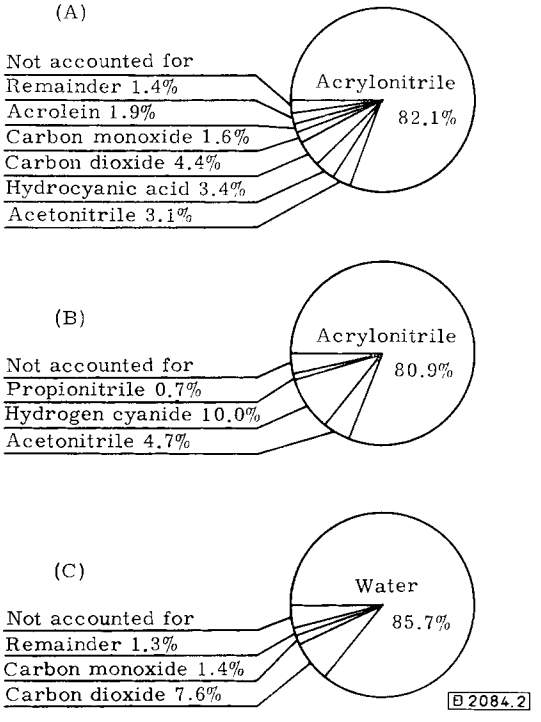

Fig. 2. Proportions of the various reaction products in relation to the consumed reaction gases propylene (A), ammonia (B), and oxygen (C).

Table 4. Reactions occurring in the reactor and the conversion [mole-%] of propylene (C), ammonia (N), and oxygen (O), based on the amounts introduced.

kcal, and the quantity of heat which has to be removed for every kilogram of acrylonitrile formed is about 3200 kcal.

### Isolation and Purification

The various stages in the isolation and purification of the crude acrylonitrile are shown schematically in Figure 3.

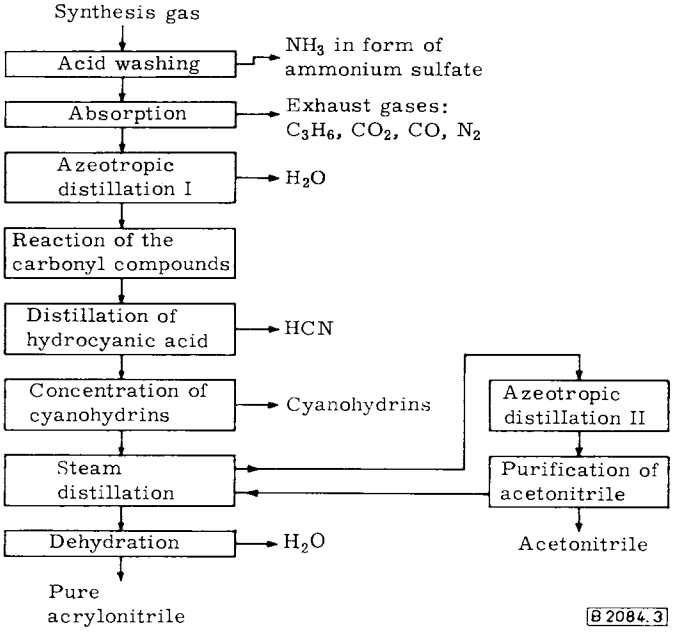

Fig. 3. Scheme of the working-up of the synthesis gas and the purification of the acrylonitrile.

1. The ammonia still present in the reactor gas was removed in a wash column at 80 °C by circulating a large quantity of ammonium hydrogen sulfate solution. The pH of the solution was maintained at 2.5 by continuous addition of sulfuric acid. Practically no loss of acrylonitrile occurred under these conditions.

2. The water-soluble components were absorbed in water in an absorption tower. The concentration of the organic components in the water was 2.5%. Less than 0.1% of the acrylonitrile was retained in the exhaust gases.

3. The organic products were driven off from the aqueous solution in a distillation column. The distillate separated into two layers. The upper layer, which consisted of crude acrylonitrile, was further purified while the lower (aqueous) layer was returned to the column.

4. The carbonyl compounds (acrolein, acetaldehyde, acetone) contained in the crude acrylonitrile were caused to react completely with the hydrocyanic acid present in excess.

5. The free hydrocyanic acid could be distilled out of the resulting mixture without decomposition of the sensitive substances present.

6. The reaction products of the carbonyl compounds with hydrocyanic acid (cyanohydrins) were concentrated by a two-stage vacuum distillation. The residue from the second evaporator stage contained about 70% of cyanohydrin.

7. After removal of the hydrocyanic acid and the carbonyl compounds, the acrylonitrile was subjected to extractive distillation with water as the extracting agent. The head product was water-saturated acrylonitrile containing no acetonitrile, while a very dilute aqueous solution of acetonitrile and acrylonitrile in a ratio of 1:1 was obtained at the bottom of the column. This relatively high proportion of acrylonitrile was left in the mixture to permit the purification of the acetonitrile under favorable conditions.

8. The acrylonitrile was dried to a water content of 0.4% by azeotropic distillation and separation of the water which formed the lower layer in the distillate. A small quantity of the organic distillate is returned to step 4, and traces of low-boiling impurities still present are removed in this way.

9. The acetonitrile/acrylonitrile mixture from the aqueous residue of the extractive distillation was driven off by column distillation (azeotropic distillation II).

10. The head product from the azeotropic distillation II was separated further by distillation. The residue consisted of acetonitrile still containing small quantities of propionitrile; water and acrylonitrile were present only in traces. The head product from this distillation consisted of an acrylonitrile/acetonitrile mixture with a high content of acrylonitrile. This fraction was returned to the extractive distillation, step 7.

With a certain water content in the upper part of the fractionating column, this difficult separation could be achieved without the need for an excessively large number of plates, and with a moderate reflux ratio.

The acrylonitrile obtained by these purification steps was sufficiently pure for use in polymerizations; it contained only about 0.01% of acetonitrile, and the concentration of all other impurities was less than 10 ppm.

### Technical Development

On the basis of the results obtained on the laboratory scale and in the pilot plant, the Lurgi Gesellschaft für Mineralöltechnik mbH, Frankfurt/Main is at present

constructing a plant (production capacity 10000 tons/year) which, in addition to pure acrylonitrile for polymerization, will produce hydrocyanic acid and acetonitrile. In four fixed-bed reactors, acrylonitrile will be synthesized in a one-step process. The crude product from the synthesis will be worked up in eight distillation columns to give the three end-products acrylonitrile, acetonitrile, and hydrocyanic acid. The plant, which is expected to begin operation in 1967, will be automatically controlled and will require a minimum of attention.

# Alcohols as Petrochemicals

BY PRIV.-DOZ. DR. H. KROPF

CHEMISCHES STAATSINSTITUT, INSTITUT FÜR ORGANISCHE CHEMIE, UNIVERSITÄT HAMBURG (GERMANY)

*Efficient processes have been developed in recent years for the large-scale manufacture of alcohols from petrochemicals. These allow production of aliphatic alcohols both with short and with long alkyl groups more economically than was previously possible by fermentation. In this paper the most important principles and the technical execution of the hydration of olefins, the air oxidation of paraffins, and especially the synthesis reactions (e.g. the catalytic hydroformylation of olefins with carbon monoxide and hydrogen according to Roelen, the Reppe synthesis, and the Ziegler growth reaction with ethylene and triethylaluminum) are described.*

## Introduction

Alcohols are among the most important products of the chemical industry. They are widely used as solvents and anti-freeze agents, and they are important intermediates, *e.g.* for the manufacture of plasticizers, synthetic lubricants, detergents, flotation agents, textile and paint adjuvants, and synthetic fibers. The principal raw materials for the production of alcohols at present are petrochemicals, *i.e.* olefins and paraffins. The reactions used can be grouped into three basic types:

1. *Hydration*, *e.g.* ethylene to ethanol; propene to isopropanol.

2. *Synthesis*, *e.g.* Roelen reaction; Reppe synthesis; Ziegler synthesis.

3. *Oxidations*, *e.g.* preparation of aliphatic or alicyclic alcohols from paraffins or cycloparaffins.

Processes recently developed to the industrial scale include the Ziegler synthesis for the production of unbranched alcohols with an even number of carbon atoms, the oxidation of cyclohexane and cyclododecane, and the Reppe synthesis for the production of n-butanol; the other methods have been in use for a longer time.

The present paper is concerned particularly with the Ziegler synthesis; a survey of the other methods is also included. The production of polyfunctional alcohols such as ethylene glycol and glycerol is not discussed, although these substances are also produced from petrochemicals, *i.e.* from ethylene and propene, respectively.

## Hydration of Olefins

Only lower olefins, particularly ethylene, propene, and butene, are used in the production of alcohols by the hydration of olefins. The hydration may be direct, *i.e.* involving the direct catalytic addition of water in the gas phase (*e.g.* in the preparation of ethanol from ethylene), or indirect, *i.e.* involving the absorption of the olefins in sulfuric acid followed by hydrolysis of the alkyl sulfates (*e.g.* in the production of isopropanol from propene and of sec- and tert-butyl alcohol from butenes).

### Direct Hydration

In the exothermic reaction

$$C_2H_4 + H_2O \rightleftarrows C_2H_5OH; \quad \Delta H = -10.9 \text{ kcal/mole}$$

the equilibrium is displaced towards the right at low temperatures and high pressures. In practice, however, the temperature must not be too low, since the rate of the reaction will otherwise also be too low; moreover, the pressure must not be too high, since some of the water vapor otherwise condenses. On the other hand, low temperatures and relatively low pressures can be used only in the presence of a sufficiently active catalyst [1].

The earliest practical experience of the direct hydration of ethylene was gathered by the Shell Chemical Co., Houston (Texas) [2]. Plants for this process are operated in the German Federal Republic by Hibernia Chemie AG, Wanne-Eickel, and by Erdölchemie, Dormagen.

Ethylene and water vapor in the molar ratio of 0.6:1 are led over phosphoric acid on a Kieselgur support (about 5 × 5 mm). With the aging of the catalyst the temperature is gradually increased from 250 to 270 °C at a constant pressure of 70 atm. The throughput for a con-

A list of earlier literature is given by *R. Seka* in *G.-M. Schwab*: Handbuch der Katalyse, Vol. VII (2) pp. 44–47. Springer, Vienna 1943.

[2] U.S.-Pat. 2579601 (1951), Shell Development Co., Chem. Abstr. *46*, 6666 h (1952); Brit. Pat. 651275 (1951), Bataafsche Petroleum Mij., Chem. Abstr. *45*, 9074a (1951).

version of 4.5% with respect to ethylene corresponds to about 1800 $Nm^3$ per $m^3$ of catalyst per hour.

The ethylene used is 97% pure, and it is recirculated. To prevent a build-up of inert substances, part of the recirculating gas is drawn off and purified in a Linde plant when the ethylene concentration falls below 85%.

The ethylene and the water vapor are led through a heat exchanger and a furnace into the reactor, where the ethylene is hydrated. The emerging gases pass through the heat exchanger, where part of the alcohol condenses, into a high-pressure trap. After cooling, the gaseous components are washed with water to remove residual alcohol, and the ethylene is returned to the cycle. The condensate from the high-pressure trap and the wash water from the washing column are combined and distilled. The ethanol condensate, which distils first, is hydrogenated over nickel catalysts to eliminate impurities such as acetaldehyde and crotonaldehyde, and the diethyl ether formed as a by-product is distilled off. The product is then concentrated to 95% alcohol in a purifying column. The residue from this column is returned to the purifying plant. The yield is 97%. In addition to diethyl ether, acetaldehyde, and crotonaldehyde, small amounts of olefin polymers, and occasionally t-butyl alcohol, are formed as by products.

The diagram of a plant is shown in Fig. 1.

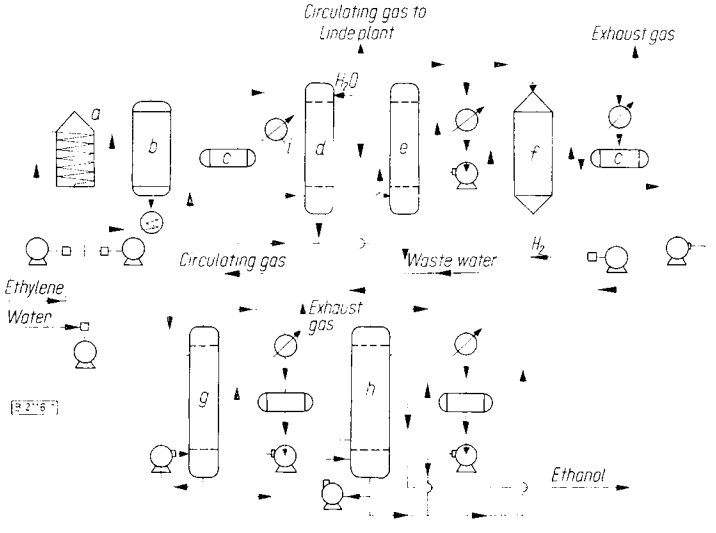

Fig. 1. Scheme of a plant for the production of ethanol by the direct hydration of ethylene [3].

a) preheater, b) reactor, c) settler, d) scrubber, e) concentrating column, f) hydrogenation reactor, g) ether column, h) ethanol column, i) heat exchanger.

The efficiency of the process is illustrated by the following example[*]. The production of 60000 tons of ethanol from natural raw materials by fermentation would require the use of about 660000 tons of grain, *i.e.* a cultivation area of about 275 sq. km. The production of the grain and the processing to make alcohol would require 8800 workers. The synthesis from petrochemicals requires about 45000 tons of ethylene, and the area covered by the plant, which is operated by 35 men, is only about 0.01 sq. km.

Imperial Chemical Industries, Wilton (England) are using a direct hydration method, probably based on earlier investigations by I.G. Farben-Industrie, for the production of isopropanol from propene. The catalyst used is a molded, so-called blue tungsten oxide having the approximate composition $W_2O_5$, which is prepared by hydrogenation of compressed tungstic acid, *i.e.* hydrated $WO_3$. The reaction is carried out at 270 °C and 250 atm, and the ratio of water to propene is about 5.6:1. Since partial condensation is observed under the conditions of the reaction, the heated mixture is allowed to trickle from the head of the reaction furnace over the catalyst. The contact loading is about 3.3 kg per hour and per liter of catalyst space at conversions of 24% with respect to propene. The product contains about 5.7 wt-% of isopropanol, which is isolated by distillation.

### Indirect Hydration

Olefins are absorbed in sulfuric acid with formation of alkylsulfuric acids or dialkyl sulfates.

The minimum concentration of the acid that gives smooth absorption decreases from ethylene to hexene, and increases again for the higher olefins. Branched olefins are absorbed more readily than the corresponding straight-chain compounds. Hydrolysis of the alkylsulfuric acids or dialkyl sulfates leads to the alcohols.

The sulfuric acid must then be reconcentrated before being used again (strong acid process). On the other hand, the absorption may be carried out under pressure, and in this case a less concentrated acid is required. When the pressure is released, the alkylsulfuric acid is hydrolysed, and the alcohol separates. This is the principle of the so-called weak acid process for the production of isopropanol from propylene[4] (cf. Fig. 2), which is much more economical than the strong acid process.

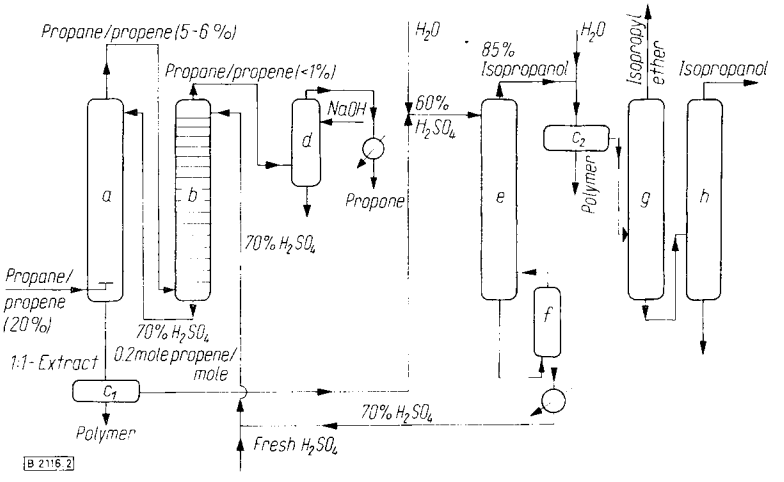

Fig. 2. Scheme of a plant for the production of isopropanol by the indirect hydration of propene.

a) 1st absorption tower, b) 2nd absorption tower (bubble-cap column), $c_1$,$c_2$) sedimentation vessels, d) alkali washer, e) wash column, f) evaporator, g) bubble-cap column, h) 50-plate column.

[*] I am indebted to Dr. *Voß*, Deutsche Benzin und Petroleum AG, Hamburg, for this comparison.

[3] Taken from *M. Sittig*: Organic Chemical Processes, p. 53, Noyes Press, Pearl River 1962.

[4] U.S.-Pat. 2473224 (1949), Standard Oil Development Co., Chem. Abstr. 6645g (1949); U.S.-Pat. 1988611 (1935), Standard Oil of California, Chem. Zbl. *1935* II 2580.

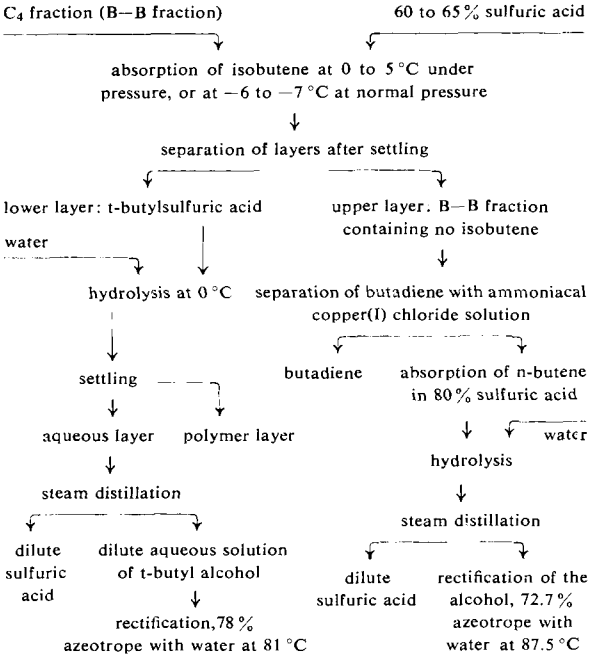
In the weak acid process, propene is absorbed in 70% sulfuric acid at 65 °C and 25 atm. The propane/propene mixture from the cracking plants, which contains about 20–25% of propene, is passed through a gas distributor into an absorption tower. This tower has no plates, and is filled to a height of 14 m with sulfuric acid already containing about 0.2 mole of propene/mole of sulfuric acid. The acid absorbs propene up to a concentration of about 1 mole per mole of sulfuric acid. The exhaust gas still contains about 5 to 6% of propene, which is absorbed (to 99%) in a bubble-cap column in regenerated sulfuric acid from the hydrolysis column. In this column the sulfuric acid absorbs propene to a concentration of about 0.2 mole per mole of sulfuric acid, and is then passed into the first absorption tower.

The 1:1 extract leaving the first absorption tower passes through a relief valve into a sedimentation vessel, where small quantities of polymer settle out. Water is added to give a 60% acid solution, and the mixture is passed into a column in which the isopropanol is distilled as an 85% product. A 70% sulfuric acid accumulates at the base of the column.

The crude alcohol is diluted to 25%, whereupon further polymer settles out after 1 to 2 days. Isopropyl ether is then distilled off in a bubble-cap column (15 plates, reflux ratio 15:1). The residue is concentrated in a 50-plate column to 91% isopropanol. The yields are between 85 and 90%, based on propene converted.

Olefins containing four carbon atoms (B–B fraction) are converted into sec- and tert-butyl alcohols by the strong acid process (cf. Scheme 1). Owing to the strong tendency of the $C_4$ olefins to polymerize, it is particularly important to maintain the correct temperature.

Isobutene is absorbed in 60 to 65% sulfuric acid at 0 to 5 °C and under slight pressure, or at −6 to −7 °C and at normal pressure. t-Butyl alcohol is obtained from the sulfuric acid phase by dilution with water followed by steam distillation.



Scheme 1. The various steps in the production of tertiary and secondary butyl alcohols from the butenes of the B–B fraction [5].

The organic phase is treated with ammoniacal cuprous chloride solution to remove butadiene, and is then absorbed in 80% sulfuric acid at 40 to 50 °C at a low pressure. The n-butylsulfuric acid is hydrolysed by dilution to 30%, and the resulting alcohol is steam distilled. sec-Butyl alcohol is largely converted into methyl ethyl ketone by dehydration. The sulfuric acid can be concentrated, *e.g.* by immersion heaters or by the introduction of air. The presence of coking organic material often leads to pronounced foaming, which frequently interferes with production.

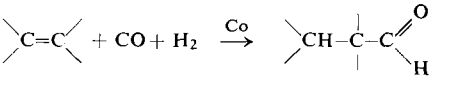
## Syntheses

### Roelen Reaction

In 1938, *O. Roelen* [6] discovered the hydroformylation of olefins with carbon monoxide and hydrogen in the presence of cobalt compounds:



The olefins used nowadays are all obtained from petrochemicals, and the initially formed aldehydes are nearly always converted into the corresponding alcohols by hydrogenation (sometimes in a single reaction step).

The reation is carried out at 150 to 200 °C and about 200 atm; the actual catalyst is the hydrogen tetracarbonylcobaltate $HCo(CO)_4$ formed during the reaction. The raw materials used are generally lower olefins (*e.g.* ethylene, propene, butene), higher α-olefins, or even olefins such as isoheptene or diisobutylene. The alcohols obtained are used as solvents (n-propanol, n-butanol, isobutanol), as esterification components, *e.g.* with phthalic acid or adipic acid for plasticizers, or after sulfation as detergents.

The influence of the structure of the olefin on its reactivity in the hydroformylation and on the structure of the resulting aldehyde and alcohol was studied particularly by *A. I. M. Keulemans et al.* [7]. The following relationships were recognized:

a) Straight-chain olefins, irrespective of the position of the double bond, give a mixture of 40 to 60% of n-alcohols and 60 to 40% of 2-alkyl branched alcohols.

b) The formyl group does not add to a tertiary C atom, and no quaternary C atoms are formed.

c) Addition of a formyl group in the position adjacent to a tertiary C atom takes place only to a small extent.

d) No addition of the formyl group occurs in a position adjacent to a quaternary C atom.

e) The addition of the formyl group is not hindered by an isolated tertiary C atom.

f) The hydroformylation is generally accompanied by migration of the double bond.

The Roelen reaction can be carried out by three basic procedures:

1. Hydroformylation of the olefin, removal of the cobalt catalyst, and hydrogenation of the aldehyde mixture.

2. Hydroformylation of the olefin followed by hydrogenation at a high pressure of hydrogen without removal of the cobalt, which then acts as a heterogeneous hydrogenation catalyst.

[6] *O. Roelen*, Angew. Chem. *60*, 213 (1948); *O. Roelen* in *K. Ziegler*: Präparative org. Chemie I, 157 (1948) (Naturforschung und Medizin in Deutschland 1939/46, Vol. 36).

[7] *A. I. M. Keulemans, A. Kwantes*, and *Th. van Bavel*, Recueil Trav. chim. Pays-Bas *67*, 298 (1948).

3. The aldehyde resulting from the hydroformylation is immediately converted into the alcohol by homogeneously catalysed hydrogenation in the presence of hydrogen tetracarbonylcobaltate.

The fixed-bed process and the mash process, which operate continously, have proved suitable in industry. The fixed-bed process corresponds to the first of the above variants, and the mash process to the second. It should be borne in mind in both cases that the actual catalyst is hydrogen tetracarbonylcobaltate. Thus catalysis in both cases is homogeneous.

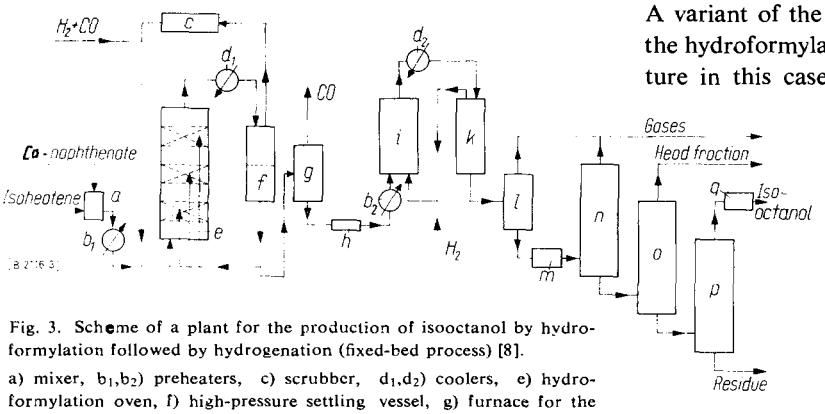


Fig. 3. Scheme of a plant for the production of isooctanol by hydroformylation followed by hydrogenation (fixed-bed process) [8].

a) mixer, $b_1$,$b_2$) preheaters, c) scrubber, $d_1$,$d_2$) coolers, e) hydroformylation oven, f) high-pressure settling vessel, g) furnace for the decomposition of the catalyst, h) filter, i) hydrogenation furnace, k) high-pressure settling vessel, l) low-pressure settling vessel, m) alkali washer, n) stabilizer, o) first runnings column, p) alcohol column.

The fixed-bed process will now be described for the production of isooctanol from isoheptane[8] (cf. Fig. 3). The catalyst is metallic cobalt on pumice or some other support. Losses are compensated by addition of cobalt naphthenate to the fresh olefin. The olefin is made to react at 175 °C and 200 atm; in order to maintain this temperature the product is circulated through a cooler and returned to the reactor at various positions. The ratio of fresh olefin to recirculating liquid is 1:4 to 5, and the residence time is 2.5 hours. Some 400 to 420 $Nm^3$ of water gas are required per 100 *l* of isoheptene; the recirculating system contains approximately 1000 $Nm^3$ of gas.

The catalyst is decomposed at 150 to 160 °C and at a hydrogen pressure of 7 to 10 atm, the metallic cobalt is removed, and the product converted into the alcohol by hydrogenation on nickel catalysts at 200 to 220 °C and 200 atm. The contact loading is 0.6. After working up, isooctanol is obtained in a yield of about 75% with respect to the isoheptene. About 25% of residue remains.

The hydrogenation can also be carried out on sulfide catalysts. This is particularly interesting in that no desulfuration is required, since the hydroformylation is not affected by sulfur.

In the mash process[9], the catalyst (3 to 5%) is slurried in the olefin in the mashing container, and the slurry is forced into the first hydroformylation oven (internal diameter 20 cm, height 8 m), where 70 to 75% of the olefin reacts at 150 to 160 °C and 200 atm (100 atm of CO, 100 atm of $H_2$). The reaction is allowed to continue in a second reactor at 160 to 170 °C. The pressure is released and the product is hydrogenated in two steps at 200 to 220 °C at a hydrogen pressure of 200 atm, the finely divided metallic cobalt formed by the decomposition of the tetracarbonylcobaltate acting as a catalyst. Since the activity of this catalyst is low, relatively long reaction times (about 2 hours) are required. The hydrogen must be essentially free from carbon monoxide (<0.2%), and for this reason a special purification step is included in the gas cycle. When the cobalt has been filtered off, the product is distilled. The filters are periodically back-flushed with fresh olefin to recover the catalyst. A simplified scheme of the process is shown in Figure 4.

In another procedure, the hydrogenation of the aldehyde is carried out under homogenous catalysis with hydrogen tetracarbonylcobaltate[10]. After hydroformylation the temperature is raised to 220 °C, whereupon the hydrogenation begins; the pressure is maintained with the aid of a hydrogen supply.

A variant of the Roelen reaction can also be used for the hydroformylation of alcohols, the reaction temperature in this case being preferably about 200 °C. The product is the next higher homologous alcohol, *e.g.* isoamyl alcohol from t-butyl alcohol or isobutanol from isopropanol[11].

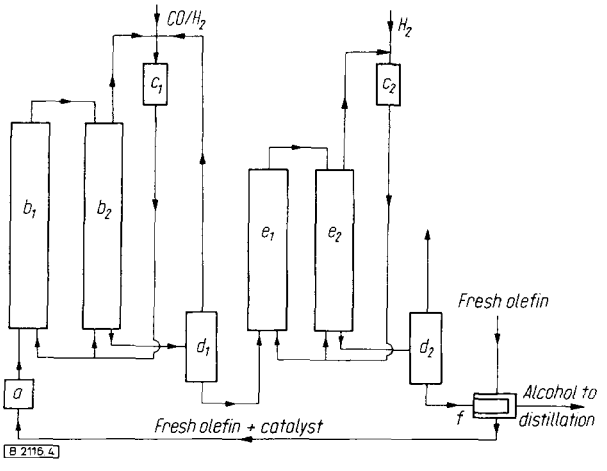

Fig. 4. Simplified scheme of a mash process for the production of alcohols by hydroformylation followed by hydrogenation. a) mashing vessel, $b_1$,$b_2$) hydroformylation furnaces, $c_1$,$c_2$) gas purifiers, $d_1$,$d_2$) decompression vessels, $e_1$,$e_2$) hydrogenation furnaces, f) filter.

## Reppe Synthesis

*W. Reppe et al.*[12] showed that olefins can be converted into alcohols by carbon monoxide/water in the presence of dihydrogen tetracarbonylferrate/tertiary amine at

[8] U.S.-Pat. 2595096 (1952), Standard Oil Development Co., Chem. Abstr. *47*, 141f (1953), U.S.-Pat. 2637796 (1953), Standard Oil Development Co., Chem. Abstr. *48*, 2757d (1954); cf. Chem. Engng. *60*, 346 (1953).

[9] *R. Holroyd*, U.S. Bureau of Mines. Inform. Circ. 7370 (1946).

[10] *J. Wender et al.*, J. Amer. chem. Soc. *71*, 4160 (1949); *72*, 4375, 4842 (1950); *73*, 2656 (1951); *74*, 4079 (1952).

[11] *J. Wender et al.*, J. Amer. chem. Soc. *71*, 4160 (1949); Science (Washington) *113*, 206 (1951).

[12] *W. Reppe* and *H. Vetter*, Liebigs Ann. Chem. *582*, 133 (1953).

temperatures above 100 °C and pressures above 10 atm gage:

$$R\text{-}CH{=}CH{-}R' + 3\,CO + H_2O \rightarrow \begin{matrix} CH_2OH \\ | \\ R{-}CH_2{-}CH{-}R' \end{matrix} \quad \text{and} \quad \begin{matrix} CH_2OH \\ | \\ R{-}CH{-}CH_2{-}R_2 \end{matrix} + 2\,CO_2$$

In contrast to the production of alcohols by hydroformylation and subsequent hydrogenation, the acolhols in this case are produced in a single reaction step at a low pressure and a relatively low temperature.

This process is used by BASF for the production of n-butanol from propene [13]. A plant with an annual capacity of 15000 tons has recently been built in Japan by Nikon, and was put into operation early in 1965. The process is carried out at about 100 °C and about 15 atm gage. The amine used is *N*-butylpyrrolidine, since the pyrrolidine ring is very stable towards transalkylation. The product conatins about 85 % of n-butanol and about 15 % of isobutanol.

Pentacarbonyliron, *N*-butylpyrrolidine, water, and butanol are placed in the reactor. The temperature is raised to 100 °C, and a homogeneous solution of the catalyst, *N*-butylpyrrolidinium hydrogen undecacarbonyltriferrate, is formed within 2 to 4 hours. The formation of butanol begins when the carbon monoxide and propene are introduced (care being taken to ensure intimate mixing). To ensure that the relative concentration of the gases remains constant, only part of the starting materials is allowed to react, and the gases are recycled; otherwise the ratio of pentacarbonyliron to carbonyltriferrate changes, with the result that the reaction is unfavorably affected.

The recirculating gas is first led, at the temperature and pressure of the synthesis, into a bubble-cap column where the *N*-butylpyrrolidine is washed out by material exchange with the refluxing liquid and returned to the reactor. Butanol, water, and pentacarbonyliron are condensed from the head fraction. The remaining gas is pumped back into the reactor, while the gaseous reaction products (carbon dioxide, hydrogen, and propane) are removed in a branch stream by multistage high-pressure scrubbing with water. The condensate flows into a separating vessel, from which the two bottom layers (mainly pentacarbonyliron and water) are returned to the washing column. The third layer (mainly butanol) is introduced into the head of another column, which operates at the pressure used in the synthesis, and fresh carbon monoxide is introduced at the bottom of this column. The pentacarbonyliron is carried to the head of the column by the carbon monoxide, while the crude butanol is drawn off at the bottom.

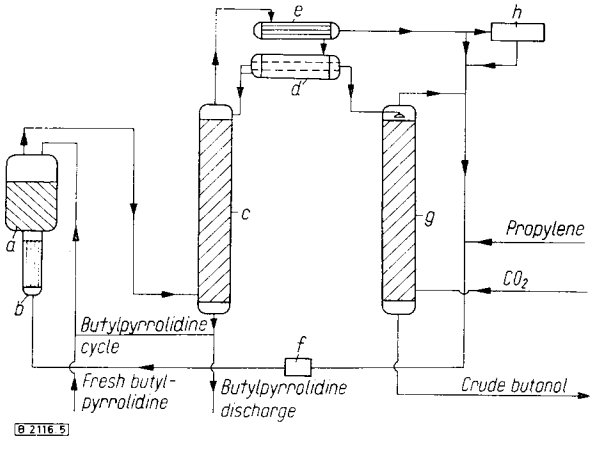

Fig. 5. Scheme of the production of n-butanol by the Reppe process [13]. a) reactor, b) preheater, c) wash column, d) separating vessel, e) cooler, f) gas-recirculating pump, g) pressure column, h) gas washer.

[13] *N. von Kupetow* and *H. Kindler*, Angew. Chem. *72*, 802 (1960).

The crude butanol is washed to remove traces of *N*-butylpyrrolidine, and traces of pentacarbonyliron are destroyed by oxidation. The residual water (about 7 %) is then distilled off, and the mixture of isomers is finally resolved into pure n-butanol and isobutanol. The yield of butanol is about 90 % with respect to propene and carbon monoxide. By-products include propane (about 4 % with respect to propene) and hydrogen (about 6 % with respect to carbon monoxide). Fig. 5 shows a diagram of a plant.

### Ziegler Synthesis

As shown by *K. Ziegler et al.* [14], triethylaluminum reacts with ethylene at high pressures and temperatures to give higher unbranched aluminum trialkyls (growth reaction), which can be converted into aluminum alkoxides by oxidation with oxygen [15]. Hydrolysis of these leads to the corresponding alcohols. Triethylaluminum can be prepared from aluminum and ethylene in a two-step reaction [16].

$$Al + 2\,Al(C_2H_5)_3 + {}^3/_2\,H_2 \rightarrow 3\,AlH(C_2H_5)_2$$

$$3\,AlH(C_2H_5)_2 + 3\,C_2H_4 \rightarrow 3\,Al(C_2H_5)_3$$

$$Al(C_2H_5)_3 + n\,C_2H_4 \rightarrow AlR_3$$

$$AlR_3 + {}^3/_2\,O_2 \rightarrow Al(OR)_3$$

$$Al(OR)_3 + {}^3/_2\,H_2O \rightarrow 3\,ROH + {}^1/_2\,Al_2O_3$$

R = higher unbranched alkyl groups.

The growth reaction gives products in which the chain lengths of the alkyl groups correspond to a Poisson distribution [15], so that the ultimate product consists of a mixture of alcohols (see Fig. 6). These alcohols, known commercially as Alfols®, can be used above all in the plasticizer and detergent fields, depending on their chain length.

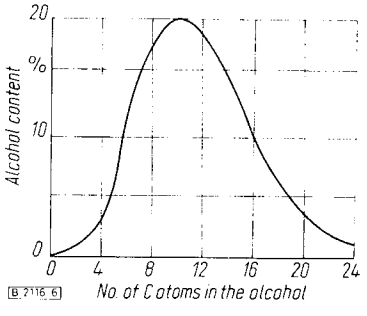

Fig. 6. Composition of the alcohol mixture from the Alfol synthesis for an average chain length of 10 C atoms.

The process has been developed for industrial use by the Continental Oil Company, New York. A plant with an annual output of 50000 tons was put on stream in Lake Charles, Louisiana (USA), around the beginning of 1962 [17]. A plant of similar capacity is being operated in Germany as a joint venture by the Deutsche Erdöl AG, Hamburg, and CONOCO (CONDEA Petrochemie Gesellschaft mbH, Brunsbüttelkoog). The scheme of the plant is shown in Fig. 7.

## Production of Triethylaluminum

The starting material is an aluminum powder obtained from 99.5% aluminum by the addition of a small quantity of a Group IVa metal[18]. The proportion of fine-grain material required depends on the operating conditions: powder grades in with 40–80% <320 mesh are preferred. The aluminum powder is ground in a ball mill for about 4 to 5 hours with kerosine (boiling range 180 to 260 °C) and hydrogen. This "mechanical activation" leads to the exposure of fresh surfaces, but the proportion of fine-grain material decreases. Activation is reinforced by the addition of 5 to 10% of triethylaluminum.

The resulting 30 to 40% aluminum slurry is mixed with the required quantity of triethylaluminum. Diethylaluminum hydride is formed in a hydrogenation reactor at about 120 °C and at a hydrogen pressure of 85 atm. The pressure is then reduced to 25 atm in an air cooler with simultaneous application of ethylene pressure, whereupon the diethylaluminum hydride is ethylated. The temperature rises to about 150 °C; two thirds of the resulting solution of triethylaluminum in kerosine (concentration about 50%), is returned to the hydrogenation step, while the other third is centrifuged and the supernatant is distilled at about 50 mm Hg. This method of purification is much more reliable than filtration, and has the added advantage that not only the unconverted aluminum particles, but also metallic impurities and the alloyed metal are retained. The result is that very pure alumina is obtained as by-product.

## Growth Reaction

The growth reaction is carried out continuously at about 120 °C and at an ethylene pressure of 100 atm[19]; the m value, *i.e.* the average number of ethylene molecules reacting per Al–C bond, can be varied. The process can therefore be adjusted to meet the market requirements, in spite of the difference in the chain lengths of the alcohols. The ethylene used has a purity of about 99%.

The reactor is a steel tube (free from Ni and Cr) which widens towards the end to allow for the increasing volume of the reaction mixture. The ethylene is injected at about 10 to 15 points. The heat-transfer agent is n-heptane at a pressure of about 0.5 atm gage. Settling out of polyethylene is only slight; the polymer can be removed by passing through hot kerosine.

## Oxidation and Purification

The oxidation is carried out with air in stirred reactors having a capacity of about 40 m³, and at 40 °C and 2 atm gage. The reaction is rapid at first, but slows down considerably towards the end, so that the complete oxidation of all the Al–C bonds is not easily possible. Thus in order to minimize side reactions and secondary reactions, the process is carried out to conversions of about 85 to 90%, the end-point being checked by the oxygen content of the exhaust gas.

Before the aluminum alkoxide is hydrolysed, the solvent and the by-products formed during the oxidation (mainly esters) are removed by a two-stage flash distillation at 260 °C and 100 and 50 mm Hg with hydrogen as the stripping gas[20]. Under these conditions the unoxidized Al–C bonds are simultaneously cracked, and the aluminum alkoxide mixture is obtained as the residue. The head product from this distillation can be regenerated and reused as the solvent.

## Hydrolysis

The aluminum alkoxide mixture can be hydrolysed in acidic, as well as in neutral or alkaline media. The simplest method is hydrolysis with sulfuric acid, since only two easily separable phases are obtained in this case. However, CONDEA decided in favor of hydrolysis in a neutral medium, in which aluminum oxide hydrate occurs as a by-product.

The alkoxide mixture and demineralized water (1:1.5) are injected into the reactor (about 15 m³) at about 100 °C. The alcohol mixture formed is removed at the head of the reactor and led to the distillation columns. The aluminum oxide hydrate is taken off at the bottom of the reactor. A two-stage

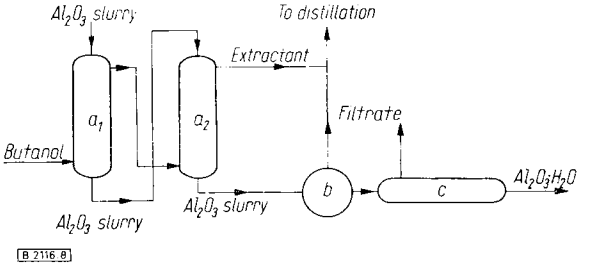

Fig. 8. Scheme of the extraction and processing of the hydrated alumina slurry. $a_1$,$a_2$) extractors, b) filter, c) drier.

[18] U.S.-Pat. 3 104 252 (Feb. 26th, 1960); Continental Oil Co.

[19] Cf. *K. Zosel*, Brennstoff-Chem. *42*, 321 (1960).

[20] U.S.-Pat. 3104251 (July 7th, 1960), Continental Oil Co.

extraction is carried out with butanol saturated with water, followed by filtration at 100 °C and drying. The extracts and the filtrate are led to the distillation plant (Fig. 8).

The aluminum oxide hydrate $Al_2O_3 \cdot H_2O$ obtained has a high purity (*e.g.* $Fe_2O_3$ *ca.* 70 ppm, $SiO_2$ *ca.* 50 ppm, and $Na_2O$ *ca.* 90 ppm).

### Distillation

A multi-stage predistillation is carried out in which first ethanol, then water, and finally butanol are distilled off. The alcohol mixture is resolved in several 30-plate columns about 35 m high. The fractions generally obtained are hexanol, octanol/decanol, dodecanol/tetradecanol, and hexadecanol/octadecanol. The residue (about 10%) is a mixture of higher alcohols, higher esters, and paraffins, which are difficult to separate by distillation.

### Reaction Products

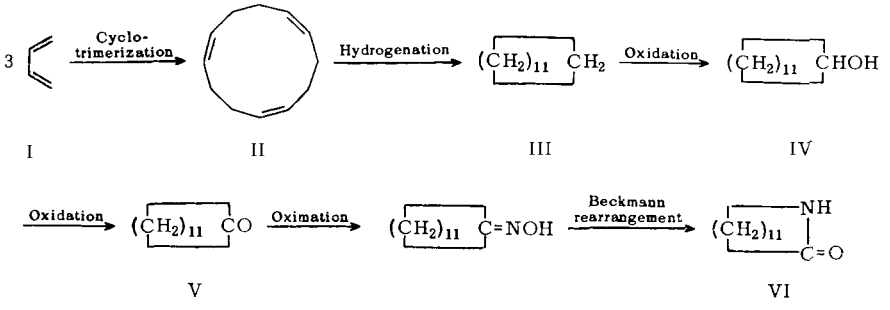
The Alfols obtained are characterized by their freedom from branching and by their low contents of impurities. The lower Alfols (6 to 10 C atoms) can be used for the production of plasticizers for PVC processing; higher Alfols (12 to 18 C atoms) are used, *e.g.* in the form of the sulfates or the products of reaction with ethylene oxide, as biodegradable detergents.

## Alcohols by Oxidation with Air

Air oxidation of unbranched paraffins and cycloparaffins proceeds by random attack on the methylene groups [21,22], *via* the hydroperoxides, to give a mixture of secondary alcohols and ketones. The ketones in particular are subject to further oxidation, and the result is a complex mixture of alcohols, ketones, carboxylic acids, esters, *etc.* In the presence of boric acid, the reaction can be directed predominantly towards the alcohols [23]. Since the alcohols are obtained in this case as esters of boric acid, they are protected against further oxidation. By-products are mainly the corresponding ketones.

The products obtained with straight-chain paraffins are secondary alcohols [24], which can be used as esterifying components for plasticizers, as well as for the preparation of detergents. The straight-chain paraffins can be obtained from petroleum fractions, *e.g.* by the molecular sieve method used by the British Petroleum Company [25], or by the Edeleanu urea-addition method [26].

*F. Broich* and *H. Grasemann* [27] studied the oxidation of cyclododecane III to cyclododecanol IV, which is then converted by a Beckmann rearrangement *via* cyclodecanone and its oxime into ω-laurolactam VI. Cyclododecane can be prepared from butadiene I *via* cyclododecatriene II [28]:



The industrial air oxidation of cyclododecane is carried out at 150 to 160 °C in the presence of about 6% of boric acid. The reaction is carried to a conversion of 20 to 25% (about 9% per hour), and the yield is about 82% of cyclododecanol/cyclododecanone. The ratio of alcohol to ketone is about 6–8:1.

The alcohol is recovered by distilling off unchanged hydrocarbon and hydrolysing the residue. The boric acid is recovered from the aqueous phase. The alcohol/ketone mixture obtained by distillation of the organic phase is dehydrogenated. A simplified scheme of this process is shown in Figure 9.

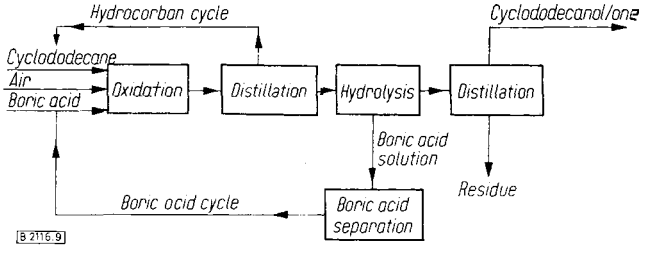


Fig. 9. Simplified scheme for the production of cyclododecanol from cyclododecane.

A plant with an annual output of 5000 tons is being operated by Chemische Werke Hüls AG, Marl (Germany).

Contrary to the procedure described above, no boric acid is present during this oxidation of cyclohexane [29], which is carried out at 140 to 155 °C and 8 to 15 atm; about 50 ppm of a cobalt salt is added as catalyst. Residence times of 10 min to 2 hours give conversions of 6 to 8%. Higher conversions give appreciably lower yields of cyclohexanol/cyclohexanone (1:1). Under the conditions described, the yield is about 60 to 70%. The principal by-products are adipic, glutaric, and succinic acids.

The alcohol/ketone mixture is dehydrogenated either to cyclohexanone or to phenol or oxidized to adipic acid. The flow sheet of a plant is shown in Figure 10.

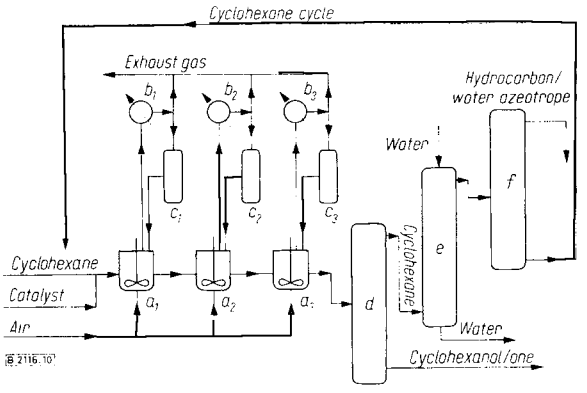

Fig. 10. Scheme of the production of cyclohexanol/cyclohexanone by air oxidation of cyclohexane [30]. $a_1$ to $a_3$) reactors, $b_1$ to $b_3$) coolers (heat exchangers), $c_1$ to $c_3$) settlers, d) cyclohexanol tower, e) wash column, f) cyclohexane tower.

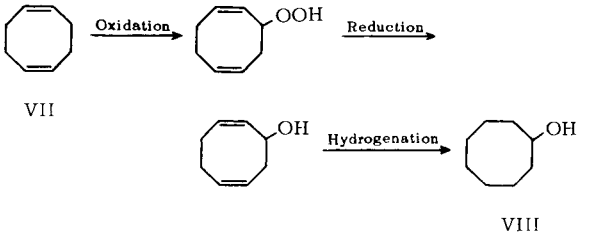
In another procedure proposed by *P. Baumgartner et al*[31] for the production of cyclic alcohols, cyclooctadiene VII and cyclododecatriene, which can be obtained by the cyclodimerization or cyclotrimerization of butadiene[28], are converted into hydroperoxides by oxidation with oxygen at 60 to 65 °C. After reduction, *e.g.* with sodium sulfite, the unchanged hydrocarbons are distilled off and the oxidation products are hydrogenated, *e.g.*:



The yields of cyclooctanol VIII are about 80 to 82%, those of cyclododecanol about 70%.

No industrial application of this process has so far been reported. The cost would probably compare unfavorably with that of the oxidation *e.g.* of cyclododecane in the presence of boric acid, mainly because of the reduction step.

*I am grateful to Dr. Broich, Chemische Werke Hüls AG, and to Dr. Kroeper, Badische Anilin- & Sodafabrik AG, for information supplied.*

# Technology of the Microbiological Preparation of Organic Substances

BY DR. R. MÜLLER AND DR. K. KIESLICH

SCHERING AG, BERLIN-CHARLOTTENBURG (GERMANY)

*The preparation of organic substances with the aid of the enzyme systems of microorganisms has become competitive as a result of recent progress in the technology of fermentation. The relatively high cost of apparatus and the lower production capacity of microbiological plants in relation to the plants used in purely chemical processes are offset in many cases by the advantages of biological methods (reactions at conventionally inactive positions in the molecule, stereospecific substitutions, coupling of several reactions, mild reaction conditions, possible use of waste products).*

The biochemical capabilities of microorganisms have been utilized in industry for only about 30 years. An exception is the old fermentation industry: empirically discovered methods for production of vinegar, sour milk, and alcoholic beverages, as well as the methods of the indigo-dyeing industry, have been known for centuries. The ability of microorganisms to cause fermentation was discovered by *Pasteur*[1].

Chemically defined products can be produced in two ways by the enzyme systems of microorganisms:

## 1. By Microbiological Transformation of Substrates

A compound is added to the growing or resting cell culture, and after a time in contact with the intracellular or extracellular enzyme, the product is recovered from the culture broth. In this respect glucose and other carbohydrates, which are transformed or broken down to smaller metabolites in the course of the normal respiratory or fermentative metabolism of the cell, may be regarded as substrates.

## 2. By Microbiological Synthesis from Nutrients

The enzyme systems in the cell convert the nutrients into suitable fragments, from which they then synthesize macro-

[1] *L. Pasteur*: Mémoire sur la Fermentation Acétique. J. F. Bergmann, Munich 1864.

molecular metabolites, which are stored in the cell or secreted into the culture broth.

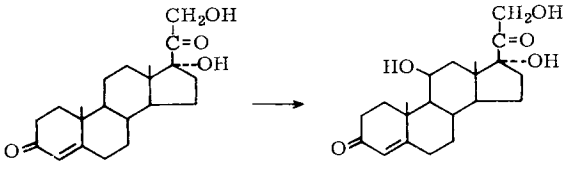
## Microbiological Transformations

The first specific transformations, such as the hydrolysis of starch [2] and the reduction of chloral to trichloroethanol [3], to be discovered after fermentation reactions, were found at the beginning of the 20th century. However, these microbiological reactions were only of academic interest.

It was only in 1934 that the conversion of sorbitol into sorbose [4] attained such importance as an intermediate in the synthesis of vitamin C that it became the first microbiological reaction to be carried out on the industrial scale [5].

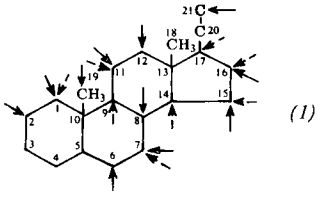
About this time, special fermentation processes were discovered or developed further, with the result that it became possible to produce glycerol, isopropanol, acetone, or butylene glycol economically by microbiological methods. These methods are based on the enzymatic transformation of glucose or of polysaccharides yielding glucose on fermentation. However, some of these fermentation products can now be more advantageously obtained by chemical methods.

Further developments received special impetus as a result of the discovery in 1952 that steroids are hydroxylated in position 11 by some strains of fungi [6].



This discovery formed the basis of an economical method for the production of adrenocortical hormones from other steroids. Many microorganisms were subsequently studied in relation to their action on steroids, and many of the reactions were found to be remarkably stereospecific.

It can be seen from the formula of pregnane *(1)* that α- or β-hydroxylation is possible on almost every carbon atom [7]. The direction of hydroxylation, indicated by arrows, depends on the microorganism used.



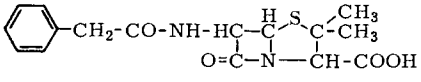
*(1)*

In addition to microbiological hydroxylation, other types of reaction, such as the oxidation of hydroxyl groups, the reduction of keto groups, the hydrolysis of ester groups, and the isomerization and introduction of double bonds, were discovered [8]. Of these reactions, 1,2-dehydrogenation has gained particular industrial importance in the production of prednisolone from hydrocortisone and of prednisone from cortisone.

Many microbiological reactions are known outside the steroid field [9], but few of these have found industrial use. Those that have (cf. Table 1) include the oxidation of naphthalene to salicylic acid, and the cleavage of diaminopimelic acid to lysine and of penicillin to 6α-aminopenicillanic acid [11].

## Microbiological Synthesis [10]

The first isolation of a microbial metabolite on the industrial scale was probably that of ergosterol. However, the special importance of microbial metabolites appeared only with the discovery of penicillin *(2)* [12]. The development of a process for the industrial production of



*(2)*

this, the first antibiotic to be used clinically, was extremely difficult; the problem was solved on the basis of studies by *Chain* and *Florey* [13]. The success of this work was due largely to the switch from the original surface culture to the submerged process, and to the complete exclusion of contaminating organisms. Other important antibiotics including streptomycin, chloramphenicol, erythromycin, tetracyclin, novabiocin, and actinomycin were isolated as microbial metabolites during the 1940's and 1950's [14], and this provided the final drive for the development of the fermentation industry.

## Isolation of Enzymes [15]

The isolation of intracellular enzymes generally involves cytolysis, and is therefore often very expensive. It is possible only in rare cases to extract intracellular enzymes from undamaged cells with solvents. With

*Notes*: 1. Only one microorganism is mentioned for each process, though for some processes several are suitable.

2. In connection with the steroid transformations, only the most important processes are mentioned. The analogous reactions on improved corticoids and the microbiological intermediates in the production of sex hormones are not listed.

3. In connection with the antibiotics listed, it should be noted that the penicillin and tetracyclin groups include several commercial products with structural variants. Some 35 microbiologically produced antibiotics are being marketed at present.

A total of 2100 tons of antibiotics, with a value of $345 million, was produced in the USA in 1963.

extracellular enzymes, on the other hand, the processes involved are simpler, since these enzymes are obtained by separation from the microorganisms by the methods used in the production of antibiotics.

Table 1 shows the enzymes produced in the fermentation industry. An important example is the production of glucoamylase, which degrades starch to dextrose [16]. The yield in this process is reported to be 100 %, whereas that obtained on cleavage with hydrochloric acid is only 86 %.

## Advantages of Microbiological Methods

### 1. Microbiological Transformations

a) Reactions at positions in the molecule at which, owing to insufficient activation, chemical changes can be brought about only by multi-stage processes or not at all.

b) Stereospecific introduction or modification of substituents; it is even possible to obtain optically active structures from optically inactive precursors.

c) Coupling of several reactions with the aid of a microorganism whose enzyme systems catalyse several reaction steps.

d) Mild reaction conditions for substances sensitive to heat, acids, or alkalis, that give unsatisfactory yields in chemical processes, or that require the use of additional reactions in order to protect labile parts of the molecule.

### 2. Microbiological Synthesis

a) The biosynthetic production of complex structures proceeds in most cases as a one-step process.

b) The raw materials are usually cheap substances such as carbohydrates, waste products containing proteins, and inorganic salts.

## Selection and Preparation of Microorganisms

It is of the utmost importance that a suitable strain of bacteria [17] should be chosen for a given process. Un-

[16] *M. Sinclair*, Chem. Engng. *72*, 90, (1965).

fortunately, however, the biological classification of microorganisms gives no information about their enzymatic properties. For this reason new microorganisms are often isolated from soil and water samples. However, this search for strains is frequently expensive. For example, in the examination of 10000 actionomycetes isolated from soil samples, 2500 antibiotically active strains were found, but only ten of these gave new compounds, and only one of these compounds was clinically useful [18].

In many microorganisms that originally give unsatisfactory conversions or metabolite yields, physical or chemical treatment can cause mutations and lead to a marked increase in enzymatic activity.

The enzyme balance of any microorganism can also be controlled within certain limits during fermentation; investigation of this control requires many experiments, owing to the large number of variables involved (composition of the culture medium, temperature, pH, aeration, addition of inhibitors or promoters, age of the culture).

Every fermentation experiment begins with the cultivation and preparation of the inoculum, which is prepared by rinsing down of agar slants or by suspension of lyophilized cultures in physiological saline or nutrient solution. The microorganisms, the quantity of which is still small, are transferred into large Erlenmeyer flasks approximately $^1/_4$-filled with nutrient solution and shaken for a few days. These inoculum cultures are the starting cultures for the industrial fermentation.

## Industrial Fermentation

The production of organic substances by means of microorganisms requires a technology that provides optimal growth conditions on a large scale. It is essential for this growth that suitable nutrient solutions should be available to the organism in a substantially sterile state and at an optimal growth temperature. A sterile air supply must be provided, except in anaerobic processes, which are relatively rarely used in industry. It must also be possible to add starting materials or growth promoters and nutrients during the cultivation. The vessels required for the culture are termed fermenters.

In the processing that follows fermentation, conventional methods such as filtration, extraction, distillation, adsorption, freeze-drying, recrystallization, *etc.*, are used to isolate the products from the culture broth and to purify them.

## Provision of Production Facilities

Low-pressure steam at a maximum pressure of 4 atm gage is adequate for the sterilization of the nutrient solutions. Significantly, however, marked peaks occur in the steam consumption when discontinuous sterilization is used. For heating the nutrient broth to 121 °C in about 1 hour, a 55 m³ fermenter [*] requires 8 to 10 tons of steam. The heating time may be increased, but then poor use is made of the fermenter capacity.

The use of cooling towers for the production of cooling water is generally adequate in Central Europe for growth temperatures of 28 °C or more. In small cooling-water systems, however, the hot water at about 90 °C proceeding from the normal sterilization must not be passed directly into the cooling tower, which is normally not designed for such a high feed temperature. In this case an additional balancing tank is required.

The nutrient solutions are normally prepared with drinking water, the purity of which, even in the biological respect, is constantly supervised. Since disturbances of the biological development, and hence of production, are always to be expected, chemical contamination of the water is very unlikely to be the cause of such disturbances if tap water is used. The chlorine in the mains supply of large towns has not so far been found to interfere, since it escapes during the sterilizing process.

The use of cold water (about 4 °C) for the termination of a reaction is generally unnecessary. With unstable fermentation products, the capital saved on the cooling plant can be much better used to ensure rapid processing.

Modern fermentation plants are protected against explosion. Consequently, fermentative processes can often be stopped by the addition of even a combustible extracting agent. Further, the quantities of solvents required for the addition of starting materials to the culture are generally so large that protection against explosion must be provided in any case.

The oxygen required for the respiration of the microorganisms is introduced as compressed air, the carbon dioxide formed being removed with the exhaust air. In strictly anaerobic processes, the oxygen must be displaced by nitrogen. In the case of facultative anaerobes, the oxygen in and above the liquid is consumed first.

The required pressure of air is determined mainly by the hydrostatic pressure of the column of liquid in the fermenter, the filter resistance, and the pipeline resistance. The pressure drop across a glass-wool filter is about 0.1 to 0.5 atm. No special resistance is normally provided in the air-distributing system of the fermenter. For 50 to 100 m³ fermenters, this gives a preliminary air pressure of 1.5 to 3 atm gage. The turbocompressors used in the yeast industry cannot be used at these relatively high pressures. However, the quantities of air required are not generally as large as in the yeast industry. Consequently screw compressors, which are available in all the required power outputs, are very well suited for the pressure range indicated. These compressors deliver oil-free air, and unlike piston-type compressors, they have no parts that are subject to wear, apart from the ball bearings.

[17] Microorganisms can be obtained from the following collections: 1. American Type Culture Collection (ATCC), Rockville, Maryland (U.S.A.); 2. Agricultural Culture Collection, Northern Utilization Research and Development Div. (NRRL), Peoria, Illinois (USA); 3. Centraalbureau voor Schimmelcultures (CBS), Baarn (Netherlands).

[*] The volumes quoted for fermenters are net volumes (content of liquid). The gross volume is 10 to 15 % higher.

## Production and Sterilization of the Nutrient Solution

The principal components of the nutrient solution are glucose (solid or as syrup), corn steep liquor, yeast extract, malt extract, molasses, soybean meal, inorganic phosphates, inorganic nitrates, and metal salts. The simplest method of preparing and sterilizing the nutrient solution is to fill the fermenter with water, add the nutrient components, and heat at 120 °C for 20 to 40 minutes. Sterile compressed air must be supplied during cooling. Otherwise, non-sterile air is sucked through leaks owing to the decrease in pressure following the condensation of steam. The nutrient solution may be heated (a) by direct injection of steam, in which case the water that condenses is lost as far as the boiler-house is concerned, or (b) by indirect heating with a steam coil, in which case the time required for heating is considerably increased. In case (a), the dilution with condensed water must be taken into account when the fermenter is being charged with water and nutrients.

Continuous sterilization is preferred on the grounds of energy saving. This gives a 70 to 80 % saving in steam and cooling water, and avoids large peaks in consumption. The possibility of continuous sterilization depends on the fact that the sterilization time at 120 °C is about 20 min, whereas at 135 °C only 4 to 8 min are required [19,20]. At the same time, the short-time sterilization should be a very mild treatment to ensure that decomposition is only slight, and hence that the solution obtained will have a particularly high content of thermally labile nutrients.

Figure 1 shows the flow sheet of a continuous sterilization plant. The liquid nutrients are added by weight. The water required to give a nutrient solution having a concentration of 10 to 50 times that used in the transformation is placed in the mixing vessel, and is pumped through a solid elevator by a circulating pump. The liquid or solid nutrients are introduced into the hopper of the solid elevator, and are transported and mixed by the water jet.

Acid or alkali is added so that the pH of the nutrient solution after sterilization favors the development of the microorganisms.

A dosing pump is used to convey the concentrate into the transfer vessel of the sterilization plant, where it is mixed with the required amount of water taken directly from the mains supply. The resulting solution, which is now at the correct concentration, is preheated in the heat exchanger I by the solution that has already been sterilized, the temperature of which is about 135 °C. In the heater, the preheater solution is brought to the sterilization temperature with steam. The solution is kept at the sterilization temperature for a predetermined average time by introduction at a constant rate into a heat reservoir, which consists of a pipe coil of suitable dimensions. The sterile nutrient solution flows through the heat exchanger II and the cooler I, which cools it to the desired final temperature, and it then passes into the fermenter.

The effectiveness of the continuous sterilization process depends on the fact that if the sterilization temperature is not maintained, no non-sterile solution can enter the sterile part of the plant. This is ensured by monitoring the temperature downstream from the heater; if the temperature becomes too low, magnetic valves are operated to prevent the entry of nutrient solution into the heat retainer, with the result that the solution is recirculated. The water supply is then cut off by a float valve and the dosing pump switched off by a maximum-level electrode in the transfer vessel. In this case the passage of the solution through the plant cannot begin again until the correct sterilization temperature has been reached.

The sterilization efficiency of a plant of this type is best checked by filling a large fermenter with sterilized nutrient solution, which is allowed to stand for 40 to 60 hours at about 30 °C without inoculation. If, for example, the sterilization plant leaves one living microorganism per liter, this cannot be detected by the normal sterility controls (tube or plate test). When allowed to stand in the fermenter, however, the remaining microorganisms propagate and can be detected by the usual methods. This also provides a check on the sterility of the fermenter itself.

A third method for the production of the nutrient solution consists in the sterilization of the nutrient concentrate by heat in the fermenter. The water used for sub-

sequent dilution is freed from microorganisms by sterile filtration and added to the concentrate. Sterile filters with filtration rates of 20 to 40 $m^3$ of water per hour (filter area 30 to 50 $m^2$) are arranged in series. However, the reliability of the filtration depends on the absence of pores and cracks in the filter layers, for which there is no reliable check method. It must also be borne in mind that all nutrient solutions have a certain limiting concentration beyond which sterilization by heat leads to excessive decomposition, with the result that the growth of the microorganisms is inhibited. Frequently, however, some thermal decomposition is essential for optimal culture conditions [21], and heat sterilization is absolutely necessary in these cases.

In a fourth method of sterilization, 0.05 to 1 % of β-propiolactone is added to the nutrient solution. Even spores are destroyed within 1 to 3 hours. The propiolactone is converted more or less rapidly (depending on the temperature) into harmless propionic acid, so that the solution can then be inoculated. The use of β-propiolactone in large quantities of liquid is costly; it is therefore particularly suitable for smaller quantities of solution where sterilization by heat or by filtration is not possible [21, 22].

## Operation and Construction of the Fermenter

The flow sheet of a fermentation plant is shown in Figure 2. Large production fermenters are linked with seed tanks and second-step seed tanks, the main difference between these being their capacity, cf. Figs. 3 and 4. The inoculum, which is prepared in the laboratory, is introduced under sterile conditions into the seed tank, which has a capacity of 250 to 5000 *l*. After a propagation time of 10 to 80 hours, depending mainly on the microorganism used, this culture broth is pumped, or forced with compressed air, through pipes that have previously been sterilized with steam into the next larger fermenter, which contains sterile nutrient solution. The volume of the preculture is about 10 % of that of the following stage. This procedure leads to a reduction of the proagation time and to optimal utilization of the plant. The growth of mycelium in a 50000 *l* fermenter with and without propagation in seed tanks is shown in Figure 5. The quantity produced in a given time with precultures is about twice as large, since the time required for the cultivation of the microorganisms in the reaction tank is shorter. Similar diagrams are obtained when instead of the weight of fungus the bacteria count per ml is given for bacterial fermentations.

Fig. 3. Seed tank.

The fermenters and cooling coils must be made of chrome-nickel steel, irrespective of their size. Many fermentations must be carried out at relatively low pH. Moreover, when indirect sterilization is used, the cooling coils are corroded by the condensate so severely that they have to be replaced after 5 to 7 years when made of normal steel.

The diameter: height ratio of the fermenter is between 1:2 and 1:5. A slim design leads to a relatively long residence

time of the air in the liquid, and so favors gas exchange. Moreover, in this design the quantity of air passing per unit of surface area is relatively high, so that strong turbulence can be produced, with a consequent saving in stirring. On the other hand, a tall column of liquid requires greater compression work in the production of the compressed air.

The temperature is generally controlled by adjustment of the cooling-water supply, since the heat produced by stirring and by the biological process must be dissipated. It is impossible to specify accurately the cooling surface of a fermenter, since the temperature of the cooling water, the sterilization process, the cultivation temperature, the energy supplied by stirring, and the nature of the microorganisms used can differ widely in the various processes. Fermenters with capacities of up to 500 *l* are normally fitted with a cooling jacket, while internal cooling coils (cf. Fig. 6) or welded half-tubes are used in larger units. Though optimal cooling areas can be obtained with internal cooling coils, these are sometimes undesirable, since they divide the space inside the fermenter. Unfavorable circulation conditions can arise between the cooling coils and the walls of the fermenter, leading to poor aeration and temperature control when fungi are being cultivated without stirring. In yeast fermentations, the heat of reaction can be so great that the culture broth must be pumped through another cooler for additional cooling. A cooling area of 50 to 70 $m^2$ may be taken as an average for a 55 $m^3$ fermenter. With a coolant temperature of 14 °C and a water consumption of 140 to 200 $m^3$ this fermenter can be cooled from 120 °C to a working temperature of 30 °C within 4 to $2^1/_2$ hours without stirring. The consumption of cooling water for the dissipation of the heat of fermentation from a 55 $m^3$ fermenter is 0.5 to 2 $m^3$/hour for bacteria and 2 to 10 $m^3$/hour for fungi.

Fig. 6. Interior of a reaction tank.

Aeration is generally effected with pipe coils fitted at the base of the fermenter, with suitable holes having a diameter of at least 3 mm. The volume of air required per minute is 0.05 to 1.5 times the volume of the nutrient solution, depending on the nature of the fermentation. The air is sterilized by filtration through layers of glass wool or active charcoal, which are themselves sterilized with steam before each run. The air velocity in glass-wool filters should be about 0.3 to 0.8 m/sec [23–26].

The air bubbles can be dispersed by stirring, and the resulting increase in surface area leads to an increase in the oxygen supply to the fermenter. Flat-blade turbine impellers with a peripheral velocity of 2.5 to 4.5 m/sec are often used. Continuous adjustment of the stirrer speed is unnecessary in production fermenters, and reasonable latitude can be achieved by the use of V-belt pulleys of different sizes. Excessive stirring can lead to failures, particularly in fungal fermentations when the mechanical stresses on the mycelium are too great.

Foaming, which is strongly dependent on the nature of the nutrient solution, the microorganism, and the stage of development of the culture, must in most cases be controlled for at least part of the time by the addition of antifoam agents. Otherwise the loss of liquid is high, or the air supply for aeration must be reduced to such an extent that the growth of the microorganisms is inhibited by lack of oxygen. Examples of antifoam agents used are oils (lard oil, soybean oil), fatty acid derivatives, silicones [29], and polypropylene oxide or

[29] Chem. Engng. *65*, 11, 54 (1958).

polyethylene oxide derivatives; large quantities of these agents can interfere both with the aeration and with the subsequent isolation of the fermentation products. The foam height is controlled by electrodes which either give a signal to the operator or cause automatic addition of antifoam agent, depending on the frequency of the additions. In some cases the oils added also act as nutrients.

The substrates, *i.e.* the chemical precursors of the desired end products or the special nutrients or growth promoters, are added during the culture time from a substrate container of a suitable size fitted with a stirrer and heating and cooling equipment for the dissolution of the substances. The solution is transferred to the fermenter by means of compressed gas or by pumping. Organic solvents that are frequently used are methanol, ethanol, dimethylformamide, methyl cellosolve, and acetone. The solution is most easily sterilized by passage through a layered filter. If filtration is impossible, *e.g.* in the case of suspensions, other sterilization processes must be used.

The sterility of a fermenter depends primarily on the preculture and on the air filter. However, structural details of the fermenter are also involved. One source of contamination is fine fissures or gaps (*e.g.* flange seals) filled with nutrient solution and microorganisms. If the gaps or flange seals cannot be properly heated during sterilization, it must be expected that the surviving microorganisms will subsequently propagate and grow into the inertior of the fermenter. There is also a danger that the microorganisms in somewhat cooler parts of such gaps may, by exposure to a sterilization temperature that is only slightly too low, become adapted to higher sterilization temperatures and longer times. Further, air-filled cavities can sometimes be formed in these gaps. However, the times and temperatures normally used in the sterilization of fermenters are valid only for an atmosphere of pure steam, and may be increased by up to 200 % in air. Such sources of contamination must be avoided as far as possible in construction. Where flanges are used, additional steaming is sometimes required to ensure sterility. For example, in fermenters having a drain valve in the base, the resulting pocket of liquid cannot normally be brought to the sterilization temperature. This part of the fermenter must therefore be specially heated by the introduction of steam through an open tube that reaches to the lowest point in the pocket; the steam must also be led up to the valve from the outside of the discharge pipe.

Non-sterility can have the following disadvantages, either individually or simultaneously:

1. The normal yield is not obtained.

a) the substance to be transformed by fermentation may be transformed too slowly or only partially, or it may be decomposed.

b) The product formed may be destroyed again.

2. Excessive foaming leads to a need for extra antifoam agent or reduction of the essential aeration.

3. The filtration of the broth before recovering is upset by the formation of slimy substances or by partial decomposition of the mycelia.

4. Extraction is made difficult by formation of an emulsion.

5. The end-products are contaminated with toxins.

The fermentative transformation is controlled analytically. The sterility and the development of the microorganisms are also checked. Since the processes take a long time, the temperature, the pressure or quantity of air, and if necessary the pH are plotted by a pen recorder. The fermentation times range from 8 to 150 hours. No general rules can be given regarding yields and throughputs. In the transformations of steroids, for example, the yields are often around 90 %, and from 10 to 800 kg of pure product are obtained from a 55 $m^3$ fermenter.

The advantages of continuous operation, such as economy of labor, optimal utilization of the fermentation capacity, and faster transformation owing to the fact that the most favorable physiological conditions of the microorganisms are maintained, are subject to the following conditions and disadvantages: The microorganisms must not lose their original enzymatic properties at faster rates of multiplication. However, highly cultivated strains very often degenerate on uninterrupted cultivation. Moreover, the slightest non-sterility causes much greater interference, since this cannot be eliminated. Where several substances are being produced simultaneously it is also more difficult to adapt production to suit the market. Further, owing to the greater research investment required, continuous operation only lends itself to long-term large-scale production. Consequently, continuous fermentation processes are not yet commonly used in industry [30].

## Isolation of the Fermentation Products

Whereas the fermentation scheme can be used for all fermentation processes, only two isolation methods can be outlined in this paper, owing to the wide range of substances that may be involved; however, the processes described include the essential steps. The first process can be used in most steroid transformations and for some antibiotics, such as penicillin. The second method is suitable *e.g.* for the isolation of streptomycin. Sterility is not absolutely essential for the processing, provided that the products are not to be isolated for direct consumption.

### Method I

After fermentation the mycelium is separated by filtration. Filtration rates of 2 to 5 $m^3/h \cdot m^2$ are obtained with a vacuum rotary filter (cf. Fig. 7), which uses a cord take-off in the case of easily filtered mycelium. If the mycelium contains large quantities of slimy matter, so that filter aids (*e.g.* celite) have to be used, the filtration rate is about 0.5 to 2 $m^3/h \cdot m^2$. Depending on the

process, the mycelium, the filtrate, or both are then processed further. Figure 8 shows the flow sheet of such a process, in which the product is isolated both from the mycelium and from the culture broth.

out of the mycelium. When the extraction is complete, the mycelium is freed from adhering extraction solvent by distillation.

The desired product is transferred from the culture filtrate, or from the culture broth in the case of bacterial fermentations, into a water-immiscible solvent (*e.g.* methyl isobutyl ketone, amyl or butyl acetate) by countercurrent extraction. This operation is nearly always carried out in multistage centrifugal extractors. The construction of the three principal types is shown in Figure 9. Type I, which has a horizontally rotating drum, has the advantage of considerable latitude with regard to the drum size, owing to its double bearing, so that total throughputs of up to 100 m³/hour are possible with the largest units of this type. The disadvantage that the drum had to be cleaned and inspected through only a few small holes has been eliminated in recent designs. The drum is no longer completely welded together, but is fitted with a screw cover. Type II

*a* reservoir for culture broth, *b* chopper for mycelia, *c* extraction tank, *d* distillation vessel, *e* cooler, *f* ion exchanger, *g* centrifugal extractor, *h* adsorption vessel, *i* desorption vessel.

After separation by filtration, the mycelium is chopped and pumped into the extraction tank with the extracting agent. The mycelial extract is filtered through a mesh, and the extraction is repeated. In the isolation of steroids, for example, hot extraction is not recommended, since too many impurities are then dissolved

operates on the same principle but has a vertical axis and is easily dismantled for cleaning. However, the maximum throughput is only 20 m³/hour. Type III is particularly useful when small quantities of solids are to be separated from the culture broth during the extraction. However, the maximum throughput with the largest three-stages type is only 6 to 8 m³/hour.

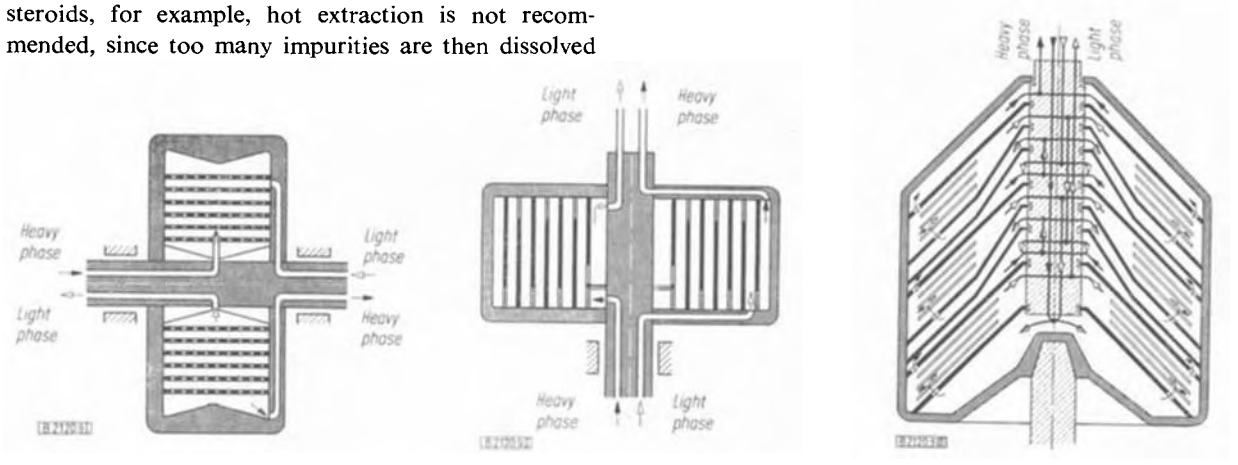

Fig. 9. Centrifugal extractors (Types I to III).

In favorable cases the substance to be isolated can be concentrated by a factor of 15 during the extraction. At the same time, many components of the nutrient solution and many metabolites are retained in the aqueous phase. Penicillin, which contains a carboxyl group, can be obtained pure by repeated pH-controlled partitioning between water and organic solvent, followed preferably by freeze-drying from an aqueous concentrate.

In the case of steroids, the extract obtained is evaporated under moderate vacuum until crystallization occurs. The thin-film evaporators with a rotating wiper system, which have been developed over the past 15 years, are particularly suitable for this purpose. These evaporators have a very high distillation capacity. The substance is heated for only 10 to 30 sec, and the movement of the wipers over the heating surfaces prevents incrustation by crystals that have separated out. The heating surfaces can be satisfactorily cleaned with weighted bronze wipers. The crystal suspension obtained in this way by single-stage or multi-stage evaporation is generally pumped directly into centrifuges without cooling. Depending on the process in question, the resulting crude crystals contain from 40 to 92 % of the desired substance, which is dried if necessary and purified by the usual methods.

### Method II

The microorganisms are removed from the culture broth with or without filtration aids. The pH is adjusted to a predetermined value if necessary, and the filtrate is then treated with active charcoal or ion exchangers. The added solids are filtered off and washed. After readjustment of the pH, the desired substance is desorbed, and the solids removed by subsequent filtration are returned to the process. The end-product is obtained from the extract in more or less pure form by evaporation, spray drying, or precipitation.

At high streptomycin contents, it is possible to dispense with the preliminary filtration, the original culture broth being passed directly through modified ion-exchange columns, where the active substance is absorbed [32].

The relatively large quantities of waste water from the extraction generally still contain some extraction solvent. For example, the solubility of methyl isobutyl ketone in water is 2 wt-%. In this case the solvent can be readily recovered as an azeotropic mixture (b.p. 87.9 °C, 24.3 wt-% of water). The waste water to be purified is passed, with heat exchange, to a single column (cf. Fig. 10), into which enough steam is blown to cause about 5 vol-% to distil over. The distillate separates into two phases in a settling vessel, and the

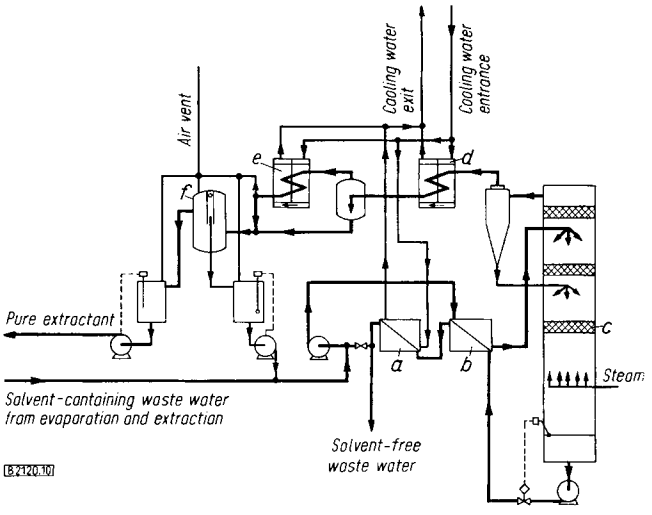

Fig. 10. Diagram of the waste-water treatment.
*a* cooler, *b* heat exchanger, *c* column, *d* condenser, *e* after cooler, *f* separation vessel.

upper phase is returned to the extraction-solvent reservoir. The aqueous phase, which is saturated with methyl isobutyl ketone, is returned to the waste-water distillation unit. The waste water residue from the column is used for heat exchange and is then passed into the sewage system (methyl isobutyl ketone content 0.01 %). With a plant of this type, 20 to 40 $m^3$ of waste water per hour can easily be cleaned, and the value of the solvent recovered far outweighs the cost involved.

The microorganisms obtained as by-products can sometimes be used as feed additives. In most cases, however, they present an appreciable waste and sewage disposal problem, except where large biological sewage farms are available [37].

*The present article is based partly on our own industrial experience. The authors are grateful to Ing. K. Brinkmann and Ing. K. Weber for their substantial design contribution to the construction of fermentation plants.*

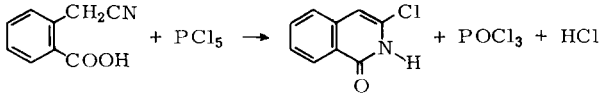
## New Synthesis of Derivatives of Isoquinoline and 1,3-Benzothiazin-4-one

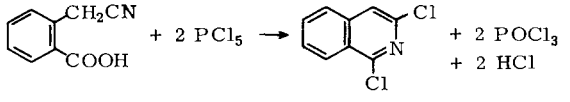
By Dr. G. Simchen

Institut für Organische Chemie und Organisch-Chemische Technologie der Technischen Hochschule Stuttgart (Germany)

When *o*-cyanomethylbenzoic acid *(1)* is treated with phosphorus pentachloride, 3-chloro-1-isoquinolinol *(2)* is at once obtained. If the reaction is carried out with 2 moles of phosphorus pentachloride in phosphorus oxide chloride as solvent, 1,3-dichloroisoquinoline *(3)* is formed by chlorination of the intermediate *(2)*.

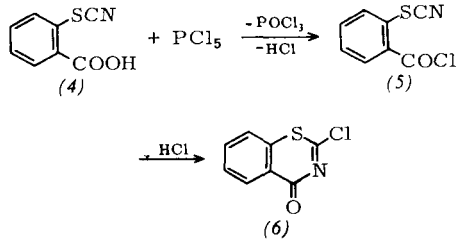


*(1)* *(2)*



*(1)* *(3)*

In order to determine the course of reaction we treated *o*-thiocyanatobenzoic acid *(4)* with phosphorus pentachloride under mild conditions. The *o*-thiocyanatobenzoyl chloride *(5)* [1] first formed then was cyclized to 2-chloro-1,3-benzothiazin-4-one *(6)* in the presence of hydrogen chloride at 60 °C. However, cyclization does not occur in the absence of hydrogen chloride. It seems to follow that cyclization of ω-cyanocarbonyl chlorides depends on acylation of the unstable imide chlorides formed as intermediates [2, 3].



*(4)* *(5)* *(6)*

*3-Chloro-1-isoquinolinol (q)* [4]

6.8 g (0.033 mole) of $PCl_5$ is added to 4.8 g (0.03 mole) of *o*-cyanomethylbenzoic acid in 25 ml of methylene chloride and the mixture is stirred for 2–3 hr first at 0 °C and then at room temperature, then kept overnight. The methylene chloride is distilled off and the residue recrystallized from water. Yield: 5.0 g (94 %), m.p. 218 °C.

*1,3-Dichloroisoquinoline (3)* [4]

A solution of 42.0 g (0.20 mole) of $PCl_5$ in 80 ml of $POCl_3$ is treated slowly with 16.1 g (0.1 mole) of *o*-cyanomethylbenzoic acid. The mixture is stirred for 2 hr at room temperature and 2 hr at the boiling point. The $POCl_3$ is distilled off at atmospheric pressure and the residue recrystallized from alcohol. Yield: 18.5 g (94 %), m.p. 120 °C.

*o-Thiocyanatobenzoyl chloride (5)* [1]

To a slurry of 7.7 g (0.043 mole) of *o*-thiocyanatobenzoic acid in 50 ml of $CCl_4$, is added 9.0 g (0.043 mole) of $PCl_5$ and the mixture is stirred for 2 hr at 0 °C and 6 hr at room temperature. The $CCl_4$ and the $POCl_3$ formed are distilled off in a vacuum, and the solid residue is taken up in benzene and precipitated with light petroleum. Yield: 7.8 g (92 %), m.p. 104–106 °C.

*2-Chloro-1,3-benzothiazin-4-one (6)*

A solution of 0.7 g (0.0035 mole) of *o*-thiocyanatobenzoyl chloride in 3 ml of dibutyl ether is treated with a saturated solution of HCl in diethyl ether. The mixture is heated for 4 hr at 60 °C. The product crystallizes on cooling. Yield: 0.5 g (71 %), m.p. 115–117 °C.

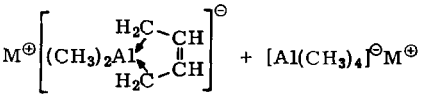
## Butadienedimethylaluminate Complexes

By Dr. H. Lehmkuhl

Max-Planck-Institut für Kohlenforschung, Mülheim/Ruhr (Germany)

Butadiene and its homologues react with alkali metals (M = Li or Na) with formation of salts $M_2^{\oplus}[C_4H_6]^{2\ominus}$, which immediately add further diolefin stepwise [1]. The butadiene dianion can be trapped as 2-butene by sufficiently acidic reagents, *e.g. N*-methylaniline.

On reaction of butadiene with alkali metal in an ether [$(CH_3)_2O$, THF, $(C_2H_5)_2O$] in the presence of an amount of trimethylaluminum-ether adduct equivalent to the metal, the butadiene dianion $C_4H_6^{2\ominus}$ probably forms an adduct *(1)* with the dimethylaluminum cation present in the dissociation-equilibrium mixture from trimethylaluminum [2, 3]. Suitable reaction conditions are alkali metal: $Al(CH_3)_3$:$C_4H_6$ = 2:2:1, −30 to +20 °C.



*(1)* *(2)*

This complex formation protects the dianion $C_4H_6^{2\ominus}$ from further reaction with butadiene. When the experiment is conducted in tetrahydrofuran with Li or Na, the product *(1)* is precipitated as large colorless crystals and can be purified by recrystallization from a small quantity of THF. The alkali tetramethylaluminate *(2)* formed in equivalent amount can be isolated by distillation of the solvent from the first filtrate, finally at 100 °C/$10^{-3}$ mm. The reaction with butadiene derivatives resembles the formation of alkali metal naphthalenedialkylaluminate and tetraalkylaluminate from alkali metal, naphthalene, and trialkylaluminum in ethers [4].

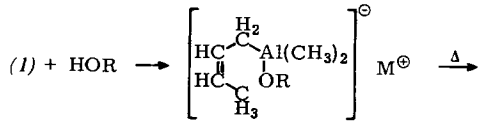
The compound *(1)*·4 THF readily loses 3 moles of THF in vacuum ($10^{-3}$ mm); at 90 °C under the same sonditions all the bound THF is lost. Compound *(1)* is insoluble in aliphatic hydrocarbons and benzene; it decomposes above 150 °C without melting. Its infrared spectrum includes a sharp C=C stretching band at 1580 $cm^{-1}$, this being at longer wavelength than for butadiene (1597 $cm^{-1}$) and indicating a strongly polarized double bond. The $^1$H-NMR spectrum of a solution of *(1)* in THF renders the proposed structure very probable [5]: it contains a well resolved triplet at $\tau$ = 4.86 for the two olefinic protions (a), a moderately split doublet at $\tau$ = 9.46 for the $CH_2$ protons (b) (intensity ratio a:b = 2:3.9), and a singlet at $\tau$ = 11.21 for the $CH_3$ protons (c) (intensity 6.5). For the analogous compounds to *(1)* from 2,3-dimethyl-1,3-butadiene the signal for (b) changes to a singlet at $\tau$ = 9.81 [$Si(CH_3)_4$ as internal standard: $\tau$ = 10].

The bonds[*] between the dianion $C_4H_6^{2\ominus}$ and the $[(CH_3)_2Al]^{\oplus}$ cation are very reactive; on oxidation with dry $O_2$ they are preponderatingly attacked before the Al–$CH_3$ bonds, butadiene being regenerated:

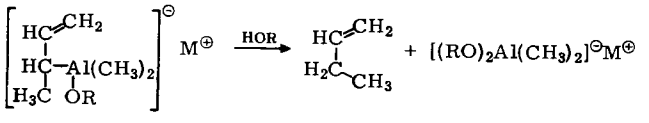
$$(1) + {}^1/_2\,O_2 \rightarrow CH_2{=}CH{-}CH{=}CH_2 + [:\ddot{O}{\rightarrow}Al(CH_3)_2]^{\ominus}Na^{\oplus}$$

(3)

The structure of the oxidation product *(3)* has not been conclusively elucidated. On alcoholysis of the Na compound *(1)*, 1-butene and at most 1 to 4 % of 2-butene are formed alongside methane; the proportion of 2-butene rises to 15 % for the Li compound. *Hoberg*[6] has recently reported an allylic rearrangement of aluminum compounds of the type R'R''Al–$CH_2$–CH=CHR to R'R''Al–CHR–CH=$CH_2$; an apparently analogous rearrangement by way of *(4a)* and *(4b)* evidently occurs on alcoholysis of compounds *(1)*:



(4a)



(4b)

The following considerations are also in favor of a reaction *via (4a)* and *(4b)*:

(a) On the basis of structure *(1)* (which is strongly indicated by the NMR spectra), only 1-butene can be formed if a rearrangement intervenes on hydrolysis. 2-Butene does not rearrange to 1-butene under the reaction conditions.

(b) Hydrolysis of compounds *(1)* with $D_2O$ affords $CH_2{=}CH{-}CHD{-}CH_2D$. The $CH_2D$ group can be identified mass-spectroscopically, and the CHD group infrared-spectroscopically. The NMR spectrum confirms the appearance of [3,4-$D_2$]-1-butene.

[*] The ionic structure seems justified because groups R (*e.g.* $CH_3$) that certainly are covalently bound to Al react with insertion of oxygen, yielding >Al–O–R, and, on the other hand, compounds such as naphthalenesodium that are certainly to be formulated as ionic are cleaved by oxygen with regeneration of the original hydrocarbon.

## Preparation of Bis(dialkylcarbamoyl)mercury Compounds by Carbonylation in Amines

By Prof. U. Schöllkopf and F. Gerhart

Organisch-Chemisches Institut
der Universität Göttingen (Germany)

Although carbamoylmetal compounds containing σ-bonded carbonyl groups may play a decisive role in metal-catalysed carbonylation of amines[1], it has hitherto not been possible to isolate such compounds[2]. We have now found that stable bis(dialkylcarbamoyl)mercury compounds (see table) are formed in accordance with Equation (a) when mercury(II) acetate and a tenfold amount (by weight) of a secondary amine are shaken with carbon monoxide for several days at room temperature. The excess of amine is removed in a vacuum and the residue is crystallized from benzene, ether, or tetrahydrofuran.

| $R^1R^2NH$ | $p_{CO}$ [atm] | $R^1$ | $R^2$ | Yield [%] | M.p. [°C] | $\tilde{\nu}_{CO}$ [$cm^{-1}$] | τ (N–CH–) |
|---|---|---|---|---|---|---|---|
| Dimethylamine | 60 | $CH_3$ | $CH_3$ | 43 | 148–149 | 1555 | 6.72 (s), 6.10 (s) |
| Diethylamine | 1 | $C_2H_5$ | $C_2H_5$ | 64 | 138–139 | 1575 | 6.29, (q), 6.58 (q) |
| Methylbenzylamine | 1 | $CH_3$ | $CH_2C_6H_5$ | 67 | 138 | 1560 | 6.83, 6.98, 7.17, 7.22, 5.12, 5.26, 5.40, 5.43 (each s) |
| Pyrrolidine | 1 | $(CH_2)_4$ | | 45 | 96 | 1530 | 6.20, (t), 6.62 (t) |
| Piperidine | 1 | $(CH_2)_5$ | | 25 | 102 | 1555 | 6.26 (t), 6.47 (t) |
| Morpholine | 1 | $(CH_2)_2{-}O{-}(CH_2)_2$ | | 20.5 | 196 | 1560 | 6.26 (m), 6.38 (m) |

$$R^1R^2NH + Hg(OAc)_2 \xrightarrow{CO} R^1R^2N{-}OC{-}Hg{-}CO{-}NR^1R^2 + 2\,HOAc \qquad (a)$$

The bis(dialkylcarbamoyl) structure and σ-bonded carbon monoxide are indicated by the result of the bromine cleavage (see below), by the carbonyl infrared bands, and by the NMR signals of the N–CH-protons (see table).

The compounds are stable towards concentrated sulfuric acid but decompose in dilute mineral acids:

$$(R^1R^2NCO)_2Hg + 4\,HX \rightarrow 2\,CO + HgX_2 + 2\,R^1R^2\overset{\oplus}{N}H_2 + 2\,X^{\ominus} \qquad (b)$$

The rate of decomposition ($\tau_{1/2}$) depends on the nucleophilicity of the anion. Thus if $R^1{=}R^2{=}C_2H_5$ (0.03 M; pH 4.75), $\tau_{1/2}$ in the presence of 0.56 M $Cl^{\ominus}$, $Br^{\ominus}$, or $I^{\ominus}$ ions amounts to 26, 4.2, and 0.4 min, respectively.

As shown by experiments with bis(dimethylcarbamoyl)mercury and bis(diethylcarbamoyl)mercury, the amino or carbamoyl group can be transferred to other atoms. For instance, with acetyl chloride we obtained *N,N*-diethylacetamide (59 %), with benzyl chloride, *N,N*-dimethylbenzylamine (23 %), and with bromine, *N,N*-diethylcarbamoyl bromide (72 %)[3].

## Synthesis of 6-Deoxy-D-gluco-dialdoheptose and Ring Closure to 8(a),10(a)-Dihydroxy-2,4,6-trioxaadamantane

By Dr. W. Meyer zu Reckendorf

Institut für Pharmazeutische Chemie,
Universität Münster (Germany)

The discovery of a dioxaadamantane system in tetrodotoxin[1] suggested an examination of the cyclization of a correspondingly substituted polyhydroxy compound derived from a natural product. The pyranose ring of β-D-glucose in its 1C conformation carries the hydroxyl groups at C-1 and C-3 and the C-6 hydroxymethyl group in axial positions. A ring closure might therefore be possible after the introduction of a bridgehead atom.

The nitrile *(1)*[2] served as the starting material. Hydrolysis for 1 hour with 0.5 N NaOH at 100 °C gave the labile acid *(2)*, which was isolated in the form of its ammonium salt. This was transformed with a Linde molecular sieve 3 A in refluxing toluene to the lactone *(3)*, m.p. 111–113 °C, $\lambda_{CO}$ = 5.85 and 5.90 μ, in 49 % yield [based on *(1)*]. Reduction of *(3)* with diisobutylaluminum hydride[3] in tetrahydrofuran/toluene (1:2 v/v) afforded the hemiacetal *(4)*, m.p. 157–158 °C, yield 72 %, $[\alpha]_D^{20} = +62.6°$ (c = 1 in water), which exhibits no carbonyl absorption[4]. Careful hydrolysis of *(4)* with the acid form of Amberlite IR 120 in water gave two products: a hygroscopic powder of 6-deoxy-D-*gluco*-dialdoheptose, $[\alpha]_D^{20} = +49.0 \rightarrow +34.0°$ (c = 1 in water), which occurs in a cyclic form of as yet unknown ring size, and a 50 % yield of ether-extractable 8(a),10(a)-dihydroxy-2,4,6-trioxaadamantane *(5)*, m.p. 247–248 °C (slight sublimation), $[\alpha]_D^{20} = +4.1°$ (c = 1 in water) after purification by chromatography[5]; NMR spectrum (ppm in $D_2O$ with tetramethylsilane as external standard]: $>CH_2$, 2.23 (quartet);

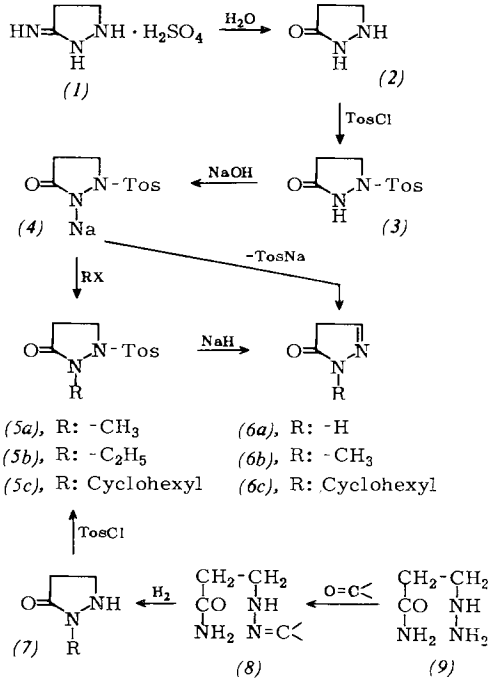
## Synthesis of 5-Pyrazolone and 1-Substituted 5-Pyrazolones [1]

By Dr. H. Dorn, Dr. A. Zubek, and Prof. G. Hilgetag

Institut für Organische Chemie, Deutsche Akademie der Wissenschaften, Berlin-Adlershof (Germany)

The classical syntheses[2] of 5-pyrazolone *(6a)* are unsatisfactory but have not yet been improved. A new, preparatively advantageous route to compound *(6a)* resulted when it was found that 3-iminopyrazolidinium sulfate *(1)*, which has recently become readily accessible[3], is quantitatively converted into the hitherto difficultly accessible compound *(2)* by heating of its aqueous solution. This product can be sulfonylated at one of its two N atoms by arenesulfonyl chlorides at 20 °C in methylene chloride containing 1 mole of pyridine as HCl-acceptor; *e.g.* with *p*-toluenesulfonyl chloride it gives 1-(*p*-toluenesulfonyl)-3-pyrazolidone *(3)*, m.p. 168–169 °C. With alkali hydroxides compound *(3)* gives alkali salts, *e.g.* *(4)*, which when heated in an indifferent solvent, *e.g.* toluene, at 105 °C for a few minutes lose 1 mole of sulfinate and give an excellent yield (90 %) of compound *(6a)*, m.p. 163–164 °C (m.p. of the 4-phenylazo derivative: 195–197 °C).

Sulfinate elimination from 1-substituted 2-tosyl-5-pyrazolidones *(5)* does not occur so easily, but yields of 70–90 % are obtainable by use of sodium hydride in boiling dioxane. This is a synthetic route to the hitherto unknown 1-alkyl-5-pyrazolones, *e.g.* *(6b)*, m.p. 108–100 °C (m.p. of the 4-phenylazo derivative: 115–117 °C), and *(6c)*, m.p. 122 to 123 °C (m.p. of the 4-phenylazo derivative: 98–99 °C). The intermediates *(5a)* [m.p. 128–130 °C, ν(CO) = 1707 $cm^{-1}$, ν($SO_2$ sym) = 1166 $cm^{-1}$, ν($SO_2$ asym) = 1352 $cm^{-1}$], *(5b)* (m.p. 126–127 °C), and *(5c)* (m.p. 118–120 °C) are accessible by alkylation of the alkali salts *(4)* or by treatment of the 1-substituted 5-pyrazolidones *(7)* with arenesulfonyl chlorides in methylene chloride at 20 °C with triethylamine as HCl-acceptor.



The only previously known 1-substituted 5-pyrazolidones *(7)* are those with R = aryl[4]. Representatives with R = alkyl have now been obtained by catalytic hydrogenation (Adams Pt, 20 °C, 200 atm, glacial acetic acid) of hydrazones *(8)* derived from 3-hydrazinopropionamide *(9)* and ketones, *e.g.* 1-cyclohexyl-5-pyrazolidone *(7)*, R = cyclohexyl, m.p. 84.5–85.5 °C (43 % yield).

The position of the tosyl substituent in *(3)* was proved by tosylation of 1-methyl-3-pyrazolidone to an isomer of *(5a)*, *i.e.* 2-(*p*-toluenesulfonyl)-1-methyl-3-pyrazolidone, m.p. 111 to 113 °C, ν(CO) = 1744 $cm^{-1}$, ν($SO_2$ sym) = 1159, 1175 $cm^{-1}$, ν($SO_2$ asym) = 1359 $cm^{-1}$.

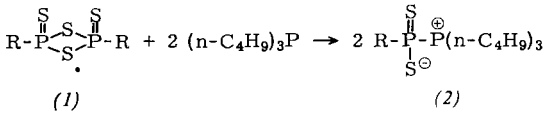
## Inner Phosphonium and Ammonium Dithiophosphonates

By Doz. E. Fluck[1] and H. Binder

Anorganisch-Chemisches Institut,
Universität Heidelberg (Germany)

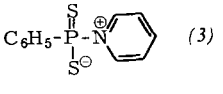
If a suspension of a perthiophosphonic anhydride in benzene, boiling in an $N_2$-stream, is treated with 2 moles of tri-n-butylphosphine (*e.g.* 5 g of $[C_6H_5PS_2]_2$ *(1)*, 5.9 g of $(n\text{-}C_4H_9)_3P$, and 50 ml of benzene), complete solution occurs in *ca.* 5 minutes. When the solution is cooled, or if necessary concentrated, colorless crystals separate which can be obtained analytically pure by washing with a little benzene. The resulting compounds *(2)* are to be considered as inner phosphonium salts stabilized by resonance. They are stable in air, and cryoscopic molecular-weight determinations in benzene, bromoform, and nitrobenzene indicate that they are monomeric. Their $^{31}P$-NMR spectra include two doublets with coupling constants characteristic of P–P linkages.



*(1)* *(2)*

| *(2)*, R = | M.p. (°C) | δ (ppm) | J (cps) |
|---|---|---|---|
| $C_6H_5$– | 97–98 | – 60.0; – 6.8 | 118 |
| *p*-$CH_3O$–$C_6H_4$– | 87 | – 60.0; – 7.4 | 109 |
| *p*-$C_2H_5O$–$C_6H_4$– | 85–87 | – 60.9; – 6.8 | 108 |

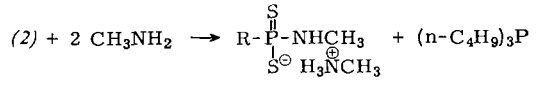
Strongly basic tertiary amines react like phosphines with perthiophosphonic anhydrides, giving inner ammonium salts. If, for instance, phenylperthiophosphonic anhydride is boiled for 1 hour with 10 moles of pyridine and the cooled solution is treated with benzene to turbidity, the crystalline pyridine *N*-phenyldithiophosphonic betaine *(3)* separates (m.p. 122–125 °C; $\delta_P$ = 82.2 ± 1.0 ppm; yield 80–85 %).



*(3)*

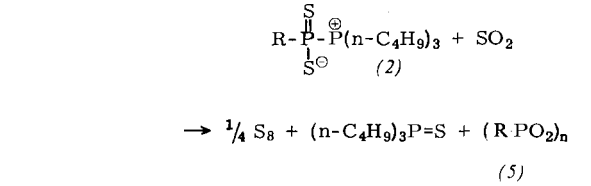
This compound reacts with tributylphosphine with elimination of pyridine and formation of compound *(2)*.

The inner phosphonium salts *(2)* react with primary and secondary aliphatic amines (spontaneously at room temperature in a pressure tube) with fission of the P–P bond, yielding ammonium phosphonoamidodithioates *(4)* and tributylphosphine.



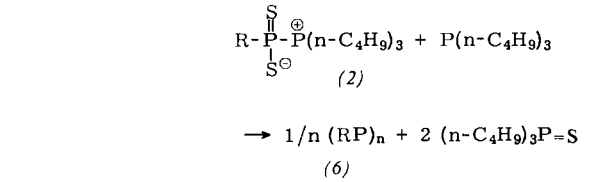
*(4)*

With liquid sulfur dioxide the compounds *(2)* yield tributylphosphine sulfide, sulfur, and the corresponding phosphonic anhydride *(5)* [2], whereas with an excess of tributylphosphine



*(5)*

(15 hr at 80 °C in benzene) they give arylcyclophosphines *(6)* and tributylphosphine sulfide.



*(6)*

Investigation of the reaction of amines and phosphines with phosphonic anhydrides are in progress.

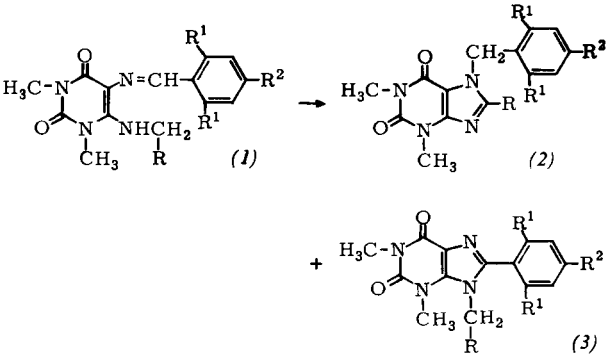
## Novel Purine Syntheses

By Prof. W. Pfleiderer and H.-U. Blank

Institut für Organische Chemie,
Technische Hochschule Stuttgart (Germany)

In the dehydrogenating cyclization of 4-amino-5-benzylideneamino-1,3-dimethyluracil to 8-phenyltheophylline *Traube*[1] found a synthesis of imidazole derivatives which was later used mainly for preparation of benzimidazoles[2]. If $N^4$-alkyl-5-benzylideneamino-1,3-dimethyluracil-4-amines are chosen as starting materials and cyclized in nitrobenzene, the main products are not 9-alkyl-8-phenyltheophyllines, but instead 7-benzyltheophylline or its 8-alkyl derivatives, in analogy with the cyclization of 3-substituted or 1,3-disubstituted 6-alkylamino-5-nitrosouracils[3].



*(1)* *(2)* *(3)*

| R | $R^1$ | $R^2$ | Yield (%) of *(2)* | Yield (%) of *(3)* |
|---|---|---|---|---|
| *(a)* H | H | $NO_2$ | 40 | 12 |
| *(b)* H | H | H | 48 | |
| *(c)* H | Cl | H | 51 | |
| *(d)* $C_6H_5$ | H | H | 50 | |

However, many side reactions occur, in contrast to the cyclization of nitrosouracils. When, for instance, a solution of 4-methylamino-5-*p*-nitrobenzylideneaminouracil *(1a)* in nitrobenzene is refluxed for only a short time (2–5 min), fractional crystallization of the product leads to a 40 % yield of 7-*p*-nitrobenzyltheophylline *(2a)* and a 12 % yield of 8-*p*-nitrophenylisocaffeine *(3a)*. Since the Schiff bases *(1b)–(1d)* also afford 7-benzyltheophyllines *(2b)–(2d)* as main products in yields around 50 %, the reaction must proceed by attack of the alkyl substituent on the 4-amino group onto the azomethine portion of the molecule. This is thus a new type of imidazole ring closure.

Cyclization in *Traube*'s sense can be achieved by the use of aqueous alcohol in presence of Cu(II) ions as solvent, instead of nitrobenzene. Compound *(3a)* is formed from *(1a)* in 61 % yield after only 5 minutes' boiling. The reaction-determining factor is probably complex formation between the Cu and the azomethine group.

A novel purine ring closure was also found in the cyclization of 4-alkylamino-1,3-dimethyl-5-phenylazouracil *(4)*. If the derivative *(4a)* is boiled in nitrobenzene for about 4 hr under reflux, theophylline *(5a)* is obtained in 50 % yield; heating of the compound *(4b)* alone above its melting point gives 8-methyltheophylline. In both cases the α-C atom of the substituent on the 4-amino group enters into reaction and appears as C-8 in the purine derivative.

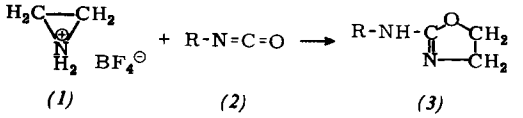
## Synthesis of 2-Oxazoline-2-amines and 2-Thiazoline-2-amines by Reaction of Aziridinium Tetrafluoroborate with Isocyanates and Isothiocyanates

By Prof. E. Pfeil and K. Milzner

Chemisches Institut, Universität Marburg (Germany)

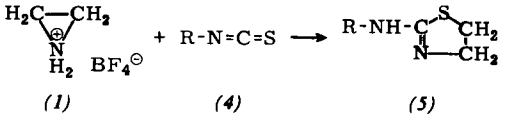
Aziridinium tetrafluoroborate *(1)* [1] adds to
(a) isocyanates *(2)* with formation of 2-oxazoline-2-amines *(3)*:



*(1)* *(2)* *(3)*

| *(3)*, R | M.p. [°C] | Yield [%] |
|---|---|---|
| $C_6H_5$ | 117–119 | 89.6 |
| $C_6H_{11}$ | 131 | 44.3 |

and (b) to isothiocyanates *(4)* with formation of 2-thiazoline-2-amines *(5)*.



*(1)* *(4)* *(5)*

*(5)*, R = $C_6H_5$, m.p. 160–161 °C, yield 47.2 %.

Equivalent amounts of compounds *(1)* and *(2)* or *(4)* are mixed and kept at a bath temperature of 130 °C for (a) 22 hr and (b) 3 hr, respectively. After cooling, the unchanged isocyanate or isothiocyanate is extracted with ether, and the 2-oxazoline-2-amine or 2-thiazoline-2-amine is liberated from the residue with sodium methoxide/methanol. After removal of the methanol the product is extracted with diisopropyl ether and recrystallized from the same solvent. The structures of the products are proved by mixed melting points, IR and NMR spectra, and elementary analysis.

## cis-Selective Olefin Syntheses

By Dr. M. Schlosser, G. Müller, and Dr. K. F. Christmann

Organisch-Chemisches Institut,
Universität Heidelberg (Germany)

In many examples reaction of phosphorus ylides with aldehydes affords preferentially the thermodynamically less stable *cis*-olefin [1]. There are various interpretations as to whether and how the lithium salt present influences the stereochemistry of the carbonyl olefination [1c, 1d, 2].

We have found that alkylidenetriphenylphosphoranes tend in general towards *cis*-olefination. Here the proportion of *cis*-olefin in the isomer mixture is highest when the ylide is prepared in "salt-free" form [3]. Lithium salts favor the formation of *trans*-isomers, the more so the larger the radius of the anion. For example, salt-free alkylidenetriphenylphosphorane and benzaldehyde in benzene/light petroleum (4:1) at 0 °C [4] give *cis*- and *trans*-1-phenyl-1-butene in the ratio 96:4; the *cis*/*trans* ratio becomes 90:10, 86:14, 83:17, and 52:48 if the reaction is carried out in the presence of an equivalent amount of lithium chloride, bromide, iodide, or tetraphenylborate, respectively. Benzylidenetriphenylphosphorane and other ylides with α-substituents capable of resonance are not suitable for *cis*-selective olefination.

*Experimental*:

Liquid ammonia (200 ml) is distilled from sodium under nitrogen and condensed through a dry ice-cooled condenser into a three-necked flask. After dissolution of 2 g of solid sodamide with stirring by a magnetic stirrer, 50 mmole of

alkyltriphenylphosphonium bromide is added. The mixture is refluxed for 1 hr, whereafter the ammonia is evaporated through a mercury seal. The residue is boiled for 1 hr with 200 ml of anhydrous benzene. The benzene solution is cooled and allowed to flow with vigorous stirring into a mixture of 20 mmole of aldehyde and 50 ml of benzene/light petroleum (1:1) cooled to 0 °C. After 1 hour's stirring the *cis-trans* ratio of the olefin produced is determined by gas chromatography; the olefin is then isolated by distillation.

The structures of the products were determined by C–H analysis, IR spectra, and comparison with authentic samples.

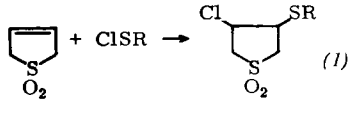
## Synthesis of 2-Alkylthio- and 2-Arylthio-1,3-butadienes

By Prof. K.-D. Gundermann and P. Holtmann [1]

Organisch-Chemisches Institut, Bergakademie-Technische Hochschule, Clausthal-Zellerfeld (Germany)

We have found that alkanesulfenyl chlorides and benzenesulfenyl chloride add smoothly to $\Delta^3$-thiolene 1,1-dioxides in tetrahydrofuran at 0 to 5 °C, yielding 3-alkylthio- or 3-arylthio-4-chlorothiolane 1,1-dioxides *(1)* (cf. Table).



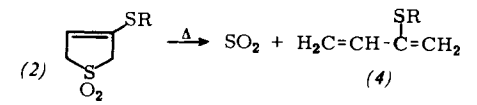
*(1)*

| R | Yield of *(1)* [%] | M.p. of *(1)* (C °) |
|---|---|---|
| $CH_3$ | 88 | 52–53 |
| $C_2H_5$ | 80 | 25 |
| $C_6H_5$ | 87 | 81 |

When the products *(1)* are warmed with an equivalent amount of triethylamine in dimethyl sulfoxide for 2 hr at 90 °C, they give 3-alkylthio- or 3-arylthio-$\Delta^3$-thiolene 1,1-dioxides *(2)* (yields 60–90 %), respectively, whose structures follow from the NMR spectra [2].

*(2)* *(3)*

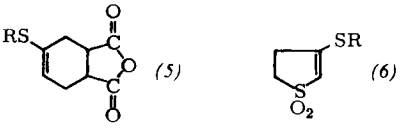
If the alkylthiochloro compounds *(1)* are left with triethylamine in benzene solution für 15 hr, the alkylthio-2-thiolene 1,1-dioxides *(3)* are formed in *ca.* 80 % yield. These products isomerize to the 3-thiolenes *(2)* when heated for 1 hr with triethylamine in dimethyl sulfoxide at 90 °. Only the 3-thiolenes *(2)* are cleaved by heating at 105–110 °C in presence of t-butylpyrocatechol as polymerization inhibitor, losing $SO_2$ and giving the butadienes *(4)* (see table).



*(2)* *(4)*

| *(4)*, R | Yield (%) | B.p. (°C/mm) | $n_D^{20}$ | *(5)*, M.p. (°C) |
|---|---|---|---|---|
| $CH_3$ | 79 | 62/90 | 1.5241 | 117 |
| $C_2H_5$ | 55 | 67/70 | 1.5123 | 104 |
| $C_6H_5$ | 64 | 65/0.3 | 1.5922 | 87 |

Analytical data and infrared and NMR spectra confirm the structures of compounds *(4)*, which are stable for weeks when kept at 0 °C under nitrogen. Warming them for 1 hr with maleic anhydride in boiling benzene affords 63–80 % yields of the Diels-Alder adducts of type *(5)*. When the butadienes are heated at 90 °C for 5 hr without a solvent, dimers are formed which on desulfuration with Raney nickel in methanol at 50 °C give ethylcyclohexane with small amounts of *trans*-1,2-diethylcyclobutane and cyclooctadiene.



*(5)* *(6)*

Two hours' warming in 1 % sodium methoxide solution rearranges the thiolenes *(2)* and *(3)* to 3-alkylthio-2-thiolene 1,1-dioxides *(6)*, whose infrared spectrum is characterized by a particularly intense C–C band at 1565 $cm^{-1}$.

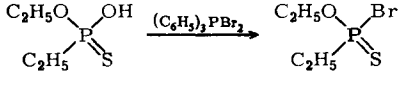
## Stereospecific Synthesis and Hydrolysis of Optically Active *O*-Ethyl Ethylphosphonobromidothioate

By Prof. J. Michalski, Dr. M. Mikołajczyk, and Dr. B. Pliszka-Krawiecka

Institute of Organic Chemistry, Polish Academy of Sciences, Lodz (Poland)

Optically active *O*-ethyl ethylphosphonochloridothioates are obtained from the antipodes of *O*-ethyl hydrogen ethylphosphonothioate *(1)* and phosphorus(V) chloride [1].

We have found a simple route to the optically active bromides *(2)* in treatment of the acid *(1)* with triphenylphosphine dibromide, $(C_6H_5)_3PBr_2$.



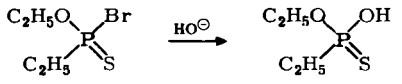
*(1)*, $[\alpha]_D^{23} = +13.90°$ *(2)*, $[\alpha]_D^{23} = +140.4°$

The (+)-thiophosphonic acid *(1)* in ether is dropped into an ethereal solution of an equimolar amount of triphenylphosphine dibromide obtained *in situ* from triphenylphosphine and bromine [2]. The mixture is stirred for 8.5 hr at room temperature and then filtered. The residue remaining

after removal of the ether is vacuum-distilled, yielding the (+)-bromide *(2)* as a colorless, optically stable liquid, b.p. 23–24 °C/0.1 mm, $n_D^{23} = 1.5235$, in 53 % yield.

A similar reaction in boiling ether (6.5 hr) gives a 50 % yield of a (+)-bromide with $[\alpha]_D^{23} = +135.3°$ [*].

For determination of its optical purity and relative configuration the (+)-bromide *(2)*, $[\alpha]_D^{23} = +140.4°$, was hydrolysed by 2.85 N KOH in dioxane-water (4:7 v/v) at °C to the (+)-thiophosphonic acid *(1)*, $[\alpha]^{23} = +13.0°$ (yield 80 % in $2^1/_2$ hr).



*(2)*, $[\alpha]_D^{23} = +140.4°$ *(1)*, $[\alpha]_D^{23} = +13.0°$

Comparison of the rotation of the acid obtained by alkaline hydrolysis with that of the starting material showed that the (+)-bromide *(2)* had an optical purity of at least 94 %. If we assume that the alkaline hydrolysis occurs with inversion [3] then the thiophosphonic acid *(1)* reacts with $(C_6H_5)_3PBr_2$ also with inversion. It is remarkable that the reactions of the acid *(1)* with $PCl_5$ and $(C_6H_5)_3PBr_2$ occur in stereochemically identical ways.

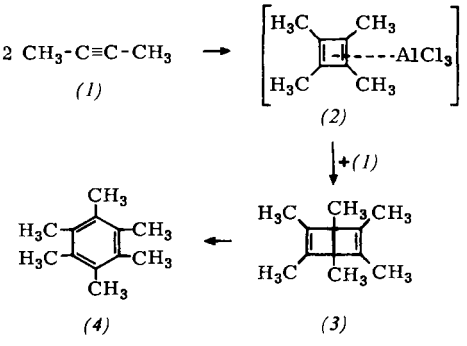
## One-Stage Synthesis of Hexamethyl-Dewar-Benzene from 2-Butyne [1]

By Dr. Wolfgang Schäfer

Forschungslaboratorien, Chemische Werke Hüls AG., Marl (Germany)

Hexamethylbicyclo[2.2.0]hexa-2,5-diene (hexamethyl-Dewar-benzene) *(3)* can be prepared by trimerization of 2-butyne *(1)* with anhydrous aluminum chloride as catalyst at 20 to 35 °C. Benzene may be used as solvent. Compound *(3)* was not previously known [2].

The trimerization of 2-butyne *(1)* may occur by way of a complex *(2)* of $AlCl_3$ with the tetramethylcyclobutadiene, which does not exist in the free form.



*(1)* *(2)* *(4)* *(3)*

The compound *(3)* is quantitatively isomerized to hexamethylbenzene *(4)* in the presence of catalysts at room temperature (enthalpy of rearrangement: $\Delta H = -62.4 \pm 0.4$ kcal/mole).

If 2-butyne *(1)* is trimerized above 50 °C the benzene derivative *(4)* is formed predominantly and only a small amount of the bicyclic compound *(3)* can be isolated. Trimerization in boiling benzene gives hexamethylbenzene *(4)* in 80 to 90 % yield, and a mixture of oils. Some of these oils are dimerization products of tetramethylcyclobutadiene previously obtained in a different way [3].

1 kg of 2-butyne [4] is dropped, with stirring, during 2.5 hr into a suspension of 50 g of freshly sublimed $AlCl_5$ in 1 *l* of benzene (dried over sodium), care being taken, by water-cooling, that the temperature does not exceed 35 °C. For completion of the reaction the mixture is stirred for a further 4 hr at 35 °C. (At 20 °C the reaction time is approximately 20 hr.) Then the mixture is cooled to 0 °C and the catalyst is decomposed by adding dropwise 50 to 100 ml of water, until the initially brown mixture turns pale yellow. Unchanged 2-butyne is removed with some benzene by distillation at room temperature and 200 mm, being collected in two successive receivers cooled by dry ice/methanol. Fractionation of the condensate allows recovery of *ca.* 200 g of 2-butyne.

The butyne-free benzene solution is washed with water until neutral and fractionated in vacuum, yielding a first fraction of benzene and then 490 to 510 g of a colorless liquid *(3)*, b.p. 43–45 °C/15 mm, $n_D^{20} = 1.4479$, m.p. 7 °C. After cooling, the distillation residue affords 150–165 g of hexamethylbenzene. Compound *(3)* can be kept for months in a refrigerator and for a long time even at room temperature protected from light.

The NMR spectrum of the bicyclic compound *(3)* in $CCl_4$ (with tetramethylsilane as internal standard) contains two singlets at 8.4 and 8.9 τ, of relative areas 2:1. The signal at 8.4 τ is assigned to the $CH_3$ groups attached to the doubly bound C atoms, and that at 8.9 τ to the methyl groups attached to tertiary C atoms. The NMR spectrum of hexamethylbenzene *(4)* contains only one signal at 7.85 τ.

In the IR spectrum of the bicyclic compound *(3)* there is a weak band at 1680 $cm^{-1}$ (C=C in strained ring systems), also bands at 1370 $cm^{-1}$ ($-CH_3$) and 1060 $cm^{-1}$ ($CH_3$-C=C), as well as at 1280, 1220, 735, and 660 $cm^{-1}$.

This synthesis enables a Dewar-benzene derivative to be prepared on a technical scale for the first time [5].

[4] Dried over sodium; according to gas chromatography it contained 92.7 % of *(1)*.

[5] 2-Butyne is obtained, *e.g.*, as by-product on dehydrogenation of butane to 1,3-butadiene by *Houdry*'s procedure.

## Synthesis and Formula of Biological and Mineral Carbonate-apatite

By Prof. E. Hayek, Dr. H. Konetschny, and Dr. E. Schnell

Institut für Anorganische und Analytische Chemie, Universität Innsbruck (Austria)

The designation carbonate-apatites is given to minerals (dahllite, staffelite, kollophane) that are analogous to apatite $Ca_5(PO_4)_3(F,OH,Cl)$ in crystal structure but contain also carbonate. Carbonate-apatites also form the mineral substance of bones and teeth. All carbonate-apatites contain calcium phosphate and carbonate (the latter in amounts

corresponding to only a few percent of $CO_2$), together with smaller amounts of other cations and anions.

We have found that the reaction between calcium hydrogen phosphate and calcium carbonate in an aqueous slurry can be used to prepare the basic substance of mineral as well as of biological apatites. Passing air (purified by KOH) through an aqueous suspension of $CaHPO_4 \cdot 2H_2O$ and $CaCO_3$ (molar ratio 3:2) at 37 °C for some days, and subsequent filtration and washing with water, gives preparations in which about a third of the carbonate used is incorporated homogeneously.

Of the infrared bands of the calcite used, only those at 1430 $cm^{-1}$ (strong) and at 880 $cm^{-1}$ (weak) are found in the spectrum of the new preparation. In other respects its IR spectrum is the same as that of octacalcium phosphate $Ca_4H(PO_4)_3 \cdot 2H_2O$, and agrees completely with that of the mineral substance of bones. Its X-ray diagram shows none of the reflections characteristic of the $CaCO_3$ used and coincides in general with those of octacalcium phosphate and of the mineral substance of bones.

These facts and analysis of the product lead to the following formulation of the reaction (water of crystallization being neglected):

$$3\ CaHPO_4 + 2\ CaCO_3 = 5/4\ [Ca_4(PO_4)_2(HPO_4)_{0.4}(CO_3)_{0.6}] + 5/4\ H_2O + 5/4\ CO_2$$

The ratio 6.67:1 of Ca:$CO_2$ corresponding to this formula is somewhat exceeded in the synthetic product, as also in biological apatite, owing to side reactions that do not incorporate carbonate (formation of octacalcium phosphate and hydroxyapatite). In the electron microscope the synthetic product shows a leaflet structure resembling that of the bone substance but being more pronounced.

The above formula is in keeping with the chemical and structural properties of the principal component of biological carbonate-apatite. The octacalcium phosphate thus not only acts as nucleus for the hard tissues[1], but also as its major component after partial replacement of $HPO_4^{2-}$ by $CO_3^{2-}$. Complete conversion of $HPO_4^{2-}$ into $PO_4^{3-}$ leads to $Ca_4(PO_4)_{2.4}CO_{3)0.4} = Ca_5(PO_4)_3(CO_3)_{0.5}$. If the reactants are boiled for 10 hr the carbonate-containing product gives a very sharp X-ray diagram which is identical with that of pure hydroxy-apatite[2] except for intensity differences and minimal changes of position. Once again there are no calcium carbonate interferences. The IR spectrum is also analogous to that of hydroxy-apatite, but the bands at 3850 and 635 $cm^{-1}$ characteristic of OH groups are, at most, weak and of the carbonate bands only those at 1430 and 880 $cm^{-1}$ appear. Here again there are variations in the carbonate content, but the above composition is almost reached and the product thus to a great extent resembles mineral carbonate-apatites with not too high fluorine contents. In the electron microscope needles are seen (some longer than 1 μ) similar to those in crystalline hydroxy-apatite[3].

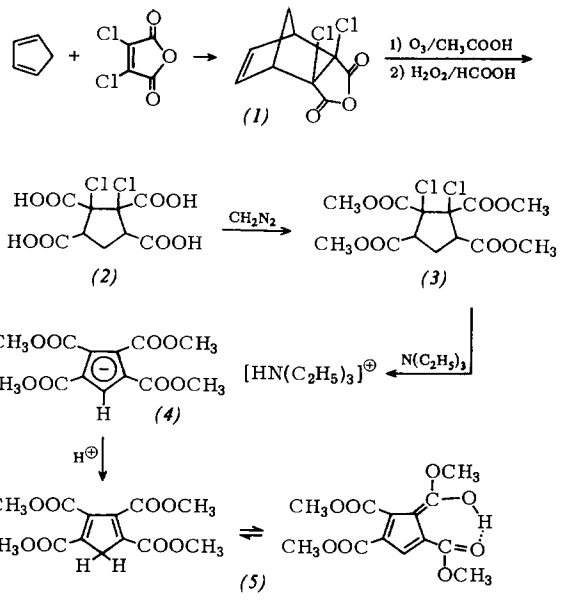
## Synthesis of Tetramethyl Cyclopentadiene-1,2,3,4-tetracarboxylate

By Dr. G. Seitz

Institut für Pharmazeutische Chemie und Lebensmittelchemie, Universität Marburg (Germany)

*Webster*[1] and *Friedrich*[2] recently described syntheses of cyano-substituted cyclopentadienes. We have prepared tetramethyl cyclopentadiene-1,2,3,4-tetracarboxylate *(5)* by the route shown in the scheme below.



Cyclopentadiene and dichloromaleic anhydride in benzene give the Diels-Alder adduct *(1)*, m.p. 192 °C[3], which was ozonized in 95 % acetic acid at room temperature. The crystalline ozonide (decomp. 125 °C) can be oxidized by hydrogen peroxide in formic acid to crystalline 3,4-dichloro-cyclopentane-1,2,3,4-tetracarboxylic acid *(2)*. This acid decomposes readily and is immediately converted by etheral diazomethane into its tetramethyl ester *(3)*, m.p. 110 °C. Removal of two molecules of hydrogen chloride with triethylamine leads to *(4)*, the resonance-stabilized, water-soluble triethylammonium salt of *(5)*. Acidification of the aqueous solution of *(4)* with HCl precipitates the crystalline compound *(5)*, which is obtained in analytically pure, yellowish crystals from methanol. This ester *(5)* does not melt sharply. When heated above 130 °C it slowly decomposes, assuming an intense red color. Like all cyano- and carbonyl-substituted cyclopentadienes[4–6], compound *(5)* is strongly acidic. As in the case of cyclopentadienetricarbaldehyde[6] the NMR and IR spectra can be unambiguously interpreted only by ascribing to compound *(5)* a tautomeric fulvene structure with an intramolecular O···H–O hydrogen bond. Thus the NMR spectrum (measured in $CDCl_3$ with tetramethylsilane as internal standard) shows four singlets for the twelve methoxy protons, close together but distinctly differentiable, of intensity 3 at 3.82 ppm, 3.98 ppm, 4.05 ppm, and 4.09 ppm. The ring proton at position 5 gives rise to a sharp singlet at 7.63 ppm of intensity 1, whereas there is no recognizable signal for the acidic proton (up to 32 ppm). The IR spectrum in $CCl_4$ and in KBr shows two sharp bands at 1739 $cm^{-1}$ and 1715 $cm^{-1}$ which can be assigned to the differently conjugated ester carbonyl groups. The broad, intense band at 1600 $cm^{-1}$ must originate from a delocalized C=O and C=C double bond, as is typical of carbonyl-substituted fulvenes with intramolecular hydrogen bonds[6]. Equally characteristic of the fulvene system is a strong band at 1330 $cm^{-1}$[7,8], while a somewhat weaker band at 1445 $cm^{-1}$ arises from the $CH_3$ deformation vibration. It appears with equal intensity in the IR spectrum of the chloro-ester *(3)*. No free hydroxyl group can be recognized. The O···H-O chelate band, which is usually broad, probably occurs in the region of the C–H stretching vibrations at about 3050 $cm^{-1}$ to 2650 $cm^{-1}$, which would explain why all the bands in that region appear diffuse. Only after deuteration (by shaking of the solution with $D_2O$) can sharp bands be obtained for the C–H stretching vibrations (3060 $cm^{-1}$, 3020 $cm^{-1}$, 2960 $cm^{-1}$); there is, however, no band near 2000 $cm^{-1}$ that would be produced by a deuterated hydrogen bond.

## Synthesis of Pyrimidine-5-carbaldehyde

By Prof. H. Bredereck, Dr. G. Simchen, Dr. A. Santos, and H. Wagner

Institut für Organische Chemie,
Technische Hochschule Stuttgart (Germany)

In the course of our studies on the nucleophilicity of the 5-position of substituted pyrimidines we obtained 4,6-dihydroxypyrimidine-5-carbaldehyde *(2)*[1] by reaction in chloroform at 0 to 20 °C of 4,6-dihydroxypyrimidine (prepared from malondiamide and formamide) with the reaction product of dimethylformamide and phosgene[2]. The formylation was exothermic with a yield of 93 % after 2 to 3 hr.

Chlorination of the quaternary salt *(1)* with phosphorus oxychloride/dimethylaniline, or of *(1)* in dimethylformamide with phosgene/dimethylaniline (10 hr at 110 °C) and subsequent removal of the solvent, treatment of the residue with ice, and extraction with chloroform afforded 4,6-dichloropyrimidine-5-carbaldehyde *(3)* in 63 % yield[1,3].

The formylation and chlorination can be carried out in one experiment: after the reaction with the dimethylformamide-phosgene product the chloroform is removed and replaced by dimethylformamide, and phosgene is passed into the mixture for 10 hr at 110 °C.

Hydrogenation of the chloro-aldehyde *(3)* with hydrogen and palladium-charcoal in methanol containing an excess of magnesium oxide (to remove the HCl) at room temperature and pressure and subsequent filtration, distillation of the methanol, and extraction of the residue with methylene chloride yielded the new compound pyrimidine-5-carbaldehyde, m.p. 38–41 °C, in 79 % yield (40 % calculated on malondiamide).

## On the Secondary Structure of Serine-Specific Transfer Ribonucleic Acid [1]

By H. Doepner, Dr. H. Seidel, and Prof. F. Cramer

Max-Planck-Institut für Experimentelle Medizin,
Göttingen (Germany)

Recently we described a relation[2] between the thermal hyperchromicity of variously pre-treated s-RNA's[3] of different origins and the extent of their base-pairing as determined by *N*-oxidation.

We have now examined ser-t-RNA from brewer's yeast, whose nucleotide sequence has been elucidated by *Zachau et al.*[4]. The figure shows the change in absorption on thermal denaturation of this t-RNA.

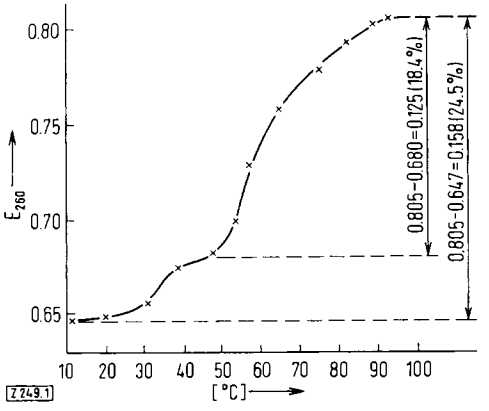

Fig. 1. Change of extinction at 260 mμ ($E_{260}$) on thermal denaturation of ser-t-RNA in 0.4 M phosphate buffer (pH 7.0) without $Mg^{2+}$.

The denaturation curve exhibits two steps. The first stage in the denaturation (between 30 and 45 °C) accounts for only a small part of the total hyperchromicity (breakdown of tertiary structure?)[5,6]. The second stage may correspond to destruction of the secondary structure (helix-coil transition).

As seen from the figure, the total hyperchromicity amounts to 24.5 %, which according to our previous relationship[2] corresponds to about 27 base pairs per molecule of ser-t-RNA. The hyperchromicity in the second stage is 18.4 %, corresponding[2] to 24 to 25 base pairs per molecule of ser-t-RNA.

This result agrees well with the optimal amount of base-pairing attainable by arrangement of the nucleotide sequence in five helical regions as proposed by *Zachau et al.*[4] for ser-t-RNA.

## Synthesis of Oligodeoxynucleotides with Terminal 5'-Phosphate Groups

By Dr. F. Eckstein

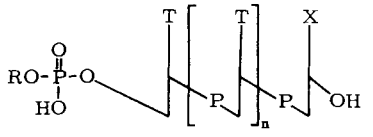
Max-Planck-Institut für Experimentelle Medizin,
Chemische Abteilung, Göttingen (Germany)

Unless enzymatically obtained, all the oligodeoxynucleotides larger than the dinucleotide synthesized through a dinucleotide intermediate have a hydroxyl group at the 5'-end[1].

We have now achieved a stepwise synthesis of oligodeoxynucleotides with a terminal 5′-phosphate group.

Condensation of thymidine-5′-(2,2,2-trichloroethyl hydrogen phosphate) *(1)* [2] with 3′-*O*-acetylthymidine-5′-phosphoric acid *(2)* by means of dicyclohexylcarbodiimide in pyridine and subsequent removal of the acetyl group and separation on a DEAE-cellulose column give the dinucleotide *(3a)*. This can be converted by condensation with *(2)* into the trinucleotide *(3b)*. We have carried out this condensation up to the tetranucleotide *(3c)*. $N^6$,3′-*O*-Diacetyldeoxycytidine-5′-phosphoric acid *(4)* can be used in place of *(2)* in the last condensation, and then the oligonucleotides *(5a)* to *(5c)* are obtained.

After conversion of these compounds into the pyridine salts, the 2,2,2-trichloroethyl group can be removed from all of them with activated Cu/Zn [3] in dimethylformamide (50 °C, 1 hr) [2]. The yields of oligonucleotide in these processes amount to 85–90% for *(3a)*–*(3c)*, 65% for *(5a)* and *(5c)*, and 90% for *(5b)*.



*(3)*, X = Thymyl
*(5)*, X = Cytosyl

After conversion into the ammonium salts the oligonucleotides can be cleaved to mononucleotides by snake-venom phosphodiesterase.

## Osazone Formation by D-Glucosamine

By Prof. F. Micheel and H. Dallmann

Organisch-Chemisches Institut,
Universität Münster (Germany)

The literature and textbooks express the view, based on experiments by *F. Tiemann* [1], that D-glucosamine gives D-phenylglucosazone analogously to D-glucose. As there is a close relation between the mechanism of the Amadori rearrangement and formation of osazones by aldose we have re-examined the behavior of D-glucosamine towards phenylhydrazine.

We have established that on complete exclusion of atmospheric oxygen D-glucosamine does not form D-glucosazone, but only a phenylhydrazone (m.p. 118–120 °C, $[\alpha]_D^{25} = -13.2°$ (after 10 min) → −72.3 ° ($c = 1$, water)]. This hitherto unknown substance was separated by way of the *N*-tosyl derivative. It can be obtained from the components in good yield without addition of acid. The *N*-formyl, *N*-acetyl, *N*-benzyloxycarbonyl, and *N*-tosyl derivatives of D-glucosamine also form the phenylhydrazone, with loss of the acyl group attached to the N atom. From the *N*-tosyl derivative, *N*-tosyl-D-glucosamine phenylhydrazone can be isolated as intermediate.

In the presence of atmospheric oxygen, however, D-glucosazone is formed, the yield depending on the amount of oxygen admitted. Our maximal yield was 61%. Clearly a dehydrogenation by the oxygen, and probably also loss of ammonia from an imino group, must occur before entry of the second phenylhydrazine residue.

The fact that D-glucosamine does not form an osazone in the absence of oxygen is in agreement with the behavior of its *N*-glycosyl derivatives. In no case is it possible to induce the *N*-glycosyl derivative to undergo the Amadori rearrangement [2]. Since osazone formation is preceded by an Amadori rearrangement it is understandable that there can be no osazone formation from D-glucosamine in the absence of oxygen.

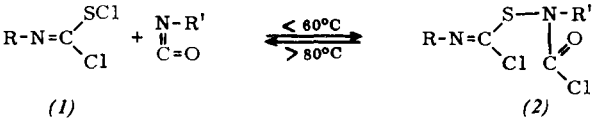
## Reactions of N-Alkyl- and N-Aryl-S-chloroisothiocarbamoyl Chlorides with Isocyanates; Synthesis of 1,2,4-Thiadiazolidine-3,5-diones [1]

By Dr. G. Ottmann and H. Hooks, Jr.

Olin Mathieson Chemical Corporation, Chemicals Division,
New Haven, Connecticut (U.S.A.)

*N*-Alkyl and *N*-aryl-*S*-chloroisothiocarbamoyl chlorides *(1)* [2] react with aliphatic and aromatic isocyanates to form *S*-(chlorocarbonylamino)isothiocarbamoyl chlorides *(2)*. The weakly exothermic reaction proceeds quantitatively below 60 °C according to IR-spectroscopy, but is reversible at elevated temperatures.

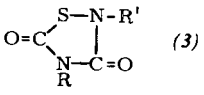


*(1)* *(2)*

| *(2)*, R | R′ | M.p. [°C] | Yield [%] |
|---|---|---|---|
| $C_2H_5$ | n-$C_8H_{17}$ | 132–133 | 77 |
| n-$C_4H_9$ | n-$C_4H_9$ | 133–134 | 85 |
| n-$C_4H_9$ | n-$C_8H_{17}$ | 114 | 65 |
| $C_6H_5$ | $C_2H_5$ | 108–109 | 90 |
| $C_6H_5$ | i-$C_3H_7$ | 101–102 | 78 |
| $C_6H_5$ | n-$C_4H_9$ | 97–99 | 86 |
| $C_6H_5$ | n-$C_8H_{17}$ | 92–93 | 68 |
| $C_6H_5$ | $C_6H_5$ | 79–80 | 97 |
| $C_6H_5$ | $CH_3$·$C_6H_4$ | 95–96 | 91 |
| $C_6H_5$ | *p*-Cl·$C_6H_4$ | 72–73 | 95 |
| $C_6H_5$ | *p*-$CH_3OC_6H_4$ | 85–92 | 98 |
| $C_6H_{11}$ | i-$C_3H_7$ | 131–132 | 55 |

The structure of the products *(2)* is supported by elemental analysis, molecular-weight determination, IR spectra, and their reactions. The infrared spectrum is void of the characteristic isocyanate absorption around 2270 $cm^{-1}$ but features absorptions at 1760 $cm^{-1}$ and 1670 $cm^{-1}$, which indicate the presence of a C=O group and a C=N linkage.

*S*-(Chlorocarbonylamino)isothiocarbamoyl chlorides *(2)* are exceptionally reactive, white solids, which fume heavily in moist air. With water and particularly with aqueous alcohols a vigorous, highly exothermic reaction ensues, accompanied by evolution of HCl and precipitation of the previously unknown 1,2,4-thiadiazolidine-3,5-diones *(3)* as white, crystalline solids.



*(3)*

| *(3)*, R | R′ | M.p. [°C] | B.p. [°C/mm Hg] | $n_D^{25}$ | Yield [%] |
|---|---|---|---|---|---|
| $C_2H_5$ | n-$C_8H_{17}$ | | 134/0.6 | 1.4920 | 76 |
| n-$C_4H_9$ | n-$C_4H_9$ | | 111/0.6 | 1.4960 | 77 |
| n-$C_4H_9$ | n-$C_8H_{17}$ | | 142/0.25 | 1.4890 | 71 |
| $C_6H_5$ | $C_2H_5$ | 94–95 | | | 91 |
| $C_6H_5$ | iso-$C_3H_7$ | 112–113 | | | 95 |
| $C_6H_5$ | n-$C_4H_9$ | 81–82 | | | 90 |
| $C_6H_5$ | n-$C_8H_{17}$ | 70–71 | | | 86 |
| $C_6H_5$ | $C_6H_5$ | 114–115 | | | 84 |
| $C_6H_5$ | *p*-$CH_3$–$C_6H_4$ | 136–137 | | | 76 |
| $C_6H_5$ | *p*-$CH_3O$–$C_6H_4$ | 157–158 | | | 85 |
| $C_6H_5$ | *p*-Cl–$C_6H_4$ | 170.5–171 | | | 91 |

Structure *(3)* was assigned because reduction of the hydrolysis products of *(2)* with lithium aluminum hydride in tetrahydrofuran renders 1,3-disubstituted ureas in up to 65% yield. Structure *(3)* is also verified by elemental analysis, infrared and mass spectroscopy, and by the fact that the compounds do not form hydrochlorides. The infrared spectra display two carbonyl absorptions at about 1735 $cm^{-1}$ and 1665 $cm^{-1}$. A weak absorption at about 1700 $cm^{-1}$ is noted with R = aryl. The formation of the 1,2,4-thiadiazolidine-3,5-diones *(3)* suggests that the imidoyl chloride portion of structure *(2)* and not the carbamoyl chloride group is the primary center of the nucleophilic attack.

*Synthesis Example*:

A solution of 412 g of *N*-phenyl-*S*-chloroisothiocarbamoyl chloride in 150 ml of dry pentane is added to a stirred solution of 307 g of 4-chlorophenyl isocyanate in 1000 ml of dry pentane at such a rate that a reaction temperature of 20–25 °C is easily maintained (external cooling bath at 10–15 °C). The mixture is allowed to stand for 12–15 hours, and the white precipitate is separated in a dry $N_2$ atmosphere by suction filtration and washed with fresh pentane.

The product of the first reaction step is added portionwise with stirring to 1500 ml of water, thereby maintaining a temperature of 60–70 °C. The mixture is filtered after cooling to room temperature; the filter cake is washed with water until the filtrate is free of chloride ions, and then with cold alcohol. The product may be recrystallized from methanol.

## Preparation of Di-2-naphthyltrisulfane 2-Oxide

By Prof. P. W. Schenk, Dr. R. Steudel, and J. Bilal

Institut für Anorganische und Analytische Chemie, Technische Universität Berlin (Germany)

We have prepared di-2-naphthyltrisulfane oxide *(1)*, the first stable substituted sulfane oxide. The compound is formed in about 10% yield, alongside $(C_{10}H_2)_2S_2$, when 2-thionaphthol is condensed with thionyl chloride (molar ratio 2:1) in anhydrous ether at −20 °C:

$$2\ RSH + SOCl_2 \rightarrow RS{-}SO{-}SR + 2\ HCl \qquad R: 2\text{-Naphthyl}$$
*(1)*

It is a yellow, crystalline powder of m.p. 115–118 °C (decomp.), insoluble in ether. The formula given is confirmed by elemental analysis and cryoscopic molecular-weight determination in benzene.

A strong band at 1118 $cm^{-1}$ in the infrared spectrum (in KBr) indicates the SO stretching vibration of the thionyl group attached to two sulfur atoms.

The compound is reduced quantitatively by anhydrous hydrogen iodide at 20 °C:

$$R_2S_3O + 2\ HI \rightarrow R_2S_3 + I_2 + H_2O$$

The trisulfane formed was identified by IR spectroscopy. Di-2-naphthyltrisulfane 2-oxide decomposes quantitatively at 130 °C:

$$2\ R_2S_3O \rightarrow 2\ R_2S_2 + S(\text{solid}) + SO_2$$

It is stable for several days at room temperature. We ascribe its relative stability, compared with that of polysulfur oxides and other polysulfane oxides, to steric hindrance of disproportionation by the large substituents.

## Synthetic Steroids with Moulting Hormone Activity [1]

By Dr. P. Hocks, Dr. A. Jäger, Dr. U. Kerb, and Dr. R. Wiechert

Hauptlaboratorium, Schering A.-G., Berlin (Germany)

and Dr. A. Furlenmeier, Dr. A. Fürst, Dr. A. Langemann, and Dr. G. Waldvogel

Chemische Forschungsabteilung, F. Hoffmann La-Roche und Co. A.-G., Basel (Switzerland)

During our work [2] on the synthesis of the insect moulting hormone ecdysone we have obtained, *inter alia*, the ecdysone homologues *(1)*–*(3)* which differ from the natural hormone *(4)* only in lack of one, two, and three hydroxyl groups, respectively.

These compounds showed 1/80, 1/50, and 1/15, respectively, of the activity of ecdysone in the Calliphora test. They are thus the first non-natural steroids with moulting hormone activity.

Recently we isolated a 20-ξ-hydroxyecdysone *(5)* [1] from the dried pupae of the silkworm (*Bombyx mori*); it has been found to be 1.25 times as active as ecdysone in insect metamorphosis [3].

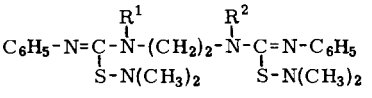
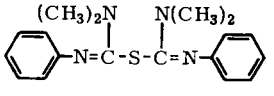
| Cyclohexyl | Dimethylamino | $CH_3OH/H_2$ | 82 | Pale yellow cryst., 64 |



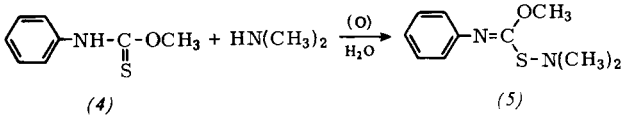
| $R^1$ | $R^2$ | Reaction in | Yield [%] | Appearance, m.p. [°C] |
|---|---|---|---|---|
| Methyl | Methyl | $DMF/H_2O$ | 90 | Pale yellow, undistill. oil |
| $-CH_2-CH_2-$ | | $DMF/H_2O$ | 29 | Pale yellow cryst., 114 |

Action of acids on *(2)* gives the sulfide *(3)* with loss of sulfur and amine.

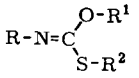


*(3)*

Thiourethanes, *e.g. (4)*, are oxidized to *S*-aminoisothiourethanes *(5)*.



*(4)* *(5)*



| R | $R^1$ | $R^2$ | Reaction in | Yield [%] | Appearance, m.p. [°C] |
|---|---|---|---|---|---|
| Phenyl | Ethyl | Dimethylamino | $CH_3OH/H_2O$ | 75 | Colorless cryst., 48 |
| Phenyl | Isopropyl | Dimethylamino | $CH_3OH/H_2O$ | 76 | Colorless cryst., 53 |
| *p*-Chlorophenyl | Methyl | Dimethylamino | $CH_3OH/H_2O$ | 90 | Yellow undistill. liquid |
| *p*-Nitrophenyl | Methyl | Morpholino | $DMF/H_2O$ | 33 | Pale yellow cryst., 115—116 |
| Cyclohexyl | Methyl | Cyclohexylamino | $CH_3OH/H_2O$ | 54 | Yellow undistill. oil |

The reactions were carried out in aqueous suspensions or water-miscible solvents.

Only the compounds containing short-chain amine groups can be distilled in a high vacuum without decomposition.

Some of the compounds have herbicidal properties.

*Examples:*

1. *S*-Dimethylamino-*N,N*-dimethyl-*N'*-phenylisothiourea:

180 g (1 mole) of *N,N*-dimethyl-*N'*-phenylthiourea are suspended in 500 ml of 40 % aqueous dimethylamine, and 650 ml of 12 % sodium hypochlorite are added during an hour, with stirring, the temperature being kept between 30 and 35 °C by cooling. The mixture is then stirred for three hours at this temperature and the oil that separates is collected, washed with water, dried over sodium sulfate, and distilled in a high vacuum. 190 g (= 81 %) of a pale yellow oil of b.p. 88–90 °C/0.015 mm are obtained.

2. *S*-Dimethylamino-*O*-methyl-*N*-phenylisothiourethane:

200 g (1.3 moles) of *O*-methyl-*N*-phenylthiourethane are suspended in 500 ml of water and 300 ml of 40 % aqueous dimethylamine, and then oxidized as in example 1. The resulting oil is distilled in a high vacuum, yielding 206 g (= 82 %) of a pale yellow liquid of b.p. 94–95 °C/0.12 mm.

## Preparation and Properties of Imidazole-2-carbaldehyde

By Prof. H. Schubert and H.-D. Rudorf

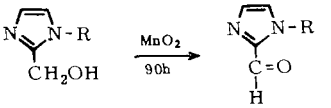
Institut für Organische Chemie,
Universität Halle (Germany)

*Dedicated to Professor A. Lüttringhaus on his 60th Birthday*

Of the two imidazolecarbaldehydes the 4-aldehyde has long been known [1]. Anomalies in its behavior (failure to undergo the benzoin or Cannizzaro reaction) make its comparison with the 2-aldehyde desirable.

Attempted oxidation of 2-methylimidazole by $SeO_2$ in dioxane or xylene does not proceed beyond formation of an adduct; if the mixture of the reactants is heated above the melting point of the base, the imidazole ring is largely destroyed. Methods of oxidation that yield imidazole-4-carbaldehyde from 4-imidazolemethanol cannot be transferred to the 2-imidazolemethanols *(1a)* and *(1b)*; only by use of $N_2O_4$ or potassium peroxodisulfate [2] could we achieve dehydration and then in very small amounts that were preparatively useless.

We found, however, that treatment of the bases *(1a)* and *(1b)* with a six-fold amount of activated manganese dioxide B [3] in anhydrous ether, acetone, or $CCl_4$ at room temperature afforded the imidazole-2-carbaldehyde.



*(1)* *(2)*

*(a)*, R: -H
*(b)*, R: $-CH_2-C_6H_5$

Imidazole-2-carbaldehyde *(2a)* is precipitated in crystalline form on removal of the solvent by distillation, the yield being 70 %. Purification is effected by sublimation in a vacuum or by recrystallization from water, yielding colorless crystals of m.p. 204 °C (sealed tube), $\tilde{\nu}_{CO}$ = 1700 $cm^{-1}$, $\lambda_{max}$ =

285 mμ, ε = 12,500 (in alcohol); the aldehyde gives a 2,4-dinitrophenylhydrazone perchlorate, m.p. = 319 °C (from 50 % acetic acid). As with the 4-aldehyde, it does not undergo the benzoin or Cannizzaro reaction, giving instead intractable brown, tarry products.

1-Benzylimidazole-2-carbaldehyde *(2b)* (b.p. 128 °C/4 mm Hg), prepared similarly, gives the usual carbonyl reactions, affording an oxime, m.p. 167 °C (from alcohol), semicarbazone, m.p. 196 °C (from dilute alcohol), phenylhydrazone, m.p. 169 °C (from alcohol), 2,4-dinitrophenylhydrazone perchlorate, m.p. 228 °C (from alcohol), and hydrochloride, m.p. 142 °C (from dilute HCl). The benzoin condensation occurs smoothly in alcoholic solution, giving pale yellow 1,1′-dibenzyl-2,2′-imidazoloin, m.p. 140 °C, whose IR spectrum confirms the ene-diol structure expected by analogy with pyridoin[4]. The imidazoloin is oxidized in boiling dioxane by a current of air to the almost colorless diketone 1,1′-dibenzyl-2,2-oxalyldiimidazole, m.p. 148 °C.

## An Unusual Diazo-Coupling Reaction

By Dr. W. Kullick

Azo-Laboratorium,
Farbenfabriken Bayer AG., Leverkusen (Germany)

*Dedicated to Prof. A. Lüttringhaus on his 60th birthday*

On diazotization of anthranilamides whose amide group is not fully substituted, benzo-1,2,3-triazin-4-ones *(1)*[1] are formed, which do not undergo diazo coupling in an aqueous medium.

Opening of the triazinone ring and coupling to yield azo dyes can, however, be achieved by heating *(1)* with 3-hydroxy-2-naphthamides *(2)* or acetoacetamides in polar organic solvents (*e.g. o*-dichlorobenzene or nitrobenzene) at 100–150 °C. The solution, initially clear and colorless, soon becomes colored and the dye *(3)* usually crystallizes during the reaction.

This reaction is of interest for preparation of azo dyes containing only partially substituted carboxamide groups adjacent to the azo group, since such dyes are not accessible by normal diazotization and coupling.

The structures of the products were proved by degradation.

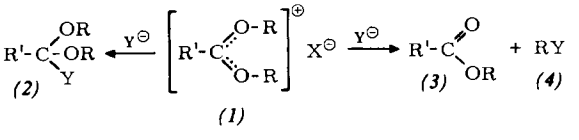
## Alkylations by Dialkoxycarbonium Salts

By Dr. S. Kabuß

Chemisches Laboratorium, Universität Freiburg (Germany)

*Dedicated to Prof. A. Lüttringhaus on his 60th Birthday*

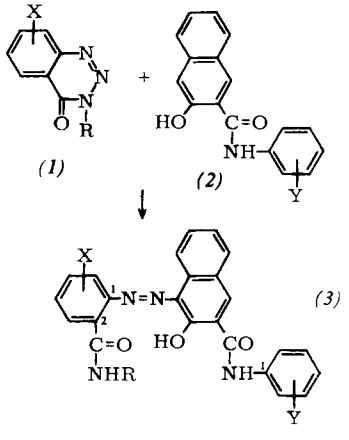
Dialkoxycarbonium ions [as in *(1)*][1] are typical ambident cations[2] which, according to the reaction conditions, react with nucleophiles either in a kinetically controlled reaction to give orthoacid derivatives *(2)* or in a thermodynamically controlled reaction with dealkylation to give carboxylic esters *(3)*.



*(1)*

*(1a)* R′ = H, R = $C_2H_5$, X = $SbCl_6$
*(1b)* R′ = $CH_3$, R = $C_2H_5$, X = $SbCl_6$

In alkylation reactions *(1)* → *(4)* the ester molecule *(3)* is the leaving group. Since replacement reactions occur the easier the more weakly basic is the leaving group, we should expect that dialkoxycarbonium salts *(1)*, like trialkyloxonium salts, would be very strong alkylating agents, able to react by transalkylation with even weak nucleophiles.



*(1)* *(2)* *(3)*

| Carbonium salt | Nucleophile | Alkylation product $X^+SbCl_6^-$; $X^+$ = | M.p. (°C) | Yield (%) |
|---|---|---|---|---|
| *(1a)* | $C_6H_5-CO-N(C_2H_5)_2$ | *(5)* $[C_6H_5-C(=OC_2H_5)-N(C_2H_5)_2]^+$ | 131–132 | 95 |
| *(1b)* | | | | 91 |
| *(1a)* | $CH_3-CO-N(C_6H_5)_2$ | *(6)* $[CH_3-C(=OC_2H_5)-N(C_6H_5)_2]^+$ | 166–168 | 97 |
| *(1a)* | $(C_6H_5)_2S=O$ | *(7)* $[(C_6H_5)_2S=OC_2H_5]^+$ | 123–125 | 92 |
| *(1a)* | $C_6H_5-C\equiv N$ | *(8)* $[C_6H_5-C\equiv NC_2H_5]^+$ | 72–74 | 90 |
| *(1b)* | | | | 61 |
| *(1a)* | $O(C_2H_5)_2$ | *(9)* $[O(C_2H_5)_3]^+$ | 129 [a] | 87 |

[a] With decomposition.

Experiment confirmed this expectation. Dialkylamides, sulfoxides, ethers, aldehydes, and ketones are alkylated to the corresponding salts by dialkoxycarbonium salts, the reactions being quantitative and often very fast[3]. Even esters of higher carboxylic acids can be alkylated in good yield if they are added in excess and if the lower-boiling ester is removed from the equilibrium mixture.

Dialkoxycarbonium salts are among the strongest alkylating agents known, being even stronger than trialkyloxonium salts.

For instance, the salts *(10)–(14)* cannot be obtained by reaction of nucleophiles with trialkyloxonium salts[4].

The reaction is best carried out by using the unsubstituted dialkoxycarbonium salts that are readily accessible from orthoformic esters[3], and it is convenient to use these as the well-crystalline hexachloroantimonates, *e.g. (1a)*. The substance to be alkylated is added in slight excess to a solution of this salt in $CH_2Cl_2$. The products crystallize immediately [*e.g. (11)* and *(12)*] or overnight [*e.g. (7)* and *(8)*] or can be precipitated by $CCl_4$.

Dialkoxycarbonium salts derived from higher carboxylic esters react appreciably more slowly, *e.g. (1b)*, and often give poorer yields and less pure products[5].

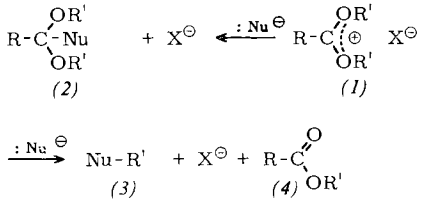
## Aryl-Substituted Dialkoxycarbonium Ions as Alkylating Agents

By Prof. K. Dimroth and P. Heinrich

Institut für Organische Chemie, Universität Marburg (Germany)

Dialkoxycarbonium ions *(1)* can react with nucleophiles (:Nu) either by addition, to give saturated 1,1-dialkoxy compounds *(2)*, or by alkylation of the nucleophile, to give compounds *(3)* and carboxylic esters *(4)*[1,1a].



*(2)* *(1)*

*(3)* *(4)*

*(a)*, R : H; R' : $CH_3$, $C_2H_5$; $X^{\ominus}$ : $SbCl_6^{\ominus}$

*(b)*, R : $CH_3$; R' : $CH_3$, $C_2H_5$; $X^{\ominus}$ : $SbCl_6^{\ominus}$

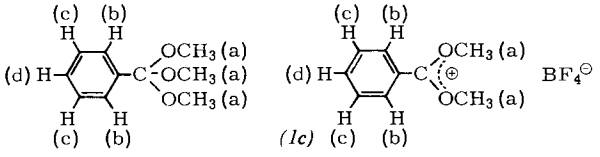
*(c)*, R : $C_6H_5$; R' : $CH_3$; $X^{\ominus}$ : $BF_4^{\ominus}$

*(d)*, R : 2,4,6-$(CH_3)_3C_6H_2$; R' : $CH_3$; $X^{\ominus}$ : $BF_4^{\ominus}$

Independently of *Kabuss*[2], who worked with *(1a)* and *(1b)*, we have found that the aryl-substituted dimethoxycarbonium salts *(1c)* (m.p. 88–90 °C[1a]) and *(1d)* (m.p. 89–91 °C) are powerful alkylating agents. For instance, on addition of 2,6-dimethyl-4-pyrone to a solution of the salt *(1c)* or *(1d)* in $C_2H_4Cl_2$ at room temperature, 4-methoxy-2,6-dimethylpyrylium fluoroborate is at once precipitated in *ca.* 60% yield.

However, under the same conditions pyrocatechol gives no detectable amount of its mono- or di-methyl ether with the salt *(1c)* but instead adds to it; the product, which is at once precipitated, yields *o*-hydroxyphenyl benzoate on addition of water. If it is desired to add both OH groups of pyrocatechol to *(1c)*, giving methyl *o*-phenylene orthobenzoate, then it is necessary to treat pyrocatechol with trimethyl orthobenzoate and a catalytic amount of a strong acid, such as 2-hydroxy-5-sulfobenzoic acid, the reaction then occurring *via (1c)*[3]. The salt *(1d)* is readily obtained crystalline from trimethyl 2,4,6-trimethylorthobenzoate and anhydrous $HBF_4$ in ether (93% yield); for steric reasons the cation thereof no longer gives addition reactions but merely methylates the pyrocatechol to guaiacol (83% yield).

Compound *(1c)* is the first containing a reactive ambident cation for which the normally favored kinetically controlled addition is linked, owing to the high activation energy due to steric hindrance, with a thermodynamically favored alkylation[4].



*(1c)*

a: 2.52ppm (S)

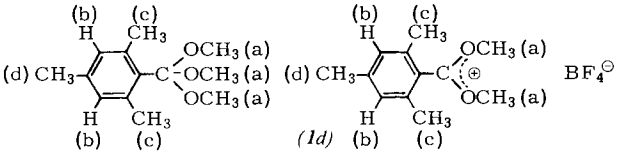
a: 4.23ppm (S)
b + c + d: 7.48ppm (M)



*(1d)*

a: 2.62ppm (S)
b: 6.39ppm (S)
c: 2.02ppm (S)
d: 1.77ppm (S)

a: 4.23ppm (S)
b: 6.71ppm (S)
c, d: 1.88ppm (S)

NMR spectra of *(1c)* and *(1d)* in liquid $SO_2$ at −10 °C (TMS as external standard) show equal chemical shifts for the $OCH_3$ protons in *(1c)* and *(1d)*; the polarization of the $OCH_3$ groups should therefore also be about equal. Studies with *para*-substituted cations analogous to *(1c)* are in progress.

# Modern Methods of Analysis

The section *Analytische Chemie* of the *Gesellschaft Deutscher Chemiker*, the *Österreichische Gesellschaft für Mikrochemie*, and the *Schweizerische Gesellschaft für Analytische Chemie und Angewandte Chemie* held a symposium from the 13th to the 16th April 1966 in Lindau (Germany).

From the lectures:

## The Importance of Ultramicroanalysis of Streak Samples for Trace Analysis

*H. Ballczo*, Vienna (Austria)

Ultramicroanalysis of streak samples has become possible by use of the corundum rod, a small sintered rod of pure alumina [1]. It is now possible to isolate minute amounts of inclusions (inhomogeneities) in, *e.g.*, minerals and to subject them to complete microanalysis. In this method, not only are the difficulties of sampling (comminution) and of working up (choice of material for the containing vessel) overcome, but the concomitant advantages (better distribution, use of up to 2000 μg) make it possible to subject the sample to evaporation analysis and thus to determine also traces. When it is to be heated (for sublimation) the rod is placed in a small quartz cylinder, inclined so that the streak is at the top, covered with a small quartz tube that is somewhat narrowed in the middle, and heated at the lower end.

If, *e.g.*, a molybdenite contains arsenopyrites, wolframite, and zinc blende as impurities, the volatile oxides are collected one after the other (*e.g.*, $SeO_2$ from 316 °C, $As_2O_3$ from 321 °C, $MoO_3$ from 800 °C) and, if the cover tube is changed, can be investigated separately in turn; the difficultly volatile impurities such as $WO_3$, $Bi_2O_3$, $Sb_2O_3$, ZnO, and $SnO_2$ remain behind and they too can be further separated. For example, evaporation with HCl converts ZnO into the volatile (from 732 °C) $ZnCl_2$. Further, the quartz test tube can be subjected to reducing conditions (*e.g.*, heating with sodium azide at 275 °C or with sodium formate at 440 °C), which results in sublimation of the metals Cd (from 260 °C), Zn (from 360 °C), and simultaneously also Pb, Ag, and Ga; or by means of the hydrogen chloride evolved from $ZnCl_2$ (from 365 °C) $SO_3$ can be driven out of sulfates and $H_2S$ out of sulfides, as shown by *F. Feigl*. The sulfide formed during the reduction can be removed by cautious heating with ammonium chloride (evolution of HCl at 135 °C). The detection of $H_2S$ has been improved by more than two powers of ten (5 ng instead of 2 μg) by a development process (CdS → $Ag_2S$ → Ag). The solubilizing medium is conveniently sprayed on in aqueous or alcoholic solution ($ZnCl_2$). However, very small amounts of water or OH groups (OH-apatite, *etc.*) or free sulfur (in sulfides) can also be determined – for the first time – in a streak (in a melt with KSCN or benzoin by *F. Feigl*'s method).

## An Oscillometric Analytical Procedure with Continuous Recording

*R. Bertram*, Clausthal-Zellerfeld (Germany)

In oscillometry chemical processes are followed by measuring the electrical properties of the reaction mixture. Generally changes in conductivity and dielectric constant are determined. For the procedure in question the measuring cell containing the mixture is placed in a special circuit element coupled to the rest of the circuit so that the resulting frequency is an unambiguous measure of the changes occurring in the cell. The resulting frequencies (50 c/s to 1 Mc/s), are measured by a receiver, and an attached high-speed recorder ensures instantaneous and complete recording. The process is applicable over the whole ionic conductivity range for cells with or without direct electrode contact. Among other reactions, the rapid hydrolysis of phenyl trifluoroacetate and the slow adsorption of sodium hydroxide on quartz powder has been investigated; finally, a new mode of dissolution of molten lead in a cadmium chloride melt has been discovered. Drying processes have been recorded for solids in platelet form down to water contents of $10^{-2}$ wt.-%. Even though recording is instantaneous a relative accuracy of $10^{-3}$ % is obtained, which is beyond that of any other conductivity method.

## Determination of Traces of Arsine in Inert-Gas Mixtures in Presence of a Large Excess of Stibine. Influence of Precipitation Conditions on the Enrichment of Arsenate during Coprecipitation with Phosphate

*W. Gann*, Hagen (Germany)

Arsine and stibine are removed from the gas mixture to be analysed by absorption in a perchloric acid solution of sodium triiodide. Antimony is determined in an aliquot of the absorbing solution by reduction with hypophosphite and photometric determination of the resulting iodoantimonate-(III). Traces of arsenate are enriched from the absorbing solution by addition of sodium phosphate and then of calcium chloride at pH ≥ 12, causing coprecipitation with calcium phosphate. The phosphate precipitate is dissolved in a little hydrochloric acid, and after a reduction with hypophosphite the arsenic is determined in this solution photometrically as brown arsenic sol. The range of applicability is 20 μg to the mg region per 50 ml of absorbing solution for stibine, and 5 μg to 60 μg per 50 ml for arsine. There is no interference with the determination of arsine unless more than 10 mg of antimony is present in the absorbing solution.

## Interpretation of Potentiometric and Photometric Titration Curves Obtained on Recording Apparatus

*E. Greuter*, Herisau (Switzerland)

Automatically recorded titration curves have the advantage of showing the complete course of the titration, so that anomalies can be recognized immediately. A potential-volume curve is produced. For its generation the advance of the paper and the addition of the reagent must be accurately proportional. The equivalence point is preferably determined graphically from the curve; parallel tangents to the curve are drawn in front of and behind the equivalence point; a parallel line drawn midway between these two tangents cuts the curve at the equivalence point.

Tests have been made to determine what faults can arise on use of automatically recording analytical apparatus. The errors observed are caused by the recording itself and during measurement along the volume axis of the potentiogram. Titrations of hydrochloric and acetic acid with sodium hydroxide, with various experimental programs, gave deviations of +3.3 %, +1.8 %, −2.0 %, and +1.9 % in the results relative to the standard values.

Unsymmetrical curves are harder to evaluate; no mathematically sound method is known for this purpose.

Electrical differentiation of the potentials arising during the titration with respect to the time, and recording of the derivatives against volume, are often advantageous. End-points close to each other often give only one potential jump on the integral curve, whereas the derivative curve often shows the two equivalence points separated. The simplest method of electrical differentiation is by means of a capacitance-resistance circuit.

Photometric titration curves can be recorded by coupling a potentiograph to a spectrophotometer. Acid-base titrations give symmetric curves if the pK of the indicator equals that of the acid (or base) to be titrated. The photometric titration curve can be obtained by graphical addition of a potentiometric titration curve to the curve showing the change in extinction of the indicator in relation to pH.

## Micromethod for Analytical Determination of Lower Oxidation States

*R. Gruehn*, Münster (Germany)

A new method permits determination of lower oxidation states in substances that react in a KOH melt with evolution of $H_2$. 0.5–15 mg samples, including single crystals, are added to a degassed KOH melt in a vacuum; all the substance dissolves in its highest oxidation state, while an equivalent amount of hydrogen is set free. The hydrogen is pumped off, compressed in a Töpler pump, and measured in a Hg buret; it can be identified by combustion over CuO. For instance, the compositions of six $NbO_x$ phases have been accurately determined, giving the following values of x: 2.417 ± 0.003 (2 modifications); x = 2.454 ± 0.002; x = 2.462 ± 0.002 to x = 2.467 ± 0.001 (phase range); x = 2.467 ± 0.001 to 2.479 ± 0.001 (phase range); x = 2.483 ± 0.001. Moreover, the lower phase limit of the H modification of niobium pentoxide has x = 2.489 ± 0.001. Other lower oxides, oxide halides, and halides of Mo, W, Nb, Ta, and Ti have been investigated. The oxidation states of the compounds $NbCl_{2.33}$, $Ta_6Cl_{14}{\cdot}8H_2O$, and $Ta_6Br_{14}{\cdot}8H_2O$ have been confirmed by this method.

## Direct UV-Spectrophotometric Evaluation of Thin-Layer Chromatograms

*H. Jork*, Saarbrücken (Germany)

In thin-layer chromatography one obtains discrete zones, for the localization, identification, and/or quantitative analysis of which spectrophotometric methods can be used. By use of the Zeiss chromatogram-spectrophotometer, reflection fluorescence and absorption spectra can be obtained directly from the chromatogram layer, both for the visible and the ultraviolet region.

For localization of invisible, absorbing zones the whole chromatogram is examined at a wavelength specific for the compound in question. Then differences in the amount of reflection are found for various parts of the layer.

The reflection spectrum of a zone that has thus been located is best taken with a slit width corresponding approximately to the radius of the spot. It usually corresponds exactly to the absorption spectrum measured in solution (*e.g.* for *p*-ethoxyacetanilide and trimethylxanthine). If this is not the case, as for 2,3-dimethyl-4-dimethylamino-1-phenylpyrazol-5-one or acetylsalicyclic acid, then these medium effects, *e.g.*, that of Kieselgel G as a layer, can be used for characterization of the substance present. The sensitivity obtained by taking the spectrum directly is at least ten times greater than for measurement in the usual cells. For absorption spectra at least 3 μg of substance is required, for fluorescence spectra only 30 to 50 ng.

Direct quantitative evaluation of thin-layer chromatograms is possible with the Kubelka-Munk function (relative deviation ± 3 %).

## Analytical Use of Infrared Spectroscopy with Gratings. Quantitative Analysis of Gas Traces

*G. Kemmner, G. Nonnenmacher*, and *W. Wehling*
Überlingen (Germany)

The sensitivity and detection limits of the quantitative infrared-spectroscopic analysis of gas traces depend on the cell length and on factors related to the apparatus: resolving power, signal-to-noise ratio, and the scale of the ordinate. The cell thickness can be varied independently of the instrument; the recording parameters, on the other hand, are connected with the design of the instrument, and are essentially determined by energy relationships.

The influence of the apparatus parameters on the quantitative analysis of $C_2H_2$, $N_2O$, and CO has been tested on dilution series of these gases in nitrogen. Concentrations between 100 ppm and close to the detection limit (see below) were determined by means of two grating instruments and one NaCl-prism instrument in a 1 m gas cell and at various scanning conditions.

According to the distance between their rotational lines the investigated absorption bands show varying dependence on the spectral slit width ΔS. The effect is slight in the case of $N_2O$. CO and $C_2H_2$ exhibit increasingly resolved fine structure with decreasing ΔS; the molar extinction coefficients of the analytical lines increase by a factor of 4 to 6 when ΔS is reduced from 4 to 0.6 $cm^{-1}$ in the case of $C_2H_2$, and from 18 to 0.5 $cm^{-1}$ in the case of CO.

The high dispersion of grating instruments gives flexibility in the adjustment of the recording parameters under the conditions of the quantitative analysis: narrow slits for the highly sensitive measurement of larger concentrations, and wide slits for a favorable signal/noise ratio with relatively good resolving power for measurements in the lower ppm range with ordinate scale expansion.

The smaller the spectral slit width and the greater the signal/noise ratio, the lower are the detection limits. For an optical path of 1 m, the detection limits in the most favorable case (Perkin-Elmer 225 with a 50-fold expansion of the ordinate) were found to be 2.5 ppm for CO, 0.4 ppm for $N_2O$, and 0.1 ppm for $C_2H_2$. These values lie in a range that, without ordinate scale expansion, is analytically attainable only by the use of a 10 m gas cell.

## Element-Specific Determination of Gas-Chromatographically Separated Metal Compounds by Use of Atomic Absorption Spectroscopy; Determination of Lead Alkyls in Gasoline

*B. Kolb, G. Kemmner, Fr. H. Schleser*, and *E. Wiedeking*
Überlingen (Germany)

Atomic absorption spectroscopy can be used for determination of the concentration, in a sample, of an element amenable to this method. Since, however, a given element may occur as various compounds, these must be separated when it is necessary to differentiate between them. For volatile compounds this is most simply done by gas chromatography, the column being connected directly to the burner of an atomic absorption spectrophotometer. The recorder draws a chromatogram in which, of all the components separated, only the compounds to be analysed appear as peaks. The combination of gas chromatography with atomic absorption spectroscopy is particularly suitable for analysis of traces of volatile metal compounds in complex mixtures. Since the process is specific to an element no compound-specific response factor is required.

In the determination of tetramethyl- and tetraethyl-lead in gasoline, use of the 217 mμ line of a lead hollow-cathode lamp gave a detection limit of $4\times10^{-11}$ g-atom of Pb per sec, which under the given working conditions and a sample size of 5 μl corresponds to a concentration of 32 mg $Pb(CH_3)_4$ and 85 mg $Pb(C_2H_5)_4$ per liter of gasoline, respectively.

## Use of Activation Analysis for Determination of Traces in the White Lead of Paintings

*F. Lux* and *L. Braunstein*, Munich (Germany)

In collaboration with the Dörner Institut of the Bavarian State Collection of Paintings a study has been begun of the use of activation analysis for determining the content of trace components in the white lead of paintings. Its object is to test the possibility of dating pictures and of ascribing them to various schools on the basis of the trace components in the white lead,the chief pigment all paintings.This can be achieved only by activation analysis since only microgram samples are available from a painting and the content of trace material often amounts to only a few ppm, so that the amounts of the trace ingredient will sometimes lie in the range $10^{-11}$ to $10^{-10}$ g. In similar studies of the white lead of paintings by Dutch artists, *Houtman* and *Turkstra*[2] concluded that the trace content decreased after about 1850.
