Dextran is not formed after the manner of a phosphorylase-catalyzed reaction in which energy is supplied; the energy required for the synthesis is provided instead by the high-energy bonds of the sucrose. The enzymatic synthesis itself proceeds by the insertion mechanism[15]. The culture medium, which contains the nutrients necessary for the growth of the bacteria and the buffer substances needed to keep the pH value within the most favorable range, thickens in the course of a few days to a viscous mass, whose viscosity maximum coincides with the maximum yield. The native dextran is precipitated with methanol, ethanol, or acetone and then isolated. In the next step the dextran must be partly depolymerized. Acid hydrolysis is used almost exclusively in the industrial process; for special purposes, and in particular for the preparation of small quantities of highly fractionated dextrans, the native dextran can be degraded by ultrasonic radiation or enzymatically with dextranase.

The hydrolysis mixture has a very wide molecular weight distribution, and is unsuitable for clinical use. The product can be further fractionated by precipitation with ethanol or acetone, since the solubility of dextran in organic solvents decreases with increasing molecular weight. Both the absolute position and the width of the molecular weight distribution can be fixed by the choice of hydrolysis conditions (concentration and nature of the acid, temperature, pressure, time) and the precipitation conditions (alcohol concentration, time).

5.3. Chemistry, Structure, and Properties of Dextrans

Dextrans consist of a chain of glucose molecules joined by glycoside linkages (Fig. 1). Other linkages are also present in varying numbers, particularly between C (1) and C (3) or C (4). The degree of branching depends almost exclusively on the type of dextran-producing organism used. Native dextran has a molecular weight

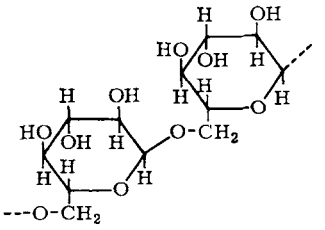

Fig. 1. Part of an unbranched dextran chain.

of 10^7–10^8, and exists in aqueous solution as an unoriented coil. A molecular weight of less than 10^6 in conjunction with a helical conformation has recently been discussed[16]. Native dextran forms highly viscous, structured solutions in water, and these solutions do not mix readily even with water.

Clinical dextran consists of filamentous molecules consisting of about 200–450 glucose units and with about 15–30 branching points. The molecules are electrically neutral, and are hydrated in aqueous solution. The filamentous arrangement of the chains allows high flexibility.

Table 1 shows physico-chemical data for two dextrans available for clinical use.

Table 1. Physico-chemical data for Macrodex® (dextran 60) and Rheomacrodex® (dextran 40) (Producers: Knoll AG, Ludwigshafen and AB Pharmacia, Uppsala).

	Macrodex®	Rheomacrodex®
Molecular weight		
Weight average $\overline{M}_w$	60000	40000
Number average $\overline{M}_n$	30000	25000
Viscosity average $\overline{M}_v$	50000	32000
Intrinsic viscosity $[\eta]$	0.230	0.190
1,6-Bonding (%)	> 93	> 93
$\overline{M}_w/\overline{M}_n$	2.0	1.6
Molecular weight distribution		
Higher peak fraction, 10%	< 110000	< 70000
Lower peak fraction	> 20000	> 15000

The molecular weight distributions of three dextran 60 preparations are shown in Figure 2, which illustrates the differences that can exist between nominally equivalent preparations. Table 2 shows the properties of Macrodex® and Rheomacrodex® infusion solutions.

Oncotic pressure (mm H_2O)	920	2600
Water bonding capacity (ml H_2O/g dextran) [c]	25.6	29.2
pH	5.1–5.7	4.5–5.6
Titration acidity (ml 0.01 N NaOH/50 ml solution)	< 2.0	< 2.0

[a] Solutions with added glucose, sorbitol, or electrolytes are prepared for special purposes.

[b] The blood isooncotic concentration is that concentration of a substance that gives the same oncotic pressure as blood.

[c] Volume of water bound at the indicated concentration by a polymer molecule (dextran) that cannot diffuse through a semipermeable membrane.

5.4. Clinical Use

The clinical dextrans are designated dextran 20, 40, 60, 75, 80, and 120, according to their M_w values (20 = average molecular weight of 20000 *etc.*). The grades first commonly used in clinical work were dextrans 60, 75, and 80. Dextran 40 has also attained some importance in recent years, since it gives excellent results in the treatment of shock, particularly hemorrhagic shock.

This circulatory failure is largely due to disturbances of the microcirculation in the tissue and in the periphery. The inadequate perfusion that occurs in cases of shock is a result of aggregation of the red blood cells, and partly of the platelets; the capillaries are consequently "blocked", and the flow of blood reduced. Long persistence of this state can have catastrophic results (cell metabolism). Dextran 40 is able to break down these aggregates ("deaggregating action") and so improve or restore the blood supply in the peripheral blood vessels (flow improvement).

Recognition of the factors involved in shock greatly widened the scope of therapeutic methods. Possible applications include traumatic, toxic, protracted, hemorrhagic, and burn shock prevention and treatment of after-effects such as hepatorenal syndrome, oliguria, thrombosis, and fat embolism, and operations on cachectic or old patients, extracorporeal circulation, hypothermia, and vasular operations.

5.5. Biochemistry and Pharmacology of Dextrans

The greater part of a parenterally administered dose of dextran is eliminated by the kidneys. The renal threshold occurs at a molecular weight of about 50000. In the case of dextran 40, about 60% are eliminated in 6 hours and about 70% in 24 hours. The fate of the remaining dextran in the organism has been established with the aid of ^{14}C-labeled dextran. About 90% of the quantity infused are eliminated within 10 days, 64% in the urine and 26% as CO_2 in exhaled air. Approximately 2% appear in the feces.

Ebert et al. [17] recently carried out an enzymatic synthesis of dextran from ^3H-labeled sucrose. Hydrolytic degradation of the dextran with ultrasonic radiation gave the desired average molecular weight. The preparation was then divided into the clinical fractions.

Experiments with several types of animals showed, in agreement with literature data, that dextran is not stored in the body. Temporary storage, *e.g.* in the liver, skin, or kidneys, causes no pathological cell changes or disturbances of the organ function. Water was found as the metabolic end product in urine condensate and in the exhaled air. It should be mentioned, however, that these observations apply only to highly fractionated clinical dextran of an optimal molecular weight range, such as Rheomacrodex.

The enzymatic degradation of dextran by a dextranase (α-dextran-1,6-glucosidase) present in animal organs has also been detected in humans. *Saenko* and *Rosenfeld* [18] found dextranase in liver, kidneys, and spleen. Depending on the residence time of the dextran administered, partially degraded dextrans are formed first, and these are then completely degraded to glucose; thus enzymatic hydrolysis of α-1,3-linkages occurs. The enzyme can be induced in the liver by repeated doses of dextran and hydrocortisone. A dextranase activity has recently also been found in canine serum.

6. Gelatins

Pure gelatin solutions are unsuitable for infusion purposes. The first modified gelatin was a polyhydroxygelatin developed by *Campbell* [19] in 1951 (Gelifundol®). In 1954, *Tourtelotte* [20] prepared a depolymerized "modified liquid gelatin" containing succinic acid, which is marketed as Plasmagel®. Probably the most important gelatin preparation in Germany today is a urea-crosslinked, partly degraded gelatin described by *Schmidt-Thomé et al.* [9] in 1962 (Haemaccel®).

The gelatin in Haemaccel is obtained from bovine bone gelatin having an average molecular weight of about 100000. The gelatin molecules have a rod-like structure. The material is thermally degraded to polypeptides having a $\bar{M}_w$ of 12000–15000, which are crosslinked with isocyanate (Fig. 3).

A 3.5% aqueous Haemaccel solution (pH = 7.1) contains 145 mequiv of Na^+, 5.1 mequiv of K^+, 12.5 mequiv of Ca^+, and 162.5 mequiv of Cl^- per liter, and has an oncotic pressure of 350–390 mm H_2O. The molecules are approximately globular. The average half-life of such a solution is about 4 hours, the substance being eliminated largely unchanged by the kidneys. A minor portion may be enzymatically degraded by body proteinases of the cathepsin type; past experience suggests that it is not stored in the body. No

disturbances of organ functions, blood clotting, or blood group diagnosis, antigenic action, or other general or local incompatibilities have been observed. For its effectiveness as a plasma expander *in vitro* and in animals, as well as therapeutic results, particularly in comparison with dextran preparations, the reader is referred to the special literature [21a]. So far as is known at present, gelatin derivatives do not cause deaggregation of erythrocytes and apparently have no effect on the microcirculation in the treatment of shock.

7. Polyvinylpyrrolidone

At the beginning of the second world war, many synthetic polymers were examined for use as plasma expanders. Extensive clinical tests showed that polyvinylpyrrolidone (PVP) was suitable, and this polymer was introduced into therapy in 1943 by *Hecht* and *Weese* [10] under the trade name Periston®. (PVP was also marketed for the first few years under the name Kollidon®.)

The starting material for the preparation of PVP is pyrrolidone, which is converted into *N*-vinyl-2-pyrrolidone by *Reppe* vinylation [21b] and polymerized to PVP. Some physico-chemical data for this substance are given in Table 4.

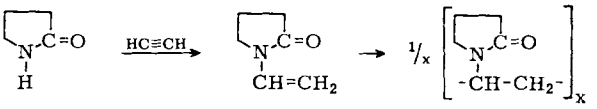

Table 4. Physico-chemical data for Periston® (from data provided by the manufacturer Farbenfabriken Bayer, Leverkusen, and by *Scholtan* [22]).

Weight average mol. wt. $\overline{M}_w$	25000–30000 [a]
Number average mol. wt. $\overline{M}_n$	15000 [21]
$\overline{M}_w/\overline{M}_n$	1.7–2.0
Relative viscosity η_{rel}	2.0
Highest molecular portion, $\overline{M}_w$	80000

[a] Determined from sedimentation and diffusion constants and from viscosities. Until 1952, Periston having $M_w = 50000$ was commercially available.

A 4% aqueous solution (pH = 6) contains 0.70 g of NaCl, 0.042 g of KCl, 0.05 g of $CaCl_2$, 0.0005 g of $MgCl_2$, and 0.025 g of $NaHCO_3$ per 100 ml of solution, and has an oncotic pressure of 670 mm H_2O. The filamentous molecules exist in the solution as coils having an average diameter of about 100 Å. The molecular weight distribution is shown in Figure 4.

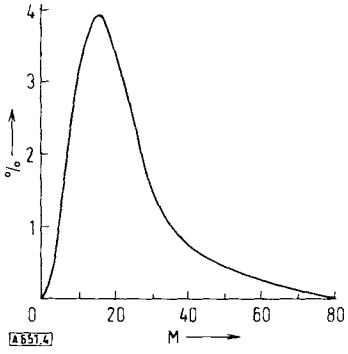

Fig. 4. Molecular weight distribution of Periston® according to information provided by the manufacturer.
Ordinate: weight portion in $\% \cdot 10^3$.

[22] *W. Scholtan*, Makromolekulare Chem. *8*, 209 (1951); *36*, 162 (1960).

In spite of its good volume-expanding effect, PVP has now been pushed somewhat into the background, since objections have been raised to the use of completely synthetic polymers. A particularly significant question is that of the storage of PVP in the organism [23]. 80% of the material infused is eliminated by the kidneys during the first three days, the molecules with $\bar{M}_w < 30000$ being eliminated rapidly and those with $\bar{M}_w > 30000$ only slowly. Though *Hecht* and *Scholtan* [24] were able to show that in the case of the rabbit, the glomerulus filtrate even contains molecules with $\bar{M}_w = 150000$, *Ravin*, *Seligman*, and *Fine* [25] found ^{131}I-labeled PVP having $\bar{M}_w = 40000$ in the tissue. It seems clear that PVP cannot be degraded in the organism. The decisive question, which ultimately arises for all high molecular weight plasma expanders, is whether and to what extent storage in an organ can cause irreversible damage.

8. Hydroxyethyl Starch

Native starch is not suitable for use as the base for a plasma expander, since it is degraded too rapidly by the α-amylase in the blood serum. Of several starch derivatives that have been tested, the best appears to be hydroxyethyl starch, which was proposed by *Wiedersheim* [12] in 1957.

The starting material is not the amylose, but the highly branched amylopectin of starch from plants such as maize, grain, or millet, and particularly "waxy sorghum-starch". Millets and maizes in which the amylopectin content of the starch is higher than 90% instead of the usual 75% have been cultivated. The purified amylopectin is partly degraded to the desired degree of hydrolysis with dilute hydrochloric acid, and the neutralized mixture is treated with dilute sodium hydroxide and ethylene oxide until about 90% of the glucose molecules have been substituted.

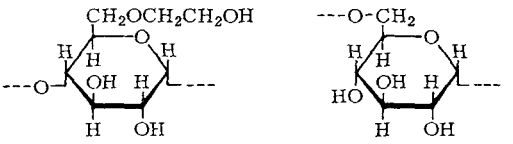

Fig. 5. Hydroxyethyl starch unit (left) and dextran unit (right).

Figure 5 shows a hydroxyethyl starch unit and a dextran unit. Some physico-chemical properties of hydroxyethyl starch are shown in Table 5.

9. Conclusion

The decades of work on the transfer of the functional organ "blood" are not so well known to the public as their importance would merit. However, the difficulties are comparable (though different in nature) to those involved in skin, kidney, or heart transplants. The plasma substitute problem may now be regarded as largely solved. The therapeutic success of plasma substitutes speaks for itself – the number of people who owe their lives to solutions of this type cannot be estimated. Furthermore, the use of synthetic colloidal plasma substitutes has provided stimuli that have led to successful cures in quite unexpected fields.

The Cytogenetics of Human Tumors[**]

BY K. D. ZANG AND H. SINGER[*]

Chromosome changes can be observed in many tumors, suggesting that a connection exists between chromosome aberrations and tumor formation. A general introduction to the techniques and objectives of research in cytogenetics is followed by a discussion of the modern theories of the etiology of tumors, using human meningioma as an example. Meningiomas are relatively benign, slowly growing tumors of the meninges.

1. Introduction

Depending on the techniques involved and the aims of the particular research project, the field of work of the cytogeneticist lies between that of the chemist and molecular biologist on the one side, and that of the pathologist and anatomist on the other. The cytogeneticist also works with morphological structures, thereby obtaining information not accessible by purely histomorphological techniques about the fine structure of genetic material. This information, however, does not provide any evidence of the function of these structures. The aim of the geneticist to discover correlations between functions and structures can be realized only through a comparison of the cytogenetic findings with morphological, physiological, and chemical evidence.

In this article we shall give a brief outline of the techniques and aims of the cytogeneticist, using as an example the chromosome pattern observed in human tumors. Special attention is paid to meningiomas, as the chromosome changes in these tumors are clear and distinctive, and are thus particularly suitable for purposes of demonstration.

2. The Preparation of Human Chromosomes

The chromosomes, carriers of the genetic information of the cell, exist in the non-dividing nucleus in an extremely decondensed form whose finer structure cannot be revealed by light microscopy. In the course of cell division in mammals they contract to form 1–10 μm long structures arranged in a three-dimensional system. This produces considerable overlapping in cell preparations (see Figure 1) and until a few years ago it was impossible to identify and count the individual chromosomes. Until 1956 the chromosome number in man was assumed to be "about 48" [1].

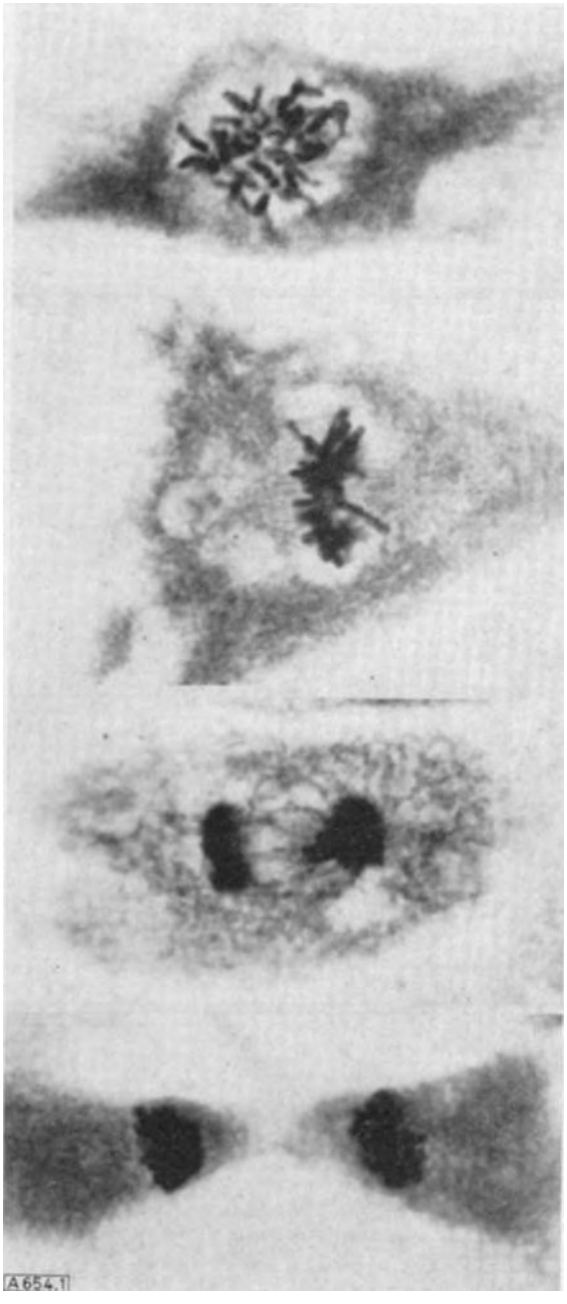

Fig. 1. Division of a brain tumor cell (meningioma) of man. Hematoxylin-Eosin staining, magnification 1200 ×.

The present form of routine chromosome analysis was made possible by three fundamental findings. In 1960, *Nowell* [2] discovered that lymphocytes in the circulating blood, which do not normally divide, undergo

transformation into lymphoblasts and divide after the addition of an extract from *Phaseolus vulgaris*. (This finding is of no importance in the investigation of tumor cells, since such cells undergo spontaneous division.) An important technical improvement was the pretreatment of the cells with a hypotonic solution. This produces a swelling of the cells, resulting in improved separation of the chromosomes [3]. The third fundamental advance is based on the treatment of cells with colchicine derivatives. It has permitted the number of human chromosomes to be definitely established as 46 [4, 5].

Colchicine has several effects: one is that the spindle apparatus (see Section 4), to which the chromosomes are fixed, is destroyed, so that the chromosomes have a better chance to spread out. Furthermore, the chromosomes contract more, acquire clearer outlines, and can be more easily identified under the microscope. The cytostatic effect of colchicine is also very advantageous: on blocking of the cell division, more mitotic cells accumulate and are available for analysis. (For further particulars of the preparation of chromosomes see [6–8].)

The modern cytogeneticist works with cell suspensions or monolayer tissue cultures, in contrast to the section preparations formerly used. Air drying of the cells after hypotonic treatment further improves the spreading out of the chromosomes. This is followed by fixation in the usual way (*e.g.* with acetic acid/alcohol or formalin) and staining with a stain as specific as possible for chromatin structures (*e.g.* Feulgen or Orcein). In cells prepared in this way the chromosomes lie mainly in one optical plane, so that photography and further analysis are substantially facilitated (Figure 2). Most of the methods of preparation employed are modifications of the method developed by *Moorhead et al.* [9].

Fig. 2. Normal human metaphase chromosomes. Orcein staining, magnification 1300 ×.

3. The Preparation and Culture of Tumor Tissues

Preparation of cells is preceded by treatment of the tissue in a manner that varies according to the respective tissue and to the aim of the investigation. Three methods of preparing tissues are used in the cytogenetic study of human tumors: 1) direct preparation; 2) short-time culture; 3) long-time culture of biopsy material.

The direct preparation method is the most reliable for ensuring that the chromosome sets are representative of the tumor sampled. This procedure is particularly suitable for malignant tumors which at any moment contain a relatively high percentage of dividing cells. In the sudden change from body temperature to ambient temperature the cell metabolism and the continuation of initiated cell divisions are slowed down considerably; in addition, no more cells start the process of division. For analysis the tissue is comminuted mechanically and is then subjected to enzyme treatment (*e.g.* with trypsin) to achieve maximum possible conversion of the tissue into a cell suspension. The chromosomes are prepared as described in Section 2.

However, the number of dividing cells is often insufficient for evaluation. In such cases the cell suspension is incubated for some hours in a culture medium, consisting of an isotonic salt solution enriched with supplements whose necessity for the growth of the tissue in question is determined empirically. Besides amino acids, vitamins, trace elements, *etc.*, the addition of 10–30% of homologous or heterologous serum is recommended in many cases. By addition of a small amount of Colcemid (deacetylmethylcolchicine, 0.1 to 1.0 μg per ml of medium, for 2–16 hours) the cells beginning to divide during this period are collected. The chromosomes are prepared in the same way as described above (Section 2).

Prolonged culture of the tumor biopsy material presents both advantages and disadvantages in chromosome analysis. In this method an attempt is made to culture the tumor *in vitro* for a longer period of time. Either small pieces of the tumor are placed in a glass vessel in a plasma clot (a coagulated mass of plasma and homologous embryo extract, generally chicken plasma and chick embryo extract), which is covered with a layer of nutrient medium, or a cell suspension is allowed to establish itself on the bottom of the vessel. In the first case the tumor grows out radially around the original particle, which is both anchored by the clot and nourished by it, and in the second case a uniform sheet of cells is produced. In both techniques the nutrient medium is renewed regularly once or twice a week, and is maintained at a uniform physiological

pH. When the cells have multiplied sufficiently, they are freed from the bottom of the flask by enzyme treatment. One part is used for chromosome analysis, and the other can be cultured again (subculture).

The advantage of this method is that chromosome analysis can be repeated as often as desired; the disadvantage is that on more prolonged culture a selection or evolution of certain cell types can occur, so that the chromosome sets found do not necessarily correspond to those of the original tumor.

As the chromosomal aberrations of human tumors will be demonstrated in the following section on brain tumors, some particulars of their culture may be mentioned. We used particle cultures (in accordance with the third method), in which the chromosomes of the primary cultures could be analyzed even after a few days. Culture of the tumor particles was performed on cover slips, which were placed in test-tubes filled with the culture medium. The tubes were slowly rotated to ensure oxygen saturation for the tissue [10]. The chromosomes were prepared directly on the cover slips, without preliminary removal of the cells. In this way the cell sheet was preserved, and almost all the cell division figures present were available for study [11].

4. Cell Division and Possible Abnormalities

Under normal conditions the body cells always reproduce in the same way. Figure 3 gives a schematic representation of the cell cycle. In the prophase the thread-like chromatin structures condense to form "chromosomes" with two genetically identical chromatids. During the next stage, the metaphase, the chromosomes contract further and arrange themselves in the "equatorial plate", a disk-shaped structure in the central plane of the cell. The nuclear membrane has disappeared. Each chromosome is stretched between two spindle fibers which end in the centrioles. In the anaphase the two chromatids of each chromosome separate at the centromere, the point of spindle-fiber attachment, and migrate by the progressive shortening of the spindle fibers to their respective poles. In the telophase a new nuclear membrane is formed around the halved chromosome sets, and the chromosomes again disappear by despiralization.

The following G_1 phase (from "growth") is a period of high metabolic activity without observable changes in the cell morphology. Most of the body cells are found in this phase. It can last for days, even months and years, as long as the cell is not preparing to divide. In the latter case the S phase (from "synthesis") begins, during which the nucleus doubles its DNA content (*e.g.* the DNA content of each chromatid) as can be measured cytophotometrically. During this phase the basic structure of the chromosome, a DNA strand wound in a double helix, is doubled. This synthesis phase lasts on average 6–8 hours.

The following, G_2 phase is a short period of high metabolic activity, generally lasting less than an hour, during which the nucleus prepares for its subsequent division. In the following prophase each chromosome again consists of two chromatids instead of one. Mitotic division occurs in this way in all body cells; on average it takes about an hour. In tumor cells the G_1 phase is greatly shortened, and in certain circum-

[10] *G. Kersting*: Die Gewebezüchtung menschlicher Hirngeschwülste. Springer, Berlin 1961.

[11] *J. Lejeune, R. Turpin*, and *M. Gautier*, Rev. franc. Études clin. biol. *5*, 406 (1960).

stances amounts to but a few hours. In these cells reproduction has apparently become an end in itself, the interphase being limited to the minimum time necessary to provide the structures and energy required for further division.

Defects in division can also occur in normal mitosis and lead to numerical and structural changes in the nucleus, but the number of such pathologically altered cells remains relatively small. In tumor cells, on the other hand, they occur in especially high numbers (see Section 6).

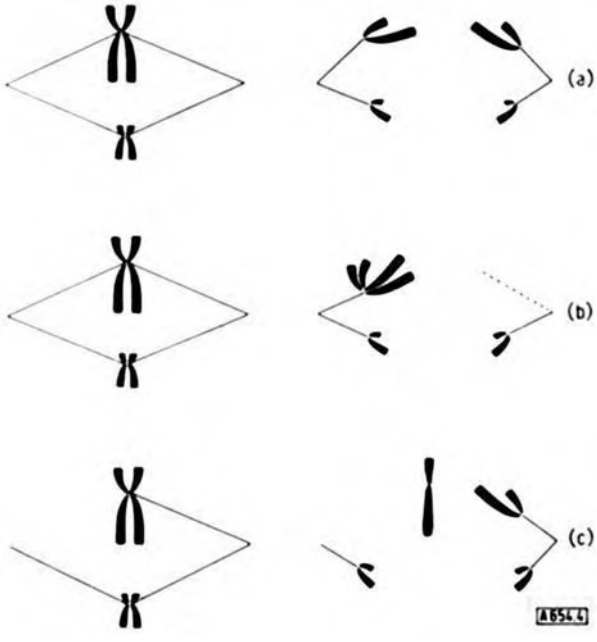

Fig. 4. Mechanism of the most common types of chromosome aberrations.

Left row: arrangement of the chromosomes in the metaphase plate. Right row: separation in the anaphase. (a) normal division, (b) non-disjunction, (c) anaphase lag.

Fig. 4 shows the mechanism of numerical chromosome aberrations. As a result of the non-separation of a centromere, both chromatids can migrate to one daughter cell, so that the chromosome concerned is doubled in one daughter cell and absent in the other (non-disjunction). The second possibility is the absence of the spindle fiber on one side of a chromosome, so that one chromatid does not move to its corresponding pole. It can either move to the other side or remain where it is and finish in either one of the daughter cells according to chance (lag). As a result of the absence of the spindle fiber attachment the affected chromosome is quickly lost.

Another common aberration of the chromosome set is its multiplication (polyploidy). This is one of the fundamental defects of cell division in tumors. Here the doubling process of the chromosomes takes place several times in succession, without any mitosis occurring in the meantime (endo-reduplication). The process is first recognizable in the next cell division, in which the chromosomes mostly appear arranged in double pairs (Figure 5).

Another possibility is that the chromosomes begin to contract as if in prophase, but owing to the absence of spindle fiber formation they soon again lose the condensed form and begin a new cell cycle without preceding division (endomitosis). Here too doubled chromosome sets are found in the next cell division but the paired arrangement of the chromosomes is generally missing (Figure 6). Besides these numerical chromosome aberrations, structural anomalies also play an essential role

Fig. 5. Tetraploid chromosome set after endoreplication (see text). The homologous chromosomes are arranged in pairs.

Fig. 6. Tetraploid chromosome set after endomitosis, a special form of endoreplication (see text). The chromosomes are arranged randomly.

in tumors. Figure 7 shows the commonest structural chromosome aberrations and their formation (for details see legend). The possible origins of these structural aberrations are discussed in Section 6.

5. The Morphology of Human Chromosomes

In considering human chromosomes prepared under standardized conditions, we shall first mention the various shapes of these chromosomes (see Figure 2).

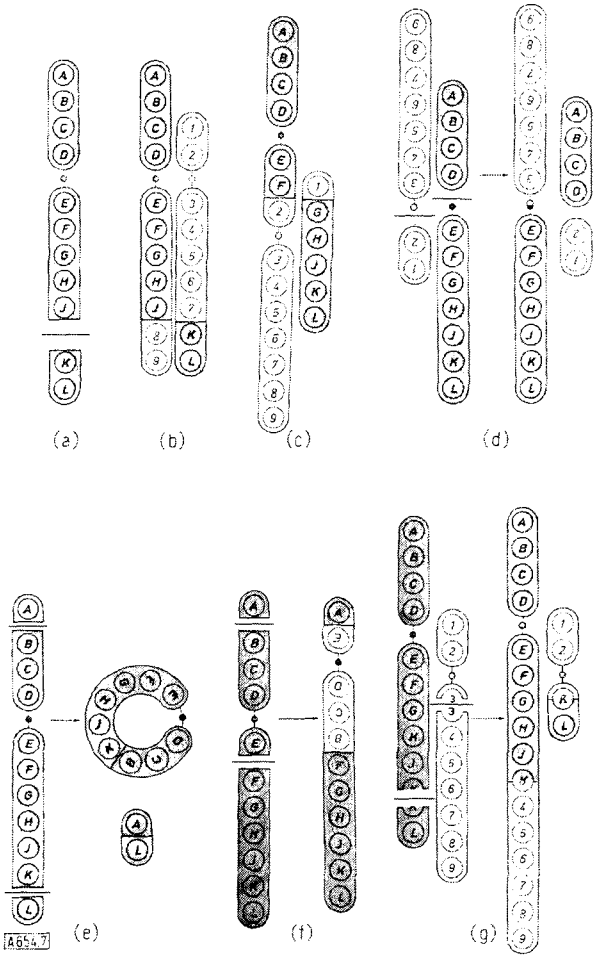

Fig. 7. Schematic representation of the most common structural chromosome aberrations. (a) Break. (b) Reciprocal translocation, generally combined with a change in the shape of both partners; a translocation involving fragments of similar size is not recognizable morphologically. (c) Formation of a dicentric chromosome by translocation. The two recombined fragments (1/GHJKL) become lost as they contain no centromere (—•— or —o—). (d) Central fusion after break of both partners in the immediate neighborhood of the centromere; the chromosome formed from the remainder of the two chromosome arms often becomes lost because of its missing or incomplete centromere. (e) Formation of a ring chromosome after a break at each end of the chromosome. The two fragments can recombine, but will in any case be lost. (f) Pericentric inversion, *i.e.* a double break as in (e); the middle piece is set in again, but in an inverted form (shown white in the figure). (g) Telomeric or tandem fusion. In this one chromosome is broken at the end of the arm and the other near the centromere. During recombination the almost complete arm of the second chromosome becomes attached to the first. The process takes place in marker chromosomes having one short and one excessively long arm.

Independently of the differences in size, three main types can be distinguished: 1. mediocentric chromosomes (the centromere, the point of spindle fiber attachment, occurs approximately in the middle); 2. submediocentric chromosomes (the centromere lies between the middle and the end); 3. subtelocentric or acrocentric chromosomes (the centromer is in the immediate vicinity of the end of the chromosome). A classification of human chromosomes according to size and shape was suggested in 1960 in the "Denver nomenclature" [12], and was then revised and improved in London in 1964 [13] and in Chicago in 1966 [14].

[12] Human Chromosome Study Group: Proposed Standard System of Nomenclature of Human Mitotic Chromosomes. Lancet *i*, 1063 (1960).

Figure 8 gives a schematic representation of the normal human chromosome set. Figure 9 shows the arrangement of a normal female chromosome set obtained under standard conditions of preparation (karyogram).

The autosome pairs (chromosomes with purely somatic information) are numbered from 1 to 22; the gonosomes (sex chromosomes, which besides containing information for the normal development of sex also carry somatic genes) are not numbered. In addition to the numbers the letters A–G are frequently employed; this is *Pätau*'s classification (1960) [15],

which places special emphasis on the chromosome shape. Its use is especially recommended for the chromosome groups C, D, F, and G, in which it is often impossible to determine the order of the chromosome pairs within the group. This identification, as well as the allocation of the respective pairs (whose partners derive from the father's and the mother's side), is often greatly facilitated by the use of autoradiography. For this purpose, use is made of the fact that during the S phase the chromosomes follow a certain sequence in their reduplication by labeling them with radioactive thymidine. Figure 10 shows such a labeling pattern of metaphase chromosomes [16].

Fig. 10. Metaphase chromosomes labeled with tritiated thymidine. At the moment of fixation the chromosomes show different labeling patterns, with, however, a general agreement between homologous partners. Upper figure: Microphotographic representation of the metaphase chromosomes. Lower figure: Demonstration of the uptake of radioactive thymidine by covering the slide with a photoemulsion. The arrows indicate the position of the chromosome pair A_1.

6. Chromosome Changes in Human Tumors

The human tumors studied most intensively with regard to their chromosomes are the leukemias, probably because blood or bone marrow are readily accessible without an operation, and because repeated examinations are possible. In one type of leukemia, chronic myeloic leukemia, a definite and reproducible chromosome aberration is demonstrable: the "Philadelphia" chromosome, a deleted chromosome of the G-group [17] (see Figure 11).

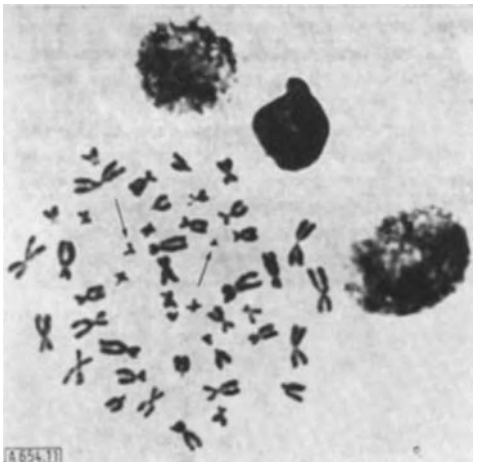

Fig. 11. Metaphase chromosomes in chronic myeloic leukemia. The arrows show the Ph^1-chromosome and its homologous partner [17a].

The importance of this finding lies in its regularity and in the fact that the chromosome is found only in pathologically altered cells. From this one can conclude that the Philadelphia chromosome is not a congenital defect. Such structurally abnormal but typical and recognizable chromosomes are called "marker" chromosomes in cytogenetics.

A similar, defined chromosome aberration, in the sense of a marker chromosome, occurs in Waldenströms macroglobulinemia [18]. In the mosaic form (hence not in all cells) there appears an additional 47th chromosome, which generally has the size of chromosome No. 2 and the shape of chromosome No. 5. This is also a pathological cell strain, which is demonstrable in the blood, but, just as with leukemia, is not a "tumor" in the strict sense.

Such marker chromosomes have also been described in most solid tumors of man, though they are seldom the only pathological finding in the tumor chromosomes. In most cases there are considerable numerical deviations, generally consisting in a moderate to considerable increase in the chromosome numbers between the diploid (46) and tetraploid (92) chromosome sets. Analysis is made more difficult in most cases by the fact that the chromosome changes are not the same in all tumor cells. The number of chromosomes varies from cell to cell, so that only a "modal number" can be given which again can differ from case to case. A great number of chromosome breaks and all types of recombinations given in Figure 7 can also occur.

As an example, reference will be made to HeLa cells, a permanent cell line, derived originally from a carcinoma of the cervix and used today throughout the world for genetic and biochemical studies. The chromosome number and the morphology of these cells can vary considerably from laboratory to laboratory. However, the establishment of such a permanent cell line, which derives from a tumor and is reproducible in subcultures for as long as required, is an exception. Normally, the capacity of cells for division and growth *in vitro* is limited. After an average of 50 subcultures (about $1-1^1/_2$ years) the reproduction capacity of the cultures usually diminishes and the cells die. This occurs not only with cultures

of tumor origin but also with fibroblast cultures from normal human connective tissue. That further cultivation is no longer feasible is indicated in normal and so far euploid cultures (*i.e.* cultures with a normal diploid set of chromosomes) by increasing polyploidization and the beginning of structural chromosome aberrations.

Up to the present the chromosome sets of about 200 malignant human primary tumors have been described [e.g. 19–23]. The results are unsatisfactory for the above reasons. It is impossible to find a typical combination of chromosomal changes for a particular tumor, *e.g.* cancer of the stomach. A similar lack of agreement exists between different kinds of tumors.

The occasionally expressed presumption that the chromosome E_{16} increases to a substantially greater extent in tumor tissue than the other chromosomes should also be treated with reserve. Deletion of the long arm of chromosomes of the C-group are a common finding in tumors and can lead to chromosomes morphologically indistinguishable from chromosome No. 16. As only two chromosomes of this type are normally present, a considerable increase can easily be simulated in this way, without the relative decrease in the numerous chromosomes of the C-group being noticed. A similar finding, *i.e.* the relative decrease in chromosomes of the G-group, has been discussed by several authors [24–27] on the basis of the material reported in the literature (see Section 7).

In our studies on brain tumors we looked for chromosome changes in relatively benign and slow growing tumors. In this we paid special attention to meningiomas, tumors that do not originate from the brain but from the meninges, forming a histologically particularly uniform system. As a rule they grow only by displacing the surrounding tissue, without infiltrative and metastasizing growth like malignant tumors.

We have demonstrated the loss of a chromosome of the G-group [28] as the basic change in meningiomas. This can occur as the only finding. Furthermore, this loss is sometimes demonstrable as a mosaic pattern together with cells having a completely normal chromosome complement, and in some tumors only normal cells could be found. (Perhaps in this small group a cell line with a missing G chromosome simply could not be detected.) Some tumors in our series of over 30 cytogenetically investigated meningiomas showed more severe histological abnormalities; in this group, besides the G-chromosome, 1–5 other chromosomes were missing (Figs. 12 and 13). However, each chromosome set was uniform and characteristic for the tumor concerned. No great variations from cell to cell, such as those described for malignant tumors, were found in any of the samples investigated by us.

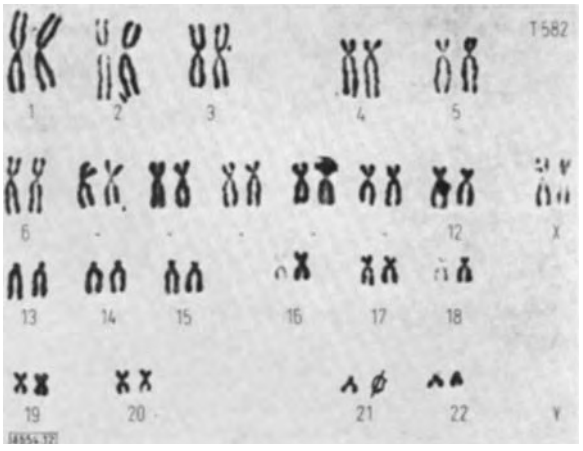

Fig. 12. Karyogram of a meningioma cell. Loss of a chromosome of the G-group (uniform cell strain in the whole tumor).

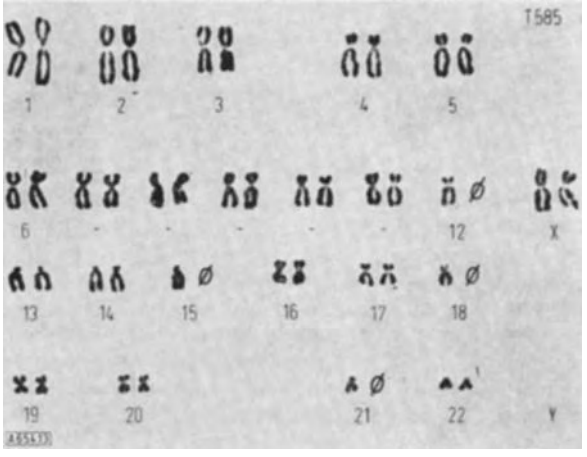

Fig. 13. Karyogram of a meningioma cell. Loss of a chromosome of the G-group and three other chromosomes of different groups (uniform cell strain in the whole tumor).

In some tumors, but even here in only a few cells, there was a doubling of the set of chromosomes and small structural changes, such as are shown in Figure 7. These variations are summarized in Figures 14 and 15.

However, it should be emphasized once more that the structural aberrations described in the benign meningiomas examined by us are rare and of limited importance compared to the constant numerical aberrations. Two chromosomes of the G-group are also missing in the endoreplicated cell shown in Figure 5. We assume that the loss of the G-chromosome was the primary event and the doubling of the chromosome set was the secondary event, possibly occurring *in vitro*.

It is rather unlikely that the chromosome aberrations found by us were influenced by the formation of clones during the period of cultivation. It has been possible to show in over a thousand brain tumors cultured at the Neuropathologisches Institut of Bonn University and at our Institute, that the medium used by us is especially suitable for the propagation of the primary structure of these tumors, though in a two-dimensional system. Neither an overgrowth of connective tissue cells nor further dedifferentiation of nuclear structures has been observed. Comparison with cultures of the same tumors in a typical nutrient medium for fibroblasts was very informative (McCoy 5 A). The cultures grew more slowly, the morphology of the cell sheets was clearly changed, and chromosome analysis showed almost entirely normal chro-

mosome sets [29]. This example shows the danger of a selective propagation of the connective tissue of a tumor by using an inappropriate technique, and of subsequent interpretation of the observed normal chromosome sets as evidence that the tumor in question is benign. On the other hand, we find in the culture of glioblastomas, the true carcinoma of the brain, the same abundance of numerical and structural chromosome changes as described in other malignant tumors [29].

7. The Relationship between Chromosome Aberrations and Tumor Formation

In his theory of cancer, *Boveri* in 1914 [30] was the first to propose a relationship between chromosome aberrations and tumor formation. The chromosome aberrations found in human tumors in the last ten years have established his theory. Three possible types of relationship are discussed today: 1. It has been suggested that tumors are caused by chromosome changes, as chromosome changes have been demonstrated in many tumors and in the remainder the morphological changes were of such an order that they could not be detected by light microscopy. 2. The chromosome changes are not the primary cause of tumor formation, but the result of it. They can be present or lacking, and vary in most tumors from sample to sample. 3. Morphological chromosome changes can be one of the possible ways in which tumors arise; conversion of normal into tumor tissue (neoplastic transformation) can, however, also occur in another way, without morphological chromosome changes being observable.

[29] *K. D. Zang*, unpublished.

[30] *T. Boveri*: Zur Frage der Entwicklung maligner Tumoren. Fischer-Verlag, Jena 1914.

A common feature of these three at first apparently contradictory views is that today it is no longer possible to maintain the argument that tumors occur without changes in the genetic structure of the cells. Consequently, chromosome changes in the widest sense must also be present. But these changes need not necessarily be detectable microscopically.

It must, however, be left an open question whether the chromosome aberrations found are the (constant) visible expression of these genetic changes, or whether they can be interpreted only as an expression of uncontrolled cell multiplication [31]. On this point even the appearance of marker chromosomes gives no clear information; for the present it only indicates a unicellular and not a multicellular origin of a particular tumor cell population [32].

In chronic myeloic leukemia the deletion of the long arm of a G-chromosome occurs, resulting in a loss of about 40% of the chromosomal DNA. In meningiomas a whole chromosome of this group is missing, and in many malignant tumors with a great increase in the number of chromosomes there seems to be a relative decrease in the chromosomes of the G-group. Consequently, it can be postulated that there is a relationship between this stereotype chromosome aberration and the tumor formation. This hypothesis does not reject other possibilities. It cannot be denied that during the development of (malignant) tumors the chromosome set becomes increasingly abnormal, and that there is no specific correlation between this and the malignity. Thus, in the late stages of chronic myeloic leukemia there is found, apart from the Philadelphia chromosome, an abundance of numerical and structural aberrations. It should rather be supposed that in growing tumors those cells multiply preferentially whose chromosome sets have a genetic constitution promoting their metabolism and reproductive capacity under the respective *in vivo* or *in vitro* conditions. It may well be argued that, as a result of several deletions and translocations, cells with morphologically and numerically different chromosome sets are genetically identical. We are merely attempting, on the basis of our findings, to support the hypothesis that the loss of G-chromosome material could trigger off uncontrolled cell multiplication (see Section 7.1.).

7.1. Chromosome Changes and Tumor Formation due to Exogenous Effects

There are essentially three groups of exogenous factors which are known to induce tumors: 1. ionizing radiation; 2. oncogenic viruses; 3. mutagenic chemicals. It is also known that all these factors can cause chromosome aberration. Using human cells, *Koprowski et al.* [33] established for the first time in 1962 that chromosome aberrations can be caused by the SV40 virus in tissue culture. These aberrations began with the loss

of chromosomes of the G-group. Considerable variations in the chromosome number and all the described structural changes, as observed in the chromosome sets of malignant tumors, arose on further culture. These findings have been confirmed repeatedly, and have been found in the meantime also in tissue cultures infected with Rous sarcoma virus, polyoma virus, and adenovirus type 12. All these viruses can cause tumors *in vivo* in animals. On the other hand, however, non-oncogenic viruses, *e.g.* the measles virus, also have the capacity to cause chromosome breaks [34].

Fig. 16. Chromatid breaks and recombination figures in the chromosomes of a peripheral lymphocyte after cyclophosphamide therapy [34a].

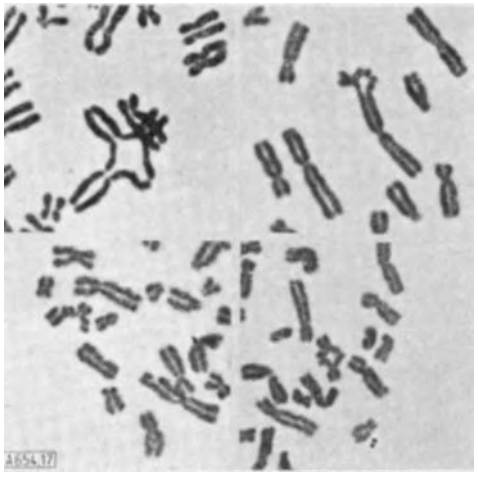

Fig. 17. Chromosome breaks and multiradial recombination figures in chromosomes of peripheral lymphocytes after radium and X-ray therapy [34a].

It is also known that ionizing radiation can cause chromosome changes *in vivo* and *in vitro* (see Figure 16) and that tumors can be induced by X-rays. An interesting example is the case described by *Engel* [35] in which a chronic myeloic leukemia with the typical Philadelphia chromosome occured in a patient several years after X-ray treatment for a bronchial carcinoma.

A finding familiar to the chemist is the production of tumors by the application of mutagenic chemicals. With most substances the induced transformation of the cells is associated with a change in the chromosomes. The effects of urethane [36] and mustard gas [37] in inducing chromosome changes were the first described. Since that time it has been discovered that many alkylating agents have the capacity to cause chromosome aberrations (cf. Fig. 16), and the same occurs with many purine and pyrimidine derivatives [38]. Most DNA-base analogs have a mutagenic effect; it is assumed that they act directly on the DNA of the cell nucleus and alter the chromosome structure. Thus, for example, the effect of urethane can be partly counteracted by thymine [39]. Other chemicals, such as caffeine and colchicine, as well as some other cytostatics, do not affect the DNA but alter or impede the function of the spindle fibers [38]. Considerable chromosome aberrations are also produced in this way.

There is a great similarity between the visible effects of all the chemical, radiological, and viral agents capable of inducing both tumors and chromosome aberrations; primarily, there are disturbances in chromosome disjunction, and, furthermore, chromosome breaks occur. Apparently these exogenous agents have definite and constant predilection sites for the induction of breaks. The broken ends of chromosomes have a predisposition to recombination, *i.e.* to combine with other sites where breaks have taken place, so that numerous recombinations are possible after the simultaneous occurrence of breaks in several chromosomes in the same cell cycle. Thus cell strains differing in chromosome morphology but genetically identical can be produced.

7.2. Chromosome Changes and Tumor Formation due to Endogenous Factors

There is some evidence for the assumption that endogenous as well as the described exogenous factors can play a part in tumor formation and in the increase in chromosome changes.

As an example, we may recall the existence of "tumor families", in which tumors occur over the course of several generations; the tumors are generally malignant, and can show similar or different localization and morphology [39,40]. Such families are said to have a "predisposing factor", but no more definite etiological and pathogenic information can be given.

A correlation has also been found between chromosome anomalies and immunological diseases. Many autoimmune diseases and tumors have been associated, *e.g.* pernicious anemia with carcinoma of the stomach, as well as Hashimoto's thyroiditis with cancer of the

thyroid gland [41]. On the other hand, mothers having demonstrable thyroid antibodies (Hashimoto's thyroiditis) have children with chromosome anomalies, especially children with a G-trisomy (Down's syndrome), more commonly than healthy mothers. In addition, patients with numerical or structural chromosome anomalies are more inclined to develop malignant tumors than the general population [42].

Chromosome aberrations can be caused *in vitro* in primary normal fibroblast cultures if an extract of genetically foreign lymphocytes is added. It has not yet been made clear whether a classical immune mechanism is involved, or something else [43]. Chromosome changes also arise in normal tissue cultures after activation of lysosomal enzymes [44]; a tumor-inducing factor could, for example, produce a breakdown of lysosomes, whose released enzymes could cause chromosome breaks to recombine in a way that leads to the formation of tumor cells.

We must assume that the majority of the possible morphological chromosome changes are not consistent with cell life. Many findings indicate that immunological mechanisms can lead to chromosome changes. For this reason it can be argued that such immune reactions have a kind of self-protection function, in which the "abnormal" cells are eliminated through an alteration of the chromosome structure. A possible defect in this self-protection system could be that not all cells undergo lethal chromosomal damage and some become so changed that, on the contrary, they exhibit uncontrolled growth [41,45].

8. Outlook

Human chromosomes are very unsuitable for the investigation of many questions in genetics, especially biochemical genetics, mainly because of their small size. On the other hand, some of the difficulties could be eliminated by greater cooperation in morphological, virological, and biochemical research. Thus, there is a possibility of fractionating dividing cells and concentrating the chromosomes [46]. The separation of chromosomes or chromosome groups by physical methods could yield further information on chromosome structure. An "*in vitro* system" of concentrated chromosomes of defined morphology could reveal the functional differences between individual chromosomes. On the cytogenetic side, experiments are already being undertaken to culture strains with defined chromosome aberrations. Biochemical methods can be used to try to find structural or functional differences between these cells and normal cells. Already, for example, a series of observations indicate that in chronic myeloic leukemia the activity of the alkaline leukocyte phosphatase is decreased, whereas in patients with Down's syndrome it is increased.

The goal of drawing up a gene map of the human chromosomes is still far in the future, and will probably never be attained on the same scale as in the case of the giant chromosomes from the salivary gland of *Drosophila melanogaster*, but it is not completely hopeless; for instance, a large number of genes can already be localized on the human X-chromosome, and their sequence and approximate distance apart can be determined.

Element and Compound. On the Scientific History of Two Fundamental Chemical Concepts[**]

BY E. STRÖKER[*]

A wish is often expressed that any purely factual account be completed by an historical dimension, where not only a science's past, like a venerable arsenal of the factual knowledge possessed in earlier times, but also the thought-structures which led to such knowledge in the first place, should be called to memory. These thought-structures, however, never belong exclusively to the past; they still find themselves as a precipitate in contemporary scientific methods – a sediment in present-day concepts.

In the following article we do not wish to compile a mere inventory of what was regarded at different times as element and as compound, but rather to examine a few, typical, clearly definable thought-structures, which have become what they now are through the changing usage of the concepts of "element" and of "compound" in the course of the history of chemistry. The alchemistic doctrines of

[*] Prof. Dr. Elisabeth Ströker
Seminar für Philosophie der Technischen Universität
33 Braunschweig, Pockelsstrasse 14 (Germany)

[**] Based on a paper read at the general meeting of the *Gesellschaft Deutscher Chemiker*, in Berlin (September 18–23, 1967).

elements shall not be examined at all, and the concepts of "element" and "compound" will be considered only insofar as the history of their development has been significant for chemical science.

*

These two concepts recall a very distant past. It is commonly known that the earliest reflections on nature are to be found in the Ionian philosophy of the Vth century B.C. Just one hundred years later we find the first "doctrine of elements", which was to play an important role in chemistry right down to the Renaissance.

Fragments of a poem "On Nature" by the author of this doctrine, Empedocles, a follower of the old Pythagoreans, are still extant. In his poem, Empedocles raises the question of the *rhizomata*, of the "roots" of all things. He conceived them as four divinities (that there should be four may be explained on the basis of the Orphic-Pythagoric tradition, which regarded the number four as sacred): fire, earth, air, and water. Empedocles supposes that all that exists is composed of these. Things share in them in different ways, and this is the reason why things are different. Their composition may vary. Also the qualitative changes, the coming-to-be and the passing-away of things, are based on the mixture and exchange of such particles. Each of the four "roots" is in itself unchangeable in mode and in quantity, and is not subject to growth or decrease. It is likely that Empedocles also conceived the idea of continuous exchange of fire, water, earth, and air as an exchange of small particles, imperceptible because of their smallness, so that all obvious quantitative as well as qualitative changes are ultimately based on the motion of such particles.

To be sure, the present-day chemist cannot expect to do anything on the basis of this Empedoclean doctrine of elements, which is still tangibly captive of the archaic-mythical *Weltanschauung*. But let us bring out the posing of the question from which this doctrine originated, in order to see how its significance went far beyond just the material content of its own statements.

With the advent of Ionian natural philosophy a way of thinking came into being, which would be of decisive significance for the whole of Western science. Confronting the world, man asked of it as a whole – what it was. He was not satisfied, however, with the mere evidence of things and sought a deeper understanding about what lasts as permanent behind their change, about what their *hypokeimenon* – that which "underlies" all coming-to-be and all passing away – may be. And it was peculiar to this earliest philosophical thinking, that it regarded no longer demons but *material* principles as being involved in the foundation of the world. By assuming four such principles, which should explain the plurality and changeableness of sensible phenomena, Empedocles establishes himself and his doctrine within a much older tradition of thought. He may be regarded, however, as the advocate of the first doctrine of elements; the concept of the material element originates from him. Though the designation *stoicheion* was introduced later by Aristotle, the four "roots" of all things, as Empedocles conceives them, are already properly *stoichaia*, or elements – in the specific sense, at least, and as understood not only by the Greeks in their later classical doctrine of nature but also by chemists up to the time of Robert Boyle. This means that from the era of Empedocles on *elements* are *basic materials*, insofar as all material is composed of them, *i.e.* all natural things originate from them. The elements themselves, on the other hand, are unoriginated, unchangeable, indestructible; their total quantity in the universe must be regarded as constant.

*

We shall not concern ourselves here with an examination of the reasons which later led to the peculiar revision of this doctrine of elements by Leucippus and Democritus. The most far-reaching aspect of their philosophy of nature was that in it the qualitative difference of the elements was annulled, *i.e.* all material qualities were reduced to purely mechanical processes of motion of the corpuscles of a single matter. All Democritean particles were of the same kind, distinguished from one another only in shape and magnitude. They were also thought to be unchangeable, unoriginated, imperishable, of finite magnitude, and yet indivisible – *átoma*. The concept of *atom* was used from then on to denote the smallest, reputedly (mechanically) indivisible particles of matter.

It has been necessary to briefly recall the Democritean atomism, even though it not only failed to foster the development of the previous doctrine of elements but also actually did away with the very notion of element. In so doing, however, this atomism was to be a constant and determining factor in the later discussion on the nature of matter.

*

Democritus' sharpest opponent, Aristotle, was the successful continuator of this discussion but nowhere in the history of chemistry does he find adequate appreciation; only the accusation of having fallen back into the old doctrine of the four elements is leveled against him. We are fully justified, then, in stressing Aristotle's role as author of a doctrine, which permanently influenced subsequent chemical thinking. Problems of matter and of material change found their honored place in the Aristotelian philosophy. The first precise determination and elaboration of the concept of matter – *hyle* – was done by Aristotle.

For Aristotle, however, matter is always qualitatively determined matter. The assumption of a matter deprived of quality, whose *átoma* are merely differently formed and only mechanically moved and ordered – the Democritean corpuscular kinetic pattern of change – is, according to Aristotle, wholly irreconcilable with that of experienced reality. Aristotle's main argument against Democritus presupposes quite def-

initely the acceptance of the tangible world. No aggregation of atoms but qualitative manifoldness and fullness, not only mechanical motion but also development and change, coming-to-be and passing away – this is what such a world exhibits.

Significantly, however, it is with this particular set of problems that Aristotle runs into difficulties in his criticism of Democritus. He was the first to see clearly the distinction between a *mixture* and what was later to be termed a chemical *compound*. The Greek word *mixis* explicitly denotes a chemical compound as opposed to a mixture, for which the term *synthesis* is used [1].

According to Aristotle, it is precisely here in the interpretation of *mixis* – of the compound, therefore – that atomism fails, since it does not succeed in explaining the amazing effect of *henosis*, of the "becoming one" of different material elements in the entirely new kind of matter of the *mixis*: for the qualities of a *mixis* are not the summation of the peculiarities of the original materials but are wholly new and of a different kind. Hence, Aristotle assumes that in the *mixis* the original materials could not have remained unchanged, even in their smallest particles, since otherwise the compound would be nothing but a macroscopic illusion and actually only a mixture of the atoms of the original materials.

Aristotle is well aware, on the other hand, that the original substances which go into the making of a compound – that is in the *mixis* – can be retrieved; therefore, these substances can neither be lost nor destroyed. The possibility of decomposing a compound into its component parts would seem to involve precisely the opposite of what is suggested by the new quality of the compound – no sooner is the problem of the *mixis* seen and formulated with clarity, than it leads to an aporia.

Briefly, Aristotle attempted to overcome this difficulty as follows: it must be granted that in the *mixis* an entirely new matter has arisen from the original materials; nevertheless, the components are present *dynamei*, "potentially", also in the compound. In the compound the components are no longer what they were as individuals; it is likely that they have undergone an intrinsic change. It is also true, however, that the elements do not perish in the compound, since it is always possible to retrieve them by analysis of the compound itself.

For the first time, some very significant questions are raised, questions which have concerned chemists ever since. It would no doubt be an error to regard Aristotle as a chemist in order to easily dismiss him as an amateur. The Aristotelian doctrine of *mixis* must be regarded explicitly as a philosophical discussion of principles. In other words, the doctrine must be considered here in its true context as an aim at clarifying not chemical *facts* but rather those concepts without which we would find it impossible to state with precision questions about such facts. The problem is not, "what is matter and how is a *mixis* made from it", but, how is one to think of this *mixis* as existent *tout court*.

*

On the other hand, however, the question whether a *mixis* can be understood as matter which "consists of" other materials, is a later differentiation of the Aristotelian problem. Aristotle develops his discussion on principles wholly within the framework of ordinary language. In ordinary language, however, it is taken for granted that a compound owes its *ex*istence to the same materials of which it *con*sists. (The present-day chemist still says, for instance, that hydrochloric acid "consists of" oxygen and chlorine, and finds this way of expressing himself meaningful throughout.)

Aristotle established a way of questioning and reasoning, which was used in, and strongly influenced, discussions on the composition and structure of matter until late in the XVIIth century. Such discussion was carried on – though not without frequent interruptions owing to the dominance of alchemy – in the main in two clearly separate philosophical camps, without first being related to chemical experience.

On the one hand, the old Democritean doctrine was revived in the philosophy of the Stoics and found its continuation in the so-called philosophical atomism. According to its fundamental concept, however, atomism could never have solved the Aristotelian problem, viz.: how to interpret the formation of chemical compounds from the elements and the possibility of analyzing the former into the latter. Atomism was even incapable of distinguishing between these two categories of matter.

On the other hand, this distinction, clearly formulated for the first time by Aristotle, became the cause of a heated controversy in the Aristotelian camp on the problem of the divisibility of matter. The appeal to Democritus' non-qualitative atoms of a single matter did not at first contribute to its solution. There seemed to be also a qualitative difference between the smallest chemical particles of a given matter and those of another. This assumption of the existence of the specific smallest particles of a given matter – of the *minima naturalia* – played an important role throughout the Middle Ages, since it constituted the background on which was based the question of the nature and the fate of the *minima naturalia* of the elements when the latter form a *mixis*. In the *minima naturalia* of the Aristotelian tradition we may easily recognize the conceptual forerunners of the molecules of modern-day chemistry. It is also easy to see how the distinction between atom and molecule became possible only in the realm of the doctrine of *minima*; it found no place in ancient atomism.

*

Two reasons justify our turning our attention to Robert Boyle who, in the middle of the XVIIth century, dealt thoroughly with the traditional doctrines of elements and finally developed an entirely new conception of the *chemical element*. At last chemistry was

[1] *Aristotle*, De generatione et corruptione, 328a 1–13.

established as an *empirical science*. Further, in a remarkable attempt to derive a compromise between the doctrines of atomism and of the *minima naturalia*, Boyle was the first to successfully resolve the conflicting ideas surrounding the precise conceptual interpretation of the notion of a *chemical compound*.

Let us first consider this latter attempt of Boyles to establish a compromise between the two doctrines – an attempt which was based in part on important preliminary work done by Sennert and Gassendi. On the one hand, the atoms conceived by the atomists were considered, at that time, to be too little "chemical", in their qualitative indistinction, to be accepted as ultimate building-stones of the material world. On the other hand, the few basic principles of this doctrine – magnitude, form, and motion – did prove their usefulness in a mechanistic conception, which in the physics of the time was scoring one success after the other. From this standpoint one can understand Boyle's attempt to reduce once more all chemical qualities to mechanical principles, and yet to take into account that Democritus' heaps of atoms apparently were of no use to the chemist. For the elementary materials, then, Boyle introduced the notion of texture – of an atomical pattern, as it were – to be determined exclusively on the basis of the geometrical and topological properties of the smallest Democritean particles. Chemical compounds could be explained then as the coming together of several textures and their re-organization into a structure through the motion of particles – as the heterogeneous particles taking part in the formation of a definite pattern [2].

This resulted in a doctrine that was a peculiar mixture of atomism and that of *minima naturalia*. On the one hand, it recognized the right of the doctrine of *minima naturalia* to stress the specificity of material particles; on the other hand, it tried to *explain* this specificity in terms of the corpuscles, and of their texture and structure. Though the explanation was mechanistic, it was able to overcome to a certain extent the determined opposition which such explanation had encountered up to that time. The Democritean notion of mere aggregates of corpuscles was superseded here by the notion of *structure* – in place of the disordered aggregate the organization of particles into *structures* was now envisaged. The concept of structure, introduced by Boyle and so eminently important for chemistry, first silenced the centuries-old controversy on the union of elements in chemical compounds.

*

Of no lesser importance, however, was Boyle's new conception of an element [3]. This notion, which different traditions had made obscure, is discussed by Boyle for the first time within the framework of empirical research. *Experiments* at last should decide whether the materials which were hitherto considered "elements" are indeed such and not actually compounds. As elements they had to exhibit themselves as "perfectly homogeneous and simple", not composed of other materials or of one another. And why should there be only four elements? Indeed no reason had yet been put forward which could have excluded the possibility of a large number of elements.

The fundamental change in methodical outlook, which Robert Boyle's considerations brought about, can only be fully appreciated, as it were, against the background of tradition. The older doctrines viewed the elements only from the standpoint of their being *in* all *other* materials, as basic materials; the question of the existence of elements arose only in connection with "compounds". Boyle, on the contrary, asked what sort of materials the elements were *in themselves* and *among other* materials. By taking only *chemical simplicity* into account and regarding it as the only chemically essential determination, and further by accepting the possibility of a large, *still indeterminate multiplicity of elements*, Boyle opened up entirely new fields of chemical research. He forcefully confronted chemistry with its proper aim, viz.: to enquire into the multiplicity of materials in order to differentiate between elements and compounds of such elements.

Boyle's new concept of elements was bound to raise questions, on whose answer alone would depend how and in what sense other materials could be envisaged as being composed of elements. It had to be experimentally established which of the materials could be further analyzed, and whether, and if so how often, this process could be repeated. These questions show how stimulating Boyle's ideas were for analytical chemistry – it is not by chance that this name originated from him.

Can it be convincingly established, however, whether a material is simple or compound? The chemist, apparently, would never be able to decide with absolute certainty whether the products obtained by an analysis are really the ultimately simple chemical materials or whether new analytical methods would show that they are still compounds.

Consequently, Boyle did not venture to actually identify any materials as elements. The objection voiced against him on this account fails to duly appreciate these considerations and overstates a rather widespread interpretation of Boyle's views on the elements.

Boyle is often regarded as the author of the "analytical definition" of elements. In such definition the notion of element is explicitly determined in relation to the status of the analytical methods used for its discovery. The definition accordingly refuses to speak of elements "as such". It is easy to see, however, that this interpretation is anachronistic; it is also easy to see how effortlessly it slipped into the history of science. It is one thing to think of a chemical element as a material which in itself *is* simple and cannot be further analyzed chemically, but quite another thing to define an element as a material which *cannot* be further analyzed by experimental methods current at the time.

[2] The Works of the Honourable R. Boyle, 1772 (repr. Hildesheim, 1964–66), Vol. I, p. 493f.; Vol. III, pp. 17f., 49f.

[3] Ref. [2], Vol. I, pp. 495f., 530f., 562.

The statement that "there are chemical elements" does not mean the same thing in both cases. In the first case we are confronted with a metaphysical statement about a quality regarded as pertaining to the material world. Boyle had this in mind when he asserted that "nature makes use of elements". Only in the second case, however, where the existence of chemical elements is tied to their experimental demonstrability, does it correspond to an analytical definition. Boyle did indeed clear the way for it, but it was Lavoisier who first formulated it explicitly.

*

In the latter half of the XVIIIth century, a number of epoch-making accomplishments in chemistry are connected with the name of Lavoisier. This seems to substantiate the opinion of those who identify Lavoisier with the climax of a Copernican revolution in chemical thinking. He was responsible for the first systematic application and use of quantitative methods, which led to the confutation of phlogistics and to the grounding of the modern doctrine of oxidation. Among other things, however, this brought about also a decisive reform of the basic views on elements and compounds – and this in a twofold way.

For one thing, the above-mentioned analytical definition of elements aquired significance. Seizing upon Boyle's insight that one could not be sure about the elementary nature of any material if its chemical analysis did not take place, Lavoisier gave it a methodically decisive interpretation, which constituted a turning-point in chemistry's scientific consciousness. Lavoisier purged Boyle's concept of element of all metaphysical implications and directed this concept exclusively on the expediency of the analytical experiment. Certain materials are chemically determined as elements, insofar and so long as there is no way of further analyzing them. They are elements "*pour nous, à notre égard*". The question whether nature itself has produced elements as such lies beyond the ken of chemical science [4].

If one is now to consider that for chemistry elements are not only *basic materials* as a definite class of materials of which other materials are composed, but also basic materials in a wider sense – that is, that the notion of element as such is also the foundation of the kind and structure of our *knowledge* of all remaining materials – then it is clear that Lavoisier's analytical definition means much more than the prudent reserve and self-criticism of its author would lead one to believe. It was an expression of a state of things, whose main significance could be grasped only by the later theoretically advanced chemical science, viz.: that all its statements could not refer ultimately to elements as something simply given in nature but to fundamental hypotheses on the nature of the elements. Most of these hypotheses have brilliantly stood the test of time.

The second result of Lavoisier's reform – much more tangible for positive research than the first – was his interpretation of the processes of oxidation and of reduction, which led to the objective determination of several elements and compounds [5]. Substances which in earlier times were considered as chemically simple as, for instance, water and calcareous metals, now proved to be further decomposable compounds. And conversely, materials which phlogistonists had held to be compounds now had to be considered elements, *e.g.*, sulfur, phosphorus, hydrogen, oxygen, and particularly the metals. What Lavoisier accomplished with this transformation of views on elements and compounds can be measured only in the light of chemistry's later development – it was the start of an entirely new orientation of material systematics.

The first chemical terminology, developed in 1787 by Lavoisier in association with G. de Morveau, Berthollet, and Fourcroy, was firmly constructed on the principle of the new distinction between element and compound. That this terminology has proved itself useful up to the present day, if not in detail still in the essentials of its systematics, is a clear sign of the level of chemical knowledge attained through Lavoisier's work. It was the beginning of a chemical technical language, of whose significance hardly anybody is still aware, since it has long been taken for granted that each science has its own technical terms.

*

At the same time, however, this terminology plainly reflects the limits of XVIIIth century chemistry, especially with regard to the element-compound problem. It was not by chance that it went no further than a terminology; all efforts to construct a symbolism, in fact, failed. It still lacked the theoretical foundation which was to be layed down for the first time during the XIXth century. Through his quantitative research on metal-ion precipitates, neutralization, and metathesis, Richter, who was practically unknown in his own day, managed for the first time to give the concept of chemical equivalence a clearly defined meaning and to lay down the foundations of stoichiometry. Lastly, Dalton's atomic theory furnished the basis for the clarification of Richter's stoichiometric results and for a first glimpse into the quantitative composition of compounds. Dalton was the first to recognize the significance of atomic weight in chemical research. From then on the relative atomic weight became the essential characteristic of an element [6].

Though the weights determined by Dalton have today only an historical interest, his view must be regarded as one of the most decisive turning points for XIXth century chemistry. With it, in fact, not only was the way open for a precise study of the chemical proportions for individual compounds, and thus for precise quantitative knowledge on the structure of the material world and its laws, but Dalton's insight also served as a basis for the construction of a set of char-

[4] Oeuvres de Lavoisier, Paris (1862), Vol. I, p. 4.

[5] Ref. [4], Vol. II, pp. 225–233, 623–655.

[6] *J. Dalton*, A New System of Chemical Philosophy. London 1808; German translation by *Fr. Wolff*, Berlin 1812, Vol. I, p. 237.

acteristic symbols, with few and very simple syntactical rules for their application, so that one could speak of a language of signs and formulas in the full meaning of the term. Berzelius developed the symbolic language further, and it was soon supplemented by structural formulas. In its present form, this language is not only a means of information but belongs so inalienably as an essential methodical tool to modern chemistry, that the latter would be simply unthinkable without it. Furthermore, the elegance of this chemical sign-language lies in its ability to illustrate the basic structure of chemical thinking in the simplest terms – the basic distinction between element and compound; any systematics with which the chemist attempts to bestow order and clarity on the fullness and multiformity of the material world is finally oriented on this distinction.

Thanks to Daltonian chemistry's forceful stand on the importance of atomic weight, a third important factor comes into play in this connection. Far from simply remaining a characteristic number for each element, it served as a means of investigating the possibility of *relationships* between different elements. This led in the 1870's to the drawing up of the periodic system of elements, which constituted the basic structure for all further systematization of matter. The atomic weight – or better, the atomic mass – later lost its fundamental significance for this system and had to be replaced by the nuclear charge of the atom. It still remains, however, an historically essential fact that atomic weight offered only one aspect – the most important among several, however – to at least attempt to systematize the elements, an ever greater number of which was being discovered.

*

Timidly begun in 1817 with Döbereiner's doctrine of triads, carried on in the fifties about just as promisingly by Pettenkofer and Dumas, half a century was to pass before the periodic system of the elements was established. About 1865 Newlands spoke of a "law of octaves", which he believed he had found in his drawing up of the elements in horizontal series (according to increasing atomic mass) and in vertical series (according to alleged chemical analogy of the elements) [7]. At the beginning this theory was regarded as something of a game and not taken very seriously. However, the fundamental idea of *periodicity*, led later to Meyer's and Mendeléeff's periodic system of the elements – a system that has proved of immense value for science up to our own day [8].

The historical details of this discovery, its testing and verification, and lastly its subsequent completion and correction [9] will not be dealt with here. The pertinent question arises, however, what this system of the elements has meant for chemistry. For the present-day chemist it may have long ago become a triviality; the historian of science, however, may point out how little this system can be taken for granted. For what does it imply to say not only that chemistry has a system, as indeed do some other sciences, but that this system is (i) a system of the chemical *elements*, and (ii) is determined by a *periodic law*?

That chemistry's fundamental norm lies in a system of elements is a statement of fact which for a long time has been a banality for the present-day chemist. However, several centuries were required for this statement of fact to attain clear scientific identity from the obscurity of a host of confused ideas. The final outcome then, was that the chemist must understand the whole of his object of research only in terms of an element or as a combination of elements and nothing else, so that to the chemist, the question of *how* a chemical substance is *constituted* is, therefore, equivalent to the question about its *composition* of elements.

In order to illustrate the meaning of the periodicity of this system, let us again refer to Boyle. It is difficult for us to appreciate the magnitude of the result he achieved and its effects on the history of science. By breaking the chains of the old doctrine of the four elements, Boyle confronted chemistry for the first time with the possibility of an unlimited multiplicity of elements and with the prospect of a series of continued discoveries of elements. Though the establishment of the periodic system did not actually limit Boyle's indeterminate multiplicity of elements, the latter was strictly regulated according to the principles of the system. The fact that up to that time every discovery of an element had been more or less accidental or, at any rate, could be directed by no possible forecast, caused also its chemical properties to appear more or less arbitrary. Through its unequivocal place-disposition the periodic system therefore directed the searching and regulated the expectations of the finding of new elements and their possibilities of forming compounds.

Its uniqueness consists precisely in the periodicity of this system of elements. In the periodic recurrence of a few basic properties, and in the regulated declension of all other chemical and physical properties of the elements, lies, in the final analysis, the normative and real system-generating impulse of chemical science as a whole. For although the periodicity of the system is unable in principle to limit the number of elements, it does in fact radically exclude the arbitrariness of unendingly "new" and forever "other" elements. It seems to be an idle question to inquire whether chemistry could at all be possible as a science if it were not based on a two-dimensional order of elements but only on a one-dimensional series of "totally different" elements. At least it would not be so systematic as it actually is.

*

On the threshold of the XXth century, chemistry could afford less than ever to rest confidently on its own laurels. New kinds of experiences not only urged it

[7] *J. A. R. Newlands*, On the Discovery of the Periodic Law. London 1884.

[8] *L. Meyer*, Die modernen Theorien der Chemie und ihre Bedeutung für die chemische Mechanik. Breslau 1864; 5th Edit. 1884. *D. Mendeléeff*, Die Grundlagen der Chemie. Petersburg 1869; German translation Petersburg 1891, p. 666f.

[9] See *E. Ströker*, Denkwege der Chemie. Freiburg-München 1967, p. 189f.

beyond the already inquired but also compelled it to radically revise its basic assumptions. The discovery of radioactive elements that disintegrate spontaneously, and the discovery of cathode rays and of their corpuscular nature posed peremptorily the problem of the *structure of the atom*. The old notion of the unchangeability and indivisibility of the atom – and with it of the elements – had finally died.

The gradual recognition of the mysterious language of atomic spectra as a code on the subtler structure of matter, culminating in Bohr's concept of atomic structure in 1913, marked the beginning of a new era, and of a new understanding of all that was contained in the age-old question on the elements and their compounds. Modern atomic physics has given us the tools for a deeper understanding of the hitherto enigmatic order of the elements in the periodic system, and of their existence and reactivity. "Atomic shell" "atomic nucleus", and electron "shell-structure" furnished the first important concepts for the explanation of what was traditionally called the "properties" and the "qualities" of the elements. Finally, the Pauli principle also provided a solution to the enigma of the periodic law, which Mendeléeff had already sought to resolve by ever renewed and unsuccessful attempts. The wonderful ground-plan of the periodic system could now be reconstructed, and one could at last rationalize the hitherto hidden order of the chemical elements.

*

Surely, also the chemically most important property of the elements, viz.: the ability to enter into combination *tout court*, posed new and difficult theoretical problems. Bohr's theory of the atom still lacked the adequate means to explain the mechanism of chemical composition. It is well known that only with the help of wave mechanics has it become possible to tackle the theoretical problems which arose from the extensive experimental work of molecular physics. Because of the endless difficulties which stand in the way of a complete wave-mechanical explanation of chemical bonding for all possible molecules, it is legitimate to doubt whether one can speak strictly of a *theory* of chemical bonding. Nevertheless, wave mechanics must be regarded today as the basis of any explanation of chemical bonding.

To be sure, the exemplary mathematical exactness of this basis can blind no one to the fact that with it the world of matter has become for us something very strange. Elements and compounds which, according to a long-cherished view, the world still consists of, could indeed be fully explained in the conditions of their existence. But the natural scientist's ageless search for something permanent and unchangeable in the material world cannot reach its goal. It has to yield in our day to the knowledge of the essential changeability, impermanence, and destructibility of the old matter.

In conclusion, it should not be overlooked that this knowledge has finally reconciled an ancient contradiction which lasted until modern times and whose earliest rudimentary expression can be seen in the Democritean-Aristotelian controversy. The latest developments of chemistry have carried it beyond the ancient aporetic and have basically mediated the two positions. Still based as mechanics on "atomistic" foundations, it has dissociated itself nevertheless from the Democritean conception and is now to be thought of in terms of *structures* and such structures are to be considered *dynamically*. The ancient quest of Aristotle has thus been satisfied – his *mixis*, starting point of all future problems regarding the concepts of "element" and "compound", can be interpreted without contradiction in present-day research.

High-melting Aromatic Compounds as Stationary Phases in Gas Chromatography

By *F. A. Holdinghausen, D. Freitag, W. Ried,* and *I. Halász* [*]

Dedicated to Professor K. Winnacker on the occasion of his 65th birthday.

When used as stationary phases [1,2], solid organic substances combine advantages of gas-solid and distribution chromatography. Whereas the organic compounds used previously were not particularly stable to heat, our experiments were conducted with high-melting aromatic compounds.

We built our own gas-chromatographic apparatus [3], which contained a flame ionization detector with an appropriate rapid pen recorder and a flow-programming unit [4].

We obtained a stationary phase by mixing a solution of rubrene (5,6,11,12-tetraphenylnaphthacene, m.p. ~330 °C) in benzene with glass beads and evaporating the solvent under an IR lamp [5]. The rubrene cannot then be rubbed off the carrier. The stationary phase consists of 1 wt-% of rubrene

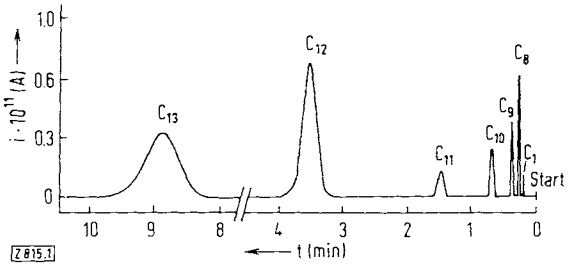

Fig. 1. Separation of C_8- to C_{13}-normal paraffins on solid-coated glass beads. Stationary phase: 1 % of rubrene on glass beads; 50 mg of rubrene per meter of column. Internal diameter of column 2.3 mm; sieve fraction 0.10–0.12 mm. Carrier gas N_2. Δp = 3.0 atm; u = 20 cm/sec. Quantity of sample 5 µg. Ordinate: ionic current of the flame ionization detector.

and 99 wt-% of glass beads. This ratio enables the desired low temperature to be used in the analysis. Figure 1 shows the separation of C_8- to C_{13}-*n*-paraffins at 54 °C. Methane was added to the sample in order to mark the passage time of an inert substance. Not only is the analysis temperature low and the rate of separation high, but also it is noteworthy that the later bands remain symmetrical even at high capacity ratios ($k' = 50$).

A considerable disadvantage of this column is the oxygen-sensitivity of the rubrene. If the traces of oxygen in commercial nitrogen carrier gas are not removed, the life of the column is only a few weeks.

Interesting separations can be carried out on graphitized carbon black [2,6,7]. As well as many advantages, this stationary phase has two disadvantages: the carbon black pellets have not sufficient mechanical strength, and high analysis temperatures are necessary.

To overcome these disadvantages, pelleted graphitized carbon black [**] was covered with 1 wt-% of 2′, 3′, 5′, 6′, 2‴, 3‴, 5‴, 6‴-octaphenyl-*p*-quinquephenyl [8] (m.p. ~470 °C). For this operation a solution of the compound in boiling tetralin was mixed with the carbon black and the solvent was evaporated in a vacuum. The product does not become dusty, neither when the column is filled nor in the flow-programmed gas-chromatographic analysis. The favorable relative retentions of individual components on carbon black are retained with this low coverage [7], the bands are substantially symmetrical, and the analysis temperature can be selected to be somewhat lower. The vapor pressure of this stationary phase is less than 10^{-4} torr at 300 °C; thus the column does not "bleed" and has a long life and an impeccable base line. Figure 2 shows the separation of the ethyl esters of four

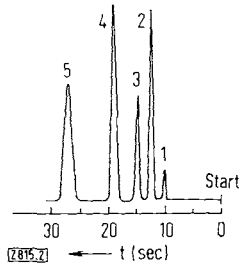

Fig. 2. Separation of fatty acid ethyl esters on graphitized carbon black coated with 1% of octaphenylquinquephenyl. 1: Methane. 2: Ethyl acetate. 3: Ethyl propionate. 4: Ethyl butyrate. 5: Ethyl valerate. Length of column 1 m; internal diameter 2 mm; sieve fraction 0.20–0.25 mm. Carrier gas N_2. $p_i = 2.4$ atm; $p_o = 1.6$ atm; $\bar{u} = 10$ cm/sec. Amount of sample 5 µg.

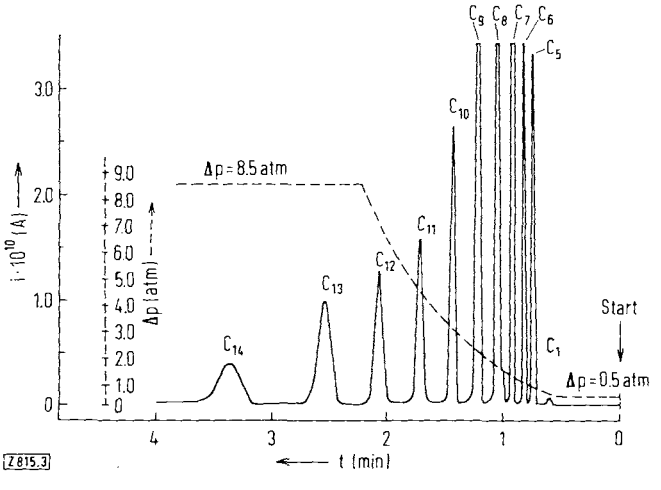

Fig. 3. Flow-programmed separation of C_5- to C_{14}-normal paraffins. Stationary phase as in Fig. 2. $T = 320$ °C. Length of column 2 m; internal diameter 2.3 mm; sieve fraction 0.20–0.25 mm. Carrier gas N_2. Amount of sample 50 µg. Ordinate: see Fig. 1.

fatty acids at 300 °C within 30 sec. In the separation of methyl esters of higher fatty acids under the same conditions the bands remain symmetrical even at extraordinarily high capacity ratios ($k' = 215$).

Figure 3 shows the flow-programmed separation of the C_5- to C_{14}-normal paraffins on the same stationary phase. The broken line shows the decrease in pressure in the column as a function of time – it increases almost exponentially from C_1 to C_{12}.

Ligand Reorganization in the Trigonal Bipyramid

By *J. D. Dunitz* and *V. Prelog* [*]

In a recent paper *Muetterties* [1] has discussed the interconvertibility of isomers [A (1,2,3,4,5)] with trigonal bipyramidal geometry through the process: trigonal bipyramid → square pyramid → trigonal bipyramid [2]. Irrespective of whether the square pyramid is regarded as corresponding to a transition state or to an intermediate, the process can be regarded (Fig. 1) as one in which the angle between a pair of apical ligands (1,2) decreases from 180° to 120°, while the angle between a pair of equatorial ligands (3,4) increases from 120° to 180°. At some stage in this process the angle between 1 and 2 must equal the angle between 3 and 4 to give the square pyramidal geometry.

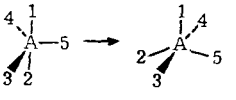

Fig. 1

The problem of keeping track of the various interconversion paths between the ten possible diastereomeric pairs of enantiomers may at first sight appear somewhat intricate; for example, it is not immediately obvious how to convert a given diastereomer into its enantiomer, an interconversion for which at least five steps are necessary [1]. In view of the current interest in problems of this kind, *e.g.* in phosphorus chemistry [1,3,4], we wish to draw attention to the usefulness of simple graph theory in dealing with them. We assume, with *Muetterties*, that the result of each interconversion step

depends at most on the result of the immediately preceding interconversion and not on any earlier interconversion. This implies that, starting from any given state of the system, the possible results of any sequence of interconversions can be represented by a Markov chain[5] or, alternatively, by the corresponding tree diagram[5]. In particular, all such interconversion paths leading from one stereoisomer to another are represented by a Petersen graph, a bridgeless regular graph of degree 3 that is constructed as follows[6]: Each of the ten couples (1,2), (1,3), ... (4,5) that can be formed from five elements is assigned to a vertex, and the vertices are then connected by edges if and only if the corresponding couples contain no elements in common (Fig. 2).

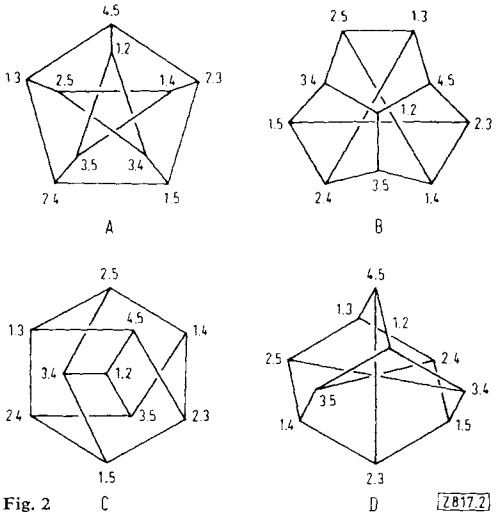

Fig. 2

The ten diastereomeric pairs of enantiomers obtainable by permutation of five different ligands in a trigonal bipyramidal arrangement may be specified by the two ligands in the apical positions (1,2), (1,3), ... (4,5) in each case. If each diastereomer is now associated with one of the vertices of a Petersen graph, the fifteen edges each represent possible interconversion steps. Any sequence of interconversions is thus associated with a corresponding path between vertices of the graph. For any such path the chirality of the resulting diastereomer depends on the chirality of the diastereomer associated with the origin of the path and on the parity of the path (whether the number of edges traversed is even or odd). In particular, a cyclic path leads back to the original enantiomer if the number of interconversion steps is even, and to the opposite enantiomer if the number is odd. From Fig. 2 it follows that a cyclic path leading to inversion of the original diastereomer must contain at least five interconversion steps. The probability that a sequence of five random steps leads back to the origin is easily seen to be $3\times 2\times 2\times 1\times 1/3^5$ or 4/81.

Various stereochemical restrictions (*e.g.* two ligands linked so that they cannot simultaneously occupy apical positions, one ligand constrained to occupy an equatorial position) can be introduced by appropriate modifications of the graph (*e.g.* all paths passing through a given vertex or through a given sub-set of vertices may be regarded as forbidden).

In Fig. 2 we have shown in addition to the usual representations A, B, and C of the Petersen graph another representation D that may have some mnemonic value for chemists. In this new representation the ten couples (1,2), (1,3), ... (4,5) are associated with the ten vertices of an adamantane skeleton in which the six secondary atoms are linked by the three diagonals of the corresponding octahedron. Notice that all cyclic paths that run exclusively along the adamantane skeleton contain an even number of edges and hence lead back to the original enantiomer; cyclic paths that contain an odd number of edges must include an odd number of diagonals.

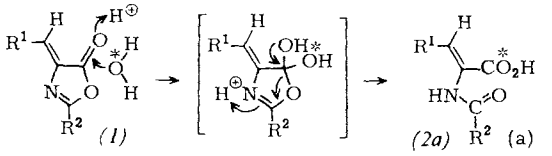
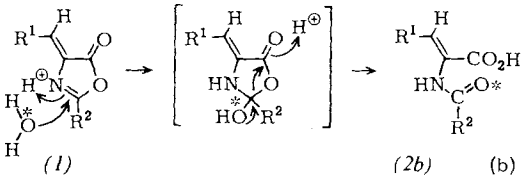
Course of Acid Hydrolysis of 4-Alkylidene- and 4-Arylalkylideneoxazol-5-ones

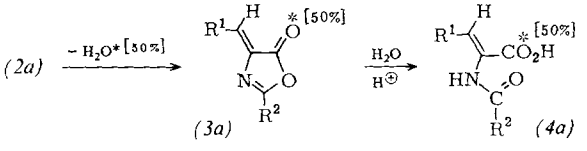
By *W. Steglich*, *V. Austel*, and *A. Prox*[*]

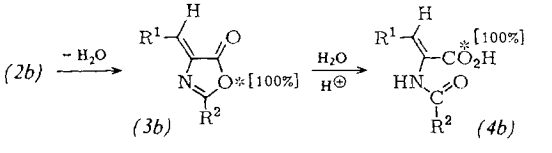
In principle, water can add to the C=O or to the C=N double bond on acid hydrolysis of 4-alkylidene- and 4-arylalkylideneoxazol-5-ones *(1)* to 2-acylaminoacrylic acids *(2)*.





If $H_2{}^{18}O$ is used, the carboxyl group of the 2-acylaminoacrylic acid *(2a)* is labeled by route (a), but the acyl group becomes labeled by route (b). The position of the label can be easily determined, namely, by recyclizing the 2-acylaminoacrylic acids *(2)* by trifluoroacetic anhydride to the oxazolones *(3)* and opening these to 2-acylaminoacrylic acids *(4)* by $H_2{}^{16}O/H^+$.





On cyclization, the acid *(2a)* loses 50 % of its ^{18}O, but *(2b)* does not lose any. Opening of *(3a)* by $H_2{}^{16}O$ according to route (a) yields *(4a)*, which in contrast to *(2a)* contains only 50 % of the ^{18}O in the carboxyl group. However, *(2b)* gives *(4b)* by mechanism (b), without loss of ^{18}O. In the conversion of *(2b)* into *(4b)* the label of the acyl group migrates to the carboxyl group.

For mass-spectrometric comparison of the ^{18}O content of the acids *(2)* and *(4)*, several 4-alkylidene- and 4-arylalkylidene-oxazolones were hydrolyzed to acids *(2)* and these were converted into acids *(4)* as described above. Table 1 records the ^{18}O contents of *(2)* and *(4)*; it shows that there is no loss of ^{18}O in any of the cases studied for conversion of *(2)* into *(4)*, thus proving route (b) to be correct. An additional proof is provided by the mass-spectrometric fragmentation, which shows that all the ^{18}O of *(2)* occurs in the acyl group, whereas in *(4)* it is all in the carboxyl group.

Table 1. Mass-spectrometrically determined content of ^{18}O-labeled 2-acylaminoacrylic acids *(2)* and *(4)* [a].

(1)		*(2)*	*(4)*
R^1	R^2	content of ^{18}O-*(2)* (%)	content of ^{18}O-*(4)* (%)
H	CH_3	56	56
CH_3	CF_3	54	55
C_6H_5	CH_3	56	55
C_6H_5	C_6H_5	14.5 [b]	

[a] The oxazolone *(1)* (0.5 mmole) in CF_3CO_2H (0.7 ml) was treated with 61 % $H_2{}^{18}O$ (0.04 ml) and kept for 3 h at room temperature or, where $R^1 = R^2 = C_6H_5$, for 1.5 h at 90 °C (bomb tube). After removal of CF_3CO_2H by distillation under vacuum the radioactivity of the product *(2)* was determined by a MS 9 (AEI) mass spectrometer at 20 eV. For conversion into *(4)*, the product *(2)* (0.5 mmole) was set aside in trifluoroacetic anhydride (1 ml) for 15 min; the solution was then evaporated under vacuum and *(3)* was treated as above with $H_2{}^{16}O$.

[b] Owing to slow hydrolysis the $H_2{}^{18}O$ was diluted by exchange with CF_3CO_2H. The isotope ratio of the benzoyl ion (13.5 % *m/e* 107) shows that the ^{18}O is in the benzoyl group.

A 1,4-addition of water is excluded by the hydrolysis of 4-ethylidene-2-trifluoromethyloxazol-5-one by D_2O/CF_3CO_2D, since the NMR spectrum shows that no deuterium is incorporated into the 3-position of the resulting 2-(trifluoroacetamido)crotonic acid. H_2S[1] and HN_3[2] also add to C-2.

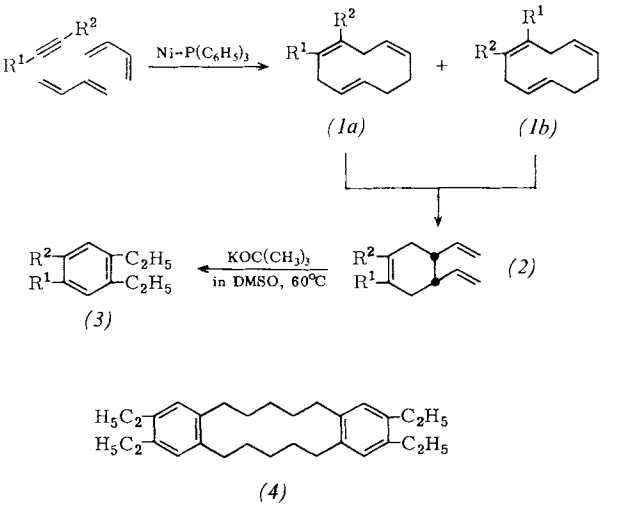
Preparation of Tri- and Tetra-substituted Aromatic Compounds

By *P. Heimbach* and *R. Schimpf*[*]

4,5-Disubstituted *cis,cis,trans*-1,4,7-cyclodecatrienes *(1a)* and *(1b)* can be prepared from 1,3-butadiene and disubstituted alkynes in high yield on use of a nickel catalyst bearing triphenylphosphine as ligand[1]. If monosubstituted alkynes are used, the corresponding ten-membered rings are obtained in yields of only 40–70 % calculated on the alkyne used. The cyclodecatrienes *(1a)* and *(1b)* are valuable for further syntheses, and so are the 1,2-disubstituted *cis*-4,5-divinylcyclohexenes *(2)* that can be obtained from them by stereospecific valence isomerization[2,3]. Isomerization of compounds *(2)*, by, *e.g.*, potassium *tert*-butoxide in dimethyl sulfoxide[4], affords on complete conversion almost quantitative yields of aromatic compounds of the durene type, such as *(3)*, which are difficultly accessible by other methods.

IR and NMR spectra are in accord with the structures assigned. Product *(3a)* can be oxidized to pyromellitic acid. Product *(3d)* is obtained in almost quantitative yield on complete conversion of 1,2,4-trivinylcyclohexane, which is



Cpd.	R^1	R^2	B.p. (°C/torr) (m.p. (°C))	n_D^{20}	n_D^{20} (lit.)
(3a)	CH_3	CH_3	106/14	1.5080	1.5095 [5]
(3b)	C_2H_5	CH_3	111/13	1.5060	
(3c)	$-(CH_2)_{10}-$		(31.5–32)		
(3d)	C_2H_5	H	93/12	1.5010	1.5009 [6]
(4)			(149–150)		

formed by thermal isomerization of 1,5,9-cyclododecatriene[1].

The isomerization of trivinylcyclohexane occurs also with lithium in ethylenediamine or sodium in *o*-chlorotoluene[6], but yields are only 61 % at 90 % conversion. We have also used substituted 1,3-dienes in place of butadiene for the synthesis of *(3)*.

Experimental:

Compound *(2)* (0.15 mole) is heated with potassium *tert*-butoxide (15 mmole) and dimethyl sulfoxide (35 ml) at 60 °C for 4 to 24 h (reaction course followed *e.g. via* the refractive index). All volatile components are then removed at 10^{-4} torr and condensed. DMSO is extracted from the condensate with water and the residue *(3)* is dried. Conversion and yield: 98–100 %.

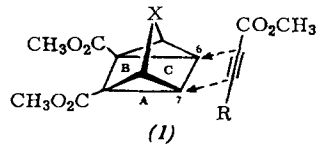
Cycloadditions to Derivatives of 3-Azaquadricyclane (Bishomopyrrole)[1]

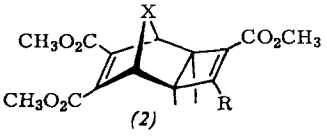
By *H. Prinzbach, R. Fuchs, R. Kitzing*, and *H. Achenbach*[*]

Isocyclic tetracyclo[3.2.0.$0^{2,7}$.$0^{4,6}$]heptane derivatives *(1)* usually add dienophilic reagents at positions 6 and 7, yielding *exo*-tricyclenes *(2)* with cleavage of the cyclopropane link-

ages A [2]. In contrast, the bridge oxygen atom of the 3-oxa systems *(3)* directs the same dienophiles to positions 2 and 4, whereby bonds B are broken with formation of compounds *(4)* [3].

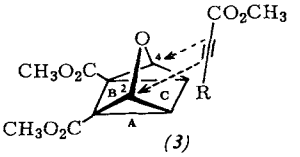


(1)

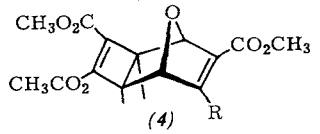


(2)

X = CH_2, $C(CH_3)_2$, $C{=}C(CH_3)_2$, $C{=}C(C_6H_5)_2$, $C{=}CHC_6H_5$, $C{=}O$

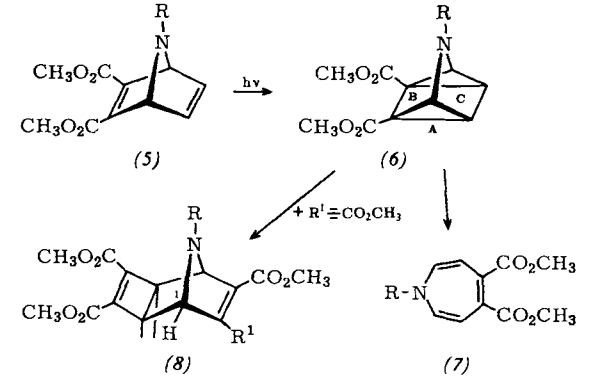


(3)



(4)

Like *(1)* and *(3)*, 3-azaquadricyclanes *(6)* [4] (accessible from pyrroles by way of *(5)* [5,6]) also have diene properties. However, valence isomerization requires only slight thermal activation, leading to the azepines *(7)*, so that good results in the addition reactions are obtained only on use of very reactive reagents. Dimethyl acetylenedicarboxylate or methyl propiolate and *(6a)* to *(6d)* give 50–70% yields of the adducts *(8a)* to *(8d)*.

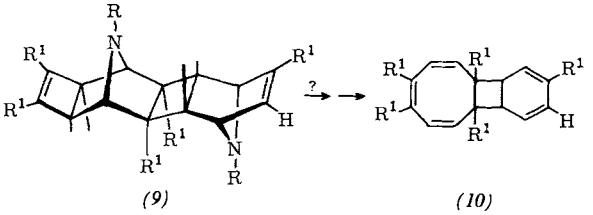


(5) *(6)* *(8)* *(7)*

(a), R = $SO_2C_6H_4CH_3$, R^1 = CO_2CH_3
(b), R = $SO_2C_6H_4CH_3$, R^1 = H
(c), R = $COCH_3$, R^1 = CO_2CH_3
(d), R = $COCH_3$, R^1 = H

For this purpose, the compound *(6)* is kept for 24 to 48 h at −15 to −30 °C in a 10- to 20-fold excess of the dienophile. The azepine *(7)* formed can be separated cleanly by chromatography. *(8a)–(8d)* are isolated by crystallization from CH_2Cl_2.

The structures *(8)* are proved by elemental analysis, mass spectra, UV, IR, and, in particular, NMR data (Table 1). The parallelism of *(1)* and *(3)* observed for course of pyrolysis and direction of addition [5] is thus valid also for the aza skeleton *(6)*. In batches containing equimolar amounts of *(6)* and dimethyl acetylenedicarboxylate or methyl propiolate the products *(8)* can compete as dienophile; *e.g. (8b)* and *(6a)* give a product that for spectroscopic reasons (Table 1) is assigned structure *(9)*. We are testing whether the [8.4.1.1^{4,7}.0^{2,9}.0^{3,8}.0^{11,14}]hexadeca-5,12-diene derivatives *(9)*, which are thus readily accessible, can provide a route to C_{14} compounds of type *(10)* by elimination of both aza bridges.



(9) *(10)*

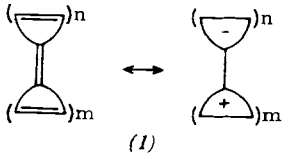
11,12,13,14-Tetraphenyl-3,8-methanopentahendecafulvalene [1]

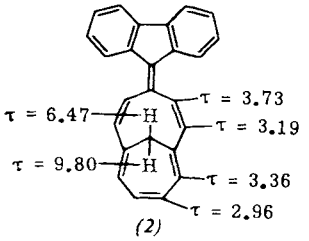
By *H. Prinzbach* and *L. Knothe* [*]

Cyclic, cross-conjugated compounds *(1)* containing two potentially "aromatic" partial systems ($m = 1, 3, 5..$; $n = 2, 4..$) are very readily polarizable, equally reactive towards electrophiles and nucleophiles (also radical reagents), and correspondingly unstable [2]. So far, none of the parent compounds *(1)* has been isolated; only *(1b)* has been prepared [3] in very dilute solution.



(1)

(a), n = 2, m = 1
(b), n = 2, m = 3
(c), n = 2, m = 5



(2)

We have now obtained the non-annelated, phenyl-substituted compound *(4)* by a method similar to that used [4] for compound *(2)*, which was the first stable derivative of the $6\pi - 10\pi$ series *(1c)*. When 9.6 mmoles of lithium tetraphenylcyclopentadienide was treated with 8.3 mmoles of compound *(3)* [5] in 100 ml of tetrahydrofuran at −30 °C a very complex mixture was formed. This was not separated but was oxidized with 20 mmoles of chloranil in boiling carbon tetrachloride, the oxidation products being separated on a silica gel column. One of the brownish-red zones afforded hydrocarbon *(4)*, m.p. 229–232 °C (yield 3–4%), which crystallizes from carbon tetrachloride as thin reddish-brown needles. The structure *(4)* was proved by elemental analysis, mass spectrum [6], IR and particularly UV and NMR data.

m/e: 522 (M^+, 100%), 523 (46%), 524 (9%), 315 (5%), 261 (M^{2+}, 3%), 121 (6%), 119 (20%), 117 (20%), 82 (5%), 38 (6%), 36 (19%), 28 (10%).

IR (KBr): ν = 1595, 1515, 1492, 1437, 1246, 1214 cm^{-1}.

UV: λ_{max}(cyclohexane) = 439 (ε = 22200), 349 (24400), 256 nm (42200).

λ_{max}(nitromethane) = 445 (ε = 18900), 371 nm (12100).

The presence of the symmetry plane in *(4)* is shown by the NMR spectrum (Fig. 1) which contains a multiplet due to 20 phenyl protons, the A_2B_2 system for H (4), H (5), H (6), and H (7), the AB quartet for H (1), H (2) and H (9), H (10), and the AX quartet for H (17a) and H (17b); the coupling constants agree with those for *(2)*, but the chemical shifts show clearly the anisotropic influence of the phenyl groups.

As was to be expected, the signals of H (1), H (2), H (9), H (10), and H (17a) show a marked diamagnetic shift. On the other hand the protons H (4), H (5), H (6), H (7), and H (17b), which are further removed from the phenyl groups, resonate at about the same frequencies as in *(2)* and are clearly only slightly more deshielded than are the corresponding protons in the tropylidene [τ H (2,5) = 3.88; τ H (3,4) = 3.45; $CDCl_3$]. The resulting alternation in the π-electron density distribution in *(4)* is evident from the coupling constants J_{12}, which at 12 Hz indicate the high bond order of a largely localized olefinic C=C double bond [7]. The value of

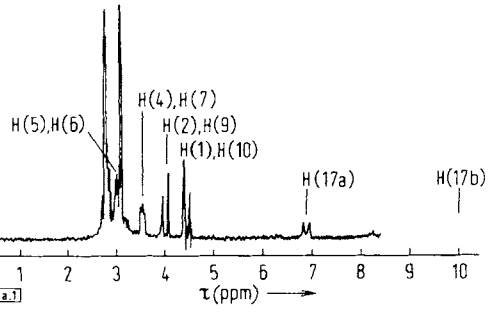


Fig. 1. NMR spectrum (100 MHz) of *(4)* in $CDCl_3$. A doublet having J = 11.0 Hz occurs at τ = 10.0.

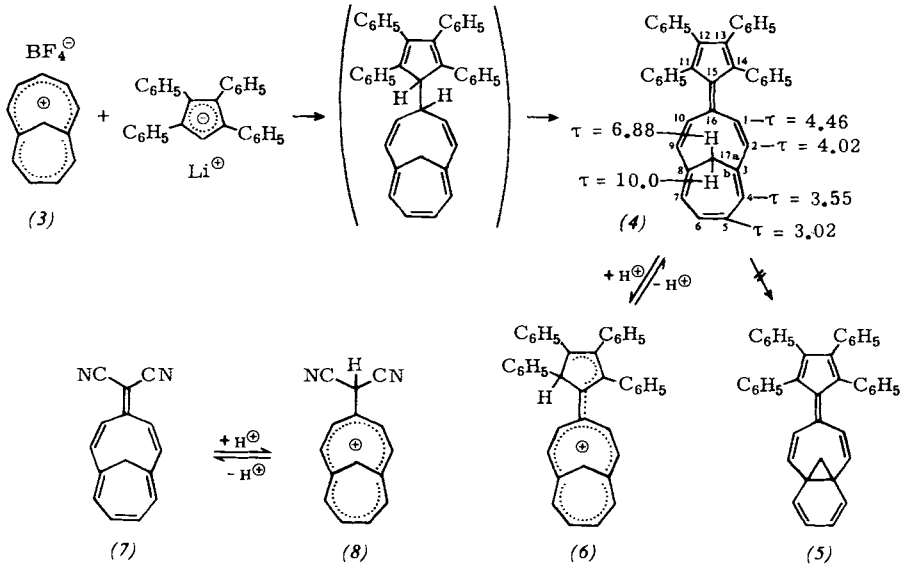
J_{17a17b} (11 Hz) excludes the valence-isomeric form *(5)* [8]. In contrast to *(2)*, however, but like the analogous calicene [9] and sesquifulvalene derivative [10], compound *(4)* is protonated in CF_3CO_2H or in perchloric acid/ethanol [**]. UV and NMR measurements prove that electrophilic attack by the proton occurs mainly, if not exclusively, at position 11, yielding ion *(6)*, with the positive charge also delocalized over the aryl-substituted five-membered ring and the charge



(3) *(4)* *(7)* *(8)* *(6)* *(5)*

deficit in the eleven-membered ring correspondingly diminished. When compared with the π-π^* excitation of the unsubstituted cation *(3)*[11] (λ_{max} = 423 nm; ε = 4000; 60% sulfuric acid) or the conjugate acid *(8)* of dicyanohendecafulvene *(7)* (λ_{max} = 426 nm; perchloric acid/ethanol[**][12]), the transition of longest wavelength for *(6)* (λ_{max} = 610 nm, ε = 24400; perchloric acid/ethanol[**]) is greatly shifted towards longer wavelengths. The τ values of the protons of the eleven-membered ring in *(6)* (multiplet between τ = 1.6 and 2.1; CF_3CO_2H) are, on the average, about 0.85 ppm units greater than the τ values of *(3)*.

An X-Ray Study of Non-stabilized Ylids

By *J. C. J. Bart*[*]

No X-ray crystallographic work on the air-sensitive, non-stabilized phosphonium ylids (Wittig reagents) has hitherto been reported. Alkylenetriphenylphosphoranes, which may be pictured as

$$(C_6H_5)_3P{=}CR_2 \leftrightarrow (C_6H_5)_3\overset{\oplus}{P}-\overset{\ominus}{C}R_2$$

afforded the following crystallographic data[1]:

$(C_6H_5)_3PCH_2$ *(1)* (yellow): a = 18.455, b = 9.614, c = 18.103 Å; β = 106°56′.

Space group $P2_1/c$, with 2 molecules per asymmetric unit.

$(C_6H_5)_3PC(CH_3)_2$ *(2)* (red): a = 19.201, b = 11.289, c = 16.950 Å; α = 89°36′, β = 70°55′, γ = 88°44′.

Space group $A\,1$ or $A\,\bar{1}$, Z = 8, V = 3471.3 Å^3; d (calc) = 1.165 g/cc.

A three-dimensional structure analysis of *(1)* has now been completed. The atomic positions were determined by Patterson and Fourier methods and refined by a least-squares procedure with 2586 linear diffractometer data. The hydrogen atoms were located by difference maps; final R-factor 0.064. No significant differences were found between the two independent molecules in the asymmetric unit. The average length of the bond formally written as P=C is 1.661 Å (estimated standard deviation 0.008 Å). This is considerably less than the single bond distance (~ 1.85 Å) in tertiary phosphines and significantly shorter than that in the stabilized ylids $Ph_3P{=}CXY$ for which structural data are available[2]. Similar phosphorus-carbon lengths were found only in $Ph_3P{=}C{=}C{=}X$ (X = O,S)[3]; the nature of the P=C bond is not yet clear in these compounds. The value of 1.661 Å is close to that obtained according to *Pauling*[4] by summation of the double bond radii of P and C (1.665 Å) and indicates π-bonding character[5].

Other studies give evidence for a polar formulation ($\overset{\oplus}{P}$-$\overset{\ominus}{C}$) of *(1)*. *Lüttke* and *Wilhelm*[6] estimate a bond order of 1.3 for the phosphorus-methylene bond from IR data. The near identity of the ^{31}P–NMR chemical shifts[7] in *(1)* and in $[(C_6H_5)_3P^{\oplus}CH_3]Br^{\ominus}$ suggests little delocalization of the electron-density at the carbanion. The observed short $P{=}CH_2$ distance would evidence overlap of the empty d-orbital of P with the CH_2 p-orbital and consequent stabilization of the carbanion. If it is assumed that the phosphorus d-orbitals are of suitable size and energy for effective bonding[5,8], then the overlap with the CH_2 p-orbital is close to the carbon atom, thus giving polarity to the bond. The methylene carbon atom is sp^2 hybridized. The overlap of a sp^3-hybrid orbital and a d-orbital of P is clearly less efficient than that between a p- and a d-orbital.

The P–C (phenyl) bond lengths are close to the average 1.823 Å, which is slightly longer than the average of similar bonds in most other quadruply connected phosphorus compounds[2,3]. Phosphorus has a distorted tetrahedral coordination in *(1)* with C(phenyl)-P-C(methylene) angles ranging between 111.4° and 115.0° (average 113.5°) and C(phenyl)-P-C-(phenyl) angles between 102.8° and 107.4° (average 105.0°). The latter value is slightly larger than that found in $P(C_6H_5)_3$ (103.0°)[9]. The phenyl groups have unequal rotations around the P–C bonds and adopt a paddle-wheel arrangement. Despite the presence of two molecules in general positions in the asymmetric unit and the polar nature of the $P{=}CH_2$ group, no dimerization or strong molecular interaction is observed in the solid. The molecules are packed by ordinary van der Waals forces. The arrangement of the molecules in the crystal structure is pseudo $P2_1/a$.

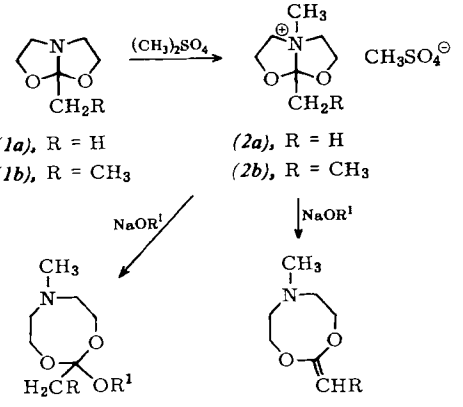
Synthesis of 1,3-Dioxa-6-azacyclooctanes from 4,6-Dioxa-1-azabicyclo[3.3.0]octanes

By *R. Feinauer* [*]

On reaction with carboxylic acids or anhydrides[1], phenols, or secondary amines[2], 4,6-dioxa-1-azabicyclo[3.3.0]octanes *(1)* yield carboxamides by ring fission. The reaction with aliphatic aldehydes[3] leads to 3-acyloxyalkyl-2-alkyloxazolidines.

We have converted compounds *(1)* into 1,3-dioxa-6-azacyclooctanes *(3)* and *(4)* by methylation with dimethyl sulfate and treatment of the methylation products *(2)* with Na alkoxide.



(1a), R = H; *(1b)*, R = CH_3 — *(2a)*, R = H; *(2b)*, R = CH_3

(3a), R = H, R^1 = CH_3; *(3b)*, R = CH_3, R^1 = CH_3; *(3c)*, R = H, R^1 = C_2H_5; *(3d)*, R = CH_3, R^1 = C_2H_5 — *(4a)*, R = H; *(4b)*, R = CH_3

Starting material	Yield (%)		B.p. (°C/torr)		n_D^{20}	
	(3)	*(4)*	*(3)*	*(4)*	*(3)*	*(4)*
(2a)	*(3a)*, 38	*(4a)*, < 5	57/3	—	1.4546	—
(2a)	*(3c)*, 20	*(4a)*, < 5	50/1	—	1.4490	—
(2b)	*(3b)*, 42	*(4b)*, 5	66/2	54/2	1.4556	1.4780
(2b)	*(3d)*, 10	*(4b)*, 37	70/2	54/2	1.4522	1.4780

1-Methyl-5-alkyl-4,6-dioxa-1-azoniabicyclo[3.3.0]octane methosulfate (2):

Dimethyl sulfate (0.4 mole) was added with cooling and stirring to a solution of *(1a)* or *(1b)* in CH_2Cl_2 (200 ml) at such a rate that the internal temperature did not exceed 30 °C. After 30 minutes' stirring, the vessel was placed in ice. The colorless crystals of *(2a)* or *(2b)* that separated were filtered off, washed with CH_2Cl_2, and dried in a desiccator. *(2a)*, yield 79%, m.p. 100–101 °C. *(2b)*, yield 82%, m.p. 112 to 113 °C.

2-Alkoxy-2-alkyl- (3) and 2-alkylidene-6-methyl-1,3-dioxa-6-azacyclooctane (4):

The methosulfate *(2)* (0.4 mole) was dissolved in methanol or ethanol (100 ml), and to it was added at 60 °C with stirring a solution of Na (0.4 mole) in the corresponding alcohol (150 ml); the whole was then kept at 60 °C for a further 2 h. After cooling the solution was filtered from precipitated $NaCH_3SO_4$, the excess of alcohol was distilled off through a column, and the residue was distilled and fractionated through a rotating band column under vacuum. The properties of the compounds *(3)* and *(4)* obtained are summarized in the Table.

Reaction of *(2a)* with methoxide or ethoxide gives mainly *(3a)* or *(3c)*, respectively; *(4a)* could only be detected in traces spectroscopically, presumably because of its lower stability. With Na methoxide *(2b)* gives mainly *(3b)* but with Na ethoxide gives mainly *(4b)*. *(3b)* could not be converted thermally into *(4b)*. This indicates that addition of the alkoxide anion and elimination of a proton compete in formation of *(3)* or *(4)* from *(2)* and alkoxide. The products *(3)* and *(4)* are colorless liquids; their structures are proved by elemental analyses, determination of molecular weights, and IR, NMR, and mass spectra.

Fixation of Molecular Nitrogen on Nickel(0)

By *P. W. Jolly* and *K. Jonas* [*]

Since 1965 several complexes of transition metals (Ru[1], Os[2], Co[3], and Ir[4]) have been found that contain nitrogen as ligand. We now report a nitrogen-nickel(0) complex in which two nickel atoms are bound to one nitrogen molecule. If nickel acetylacetonate is treated with trimethylaluminum in the presence of tricyclohexylphosphine and nitrogen at −30 to +20 °C, a yield of *ca.* 40% of bis[bis(tricyclohexylphosphine)nickel]dinitrogen is obtained as dark red crystals.

$$2\ Ni(acac)_2 + 4\ (C_6H_{11})_3P + 4\ Al(CH_3)_3 + N_2 \rightarrow N_2[Ni(P(C_6H_{11})_3)_2]_2 + 4\ (CH_3)_2Al(acac) + 4\ CH_3\cdot$$

The nitrogen molecule can easily be replaced by other ligands, such as olefins, phosphines, or CO. When ethylene or the isomers of 1,5,9-cyclododecatriene are used, known bis(tricyclohexylphosphine)nickel-olefin complexes[5] are obtained and exactly $^1/_2$ mole of N_2 is liberated per g-atom of Ni.

Cryoscopic determination of the molecular weight in benzene and the IR spectra show that the complex *(1)* in the dark red solution presumably exists as an equilibrium mixture of *(2)* and *(3)*.

$$\underset{(1)}{N_2[Ni(P(C_6H_{11})_3)_2]_2} \rightleftharpoons \underset{(2)}{N_2{\cdot}Ni(P(C_6H_{11})_3)_2} + \underset{(3)}{Ni(P(C_6H_{11})_3)_2}$$

$$(1) \xrightleftharpoons[N_2]{Ar} 2\ (3)$$

The band at 2028 cm^{-1} is probably to be ascribed to the NN stretching vibration; it disappears if argon is passed through the solution, which then becomes yellow and gives a freezing-point depression indicating that the equilibrium has been shifted entirely towards the right. The yellow solution absorbs nitrogen with red coloration, and the starting system is reformed (mol. wt. and band at 2028 cm^{-1}).

(1) presumably has the structure:

$$[C_6H_{11})_3P]_2Ni : N \equiv N : Ni[P(C_6H_{11})_3]_2$$

X-ray structure analysis is in progress[6] (cell data: $P2_{1/n}$, a = 21.83 Å, b = 16.54 Å, c = 21.24 Å, β = 102.7°, Z = 4, d (X-ray) = 1.12, d (pycn.) = 1.13).

Experimental:

A solution of $Al(CH_3)_3$ (2.2 ml) in toluene (5 ml) is added dropwise and slowly to a solution of $Ni(acac)_2$ (5 g, approx. 20 mmole) and tricyclohexylphosphine (12 g, approx. 40 mmole) in toluene (50 ml) at −20 °C with stirring and passage of nitrogen. The reaction mixture is allowed to warm to room temperature and stirred for a further 10 h. Red crystals

are precipitated, which are sucked off, washed with ether, and dried. The compound can be recrystallized from toluene under nitrogen.

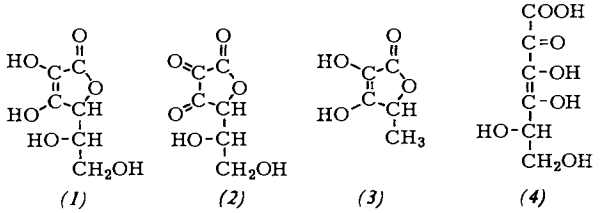
Constitution and Synthesis of an *aci*-Reductone Formed on Non-oxidative Degradation of Dehydroascorbic Acid[**]

By *K. Wisser*, *W. Heimann*, and *E. Mögel*[*]

On two-electron oxidation L(+)-ascorbic acid *(1)* (vitamin C) is converted into L(+)-dehydroascorbic acid *(2)*, which can be reduced back to *(1) in vivo* and *in vitro*. The dehydro acid *(2)* decomposes non-oxidatively and non-enzymically to products that are of interest in food chemistry because they cause discoloration and changes in taste.

CO_2, oxalic acid, threonic acid, furfuryl alcohol, L-xylosone (?), ethylglyoxal, and 2-keto-3-deoxy-L-pentono-γ-lactone (5-hydroxymethyltetrahydro-2,3-furandione) have been detected as degradation products[1–5]. Little is reliably known about the course of the degradation. A strongly reducing compound arising on degradation of *(2)* has been formulated as *(3)*[1] but also as *(4)*[3].

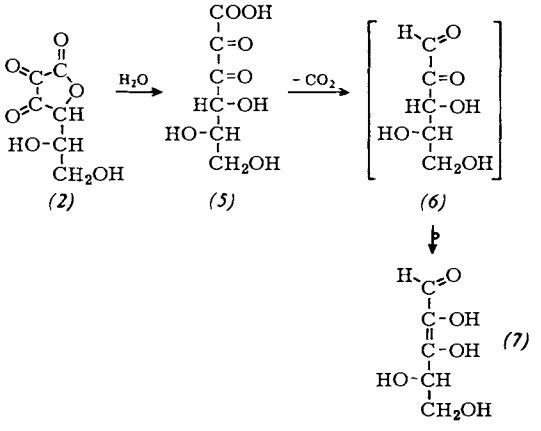


(1) *(2)* *(3)* *(4)*

Developing a thin-layer chromatogram of an aqueous solution of *(2)* obtained on silica gel or aluminum oxide at room temperature affords many zones that obviously arise from products formed by catalytic decomposition of *(2)* on silica gel or aluminum oxide but have been held by most authors to represent the initial stage of the degradation of *(2)*. 2,3-Diketogulonic acid *(5)* (R_F = 0.1) is obtained after about 1 h at room temperature on thin-layer chromatography on cellulose with butanol/glacial acetic acid/water (4:1:1); after some weeks a new substance of R_F = 0.8 appears which is strongly reducing analogous to *(1)*. This second zone appears homogeneous in several eluants and on two-dimensional thin-layer chromatography.

On use of 1-^{14}C-labeled *(2)* autoradiography of the chromatogram shows that the new compound no longer contains C-1; apparently the acid *(5)* is decarboxylated slowly even at room temperature. Polarography of the eluted zone indicates an enediol grouping and an aldehyde group activated by conjugation. K_{diss} for sulfite addition was determined, also polarographically, as 1.1×10^{-3}. The IR spectrum contains a sharp absorption band at 1700 cm^{-1}; compounds of tetronediol type, such as *(1)*, *(3)*, 3,4-dihydroxy-2,5-dihydrofuranone, and the corresponding deuterated compounds, however, show two sharp bands, one between 1630 and 1665 cm^{-1} and the other between 1737 and 1754 cm^{-1}. At pH 5 the compound gave a UV band with λ_{max} = 291 nm, similar to that of triosereductone (λ_{max} = 288 nm).

From these results it is concluded that decomposition of *(2)* leads by way of *(5)* and *(6)* to *(7)*; and this has been prepared also from L-arabinose by way of the osazone and osone[6,7].



(2) *(5)* *(6)* *(7)*

Enolization of the arabosone to give *(7)* occurs analogously to the proton-catalyzed isomerization of hydroxypyruvaldehyde to triosereductone[8].

The L-2,3,4,5-tetrahydroxy-2-pentenal prepared from L-arabinose is chromatographically, polarographically, and UV- and IR-spectroscopically identical with the non-oxidative degradation product of *(2)*.

Substance *(7)*, which was obtained in mg quantities, is a yellow syrup and decomposes slowly at room temperature with browning. We suggest that it be called L-pentosereductone or erythroreductone.

The *aci*-reductone formed on warming *(2)* in dilute sulfuric acid is not compound *(3)* as previously postulated[1]; authentic *(3)* has different UV and IR spectra. The product isolated by the procedure of reference[1] is mainly an as yet unidentified reducing compound plus a smaller amount of *(7)*.

Substituted 1-Phosphabarrelenes (1-Phospha[2.2.2]octa-2,5,7-trienes)[1]

By *G. Märkl* and *F. Lieb*[*]

2,4,6-Trisubstituted phosphorins *(1)*[2] have only slight diene reactivity. 2,4,6-Triphenylphosphorin *(1a)*, $R^1 = R^2 = R^3 = C_6H_5$, for example, reacts neither with diethyl acetylenedicarboxylate nor with maleic anhydride; with tetracyanoethylene only a charge-transfer band at 450 nm is to be observed[3].

However, the highly reactive dienophile hexafluoro-2-butyne reacts with 2,4,6-triaryl- or 2,4,6-trialkyl-substituted phosphorins even at 100 °C, whereas the analogous reaction with aromatic hydrocarbons such as benzene and durene[4,5] requires about 200 °C.

In accord with the mode of reaction observed for durene[4], cycloaddition of hexafluorobutyne to the phosphorins *(1)* occurs exclusively in the 1,4-position, yielding the substituted 1-phosphabarrelenes *(2)* described in the Table.

	$R^1 = R^3$	R^2	M.p. (°C)	Yield (%)	UV-Spectrum λ_{max}, nm (ε) [a]	IR-Spectrum $\nu_{C=C}$ (cm^{-1})
(2a)	C_6H_5	C_6H_5	189	53	291 (7600); 226 (27600)	1589 (m); 1633 (m)
(2b)	$C(CH_3)_3$	CH_3	92–93	89	286 (520); 247 (630); 218 (1280)	1600 (m); 1650 (w)
(2c)	CH_3	C_6H_5	105–106	41	292 [b] (450); 248 [b] (1260); 220 (3450)	1594 (m); 1651 (w)

[a] In ethanol. [b] Shoulder.

The molecular weight of *(2a)*, determined osmometrically in $CHCl_3$, was 474.5 (calc. 486.4).

NMR spectra of *(2)* in $CDCl_3$: *(2a)*: aromatic protons (15 H), τ = 2.12–2.88 (m); ring protons (2H), τ = 2.0 (d), $^3J_{P-H}$ = 7 Hz. *(2b)*: $(CH_3)_3C-$ (18H), τ = 8.86 (s); CH_3- (3H), τ = 8.0 (q), $^5J_{F-H}$ = 2.7 Hz; ring protons (2H), τ = 3.39 (d); $^3J_{P-H}$ = 7 Hz. *(2c)*: aromatic protons and ring protons (7H), τ = 2.22–2.83 (m); CH_3- (6H), τ = 7.92 (doublet of doublets), $^3J_{P-H}$ = 14 Hz, $^4J_{H-H}$ = 2 Hz.

The ^1H–NMR spectra confirm the symmetrical structure of *(2)*. The protons in the hetero ring system are at lower field than those in the known homoannular barrelenes[1,4-6]. The ^{31}P resonance (H_3PO_4 as external standard) for *(2a)* amounts to + 65 ppm (in benzene) and by comparison with that of *(1a)* (−178 ppm[2]) confirms the presence of a tertiary phosphine[7]. The UV spectra do not permit an unambiguous opinion about p_π- and d_π–p_π-orbital interactions.

The formation of *(2)* from phosphabenzene derivatives makes it probable that the 1,4-diphosphabarrelene derivative *(3)* formed, according to *Krespan*[8], on reaction of hexafluorobutyne with red phosphorus arises from tetrakis(trifluoromethyl)-1,4-diphosphabenzene (which has not yet been isolated).

6,7-Di-tert-butyl-4-methyl-2,3-bis(trifluoromethyl)-1-phosphabarrelene (2b):

2,6-Di-*tert*-butyl-4-methylphosphorin (m.p. 54–55 °C; 2.5 mmoles, 0.56 g) was dissolved in anhydrous methylcyclohexane (12 ml). Hexafluoro-2-butyne (*ca.* 10 mmoles, 1.6–1.7 g) was condensed into the solution which was then heated for 48 h at 100 °C. After cooling, the solvent was removed. The residue crystallized when rubbed (yield 0.85 g; m.p. 88–90 °C; recrystallization from ethanol/water).

A Synthesis of Pyrrole Derivatives

By *P. Rosenmund* and *K. Grübel*[*]

We describe here a synthesis of alkyl-substituted pyrroles in acceptable yield from starting materials that are technically readily accessible and thus cheap.

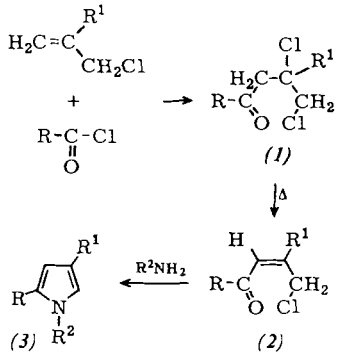
Addition of acid chlorides to alkenes under Friedel-Crafts conditions is known. We have allowed complexes of acid chlorides with $AlCl_3$ to react with allyl or methallyl chloride, this technique being, we believe, new. We thus obtained almost homogeneous addition products in 80 to 90 % yield. These are mainly the β,γ-dichloro ketones *(1)* that are formed in accord with the Markownikoff rule; the products cannot be distilled entirely without decomposition even under the mildest conditions. They eliminate 1 molar equivalent of HCl, *e.g.*, when warmed gently with dicyclohexylethylamine, being converted into the pungent α,β-unsaturated ketones *(2)*.

For preparation of the pyrrole derivatives, the crude product *(1)* was heated with an excess of an amine R^2NH_2 in methanol for several hours at 150–200 °C (autoclave). Substituted pyrroles *(3)* (see Table) corresponding to the starting materials resulted; they could also be obtained from *(2)* and the amine.

The route by which the pyrroles are formed is not yet clear. If the reaction is carried out below 100 °C a substance is obtained that is volatile in steam, begins to boil at 75 to 80 °C and explodes violently after a few ml have passed over. It is possible that an aziridine is present.

2-Methylpyrrole (3a):

1.1 moles of anhydrous aluminum chloride is added to 3 moles of acetyl chloride with good stirring and cooling to −5 °C. The mixture is cooled to −10 °C and 1 mole of allyl chloride is added at such a rate that the temperature does not



Compound	R	R^1	R^2	Yield (%)	B.p. (°C/torr) M.p. (°C)
(3a)	CH_3	H	H	39	147/760
(3b)	$CH_3(CH_2)_2$	H	H	30 [a]	75/13
(3c)	C_6H_5	H	H	24 [a]	129
(3d)	CH_3	CH_3	H	36	67/13
(3e)	CH_3	H	C_2H_5	33	157/760
(3f)	CH_3	CH_3	CH_3	42	48/13

[a] Instead of 3 moles of acid chloride per mole of allyl chloride, 1.2 moles of acid chloride + 200 ml of CH_2Cl_2 may be used.

rise above −5 °C (heat of reaction!); the whole is then stirred for about 1/4 h, and hydrolyzed by dropwise addition to a violently agitated mixture of ice and water. After decomposition of the acetyl chloride the liquid is extracted several times with methylene chloride, and the organic phase is washed with $NaHCO_3$ solution, dried, and kept *in vacuo* in a rotating evaporator at room temperature until the weight remains constant. There remain 85 to 90 % of the addition product, calculated on 4,5-dichloro-2-pentanone *(1)*, R = CH_3, R^1 = H.

The dichloro ketone is added without further purification to a ten-fold amount of methanol and a ten-fold molar amount of ammonia in an autoclave and kept there for 4 h at 170 to 190 °C. Methanol is then removed from the autoclave contents by distillation through a column and the residue is distilled in steam. Extraction with ether gives 0.39 mole of 2-methylpyrrole, b.p. 147 °C.

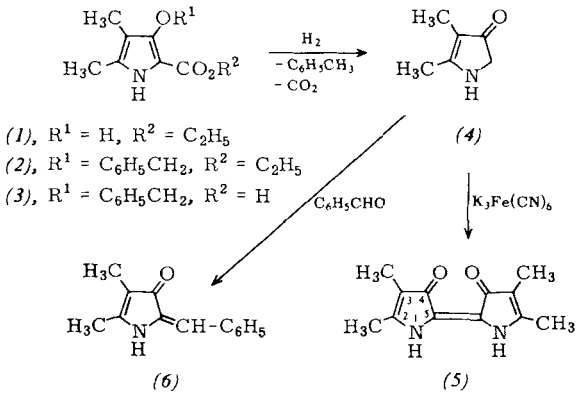
Tetramethylpyrrole-indigo

By *H. Bauer* [*]

Continuing studies of colored oxidation products from β-hydroxypyrrole derivatives [1] we have synthesized an alkyl-substituted β-hydroxypyrrole *(4)* containing a free α-position, oxidation of which to an indigoid dye *(5)* [2] led to the conjugated system that is smaller than any other to date. Pyrrole-indigo compounds have hitherto been confined to the 2,2'-diphenyl [3], 3,3'-bis(ethoxycarbonyl)-2,2'-dimethyl [4], and 2,2'-bis(methoxycarbonyl) compound [5].

2,2',3,3'-Tetramethyl-5,5'-bipyrrolinylidene-4,4'-dione (tetramethylpyrrole-indigo) *(5)* is obtained as follows: Ethyl 3-hydroxy-4,5-dimethyl-2-pyrrolecarboxylate *(1)* [6] is converted by benzyl chloride in acetone/K_2CO_3 (9–10 h under reflux) into the benzyloxy compound *(2)*, whence saponification with 2 N NaOH/CH_3OH affords the carboxylic acid *(3)*. On hydrogenolytic debenzylation with PdO/H_2 in ethanol simultaneous decarboxylation occurs, giving the hydroxypyrrole *(4)*. According to the NMR spectrum in D_6–DMSO [(τ = 2.63 (1 H); τ = 6.42 (2 H), d; τ = 7.95 (3 H),



s; τ = 8.48 (3 H), s] this exists as the ketone; its condensation with benzaldehyde affords 5-benzylidene-2,3-dimethyl-4-pyrrolinone *(6)* [orange prisms from ethanol/water; m.p. 195–198 °C; IR spectrum (in KBr), 3250, 3045, 3010, 2915, 2855, 1673, 1650, 1560 cm^{-1}; UV spectrum (in CH_3OH), λ_{max} = 313 nm (log ε = 4.28), 428 (3.81)]. $K_3Fe(CN)_6$ in aqueous ethanol oxidizes *(4)* to *(5)*, which separates as reddish-brown needles (recrystallizes from nitrobenzene, pyridine, or DMF; sublimes at 200 °C in a high vacuum; does not melt below 340 °C; sparingly soluble in the usual solvents).

IR (KBr): 3250, 2910, 2850, 1628, 1560, 1550, 1537 cm^{-1}. UV ($CHCl_3$): λ_{max} = 315 nm (log ε = 4.07), 528 (3.85). NMR (CF_3COOH): τ = 0.1 (1 H); τ = 7.48 (3 H); τ = 8.03 (3 H). Mass spectrum: molecular ion at *m/e* = 218.

S-Thioacylation of the Sulfinate Anion: Preparation and Properties of Some Sulfonylformamides, -thioformamides, and -formamidines

By *A. Senning, O. Nørgaard Sørensen*, and *Ch. Jacobsen* [*]

Although treatment of metal sulfinates with acid chlorides is known to give mixed anhydrides by *O*-acylation [1], we have observed that thioacylation with *N,N*-dimethylthiocarbamoyl chloride takes place at the sulfur atom.

$$R{-}SO_2^{\ominus} + (CH_3)_2N{-}CS{-}Cl \rightarrow R{-}SO_2{-}CS{-}N(CH_3)_2 + Cl^{\ominus}$$
(1)

The *N,N*-dimethylsulfonylthioformamides *(1)* (see Table 1) are yellow crystalline compounds whose IR spectra contain the expected sulfonyl bands [which together with the stability of the compounds towards hydrolytic influences and their comparatively high melting points rules out the alternative structure, *i.e.* the isomeric mixed anhydrides $R{-}SO{-}O{-}CS{-}N(CH_3)_2$] and whose *N*-methyl groups are non-equivalent in nuclear resonance spectroscopy at room temperature. Pyrolysis of *(1a)* at 200 °C affords diphenyl sulfide and tetramethylurea in a reaction whose mechanism is not yet understood.

Oxidation of *(1)* with ozone or *m*-chloroperbenzoic acid in chloroform at 0 °C leads to colorless sulfonylformamides *(2)*, which are the first authentic compounds containing an

$$\underset{(1)}{R\text{-}SO_2\text{-}CS\text{-}N(CH_3)_2} + O_3 \rightarrow \underset{(2)}{R\text{-}SO_2\text{-}CO\text{-}N(CH_3)_2} + SO_2$$

α-oxosulfonyl grouping[2]. The IR spectra of the sulfonylformamides *(2)* (see Table 1) contain the expected CO and SO_2 bands and the NMR spectra at room temperature again show non-equivalence of the *N*-methyl groups.

A quasi-Wittig reaction[3] of *(1)* with *N*-sulfinyl-*p*-toluenesulfonamide leads to colorless sulfonylformamidines *(3)*.

$$\underset{(1)}{R\text{-}SO_2\text{-}CS\text{-}N(CH_3)_2} + (p)\text{-}CH_3\text{-}C_6H_4\text{-}SO_2\text{-}N{=}S{=}O \rightarrow$$

$$R\text{-}SO_2\text{-}\underset{\underset{N\text{-}SO_2\text{-}C_6H_4\text{-}CH_3\text{-}(p)}{\|}}{C}\text{-}N(CH_3)_2 + [S_2O]$$

$$\underset{(3)}{}$$

The IR spectra of the sulfonylformamidines *(3)* (see Table 1) contain the expected C=N and SO_2 bands. In *(3)* the *N*-methyl groups are equivalent in the NMR spectrum at room temperature, in contrast to those in *(1)* and *(2)*.

Table 1. Compounds *(1)*–*(3)* prepared.

	R	M.p. (°C)	Yield (%)	νSO_2 (cm^{-1}) (in KBr)	νCO or $\nu C{=}N$ (cm^{-1}) (in KBr)

(3b)	*p*-CH_3-C_6H_4	178–179	55	1140, 1290, 1300	1625
(3c)	*p*-Cl-C_6H_4	146–148	50	1143, 1287, 1310	1630

Experimental:

Synthesis of *(1)*: *N,N*-Dimethylthiocarbamoyl chloride (0.15 mole), sodium sulfinate (0.15 mole), benzene (200 ml), and water (200 ml) are refluxed for 3 h. After drying and evaporation the benzene layer affords crude *(1)*, which is recrystallized from methanol/acetone (9:1).

Synthesis of *(2)*: A stream of O_3/O_2 (6% O_3) is passed through a solution of *(1)* (0.03 mole) in chloroform (200 ml) at 0 °C. When the solution is saturated with O_3, it is evaporated and the crude *(2)* recrystallized from absolute ethanol. The compounds decompose upon prolonged standing.

Synthesis of *(3)*: A mixture of *(1)*, (0.04 mole), *N*-sulfinyl-*p*-toluenesulfonamide (0.04 mole), and dry benzene (200 ml) is refluxed until evolution of SO_2 ceases. The solution is shaken with 2 N NaOH and with water, dried, and evaporated. The residue, *(3)*, is recrystallized from absolute ethanol.

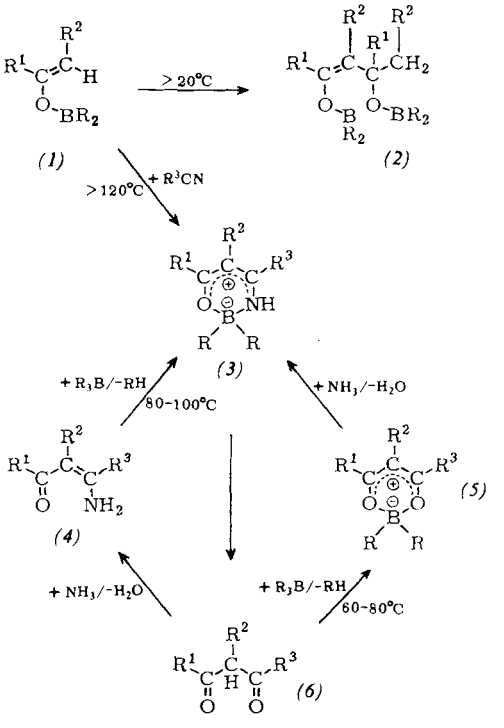
Addition of Substituted Vinyloxyboranes to Nitriles

By *R. Köster* and *W. Fenzl*[*]

Substituted vinyloxyboranes of type *(1)* undergo dimerization to *(2)* even at room temperature, whereas compounds $R_2B\text{-}O\text{-}CH{=}CR^2_2$ and $R_2B\text{-}O\text{-}CR^1{=}CR^2_2$ are stable compounds that can mostly be distilled without decomposition[1]. As expected, reaction of *(1)* with nitriles affords the heterocyclic compounds *(3)* (cf. Table 1) which have a resonance-stabilized π-system, are usually yellow to orange, and are stable to heat and hydrolysis. Their structure is proved mainly by ^1H-NMR and mass spectra [($R = C_2H_5$) main fragment: M-ethyl]. Compound *(3d)* [obtained from *(4d)*] and a few aryl derivatives were previously known[2]. We have now prepared *(3d)* from *(6d)* by way of *(4d)* and *(5d)*[2a].



Addition of *(1)* to nitriles yields *(3)* rapidly at temperatures above 120 °C. *(1)* is best prepared (variants A–F) in presence of a nitrile and not isolated.

Substituted vinyloxyboranes *(1)* are formed alongside ethane from triethylborane and a carbonyl compound with the partial structure $-CH_2CO-$ (variant A). Ketones afford *(1)* in *ca.* 90% yield, but aldehydes give yields of only about 40%. Alkoxydiethylboranes are formed simultaneously with loss of ethylene[3,4]. No appreciable quantity of *(1)* or *(3)* (*ca.* 7%) is obtained from ketones and tripropyl- or higher trialkyl-boranes. Because of the almost quantitative enolysis the aldehydes CHR^2_2CHO and triphenyl- or tribenzyl-borane give the thermally stable alkenyloxydiorganoboranes $R_2BOCH{=}CR^2_2$.

Compounds *(1)* can also be obtained, like vinyloxymetal compounds[5], by 1,4-addition of triethylborane to methyl vinyl ketone[6] (variant B) or acrolein[7] (variant C).

Compounds *(1)* are also formed from enolizable aldehydes or ketones with methoxy- (variant D) or diethylaminodialkylboranes (variant E), also by addition of, *e.g.*, chlorodiethylborane to enolizable aldehydes or ketones followed by loss of HCl (variant F). Alkenyloxyboranes are in general also accessible by oxidation of alkenylboranes with trimethylamine oxide[8]. The yields of *(3)* obtained on addition of nitriles to compounds *(1)* obtained by variants A, B, D, or E are appreciably higher than are obtained by working with variants C and F.

The route *(1)* → *(3)* permits greater variation (formation of a new C skeleton) than does route *(6)* → *(4)* → *(3)*. In spite of the C skeleton provided in *(6)*, the route *(6)* → *(4)* → *(3)* is not necessarily available: it is known that only the isomers *(4)* with R^1 = aryl and R^3 = alkyl, and not those with R^1 = alkyl and R^3 = aryl, are accessible from NH_3 and *(6)* (R^1, R^3 = alkyl and aryl). If R^1 and R^3 are similar, *e.g.*, two alkyl groups, then the route *(6)* → *(3)* by way of *(4)* as well as by way of *(5)* affords inseparable mixtures of the two isomers.

Table 1. 2,2-Diethyl-2,3-dihydro-2*H*-1,3,2-oxazaborines *(3)*.

(3i)	C_6H_5	H	C_2H_5	119–121/0.3	19	E
(3j)	C_6H_5	CH_3	C_6H_5	124–126/10^{-4}	66 (19)	A (E)

[a] M.p. = 83–85 °C; [b] M.p. = 61–63 °C; [c] M.p. = 48–49 °C.

2,2-Diethyl-2,3-dihydro-4,6-diphenyl-2H-1,3,2-oxazaborine (3a) by way of (1a) according to variant A:

Triethylborane (49 g, 0.5 mole), acetophenone (60 g, 0.5 mole), and benzonitrile (103 g) are shaken in a 500-ml autoclave at 160 °C for 5 h. 10.1 l (at S.T.P.) of gas (C_2H_6 84.2 %, C_2H_4 12.8 %, H_2 3.0 %) are then released; the residual 196 g of reddish-brown liquid, when distilled in a vacuum, gives 82 g of forerun (by-products and excess of benzonitrile) and 108 g (70 %) of the orange compound *(3a)*, which solidifies. After recrystallization from hexane this melts at 83–85 °C. ^1H–NMR spectrum (CCl_4): [τ = 2.13 m, 2.54 m], 3.68 s, broad, 4.05 s, [9.12 m, 9.48 m] in the proportions [2:(3 + 5)]:1:1:10.

2,2-Diethyl-2,3-dihydro-6-methyl-4-phenyl-5-propyl-2H-1,3,2-oxazaborine (3h) by way of (1h) according to variant B:

To 0.1–0.2 mole of benzonitrile at 140 °C are added 1 ml of triethylborane and then, slowly, equivalent amounts (each 0.1 mole), separately, of methyl vinyl ketone and triethylborane. The temperature of the mixture must not fall below 120 °C. The mixture is then heated for 3–4 h at 145 °C and on distillation in a vacuum affords a forerun (up to 57 °C/10 torr) followed by 15.4 g (57 %) of orange-yellow *(3h)* (slight residue). If the nitrile and triethylborane are first mixed, the yield of *(3h)* falls to *ca.* 24 %.

Our methods permit the preparation of compounds, some of which have been very difficultly accessible. Of the condensations of nitriles with ketones in the presence of various catalysts, as previously known, only the route from *(1)* by way of *(3)* (after hydrolysis) led to *(6)*. Acylation of ketones with carboxylic anhydrides in the presence of BF_3 [9] leads analogously to *(6)* by way of *(5)* (R = F) [10]; it is possible that in this reaction compounds *(1)* with R = F, although not yet isolated, function as intermediates. Addition of alkenyloxyboranes to nitriles [*(1)* → *(3)*] is to be regarded as a new type of Claisen condensation [11]. Similarly, as in aldol condensations [12], a suitable intermediate, here *(1)*, makes the desired syntheses possible.

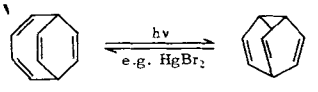
Rearrangements in the Bullvalene System Induced by Heavy-metal Salts

By *H.-P. Löffler* and *G. Schröder* [*]

Bullvalene *(2)* is formed in good yield on irradiation of bicyclo[4.2.2]decatetraene *(1)* with ultraviolet light [1,2]. We now report the reverse reaction, *(2)* → *(1)*, induced by heavy-metal salts.



(1) *(2)*

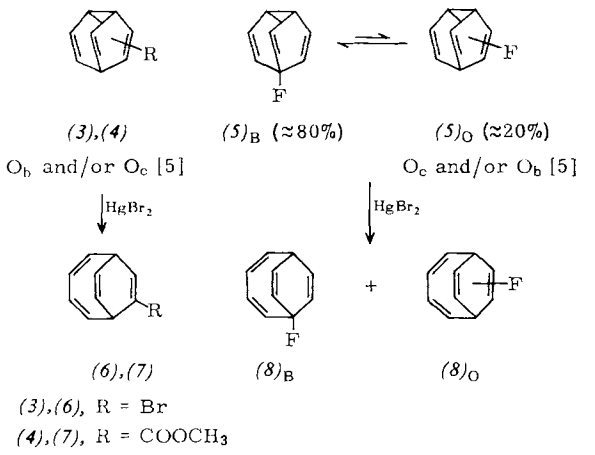
Preparation of (1) from (2):

A mixture of bullvalene *(2)* [3] (5 g), $HgBr_2$ (3 g), and ether (90 ml) is stirred for 24 h at 22 °C. The ether is removed by fractional distillation under slight vacuum and the residue is extracted with pentane; the pentane solution is then concentrated in a fractionating column and the residual concentrate thus obtained is sublimed in a vacuum (yield 4.5 g).

A gas chromatogram (column: 20 % Carbowax on Chromosorb W; 140 °C) indicates that the product is substantially homogeneous (*ca.* 98 %); there are small amounts of bullvalene (0.5 %) and *ca.* 1 % of *cis*-9,10-dihydronaphthalene [**] (identified by comparison of the retention times and IR spectra of the separated components with those of authentic materials [4]). According to the IR, UV, and NMR spectra the main component (m.p. 39–39.5 °C) is unambiguously bicyclo[4.2.2]deca-2,4,7,9-tetraene *(1)* [1,2]. Thus *(1)* can be synthesized readily and in preparatively useful yield from bullvalene by use of $HgBr_2$. The rearrangement has also been brought about so far by HgX_2 where X = Cl, Br, or I, and by $ZnBr_2$ (in CH_3OH, 36 h at 20 °C, 34 % yield) or $SbBr_3$ (in CS_2, 14 h at 0 °C, 12 % yield), these yields being determined gas-chromatographically.

Monosubstituted bullvalenes *(3)*–*(5)* afford monosubstituted bicyclo[4.2.2]decatetraenes *(6)*–*(8)*, in which the position of the substituents in the bicyclic rearrangement product appears to depend on the position isomer that preponderates in the equilibrium mixture of the monosubstituted bullvalene.

Bromo- *(3)* [5], methoxycarbonyl- *(4)* [6], and fluoro-bullvalene *(5)* [7] can be preparatively rearranged in the same way as bullvalene. The pentane extracts of the rearrangement mixtures from *(3)* (in CH_3OH, 24 h at 20 °C) and *(5)* (in



(3),(6), R = Br

(4),(7), R = $COOCH_3$

Table 1. Rearrangements of the monosubstituted bullvalenes (3)–(5).

[d] Since this signal, due to the protons of the ethylene bridge [1], corresponds to only 2 H, the Br must be on the ethylene bridge.

[e] ^{19}F–NMR: δ = +99.2 ppm (J = 4.8 Hz), pseudodoublet; δ = +99.5 ppm (J = 4.8 Hz), pseudotriplet; δ = +99.8 ppm (J = 4.8 Hz), pseudodoublet. Distance from the middle of the doublets to the middle of the triplet = 20.8 Hz; CCl_3F as external standard.

CH_3OH, 48 h at 20 °C) were concentrated and analyzed gas-chromatographically (for yields see Table 1); the bicyclo-[4.2.2]decatetraene derivatives (6) and (8) were separated by preparative gas chromatography.

Product (7) was obtained by distillation of the concentrated pentane extract from the rearrangement mixture of (4) (in CH_3OH, 40 h at 20 °C) and was obtained pure (m.p. 45 to 45.5 °C) by recrystallization. Compounds (5)–(8) were characterized by their spectra (UV, IR, NMR). It is not possible to tell from the results so far available to which of the three possible positions the olefinic fluorine atom of $(8)_O$ is attached.

The heavy-metal salts are probably involved in the reaction more as complex-formers [8] than as Lewis acids. Bullvalene (2) in ether is unaffected by boron trifluoride-ether even after long contact times.

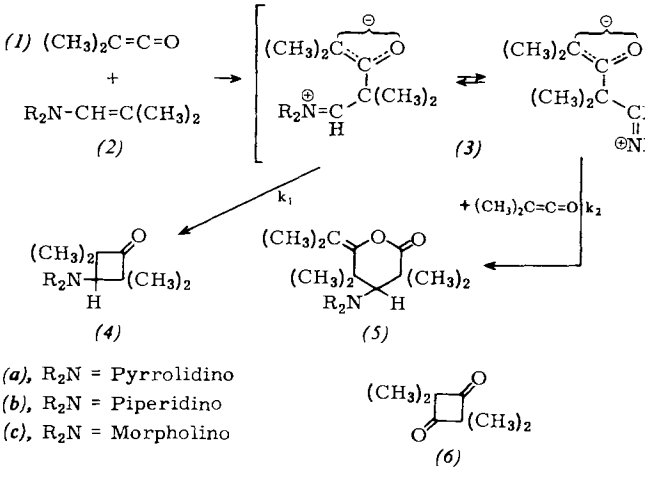
Cyclobutanones from Enamines and Ketenes by Two-stage Addition

By P. Otto, L. A. Feiler, and R. Huisgen [*]

cis-Stereospecificity [1–3] and solvent-dependence of the addition constants [4] provide strong evidence that cycloadditions of ketenes to olefins and vinyl ethers are one-stage multicenter reactions. Exclusive formation of cyclobutanones (and not Diels-Alder adducts) from ketenes and 1,3-dienes points in the same direction [5]. Enamines appear, however, to react by a different mechanism, at least in polar solvents. Here apparently a two-stage process involving a zwitterion [see (3)] occurs.

After treatment of dimethylketene (1) with 1-isobutenylpiperidine (2b) or *N*,*N*-dimethylisobutenylamine in polar solvents, Hasek and Martin [6] isolated the cyclobutanones (4) as well as the 2:1 adducts (5) [7] and 3:1 adducts, the structure of the latter still being unknown.

We have found that the cyclobutanones (4) are unaffected by dimethylketene in acetonitrile over many days. The 2:1 adducts (5) are formed only in presence of 1 equivalent of boron trifluoride-ether in CH_2Cl_2.



We show here that (4) and (5) arise through a common intermediate and propose that this is the zwitterion (3). At low stationary concentration of (1), (3) cyclizes irreversibly to the cyclobutanone (4). As the concentration of (1) is increased, the 1,4-dipolar cycloaddition [8] of (3) to (1) to give (5) increases in importance. The competing reactions

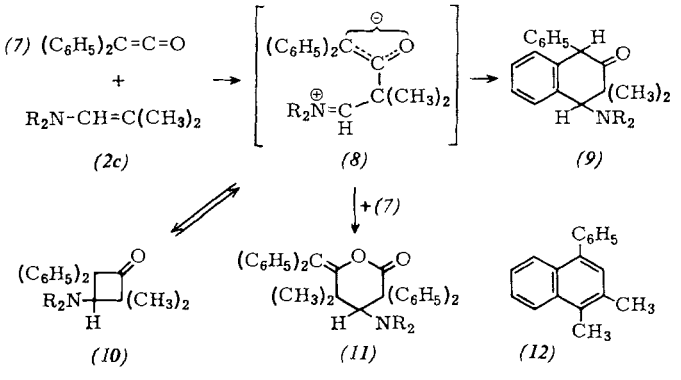
d(4)/d(5) = k_1/k_2(dimethylketene)

rapidly occur after the rate-determining step, namely the formation of *(3)* from *(1)* and *(2)*.

The following experiments (1) and (2) prove the dependence of the ratio *(4)*:*(5)* on the concentration of *(1)* and on the mode of addition. (1) If 11.9 mmoles of dimethylketene *(1)* in 15 ml of acetonitrile were added to a solution of 42.6 mmole of 1-isobutenylpyrrolidine *(2a)* in 35 ml of acetonitrile during 30 min at 20 °C, then dimethyketene *(1)* was consumed so rapidly that the solution became merely pale yellow; distillation in a high vacuum gave 5.7 mmoles of 1:1 adduct *(4a)* and 0.34 mmole of 2:1 adduct *(5a)*, *i.e.*, a ratio of 17:1. (2) However, when 2.6 mmoles of *(2a)* were added all at once to 11.9 mmoles of *(1)* in 15 ml of acetonitrile, then the yellow ketene solution was decolorized only after 10 h; the excess of *(1)* was converted into the dimer *(6)*; working-up in this case yielded 1.26 mmoles of *(4a)* and 0.87 mmole of *(5a)*, *i.e.* a ratio of only 1.4:1.

The enamines *(2b)* and *(2c)* react more slowly with dimethylketene. Decolorization in the process (1) involving an excess of enamine requires 90 min and 10 h, respectively; dependence on the method of mixing was thus less marked. For 1-isobutenylpiperidine the ratios *(3b)*:*(4b)* by procedures (1) and (2) were 2.4:1 and 0.96:1, respectively; and for 4-isobutenylmorpholine *(2c)* the corresponding ratios *(3c)*:*(4c)* were 4.5:1 and 2.2:1, respectively.

We obtained the cyclobutanone *(10)* as main product of the reaction of diphenylketene *(7)* with *(2c)* in *n*-pentane at +5 °C if traces of acid were removed by addition of potassium carbonate. Boiling with methanol, or addition of acid even in the cold, rearranged *(10)* to the *cis-trans*-isomers *(9A)* and *(9B)* of the 2-tetralone. Conversion into 1,2-dimethyl-4-phenylnaphthalene *(12)* and mass spectra[9] confirmed the structures *(9)*, but it has not yet been possible to assign the *cis-trans*-configurations.



R_2N = Morpholino

The hypothesis that conversion of *(10)* into *(9)* also involved the zwitterion *(8)* as intermediate proved correct. The action of an excess of diphenylketene on the cyclobutanone *(10)* afforded the 2:1 adduct *(11)*; chemical and spectroscopic findings agree with the δ-enol-lactone structure *(11)*. Conversion of *(10)* into *(11)* (possible in this case) does not permit a similar proof for *(8)* as intermediate in the cycloaddition as was furnished above for the zwitterion *(3)*.

Enamines that have hydrogen on the β-carbon atom give β-acyl-enamines on reaction with ketenes[10,11]. Presumably also here an intermediate corresponding to *(3)* and *(8)* is responsible, but subsequently undergoes a proton loss.

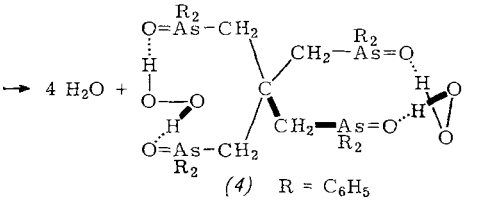
A Spirocyclic 1:2 Adduct of Tetrakis(diphenylarsorylmethyl)methane and Hydrogen Peroxide[1]

By *J. Ellermann* and *D. Schirmacher*[*]

In contrast to tetrakis(diphenylphosphinomethyl)methane[2] *(1)* which yields with H_2O_2 directly tetrakis(diphenylphosphorylmethyl)methane[3] *(2)*, tetrakis(diphenylarsinomethyl)methane[4] *(3)* and H_2O_2 give first a 1:2 tetrakis(diphenylarsorylmethyl)methane-hydrogen peroxide adduct *(4)*, which is converted into tetrakis(diphenylarsorylmethyl)-methane *(5)* with loss of H_2O_2 only when heated under high vacuum.

$C[CH_2P(C_6H_5)_2]_4$ *(1)* $\qquad$ $C[CH_2P(O)(C_6H_5)_2]_4$ *(2)*

$$C[CH_2As(C_6H_5)_2]_4 + 6\ H_2O_2$$
(3)



(4) R = C_6H_5

$$(4) \xrightarrow[\text{High vacuum}]{140^\circ C} C[CH_2As(O)(C_6H_5)_2]_4 + 2\ H_2O_2$$
(5)

The composition and monomeric nature of *(4)* and *(5)* are proved by elemental analyses and osmometric molecular weight determinations in $CHCl_3$. When *(4)* is suspended in dilute H_2SO_4, hydrogen peroxide can be detected by $TiOSO_4$. The structures of *(4)* and *(5)* follow from the IR spectra. These both show, in addition to the absorptions due to *(3)*[4], a broad band for the (As=O) stretching vibration[5] at 895 cm^{-1} (vs) and the expected[6] shifts to higher wave numbers of $\nu_{1,2}(As-C_6H_5)$[4] and $\nu(AsC_3)$[4] by about 10 and 40 cm^{-1}, respectively. The IR spectrum of *(4)* also contains the absorptions of the coordinated hydrogen peroxide, most of which correspond in position to those of crystalline H_2O_2[7] (Table 1) and in respect of the (O–H) stretching vibrations accord very well with those observed for $(C_6H_5)_3AsO \cdot H_2O_2$[8].

Table 1. IR absorption bands of *(4)* and crystalline H_2O_2 [7] (cm^{-1}).

Assignment	*(4)*	(H_2O_2)	Assignment	*(4)*	(H_2O_2)
ν_s (O—H)	3270 sh	3291	δ_{as}(O—O—H)	1388 ms	1380
ν_{as}(O—H)	3170 ms	3208	ν(O—O)	920 mw	880
ν(—O···H—)	2820 m, broad	2732 [a]	ρ_t(O—O—H)	640 mw	635
δ_s(O-O-H)	1403 mw	1404			

[a] (—O···H—) and/or overtones or combination tones of δ_s(O—O—H) and δ_{as}(O—O—H).

From comparison of the long-wave shift of ν_s- and ν_{as}(O—H) with gaseous and liquid H_2O_2 [ν(O—H) at *ca.* 3600 and 3400 cm^{-1}, respectively][9] it follows, in accord with expectations for structure *(4)*, that neither H_2O_2 molecule contains a free OH group and thus that both H_2O_2 are acting as *bidentate* ligands forming strong hydrogen bonds to the oxygen atoms that are bound to arsenic. That their bidentate function is intramolecular follows from the monomeric molecular state of *(4)*. Further, the eleven-membered spirocyclic rings enable the H_2O_2 molecules to retain the energetically favored[10] *trans*-arrangement of the H atoms. The *trans*-arrangement of H atoms is confirmed also by the low intensity of ν(O—O) (small dipole moment of the O—O group). Although the intense broad absorption of the (As=O) stretching vibration occurs in the region of the (O—O) stretching vibrations[11] and it is conceivable that it hides ν(O—O), the assignment of the band at 920 cm^{-1} to ν(O—O) seems nevertheless certain since there is no band at 920 cm^{-1} in *(5)*. The stretching vibration for the (=O···H—) bridges[5] is assigned to the broad band at 2820 cm^{-1}. With few exceptions[6] coordination of (As=O) groups to metals shifts the ν(As=O) absorptions to lower wave numbers; that such a shift is substantially absent for *(4)* may be due to the smaller mass and the smaller electron-acceptor ability of the protons of hydrogen peroxide.

Experimental:

A mixture of compound *(3)* (700 mg, 0.71 mmole) and acetone (50 ml) is treated with 30 % H_2O_2 (1 ml, *ca.* 9 mmoles) with stirring and heating under reflux. It dissolves slowly, leading in about 30 min to a clear colorless solution, which is heated for a further 30 min. Acetone, water, and excess of hydrogen peroxide are then removed under reduced pressure at 15 °C, leaving a colorless oil that crystallizes in a vacuum. This residue is dried for *ca.* 30 min under high vacuum, then dissolved in CH_2Cl_2 (10 ml) and reprecipitated with petroleum ether (50 ml). The then analytically pure product is filtered off, washed four times each with 5 ml of petroleum ether, and dried under high vacuum; it is very readily soluble in CH_2Cl_2 and $CHCl_3$, soluble in acetone and acetonitrile, and almost insoluble in ether, petroleum ether, CS_2 or benzene. Yield 80 %. M.p. from 104 °C with loss of H_2O_2.

If the adduct *(4)* is heated for 5–6 h under high vacuum at 130–140 °C, H_2O_2 distils off and a brownish product is obtained that is dissolved in CH_2Cl_2 (10 ml) and reprecipitated with petroleum ether (25 ml). Compound *(5)* is thus obtained colorless and crystalline; it is filtered off, washed several times with 5 ml of petroleum ether, and dried under high vacuum. M.p. 204–207 °C (decomp.).

CONFERENCE REPORTS

Transport Processes of Noble Gases in Solids, especially Nuclear Fuels

By *K. E. Zimen*[*]

There are solid systems in which noble gases are produced naturally: minerals that contain U, Th, or K from which ^4He, ^{219}Rn, ^{220}Rn, ^{222}Rn, or ^{40}Ar arises in geological times; also meteorites in which some primordial noble gas may be present and in which some cosmogenic noble gas may have arisen by nuclear spallation reactions.

There are also solid systems, and in particular fuels, in which noble gases are formed artificially. The fission products of U or Pu consist to about 30 % of Kr and Xe. Furthermore, noble gases can be incorporated into almost all solid bodies artificially, by nuclear reactions, ion bombardment, nuclear recoil, or entry by diffusion.

Noble gases, whether produced naturally or artificially, are normally present in the solid bodies in atomically disperse form and diffuse out after their formation because of their extremely low solubility. Further, the noble gases can escape owing to recoil during the nuclear transmutation and in certain cases by formation of bubbles, which are moving in temperature gradients. In addition, changes in the solid body – evaporation, recrystallization, and surface reactions – naturally contribute to the loss of noble gas.

Investigation of the behavior and transport of noble gases began with the so-called Hahn emanation method, in which the natural emanations were used for qualitative observation of physical and chemical changes in solids as a function of temperature or time. Today, diffusion coefficients and activation energies of noble gases can be determined quantitatively, and in individual cases the kinetics of diffusion of noble-gas atoms and observation of recoil effects can be used to provide information about fine structure and vacancies in crystalline and amorphous solids – information that cannot be obtained from diffraction methods (X-ray, neutrons), which depend on periodic structure. Of particular importance is the release of fission gases from nuclear fuels because of build-up of pressure in the fuel elements and contamination of the circulating coolant from defective fuel-element cans.

The relevant publications from the Hahn-Meitner-Institut, numbering fourty up to the present, were reviewed.

Study of the Mechanism of Dehydrogenase Reactions by Measurement of the Isotope Effects

By *D. Palm* [*]

Classical kinetic methods for the study of enzyme reactions have recently been extended by methods for selective determination of fast or slow steps in complex reaction sequences.

Slow and irreversible steps can be detected also in enzyme kinetics by differences in the reaction rate of isotopically labeled substrates. This is particularly so for the isotope effects (IE's) of the hydrogen isotopes, for which primary and secondary IE's can be detected [1]. Thus hydrogen transfer in NAD-dependent dehydrogenases is particularly suited for investigation of the empirical and theoretical relation of IE to enzyme-kinetic values.

The primary IE (4.1 to 6.8 at 25 °C) for the substrates [1-T]-ethanol, -1-propanol, and -1-butanol confirm the required rate-determining hydrogen transfer for alcohol dehydrogenase (ADH) from yeast, but an increase in IE with rising temperature also shows a change in the rate-determining step. For the ADH of liver the small secondary IE (1.4 to 1.6 at 25 °C) for the homologous alcohols is in agreement with a rate-determining dissociation of the enzyme-NADH complex, which is independent of the substrate.

The reverse reaction, studied with the stereospecifically labeled [A-4-T]NADH again shows primary IE's of 2 to 5 (depending on the corresponding homologous aldehydes) for yeast enzyme, whereas only a small difference from unity was found for the liver enzyme. The sterically hindered substrate 2-methylcyclohexanone for liver ADH stands out with an IE of 3.6; since 2-[*methyl*-T]methylcyclohexanone reacts 4.5% faster, the site of steric hindrance can be more accurately localized [2].

In the case of lactate dehydrogenase of rabbit muscle the IE of 2.5 for L-[2-T]lactate corresponds to a product of two secondary IE's, which are due to isomerization and dissociation of the enzyme-NADH complex. This interpretation excludes a kinetic influence of ternary complexes. The reverse reaction with [A-4-T]NADH also shows an IE of up to 2.0 that indicates isomerizations, but under the influence of pyruvate inhibition at concentrations $> 1 \times 10^{-3}$ M the IE disappears.

Finally, a mechanism similar to that for yeast ADH can be ascribed to glucose-6-phosphate dehydrogenase and 6-phosphogluconate dehydrogenase.

Oxidation of Pyrrolic Impurities in Polyamides

By *P. Schlack* [*]

When prepared under not quite perfect conditions, polyamides may contain pyrrole groups formed in side reactions and detectable by Ehrlich's reagent. In nylon 6 (polycaprolactam) pyrroles are observed particularly if 1,11-diaminoundecanone is formed by loss of water and CO_2 from two moles of 6-aminohexanoic acid or if the corresponding anhydro base is formed from ε-caprolactam by loss of water. This ketimine is very sensitive to oxygen and after autoxidation gives an intense pyrrole reaction.

Polycaprolactam fibers ("Perlon") that contain units of this imine show a strong tendency to yellow on fairly long exposure to light in the presence of oxygen or on thermal oxidation. *Rochas* and *Martin* have found that polyamide fibers (nylon 66) may also give a positive pyrrole reaction after photoxidation [1]. They assumed that the pyrroles were formed by reaction of amino end groups in the fiber with α,α'-dioxoadipic acid formed by oxidation of adipyl groups. *Marek* and *Larch* came to the conclusion that it was almost wholly the diamine groups that were involved in pyrrole formation; they held that primary attack by the oxygen was always on the methylene groups next to the amide nitrogen [2].

In studies of the yellowing of polyamide textiles in our Institute, *F. Sommermann* [3] found that pyrroles are also formed on oxidation of N-free olefinic substances such as 3-heptene, oleic acid, methyl linoleate, and squalene in the presence of primary amines or amino acids and also on subsequent addition of such amines. Since sweat contains glycerides of polyunsaturated fatty acids, squalene, ammonium salts, and other nitrogenous bases, pyrroles or their colored oxidation products could be formed on textile substrates even without chemical participation of the fiber substance.

Only the primary amino end groups of the fiber come into question as a nitrogen source for pyrrole formation within the fiber substance. If however, the amino groups are inactivated by acylation, *e.g.* by acetic anhydride [4], then pyrrole can no longer be formed on the fiber unless ammonia or amino groups are newly formed. Autoxidation in light is then also greatly hindered. Most of the amino groups can be blocked under remarkably mild conditions that can be realized in practice, namely, by impregnating the textile goods with solutions of anhydride-forming aromatic polycarboxylic acids, *e.g.* trimellitic acid, then drying them, and heating them for one to two minutes at 170–180 °C by passage through a thermofixing apparatus. The tendency to yellowing is much reduced by this pretreatment.

From the UV spectra of the dyes formed in the fiber by *p*-(dimethylamino)benzaldehyde it can be concluded that both α- and β-methine dyes occur side by side, whereas the dyes formed from unsaturated fatty acid esters and amino acids appear to consist mainly of β-derivatives.

Aromatic Sigmatropic Rearrangements

By *Hans Schmid* [*]

Aromatic sigmatropic rearrangements are thermal reactions whose transition states can, to a first approximation, be considered as interaction complexes between two pseudoradical halves that have arisen by homolysis of the bond that is attacked. At least one of these halves must be aromatic in nature, *i.e.* its π-system is to be described by aromatic molecular orbitals. A well-known example is the thermal Claisen rearrangement of allyl aryl ethers that occurs with inversion

of the allyl group. The transition state for the sigmatropic-[3,3]-reactions involved (allyl aryl ether $\rightleftarrows$ 2-allyl-3,5-cyclohexadien-1-one $\rightleftarrows$ 4-allyl-2,5-cyclohexadien-1-one) are controlled in accord with the Woodward-Hoffmann rules by suprafacial-suprafacial interaction of the single occupied ψ_2 of the allyl radical and the singly occupied ψ_4 of the phenoxy radical (cf. ref. [1]).

Aryl propargyl ethers behave like allyl aryl ethers. Their thermal ring closure to chromenes, observed by *Iway* and *Ide* [2] does not occur directly, but by a [3,3]-sigmatropic rearrangement, followed by enolization to *o*-allenylphenol which even at about 80 °C undergoes an aromatic [1,5]-hydrogen shift and thereupon an electrocyclization to the chromene [3].

The rearrangement of 3-(1-methyl-2,2,2-trichloroethylidene)-1,4-cyclohexadiene to 1-methyl-4-(2,2,2-trichloroethyl)benzene which occurs at 20–70 °C and was observed by *von Auwers* [4] may also be a suprafacial C,C-[1,5] aromatic sigmatropic reaction that is controlled by the ψ_3 of the tolyl radical and the p-orbital of the $CCl_3^{\bullet}$. However, this would lead to a very strained transition state.

On the basis of the MO diagrams the formation of *o*-(1-vinylallyl)phenol ([3,3]-rearrangement) and of *p*-(2,4-pentadienyl)-phenol ([5,5]-rearrangement) is to be expected in the thermolysis of 2,4-pentadienyl phenyl ether. Experiments with substituted ethers have given the following series: [5,5] > [3,3] $\gg$ ([1,5]?) [5].

Sigmatropic rearrangements in polar systems occur particularly rapidly when the charge is better distributed in the transition state than in the starting materials. In the dienol-benzene rearrangement of 2-allyl-2-methyl-3,5-cyclohexadien-1-ol and 4-allyl-4-methyl-2,5-cyclohexadien-1-ol with *p*-toluenesulfonic acid in ether at −40 °C the products formed, with loss of water, are those expected from the MO diagram (ψ_3 of the tolyl radical, ψ_2 of the allyl radical), namely: *o*-allyltoluene by [1,2]-, *m*-allyltoluene by [3,3]-, and *p*-allyltoluene by [3,4]-rearrangement. It is always the allyl group that migrates, in the first reaction without and in the others necessarily with inversion [1].

The rearrangement of 2- and 4-allylcyclohexadienones to allylated phenols effected by BCl_3 [6] occurs similarly. Competing reactions for the crotyl and dimethylallyl compounds are heterolysis to the phenolic compound and crotyl-cation or dimethylallyl-cation.

Sigmatropic reactions may also play a part in other aromatic rearrangements (*e.g.* the "acid-catalyzed" and the thermal Fischer indole synthesis [7]).

Lecture at Heidelberg (Germany) on May 1, 1968 [VB 163 IE]

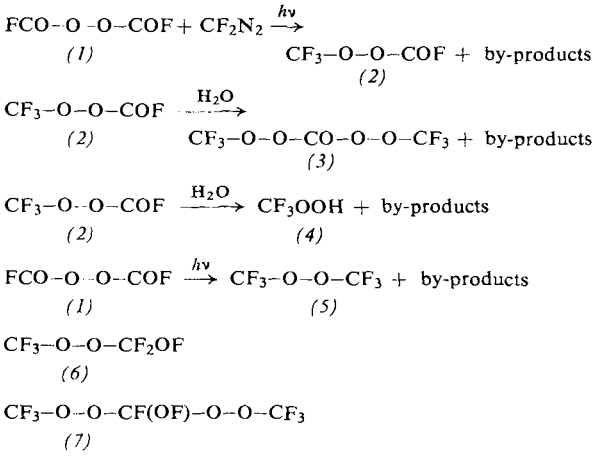
SELECTED ABSTRACTS

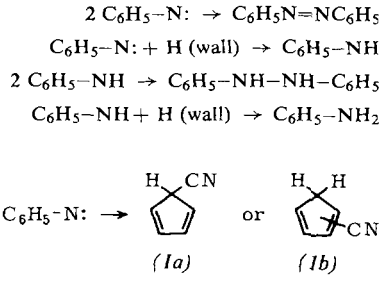
The preparation of α,β-unsaturated ketones by oxidative decarboxylation of γ-oxo carboxylic acids with lead dioxide has been described by *D. V. Hertzler, J. M. Berdahl,* and *E. J. Eisenbraun.* With γ-oxo carboxylic acids having no alkyl or aryl substituents in the α or β positions, the yield does not exceed 40 %; 84 % of ketone was obtained in the most favorable case (3-benzoyl-2-phenylpropionic acid). / J. org. Chemistry *33*, 2008 (1968) / −Kr. [Rd 878 IE]

The new fluorocarbon peroxides *(2)*—*(7)* have been prepared by *R. L. Talbott.* The photolysis of an equimolar mixture of bis(fluoroformyl) peroxide *(1)* and difluorodiazine in a quartz apparatus yields *inter alia* fluoroformyl trifluoromethyl peroxide *(2)*, which is converted by hydrolysis into bistrifluoromethyl bisperoxycarbonate *(3)* or trifluoromethyl hydroperoxide *(4)*, depending on the conditions. Prolonged photolysis of *(1)* leads to bistrifluoromethyl peroxide *(5)*.



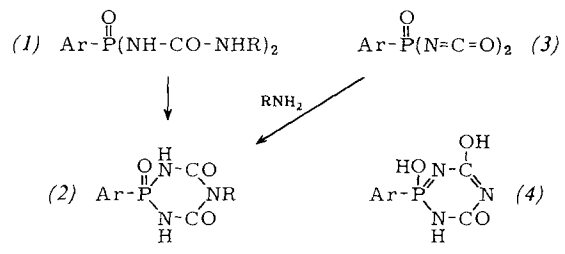
The low-temperature fluorination of *(2)* and *(3)* leads to fluoroxydifluoromethyl trifluoromethyl peroxide *(6)* and fluoroxybis(trifluoromethylperoxy)fluoromethane *(7)*. The new peroxides *(2)*—*(7)* are colorless gases or liquids with high vapor pressures, which are stable for some time at room temperature. / J. org. Chemistry *33*, 2095 (1968) / −Kr. [Rd 879 IE]

The thermal rearrangement of phenylnitrene into cyclopentadienecarbonitrile has been studied by *E. Hedaya, M. E. Kent, D. W. McNeil, F. P. Lossing,* and *T. McAllister.* The mass spectra recorded during the decomposition of phenyl azide could be best explained by the assumption of the following reactions:



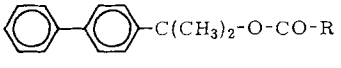
When large quantities were used (flash photolysis in a vacuum), *(1)* could even be chemically characterized. *(1a)* could not be detected. *(1b)*, *i.e.* 1- and/or 2-cyclopentadienecarbonitrile, is evidently present. The rearrangement probably proceeds *via* bicyclo[3.1.0]hex-2-en-6-ylidenenitrene. / Tetrahedron Letters *1968*, 3415 / –Kr. [Rd 881 IE]

4,6-Dioxo-2-arylperhydro-1,3,5,2-triazaphosphorine 2-oxide *(2)* has been prepared by *G. Tomaschewski, Ch. Berseck*, and *G. Hilgetag* by pyrolysis of arylphosphonic diureides *(1)* and by the reaction of arylphosphonic diisocyanates *(3)* with NH_3 or primary amines. The second method is more versatile and gives better yields.



Examples: *(2)* from *(1)*, Ar = C_6H_5, R = H (m.p. 250 °C, yield 20 %), R = CH_3 (236 °C, 75 %); *(2)* from *(3)*, Ar = C_6H_5, R = *n*-C_4H_9 (224–225 °C, 81 %), Ar = *p*-NO_2–C_6H_4, R = CH_3 (220–221 °C, 95 %). The IR spectra of *(2)*, R = H, can be best interpreted by the assumption of tautomerism between *(2)* and *(4)*. / Chem. Ber. *101*, 2037 (1968) / –Kr. [Rd 882 IE]

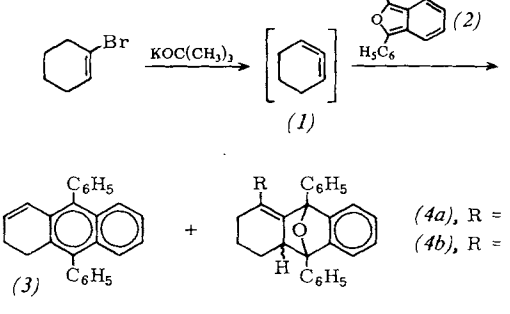
The use of 1-(*p*-biphenylyl)-1-methylethoxycarbonyl groups for the synthesis of peptides has been reported by *P. Sieber* and *B. Iselin*. α-*N*-Protected amino acids are easily obtained from amino acid esters or their salts by reaction with the carbonate *(1)* or the azide *(2)*. The group is cleaved so quickly by dilute acetic acid that even other acid-sensitive protective groups (*e.g.* those derived from *tert*-butanol) are not attacked. The cleavage of this and other aralkyloxycarbonyl groups is a first order reaction; the reaction rates depend on the stability of the corresponding carbonium ions.



(1), R = OC_6H_5 *(2)*, R = N_3

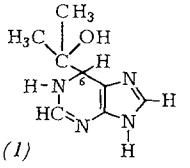
The α-(1-(*p*-biphenylyl)-1-methyl-ethoxycarbonyl) amino acids are suitable for conventional peptide syntheses and syntheses on a solid phase; no steric hindrance is observed. / Helv. chim. Acta *51*, 614, 622 (1968) / –Kr. [Rd 883 IE]

1,2-Cyclohexadiene ***(1)*** has been detected by *G. Wittig* and *P. Fritze* as a short-lived intermediate in the rearrangement of 1-bromocyclohexene with potassium *tert*-butoxide. With 1,3-diphenylbenzo[*c*]furan *(2)*, *(1)* can be intercepted as *(3)* and *(4a)*; in the absence of *(2)*, the dimer octahydrobiphenylene



is formed. In order to be sure that the reaction does not proceed *via* cyclohexyne, 1,2-dibromocyclohexene was used. Under similar conditions, the bromo compound *(4b)* was formed together with 9,10-diphenylanthracene; *(4b)* could only be formed *via* an allene. / Liebigs Ann. Chem. *711*, 82 (1968) / –Kr. [Rd 884 IE]

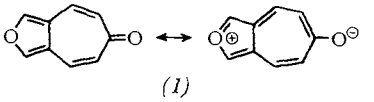
The photochemical addition of alcohols to purines has been observed by *H. Linschitz* and *J. S. Connolly* on irradiation of O_2-free solutions with UV light (2537 Å). The addition of isopropanol to purine gives *(1)*; the addition of ethanol yields two isomeric products, which can be isolated by fractional



(1)

crystallization. The addition can be followed by means of a new band at about 292 nm. Since similar changes in the absorption spectrum were observed on irradiation of ethanolic solutions of heterocyclic compounds, such as pyridine, pyrazine, benzimidazole, benzoxazole, quinoline, isoquinoline, quinoxaline, and phenazine, the reaction appears to be general. / J. Amer. chem. Soc. *90*, 2979 (1968) / –Ma. [Rd 885 IE]

***6H*-Cyclohepta[c]furan-6-one** (furo[3,4-*d*]tropone), a new heterocyclic system *(1)*, has been synthesized by *M. J. Cook* and *E. J. Forbes*, (i) from 3,4-furandicarbaldehyde by condensation with acetone in ethanol/10 % NaOH (38 % yield),



(1)

and (ii) from the dialdehyde by condensation with the diethyl ester of acetonedicarboxylic acid, hydrolysis, and decarboxylation with 0.5 % HCl (7 % yield). *(1)*, m.p. 140 °C, forms carbonyl derivatives and takes up deuterium on dissolution in D_2SO_4. The aromatic character of *(1)* is much weaker than that of tropone, and comparable to that of benzo[*d*]tropone. / Tetrahedron *24*, 4501 (1968) / –Ma. [Rd 886 IE]

Tetramethylsilane (TMS) cannot be used indiscriminately as an internal standard in NMR spectroscopy in solution, according to *P. Laszlo, A. Speert, R. Ottinger*, and *J. Reisse*. It is normally assumed that TMS does not react with the solvent, and that the van der Waals contribution of the solvent to the chemical shift is the same for TMS as for the substance whose spectrum is being recorded. When this assumption was checked for a group of solvents having aromatic character, such as pyridine, nitrobenzene, benzaldehyde, benzonitrile, and aniline, it was found that they form "complexes" with TMS (and with the tetramethyl derivatives of germanium, tin, and lead) with apparent heats of formation of 1–2 kcal/mole; this corresponds to additional chemical shifts of 0.10–0.15 ppm. Neopentane, cyclohexane, and 2,2,4,4-tetramethylpentane are suggested as replacements for TMS in such solvents. / J. chem. Physics *48*, 1732 (1968) / –Hz. [Rd 888 IE]

The vapor pressures and melting points of XeF_2 and XeF_4 have been measured by *F. Schreiner, G. N. McDonald*, and *C. L. Chernick*. The vapor pressure between 273 and 388 °K can be represented for XeF_2 by the equation

$\log P = -3057.67/T - 1.23521 \log T + 13.969736$

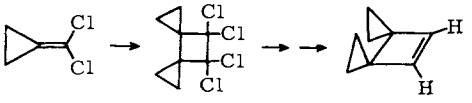
and for XeF_4 by

$\log P = -3226.21/T - 0.43434 \log T + 12.301738$

XeF_2 has the higher vapor pressure over the entire temperature range studied. The triple points were determined as discontinuities in the heating and cooling curves; they occur at 402.18 °K for XeF_2 and at 390.25 °K for XeF_4. The enthalpies of sublimation at 330 °K calculated from the vapor pressure equations are 55.2 ± 0.8 kJ/mole for XeF_2 and 60.6 ± 1.0 kJ/mole for XeF_4. The standard entropy for XeF_4 vapor at 298.15 °K was calculated from the vapor pressure and the specific heats, and was found to be 305.2 $J \cdot deg^{-1} \cdot mole^{-1}$; an entropy of 122.8 $J \cdot deg^{-1} \cdot mole^{-1}$ is given for solid XeF_2 at 330 °K. / J. physic. Chem. *72*, 1162 (1968) / –Hz.

[Rd 889 IE]

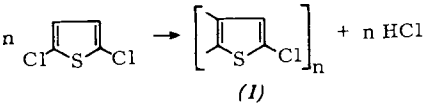
Dispiro[2.0.2.2]oct-7-ene, which is of theoretical interest, was synthesized by *W. R. Dobier jun., D. Lomas,* and *P. Tarrant.* Decomposition of Na trichloroacetate in the presence of allene gives 2,1-dichloro-2-methylenecyclopropane (20% yield), which on heating to 215 °C gives a quantitative yield of 1-(dichloromethylene)cyclopropane *(1)*. On prolonged heating at temperatures above 120 °C, the latter changes into



(1) *(2)* *(3)*

7,7,8,8-tetrachlorodispiro[2.0.2.2]octane *(2)* (100%). Zn in ethanol converts *(2)* into 7,8-dichlorodispiro[2.0.2.2]oct-7-ene (85%), the reduction of which with Na/THF/*tert*-butanol gives dispiro[2.0.2.2]oct-7-ene *(3)* (80%). The compound is thermally stable up to 300 °C. / J. Amer. chem. Soc. *90*, 3594 (1968) / –Ma. [Rd 893 IE]

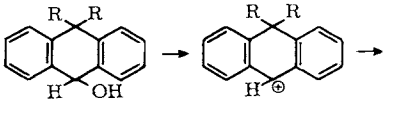
A new type of polymerization was observed by *P. Kovacic* and *J. S. Ramsey* in the reaction of 2,5-dichlorothiophene with $AlCl_3$ and $CuCl_2$ (molar ratios 1:4:2) in CS_2 at 12–29 °C. A brown polymeric powder was obtained, m.p. about 115 to 150 °C (yield 93%). The reaction apparently proceeds according to:



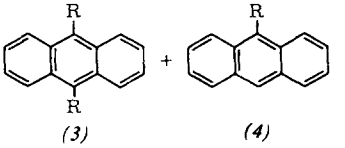
(1)

The structure *(1)* is adopted on the basis of NMR and IR spectra. Distillation of *(1)* gives the dimeric yellow $C_8H_3Cl_3S_2$; chromatography of the ether-soluble fraction of *(1)* gives the yellow tetrameric $C_{16}H_6Cl_4S_4$, m.p. 197–199 °C. Hitherto, polythienylene compounds bonded in the 2,3-positions have been unknown. The reaction is a nuclear linkage by elimination of HCl, and is presumably a cationic polymerization. / Chem. Commun. *1968*, 802 / –Ma. [Rd 894 IE]

A trans-annular rearrangement of 9,10-dihydroanthracene derivatives has been reported by *A. L. J. Beckwith, W. B. Renfrow, A. Renfrow,* and *J. K. Teuber.* Thus, for example *(1a)* rearranges on heating in acetic acid (12 hours) into 9,10-dibenzylanthracene *(3a)* and to *(4a)* in yields of 60% and 19% respectively. Analogously, 58% of *(3b)* and 23% of *(4b)* are formed from *(1b)*. On the other hand, diallylanthranol *(1c)*



(1) *(2)*



(3) *(4)*

(a), R = C_6H_5-CH_2
(b), R = *p*-Cl-C_6H_4-CH_2
(c), R = CH_2=CH-CH_2

is converted exclusively into *(3c)* (86% yield). The reaction proceeds *via* the carbonium ion *(2)* which undergoes aromatization – presumably intramolecularly. / Tetrahedron Letters *1968*, 3463 / –Kr. [Rd 904 IE]

BOOK REVIEWS

Handbuch der Lebensmittelchemie (Manual of Food Chemistry). Vol. II/2: Analysis of Foodstuffs. Compiled by *L. Acker et al.* Springer-Verlag, Berlin-Heidelberg-New York 1967. 1st Edit., xxxii, 1552 pages, 162 illustrations, bound, DM 389.– / $97.25.

28 specialists from Germany and abroad have collaborated in producing this manual [*], which is divided into 26 sections under individual headings. Such a comprehensive book is equally valuable as a reference work and for the study of food chemistry. It will prove invaluable to food chemists, food technologists, biologists, medical workers, engineers, and advanced students.

The authors provide a clear introduction to each method, followed by a detailed explanation of how to carry out the investigation, incorporating many well chosen examples. Great emphasis is placed on the interpretation of analytical data. By engaging leading experts in the individual fields it was possible to draw on their accumulated broad experience of the methods. The publisher and editor are to be specially congratulated on coordinating the lay-out of the items, which is exemplary.

Particular attention has been paid to impurities and preservatives, the treatment of which covers approximately 700 pages, nearly half of the volume. This highlights the importance of the field and indicates the direction toward which food chemistry will have to be increasingly oriented. It is very gratifying that the authors have taken the trouble to cover thoroughly both home and foreign literature and to include books as well as journals in the references.

This beautifully printed and produced volume provides an indispensable source of readily available information for every laboratory dealing with the testing and investigation of foodstuffs, and fills a long-standing gap in the German literature in this special field. *P. F. Pelshenke* [NB 737 IE]

[*] Cf. Angew. Chem. *79*, 195 (1967); Angew. Chem. internat. Edit. *6*, 189 (1967).

The Organic Compounds of Magnesium, Beryllium, Calcium, Strontium, and Barium. By *S. T. Ioffe* and *A. N. Nesmeyanov* (Vol. 2 of the series "Methods of Elemento-Organic Chemistry"). North-Holland Publishing Company, Amsterdam 1967. 1st Edit., x, 735 pp., many illustrations, bound, Dfl. 100.00.

The book is divided into two parts which differ in their size and treatment. The first part (650 pages) contains 18 chapters describing the reactions of Grignard reagents with various classes of organic compounds, as well as the preparation, analysis, and structure of Grignard compounds. This part is evidently based on the three-volume handbook on organomagnesium compounds (1950) by the same authors, which has been condensed and brought up to date by the inclusion of additional material. The second part presents a much more detailed discussion of the organic compounds of beryllium (27 pages), calcium, strontium, and barium (18 pages). The small space devoted to these topics reflects the scarcity of relevant investigations.

Each chapter has a comprehensive list of references. The literature is taken into account up to the end of 1961, and important work carried out up to the beginning of 1965 has also been added to the translation. The volume of publications to be covered was very large (much more than 10000 being known on Grignard compounds alone), and the authors are to be congratulated on the care that they have taken in this task. For many years they have been among the leading authorities in this field. It is for this very reason, however, that in the reviewer's opinion they might have made greater use of their right to criticize. For example, in the section "Structure of Grignard Reagents" (pp. 84–93), arguments and opinions that have now been revised are listed chronologically alongside those that are still valid. The once amazing ^{28}Mg-exchange experiments are described in detail, together with the (now refuted) conclusion that C_2H_5MgBr has the structure $(C_2H_5)_2Mg \cdot MgBr_2$ (p. 88). On p. 91, however, with no reference to this, we find the exchange experiments with ^{25}Mg, which led to complete equipartition, and on p. 90, without comment, is the remark that the "dominant component ... is the RMgX compound". Some comment by the authors as to what may now be regarded as definite and what may not would be of great value to readers who are unfamiliar with the subject matter.

In view of the importance of this book as a reference work, the author and subject indexes might perhaps have been more detailed. For example, the important keyword "reduction" does not appear. (The book published by *Kharasch* and *Reinmuth* in 1954 contains 30 subsidiary entries related to the reducing action of Grignard compounds under this keyword). The book provides those who are interested with a valuable reference work, which fills a gap in the long-neglected handbook and monograph literature on organometallic chemistry.

W. P. Neumann [NB 734 IE]

The Chemistry of Niobium and Tantalum. By *F. Fairbrother.* Monograph 9 of the series "Topics in Inorganic and General Chemistry". Edited by *P. L. Robinson.* Elsevier Publishing Company, Amsterdam-London-New York 1967. 1st Edit., viii, 243 pp., 16 figures, 6 tables, Dfl. 50.–.

The chemistry of niobium and tantalum is currently developing rapidly. The present compilation and selection of the existing knowledge by an expert is therefore very welcome. The book contains a short section on the separation and preparation of the elements and on the physical properties of the metals (11 pages). The author then discusses compounds containing oxygen, starting with the oxides and proceeding *via* the hydroxides, niobates, and tantalates to the complex compounds (48 pages). The chapter on the oxides is one of the few that leave something to be desired. It would have been better here *e.g.* not to have discussed the modifications of Nb_2O_5 primarily in historical order, and to have given a clearer picture of the latest position. It would also have been useful to include the formulas and structures of the very interesting Magnéli phases in the region from 2.4 to 2.5 O/Nb.

The section on halogen compounds (78 pp.) is very comprehensive. The importance of metal-metal bonds in the structures of the lower halides is also clearly explained.

Further chapters deal with the hydrides (7 pages), carbides, silicides, and borides (17 pages), the compounds of niobium and tantalum with the group V elements (18 pages), and the sulfides, selenides, and tellurides (13 pages). The latest developments are again included in these chapters.

The last chapter presents a survey of analytical methods (10 pages). However, this chapter is probably intended simply to round off the book, and it will be necessary for the analyst to refer to specialized works.

A large number of references facilitate consultation of the original papers. Complete coverage cannot be expected in a monograph of this size; it is therefore all the more important that the author selects his material well. While the essentials have been well selected and arranged, the reader is referred to the literature for other themes. This may be useful to the reader, though it would be very interesting to gain a deeper insight into the author's views on specific problems.

H. Schäfer [NB 730 IE]

Aromatic Rearrangements. By *H. J. Shine.* Monograph No. 6 of the series "Reaction Mechanisms in Organic Chemistry". Edited by *C. Eaborn* and *N. B. Chapman.* Elsevier Publishing Company, Amsterdam-London-New York 1967. 1st Edit., 405 pp., many illustrations, Dfl. 65.–.

The editors have managed to engage an author for this book who has himself made an important contribution to our understanding of the benzidine rearrangement. It is therefore understandable that considerable space in this book is devoted to the reactions of *N*-substituted amino-aromatic compounds (140 pages). Three chapters also deal with rearrangements of alkylaromatic and halogeno-aromatic compounds, aryl esters and ethers, and aromatic amine oxides. The book ends with two sections on base-catalyzed (Smiles, Sommelet, and carboxylate rearrangements, von Richter reaction) and photochemical rearrangements. Ordinary migrations of aryl groups, rearrangements *via* dehydroaromatic intermediates, and Lewis acid-catalyzed rearrangements of polynuclear aromatic compounds are not discussed.

The author has taken into account results from more than 500 original papers and discussed them critically. For reactions whose mechanisms are not yet clarified, the present position is shown and the possible interpretations of the results are considered. The numerous comparisons of rearrangements are particularly valuable.

The following observations were made regarding some of the chapters:

In the discussion of the Fries rearrangement, some reference should have been made to *K. Fries*, particularly since the histories of other reactions are outlined.

Only four of the many papers on the Claisen rearrangement by *H. Schmid* and his co-workers are considered. In the excellent section on the benzidine rearrangement, the author clearly prefers the polar-transition-state theory to the π-complex theory or the radical-cation theory on kinetic grounds. In the reviewer's opinion, there is much to be said for the possibility, mentioned on p. 325, that both the Sommelet and the Stevens rearrangements proceed *via* ion pairs. As was shown in 1966 (reference 50a in Chapter 3), *N,N'*-decamethylenebenzidine (cf. p. 135), which was first described as a monomer (reference 17, Chapter 3), has a dimeric structure.

There are few printing errors either in the text or in the illustrations; however, some of the formulas are very small.

On the whole, this book presents a comprehensive picture of the work on many rearrangements of aromatic compounds

up to about 1965/1966. Its publication will be welcomed by all who wish to learn about this field of organic chemistry, and it should be included at least in the libraries of all universities and colleges. *W. Tochtermann* [NB 738 IE]

The Organic Chemistry of Phosphorus. By *A. J. Kirby* and *S. G. Warren*. Monograph 5 of the series "Reaction Mechanisms in Organic Chemistry". Edited by *C. Eaborn* and *N. B. Chapman*. Elsevier Publishing Company, Amsterdam-London-New York 1967. 1st Edit., xi, 404 pp., 4 figures, 21 tables, Dfl. 65.–.

A great deal of expert knowledge and courage are required to present a monograph on such an extensive topic. However, it is pointed out in the preface that certain mechanistic principles are to be laid down to familiarize the newcomer with the specific problems of organophosphorus chemistry. The authors see the absence of quantitative data in the original papers as one of the limits of their commentary. The experienced reader very soon finds that the discussion of fields that have already been well covered in other monographs (cf. *R. F. Hudson*: Structure and Mechanism in Organophosphorus Chemistry), or that are particularly familiar to the authors from their own experience is of a high scientific standard. This is true of Chapter 1: Electronic Structure; Chapter 2: Structure and Reactivity; Chapter 3: Nucleophilic Attack of Compounds of Trivalent Phosphorus; Chapter 4: Elimination of Compounds of Trivalent Phosphorus; Chapter 5: Free-Radical Reactions on Phosphorus; Chapter 7: Reactions that do not occur on the Central P Atom; Chapter 8: Nucleophilic Attack on Compounds of Tricoordinated Phosphorus; Chapter 10: Nucleophilic Attack on Compounds of Tetrahedral Phosphorus(v), and Chapter 11: Phosphorylation. The last two chapters are particularly impressive for their completeness.

On the other hand, Chapter 6: Four-Center Rearrangements, and to a lesser degree Chapter 9: Nucleophilic Attack on Phosphonium Salts and Compounds of Pentacovalent Phosphorus, seem rather stunted. Chapter 6 deals almost exclusively with olefination *via* phosphonium ylides, with no regard for historical relationships. More recent developments such as PO-activated olefinations are by-passed with references, and their importance in syntheses is not mentioned. No reference is made to later variants by *Zimmer*, *Corey*, *Machleidt*, and *Bergelson*. This chapter also contains many inaccuracies and errors, which should be eliminated for the second edition. The well-informed reader also notices the absence of references to important review articles, particularly in languages other than English. No mention is made in Chapter 9 of the important work by *Hellwinkel* on the anionic hexacovalent phosphorus compounds; the book also lacks any reference to the preparation of phosphabenzene and its derivatives by *G. Märkl*. It is categorically stated on page 336 that no three-membered rings containing phosphorus are known, with complete disregard for the preparation of phosphirane by *Ross* and *Wagner*. Reactions of azides with compounds of tricoordinate phosphorus are repeatedly and wrongly formulated as proceeding *via* nitrenes. If inaccuracies of this nature and mistakes in the formulations, formulas, and literature data were corrected, this monograph could be wholeheartedly recommended. Even in its present state, however, it provides a lively insight into the complexity and vitality of organophosphorus chemistry.

L. Horner [NB 728 IE]

Perspectives in Structural Chemistry. Vol. 1. Edited by *J. D. Dunitz*, and *J. A. Ibers*. John Wiley & Sons, New York-London-Sydney, 1967. 1st Edit., ix, 199 pages, numerous illustrations and tables, bound, 80 s.

This is the first volume of a new series of detailed surveys on topics in structural chemistry. According to the foreword, the emphasis is placed on the results of structural investigations, their accuracy, and their chemical significance, and not on the aspects of methods and techniques. In addition, the results of individual structural determinations are mutually compared to establish relationships wherever possible, and to interpret these relationships.

The first volume contains three surveys, all written with regard to the above concepts: "π-Complexes of Transition Metals with Aromatic Systems" by *P. J. Wheatley*, "Structures of Natural Products" by *A. McL. Mathieson*, and "Structural Chemistry of the C≡N group" by *D. Britton*. The literature up to and including 1965 appears to be reviewed completely. In the last two contributions reference is also made to more recent literature. Characteristically, a large part of the work cited is concerned with X-ray structure analysis. The three authors and the editors are well-known practising crystallographers, who have contributed to the subjects under discussion by their own work.

The value of the book lies not only in the collection and comparative evaluation of the relevant literature, but in the critical manner in which it is presented. For this reason, and because of its emphasis on results, the book will appeal directly to the organic and inorganic chemist interested in general structural and stereo-chemistry, who often finds it difficult to understand and appraise original papers and to assess their accuracy because of the frequently strong emphasis on methodological aspects.

It is to be hoped that further volumes in this series will soon become available. *D. Mootz* [NB 732 IE]

Poly-α-Amino Acids. Protein Models for Conformational Studies. Edited by *G. D. Fasman*. Vol. 1 of the "Biological Macromolecules Series". Marcel Dekker, Inc., New York, 1967. 1st Edit. xv, 764 pages, numerous illustrations and tables, bound $34.50.

This compilation of information about polyamino acids, information that has grown very rapidly in recent years, will be especially welcomed by those who are interested in the structure and stabilization of proteins and in conformational changes. The book consists of 13 chapters written by leading specialists. Each chapter is effectively a separate monograph in its particular field.

The chapters on X-ray structure analysis (*Elliott*), IR-spectroscopy (*Miyazawa*), X-ray small-angle scattering (*Saludjian* and *Luzzati*), and hydrogen exchange (*Erlander*) are excellent both in the description of methods and in the presentation of the results. The treatment of light scattering and hydrodynamic properties by *Benoit et al.* is essentially confined to an outline of method possibilities. The chapters on UV-absorption (*Gratzer*), optical rotatory dispersion (*Yang*), and circular dichroism (*Beychok*) are considered good in themselves; a comprehensive description of these closely related effects from the point of view of the optical properties of polypeptides would certainly have been better. Here we come across the basic disadvantage of the book: the very thorough grouping according to methods, which is only complete when it more or less coincides with a grouping based on the properties of polyamino acids. Hence the individual descriptions are not very well interrelated, and there are many repetitions (even some illustrations occur twice!).

In addition to the method-oriented chapters, there are two interesting chapters on dielectric properties (*Wada*) and biological properties (*Silman* and *Sela*), and also a chapter on polyproline (*Mandelkern*). The difficult problem of presenting the theories on stabilization and conformational changes is well solved by *Poland* and *Scheraga* (with limitations as to kinetics). *Fasman* has succeeded only partially in giving in his chapter an orderly survey of the properties of the polyamino acids and their structures. The construction of the book and a poor and defective index render it impossible for the reader to acquaint himself quickly with a particular polyamino acid. The literature is covered up to 1965, and in certain exceptional cases up to 1966. *J. Engel* [NB 736 IE]

Adsorption from Solutions of Non-Electrolytes. By *J. J. Kipling*, Academic Press, London-New York 1966. 1st Edit., xii, 328 pp., numerous illustrations, 73 s.

This monograph sets out to familiarize the reader with a field that up to now has received little attention, on the one hand because the measurements are difficult to carry out and on the other because the results of such measurements frequently yield only a complex expression that is difficult to interpret. The book offers a good survey of the simultaneous adsorption of components of a liquid, as well as of a solution of a solid in an organic solvent, at the solid/liquid or gas/liquid interface.

The term "solution" in the title can be misleading, since it implies particularly the special case in which one component is normally present in large excess, and this is not the case in many of the systems treated. This term should perhaps only be used, where one component is actually present in excess (*e.g.* a solid in an organic solvent).

Methods of investigation are next considered, and these are principally concerned with the analysis of liquid mixtures. As a result, a clear distinction is made between individual and composite isotherms; the former are concerned with the adsorption of a single component of a mixture or a solution, and the latter with the simultaneous adsorption of all components. The different behavior of polar and nonpolar organic compounds at liquid/solid and gas/liquid interfaces is demonstrated with the aid of many examples. In most cases a monomolecular adsorption layer may be assumed; multimolecular adsorption occurs less frequently, and is thus difficult to estimate quantitatively. The sorption properties of molecular sieves, whose importance in analysis continues to increase, are unfortunately treated only very briefly.

The thermodynamic calculations are useful, particularly the evaluations of various isotherms. However, molecular-physical concepts based on quantum mechanics, which have been applied more recently to adsorbed gases and solids, are completely lacking in the field under consideration.

The purpose of the book – to give to the research worker interested in fundamentals a clear and well arranged exposition of a relatively complex field – is in general fully achieved. It is to be hoped that the book will provide an impetus to wider investigations in the field of adsorption phenomena.

G. Peschel [NB 727 IE]

Halogen Chemistry. By *V. Gutmann*. Academic Press, London-New York 1967. Vol. 1. 1st Edit., xiii, 473 pp., several figures and tables, bound $ 21.00 / £6.

Halogen chemistry has recently become technically and scientifically very interesting, and has consequently undergone a very rapid development. This collection of reviews of important areas of the field by eminent specialists is therefore welcome.

A. G. Sharpe presents a concise but easily understandable discussion of the "Physical Inorganic Chemistry of the Halogens". The author has approached the problems from various angles instead of simply listing the physical data. *M. F. A. Dove* and *D. B. Sowerby* describe "Isotope-Halogen Exchange Reactions". This article contains considerable experimental material, which is particularly valuable in preparative work. The "Physical and Chemical Properties of the Halogen Fluorides" are described by *L. Stein*. This is followed by a very good review by *A. J. Popov* on "Polyhalogen Complex Ions", which should prove an incentive to further investigations. The chapter on "Electronic Structure and MO Treatment of Halogen and Inert Gas Complexes in Positive, Negative, and Indefinite Oxidation States" by *C. Jørgensen* is a clear and understandable account of the theoretical aspects of the halogen complexes. *H. Selig* finally describes the recent "Fluorine Chemistry of the Inert Gases".

The author and subject indexes at the end of the volume are particularly useful. The authors do not all use the same system for references, and in some chapters the references are not indicated by numbers, which makes reading difficult. As is to be expected in a work of this kind, some of the contributions are relatively short, while others give a wider description of the field. The book is a valuable aid to chemists working in every field as a source not only of information on what has already been done, but also of inspiration for new research projects.

O. Glemser [NB 735 IE]

Chemistry and Enzymology of Marine Algal Polysaccharides. By *E. Percival* and *R. H. McDowell*. Academic Press, London-New York 1967. 1st Edit., XII, 219 pages, several figures and tables, bound, 60 s.

The authors have endeavored to present a critical review of the very numerous and widely scattered papers dealing with the polysaccharides found in marine algae and to summarize the results from the chemical and enzymological points of view.

A review of the occurrence and distribution of polysaccharides in algal species and a short chapter on the methods used for elucidating their constitution is followed by a discussion of the neutral polysaccharides, the reserve substances and skeletal substances. Alginic acids, representing the most important polysaccharides carrying carboxyl groups, are discussed next. This is followed by a discussion of the galactan sulfuric acid esters known as agar, and also of polysaccharides containing both carboxyl and sulfate groups. The last chapter is a short one, in which the algal polysaccharides are discussed in the context of their place among the plant carbohydrates.

The authors, both of whom have been working in this field for a long time, have succeeded in presenting a clear picture of the current state of knowledge. They emphasize not only the advances that were made possible by improved methods but also the many problems as yet unsolved. Readers unfamiliar with the methods of macromolecular chemistry would find a more complete treatment of molecular weight determination, and especically of the problems of viscometry – possibly with references to review articles – very helpful.

This is a painstakingly written book, and it is strongly recommended to all chemists and biologists working in this field.

Nucleophilic Reactions of Metal Carbonyl Anions with Fluorocarbons

By M. I. Bruce and F. G. A. Stone[*]

This article describes the formation of carbon-metal bonds by reacting carbonylmetalate ions with fluorocarbons. Complex formation depends on the nucleophilic behavior of the anions, and the susceptibility of fluorocarbons to this form of attack.

1. Introduction

It has been known for some time that the metal-metal bonds in polynuclear metal carbonyls (*e.g.* $Mn_2(CO)_{10}$, $Fe_3(CO)_{12}$, *etc.*) and their derivatives may be cleaved by alkali metals, either in dispersion or as an amalgam, to form the corresponding carbonylmetalate ions [1]. Other reducing agents have been used. *King* [2] found that tetrakis(dimethylamino)ethane reduced $Co_2(CO)_8$, $V(CO)_6$, or $[\pi\text{-}C_5H_5Mo(CO)_3]_2$ to the corresponding anions, but concluded that it is a less powerful reducing agent than the alkali metals. It does not react with $[\pi\text{-}C_5H_5Fe(CO)_2]_2$ or $[\pi\text{-}C_5H_5NiCO]_2$, for example. The chemistry of carbonylmetalate ions has recently been reviewed [1].

It is now well known that fluorocarbons have increased susceptibility to nucleophilic attack, compared with the corresponding hydrocarbons, owing to withdrawal of electron density onto the fluorine atoms [3]. Conversely, fluorocarbons show a much lower ability to participate in electrophilic reactions. These tendencies are more pronounced if a site of π-electron density is present, and reach a peak with polyfluoro-aromatic and -heterocyclic compounds, most of the chemistry of which is dominated by nucleophilic reactions. Ionic reactions of fluoroolefins have been summarized by *Chambers* and *Mobbs* [3], and the reactions of aromatic fluorocarbons have been similarly treated by *Tatlow* [4].

Herein we summarize reactions between fluorocarbons and carbonylmetalate ions, the latter having only recently been recognized as nucleophilic reagents. The first reported reaction of this type was that of perfluoroallyl chloride with the anion derived from manganese carbonyl to give pentacarbonyl-*trans*-perfluoropropenylmanganate [5, 6].

$$CF_2{=}CFCF_2Cl + [Mn(CO)_5]^- \rightarrow \textit{trans}\text{-}CF_3CF{=}CFMn(CO)_5 + Cl^-$$

More recently, use of these anions has encompassed a wide range of fluorocarbons, and it is timely to consider the many novel compounds that have been produced. Indeed, it can be said that this type of reaction is now of major importance in the synthesis of fluorocarbon derivatives of transition metals in which carbon is σ-bonded to these metals.

Empirical observations [7, 8] on the reactivity of the various anions employed suggest the following series in order of decreasing nucleophilicity:

$[Re(CO)_5]^- \sim [\pi\text{-}C_5H_5Fe(CO)_2]^- > [\pi\text{-}C_5H_5Ru(CO)_2]^- > [Mn(CO)_4P(C_6H_5)_3]^- > [Mn(CO)_5]^- \sim [\pi\text{-}C_5H_5Mo(CO)_3]^- > [Fe(CO)_4]^{2-} > [Co(CO)_4]^-$.

Consideration of electrochemical data and rates of reaction have recently enabled a semi-quantitative estimate of reactivity to be obtained [9]. The results, based on $[Co(CO)_4]^-$ as unity, are:

$[\pi\text{-}C_5H_5Fe(CO)_2]^-$, 7.0×10^7; $[\pi\text{-}C_5H_5Ru(CO)_2]^-$, 7.5×10^6; $[\pi\text{-}C_5H_5NiCO]^-$, 5.5×10^6; $[Re(CO)_5]^-$,

2.5×10^4; $[\pi\text{-}C_5H_5W(CO)_3]^-$, ~500; $[Mn(CO)_5]^-$, 77; $[\pi\text{-}C_5H_5Mo(CO)_3]^-$, 67; $[\pi\text{-}C_5H_5Cr(CO)_3]^-$, 4; $[Co(CO)_4]^-$, 1.

In terms of their practical utility, the anions $[\pi\text{-}C_5H_5Fe(CO)_2]^-$ and $[Re(CO)_5]^-$ are the most useful synthetically. The fluorocarbon-iron complexes are colored, and therefore are more amenable to purification by chromatographic techniques. The rhenium anion gives less complex reaction mixtures, however, with fewer by-products resulting from oxidative degradation of the anion. Where the products are volatile, the rhenium anion gives the highest yield of product.

2. Fluoroalkanes and -alkenes

No reactions between carbonylmetalate ions and fully saturated aliphatic fluorocarbons have been reported so far. On the other hand, fluoroalkenes have been used extensively. Tetrafluoroethylene gives trifluorovinyl complexes with $[\pi\text{-}C_5H_5Fe(CO)_2]^-$ and with $[Re(CO)_5]^-$, but does not react with $[Mn(CO)_5]^-$[8].

$$CF_2{=}CF_2 + [Re(CO)_5]^- \xrightarrow{THF} CF_2{=}CFRe(CO)_5 + F^-$$

Perfluoropropene[8] reacts as expected at the CF_2 group, affording the same *trans*-perfluoropropenyl complexes that are formed with perfluoroallyl chloride, *e.g.*, *trans*-$CF_3CF{=}CFFe(CO)_2(\pi\text{-}C_5H_5)$. Chlorotrifluoroethylene reacts, with replacement of the chlorine atom, with $[\pi\text{-}C_5H_5Fe(CO)_2]^-$ or $[Re(CO)_5]^-$, but with $[Mn(CO)_5]^-$, addition of the elements of $HMn(CO)_5$ occurs giving the chlorotrifluoroethyl complex $HCFClCF_2Mn(CO)_5$[10]. This process is analogous to the base-catalyzed addition of methanol to the same olefin yielding $HCFClCF_2OCH_3$[11].

Perfluorobutadiene reacts with $[Re(CO)_5]^-$ or $[\pi\text{-}C_5H_5Fe(CO)_2]^-$ to give the *trans* and *cis* isomers, respectively, of the corresponding perfluorobutadienyl complexes[12].

$$CF_2{=}CFCF{=}CF_2 + [\pi\text{-}C_5H_5Fe(CO)_2]^- \rightarrow cis\text{-}CF_2{=}CFCF{=}CFFe(CO)_2(\pi\text{-}C_5H_5) + F^-$$

$[Mn(CO)_5]^-$ is too weak a nucleophile to react with perfluorobutadiene.

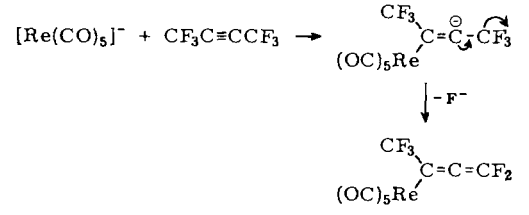
As mentioned above, perfluoroallyl chloride reacts with $[Mn(CO)_5]^-$ or $[\pi\text{-}C_5H_5Fe(CO)_2]^-$ to give *trans*-perfluoropropenyl complexes[5, 6, 13]. With $[\pi\text{-}C_5H_5Ni(CO)]^-$, on the other hand, the product is an inseparable mixture of the perfluoroallyl- and perfluoropropenyl-nickel compounds $C_3F_5Ni(CO)(\pi\text{-}C_5H_5)$[14]. A similar reaction between methoxide ion and perfluoroallyl chloride yields perfluoroallyl methyl ether, which on standing for several days rearranges to the perfluoropropenyl compound[15].

$$CF_2{=}CFCF_2Cl + CH_3O^- \xrightarrow{-Cl^-} CF_2{=}CFCF_2OCH_3 \rightarrow CF_3CF{=}CFOCH_3$$

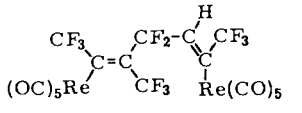
Similar rearrangements are assumed to occur with the metal complexes, either spontaneously, or during work-up and sublimation.

3. Fluoroalkynes

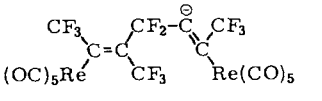
Treatment of hexafluoro-2-butyne with $[Re(CO)_5]^-$ affords the σ-bonded pentacarbonylperfluoro-1-methyl-1-allenylrhenium[12]. This reaction probably proceeds in the following manner,



A second rhenium complex formed in this reaction was thought at first to be a dimer of the allenyl compound, but subsequent studies[16] involving ^{19}F-NMR spin decoupling strongly suggest that the second product has the structure:



This novel complex could be formed by attack of the carbanion $(OC)_5ReC(CF_3){=}C^{\ominus}(CF_3)$ on pentacarbonylperfluoro-1-methyl-1-allenylrhenium to give the intermediate



which then abstracts a proton from the solvent. The anion $[\pi\text{-}C_5H_5Fe(CO)_2]^-$ and hexafluoro-2-butyne afford a single iron complex, $CF_2{=}C{=}C(CF_3)Fe(CO)_2(\pi\text{-}C_5H_5)$.

Trifluoropropyne reacts with the anions $[\pi\text{-}C_5H_5Fe(CO)_2]^-$ and $[Re(CO)_5]^-$ to afford the deriv-

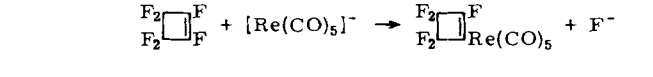
atives *cis*-$CF_3CH=CHFe(CO)_2(\pi\text{-}C_5H_5)$ and *cis*-$CF_3CH=CHRe(CO)_5$, respectively [17], the reactions proceeding with 100 % stereospecificity.

A variety of reactions occurs also with $C_6F_5C\equiv CH$ [17]. These are discussed in Section 5.

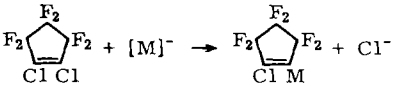
4. Alicyclic Fluorocarbons

Nucleophilic attack of carbonylmetalate ions on cyclic fluoroolefins occurs with substitution of one of the fluorine atoms attached to the C=C double bond [8, 18].



Similar reactions occur with decafluorocyclohexene, but with no anion is more than one fluorine atom replaced.

With 1,2-dichlorohexafluorocyclopentene low yields of the mono-chloro derivatives are obtained [10].



M = π-$C_5H_5Fe(CO)_2$, $Mn(CO)_5$, $Re(CO)_5$

This reaction may be contrasted with the action of alkoxide ion on dichlorohexafluorocyclopentene which rapidly replaces three fluorine atoms, even at −78 °C [10, 19]. Possibly one reason for the low yields of organometallic compound obtained is the tendency of the complexes to eliminate carbonylmetal chloride, the resulting hexafluorocyclopentyne not surviving the reaction conditions. In this connection, it may be

[17] *M. I. Bruce, D. A. Harbourne, F. Waugh*, and *F. G. A. Stone*, J. chem. Soc. (London) A *1968*, 895.

[18] *P. W. Jolly* and *F. G. A. Stone*, Chem. Commun. *1965*, 85.

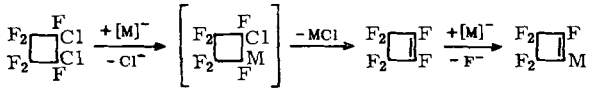
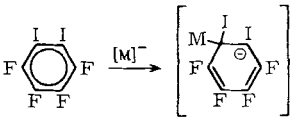
noted that the saturated alicyclic compound 1,2-dichlorohexafluorocyclobutane reacts with carbonylmetalate anions with elimination of carbonylmetal chloride. However, the resulting hexafluorocyclobutene is stable, and reacts further with the anions forming the above mentioned perfluorocyclobutenyl complexes in low yields [10].



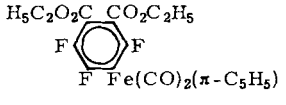
M = π-$C_5H_5Fe(CO)_2$, $Re(CO)_5$, $Mn(CO)_5$



M = π-$C_5H_5Fe(CO)_2$

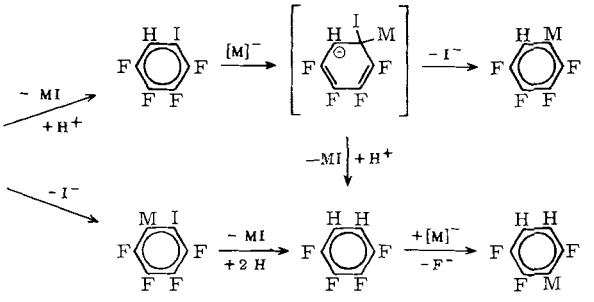
5. Aromatic Fluorocarbons

The recent availability of polyfluoroaromatic compounds has initiated much research on this interesting class of compound [4]. From the earliest investigations, it has been evident that hexafluorobenzene and related compounds are very susceptible to nucleophilic attack, and investigation of their reactions with carbonyl metalate ions followed naturally. The first report of experiments of this type was by *King* and *Bisnette* [20], who found that substitution on the aromatic nucleus occurred when C_6F_6, C_6F_5H, 1,2-$H_2C_6F_4$, or $C_6F_5CF_3$ was treated with the anion $[\pi\text{-}C_5H_5Fe(CO)_2]^-$. Substitution occurred *para* to a group other than fluorine, and it was noted that octafluorotoluene showed no tendency to substitution in the CF_3 group. A subsequent investigation [21] showed that a range of organometallic compounds could be prepared, often in relatively good yields, containing different organic functional groups. Thus pentafluorostyrene with $[\pi\text{-}C_5H_5Fe(CO)_2]^-$ gave *p*-$CH_2{=}CHC_6F_4Fe(CO)_2(\pi\text{-}C_5H_5)$ [22], and diethyl tetrafluorophthalate with the same anion afforded the following complex [21].

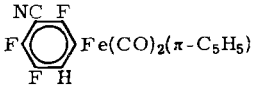


As observed with the alicyclic compounds, substitution to give a carbonylmetal group adjacent to a halogen atom other than fluorine resulted in elimination of carbonylmetal halide. Thus, treatment of 1,2-diiodotetrafluorobenzene with $[\pi\text{-}C_5H_5Fe(CO)_2]^-$ afforded π-$C_5H_5Fe(CO)_2I$ and an inseparable mixture of three complexes, their structures being established by ^{19}F-NMR [21] and mass spectroscopy [23]. The formation of the complexes is in accord with the following reaction scheme, and with the mechanism discussed in Section 7.

The nature of the carbonylmetal anion appears to determine the product formed in reactions with pentafluorophenyl acetylene [17]. Thus with $[Re(CO)_5]^-$



ring substitution occurs to give *p*-$HC{\equiv}CC_6F_4Re(CO)_5$, while with $[\pi\text{-}C_5H_5Fe(CO)_2]^-$ the complex *p*-$HC_6F_4CH{=}CHFe(CO)_2(\pi\text{-}C_5H_5)$ is formed. In the latter case, replacement of one of the ring fluorine atoms with hydrogen has occurred. Examples of this behavior are also found in reactions with C_6F_5X (X = F, Cl, Br, I), when mixtures of the two compounds $C_6F_5Fe(CO)_2(\pi\text{-}C_5H_5)$ and *p*-$HC_6F_4Fe(CO)_2(\pi\text{-}C_5H_5)$ are formed; and with C_6F_5CN, where the product



was identified by ^{19}F-NMR spectroscopy [21,23]. It is not entirely clear why products of this nature should be formed: perhaps elimination of the halide π-$C_5H_5Fe(CO)_2X$ from an S_N2-type intermediate occurs (see Section 7). Alternatively, attack by a hydridic species formed *in situ* may lead to these products.

No instance of disubstitution of an aromatic ring has been reported, even when an excess of carbonyl metal anion is used. Apparently, monosubstitution deactivates the ring towards further substitution. This deactivating effect was observed earlier with pentafluorophenylplatinum complexes [24]. The compound *cis*-$[(C_2H_5)_3P]_2Pt(C_6F_5)_2$ is unaffected by treatment with methyllithium or methylamine. The resistance of the fluorine atoms in these compounds to displacement by nucleophilic reagents can probably be attributed to electron release into the aromatic ring by the transition metal groups, both by an inductive and a mesomeric mechanism [25].

Treatment of pentafluorobenzyl bromide with $[\pi\text{-}C_5H_5Fe(CO)_2]^-$ gives in addition to the expected

[a] cp = π-C_5H_5.

$C_6F_5CH_2Fe(CO)_2(\pi\text{-}C_5H_5)$, small amounts of $(\pi\text{-}C_5H_5)Fe(CO)_2C_6F_4CH_2Fe(CO)_2(\pi\text{-}C_5H_5)$ [26]; this compound contains carbonylmetal groups attached both to the ring and to the side chain, and is stable enough to be sublimed at 200 °C/0.1 torr. This is in contrast to the mononuclear complex, which readily decomposes into decafluorobibenzyl [26].

6. Heterocyclic Fluorocarbon Compounds

The nitrogen heterocyclic compounds perfluoropyridine, perfluoropyridazine, and cyanuric trifluoride are much more susceptible to nucleophilic attack than is hexafluorobenzene; even the relatively unreactive anion $[\pi\text{-}C_5H_5Mo(CO)_3]^-$ has given stable complexes with the two last mentioned compounds [27,28]. Thus perfluoropyridine and $[Mn(CO)_5]^-$ afford *p*-$NC_5F_4Mn(CO)_5$, whereas hexafluorobenzene does not react with this anion [20]. Interestingly, although cyanuric trifluoride appears to be more susceptible to attack by the weaker nucleophilic anions $[Mn(CO)_5]^-$ and $[\pi\text{-}C_5H_5Mo(CO)_3]^-$ than any other fluorocarbon compound so far studied, the strong nucleophile $[\pi\text{-}C_5H_5Fe(CO)_2]^-$ and cyanuric trifluoride afford $\pi\text{-}C_5H_5Fe(CO)_2C_3F_2N_3$ in only very low yield [28]. [a] cp = π-C_5H_5.

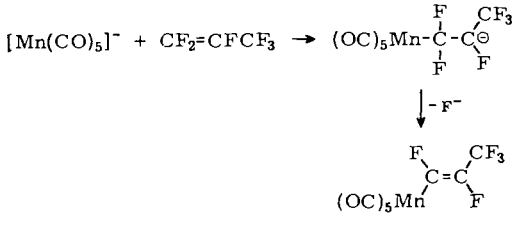
iron anion apparently brings about breakdown of the heterocyclic ring, or engages in other side reactions. The products from the reactions between the three perfluoroaromatic nitrogen heterocycles and the anion $[Mn(CO)_4P(C_6H_5)_3]^-$ are all complexes in which the triphenylphosphine group is *trans* to the C_5F_4N, $C_4F_3N_2$, and $C_3F_2N_3$ groups, respectively.

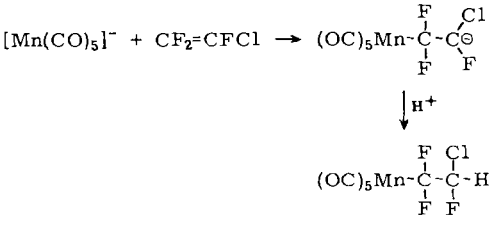
7. Mechanisms of the Reactions

Chambers and *Mobbs* [3] have summarized the three different possible fates of the intermediate carbanion formed by attack of a nucleophile on a fluoroolefin. In the context of this review the different processes can be summarized as follows, considering the anion $[Mn(CO)_5]^-$ as the nucleophile.

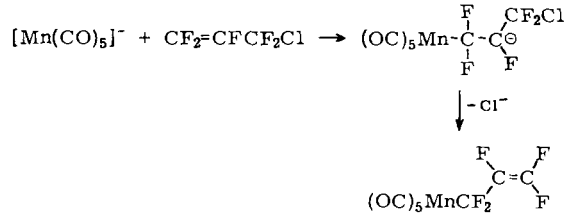
a) Loss of fluoride ion [8]:



b) Addition of a proton [10]:

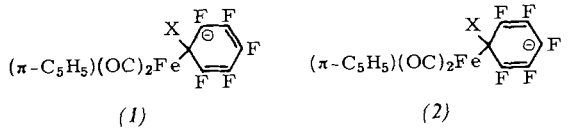


c) Displacement of halogen ions with formation of an allyl compound [5, 6, 13]:



As mentioned previously, pentacarbonylperfluoroallylmanganese rearranges to *trans*-pentacarbonylperfluoropropenylmanganese, and the σ-bonded perfluoroallyl complex is not isolated, although there seems to be some evidence [6] for its existence as an unstable intermediate. However, since NMR spectroscopy has revealed that the product from the reaction between $[\pi\text{-}C_5H_5NiCO]^-$ and perfluoroallyl chloride is a mixture of *trans*-$CF_3CF{=}CFNi(CO)(\pi\text{-}C_5H_5)$ and $CF_2{=}CFCF_2Ni(CO)(\pi\text{-}C_5H_5)$ [14], there seems little doubt that the perfluoropropenyl complexes are formed *via* the perfluoroallyl compounds. Migration of double bonds in the fluorocarbon derivatives of the transition metals is not uncommon. Addition of $HRe(CO)_5$ to perfluorobutadiene affords the complex $HCF_2CF_2CF{=}CFRe(CO)_5$, which is probably formed from $HCF_2CF{=}CFCF_2Re(CO)_5$ by a similar fluorine shift [29].

The products formed in reactions between $[\pi\text{-}C_5H_5Fe(CO)_2]^-$ and C_6F_5X (X = F, Cl, Br, or I) can be rationalized in terms of the intermediates *(1)* or *(2)*.



(1) *(2)*

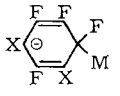
Elimination of X^- would give $C_6F_5Fe(CO)_2(\pi\text{-}C_5H_5)$, the major product [21]. The intermediates could also decompose forming π-$C_5H_5Fe(CO)_2X$ and a species which by abstraction of a proton from the solvent would yield C_6F_5H. On reaction with additional an-

[29] *B. Tattershall, A. J. Rest, M. Green,* and *F. G. A. Stone,* J. chem. Soc. (London) A *1968*, 899.

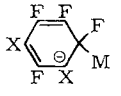
ion, C_6F_5H would give the secondary product p-$HC_6F_4Fe(CO)_2(\pi\text{-}C_5H_5)$. Some support for the suggested mechanism comes from the isolation of π-$C_5H_5Fe(CO)_2I$ when pentafluoroiodobenzene is treated with $[\pi\text{-}C_5H_5Fe(CO)_2]^-$.

The reactivity and the products produced from reactions between carbonylmetal anions and polyfluoroaromatic compounds with substituents such as H, CN, or $CO_2C_2H_5$ on the benzene ring can be understood as proceeding *via* S_N2-type intermediates *(3)–(5)*, with the negative charge centered on a carbon atom having a substituent other than fluorine [30].

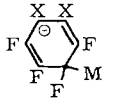
(3)



(4a)



(4b)



(5)

In the case of *monosubstituted* polyfluorobenzenes, *e.g.* C_6F_5H, in addition to *(3)* one can consider an intermediate in which the metal attacks the carbon *ortho* to the substituent (H). However, this intermediate will be less stable than *(3)*, and in accord with this no complexes have as yet been isolated in which the metal atom and the original substituent are *ortho* to each other. Following loss of fluoride, the final product from either *(3)*, *(4)*, or *(5)* is a complex in which a metal atom is substituted *para* to a substituent X. *para*-Disubstituted polyfluoroaromatic compounds, *e.g.* 1,4-$H_2C_6F_4$, react much more slowly with $[\pi\text{-}C_5H_5Fe(CO)_2]^-$ than either the 1,2- or 1,3-isomers. This is as expected, since substitution of the metal group cannot give a derivative in which this group is *para* to a substituent other than fluorine. Moreover, the product is much less stable than those formed by the other two tetrafluorobenzenes, and decomposes even in the solid state. This may be because the hydrogen atom is located at a β position relative to the metal atom, a situation which is known to lead to decomposition by migration of the hydrogen to the metal to form an unstable metal hydride, *e.g.* π-$C_5H_5Fe(CO)_2H$.

It has previously been reported [31] that the only products isolated from the reaction of tropylium bromide with $[Mn(CO)_5]^-$ were bicycloheptatrienyl and $Mn_2(CO)_{10}$. Similarly, reaction of $[\pi\text{-}C_5H_5Fe(CO)_2]^-$ with decafluorobenzhydryl bromide, $(C_6F_5)_2CHBr$, gave moderate yields of $[(C_6F_5)_2CH]_2$ [25]. It appears that if the radical R′ from RX is relatively stable, then only R_2 will be isolated from the reaction of RX with a carbonylmetalate ion. If the radical cannot be stabilized, then an R-metal bond will be formed. In the case cited, stabilization of $(C_6F_5)_2CH$ is enhanced by the presence of fluorine atoms. Even the pentafluorobenzyl radical seems to be stabilized in this way to a certain extent, some $[C_6F_5CH_2]_2$ being isolated from the reaction of $C_6F_5CH_2Br$ with $[\pi\text{-}C_5H_5Fe(CO)_2]^-$, as well as the expected $C_6F_5CH_2Fe(CO)(\pi\text{-}C_5H_5)$. This latter complex is unstable, and in solution decomposes with the formation of decafluorobibenzyl [26].

8. Properties of the Complexes

The known complexes of carbonylmetalate ions with fluorocarbons are listed in Tables 1–4. They contain carbon-metal σ bonds stabilized by the presence of fluorine atoms attached to the carbon atom or adjacent to it [25, 32, 33]. The compounds can usually be sublimed under vacuum, and some are volatile at room temperature and pressure. They are more or less air-stable in the crystalline state, but in solution they are often easily oxidized. The complexes are soluble in non-polar solvents but are generally insoluble in water; most can be recrystallized from petroleum ether, and some may be crystallized from aqueous ethanol.

Few chemical reactions have been reported; methoxide ion does not appear to further substitute the fluorocarbon group in pentacarbonylperfluorophenylrhenium, and the resistance of the platinum compounds to nucleophilic attack has already been mentioned. It has also been reported recently that SO_2 does not insert into the carbon-metal bond in π-$C_5H_5Fe(CO)_2C_6F_5$ [34]; however, it is possible to make the compound π-$C_5H_5Fe(CO)_2SO_2C_6F_5$ by the conventional method, *i.e.* by reaction of $[\pi\text{-}C_5H_5Fe(CO)_2]^-$ with $C_6F_5SO_2Cl$ [22].

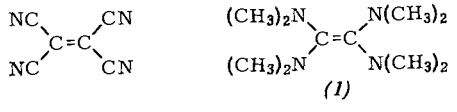
Reactions of Electron-Rich Olefins

BY R. W. HOFFMANN [*]

Olefins are normally preferentially attacked by electrophiles. This trend is strengthened in enol ethers and enamines, and is particularly pronounced in tetramethoxyethylene and in tetraaminoethylenes. These electron-rich olefins are accordingly also excellent reducing agents. In their reactivity, therefore, they behave as counterparts of tetracyanoethylene. This compound shares with the electron-rich olefins a strong tendency to undergo cycloadditions, the electron-rich olefins adding particularly readily to electrophiles.

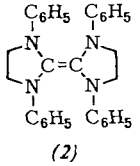
1. Introduction

The reactivity of the olefinic double bond can be strongly influenced by substituents. For example, the four electron-attracting cyano groups in tetracyanoethylene withdraw electrons so effectively from the central double bond that this compound is strongly electrophilic [1]. The opposite situation is found in the "electron-rich olefins" [2], in which four electron-donating substituents are attached to the carbons of

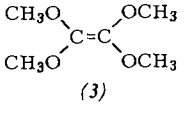


(1)

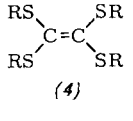
the central double bond; examples of such compounds are tetraaminoethylenes, particularly tetrakis(dimethylamino)ethylene *(1)* [3] and 1,1′,3,3′-tetraphenyl-2,2′-biimidazolidinylidene *(2)* [4].



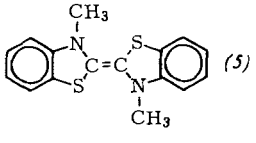
(2)



(3)



(4)

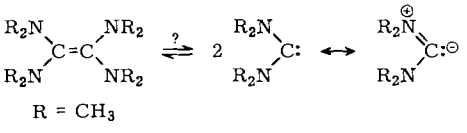


(5)

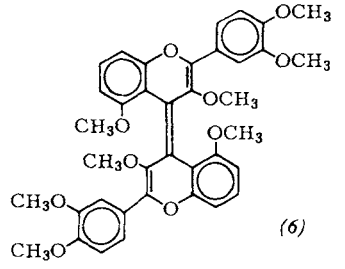
Tetramethoxyethylene *(3)*, in which the double bond is fourfold substituted with oxygen, behaves somewhat differently. Only a few of the corresponding tetraalkylthioethylenes *(4)* have been investigated.

Finally, the chemical behavior of 3,3′-dimethyl-2,2′-bibenzothiazolinylidene *(5)* (configuration not established) indicates that this compound should also be included in the class of electron-rich olefins.

In contrast to tetracyanoethylene, all these compounds should be good reducing agents, and should accordingly be readily attacked by electrophilic reagents. Nevertheless, the chemistry of electron-rich olefins is interesting not merely because it contrasts with that of tetracyanoethylene, but to a large degree because of the idea that with sufficiently strong donation of electrons by the substituents, these olefins should dissociate into two nucleophilic carbenes [4]. A dissociation energy of 40 kcal has been estimated for *(1)* [3] (cf. the estimated value of 70 kcal for tetrafluoroethylene [5]).



R = CH_3



(6)

Though compounds of the type *(2)* and *(6)* give lower results in molecular weight determinations than the calculated values [6–8], dissociation into carbenes has been ruled out in the cases of *(1)* and *(2)* by crossover experiments at 140–175 °C [9, 10]. However, slight exchange between the "carbene halves" of *(2)* and those of the corresponding *p*-tolyl derivative occurs at 225 °C [11].

[2] The designation "electron-rich olefins" is not quite accurate. These compounds should strictly speaking be described as olefins whose π-electron density on the carbon is distinctly greater than 1.0. (For example, a value of 1.16 has been calculated for *(1)* [3].)

[11] *B. Lachmann*, Dissertation, Technische Universität Berlin, 1967.

The positive results obtained in preliminary crossover experiments with *(5)* at 80 °C[12] are not sufficiently unambiguous to constitute proof of the dissociations of *(5)*. Similarly, the occurrence of the ion M/2 in the mass spectra of some electron-rich olefins[12–14] does not, without additional data, provide sufficient grounds for concluding that these compounds undergo thermal dissociation.

2. The Redox Behavior of Electron-Rich Olefins

Owing to the increased charge density on the carbon, the electron-rich olefins should be oxidized much more readily than ordinary olefins. The formation of charge transfer complexes corresponds to partial oxidation, the strength of the π acid that is just still capable of complex formation constituting a measure of the ability of the π base to donate electrons[15].

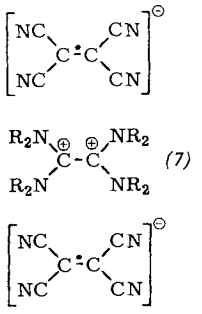
2.1. Charge Transfer Complexes

Tetramethoxyethylene *(3)* forms π complexes with weak π acids, *e.g.* fumaronitrile, in solution, as is shown by the characteristic color that develops. *(3)* gave a crystalline 1:1 complex with 1,3,5-trinitrobenzene[17,18].

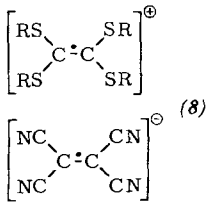
Table 1. π-Complexes of tetramethoxyethylene *(3)* in solution [16, 17].

π-acid	Color
NC–CH=CH–CN	ocher
$NC(CF_3)C=C(CF_3)CN$	violet blue
2,4,7-Trinitro-9-fluorenone	wine red

The tetraaminoethylenes[10] are much stronger π bases, and form π complexes with many π acids having widely different structures[7,10,19,20,20a], the compositions of these complexes varying from 1:1 to 1:3, some of them forming isolable crystals. The complexes exhibit high electric conductivity in the solid state, and some of them are paramagnetic[20], suggesting that electron transfer from the donor to the acceptor is possible even in the ground state. Complete transfer of two electrons is found in the stable 1:2 complexes of *(1)*[21] and *(2)*[22] with tetracyanoethylene, which



(7)

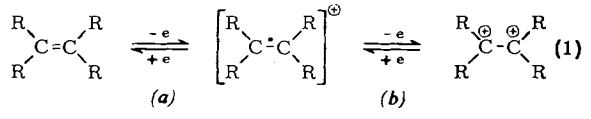


(8)

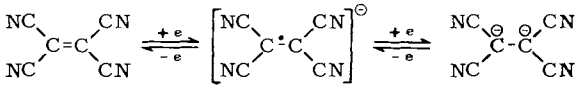
have the structure *(7)*. The reaction of *(4)* with tetracyanoethylene, on the other hand, apparently results in the transfer of only one electron to form *(8)*[23], so that the complex consists of a radical-cation and a radical-anion.

2.2. Stepwise Oxidation

The results described above show that an electron-rich olefin can be oxidized both to a radical-cation and to a dication. This two-step[24] oxidation corresponds to the reduction of tetracyanoethylene, which also proceeds in two steps[25]; like the latter, therefore, it should in principle be reversible[24].



(a) *(b)* (1)



The first observed two-step oxidation of an electron-rich olefin was that of *(2)*[9,26], which is oxidized by one equivalent of silver nitrate to the radical-cation *(9)*, and by two equivalents to the dication *(10)*. The reversibility of the two steps is shown by the fact that *(9)* can also be obtained by combining solutions of *(2)* and *(10)*, *i.e.* by coproportionation. *(10)* with $I^{\ominus}$

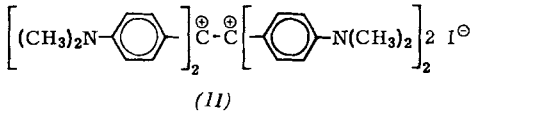
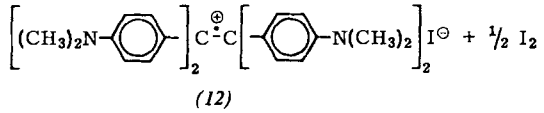
instead of $NO_3^{\ominus}$ can accordingly be reduced to *(2)* by metallic silver, since the resulting silver ions are precipitated as silver iodide [26].

Tetraaminoethylene *(1)* undergoes reversible electrochemical oxidation to the stable radical-cation at only −0.75 V (against the standard calomel electrode) and to the dication at −0.61 V [27]. Thus *(1)* corresponds in its redox behavior to a divalent base metal such as zinc, by which the dication of *(1)* can also be reduced [21,28]. *(1)* can therefore be used in batteries in place of the baser metal [29].

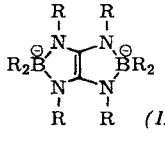
This oxidation potential of *(1)*, being very negative, is in agreement with calculations [3] according to which *(1)* possesses two electrons in an antibonding orbital (−0.19 β). The level of this highest occupied orbital is lowered by phenyl substituents on the nitrogen. Consequently *(2)* is no longer such a strong reducing agent as *(1)*, while *(11)* exists in equilibrium with *(12)* in apolar media [30]. *(12a)*, on the other hand, should be a much stronger reducing agent than *(1)* [30a].



(11)



(12)



(12a) R = C_2H_5

The question of whether the radical-cation reaches such an equilibrium concentration as to be detectable in the oxidation of an electron-rich olefin depends on the difference in the redox potentials of steps (a) and (b) in eq. (1). The equilibrium between the different oxidation states can be expressed by the semiquinone formation constant K [24].

K = [radical-cation]^2/[olefin] [dication]

The greater the value of K, the higher is the equilibrium concentration of radical-cation. Some values of K are given in Table 2.

Table 2. Semiquinone formation constants for the two-step oxidation of electron-rich olefins.

Whereas the two oxidation stages are quite distinct in the polarographic oxidation of *(13)* [32], they can no longer be separated in the oxidation of tetramethoxyethylene *(3)* [33] or of 1,1,4,4-tetrakis(dimethylamino)buta-1,3-diene [33a], *i.e.* the semiquinone formation constants for these compounds are probably lower than 100 [34].

2.3. Formation and Reaction of Dications

As expected, tetramethoxyethylene *(3)* is oxidized by iodine to the dication *(14)* [35], which, as an ambident cation [36], is demethylated in 61 % yield by the iodide formed to give dimethyl oxalate. However, *(14)* also attacks the tetramethoxyethylene *(3)* present to give 10 % of dimethyl tetramethoxysuccinate *(16)* *via* the octamethoxybutane dication *(15)* [37]. If, for example, by addition of silver tetrafluoroborate, the absence of nucleophiles is ensured during the oxidation of *(3)* with iodine, *(14)* can no longer be demethylated. The reaction then leads mainly to *(15)*, from which *(16)* is

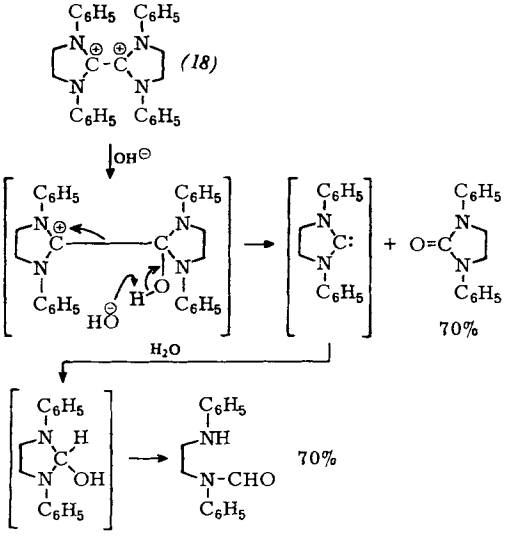
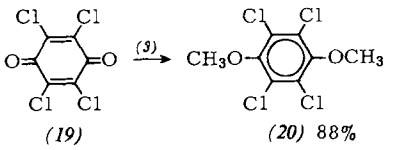
formed during workup. The assumption that *(14)* is formed on oxidation of *(3)* with iodine is finally supported by the fact that *(14)* can be intercepted with sodium methoxide to give hexamethoxyethane *(17)* in 73 % yield [35].

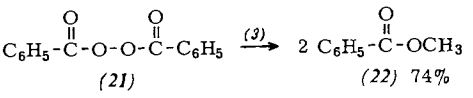
The dication *(14)* formed on oxidation of tetramethoxyethylene is so reactive [38] that its existence is only concluded from indirect evidence. On the other hand, the dications formed on oxidation of *(1)* [10,21,40], *(2)* [26,41], and *(5)* [42] with iodine or bromine can be isolated as salts. These dications are no longer dealkylated by nucleophiles; bases add instead to the positively charged C atom. Thus the addition of 2 molecules of sodium methoxide to the dication of *(5)* [42] corresponds to the addition of sodium methoxide to *(14)*. If the added base still contains mobile protons, the adduct is cleaved after only one molecule of base has been added to the dication *(18)* [26,41]. In certain circumstances the base may abstract a proton from a position α to the nitrogen [43]. (For detailed discussion see [3].)



2.4. Electron-Rich Olefins as Reducing Agents

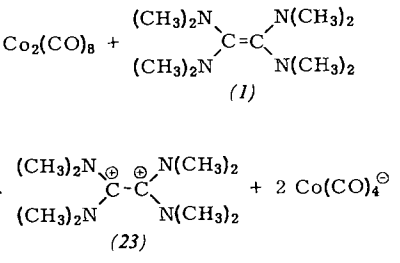
Because of their low redox potential, the electron-rich olefins can be used as strong reducing agents that are soluble in organic solvents. When used in this capacity the olefins are generally oxidized to the dications. The dication *(14)* formed in reductions with tetramethoxyethylene *(3)* is in turn a strong methylating agent [44]. Thus *(19)* and *(21)* are converted directly into *(20)* and *(22)* respectively by reductive methylation with *(3)* [35].





Sulfonyl and nitro groups are also reduced by *(3)* in a complex reaction [35]. Nitro groups, like HNO_2 [45], azidinium salts [46], and diazonium groups [46], are also reduced by *(5)*. *(2)* reduces *e.g.* peroxides, thionyl chloride, and sulfuryl chloride [41].

All electron-rich olefins are oxidized by $Ag^{\oplus}$ [9,26,35,42] and by other heavy metal ions [21,35]. *(1)* is so reactive that, like the alkali metals, it reduces complexes of zero-valent transition metals [47]. As expected, *(1)*



readily reduces a number of compounds that contain positively polarized NO_2 groups [48], but it is interesting to note that considerable quantities of *(23)* are formed in the reaction of *(1)* with various Lewis acids [21,49,50].

The reductive cleavage of carbon-halogen bonds by tetraaminoethylenes [51–54] is of great preparative value. The ease with which the halogen is released increases from fluorine to iodine. The reactivity of the substrates also increases in the order $R_3CX < R_2CX_2 < RCX_3 < CX_4$. Since secondary products of $Cl_3C^{\ominus}$ *(24)*, but not of $Cl_3C\cdot$, can be detected in the reduction of $BrCCl_3$, the reaction must proceed by an ionic mechanism.

$$(1) + BrCCl_3 \rightarrow (23) + Br^{\ominus} + [Cl_3C^{\oplus}] \quad (24)$$

(1) can be used for selective reductive dehalogenation, particularly of perhalogenated hydrocarbons [*e.g.* *(25)*]. One advantage of these substrates is that no competing dehydrohalogenation [53] is possible.

$$CF_3{-}CCl_2{-}CCl_2{-}CF_3 \xrightarrow{(1)} CF_3{-}CCl{=}CCl{-}CF_3 \quad (97\,\%)$$

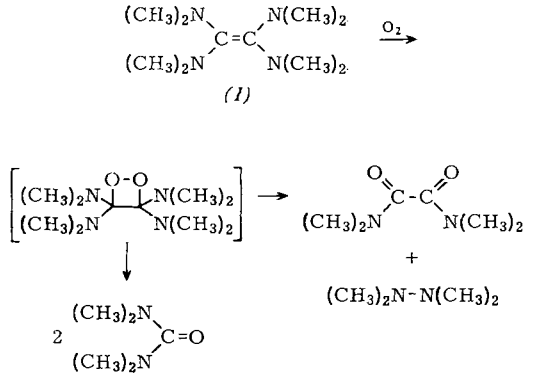
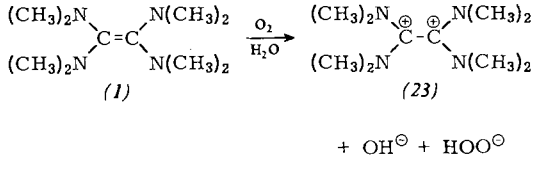
2.5. Autoxidation of Electron-Rich Olefins

All electron-rich olefins are easily autoxidized. The autoxidation of tetrakis(dimethylamino)ethylene *(1)* is particularly spectacular, since it is accompanied by an intense green chemiluminescence [40, 55]. The products formed in organic solvents are 45–65 % of tetramethylurea, 20–30 % of *N,N,N',N'*-tetramethyloxamide, and small quantities of tetramethylhydrazine and bis(dimethylamino)methane [10, 43]. The scheme [43, 55] presents only a greatly simplified picture



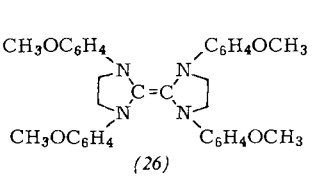
of the reaction. The various steps of the chemical process [43, 55–57] and of the steps connected with the emission of light [58–61] have now been extensively studied. (For detailed discussion see [3]).

The autoxidation of *(1)* in aqueous medium stops at the stage of the tetrakis(dimethylamino)ethylene dication *(23)*, and derivatives of the latter are obtained as the products [43, 57].

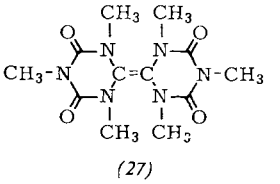


The autoxidation of *(2)* in glacial acetic acid leads to the dication *(18)* [43], whereas the reaction proceeds further in aprotic solvents to give 1,3-diphenyl-2-imidazolidinone (90 %) [6].

The autoxidation rate of a tetraaminoethylene is strongly dependent on the availability of electrons, and hence on the substituents on the nitrogen [7, 62, 63]. Thus *(26)* is autoxidized much more rapidly, and *(27)* much more slowly, than *e.g. (2)*.

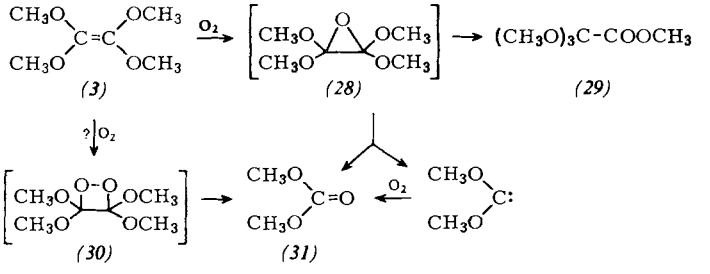


(26)



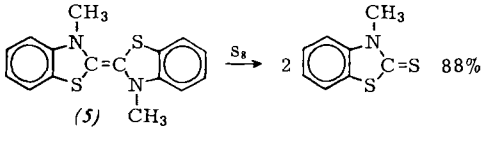
(27)

The autoxidation of tetramethoxyethylene *(3)* differs considerably from that of the tetraminoethylenes. In this case *(29)* and *(31)* are formed in yields of 51 and 39 % respectively [64].



If one compares this reaction with the autoxidation of tetrahalogenoolefins [65], which leads *via* an epoxide [66] to trihalogenoacetyl halides [67], the formation of *(29)* on autoxidation of *(3)* seems plausible if the epoxide *(28)* is assumed to occur as an itnermediate. *(31)* is probably also formed partly *via (28)*, since the reaction of *(3)* with tetracyanoethylene oxide, which can transfer only one oxygen atom onto *(3)*, yields both *(31)* and *(29)* [64]. It is not yet known whether the formation of *(31)* also involves *(30)* or polymeric peroxides.

The ozonization of *(3)* also leads to *(31)* and *(29)* [64]. The action of H_2O_2 on *(5)* [42, 68] and the reaction of *(29)* with performic acid [69] also lead to oxidative cleavage of the central double bond.



The reaction of tetramethoxyethylene with sulfur yields the *S* analogs of *(31)* and *(29)* [64]. The tetraaminoethylenes [10, 70] and *(5)* [14, 42] readily undergo oxidative cleavage by sulfur; this reaction does not, however, take place *e.g.* with tetraphenylethylene [71]. However, the autoxidation of *(5)* is a complex reaction leading to numerous products [14, 72].

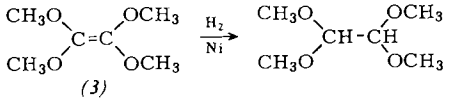
2.6. Reduction of Electron-Rich Olefins

Practically no experiments on the reduction of electron-rich olefins have been reported. *(1)* is not reduced *e.g.* by lithium diethylamine[21]. *(3)*, on the other hand, readily undergoes catalytic hydrogenation to give symmetric tetramethoxyethane[73].



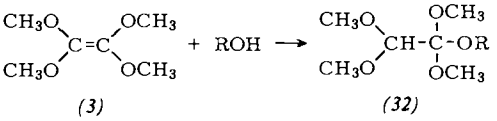
(3)

3. Reactions of Electron-Rich Olefins with Electrophiles

3.1. Reactions in which the Molecular Skeleton remains Intact

Simple olefins are preferentially attacked by electrophilic reagents. Electron-rich olefins should therefore react particularly readily with electrophiles. The reaction with Brönsted acids may be taken as a model, since this reaction involves the simplest of all electrophiles, the proton.

Benzoic acid adds readily to tetramethoxyethylene *(3)* to form *(32a)*. This adduct is an α-alkoxyalkyl ester, and so readily undergoes thermal cleavage into methyl dimethoxyacetate and methyl benzoate, which is formed in 80 % yield[73]. The weaker acid methanol is added rapidly to *(3)* only above 0 °C, to form *(32b)*, whereas no reaction occurs with *tert*-butanol even at 80 °C[74]. Nevertheless, CH acids may be sufficiently

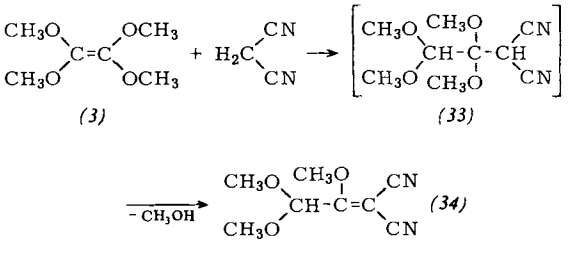


(3) *(32)*

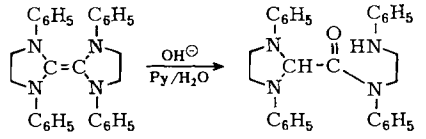
(a), R = COC_6H_5
(b), R = CH_3

acidic to add to *(3)*, as is shown by the reaction with malononitrile, during which the primary adduct *(33)* loses methanol to form *(34)*[75].

The addition of methanol and of water[76] to *(5)* is reversible[42]. Corresponding to the hydrolysis of *(3)* to give methyl dimethoxyacetate[74] (cf. also[39]), the hydrolysis of *(2)* in

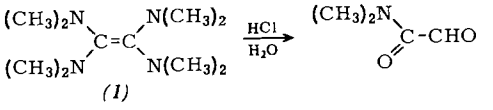


(3) *(33)* *(34)*



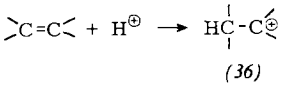
(2) *(35)*

alkaline media leads to *(35)*[4], whereas acid hydrolysis results in more extensive cleavage (see Section 3.2). Only in the case of *(1)* has cleavage to *N,N*-dimethylglyoxylamide been achieved by acid hydrolysis[50].



(1)

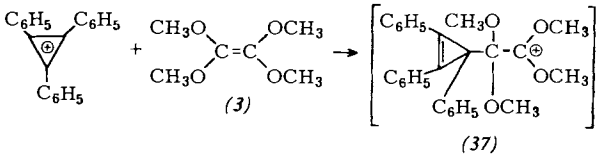
These reactions probably all begin with the addition of a proton to the electron-rich olefin. The resulting primary adduct *(36)* has been intercepted as the iodide[42] or perchlorate[72] in the case of *(5)*.



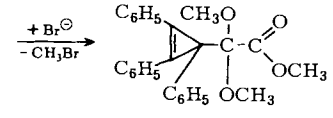
(36)

The possibility of diprotonation has been discussed for *(1)*[31] to explain differences between the acidic and neutral hydrolyses (see Section 3.2) of this compound. With Lewis acids such as BF_3, BH_3[49], $Al(CH_3)_3$[77], $AlCl_3$[49], $ZnCl_2$[49], or TiF_4[78], *(1)* forms stable adducts, the Lewis acid in some cases being bound to the nitrogen. (The structures of some of the adducts have not yet been established.)

The alkylation of electron-rich olefins, *e.g.* of *(3)* with carbonium ions, proceeds very vigorously even under mild conditions[79]. The primary adduct such as *(37)* is demethylated as a carbonium-oxonium ion by nucleophiles to form α-substituted methyl α,α-dimethoxyacetates, which can be hydrolyzed to give the corresponding α-keto acids in good yields. The positive charge in *(37)* is stabilized to such a degree that tetramethoxyethylene is no longer alkylated by *(37)*. For this reason the alkylation of *(3)* by the tetramethoxyethylene dication *(14)* (see Section 2.3) stops, once the primary adduct *(15)* is formed.



(3) *(37)*



The rate of alkylation of *(3)* depends on the tendency of the alkylating agent to form carbonium ions[79]. The fact that *(3)* is inert to *n*-butyl iodide or phenacyl bromide shows that *(3)* itself is not nucleophilic,

[73] *J. Schneider*, Dissertation, Universität Heidelberg, 1966.

[74] *R. W. Hoffmann*, *J. Schneider*, and *H. Häuser*, Chem. Ber. *99*, 1892 (1966).

[75] *J. Gehlhaus*, Diplomarbeit, Universität Heidelberg, 1967.

[76] Several structures have been proposed for the adduct of *(5)* with H_2O [14, 72].

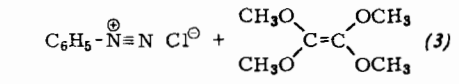
[77] *N. R. Fetter* and *D. W. Moore*, Canad. J. Chem. *42*, 885 (1964).

[78] *E. L. Muetterties*, J. Amer. chem. Soc. *82*, 1082 (1960).

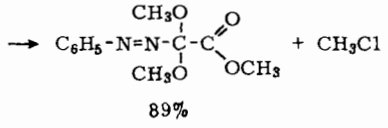
[79] *R. W. Hoffmann* and *J. Schneider*, Chem. Ber. *99*, 1899 (1966).

though it is instantaneously attacked by electrophiles. *(5)*, on the other hand, possesses nucleophilic properties, since it is alkylated by dimethyl sulfate or ethyl iodide [42]. However, the choice of alkylating agents is restricted by the reducing properties of the electron-rich olefins.

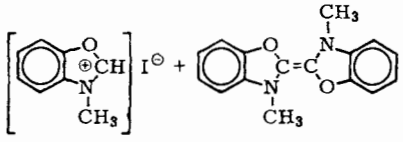
The reactions of electron-rich olefins with electrophiles, particularly their acylation [79], coupling with diazonium ions [79], and formation of cyanine dyes [80], offer interesting routes for preparative chemistry.

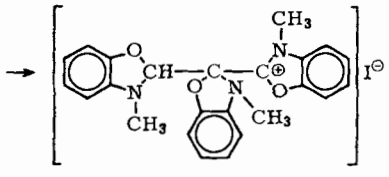


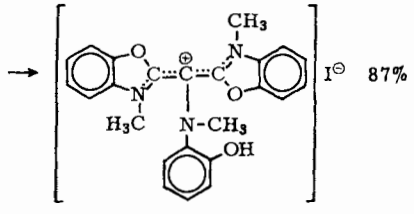
(3)



89%



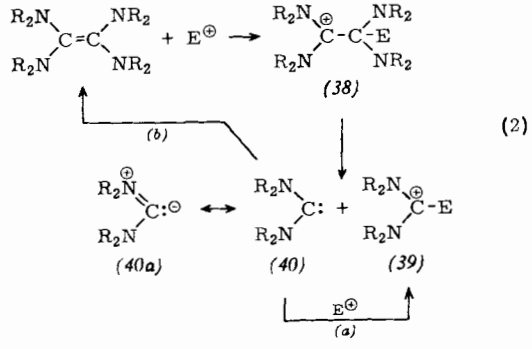




87%

3.2. Reaction in which the Molecule is Cleaved

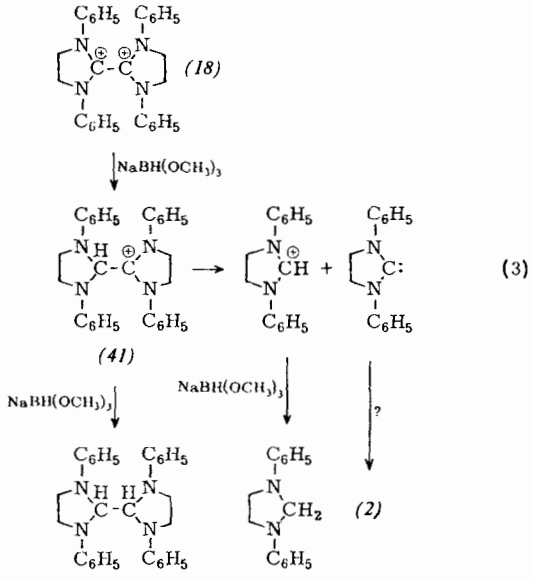
The primary adduct *(38)* formed by the reaction of *(1)* or *(2)* with electrophiles, and partly also the adduct formed from *(5)*, exhibits a strong tendency to dissociate into a amidinium ion *(39)* and a nucleophilic carbene *(40)* [9].



(2)

[80] *H. W. Wanzlick* and *H. Steinmaus*, Chem. Ber. *101*, 244 (1968).

As is shown by the few reactions described in Section 3.1, *(38)* can be intercepted before cleavage occurs only in the presence of high concentrations of active nucleophiles. The cleavage of the molecule actually starts from the intermediate *(38)*, since cleavage products are also obtained on the reduction of *(18)*, which proceeds *via* the intermediate *(41)* corresponding to *(38)* [31].

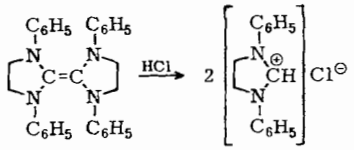


(3)

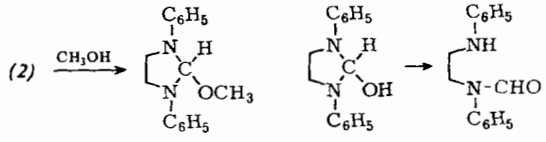
The cleavage of *(38)* into *(39)* and *(40)* is possible only because *(40a)* is so strongly stabilized by the participation of low-energy ylid structures that it becomes a good leaving group [81].

The nucleophilic carbene *(40)* liberated immediately adds on any strong electrophiles present to form *(39)* [path *(a)* in eq. (2)]. At lower electrophile concentrations or in the presence of only weak electrophiles, *(40)* might dimerize with regeneration of the original electron-rich olefin [31] [path *(b)* in eq. (2), cf. also eq. *(3)*]. The competition between paths *(a)* and *(b)* has not yet been investigated.

Mineral acids cleave *(5)* [42, 72], *(29)* [69], and *(2)* [4, 82], quantitatively in some cases, into formamidinium salts in accordance with eq. (2).



(2)



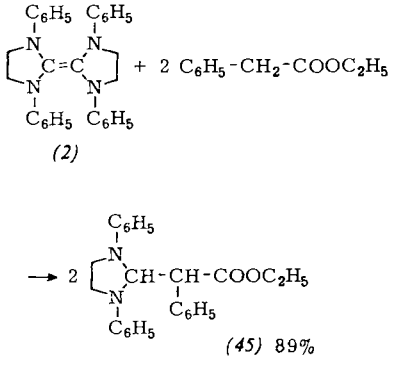
(42) *(43)* *(44)*

[81] *R. Breslow*, J. Amer. chem. Soc. *80*, 3719 (1958).

[82] *Z. Z. Ma*, *C. Y. Chen*, *H. K. Jiang*, and *M. Y. Ma*, Sci. sinica *17*, 299 (1966); Chem. Abstr. *65*, 13463 (1966).

The reaction of *(2)* with methanol yields *(42)*. In weakly acidic [7] or even weakly alkaline media, the proton activity is sufficient to hydrolyze *(2)* to *(44)*, presumably *via (43)*. The neutral hydrolysis of *(1)* at 160 °C proceeds similarly [50].

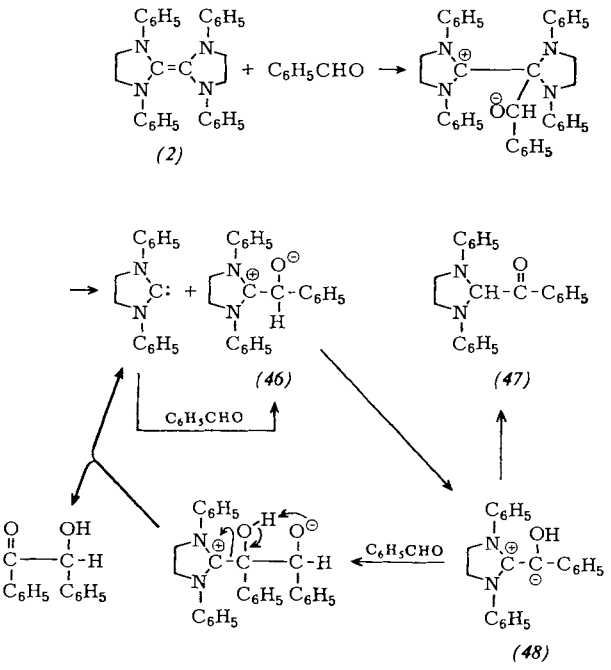
A large variety of CH acidic compounds react readily in a similar manner with *(2)* [6, 83–86], *(29)* [63], or *(5)* [42], the reaction resulting in cleavage of the molecule. It has been shown in the case of *(2)* → *(45)* that the reaction is reversible [85]. Since the aminal group in *(45)* is readily hydrolyzed to give an aldehyde, these reactions have gained some importance for the synthesis of α-substituted aldehydes.



(2) *(45)* 89%

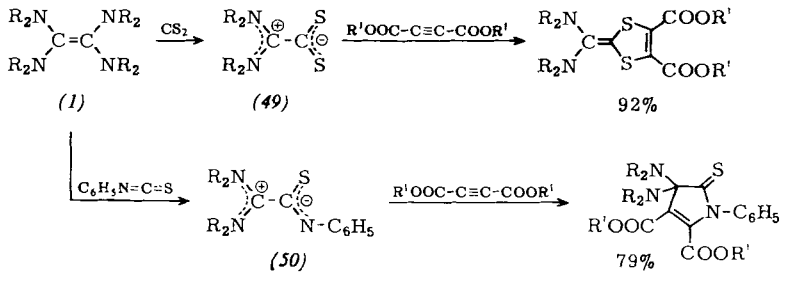
With aldehydes having no acidic α-hydrogen, electrophilic attack by the carbonyl group on *(5)* [42] or *(2)* [4, 6, 84] ensues. Corresponding to eq. *(2)*, the reaction *e.g.* of *(2)* with benzaldehyde proceeds *via* the adduct *(46)* to give *(47)* in 90 % yield [84].

The ketonization of the enol *(48)* to *(47)* is in competition with the attack of further benzaldehyde on

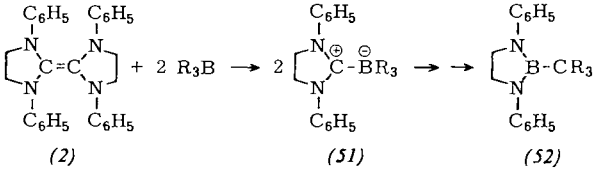


(48) to form benzoin; this process, which corresponds to the thiamine-catalyzed formation of benzoin [81], is favored to such an extent in the presence of electron-donating substituents on the nitrogen atoms, and hence by stabilization of the positive charge in *(48)*, that the formation of benzoin becomes the principal reaction [84, 87].

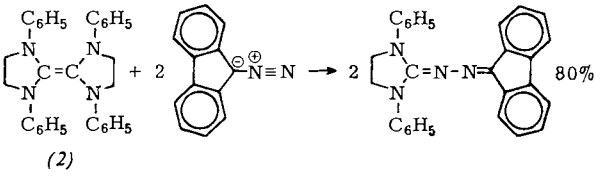
Under the action of carbon disulfide or phenyl isothiocyanate, *(1)* is cleaved in high yields in accordance with eq. *(2)* to give the stable betaines *(49)* and *(50)*, which can be readily alkylated on the sulfur [88], and which readily also undergo 1,3-dipolar additions [88, 88a, 89].



Whereas *(2)* suffers acylation and cleavage by acyl chlorides in accordance with eq. (2), acetic anhydride acts on *(2)* as a CH acid [83]. Trialkylboranes cleave *(2)* in boiling toluene to give the ylid *(51)*, which undergoes a series of inverse Stevens rearrangements to give the 1,3,2-diazaborolidines *(52)* in 85 to 95 % yield [90].



(2) [70, 91, 92] and *(5)* [14] are cleaved even by diazo compounds such as diazofluorene, which are only weakly electrophilic, to form azines in good yields.



(2)

Unlike the reaction of electron-rich olefins with azides (see Section 5.3), the reaction with diazofluorene probably does not proceed by cycloaddition, since the adduct *(53)*, as a

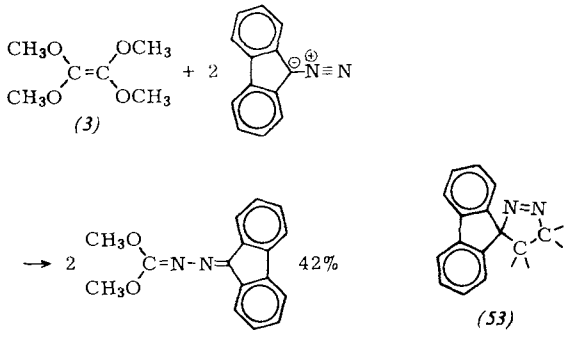
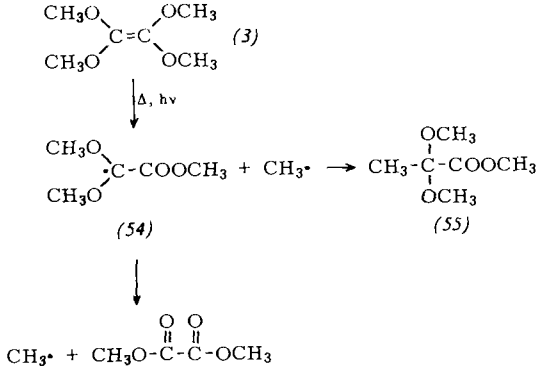
1-pyrazoline[93], should preferentially split of nitrogen and not a carbene.



Tetramethoxyethylene *(3)* also reacts with diazofluorene to give an azine[94], but it is questionable, in view of the low yield, whether the azine is formed in accordance with eq. (2), since *(3)* is not cleaved according to eq. (2) by much stronger electrophiles even in the absence of nucleophilic anions (see Section 3.1). This would support the argument that cleavage of the molecule in the course of the addition of an electrophile to an electron-rich olefin [eq. (2)] becomes increasingly favored with increasing resonance stabilization of the resulting nucleophilic carbene. The results described here accordingly lead to the conclusion that the tendency toward cleavage in accordance with eq. (2) increases in the order *(3)* < *(5)* < *(2)* ≈ *(1)*.

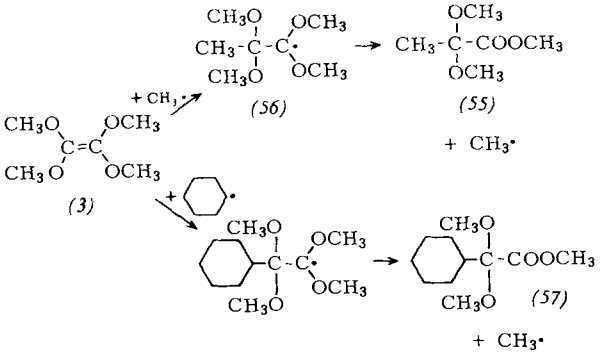
4. Free Radical Reactions of Electron-Rich Olefins

Simple ketene acetals undergo homolysis when heated to about 250 °C[95]. Tetramethoxyethylene *(3)*, on the other hand gives 17–31 % of dimethyl oxalate and 25–50 % of methyl α,α-dimethoxypropionate *(55)*[74] at 165 °C in a reaction that presumably begins with homolysis of a methyl-oxygen bond. The resulting resonance-stabilized radical *(54)* can partly recombine with the methyl radical to give *(55)*.

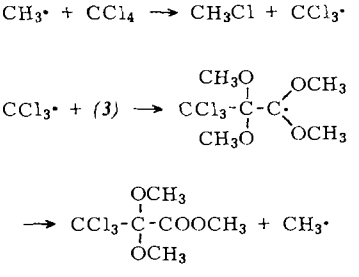


On the other hand, *(54)* decomposes very readily into dimethyl oxalate and another methyl radical, as can be shown independently by generation of *(54)* from methyl dimethoxyacetate and di-*tert*-butyl peroxide[35]. A small quantity of *(54)* also dimerizes to form dimethyl tetramethoxysuccinate *(16)*.

(16) is also formed on thermal decomposition of *(3)* in cyclohexane, where some of the methyl radicals recombine with *(54)* and some undergo chain transfer with the solvent. Both the methyl and the cyclohexyl radicals can add to *(3)* in a chain reaction. The reaction leads *e.g.* to 8 % of *(57)* and 24 % of *(55)*, since the primary adduct, *e.g.* *(56)*, as an α,α-dimethoxyalkyl radical[96], readily decomposes into a methyl



radical and *(55)*. In any case, the ratio of the yields of dimethyl oxalate (product of the initiation reaction) to *(55)* (product of the chain reaction), which has a value of 1:1 to 1.5:1, shows that the kinetic chain length[*] is short. The ratio of the yields gives an upper limit for this quantity. When tetramethoxyethylene is heated in carbon tetrachloride, no dimethyl oxalate is found, but more than 95 % of methyl β,β,β-trichloro-α,α-dimethoxypropionate can be isolated[74, 97], indicating that the kinetic chain length of the following reaction is >25, since the addition of a trichloromethyl radical to *(3)* is favored by polarity factors.



Thus the thermal decomposition of *(3)* is neither a pure radical chain reaction nor a pure radical cage reaction. Since the photolysis and the thermolysis of *(3)* yield the same products in comparable yields[74], this conclusion is probably also valid for the photolysis of *(3)*. This reaction thus differs from the formally analogous photolysis of the phenylketene acetals, which proceeds purely intramolecularly as a radical cage reaction[98].

[*] The kinetic chain length is the average number of cycles of the reaction chain initiated by one initiation step.

[97] Cf. the reaction of *(1)* or *(2)* with CCl_4, which is quite different (Section 2.4).

[98] *J. E. Baldwin* and *L. E. Walker*, J. Amer. chem. Soc. *88*, 3769, 4191 (1966).

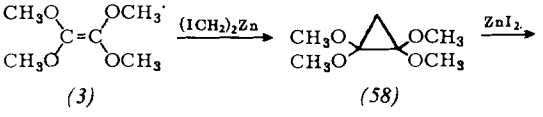
It is not yet certain whether *(1)*, which is sensitive to light [55], decomposes in the same way on irradiation. *(2)* evidently forms free radicals when heated, and may be used as a thermal initiator for the oligomerization of perfluoroolefins [82].

5. Cycloadditions to Electron-Rich Olefins

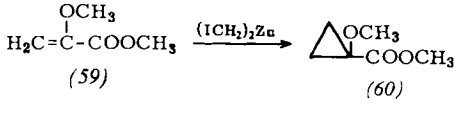
In some cycloadditions the transition states are slightly, but nevertheless definitely, polar [99]. The electron-rich olefins should therefore preferentially undergo cycloadditions with electrophilic partners. In this respect they are again counterparts of tetracyanoethylene [1], which is widely used for its pronounced tendency to enter into cycloadditions with electron-rich compounds.

5.1. Formation of Three-Membered Rings

The reaction of tetramethoxyethylene *(3)* with carbenoids [100] leads to derivatives of tetramethoxycyclopropane [16]. For example, the action of bis(iodomethyl)zinc on *(3)* yields a mixture of the compounds *(58)*, *(59)*, and *(60)*, *(59)* being formed from *(58)* by the action of zinc iodide, as has been shown independently. Thus if the zinc iodide formed by the



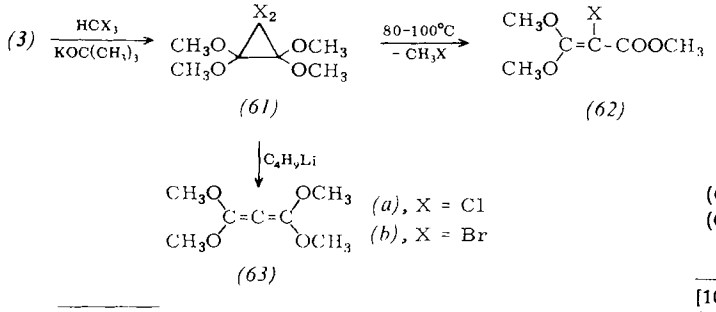
(3) *(58)*



(59) *(60)*

reaction of *(3)* with bis(iodomethyl)zinc is partly bound by complex formation with 1,2-dimethoxyethane, the yields of *(58)* can be increased to 20 %.

Dibromo- and dichlorocarbenoid (from potassium *tert*-butoxide and haloform [101]) add to *(3)* with formation of 1,1-dihalogenotetramethoxycyclopropanes



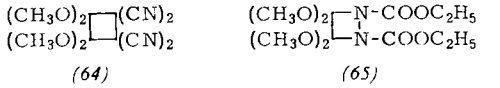
(61) *(62)* *(63)*

(61) [102], which are cleaved on heating to form the methyl 2-halogeno-3,3-dimethoxyacrylates *(62)*.

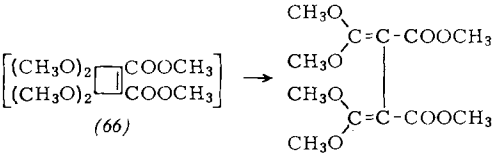
(61) is the starting material for the preparation of the electron-rich tetramethoxyallene *(63)*, which is formed in 72 % yield on reaction of *(61b)* with butyllithium [102]. (For the possibility of a reaction of *(1)* with dichlorocarbene, see [53].)

5.2. Formation of Four-Membered Rings

Tetramethoxyethylene enters extremely readily into 2 + 2-cycloadditions with electrophiles. Thus the reaction at 0 °C with tetracyanoethylene leads instantaneously to the adduct *(64)* (63 %), while addition to diethyl azodicarboxylate yields diazetidine *(65)* (98 %) [103].



(64) *(65)*



(66)

The adduct *(66)* formed by *(3)* and dimethyl acetylenedicarboxylate undergoes ring opening during workup to yield dimethyl 1,1,4,4-tetramethoxy-1,3-butadiene-2,3-dicarboxylate (97 %) [75, 104].

Interesting adducts of *(3)* include not only those with ketene and diphenylketene, but also those with phenyl isocyanate *(67)* [103] and with nitrosobenzene *(68)* [103], which are formed in high yields. On heating or on exposure to light, *(67)* and *(68)* do not undergo retrocleavage to *(3)* but are split to form dimethyl *N*-phenylimidocarbonate [73, 75].

According to the *Woodward-Hoffmann* rules [105], the thermal 2'+ 2-cycloadditions to *(3)* should proceed in two steps. In view of the difference in the polarity of the addends, the intermediate may be expected to be a 1,4-dipole [99]. The forma-

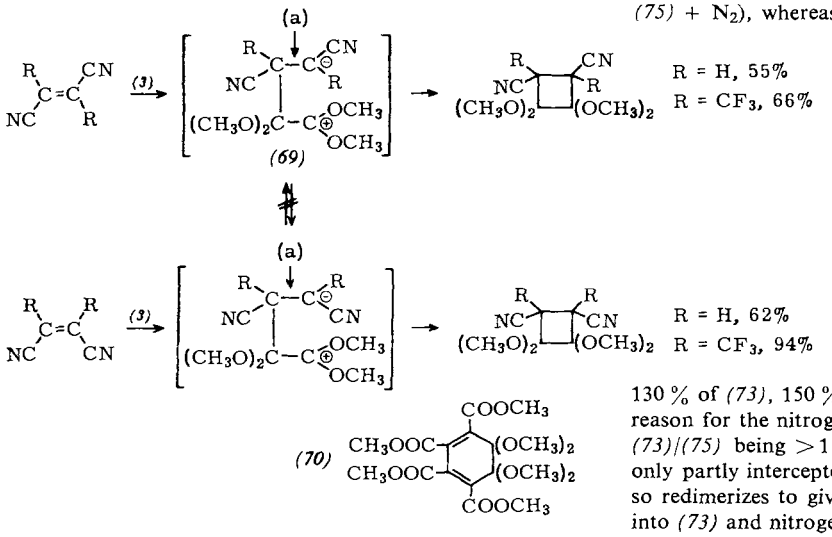
tion of a 1,4-dipole *(69)* should be recognizable from the fact that rotation about the bond (a) is possible in this species. Thus on addition of *(3)* to a pair of *cis,trans*-isomeric electrophilic olefins, the *cis* and the *trans* adduct should be formed together in each case. However, the addition of *(3)* both to 1,2-dicyanoethylenes and to 1,2-dicyano-1,2-bis(trifluoromethyl)ethylenes was found to be more than 95 % stereospecific[16,106]. The rotation about the bond (a) in *(69)* is evidently much slower than the ring closure to form cyclobutane derivatives. This is probably mainly due to the fact that the ends of the 1,4-dipole are fixed in relation to each other by electrostatic forces[99]. However, the idea that 2 + 2-cycloadditions to *(3)* proceed *via* a 1,4-dipole is supported[107] by the fact that on addition of *(3)* to dimethyl acetylenedicarboxylate, it was possible under certain conditions to obtain the 1,2-adduct *(70)* in 45 % yield [75].



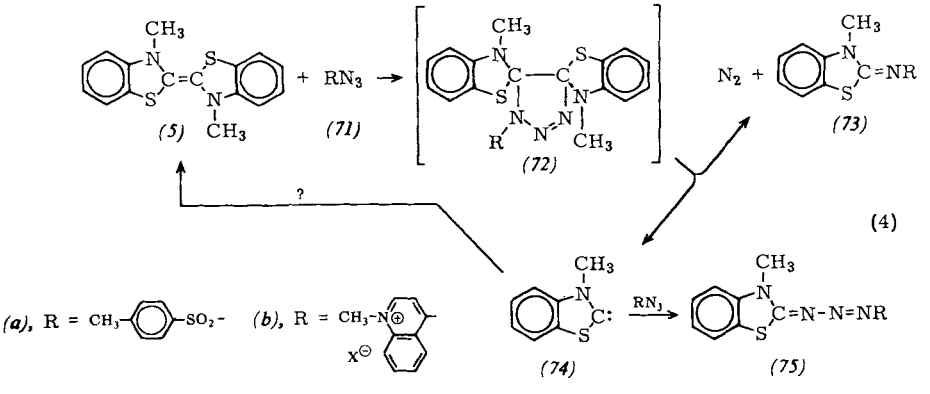
5.3. Formation of Five-Membered Rings

Adducts of 1,3-dipoles with electron-rich olefins have not yet been isolated as such. However, *Quast* and *Hünig*[46] have shown that cycloadducts are probably formed in the reaction of *(5)* with azides *(71)*. By analogy with the reaction of enol ethers[108] or enamines[109] with azides, the reaction of *(5)* with an azide *(71)* should lead first to a triazoline *(72)*. Compound *(72)* then decomposes into an imine *(73)*, nitrogen, and the nucleophilic carbene *(74)*; it is not certain whether *(73)* and *(74)* are liberated *via* a diazo compound as a further intermediate[109,110]. In any case, the induction time for the evolution of nitrogen points to the formation of an intermediate[111].

The carbene *(74)* can now add on the azide *(71)* to form the triazene derivative *(75)*, the formation of which has been shown to be characteristic of the carbene *(74)*. On the other hand, the carbene can enter into other reactions, including redimerization under certain circumstances to form *(5)*. The principal reaction path followed by *(74)* depends on the electrophilicity of the azide used. Thus *(5)* and *p*-toluenesulfonyl azide *(71a)* give 79 % of *(73)*, 107 % of N_2, and 46 % of *(75)* (based on the stoichiometry *(5)* + 2 *(71)* → *(73)* + *(75)* + N_2), whereas with the less electrophilic azide *(71b)*, 130 % of *(73)*, 150 % of N_2, and no *(75)* are obtained. The reason for the nitrogen yield exceeding 100 % and the ratio *(73)*/*(75)* being >1 may be either that the carbene *(74)* is only partly intercepted by the azide *(71)* to form *(75)*, and so redimerizes to give *(5)*, or that *(75)* partly decomposes into *(73)* and nitrogen.

This dependence of the product yield on the electrophilicity of the azide can be satisfactorily explained if a triazoline is assumed as an intermediate. If on the other hand, the reaction of *(71)* had followed eq. (2), the only product would have been the triazene derivative *(75)*, irrespective of the electrophilicity of the azide used.

The reaction of tetraaminoethylenes with azides similarly yields both guanidine and triazene derivatives[88]; if the triazenes predominate in this case, however, a reaction in accordance with eq. (2) could compete with one corresponding to eq. (4).



Much less information can be deduced from the reaction of *(3)* with azides, which yields only derivatives of dimethyl imidocarbonate *(76)*[94]. Until it is known

[106] The configurations of the adducts were assigned on the assumption that the configuration is retained on cycloaddition.

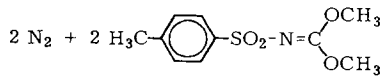
(3) (71a)

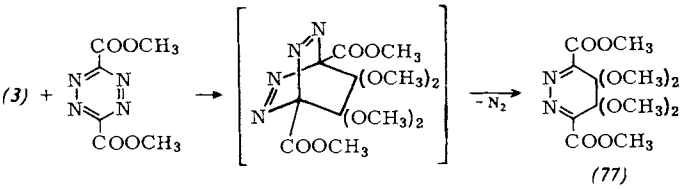


(76) 74%

whether the triazene derivative corresponding to *(75)* is stable under the reaction conditions or readily decomposes into *(76)* and nitrogen, the only way to determine whether the reaction of *(3)* with *(71a)* also follows eq. (4) is by labeling experiments. In this case the dimethoxycarbene should redimerize to form tetramethoxyethylene. However, *(76)* certainly is not formed because of prior dissociation of tetramethoxyethylene into two dimethoxycarbene fragments, since a kinetic study has shown [112] that the reaction is first order with respect to both tetramethoxyethylene and *p*-toluenesulfonyl azide. This is compatible with the reaction proceeding in accordance with either eq. (2) or eq. (4).

5.4. Formation of Six-Membered Rings

If electron-rich olefins do in fact enter into Diels-Alder additions, these should be additions with "inverse electron demand" [113]. Whereas *(3)* was alkylated by



(77)

hexachlorocyclopentadiene because of the presence of chlorine in an allylic position [79], the reaction of *(3)* with dimethyl 1,2,4,5-tetrazine-3,6-dicarboxylate leads *via* the Diels-Alder adduct to a 70 % yield of *(77)* [114].

6. Concluding Remarks

The investigation of electron-rich olefins has been decisively influenced by the desire to liberate nucleophilic carbenes from them. Though the latter occur in many reactions of the electron-rich olefins, it has been found that the original idea of generating them by dissociation of electron-rich olefins cannot generally be realized. On the other hand, these investigations have uncovered many novel reactions; the examples discussed here should provide some idea of the wide range of possible uses of electron-rich olefins in synthetic organic chemistry.

The electron-rich olefins discussed here and tetrafluoroethylene exhibit a characteristic gradation of reactivity (see Table 3).

Table 3. Reactivity of olefins having four (+M) substituents.

	$(R_2N)_2C{=}C(NR_2)_2$	$(RO)_2C{=}C(OR)_2$	$F_2C{=}CF_2$

Cleavage of the molecule on reaction with electrophiles	++	–	–
Addition of free radicals	?	+	++
Cycloadditions	?	++	+++
Addition of nucleophiles	?	?	++

The many question marks in this table show that the investigation of electron-rich olefins has by no means reached an end, rather it is fairly certain that this branch of organic chemistry still has surprises in store.

Our own investigations described here were carried out with the generous support of the Deutsche Forschungsgemeinschaft.

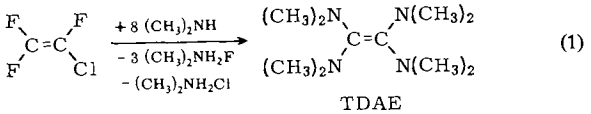
Tetraaminoethylenes as Strong Electron Donors

BY N. WIBERG[*]

Depending on the nature of the electron acceptor and of the tetraaminoethylene (TAE), the electron pairs of the ethylenic double bond (A), of the nitrogen (B), or of the entire electronic system (C) of TAE react with the acceptor. Thus oxidizing agents convert TAE into the mono- and dications TAE^+ and TAE^{2+} by path (A); acids add on to the ethylenic carbon (A) or the amine nitrogen (B) (the addition of acid is often followed by cleavage of the C=C or C–N bond); organic π-electron acceptors form deeply colored donor-acceptor complexes with TAE (C).

1. Introduction

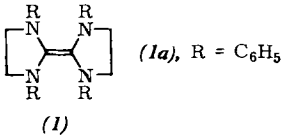
In 1950, when *Pruett et al.* [1] allowed dimethylamine to act on trifluorochloroethylene [reaction (1)], they obtained pale green, liquid tetrakis(dimethylamino)-ethylene (TDAE [2]), the first of the tetraaminoethylenes (TAE). In qualitative experiments on this product,



TDAE (1)

Pruett et al. [1] observed behavior that was unexpected in an ethylene derivative: "This (TDAE) ... was strongly luminescent in contact with air. It reacted with oxygen to form a white solid..." If a little tetrakis(dimethylamino)ethylene is placed on a filter paper, intense luminescence begins after a few minutes in contact with atmospheric oxygen. A small room can even be dimly lit for over an hour in this way with about 10 ml of TDAE [61, 61a]. *Pruett et al.* did not further examine the compound TDAE.

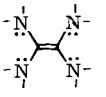
The systematic study of the properties of tetraaminoethylenes only began in 1960 with the discovery of a second member of this class of compounds, 1,1',3,3'-tetraphenyl-2,2'-biimidazolidinylidene *(1a)*, by *Wanzlick et al.* [3]. More than 30 extensively studied compounds of this class are now known.



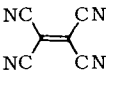
(1a), R = C_6H_5

(1)

The following is a review of the reactive tetraaminoethylenes (TAE) [5], which are found in many (often surprising) reactions to act as strong electron donors, and whose chemistry contrasts strongly with that of the electron acceptor tetracyanoethylene (TCNE) [4].



TAE



TCNE

The discussion will concentrate on tetrakis(dimethylamino)ethylene, which is a particularly simple and thoroughly studied tetraaminoethylene.

2. Preparation of Tetraaminoethylenes

The simple preparation method used by *Pruett* [reaction (1)] cannot be used as a general route to tetraaminoethylenes. The only amines that have so far been successfully used for the preparation of tetraaminoethylenes with trifluorochloroethylene are dimethylamine [1, 9] and *N,N'*-dimethylethylenediamine [10]. It appears that successful syntheses by means of reaction (1) are possible only with amines R_2NH having very small ligands R.

A general method [reaction (2)] for the preparation of tetraaminoethylenes is the elimination of acids HX

[a] Preparation by reaction (1).

[b] Two of the four groups R are CH_3 groups, and the other two are C_2H_5 groups.

In the reaction of $(C_2H_5O)_3CH$ [6, 11, 15] or $(CH_3)_2NCH(OCH_3)_2$ [12, 14] with amines, tetraaminoethylenes are formed *via (2)*, also directly if the amine does not exhibit strong steric hindrance.

The tetraaminoethylenes prepared so far (see Table 1) with the exception of the liquid tetrakis(dimethylamino)ethylene, are solids. They are sparingly soluble in apolar solvents, and apart from TDAE (pale green) and *(1)*, R = $CH_2C_6H_5$ (yellow), p-$NO_2C_6H_4$ (red), and α-naphthyl (red), they are colorless. TDAE is a strongly refracting, fluorescent, lipophilic, hydrophobic oil (n_D^{25} = 1.4785), which solidifies at 0 °C and boils at 30 °C/0.01 torr. It decomposes slowly with loss of dimethylamine at about 100 °C [9].

3. Reactivity of the Tetraaminoethylenes

Tetraaminoethylenes (TAE) are strong organic electron donors. The chemistry of these compounds is therefore dominated by the effort to give up some of their electrons to an oxidizing agent O (redox reaction) or to share them with an acid S (acid-base reaction).

$$\text{TAE} \xrightarrow[(+O)]{\text{Redox reaction}} \text{TAE}^{n+}\text{O}^{n-} \quad (3)$$

$$\text{TAE} \xrightarrow[(+S)]{\text{Acid-base reaction}} \text{TAE} \rightarrow \text{S} \quad (4)$$

3.1. Redox Reactions

3.1.1. The Tetraaminoethylene Dication

Oxidizing agents such as halogens, dinitrogen tetroxide, copper^{I}, silver^{II}, carbon tetrachloride, and tetracyanoethylene withdraw two electrons from tetrakis(dimethylamino)ethylene (TDAE) [18, 25–31]. TDAE is converted into the dication $TDAE^{2+}$, the octamethyloxamidinium ion, [reaction (5)] and is thus a chemical counterpart of tetracyanoethylene (TCNE), which can be readily reduced to the radical-anion $TCNE^{-}$, and even to the dianion $TCNE^{2-}$ [4, 23, 24] [reaction (6)].

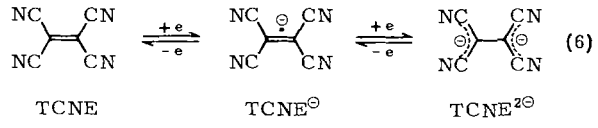
TDAE $\quad$ $TDAE^{\oplus}$ $\quad$ $TDAE^{2\oplus}$ $\quad$ (5)



TCNE $\quad$ $TCNE^{\ominus}$ $\quad$ $TCNE^{2\ominus}$ $\quad$ (6)

$R = CH_3$

This unusual readiness of the TDAE system to give up electrons is due to the presence of the four amino groups, which stabilize the positive charge by partial transfer of their free electron pairs onto the two central C atoms (the strong electron affinity of the TCNE system can similarly be attributed to the four electron-attracting cyanide groups [4]). However, the "inverse analogy" between TDAE and TCNE is not quantitative; thus the easier accessible ionization stage is the second for TDAE and the first for TCNE.

The salts of $TDAE^{2+}$ are reviewed in Table 2.

Table 2. Octamethyl oxamidinium salts $[TDAE]^{2+}X_2^-$.

X	M.p. (°C)	Color	Soluble in H_2O	Ref.

TCNE	125–127	violet black	−	[26]
$C(NO_2)_3$	122–124	?	−	[30]

[a] Polyiodides TDAE $[I_n]$ (n = 4, 5, 7) can also be obtained [26].

[b] TDAE$[Fe(CO)_4]$ cannot be prepared, since $TDAE^{2+}$ is reduced by $Fe(CO)_4^{2-}$ [38].

[c] No definite m.p.

[d] C_9H_7 = indenyl.

The TDAE salts are obtained by oxidation of TDAE *e.g.* with Hal_2, $CHal_4$, and $Co_2(CO)_8$ in organic solvents or by metathetic reaction from $TDAE(Hal)_2$. TDAE evidently reacts with carbon compounds CX_4 in accordance with reaction (7).

$$TDAE + CX_4 \rightarrow TDAE^{2+}X^-CX_3^- \qquad (7)$$

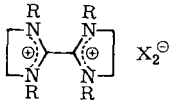
(3)

The salt *(3)* is stable when X = NO_2; it can be decomposed by water into water-insoluble $TDAE[C(NO_2)_3]_2$ and water-soluble $TDAE(NO_2)_2$ [30]. When X = Hal, *(3)* is unstable; the basic $CHal_3^-$ ion removes a proton from the $TDAE^{2+}$ (see below) or loses a halide ion to form $CHal_2$ [29]. For example, TDAE and CCl_4 give $TDAE(Cl)_2$ and $CHCl_3$ in high yields, together with other products that have not been investigated. The reaction of polyhalogenoethanes with TDAE [29] leads to dehalogenation with formation of polyhalogenoethylenes. For example, tetrachloroethylene is formed in a high yield, together with $TDAE(Cl)_2$, from hexachloroethane and TDAE [29].

Special mention should be made of octamethyloxamidinium bis (tetracyanoethylenide), $TDAE(TCNE)_2$, which precipitates out when solutions of TDAE and TCNE in acetonitrile are mixed at 0 °C. According to IR, NMR, UV, and ESR spectroscopic results and chemical investigations, this compound has a salt-like structure [26]: $TCNE^-$ $TDAE^{2+}$ $TCNE^-$. The curious reaction of TDAE with TCNE again illustrates the difference in the redox behavior [reactions (5) and (6)] of the two systems. It should also be noted that a complete electron transfer between two ethylene derivatives has been achieved in $TDAE(TCNE)_2$.

Like TDAE, 1,1′,3,3′-tetraorganyl-2,2′-biimidazolidinylidenes *(1)* can also be converted into dications (Table 3).

Table 3. 1,1′,3,3′-Tetraorganyl-2,2′-biimidazolidinylidene salts.



R	X	Color	Ref.
C_6H_5	Cl	yellow	[32, 33]
C_6H_5	Br	yellow	[32, 33]
C_6H_5	I	orange red	[16, 33]
C_6H_5	NO_3	yellow	[16]
C_6H_5	ClO_4	yellow	[16]
C_6H_5	BF_4	yellow	[10, 34]
C_6H_5	TCNE [a]	?	[35]
p-CH_3—C_6H_4	NO_3	orange yellow	[17]
Alkyl	Br, I	?	[12]

[a] TCNE is present in the first reduction stage.

The reverse process, *i.e.* the reduction of $TDAE^{2+}$, can be achieved with strong reducing agents such as zinc dust [26] or $Na_2Fe(CO)_4$ [38]. The diiodide of *(1a)* can even be discharged with silver to form *(1a)* [16]. Thus equation (5) represents a true redox equation; the oxidation process in (5) could be formally compared to the ionization of a metal:

$$TDAE \underset{\text{Red.}}{\overset{\text{Oxid.}}{\rightleftharpoons}} TDAE^{2+} + 2e$$

$$Mg \underset{\text{Red.}}{\overset{\text{Oxid.}}{\rightleftharpoons}} Mg^{2+} + 2e$$

The "quasimetal" TDAE gives up two electrons from a high energy level and retains a stable "octet of electrons" in the next lower shell (cf. Section 4.1). The electrons liberated in accordance with reaction (5) can be used to produce an electric current in a special apparatus [36a].

The dications TAE^{2+} are thermally very stable, and are also resistant to water and to acids. They can, on the other hand, be attacked by bases [reaction (8)].

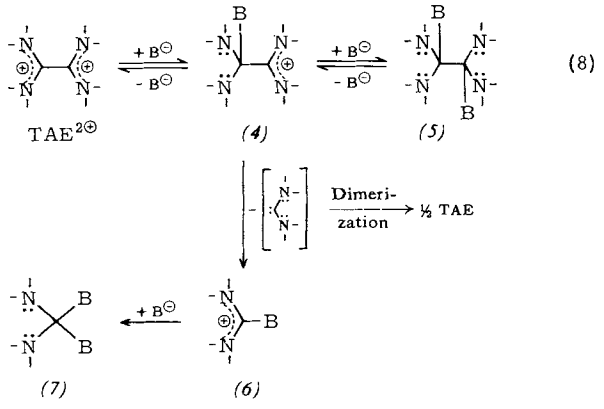
[33] *Hsi-Kuei Chiang, Chun-I Chang,* and *Yy Shih,* Hua Hsueh Hsueh Pao (Acta chim. sinica) *31,* 42 (1965); Chem. Abstr. *63,* 6993a (1965).

[34] *N. Wiberg,* unpublished.

[35] Contrary to an earlier view [6], the reaction of *(1a)* with TCNE appears to lead to a compound corresponding to TDAE $(TCNE)_2$ (*H.-W. Wanzlick,* private communication).

[36a] *W. R. Wolfe, jr.,* US-Pat. 3156587 (Nov. 10, 1964), Du Pont; Chem. Abstr. *62,* 4913b (1965).

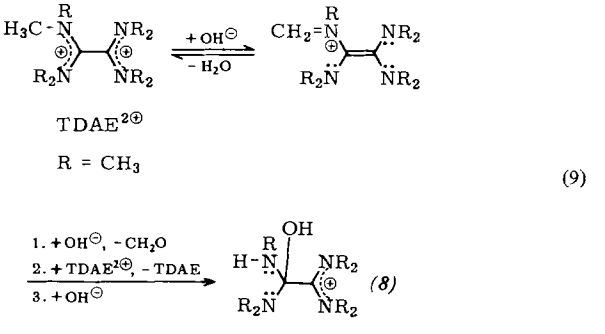


(8)

Of the compounds *(4)* and *(5)* initially formed by the addition of bases to the central carbon atoms of $TAE^{2\oplus}$, *(4)* is unstable. It formally loses the carbene $C(NR_2)_2$ (which dimerizes to give TAE (cf. Section 5)) to form the compound *(6)*, which also reacts with bases. Thus the reaction of the dinitrate of *(1)*, R = C_6H_5 or *p*-$CH_3C_6H_4$, with hydride ions ($B^- = H^-$, introduced in the form of $B(OCH_3)_3H^-$) leads to the tetraaminoethane *(5)* and the diaminoethane *(7)* in yields of 50 and 25 % respectively[10]. Unchanged tetraaminoethylene *(1)* is also formed.

Compound *(5)* is evidently formed only in the presence of extremely strong bases. If the base is only strong, *(4)* is formed and converted into *(7)* and TAE; *e.g.*, if $[TDAE]Br_2$ is heated for 5 minutes (50 °C) in 50 % sodium hydroxide solution, only tetramethylurea [—B, —B in *(7)* is =O in this case] and TDAE are formed in the expected molar ratio of 2:1[36b]. The dication of *(1)*, R = C_6H_5 or *p*-$CH_3C_6H_4$ decomposes in a similar manner in the presence of sodium hydroxide solution; however, the resulting tetraaminoethylene *(1)*, unlike TDAE, is unstable to bases and reacts further to give the *N*-formyl compound $RNH-CH_2-CH_2-NR-CHO$ *(13c)* [cf. reaction (25)]. Since the uncharged compounds TAE form the radical-cation TAE^+ reversibly with the dication TAE^{2+} (cf. Section 3.1.2), the characteristic color of TAE^+ is observed during reaction (8).

Unlike the concentrated alkali, dilute sodium hydroxide solution converts $[TDAE]Br_2$ not into tetramethylurea but into TDAE, the compound *(8)*, formaldehyde, oxalic acid bis(dimethylamide), bis(dimethylamino)methane, and dimethylamine[28]. Isotope experiments indicate that *(8)* is formed from $TDAE^{2+}$ in accordance with reaction (9), with simultaneous formation of CH_2O and TDAE.



(9)

The other reaction products result from the hydrolysis of *(8)*. The failure of reaction (8) to occur in this case is evidently connected with the fact that the equilibrium $TAE^{2+} + B^- \rightleftharpoons$ *(4)* is strongly displaced to the left in dilute alkali.

[36b] As has been shown experimentally, no free carbenes occur in this reaction (cf. Section 5). The carbenes must therefore dimerize during the reaction. *D. M. Lemal* proposes the reaction sequence 2 *(4)* → *(4)* − *(4)* → 2 *(7)* + TAE [7], and *R. W. Hoffmann* the sequence *(5)* + TAE^{2+} → 2 *(7)* + TAE.

3.1.2. The Tetraaminoethylene Radical Cation

The intermediate in the complete oxidation of tetrakis(dimethylamino)ethylene to $TDAE^{2+}$, the radical-cation $TDAE^+$, can also be prepared; it is formed as the only detectable particle in the mass spectrograph *e.g.* of TDAE at an electron collision potential of 6.5–8.0 eV (TDAE is increasingly fragmented at collision potentials >8.5 eV; rather oddly, however, no strong peak is found for the dication $TDAE^{2+}$[38]). Moreover, the ESR spectrum of a dilute solution of the compound $TDAE(TCNE)_2$ in acetonitrile indicates the existence of the cation $TDAE^+$, since the background of the $TCNE^-$ nonet contains many small signals (multiplet) due to the $TDAE^+$ cation, which is present in equilibrium with $TDAE^{2+}$ in accordance with reaction (10)[38] (cf. Section 3.1.3).

$$TDAE^{2+} + 2\,TCNE^- \rightleftharpoons TDAE^+ + TCNE^- + TCNE \qquad (10)$$

Kuwata and *Geske*[27] obtained the radical-cation $TDAE^+$ by the coproportionation reaction (11).

$$TDAE + TDAE^{2+} \rightleftharpoons 2\,TDAE^+ \qquad (11)$$

The orange solution of the cation $TDAE^+$ ($\lambda_{max}^{CH_3CN}$ = 385 nm) obtained from TDAE $(ClO_4)_2$ and TDAE in dimethylformamide gives an ESR spectrum with a multiplet consisting of 300 signals (line width: 0.04 G, cf. Section 4.2). The equilibrium constant for reaction (11) is 2.3×10^2, *i.e.* 89 % of $TDAE^+$ exists in equilibrium with 5.5 % of TDAE and 5.5 % of $TDAE^{2+}$[39]. The half-wave potentials ε_0 are[27]:

$$TDAE \rightarrow TDAE^+ + e \qquad \varepsilon_0 = -0.75\ V$$

$$TDAE^+ \rightarrow TDAE^{2+} + e \qquad \varepsilon_0 = -0.61\ V$$

The radical-cation is surprisingly stable. For example, the ESR spectrum of $TDAE^+$ in dimethylformamide does not change when the solution is heated to 120 °C.

The partial oxidation of *(1a)* with iodine, Ag^+, or the dication of *(1a)* gives the violet radical-cation of *(1a)* ($\lambda_{max}^{CH_3CN}$ = 517 nm), which, unlike $TDAE^+$, gives only a single broad ESR signal (line width: 5.4 G)[16]. Solutions of the monocation of *(1a)* in acetonitrile satisfy the Beer-Lambert law[7]; the radical-cation therefore does not dimerize with increasing concentration.

The distinctly negative potential of TDAE (which roughly corresponds to the standard potential of zinc: $Zn \rightarrow Zn^{2+} + 2e$; $\varepsilon_0 = -0.76$ V) is a quantitative indication of the electron-donor character of the tetraaminoethylene system. The surprisingly low appearance potential of TDAE in comparison with those of other tetrasubstituted ethylenes also confirms that the atomic grouping $(\rangle N)_2C{=}C(N\langle)_2$ is an "electron-rich" system. The appearance potentials of ethylene, tetramethylethylene, and TDAE are 10.5, 8.4, and <6.5 eV respectively.

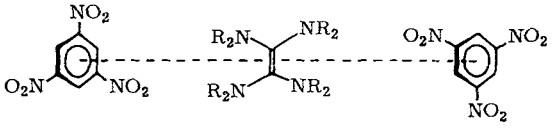
[37] *J. P. Paris*, Photochem. and Photobiol. *4*, 1059 (1965).

[38] *N. Wiberg* and *J. W. Buchler*, unpublished.

[39] The equilibrium (11) cannot be established unless TDAE and $TDAE^{2+}$ are soluble in the reaction medium.

3.1.3. Electron Donor-Acceptor Complexes of Tetraaminoethylenes

The reaction of TDAE with organic molecules having a lower oxidation potential than TCNE no longer results in complete electron transfer from the donor TDAE to the organic acceptor, but leads instead to the formation of electron donor-acceptor complexes [40]. For example, reaction with trinitrobenzene (TNB) in acetonitrile yields the crystalline, blackish-red, light-sensitive, diamagnetic [42] complex $TDAE(TNB)_2$ (m.p. 84–86 °C) [41]. Spectroscopic studies characterize it as an electron donor-acceptor complex, and are compatible with a sandwich arrangement of the molecules.



$TDAE(TNB)_2$, R = CH_3

Stronger electron acceptors such as oxygen or halogen can displace the weaker electron acceptor TNB from the TDAE and so complete the oxidation of TDAE [41], *e.g.*:

$$TDAE(TNB)_2 + Br_2 \rightarrow TDAE^{2+}\ 2\ Br^- + 2\ TNB \qquad (12)$$

The difference in the electronic structure of $[TDAE^{2+}][TCNE^-]_2$ (salt) and $TDAE(TNB)_2$ (electron donor-acceptor complex) is clear from the IR, ^{1}H-NMR, and UV spectra [26, 41] (see Table 4).

Table 4. Comparison of the spectra of $[TDAE^{2+}][TCNE^-]_2$ and $TDAE(TNB)_2$.

Spectrum	$[TDAE^{2+}][TCNE^-]_2$	$TDAE(TNB)_2$
IR (in Nujol)	$TDAE^{2+}$ and $TCNE^-$ bands	no $TDAE^{2+}$ bands
^{1}H-NMR (in CH_3CN)	$TDAE^{2+}$ signals [a]	TDAE signal [b]
UV (in CH_3CN)[c]	$TCNE^-$ absorption [24]	2 new CT bands [d]

[a] Considerably broadened and displaced to higher field strengths because of the paramagnetism of $TCNE^-$.
[b] Another signal is due to trinitrobenzene.
[c] Dilute solution.
[d] Charge-transfer bands at 545 (ε = 210) and 442 nm (ε = 300).

result indicates that the ionization of $TDAE(TCNE)_2$ is reversible (formation of ion pairs and electron donor-acceptor complexes). $TDAE(TCNE)_2$ probably exists in the solid state as an electron donor-acceptor complex of the ions $TDAE^{2+}$ and $TCNE^-$, *i.e.* as a complex in which more ionic limiting structures are involved in the ground state than in the excited state ("inverse" electron donor-acceptor complex [23]).

Electron donor-acceptor complexes of tetrakis(dimethylamino)ethylene and other tetraaminoethylenes are generally formed by the action of organic molecules containing π electrons and electron-attracting substituents (*e.g.* chloranil, cyanoethylenes, nitroaromatic compounds) on tetraaminoethylenes in organic solvents [43, 43a]. The very strong organic electron acceptors form deeply colored electron donor-acceptor complexes that are stable to above 200 °C, frequently stable to air, and generally paramagnetic, and which are probably comparable in their structure to

Table 5. Strong electron donor-acceptor complexes with tetraaminoethylenes [43].

Donor (D)	Acceptor (A)	D:A	Color	Decomp. pt. (°C)
TDAE	Chloranil	1:3	green	?
TDAE	Bromanil	1:2	green	220–230
TDAE	3,4,5,6-Tetrabromo-3,5-cyclohexadiene-1,2-dione	1:1	light brown	250
Tetrapyrrolidinoethylene	3,6-Bis(dicyanomethylene)-1,4-cyclohexadiene	1:1	blue black	185
Tetrapiperidinoethylene	3,6-Bis(dicyanomethylene)-1,4-cyclohexadiene	1:1	blue black	243
1,1',3,3'-Tetramethyl-2,2'-biimidazolidinylidene	3,6-Bis(dicyanomethylene)-1,4-cyclohexadiene	1:1	deep blue	220

$TDAE(TCNE)_2$ is evidently on the borderline between a salt and an electron donor-acceptor complex. In dilute solution it must be described as salt. However, the ESR spectra of increasingly concentrated solutions of $TDAE(TCNE)_2$ in CH_3CN show that the structure of the compound changes. At concentrations of 2.6×10^{-4} and 1.3×10^{-3} mole/l, the spectra show a nonet having line widths of 0.1 and 0.2 G respectively and at 1.3×10^{-1} mole/l a singlet having a line width of 5 G [38].

By analogy with the case of tetramethyl-*p*-phenylenediamine tetracyanoethylene (TMPD) (TCNE) [23], this

$TDAE[TCNE]_2$ [44]. TDAE is also a sufficiently strong electron donor to give electron donor-acceptor complexes with very weak electron acceptors such as tetrachloroethylene [43], anthracene [43a], or acrylonitrile [41]; however, these complexes readily decompose when

[40] *G. Briegleb*: Elektronen-Donator-Acceptor-Komplexe. Springer, Berlin 1961.

[41] *N. Wiberg* and *J. W. Buchler*, Chem. Ber. *97*, 618 (1964).

[42] In solution. In the solid state, the complex exhibits weak electron spin resonance at $g = 2$.

[43] *H. E. Winberg*, US-Pat. 3239518 (March 8, 1966), Du Pont; Chem. Abstr. *64*, 15898c (1966).

[43a] *P. R. Hammond* and *R. H. Knipe*, J. Amer. chem. Soc. *89*, 6063 (1967).

[44] Electron donor-acceptor complexes in which substantial transfer of the electrons from the donor to the acceptor has occurred are paramagnetic or diamagnetic, according as the spins of the unpaired electrons of the donor and acceptor molecules are parallel or antiparallel. The question of whether the complex is paramagnetic or diamagnetic may depend on the state (pure substance, solution), the nature of the solvent, the concentration in a solvent, and the temperature [45].

[45] *F. Schneider*, *K. Möbius*, and *M. Plato*, Angew. Chem. *77*, 888 (1965); Angew. Chem. internat. Edit. *4*, 856 (1965).

heated. The "weak" electron donor-acceptor complexes are only "slightly" colored [TDAE$(C_2Cl_4)_n$: yellow; TDAE$(C_{14}H_{10})_n$: yellow; TDAE(acrylonitrile)$_n$: orange], and unlike the very strong complexes they must evidently be regarded as "normal" electron donor-acceptor complexes, in which the excited state involves more ionic limiting structures than the ground state.

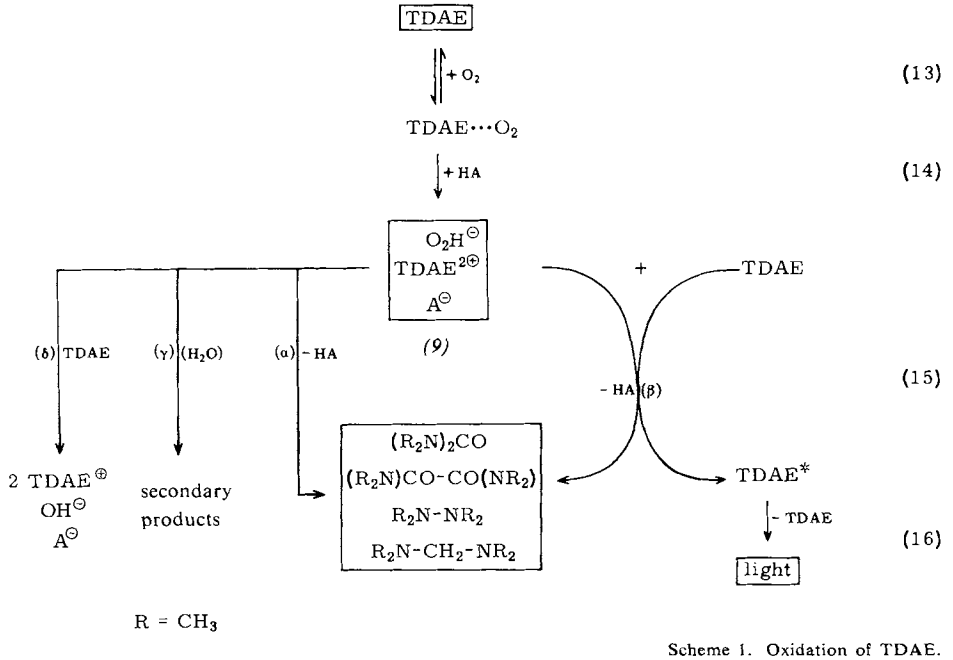
Some typical examples of strong electron donor-acceptor complexes with tetraaminoethylenes are listed in Table 5.

These complexes are not only of theoretical interest, but can also be used in practice[43], *e.g.* for the production of duplicates without the use of carbon paper. A sheet of paper impregnated with a TAE donor and another impregnated with a π acceptor are brought together, and the top sheet is written on with a hard pencil; the colored electron donor-acceptor complex appears where pressure was applied. The complex can also be used as a pigment for colored inks. Writing executed in such inks can be readily thermographically reproduced, since the complexes, unlike the pigments of most ordinary inks, absorb strongly between 500 and 2000 nm.

3.1.4. Autoxidation of Tetraaminoethylenes

Tetrakis(dimethylamino)ethylene reacts vigorously with oxygen in the presence of protonic compounds, with emission of pale green chemiluminescence; the products (based on the TDAE initially present) are 68 % of tetramethylurea, 16 % of oxalic acid bis(dimethylamide), 10 % of tetramethylhydrazine, and 4 % of bis(dimethylaminomethane)[28]. Many investigations[12,28,37,46–50] have been aimed at the elucidation of this unusual reaction. The investigations by *Urry* and *Sheeto*[28] and by *Flechter* and *Heller*[49] will now be discussed in some detail.

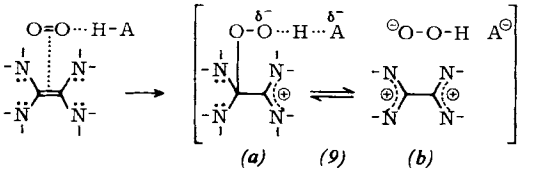
The oxidation of pure tetrakis(dimethylamino)ethylene dissolved in organic solvents or emulsified in water can be best represented by Scheme 1.



Scheme 1. Oxidation of TDAE.

Reaction (13): Colorless dilute solutions of TDAE in *n*-decane turn brown when oxygen is introduced[46]: a fast reaction leads to a low equilibrium concentration of an electron donor-acceptor complex TDAE$\cdots\cdots O_2$ (broad absorption maximum at $\lambda = 450$ nm, enthalpy of formation $\Delta H \approx -1.2$ kcal), which in vacuum can be reversibly decomposed into TDAE and O_2 at 0 °C.

Reaction (14): In the presence of protonic compounds HA (alcohol, water, silanol, acetylene, *etc.*), the complex TDAE$\cdots\cdots O_2$ changes irreversibly into *n*-decane[46]: the molecules HA induce an electron transfer from TDAE to the oxygen[51].



(14)

The oxidation to *(9)* takes place only in the presence of protonic compounds[49,50]. Corresponding to their catalytic function, the HA molecules are not consumed, except in oxidations of concentrated TDAE solutions; according to their activity and their concentration, they regulate the rate of the process (14), which evidently determines the rate of the

[50] *H. E. Winberg*, *D. R. Downing*, and *D. D. Coffman*, J. Amer. chem. Soc. *87*, 2054 (1965).

[51] The question of whether the zwitterion *(9a)* [28] or the ion pair *(9b)* [47, 49] is formed in inert solvents (both *(9a)* and *(9b)* must be thought of as being solvated by other molecules HA) has not been settled. Both compounds appear reasonable as products of the ionic reaction (14) on energy grounds ($\Delta F \approx -20$ kcal; free-radical reactions can be ruled out, since the oxidation of TDAE is not suppressed by free-radical interceptors [28]). Other ionic reactions, such as TDAE·$O_2 \rightarrow$ TDAE$^+O_2^-$ ($\Delta F = -0.9$ kcal) or TDAE·$O_2 \rightarrow$ TDAE$^{2+}O_2^{2-}$ ($\Delta F = +81.4$ kcal), are less likely [47].

overall reaction. The reaction (14) can even be catalyzed by the OH groups of the glass apparatus (HA = HO-glass)[52]. The complex TDAE·O_2 thus decomposes slowly in decane above 0 °C even in the absence of added substances HA, *i.e.* apparently without a catalyst.

Reaction (15), path γ: The ion pair $[TDAE^{2+}O_2H^-A^-]$ *(9)* formed in accordance with (14) can be extracted from the organic medium with water during the oxidation of TDAE. In the aqueous phase, *(9)* dissociates into the independent ions $TDAE^{2+}$, O_2H^-, and A^- (= OH^-), and $TDAE^{2+}$ can be precipitated in a high yield as the perchlorate[28]. If the cation $TDAE^{2+}$ is not precipitated, it reacts slowly in water (unlike in inert organic solvents, see below) with its basic counter-ions O_2H^- and OH^- to give the cation *(8)*, formate[53], dimethylamine, oxalic acid bis(dimethylamide), and bis(dimethylamino)methane [cf. reaction (9)].

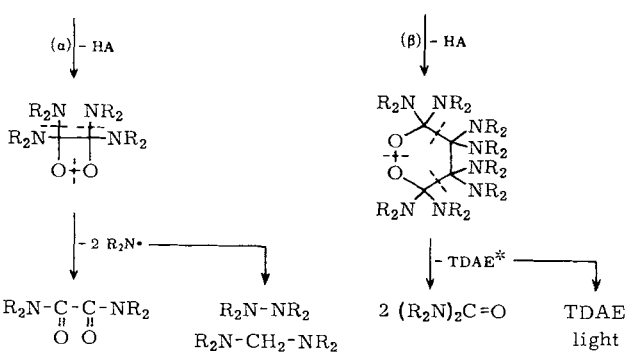
Reaction (15), path δ: In suitable solvents, the dication $TDAE^{2+}$ can also enter into an equilibrium reaction with unreacted TDAE to form the monocation $TDAE^+$ [cf. Reaction (11)]. For example, the oxidation of TDAE in alcohols is accompanied by the formation of an intensely orange solution ($\lambda_{max}^{CH_3OH}$ = 383 nm) and the appearance of ESR signals[9]. The color effect and the paramagnetism are due to the intermediate formation of $TDAE^+$.

Reaction (15), paths α *and* β: In inert solvents, the intermediate *(9)* rapidly reacts further to form the "normal" products of the oxidation of TDAE, *i.e.* tetramethylurea, oxalic acid bis(dimethylamide), tetramethylhydrazine, and bis(dimethylamino)methane. From the measured time-dependence of the intensity of the light produced during the oxidation of TDAE/*n*-decane/*n*-octanol solutions, *Flechter* and *Heller*[49] believe that the formation of the reaction products is preceded by the fast equilibrium (17)[54]:

$$\left[TDAE^{2\oplus}, O_2H^{\ominus}, A^{\ominus}\right] \underset{-TDAE}{\overset{+TDAE}{\rightleftharpoons}} \left[(TDAE)_2^{2\oplus}, O_2H^{\ominus}, A^{\ominus}\right] \quad (17)$$

(9) *(10)*

The decomposition of *(10)* (the structure of which is unknown) and of *(9)* leads to the products of the oxidation of TDAE. The formation of these products is illustrated in Scheme 2.



Scheme 2. Consecutive reactions of *(9)* in inert organic solvents [cf. Scheme 1, reactions (15α) and (15β)].

In this case the formation of tetramethylurea as a final product of the chemiluminescence reaction that proceeds *via (10)* appears probable from the following observation. The oxidation of some tetraaminoethylenes containing *N*-alkyl groups is accompanied by chemiluminescence and leads only to urea derivatives (see below)[55]. The reaction course shown in Scheme 2 is also supported by energy considerations. Thus the exothermic decomposition of *(9)* leads to high-energy amine radicals, and the exothermic decomposition of *(10)* leads to high-energy TDAE*; the simultaneous formation of $R_2N\cdot$ and TDAE* in one step consequently seems unlikely.

The formation of the complex *(10)* can be "seen" if a TDAE solution is rapidly freed from oxygen during the oxidation and allowed to solidify at −30 °C. The solid solution continues to luminesce faintly for several hours, owing to the slow (1st order) decomposition of *(10)* into TDAE* and other products. If the oxygen is withdrawn from the uncooled solution, the intensity of the chemiluminescence increases for a short time before dying away, since the quantum yield of reaction (16) is increased by the absence of the oxygen, which extinguishes the fluorescence[49].

Reaction (16): The oxidation of TDAE can proceed with emission of light (in the case of pure TDAE or solutions in hydrocarbons; λ_{max}^{decane} = 485 nm[49]) or without emission of light (*e.g.* in the solvents pyridine, tetrahydrofuran, dioxane, dichloromethane). The overall oxidation of TDAE yields 140 kcal/mole; thus the oxidation energy is easily sufficient for the emission of light wavelength ≈500 nm (57 kcal/mole of photons). The quantum yield of the reaction (16) (0.35 ± 0.05) is decreased by many substances, such as oxygen, alcohol, tetramethylurea, and oxalic acid bis(dimethylamide)[49, 57, 57a, 58]. The reason for the absence of chemiluminescence during the oxidation of TDAE in many organic solvents is probably due to the fluorescence-extinguishing action of the solvents.

All tetraaminoethylenes are sensitive to oxygen. In the case of the 1,1′,3,3′-tetraorganyl-2,2′-biimidazolidinylidenes *(1)*, the oxidation leads only to urea derivatives.

[52] This can be seen *e.g.* from the fact that the intensity of the chemiluminescence of the solution still adhering to the glass wall after pouring out the TDAE/*n*-decane solution falls only to about 20% of its original value [47].

[53] Secondary product of the oxidation of CH_2O with O_2H^-.

[54] Over a wide concentration range, the intensity of the chemiluminescence is proportional to the square of the TDAE concentration. Thus two molecules of TDAE are involved in the formation of electronically excited TDAE (= TDAE*). Since it has been conclusively shown that only one type of excited molecule is formed, *i.e.* TDAE* (identity of the chemiluminescence spectrum with the fluorescence spectrum of TDAE), TDAE* must be formed on oxidation of a complex containing two molecules of TDAE [49]. The equilibrium (17) thus expresses the experimental observation that the yield of excited molecules TDAE* increases with increasing TDAE concentration, since the equilibrium (17) must be displaced to the right with increasing TDAE concentration.

[55] The configuration of excited TDAE*, which is certainly different from that of TDAE in the ground state (cf. Section 4.3) [49, 50], could be approximately formed in the complex *(10)* or a secondary product. According to *Chandross* and *Sonntag* [56], similarity between the configurations of the reactant and the excited product increases the probability of chemiluminescence.

[56] *E. A. Chandross* and *F. I. Sonntag*, J. Amer. chem. Soc. *88*, 1089 (1966).

[57] *H. E. Winberg*, US-Pat. 3264221 (Aug. 6, 1966), Du Pont; Chem. Abstr. *65*, 13000f (1966).

[57a] *W. R. Carpenter* and *E. M. Bens*, US Clearing House Federat. Sci. Tech. Inform. AD 806625; Chem. Abstr. *68*, 104362q (1968).

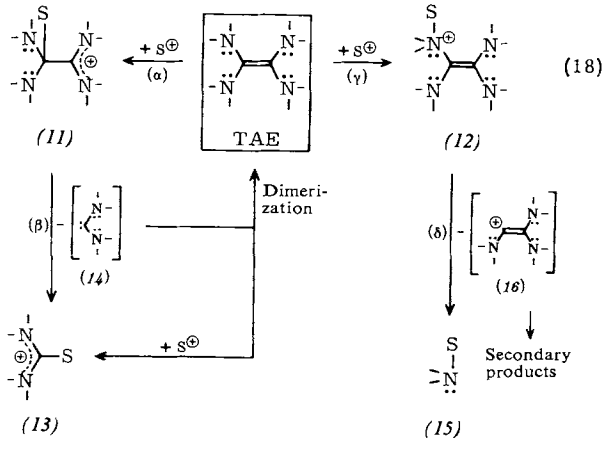
[58] For example, if 1–2 mole-% (based on the TDAE) of tetramethylurea or oxalic acid bis(dimethylamide) are added to chemiluminescing pure TDAE, the chemiluminescence is completely suppressed [50, 57]. The chemiluminescence is restored on extraction of the reaction mixture with water, which is immiscible with TDAE, but dissolves tetramethylurea and oxalic acid bis(dimethylamide).

(Similarly, compounds of the type *(1)* react with sulfur (S_8) to give thioureas[12, 59, 60]). However, chemiluminescence has been observed only in the oxidation of 1,1′,3,3′-tetraalkyl-2,2′-biimidazolidinylidenes (*e.g.* for *(1)*, R = C_2H_5: $\lambda_{max}^{cyclohexane}$ = 506 nm[12]).

The high sensitivity of TDAE and other tetraaminoethylenes to oxygen and their ability to chemiluminesce in the presence of oxygen can be used *e.g.* for the removal of traces of oxygen[14, 22], for the detection of traces of oxygen[6], for the quantitative determination of oxygen (quantitative determination of the carbonyl compounds formed)[14, 22], or for the production of light[61, 61a]. It has also been suggested[14, 22] that TDAE should be used as a high-energy rocket fuel.

3.2. Acid-Base Reactions

Tetrakis(dimethylamino)ethylene and other tetraaminoethylenes react vigorously, often at room temperature, with Brønsted and Lewis acids S. The TAE system donates either the pair of π electrons from the carbon atoms (α) or the four (nonbonded) n-electron pairs of the four nitrogen atoms (γ) to the acids [reaction (18)].



(18)

This reaction type formally also includes the additions of acceptor molecules (π acids) to the complete system of π- or n-electrons of the base TAE to form electron donor-acceptor complexes (cf. Section 3.1.3). The formation of electron donor-acceptor complexes is an illustration of the fact that it is often impossible to distinguish oxidations from acid-base reactions.

The products *(11)* and *(12)* initially formed by the addition of acid to the TAE system are unstable, and react further to give secondary products. Thus the electrophilic attack of S leads in most cases to cleavage of the C=C (β) or C–N (δ) bond; the products include compounds of the type *(13)* or *(15)* (formamidinium cations or amines, when S=H^+).

According to a suggestion by *Lemal*[7, 17], the C=C bond is cleaved by path (18α), (18β), the intermediate *(11)* losing a diaminocarbene *(14)* to form the compound *(13)*. *(14)* can then dimerize or react with the acid S to give *(13)*. It is not certain whether the carbene is formed as such or is simply transferred during the step β in accordance with

$$2\,(11) \rightarrow 2\,(13) + \text{TAE}$$

or

$$(11) + S \rightarrow 2\,(13)$$

However, cleavage of the double bond in an equilibrium

$$\text{TAE} \rightleftarrows 2\,(14)$$

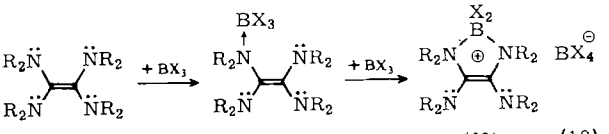
can be definitely ruled out (cf. Section 5). Since the ion *(11)* is also formed when the base B^- is added to the dication TAE^{2+}, it is not surprising that TAE^{2+} is converted into *(13)* and TAE (or its reaction products with bases) by bases [cf. reaction (8), *(4)* and *(5)*].

The cleavage of the C–N bond is probably initiated by the reaction sequence (18γ), (18δ)[62], the hypothetical cation *(16)*, as well as the carbene *(14)*, possibly being resonance-stabilized[63]. The secondary reactions of cation *(16)* are very complex (cf. Section 3.2.2), and have not been elucidated in detail[64].

Reactions with acids leading to stable addition compounds will be discussed first. Reactions with acids involving cleavage of the C–N or C=C bond of the tetraaminoethylene system are then described.

3.2.1. Addition of Acids to Tetraaminoethylenes

Whereas no stable addition products of Brønsted acids (S = H^+) with the TAE system have been obtained[66], adducts with Lewis acids can be isolated as such. Thus boron trifluoride and diborane (S = BX_3; X = F, H) react by a multistep process (19) to give the salt *(18)*, whose cation, according to spectroscopic and chemical investigations, is cyclic[62].



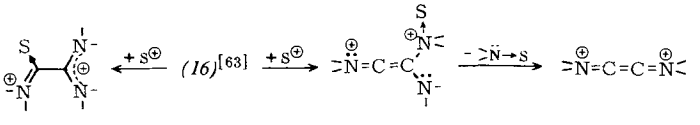
(19)

The cation in *(18)* (X = F), whose fluorine atoms are not substituted on reaction with phenylmagnesium bromide, differs from TDAE in its high thermal stability and stability to solvolysis and oxidation. The dimethylamino groups can be

[62] *N. Wiberg* and *J. W. Buchler*, Chem. Ber. *96*, 3000 (1966).

[63]  *(16)*

[64] It may be assumed that the secondary reactions are introduced by the addition of acid to a carbon or nitrogen atom of *(16)* (cf. Section 3.2.2 and [63,65]):



[59] *H.-W. Wanzlick*, *H. Ahrens*, *B. König*, and *M. Riccius*, Angew. Chem. *75*, 685 (1963); Angew. Chem. internat. Edit. *2*, 560 (1963).

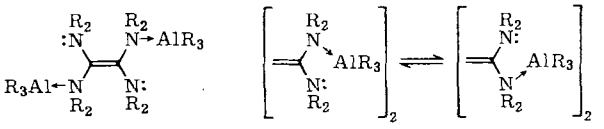
[66] When S = H^+ in reaction (18), *(11)* and *(12)* evidently decompose rapidly with cleavage of the C–C or C–N bond (cf. Sections 3.2.2 and 3.2.3).

removed only with concentrated hydrochloric acid, and $KMnO_4$ is necessary for oxidation of the compound [67].

The indicated path for the formation of the compound *(18)* *via* the intermediate *(17)* is shown by the reaction of TDAE with zinc chloride (S = $ZnCl_2$), since the reaction stops in this case at the stage of the primary addition product TDAE·$ZnCl_2$. The lability of TDAE·$ZnCl_2$ (luminesces in air, yields ZnO and [TDAE]Cl_2 on careful autoxidation) and the very strong double bond stretching vibration [68] oppose the structure *(18)* with $ZnCl_2$ instead of BX_2 for this adduct [38].

Unlike trimethylboron [62], trimethylaluminum [S = $Al(CH_3)_3$] reacts with TDAE at room temperature, again to form a 2:1 adduct [69]. This adduct is not, however, an analog of the salt *(18)*, X = CH_3, as is clear even from the low sublimation point of TDAE·[$Al(CH_3)_3]_2$ (60 °C/0.05 torr) in comparison with *(18)* [m.p. 200 °C/(dec.)]. The ^{1}H-NMR spectrum contains two proton signals of equal area for the



(19) *(19a)* *(19b)*

R = CH_3 (20)

N-methyl protons and only one signal for the *Al*-methyl protons. This leads to the structure *(19)* with two molecules of $Al(CH_3)_3$ bound to the TDAE in the same manner. Rather surprisingly the two *N*-methyl proton signals fuse when the recording temperature is raised from 3 to about 50 °C. *Mole* [70] explains this effect by a rapid change in the coordination of the aluminum from one nitrogen atom to the other in accordance with reaction (20); the life of *(19a)* or *(19b)* at 50 °C should be short in relation to the "exposure time" in the NMR spectrometer [71].

As well as 1:1 and 2:1 adducts of Lewis acids with TDAE, 4:1 adducts evidently also exist, as is shown by the complex TDAE[$TiF_4]_4$ described by *Muetterties* [73], which has not been investigated in detail.

No products formed by the addition of acid to the carbon atoms of the TAE system have been obtained, though such adducts should in fact have a certain stability, since the positive charge on the system after the addition of the acid can be stabilized by resonance [cf. *(11)*] [74].

[74] Adducts of acids to one of the ethylenic carbon atoms are, however, known in the case of 1,2-diaminoethylene-1,2-dithiols [75].

3.2.2. Cleavage of the C–N Bond of Tetraaminoethylenes with Acids

The compounds formed by the addition of acids to the TAE system are unstable in many cases. Thus an unstable adduct is first formed with the Lewis acid boron trichloride (S = BCl_3) [62]. Unlike the boron trifluoride adduct *(17)*, however, this rapidly decomposes to form dimethylaminoboron dichloride in accordance with the overall equation

$$\text{TDAE} + 2\ BCl_3 \longrightarrow \approx {}^4/_5\ (CH_3)_2NBCl_2 + \approx {}^1/_2\ TDAE^{2+} \quad 2\ Cl^- + \text{tars} \qquad (21)$$

Trimethylborane [S = $B(CH_3)_3$] reacts slowly with TDAE at 150 °C with cleavage of C–N bonds to form $(CH_3)_2N-B(CH_3)_2$. The decomposition is evidently introduced in both cases by the reaction (18γ), (18δ). Another interesting reaction is that of TDAE with methyl iodide, which leads to $(CH_3)_4NI$, [TDAE]I_2, and $[(CH_3)_3N-CH_2-CON(CH_3)_2]\ I$ [76].

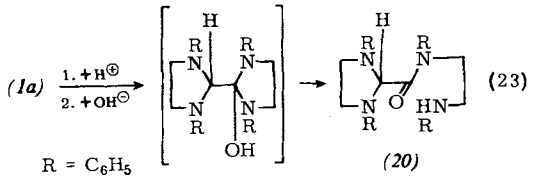
No explanation has yet been found for the formation of the dication $TDAE^{2+}$ in the decomposition of TDAE with BCl_3 (up to 50 % yield) and with CH_3I. $TDAE^{2+}$ salts are also formed in yields of up to 13 % (based on the TDAE used) in the reaction of TDAE with BF_3 or $ZnCl_2$ [but not with BH_3 or $B(CH_3)_3$]. The reaction of tetraphenyl-2,2′-biimidazolidinylidene *(1a)* with BF_3 also leads to dications [34].

TDAE reacts with the Brønsted acid hydrogen chloride (S = H^+) to form dimethylamine together with glyoxalic acid dimethylamide and [TDAE]Cl_2, probably by the reaction sequence (18γ), (18δ) [77]

$$\text{TDAE} \xrightarrow{H_2O/HCl} (CH_3)_2NH_2Cl + \approx {}^1/_2\ (CH_3)_2NCO-CHO + \approx {}^1/_4\ [\text{TDAE}]Cl_2 + ? \qquad (22)$$

Glyoxalic acid dimethylamide may be regarded as the hydrolysis product of the cation *(16)*. The oxidation mechanism is again unclear [78].

Brønsted acids of low acidity (H_2O, ROH) act on TDAE only around 160 °C (see below). The reaction rate evidently decreases rapidly with decreasing acidity of the acid used. *(1a)*, on the other hand, reacts even with concentrated sodium hydroxide solution to give cleavage of a C–N bond in accordance with reaction (23).



(1a) *(20)* (23)

R = C_6H_5

According to *Lemal* [7], the formation of *(20)* is introduced by proton addition to an ethylenic carbon atom of *(1a)*.

[75] *J. Metzger*, *H. Larivé*, *R. Dennilauler*, *R. Baralle*, and *C. Gaurat*, Bull. Soc. chim. France *1964*, 2857.

[76] *W. H. Urry*, unpublished.

[77] *N. Wiberg* and *J. W. Buchler*, Z. Naturforsch. *19b*, 9 (1964).

[78] It has been shown that the oxidation is not effected by oxygen or by protons (no H_2 is formed). In certain circumstances the cation *(16)* or a secondary product of *(16)* (dication?, cf. [64]) accepts the electrons from TDAE.

3.2.3. Cleavage of the C=C Bond of Tetraaminoethylenes by Acids

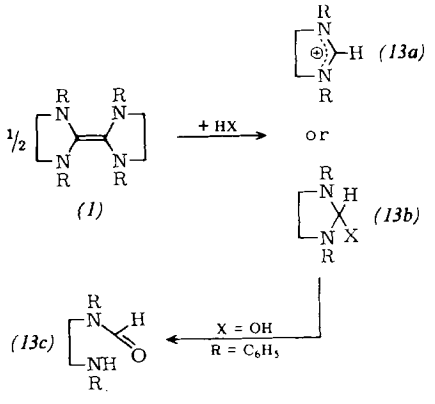
Tetrakis(dimethylamino)ethylene reacts quantitatively with water at 160 °C to form dimethylamine and dimethylformamide [77].

$$TDAE + 2\,H_2O \rightarrow 2\,(CH_3)_2NH + 2\,(CH_3)_2N{-}CHO \qquad (24)$$

No other reactions in which the C=C bond of TDAE is cleaved by acids are known [79].

The reaction of 1,1',3,3'-tetraorganyl-2,2'-biimidazolidinylidenes *(1)* with acids, on the other hand, leads preferentially to cleavage of the C=C bond. Thus acids evidently preferentially attack TDAE on the nitrogen atoms, but *(1)* on the ethylenic carbon atoms.

Thus reactions of *(1)* with Brønsted acids [apart from the case of (23)] lead to the compounds *(13a)*, *(13b)*, or *(13c)* probably by the path (18α), (18β).

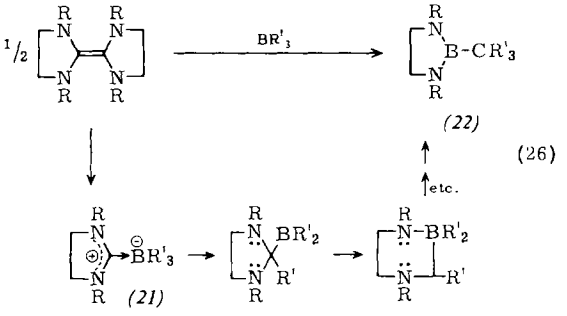


For example, the reaction of *(1a)* with hydrochloric acid (HX = HCl) leads to *(13a)* (containing the formamidinium grouping), and the reactions with methanol (HX = $HOCH_3$) or CH acids (HX = HC<) lead to *(13b)* (aminal) [6, 80–82]. The reaction with aqueous pyridine (HX = HOH) proceeds in accordance with equation (25), with cleavage of both the C=C and the C–N bonds and formation of the *N*-formyl compound *(13c)* [6]. Special mention should be made of the reaction of TDAE and *(1a)* with water, the course of which appears to be decided by the pH (cf. Table 6).

Table 6. Reaction of tetraaminoethylenes with water with retention (ret.) or cleavage (cl.) of the central C–C bond (reaction equations in parentheses).

Medium	TDAE	*(1a)*
acidic	ret. (22)	cl. (25)
neutral	cl. (24)	cl. (25)
alkaline	no reaction	ret. (23)

Lewis acids also react readily with compounds of the type *(1)* in accordance with the reaction sequence (18α), (18β). Thus carbonyl and thiocarbonyl functions can be made to react with *(1)* with cleavage of the central C=C bond [6, 52, 81, 83]. Electrophilic diazo compounds and azides react with *(1)* [53, 83–85]. Finally, an interesting course is followed by the reaction of *(1a)* with trialkylboranes [86]. The trialkylborane-carbene complex *(21)* expected from reaction (26) evidently rearranges in a multistep reaction to give *(22)*.



R = C_6H_5; R' = CH_3, n-C_4H_9, CH_2-C_6H_5

The difference in the behavior of TDAE and compounds of the type *(1)* toward acids is also seen in the reaction with trialkylboranes. TDAE reacts with BR_3 with cleavage of C–N bonds (cf. Section 3.2.2). A detailed discussion of reactions leading to cleavage of the C=C double bond may be found in ref. [8].

4. Structure of Tetraaminoethylenes

Our knowledge of the structure of tetraaminoethylenes in the charged, uncharged, or excited state is still very poor. The only compound of this class that has been studied in any detail is tetrakis(dimethylamino)-ethylene.

The foregoing discussions show that TDAE is a strong electron donor. This is also shown by a simple HMO calculation [34], the results of which are summarized in Figure 1 and in Table 7 and discussed below together with experimental data.

4.1. Electron Donor Strength of the Tetraaminoethylenes

Figure 1 shows how the energies of the six π molecular orbitals of the system $(\ddot{N})_2C{=}C(\ddot{N})_2$ varies with the parameter h (which takes into account the difference in the ionization energies of carbon ($\alpha_C = \alpha$) and nitrogen (α_N) in accordance with $\alpha_N = \alpha + h\beta$). The six energy levels (thick horizontal lines) $E = \alpha + m\beta$ (m = 2.69, 2.14, 1.50, 1.50, –0.19, –1.64) are then obtained for the value h = 1.5 recommended in [87]. As expected, two electrons occupy a high-

[79] TDAE is reported to react with CH_3OH to form $[(CH_3)_2N]_2CH(OCH_3)$. *H. E. Winberg*, unpublished.

[87] *A. Streitwieser*: Molecular Orbital theory. Wiley, New York 1961.

energy antibonding molecular orbital (b_{1u}), and can therefore be readily removed from the TAE system. Consequently, the ionization energy of TDAE (<6.5 eV)[38] is significantly lower than that of ethylene (10.5 eV). The electron donor character of TDAE is also demonstrated quantitatively by the oxidation potential (Table 7).

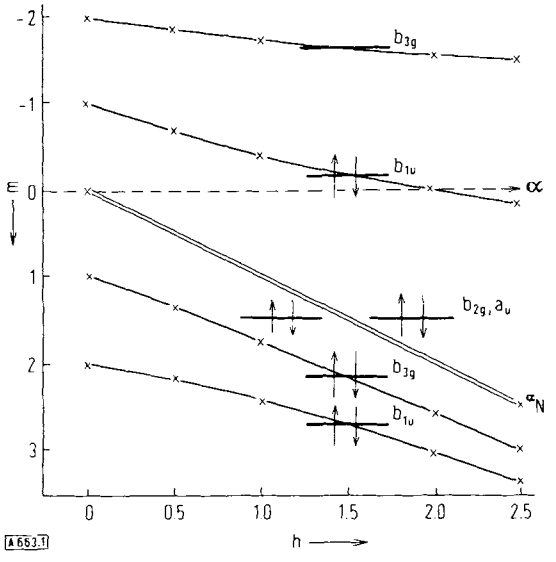

Fig. 1. π energy level scheme of the tetraaminoethylene system.

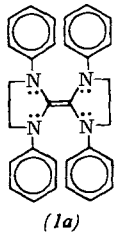
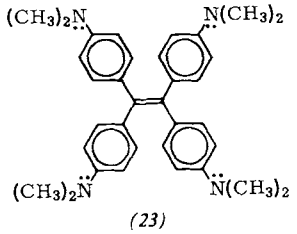
The HMO scheme also permits the comparison of the electron donor TDAE with other donors of similar structures. As the size of a carbon π system increases, the energy of the first antibonding orbital decreases. Lower donor strengths should therefore be expected for compounds derived from TDAE by the insertion of conjugated organic systems instead of the methyl groups [such as *(1a)*] the C–N bond [such as *(23)*], or the C=C bond [such as tetramethylphenylenediamine (TMPD)].



(1a)



(23)

TMPD

The monoiodide of *(1a)* can in fact be reduced even with silver[16] (Zn is required for TDAE); the half-wave potential of *(1a)* is only −0.3 V[27] (TDAE: −0.75 V). The oxidation of *(23)* with iodine is so readily reversible that in solvents having low dielectric constants, the diiodide exists in equilibrium with singly charged and uncharged *(23)* and elementary iodine[88,89]; *(23)* even exhibits a certain acceptor character, and adds on two atoms of sodium in ether [90] (TDAE does not react with lithium in diethylamine[38]). Reversible electron transfers have also been observed for the mono(tetracyanoethylenide) of TMPD, $TMPD^+$ $TCNE^-$[23,91] (→TMPD + TCNE). The ionization potential of TMPD is 6.6 V[92].

It should, however, be noted that the position of the upper b_{1u} energy level is influenced, not only by conjugative effects, but also by inductive and steric effects and by effects due to ring strain, since these factors also influence the parameter *h*. The donor strength must thus increase or decrease in accordance with Figure 1 when the dimethylamino groups of TDAE are replaced by more electropositive or more electronegative amino groups. Since methoxy groups are more electronegative than dimethylamino groups, tetramethoxyethylene should be a weaker donor than TDAE. The properties of the compound *(1a)* are undoubtedly strongly influenced by steric effects and ring strain[93].

4.2. Bonding in the System TAE^{n+} (n = 0, 1, 2)

The resonance energy of the system $TDAE^{n+}$ increases with increasing *n* (cf. Table 7). Even uncharged TDAE has the appreciable resonance energy of 24 kcal/mole if the entire system $(C_2N)_2C{=}C(NC_2)_2$ lies in a single plane. The vibration spectrum contains no IR absorption in the C=C region[9], whereas an intense $\nu_{C=C}$ band (1630 cm^{-1}) appears in the Raman spectrum[50]. This indicates that the TDAE molecule has a centrosymmetric structure. However, this does not necessarily mean that the TDAE skeleton is planar, since the dimethylamino groups could also rotate rapidly about the C–N bonds (see below and ref.[43a]). The vibration spectrum also confirms a centrosymmetric structure for $TDAE^{2+}$[34].

According to the HMO calculation, the bond order of the C=C bond decreases and that of the C–N bond increases in the order TDAE, $TDAE^+$, $TDAE^{2+}$ (Table 7). The change in the $C{-}N(CH_3)_2$ bond order can be detected in the ^{1}H-NMR spectrum. Whereas TDAE gives only one sharp proton signal at δ = −2.55 ppm[*][50] (−2.32 ppm[**][9]), the spectrum of $TDAE^{2+}$ contains two signals of equal intensity (δ = −2.90, −3.18 ppm[**], acetonitrile)[26]. The dimethylamino groups can evidently still rotate about

[88] *D. H. Anderson, R. M. Elofson, H. S. Gutowsky, S. Levine,* and *R. B. Sandin,* J. Amer. chem. Soc. *83,* 3157 (1961).

[c] Oxidation potential $\varepsilon_0 = 2.05\ m - 0.05$ V [87].

[d] β = 60 kcal/mole = 2.61 eV/molecule [87].

[e] For the radical-cation of *(1)*, $\lambda^{CH_3CN} = 517$ nm [10].

[f] β = 19 kcal/mole [87].

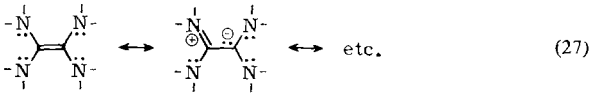
[g] Vibration spectrum (cm^{-1})

	νCC(A_g)	$\nu_s CN_2(A_g/B_{2u})$	$\nu_{as} CN_2(B_{1g}, B_{3u})$
TDAE	1630	?/1095	?/1337
$TDAE^{2+}$	1109	1541/1456	1671/1672

The following force constants have been calculated from the positions of the vibration bands [34]:
TDAE: f_{CN} = 5.80; f_{CC} = 9.4 mdyn/Å; $TDAE^{2+}$: f_{CN} = 9.71; f_{CC} = 6.85 mdyn/Å.

the C–N bond in TDAE[94], whereas they are sterically fixed in $TDAE^{2+}$ by the high C–N bond order. ESR spectroscopic studies indicate that the dimethyl amino groups in $TDAE^+$ are also fixed in the N_2C plane of the cation; thus the spectrum shows two types of hydrogen atoms in equal numbers (coupling constants a_N = 4.85 ± 0.01, $a_{H(1)}$ = 3.28 ± 0.01, $a_{H(2)}$ = 2.84 ± 0.01 G)[27]. Whereas the ESR spectroscopic studies indicate that the two N_2C halves in $TDAE^+$ lie in one plane[27], the NMR and vibration spectra of $TDAE^{2+}$ do not rule out the possibility of twisting of the N_2C halves about the central C–C bond[26]. The ESR spectrum of the compound *(1)* shows no fine structure (one signal, line width 5.4 G)[16].

The bond orders found experimentally from the vibration spectra for the CN and CC bonds (Table 7) agree with the "mobile bond orders" found from the HMO calculation. It can be seen from the table that the bond order of the TDAE double bond does not quite reach a value of 2, whereas the C–N bonds have additional double bond components. The free electron pairs on the nitrogen thus belong to the π system of TDAE:



(27)

The nitrogen accordingly also carries positive charge components and the carbon negative charge components of the π system (Table 7). However, the "mobile bond order", and hence the positive charge on the nitrogen, will be smaller than that calculated, since the HMO calculation did not take into account the rotation of the dimethyl groups around the C–N bond, which weakens the π interaction. Since the electronegative nitrogen also attracts electrons to itself *via* the σ-bond system, the nitrogen atoms in TDAE must again be regarded as negative centers of the molecule. The correctness of this view is also confirmed experimentally by the reaction of TDAE with acids (cf. Sections 3.2.1 and 3.2.2.). However, the situation is somewhat different for ethylenes of the type *(1)*, possibly because of ring strain and the impossibility of rotation of the nitrogen about the C–N bond (cf. Section 3.2.3).

[94] The energy barrier for rotation of the dimethylamino groups about the C–N bond is probably not very high since the resonance energy lost when the dimethylamino group is twisted out of the $(C_2N)_2C{=}C(NC_2)_2$ plane (max. 24 kcal/mole, see above) is counteracted by the energy gained on reduction of steric hindrance (cf. ref. [43a]).

4.3. Electronic Spectra of the System TAE^{n+} (n = 0, 1, 2)

The positions of the UV absorption maxima are given in Table 7. The UV spectrum of TDAE contains two bands: λ_{max}^{gas} = 265, 350 nm (shoulder)[50] ($\lambda_{max}^{n\text{-decane}}$ = 221, 270 nm[46]). TDAE*, life 1.9×10^{-8} sec, emits blue-green fluorescence. The position of the emission band depends on the solvent: $\lambda_{max}^{n\text{-decane}}$ = 485, $\lambda_{max}^{\text{no solvent}}$ = 505, $\lambda_{max}^{\text{dioxane}}$ = 550 nm[49]. The configuration of TDAE* is unknown. (The absorption band shows no fine structure.) It is assumed, however, that the N_2CCN_2 skeleton in TDAE* is not planar, but that the two N_2C halves are mutually perpendicular[49]. This is shown in particular by the large frequency shift of the absorption and emission bands (485–270 = 215 nm[95].) In the case of $[(C_6H_5)(CH_3)N]_4C_2$, the positions of the absorption and emission bands are almost identical[96].

According to the HMO scheme (Fig. 1), the transitions $b_{1u} \rightarrow b_{3g}$ and $b_{2g} \rightarrow b_{1u}$ in TDAE and $TDAE^{2+}$ should give absorptions in comparable positions; this is qualitatively confirmed in practice [λ (TDAE) = 221, 270; λ ($TDAE^{2+}$) = 205, 273 nm]. In view of the "rough calculation", only a very approximate agreement between the calculated and experimental UV data can be expected.

[95] ν(C=C) = 1630 cm^{-1}.

[96] *C. A. Heller*, unpublished.

Thus on the basis of the discussion in Sections 4.1–4.3, uncharged, charged, and excited TDAE probably have the structures shown in Figure 2.

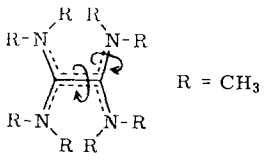


Fig. 2. Probable structures.
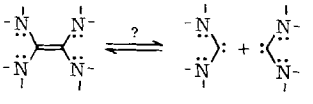
TDAE: rotation of the R_2N groups; $TDAE^+$: completely planar skeleton; $TDAE^{2+}$: N_2C halves may be twisted with respect to each other; $TDAE^*$: N_2C halves twisted through 90° with respect to each other.

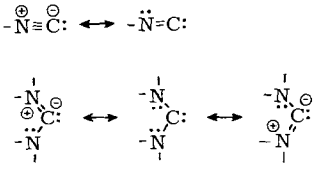
5. The Question of an Equilibrium TAE ⇌ 2 Carbene

We shall now consider the question of whether the TAE system exists in equilibrium with two diaminocarbene halves [reaction (28)].



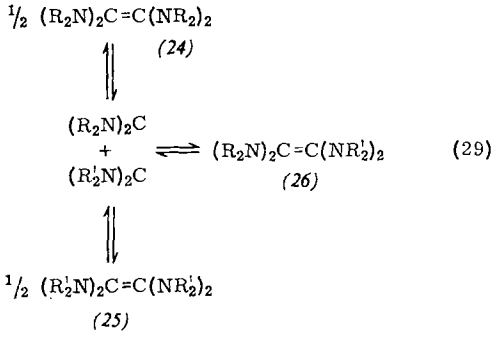
(28)

In recent years, a number of schools have been concerned with the answer to this question. The existence of carbon monoxide and of isocyanides, both of which are chemically related to diaminocarbene, and the stability of which is normally explained by resonance structures for the sake of simplicity, may be regarded as some justification for the posing of this question. If the doubly-bonded imino group in the isocyanides is replaced by two singly bonded amino groups, one obtains the carbene in question; the carbene should be more stable than the isocyanides, which can be characterized by two limiting structures, since it can be described by three limiting structures.



However, the mere fact that tetraaminoethylenes, unlike diisocyanides, actually exist shows that simple considerations of this type are not enough. Furthermore, contrary to earlier assumptions [6], a number of investigations have shown that the presence even of traces of the diaminocarbene in equilibrium with TAE can be ruled out.

Evidence against the dissociation of TDAE into bis(dimethylamino)carbene includes the mass spectrum [38], the ^{1}H-NMR spectrum [9], and chemical investigations in which attempts were made to remove the carbene from the equilibrium with TDAE by means of acceptors such as oxidizing agents or acids [62, 77]. Moreover, if traces of carbene were present in equilibrium with a tetraaminoethylene, an unsymmetrically substituted tetraaminoethylene *(26)* should be formed on reaction of two symmetrically substituted ethylenes *(24)* and *(25)*.



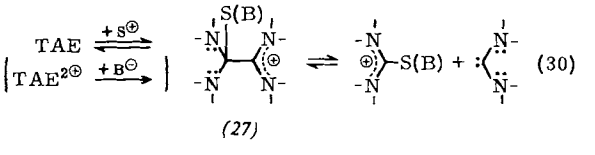
(29)

No unsymmetrical product could be detected even after reaction of TDAE and *(1a)* for one hour at 175 °C.

Attempts to obtain unsymmetrical products from *(1a)* and 1,1′,3,3′-tetra-*p*-tolylbiimidazolidinylidene [97] and from 1,1′,3,3′-tetraethyl- and 1,1′,3,3′-tetrabutyl-2,2′-biimidazolidinylidenes [12] were also unsuccessful.

An answer to the question of dissociation of TAE into carbenes can be estimated by a simple HMO examination [34]. The resonance energy of two molecules $[(CH_3)_2N]_2C$ is about 40 kcal/mole greater than that of TDAE if the Coulomb integral of the carbene carbon is taken to be approximately equal to that of the ethylenic carbon. It can also be shown by a simple HMO calculation that the resonance energy of two molecules of CF_2 is about 10 kcal/mole greater than that of $F_2C{=}CF_2$. Thus the cleavage of TDAE into carbenes is about 30 kcal/mole easier than the corresponding cleavage of tetrafluoroethylene if it is assumed as an approximation that the energy changes in the σ bond region associated with the cleavage are similar for C_2F_4 and for TDAE. Since 70 kcal/mole are required for the dissociation of C_2F_4 [98], the cleavage of TDAE into two carbenes requires about 40 cal/mole.

The formation of carbenes in the reaction of TAE with acids S^+ (Section 3.2.3) or of TAE^{2+} with bases B^- (Section 3.1.1) in accordance with reaction (30)



(30)

(27)

should, on the other hand, be energetically possible, since a new CS(B) bond is formed per CC bond broken [99].

The formation of TAE from aminals $(R_2N)_2CHX$ (cf. reaction (2)) could proceed according to

$$(R_2N)_2CHX \rightleftharpoons (R_2N)_2C + HX \qquad (31)$$

via a carbene, which could then react further in a reversal of reaction (30) or with dimerization to form TAE [100].

However, detailed studies will be required to determine whether carbenes are formed as such in reaction (30) or (31)

[97] *D. M. Lemal, R. A. Lovald,* and *K. I. Kawano,* J. Amer. chem. Soc. *86*, 2518 (1964).

[100] Cf. also *N. Wiberg* and *J. W. Buchler,* Z. Naturforsch. *19b*, 953 (1964).

or are only "transferred" in a transition complex. Evidence against the formation of free carbene in the reaction of TAE^{2+} with strong alkali is provided by the unsuccessful attempt to convert a mixture of the dibromide of TDAE and tetramorpholinoethylene into an unsymmetrical reaction product, 1,1-bis(dimethylamino)-2,2-morpholinoethylene by the action of sodium hydroxide solution [cf. reaction (8)] [101].

Though diaminocarbenes have considerable resonance stabilization, it is not sufficient for the cleavage of TAE into two carbenes. Stable carbenes are evidently formed only if both the electron vacancy and the free electron pair on the carbene carbon are chemically saturated [102]:

However, it is not yet certain whether compounds of this type (*e.g.* $R_2N^{\oplus}=C=B^{\ominus}R_2$, $R_3P=C=PR_3$, $R_2C=C=CR_2$) can still be regarded as carbenes [103].

6. Outlook

Tetraaminoethylenes are still a relatively new topic. While many surprising results for ethylene chemistry have appeared in the past six years, further surprises may be expected from these reactive compounds in the future. Apart from the practical interest that the tetraaminoethylenes deserve (*e.g.* for the qualitative and quantitative detection of oxygen and of electron acceptors with TDAE, the generation of electricity with TDAE, *etc.*), a detailed investigation of the electronic structure of TAE, TAE^{+}, TAE^{2+}, and TAE*, as well as of electron donor-acceptor complexes of tetraaminoethylene, should be of great value to the theory of π systems. However, the chemistry of tetraaminoethylenes is only a small part of the chemistry of peramino compounds of carbon. The preparation or investigation of compounds such as $(R_2N)_2C$, $(R_2N)_4C$ [105], $(R_2N)_3C-C(NR_2)_3$, and $(R_2N)C\equiv C(NR_2)$ [65] may be eagerly awaited.

I am indebted to A. N. Flechter, C. A. Heller, D. Lemal, and H. E. Winberg for valuable exchanges of information and for the communication of unpublished results. I should also like to express my gratitude to J. W. Buchler for his cooperation.

Memory Effects and Stereochemistry in Multiple Carbonium Ion Rearrangements [**]

BY J. A. BERSON [*]

The stereochemical configuration at the initial site of heterolysis in a carbonium ion process in solution controls the specificity of migration two steps later in many sequential multiple rearrangements. These "memory effects" are attributable to the presence on the potential energy surface of small, hitherto undetectable minima. A variety of structural, stereochemical, and isotopic marking techniques are used to demonstrate that memory effects are a general feature of the ring-expansion route to bicyclic carbonium ions. The intermediates formed in these reactions, although necessarily symmetrical or quasi-symmetrical at equilibrium, act unsymmetrically. The memory effect uses the rate of an intramolecular carbonium ion rearrangement as a calibration with which to compare the rate of symmetrization. In this way, the system functions as a sensor of sub-species.

1. Introduction

Much of our understanding of organic reaction mechanism derives historically from the search for solutions to intriguing puzzles of stereochemistry. The study of the phenomena we call "memory effects" is now at the point where experiment has progressed well beyond existing theory, and new principles therefore must emerge.

Stereochemistry controls the course of reaction not only when bond-making and bond-breaking are confined to a single carbon atomic center as, for example, in the familiar inversions that accompany nucleo-

[**] Part of this material was presented in a lecture at the Second EUCHEM Conference on Stereochemistry (Bürgenstock, Switzerland, May 1966).

philic substitution[1], but also when the process involves a center vicinal to that at which bond-breaking is initiated, as in the neighboring group effect[2].

In multiple carbonium ion rearrangements, such control can be exercised over sites of reaction even more remote. We call these phenomena *memory effects* and recognize their existence whenever two requirements are met: (i) a bond to a configurationally specifiable center of the reactant is broken, initiating a sequence of migrations, and (ii) the configuration of this center determines which of the potential migrating groups actually moves at each stage of the multi-step process. Superficially, the specificity of migration seems to be based on "memory" in that the set of instructions (or to pursue the biological parallel, the "engram") embodied in the original configuration guides the sequence even after one of the bonds at the initiating site no longer exists.

From the purely descriptive point of view, the study of these effects opens up a broad field of new rearrangements and intriguing stereochemical phenomena. But ultimately we are concerned with mechanism, that is, with the intimate structure of the energy-reaction coordinate surface. Memory effects serve as probes for the detection of small potential energy pockets which are impalpable by other means. The structures of the subspecies that occupy these energy minima and the precise way in which the original stereochemical "engram" is processed are subjects that have not yet passed much beyond the phenomenological stage. Before examining these questions, however, we may find it useful to discuss the bases for the characteristic stereochemical phenomena of three-center displacements and neighboring group effects. Then, after a description of several experiments demonstrating memory effects, their fundamental origin can be speculated upon.

2. Theoretical Basis of Stereochemical Control in Three-Center Displacements and Neighboring Group Displacements

Bimolecular nucleophilic (S_N2) displacement occurs with Walden inversion[3], even in the face of strongly countervailing electrostatic forces as in onium salt decompositions, where an anionic nucleophile attacks a cationic substrate[4]. In sharp contrast, electrophilic substitutions, including some specifically believed to be bimolecular (S_E2)[7], frequently give retention of configuration[5, 6]. This extraordinary pattern seems to correlate with the number of electrons involved in the reacting bonds. One therefore is stimulated to seek a common quantum-mechanical basis for the two kinds of result. A treatment of the transition state by molecular orbital methods[8] provides a simple theoretical picture[9, 10].

The substitution reaction can be approached naively as a three-orbital problem; the reacting centers form an array in which the central atom (B) and its two attached groups – the substituting agent (A) and the leaving group (C) – either are disposed linearly (A–B–C) or else form an acute angle. These correspond to the transition states of reactions giving, respectively, configurational inversion or retention at B. Regardless of what orbitals are chosen for the basis set, the idealized case will be one with equal bond integrals (β) between B and both A and C. For the linear, inversion-producing relationship of these centers, one can assume a zero A–C integral, which leads to an allyl-like set of energy levels: one bonding, one non-bonding, and one anti-bonding[1b, 11].

It is not obvious why this arrangement is so favorable in the nucleophilic case (S_N2) except by comparison with the set derived from the alternative geometry, in which the A–B–C angle is acute, corresponding to front-side substitution. This inevitably will produce a non-zero bond integral ($k\beta$) between A and C. Inclusion of this off-diagonal element in the secular determinant produces a cyclopropenyl-like arrangement of energy levels, one bonding and two anti-bonding. For any given value of k, the energy of the bonding orbital of the primitive linear case is lowered by an increment Δm_b, but that of the non-bonding level is raised (to anti-bonding, see Fig. 1) by a greater amount Δm_n. Therefore, the two-electron (electrophilic) system, in which only the bonding level is occupied, will prefer the triangular geometry. In the four-electron (nucleophilic) case, the stabilization of the bonding level produced by the finite A–C interaction in the triangular system is overbalanced because the anti-bonding level is doubly occupied. The linear, inversion-producing geometry therefore is preferred for nucleophilic displacement[12]. Of course,

[12] This treatment predicts that free-radical three-center displacements should show a rather low degree of stereospecificity, since the difference in energy between the linear and triangular systems in the three-electron case is small.

factors such as electrostatic forces, steric repulsions, and solvation effects, which are not taken into account by the simple LCAO approach, may dominate in some situations, but the basic quantum mechanical influences always will be at work.

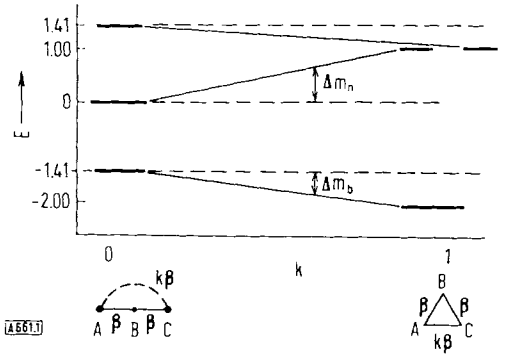

Fig. 1. Energy levels in units of β of the three-center system A—B—C as a function of the bond integral ($k\beta$) between A and C. In general, $|\Delta m_n| > |\Delta m_b|$.

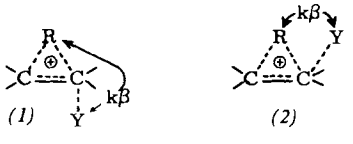
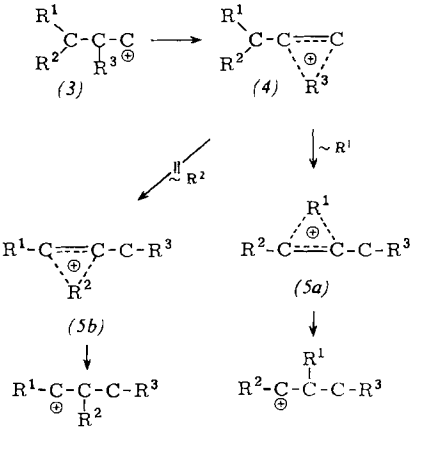
The same destabilizing effect of a front-side interaction occurs in the case of nucleophilic attack on a nonclassical carbonium ion or on the bridged intermediates responsible for the characteristic stereochemistry of neighboring group effects. These may be treated [10] as four-electron, four-center systems in which the nucleophile (Y) displaces the bridging atom (R) from a terminus of the bridge with either inversion [as in *(1)*] or retention [as in *(2)*].

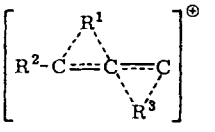


The bond integral ($k\beta$) in case *(2)* will be greater than in case *(1)*, and just as in the three-center system, the destabilization of the lowest anti-bonding level is greater than the stabilization of the bonding level.

3. Multiple Rearrangements

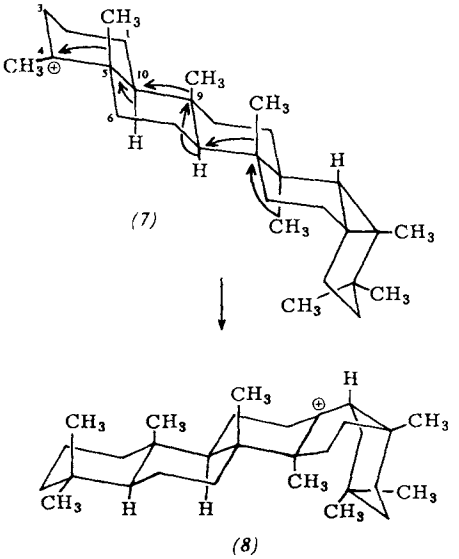
The role of Y in nucleophilic attack on bridged ions can be assumed, in a formal sense, by some internal nucleophile, such as a migrating hydrogen or alkyl group. As is borne out [10] by simple LCAO considerations, the preference for rear-side attack shown by external nucleophiles also should extend to such cases. This predicts that in the multiple rearrangement of *(3)*, shift of R^3 would be followed (or accompanied) by shift of the farther (R^1) rather than that of the nearer (R^2) group. The preference would hold regardless of whether R^1 and R^3 moved in discrete steps [with *(4)* as an intermediate] or simultaneously [one five-center transition state with structure *(6)*].





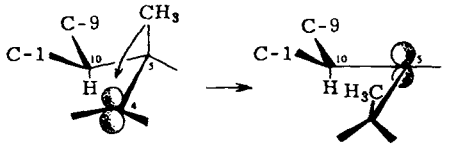
Even when nonclassical bonding is absent and hence front-side migration can occur readily, other influences may still enforce strong rear-side selectivity in the rearrangement steps that follow the initiating one. Conformational effects are potent factors of this kind and may well be influential in the remarkable multistep "backbone" rearrangements of polycyclic terpenoids [13], in which only the extra-annular groups migrate.

An example involving several such steps is that of the friedelanyl cation *(7)*, which rearranges to a cation *(8)* of the β-amyrin series. The selectivity of these transformations does not necessarily signify a "synchronous" or "concerted" multiple migration *via* a single transition state *(6)* or a step-wise process *via* discrete nonclassical intermediates *(4)*, but may also result from a series of classical ions. At each stage of such a process, the extra-annular group (H or CH_3) at the position vicinal to the electron-deficient center is bound by an orbital whose axis is nearly parallel to, and hence in excellent position to interact with, that of the empty p-orbital, whereas the corresponding orbital binding a ring carbon is badly displaced from this favorable orientation. These relationships are shown in *(9)*, which is an excision of part of the "backbone" of *(7)*. Migration of CH_3 from C-5 to C-4 leaves the C-10 hydrogen in a more favorable posi-



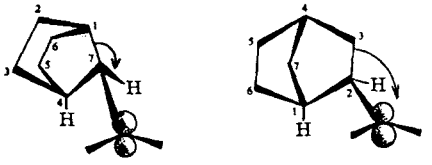
[13] For a review, see *inter alia J. F. King* and *P. de Mayo* in *P. de Mayo*: Molecular Rearrangements. Interscience, New York 1963, Part Two, Chapter 13.

tion than either C-1 or C-9 for a subsequent migration. The rearrangements of the extra-annular groups therefore are expected to be preferred, regardless of whether the intermediates are classical or nonclassical, and the observed memory effects are explicable without recourse to any special theoretical formulation. The truly novel aspects of memory effects emerge only when the commonplace stereoelectronic and conformational features are absent.



(9)

4. Forced Migration of Improperly Situated Groups



(10) *(11)*

Incorporation of the fragment *(9)* in a bridged bicyclic system, *e.g.*, *(10)* or *(11)*, prohibits migration of the bridgehead hydrogen [at C-4 of *(10)* and C-1 of *(11)*, which correspond stereoelectronically to the most favorable group, the C-10 hydrogen of *(9)*] because of the inability of the bridgehead carbon to assume a trigonal configuration. One of the ring carbons thereby is forced to migrate in the second step of the multiple rearrangement. Neither of these is in a good position to interact with the p-orbital left vacant if the first ring-expanding rearrangement leads to a classical cation, nor can either readily attack the rear side of a mesomeric bridged ion if the ring-expansion leads to a nonclassical intermediate. Such systems therefore put forward a new problem: Is memory preserved despite the attenuation of the normally dominant stereoelectronic factors? The following examples show that it is.

5. Ring-Expansions of 2-Norbornylmethyl Derivatives

The geometric restrictions embodied in structure *(11)* are met in 2-*endo*- and 2-*exo*-norbornylmethyl systems [*(12)* and *(13)*]. Studies by *Alder* and his coworkers [14] show that the deaminative ring-expansion of the *endo*-amine gives a different set of products than that obtained from the *exo*-amine. Later work on the deaminations and on solvolyses of arenesulfonates elucidates further mechanistic details and leads to a formulation [15,16] which is shown in Scheme 1. The systems derived from *(12)* and *(13)* are prototypes of a number of other examples. Scheme 2 summarizes the common phenomena of memory effects in sym-

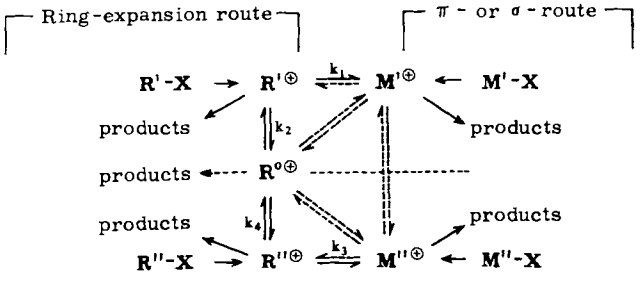
bolic form. The dashed arrows represent reactions observed in some but not all of the systems studied. To aid in comparisons, the reactants and unstable entities of Scheme 1 are labeled both with ordinal numbers and with boldface letters, which are also used in Scheme 2.



Scheme 2. Generalized scheme of memory effects.

The first cationic intermediate *(14)* from the *endo* ring expansion has a chair cyclohexane ring, whereas the cation *(15)* from the *exo* has a boat. If conformational interconversion of *(14)* and *(15)* were fast, crossover between the two systems would occur, and the products would be the same or nearly so from either *endo* or *exo* starting material [*(12)* and *(13)* respectively]. In fact, however, crossover is not extensive, and the conformationally isomeric cations *(14)* and *(15)* are trapped, both by external nucleophiles and by further intramolecular bond rearrangements [*(14)* → *(16)* and *(15)* → *(17)*].

The specificities of the second rearrangement steps constitute memory effects. Although the stereoelectronic alignments of the potential migrating bonds, (C-1)–(C-8) and (C-1)–(C-7), are not particularly good in either *(14)* or *(15)*, models suggest that the (C-1)–(C-8) bond in *(14)* and the (C-1)–(C-7) bond in *(15)* would be favored for further rearrangement [15,16], in accord with the observations.

Two kinds of access into the Schemes 1 and 2 may be recognized. From the right one forms cationic intermediates by interaction of the electron-deficient center with a nearby π- or σ-system. This mode of entry provides no opportunity for a memory effect to operate, since only one rearrangement or bond-delocalization step is involved, but it permits the generation by "conventional" routes of the cations ($M'^{\oplus}$ and $M''^{\oplus}$) which are the products of the *two-step* path in the ring-expansion route. The behavior of the cations formed by the π- or σ-routes serves as a standard of comparison for those formed by the ring-expansion route. For example, in Scheme 1, *(16)* is generated from 4-cycloheptenylmethyl or 2-*endo*-bicyclo[3.2.1]octyl precursors [*(18)* [17] or *(19)* [18]], and *(17)* from 3-cyclohexenylethyl, 2-*exo*-bicyclo[3.2.1]-octyl, or 2-bicyclo[2.2.2]octyl precursors [*(20)* [20], *(21)* [18], or *(22)* [18,19]].

From the left in Schemes 1 and 2, the entry is by ring-expansion. In the specific case of Scheme 1, the first-formed ring-expanded cations *(15)* and *(14)* are conveniently represented as boat-chair conformational isomers which interconvert by way of a transition state *(15a)* $R^{0\oplus}$. In other cases, however, $R^{0\oplus}$ is a quasisymmetric or truly symmetric intermediate from which products may be formed directly. This path is indicated in Scheme 2. In the generalized scheme, transformations of $R'^{\oplus}$ to $M'^{\oplus}$ and of $R''^{\oplus}$ to $M''^{\oplus}$ occur by second rearrangements or bond delocalization processes, which compete with crossover (interconversion of $R'^{\oplus}$ and $R''^{\oplus}$).

The competition between intramolecular trapping and crossover, measured by the ratio of rates of the reactions $R'^{\oplus} \rightarrow M'^{\oplus}$ (k_1) and $R'^{\oplus} \rightarrow R^{0\oplus}$ (k_2) gives a quantitative estimate of the magnitude of the memory effect, that is, the efficiency with which the system follows the "instructions" embodied in the specific stereochemistry R′–X. Ideally, one would prefer that the only crossover occur at the stage of the first-formed ring-expanded cations $R'^{\oplus}$ and $R''^{\oplus}$. Then the desired ratio of rates can be deduced from the product distribution data. In this kind of system, those cations which have suffered two successive rearrangements remain on a given side of the dotted line, that is, $M'^{\oplus} \rightleftharpoons M''^{\oplus}$ interconversion is negligible, and all of the selectivity inherent in the ratio of rates k_1/k_2 remains in the observed products.

The conditions for the ideal situation are that $R'^{\oplus} \rightarrow M''^{\oplus}$ be essentially irreversible and that direct as well as indirect interconversion of $M'^{\oplus}$ and $M''^{\oplus}$ be very slow relative to capture of the cations as final products. Although a few systems meet the ideal requirements, many of them form doubly rearranged cations ($M'^{\oplus}$, $M''^{\oplus}$) that drift across the barrier to some extent. The product ratios then give too pessimistic an estimate of the memory effect. This is not an insuperable difficulty, and corrections for it can be made from independent studies of the properties of $M'^{\oplus}$ and $M''^{\oplus}$ generated in the π- or σ-route entry (from the right side of Scheme 2).

The characteristic stereochemical feature of the memory effect is not given by the symbolism of Scheme 2 and must be stated separately. In all cases, the preferred migrating group in the second rearrangement step is the one that was originally remote from the site of the leaving group in the starting material [*e.g.*, C-7 rather than C-6 in the *endo*-norbornylmethyl-system *(12)*].

6. Persistence of the Memory Effect in a System of Low Conformational Stability

If the memory effect were solely caused by a conformational barrier inhibiting rapid interconversion of the isomeric cations $R'^{\oplus}$ and $R''^{\oplus}$ (Scheme 1), it should diminish greatly or completely disappear in systems so rigid that "conformations" represent very shallow

energy minima. The cations *(25)* and *(26)* produced in the ring-expansions of *syn-* and *anti*-norbornenylmethyl derivatives [21, 22] *(23)* and *(24)* are drawn here in "twisted" representations merely as a graphic device to distinguish them from the quasi-symmetric cation *(27)* $R^{0\oplus}$. Although physical evidence on the conformations of bicyclo[2.2.2]octenes is sparse, molecular models of this ring system are rather resistant to twisting distortions, and it seems unlikely that there can be a large barrier separating the two cations from each other or from the quasi-symmetric cation *(27)*. Nevertheless, memory is preserved.

The products in this system are derived from cations G (R = H) and L, which do not interconvert appreciably under the conditions and thus constitute an ideal pair for the preservation of whatever memory inheres in *(25)* and *(26)*. Cations G and L already had been encountered in solvolyses, G from *endo-* and L from *exo*-2-bicyclo[2.2.2]oct-5-en-2-yl substrate [*(28)* [23] and *(29)* [24]]. Cation G generated from optically active *(28)* gives largely the completely racemic alcohol bicyclo[3.2.1]oct-3-en-2-ol *(30)* derived from attack at equal rates at both sites of the symmetrical allylic cation system *(27)* [23]. That the product-forming cation from the ring-expansion starting with *(23)* is also G is demonstrated in the deamination of *syn*-[7-D]-7-

[e] Ratio of products of the L-series to those of the G. [f] 100 (L − G)/(L + G). [g] This value may be as much as 0.5 unit too low because of difficulty in analysis for a minor L-component. [h] Ratio of products derived from migration of the R_2 *vs* R_1-labeled bridges. [i] Duplicate runs. [j] A correction for drift is not yet available for this result, which is therefore a minimum measure of the true selectivity. [k] PVA = polyvinyl acetate sufficient to cause a 15-fold increase in viscosity. [l] 90 % formic acid, 10 % pyridine (v/v). [m] 94 % water, 6 % acetic acid (v/v). [n] Duplicate combustion and falling drop analyses for deuterium. [o] Data for parts A and B of Table are from refs. [21, 25], and *D. Donald*, unpublished observations. For part C. ref. [26] and *W. J. Libbey*, unpublished observations. [p] Ns = *p*-NO_2-$C_6H_4SO_2$. [q] Bs = *p*-Br—$C_6H_4SO_2$.

norbornenylamine *(23)*, R = D, X = NH_2, which gives[25] product from G (R = D), in which exactly half the deuterium is at each bridgehead [*(30)*, R = D]. Similarly, the product distribution from L generated from *(24)* is essentially the same[21,25] as that generated from *(29)*[24], where the major product is the tricyclic alcohol *(31)*.

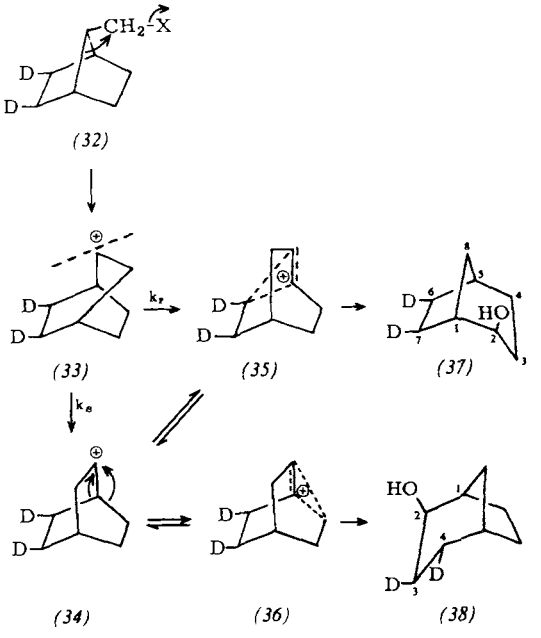
Table 1 shows that in all cases, the ratio (G/L) of products from the two cations is higher from the *syn* starting material *(23)* than from the *anti (24)*.

The ratio G/L has a range of about 200, from 5:1 in the *syn* series to 1:40 in the *anti*. In a formal conformational representation these results fall into the same pattern observed in *(12)* and *(13)*, where chair-boat isomers, the ring-expanded cations *(14)* and *(15)*, are imaginable. The specificities of the follow-up rearrangements would be plausible if *(25)* and *(26)* were twisted in the sense shown, since the p-orbital axis (dotted line) at C-2 in each then would point toward the (C-1)–(C-7) σ-bond in *(25)* and toward the π-bond in *(26)*. Which cation [*(25)* or *(26)*] is the more selective in the second rearrangement step is difficult to ascertain, since the quasi-symmetric cation *(27)* itself has an intrinsic but unknown selectivity for further bond delocalization to G or L. The observed product distribution from, for example, the *syn* substrate *(23)* therefore results not only from the competition that measures the memory effect [the relative rates of *(25)* → G and *(25)* → *(27)*] but also from the "natural" ratio that determines the distribution of the quasi-symmetric cation [the relative rates of *(27)* → G and *(27)* → L].

7. Crossover *via* a Truly Symmetrical Cation. Ring-Expansions of 7-Norbornylmethyl Derivatives

The two ethylene bridges of a 2-bicyclo[2.2.2]octyl cation can be distinguished from each other with an isotopic label, which permits the examination of memory effects in the saturated 7-norbornylmethyl system *(32)*. The unsymmetrical cation, shown here as a twisted species *(33)* for explication, can preserve the distinction between the labeled and unlabeled bridges if migration of one of them occurs at a rate that is not very much slower than conversion to the symmetrical cation *(34)*.

The "natural" partition ratio for *(34)* is unity because the follow-up rearrangements *(34)* → *(35)* and *(34)* → *(36)* necessarily proceed at the same rate (except for a small secondary isotope effect). Therefore, after correction for the drift that partially interconverts their precursor cations *(35)* and *(36)*[16,18,19] the excess of 6,7-labeled 2-bicyclo[3.2.1]octyl product *(37)* over the 3,4-labeled counterpart *(38)* represents the preference for migration of the bridge that was *anti* to the leaving group in the starting material and thereby directly measures the memory effect.



Rearrangements of *anti*-labeled substrates *(32)* (X = NH_2 or arenesulfonate) and of the corresponding *syn*-labeled series[26] (Table 1) show that memory is preserved[27a]. In the acetolysis of the *p*-bromobenzenesulfonate *(32)*, for example, the experimental ratio *(37)*/*(38)* of 1.4 leads, after correction for drift, to a competition ratio $k_s/k_r = 2$. That is, about one-third of the twisted cations *(33)* are trapped by bond rearrangement, and the remainder achieve the symmetrical condition[27b].

8. The Nature of the "Twisted" Cations

So far we have resorted to a purely phenomenological description of the species responsible for memory effects. From the results of further studies of the systems already mentioned[28,29] and those of additional ring-expansions in the nortricyclylmethyl[30], 1-methyl-2,3-

[25] *J. J. Gajewski*, Ph. D. Dissertation, University of Wisconsin, 1965.

[27a] This is not a consequence of a secondary isotope effect, since the migratory aptitude of a *syn*- or *anti*-$C_2D_2H_2$ bridge is observed to be virtually the same as that of a *syn*- or *anti*-C_2H_4 bridge, respectively [26].

[27b] The 33% efficiency of preservation of memory is derived on the assumption that bond rearrangement *(33)* → *(35)* is completely stereospecific. To the extent that some direct trapping in the opposite stereochemical sense occurs [*(33)* → *(36)*], the calculation overestimates the importance of the symmetrization path *(33)* → *(34)*.

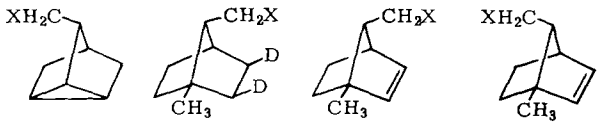
dideuterio-*syn*-7-norbornylmethyl[31] and 1-methyl-2-norbornenyl-*syn* and *anti*-7-methyl[32] systems [*(39)*, *(40)*, *(41)*, and *(42)*], we have concluded that the multiple rearrangements are most readily formulated as step-wise rather than concerted processes. The "twisted" cations therefore are true metastable intermediates, occupying minima in the potential energy surface of the reaction. The evidence for this conclusion comes from experiments on extramolecular capture and from the influence of methyl substitution on the memory effect.



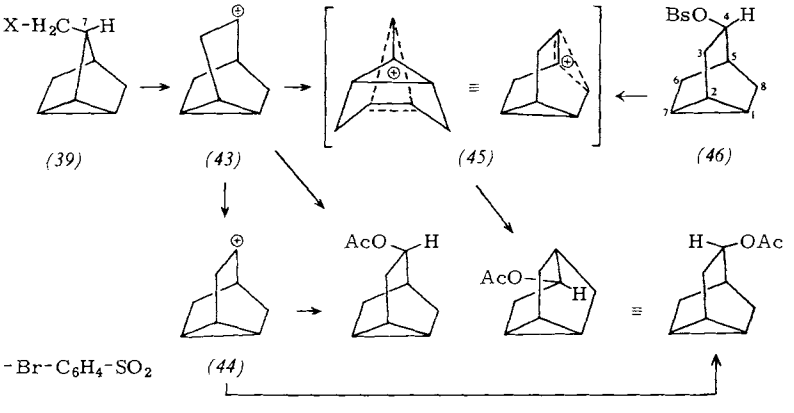
(39) *(40)* *(41)* *(42)*

8.1. Capture of the Once-Rearranged "Twisted" Species by External Nucleophiles

Scheme 2 shows a path providing for formation of product by nucleophilic capture of the first-formed, once-rearranged cation (*e.g.*, $R'^{\oplus}$) in the ring-expansion route. Evidence for the occurrence of this reaction at a rate competitive with that of the second rearrangement step (intramolecular trapping) is available from the chemistry of the chair 2-bicyclo[3.2.1]octyl cation *(14)*. Although a substantial fraction of these cations elude capture by external nucleophile and rearrange to the symmetrical nonclassical ion *(16)*, some of them are trapped before the bond delocalization step. The ring-expansion of optically active *(12)* thus leads to only partially rather than completely racemized *endo*-bicyclo[3.2.1]octyl product [*e.g.* *(14a)*][15]. However, the second rearrangement step apparently is fast enough to outstrip nucleophilic capture in some cases. For example, in the *syn*- and *anti*-7-norbornenylmethyl systems, the amount of bicyclo[2.2.2]oct-5-en-2-yl product is not observably greater when the "twisted" cationic intermediates *(25)* and *(26)* are generated by ring-expansion[21,25] than when the system is entered by conventional solvolyses of the *endo*-[23] and *exo*-bicyclo[2.2.2]oct-5-en-2-yl[24a] substrates *(28)* and *(29)*.

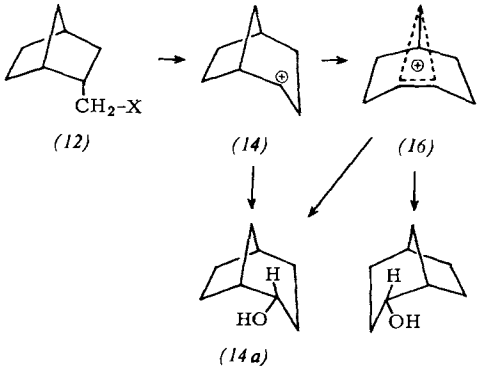
In the analogous saturated system, 7-norbornylmethyl *(32)*, the mixture of 2-bicyclo[2.2.2]- and 2-bicyclo[3.2.1]octyl derivatives formed in the ring-expansion contains a proportion of 2-bicyclo[2.2.2]-octyl product only slightly greater than that obtained[18–20] in solvolysis by conventional π- or σ-routes[26,28].

External nucleophilic capture of the cationic intermediate after one rearrangement step is also detectable in the ring-expansion of optically active 3-nortricyclylmethyl derivatives *(39)*[30,33].



(39) *(43)* *(45)* *(46)* *(44)*

Bs = *p*-Br-C_6H_4-SO_2



(12) *(14)* *(16)* *(14a)*

Rearrangement of one of the two nonequivalent ring members from C-7 to the methylene side chain produces a twisted tricyclo[3.2.1.$0^{2,7}$]octyl cation *(43)* which can lose optical activity either by conversion to the symmetrical ion *(44)* or by bond delocalization, which converts it into optically inactive non-classical ion *(45)*, an intermediate or transition state for the second rearrangement step. This second step occurs readily when the cations are generated by conventional solvolyses of tricyclo[3.2.1.$0^{2,7}$]octyl derivatives *(46)*, as is shown by the equilibration of a deuterium label equally between C-4 and C-5 in the product from [4D]-*(46)*[30b,33b]. The tricyclo[3.2.1.$0^{2,7}$]octyl product from optically active tricyclo[3.2.1.$0^{2,7}$]octyl substrate *(46)* is virtually completely racemized[30b], yet that from the ring-expansion retains about 24 % of

[31] *J. Foley*, unpublished observations.

[32] *J. M. McKenna*, unpublished observations.

[33] Previous studies on this and related systems have been carried out in the racemic series by a) *K. B. Wiberg* and *G. Wenzinger*, J. org. Chemistry *30*, 2278 (1965); b) *R. R. Sauers*, *J. A. Beisler*, and *H. Feilich*, *ibid. 32*, 569 (1967); c) *A. K. Colter* and *R. C. Musso*, *ibid. 30*, 2462 (1965).

its optical purity in arenesulfonate acetolysis or in deamination. From the absolute configurations of the starting nortricyclylmethyl substrate[30a] and tricyclo[3.2.1.$0^{2,7}$]octyl product[30b], it is established that the nucleophilic trapping of the twisted cation *(43)* occurs from the same side as the departure of X ($OSO_2-C_6H_4-Br(p)$ or $N_2^{\oplus}$) from *(39)*.

8.2. "Twisted" Cations as True Metastable Intermediates

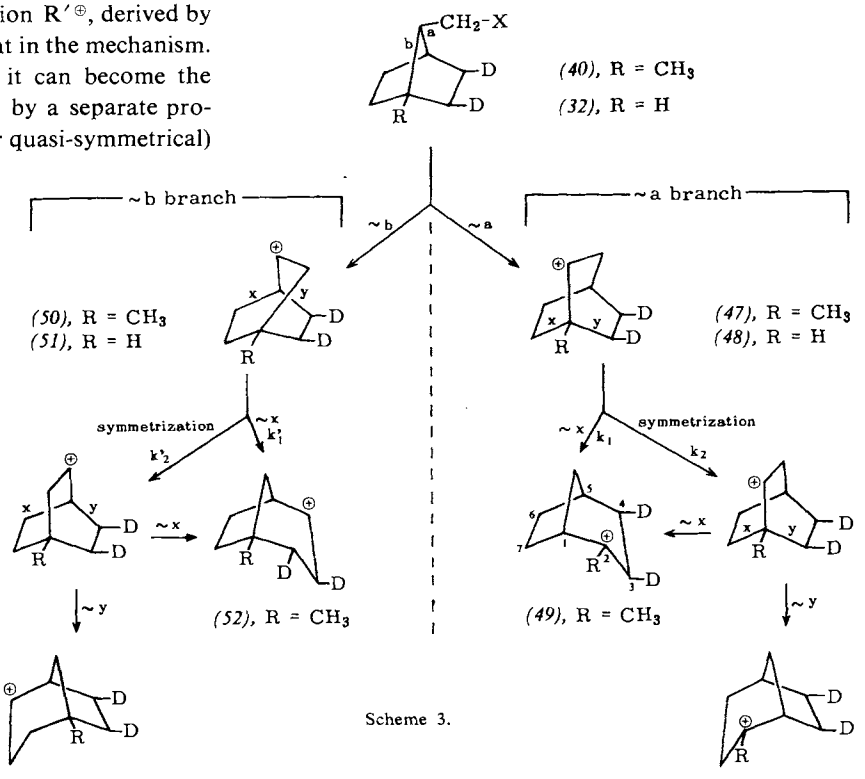
Scheme 2 shows the "twisted" cation $R'^{\oplus}$, derived by ring expansion, as a branching point in the mechanism. By a second rearrangement step, it can become the twice-rearranged cation $M'^{\oplus}$, and by a separate process, it can become symmetrical (or quasi-symmetrical) ion $R^{0\oplus}$.

The question might be raised whether the energy surface could include a small minimum after the transition state of the ring-expansion but that this minimum is by-passed by points descending from the transition state with more than enough excess vibrational energy to overcome the small second barrier. $R'^{\oplus}$ might then be considered to be a vibrationally excited form of the symmetrical cation $R^{0\oplus}$. It will seldom if ever be necessary, however, to consider explicitly such vibrationally excited entities in solution. Collisions with solvent molecules will deactivate the excited $R'^{\oplus}$ by energy transfer at a rate that is within an order of magnitude of a molecular vibration. A reaction of $R'^{\oplus}$ competing with collisional deactivation (*e.g.*, the second rearrangement step $R'^{\oplus} \rightarrow M'^{\oplus}$) therefore would have to have an activation energy not much greater than RT (<1 kcal/mole even at 100 °C). The small second barrier in question would become no obstacle, and the reaction would have, for all practical purposes, only one transition state.

9. Unsymmetrically Substituted Systems. Change in the Competition Ratio

If $R'^{\oplus}$ is an energy minimum, the rearrangement from R′–X to $M'^{\oplus}$ proceeds in two discrete steps, the second of which competes with symmetrization to $R^{0\ominus}$. If the second rearrangement step is initiated before the first is completed, the rearrangement of R′–X to $M'^{\oplus}$ then is a concerted double migration passing over only a single transition state and competing with processes $R'-X \rightarrow R^{0\oplus}$ and/or $R'-X \rightarrow M''^{\oplus}$. Recent evidence on the behavior of unsymmetrically substituted systems strongly favors the first of these possibilities.

In the ring-expansion of the *syn*-[2,3-D_2]-1-methyl-7-norbornylmethyl derivative *(40)*, the unsymmetrically placed bridgehead substituent renders nonequivalent the bonds a and b available for the first rearrangement step. Migrations of a or b lead to the corresponding



Scheme 3.

"twisted" cations *(47)* and *(50)*. The distribution of starting material between these two branches is not of great concern in the present context, as long as some of the reaction goes by each path. The mechanistically significant branching points occur at the next rearrangement stage. If the "twisted" cations are true intermediates and their stereochemical behavior is controlled by Scheme 3, then competition occurs between intramolecular entrapment by a second rearrangement (k_1 and k_1') and symmetrization by some process (k_2 and k_2').

Although the nature of the symmetrization step remains to be discussed, it seems reasonable to suppose that these rates (k_2 and k_2'), whether they involve a conformational change or some kind of extramolecular process (see Section 11), should not be sensitive to methyl substitution. On the other hand, the rates of the second migration step (k_1 and k_1') should be very sensitive.

The second step (~x) in the path initiated by ~b involves conversion of a secondary cation *(50)* to a rearranged secondary cation *(52)*. The methyl substituent is at a remote position and should exert only a feeble effect. Therefore, the ~x step should proceed at

a rate k_1' not greatly different from that in the "twisted" cation *(51)* lacking the methyl group. In the second rearrangement step (~x) of the path initiated by ~a, the "twisted" secondary cation *(47)* is converted into a rearranged tertiary cation *(49)*. The methyl group is directly attached to the site of developing positive charge and provides a large kinetic driving force. One would predict, therefore, that k_1/k_2 in *(47)* should be greater than k_1'/k_2' in *(50)*; that is, the selectivity for

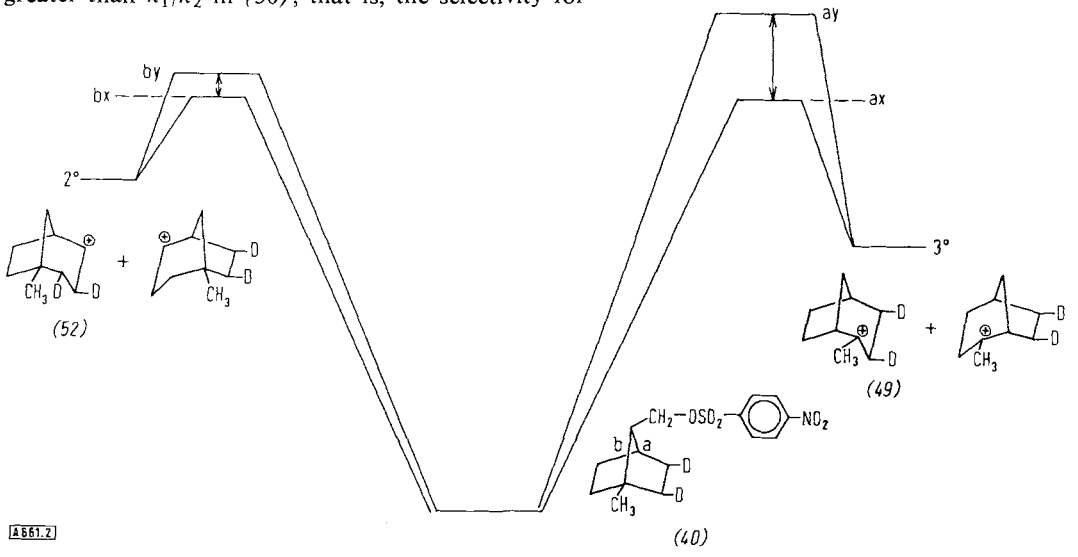


Fig. 2. Energy surface for the acetolysis of [2,3-D_2]-*syn*-1-methyl-7-norbornylmethyl *p*-nitrobenzenesulfonate *(40)* by a double rearrangement mechanism.

total amounts of products derived from the ~a and ~b branches are about equal, but whereas the part derived from the ~b branch shows [34] a selectivity (k_1'/k_2') that is nearly the same as that observed [26] in the unsubstituted series *(32)* the selectivity in the ~a branch is substantially higher [34].

These results are difficult to reconcile with a concerted double rearrangement mechanism having an energy surface like Fig. 2, where the two rearrangement steps in each branch are telescoped into one. In the ~a branch, leading to tertiary doubly rearranged cation *(49)* or its [6,7-D_2]-isomer, the reactants would pass over either single transition state ax or

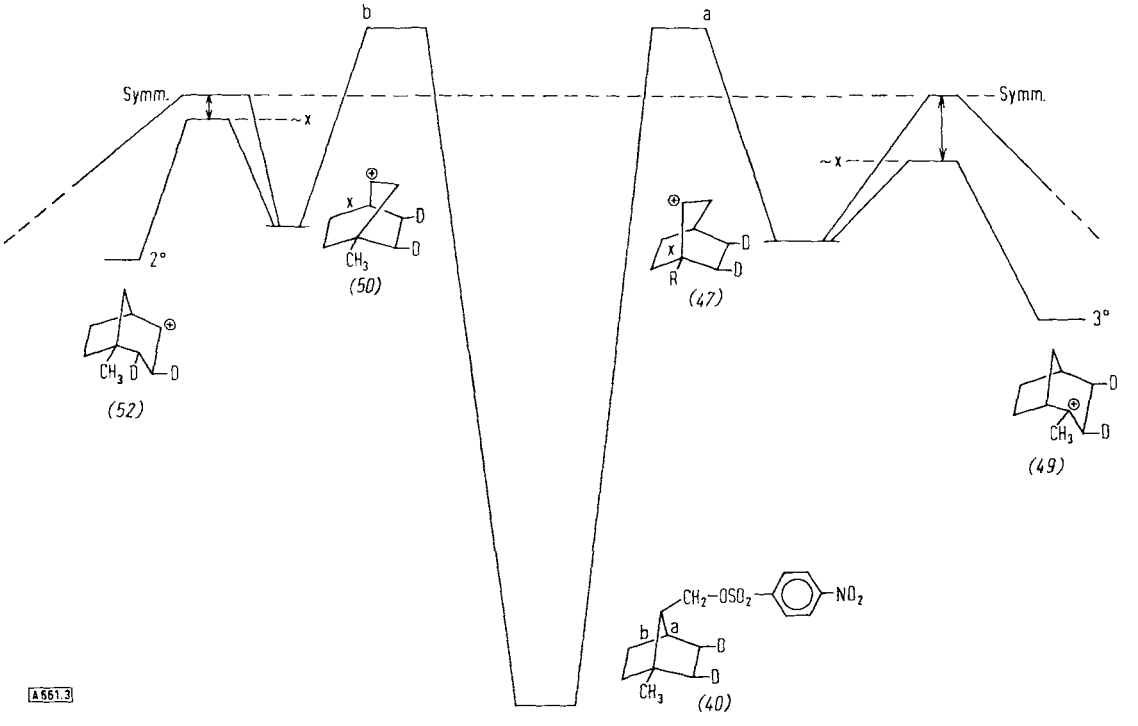

Fig. 3. Energy surface for the acetolysis of [2,3-D_2]-*syn*-1-methyl-7-bornylmethyl *p*-nitrobenzenesulfonate *(40)* by a stepwise mechanism. Symm. = symmetrization.

stereospecific migration of x in the branch of the ring expansion of *(40)* initiated by ~b should be about the same as that in *(32)*, but this selectivity in the ~a branch should be substantially higher.

These predictions are confirmed in the acetolysis of [2,3-D_2]-*syn*-1-methyl-7-norbornylmethyl-*p*-nitrobenzenesulfonate *(40)*, X = $OSO_2-C_6H_4-NO_2(p)$. The

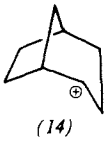
[34] a) *J. Foley*, unpublished observations; b) Similar investigations are under way in the unsaturated series 1-methyl-*syn*- and 1-methyl-*anti*-7-norbornenyl derivatives (*J. M. McKenna*, unpublished observations); c) The selectivity in the second stage of ring expansion of a 1-methyl-2-*endo*-norbornylmethyl derivative is considerably higher than in the case of the unsubstituted compound (*H. Junge*, unpublished).

single transition state ay. In the ~b branch, leading to secondary doubly rearranged cation *(52)* or its [6,7-D_2]-isomer, reactants would pass over single transition states bx or by. The selectivities in each branch would be determined by the differences $F_{ay} - F_{ax}$ and $F_{by} - F_{bx}$. The experimental facts given would have to be interpreted as being caused by a much larger difference between the competing transition states in the ~a branch than in the ~b branch ($F_{ay} - F_{ax} > F_{by} - F_{bx}$). The difficulty with this interpretation is that it is not obvious why one of the four transition states should be so much higher in energy than the other three.

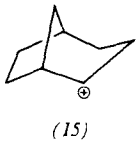
On the other hand, a very natural explanation for the observed behavior emerges from the step-wise mechanism (Fig. 3). Once the first barrier a or b is passed in the ring-expansion step, intermediate once-rearranged secondary cations [*(47)* and *(50)*] of very nearly equal energies result. The relative heights of the a and b barriers for this first step are not readily predicted, but it would not be surprising if they were nearly the same and if, consequently, the starting material were about evenly divided between the ~a and ~b branches, as is observed. The major point, however, concerns the second step. There the further partitioning of the individual once-rearranged "twisted" cations so as to favor ~x *vs.* symmetrization *specifically in the a branch* is clearly to be expected. The "twisted" cations $R'^{\oplus}$ are thus most simply formulated as true intermediates. They are unsymmetrical and can be trapped intramolecularly or intermolecularly before symmetrization. The major remaining problem concerns the source of their asymmetry.

10. Possible Intramolecular Origins of Memory Effects

In the earliest examples of the memory effect [ring-expansion of the 2-norbornylmethyl derivatives *(12)* and *(13)*], the first-formed cations *(14)* and *(15)* were



(14)

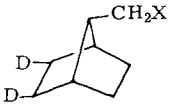


(15)

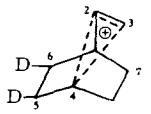
(33)

thought to be conformational isomers of the chair-boat cyclohexane type. Although it is easy to visualize an energy barrier for interconversion of these cations, and such a barrier may well contribute to the observed mechanistic insulation from each other of the 2-*endo* and 2-*exo*-norbornylmethyl systems, it is clear that cyclohexane-type conformational isomerism is not a requirement for the operation of the memory effect. In the case of 2-bicyclo[2.2.2]octyl cation, molecular models suggest that any barrier between the twisted form *(33)* and its enantiomer must be very small. Further, although one perhaps might not be surprised if bicyclo[2.2.2]octane preferred to exist in a slightly twisted conformation so that the vicinal hydrogen-hydrogen repulsions of the symmetrical eclipsed form would be relieved[35], large departures from the eclipsed form would not be expected[36f, 36g]. The weight of physical evidence from X-ray crystallography and infrared-Raman spectroscopy on the parent hydrocarbon and some of its derivatives is compatible with the eclipsed or almost eclipsed structure[36]. It seems likely that any conformational barrier separating twisted and eclipsed forms or enantiomeric twisted forms must be small. Introduction of a double bond into the bicyclo[2.2.2]octyl cation system to give bicyclo[2.2.2]octenyl cation results in an even stiffer structure. If one, nevertheless, insists upon a conformational rationalization of the observed behavior in these cases, the memory effect then constitutes a very sensitive probe for small conformational minima.

Nonclassical bonding might be another imaginable intramolecular source of asymmetry. Thus, in the ring-expansion of 7-norbornylmethyl derivatives *(32)*, the "twisted" cation might be assigned the nonclassical structure *(53)*, in which partial bonding of C-4



(32)



(53)

to C-2 and C-3 makes the two faces of C-2 nonequivalent. This explanation is not very satisfactory, since opening of the mesomeric bridge should occur with inversion, whereas neither C-6 nor C-7 is in a favorable position to accomplish this. The reason for the observed specificity C-6 > C-7 in the second rearrangement step therefore is not immediately evident. A possible explanation comes from consideration of a model which shows that the (C-1)–(C-7) bond axis lies almost in the nodal plane of the (C-2)–(C-3) π system. The (C-1)–(C-7) σ electrons therefore cannot interact with the π system. In contrast, the (C-1)–(C-6) bond axis assumes an angle of about 60° to the π nodal plane. The (C-1)–(C-6) σ electrons cannot approach from the preferred rear side of the π system, but if bond migration does take place in spite of this, then the only bond interaction possible is that between the (C-1)–(C-6) σ electrons and the front side of the π system. If this interpretation is correct, the memory effect is a much more sensitive test for nonclassical intermediates than any previously used technique.

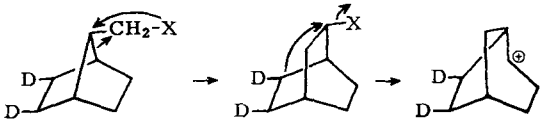
11. Possible Extramolecular Origin of Memory Effects

Since the intermediates in these rearrangements are formed in solution, any temporarily asymmetric arrangement of this extramolecular environment might persist long enough to evoke a correspondingly asymmetric response, even from a cation of intrinsically symmetrical constitution. Several potential sources of such effects might be imagined.

Perhaps the most obvious of these is ion-pair return. In the case of 7-norbornylmethyl arenesulfonate solvolysis, for example, stereospecific ion-pair return from *(32)*, X = $SO_2-C_6H_4-Br(p)$ to [5,6-D_2]-bicyclo-[2.2.2]octyl-2-*exo*-*p*-bromobenzenesulfonate *(54)* followed by anchimerically assisted solvolysis of the latter would produce qualitatively the observed pattern of the memory effect, that is, preferred migration of the *anti* bridge in the second rearrangement step.

In detail, however, this process cannot be responsible for all of the memory effect, which occurs not only in solvolysis but also with equal or greater selectivity in deamination *e.g.* of



(32) *(54)*

(32), X = $N_2^{\oplus}$. The return process in deamination would involve molecular nitrogen, which if it traps the once rearranged cation at all, should do so with much lower efficiency than *p*-bromobenzenesulfonate. Further, even in solvolysis not all of the rearrangement can pass through the ion-pair return product *(54)*, since independently synthesized *(54)* rearranges with considerably higher selectivity than does *(32)* [26b]. There must then be some mechanism for symmetrization on the path between *(32)* and *(54)*, which in the ion-pair context would be ascribed most simply to separation of the ions into independently solvated species. This separation process should be extremely sensitive to solvent, as has been observed with other ion-pair → solvated-ion reactions. For example, ion-pair return, which is pronounced in the acetic acid solvolysis of 3-*p*-anisyl-2-butyl derivatives, is almost completely obliterated in the more proficient ion-solvating solvent, formic acid [37]. If the memory effects observed with *(32)* were caused by ion-pair return, they should be drastically diminished by similar changes of solvent, but they do not show this response. Especially striking is the behavior of the *syn*-7-norbornenylmethyl series *(23)* (Table 1). Although there seems to be a small temperature effect, the selectivity is nearly invariant over a large range of solvents, leaving groups, and electrophilic catalysts [21, 25, 38].

The same results argue against a variant of the ion-pair return hypothesis in which the counter-ion, instead of capturing the cation covalently, merely remains in its vicinity but stays predominantly on one side of it.

Starting from a purely electrostatic point of view, one might develop a more general hypothesis of the origin of memory effects. The positive charge in a carbonium ion interacts with all the other ionic charges in the solution to produce an equilibrium distribution of surrounding ions. For a uni-univalent electrolyte in aqueous solution at 25 °C and a concentration of 0.05 M, the mean radius of this ionic atmosphere of a given ion is about 13 Å [39].

A Wagner-Meerwein rearrangement of the carbonium ion would displace the central charge by a distance of about 1.5 Å. If this rearrangement were fast relative to the rate at which the ionic atmosphere could adapt itself to the new location of positive charge, there would exist a finite time during which a non-equilibrium state prevailed. Even a symmetrical cation (*e.g.*, 2-bicyclo[2.2.2]octyl) when formed by rearrangement would have a temporarily asymmetric ionic atmosphere and in principle could behave in an asymmetric manner.

How fast must the characteristic second rearrangement step be in order to compete with relaxation of the ionic atmosphere to the normal, symmetrical condition? The relaxation time τ for a model electrolyte, tetraethylammonium acetate, in aqueous solution can be calculated [39] to be approximately $10^{-10}/c$ sec, where c is the molar concentration of ions. At 0.05 M, $\tau \approx 2\times10^{-9}$ sec.

The second rearrangement step thus would have to be an extremely fast reaction with a rate only a few thousand times slower than that of a molecular vibration. Since not much is known about the absolute rates of such rearrangements, one has no strong basis *a priori* upon which to evaluate the hypothesis. Fortunately, however, the whole matter is subject to experimental test, since the relaxation time and thereby the memory effect should decrease with increasing total ionic concentration. The experimental results [38] with 7-norbornenylmethyl solvolyses show that the selectivities are unaffected by a three-fold increase in ionic concentration. Therefore, the memory effect in this system (and, by implication, in the others) does not originate in an asymmetric ionic atmosphere. Although the asymmetric atmosphere may well exist temporarily around the newly-formed cation, it either relaxes much more rapidly than the second rearrangement can occur, or else its contribution to the asymmetric behavior of the cation is negligibly small.

A superficially similar but more readily defensible argument can be constructed in terms of the intimate details of the solvation shell of the freshly-formed rearranged ion. Little is known about the relaxation rates of solvent structures, but it seems likely that the necessary reorganization in hydroxylic media must involve readjustments of hydrogen-bonded aggregates or networks in the immediate vicinity of the cation. These processes should be rather insensitive to the macroscopic viscosity, since long-range diffusion is not a major contributor. The evidence is at least consistent with this picture. The memory effect (selectivity) in the 7-norbornylmethyl arenesulfonate solvolysis system is hardly affected by the fifteen-fold change in macroscopic viscosity resulting from a change of pure

acetic acid to an acetic acid-polyvinyl acetate solution [26b].

A guess at a reasonable upper limit for the solvent reorganization rate derives from the study of the dissociation of ε-aminocaprolactam dimers, which occurs at a rate between 10^9 and 10^{10} sec^{-1} in various solvents [40, 41]. Since the reorganization of solvent clusters under consideration in connection with memory effects would require several such elementary steps, the rate would be substantially lower than this limit.

12. Conclusions

Although it is plausible to attribute some of the memory effects to the occurrence of conformationally isomeric cations, there are many cases in which the conformational barriers between the "twisted" and symmetrical forms are so low that non-classical or extramolecular causes for the observed effects must be considered.

The systems exhibiting memory effects provide uniquely suitable devices for revealing the existence of subspecies. The problem of defining the nature of these intermediates is at the heart of carbonium ion chemistry. We hope that the observations reported here will provide some stimulus to the more intensive study of the microscopic structure of solutions, which may provide the key to an understanding of the extramolecular group of memory effects.

The physical phenomena underlying memory effects are very probably present whenever carbonium ions are formed in solution. In the most general terms, one can conclude that a description of the "structure" of a carbonium ion in solvolytic medium is incomplete without a specification of the means by which it is generated.

This work has been supported in part by the National Institute of Arthritis and Metabolic Diseases (Grant AM 07505), the Petroleum Research Fund, the Wisconsin Alumni Research Foundation, and the National Science Foundation, to whom we are grateful. All of the experimental observations and many of the concepts have been contributed by the dedicated and enthusiastic group of collaborators whose names are given in the text references. To work with them has been both challenge and reward.

Dehydration of Alcohols on Aluminum Oxide

BY H. KNÖZINGER [*]

The dehydration of alcohols on γ-aluminum oxide, which yields water, olefins, and/or ethers, was studied with the aid of kinetic methods and IR spectroscopy. The unimolecular olefin formation probably proceeds via a surface compound, in which an alcohol molecule is joined by two angular H-bonds to an OH group and an oxygen ion on the surface. The ether formation (bimolecular reaction), on the other hand, requires OH groups and oxygen and aluminum ions on the surface. The ether is formed from a surface alkoxide group and molecularly adsorbed alcohol.

1. Introduction

The heterogeneous alumina-catalyzed dehydration of alcohols has been known since the end of the 18th century. Nevertheless, it is only recently that efforts have been made to explain the elementary processes in heterogeneously catalyzed eliminations, whereas the elucidation of reaction mechanisms in the liquid phase has reached a much more advanced stage [1]. In the dehydration on aluminum oxide (which has been mainly studied with ethanol as the alcohol), efforts have often been made to find analogies with the reaction in the liquid phase. An excellent review of developments up to 1960 has been published by *Winfield* [2].

Widely differing views are still held concerning the mechanism of the heterogeneously catalyzed dehydration of alcohols on aluminum oxide. In the case of aliphatic and some other alcohols the situation is complicated, particularly by the simultaneous occurrence of a bimolecular reaction leading to ether formation.

Kinetic studies are then meaningful only if the reaction scheme is known.

An oxonium-carbonium ion mechanism similar to that assumed for the liquid-phase reaction in acidic media is also supported by several authors [3–6] for the dehydration of alcohols on solid surfaces. A proton from the surface is assumed to add to the alcohol in the adsorption step. This process can be explained by the formation of more or less strongly polarized H-bonds [2]. Taking into account the surface properties of aluminum oxide, *Pines* and *Haag* [7] showed that this mechanism is also valid for the dehydration of 2-butanol (cf. however, [8]). The participation of surface protons or OH groups is supported by the need for water to be present at the contact surface [9, 10]; however, there appears to be no unambiguous relationship between the dehydrating activity and the acidity of the surface [7]. For an oxonium ion to be formed by proton addition, the surface of the aluminum oxide must contain acid centers of the Brønsted type; *Parry* [11], however, found only centers of the Lewis type in IR studies on aluminum oxide with adsorbed pyridine. Any Brønsted acids present are certainly only weakly acidic [12], so that ionic addition of protons to alcohols is not very likely.

On the basis of the need for water to be present at the catalyst surface [9, 10], and taking into account the principle of the least structural change, *Eucken* and *Wicke* [10, 13, 14] derived a hydrogen exchange mechanism, in which the substrate molecule is adsorbed in such a way that it already approximates as closely as possibly to the structure of the product molecule. In an oxonium-carbonium ion mechanism and in some other mechanisms, hydrogen must be exchanged with the catalyst surface.

In opposition to ionic mechanisms, a covalently bound adsorption complex in the form of a surface alkoxide has been postulated for the dehydration of ethanol [15–17]. The dissociation of this surface compound yields ethylene, whereas the condensation of two adjacent alkoxide groups leads to ether formation. *Topchieva et al.* [17] believe the active centers to be the surface OH groups. Though alkoxide structures have been detected in the IR spectra of some alcohols adsorbed on aluminum oxide [18, 19], this does not provide conclusive proof of the mechanism described.

Heiba and *Landis* [20] compared the products obtained in the dehydration of alcohols with those obtained on pyrolysis of the corresponding alkoxides. However, since the authors certainly did not obtain the primary products above 300 °C, the results cannot be taken as conclusive proof of a given mechanism.

Vasserberg [21] suggested a free-radical mechanism, and free radicals of compounds having extremely strong electron donor properties have in fact been detected on aluminum oxide surfaces by visible and UV adsorption spectroscopy and by ESR studies [22–25]. These donor properties are not so pronounced in alcohols as in the aromatic compounds studied. Moreover, since free-radical mechanisms proceed preferentially in apolar media, whereas the surfaces of metal oxides must be regarded as polar [26], this route is rather unlikely.

Some authors regarded the dehydration (and the dehydrogenation) of alcohols as electron donor-acceptor reactions in the electronic theory of heterogeneous catalysis. Thus *Wolkenstein* [27, 28] and *Garner* [29] postulate a rate-determining electron acceptor step for the dehydrogenation and a rate-determining donor step for the dehydration. *Hauffe* [30], on the other hand, regards the rate-determining step in the dehydrogenation of ethanol as a donor step, *i.e.* the desorption of acetone. It seems very doubtful, however, whether the dehydration of alcohols is a donor-acceptor reaction, since it presumably involves the displacement, not of single electrons, but of electron pairs. Thus *Meye* [31] showed that neither p- nor n-doping of α-Al_2O_3 had any definite effect on the rate and activation energy of the dehydration of methanol to dimethyl ether.

Different conclusions were reached by *Pines et al.*, who studied the effect of the structure of the substrate on the distribution of the primary products. Secondary isomerization of the primary products, which generally

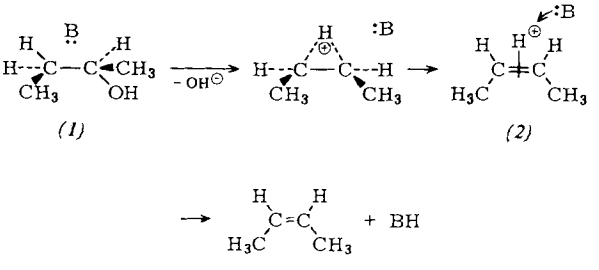
occurs on pure aluminum oxide[32], was suppressed by modification of the catalysts with ammonia, pyridine, or piperidine.

Pines and *Pillai*[33] found preferential *trans*-elimination in the dehydration of menthol and neomenthol. To explain this, they suggested neighboring-group effects and reaction at preferred sites on the catalyst, *e.g.* on steps or in sufficiently narrow pores and cracks; this view had already been advanced by Schwab[34]. The heterogeneously catalyzed dehydrochlorination of menthyl and neomenthyl chlorides also proceeds by *trans*-elimination[35]. The principal product in the dehydration of 2-*endo*- and 2-*exo*-bornanol is camphene. *Pines et al.*[36] interpret this reaction as resulting from a synchronous *trans*-elimination in which the hydroxyl group is attracted by an acidic surface center (A) and the proton by a basic center (B). They also reached the same conclusion for the dehydration of *endo*- and *exo*-norbornanol, which is assumed to proceed in pores of a suitable size. *Pines et al.* also assume that *trans*-elimination is preferred in the dehydration of primary aliphatic alcohols. This conclusion is based on the distribution of primary products in the dehydration of 1-butanol[7], isobutanol, and 2-phenyl-1-propanol[37] with and without ^{14}C-labeling[8], the effects of neighboring groups also being taken into account. The authors rule out an oxonium-carbonium ion mechanism in these cases.

To clarify the question of the order in which the elementary steps take place, the dehydration of primary and secondary alcohols was compared with that of tertiary alcohols. *Pines et al.* concluded from this comparison that the dehydration of *tert*-pentyl alcohol proceeds by a carbonium ion mechanism, whereas the hydroxyl group and the γ-proton are removed simultaneously from the primary neopentyl alcohol[38]. *trans*-Elimination is also claimed for the pairs 3,3-dimethyl-2-butanol and 2,3-dimethyl-2-butanol[38] and 3,3-dimethyl-2-pentanol and 2,3-dimethyl-2-pentanol[38], the secondary alcohol being preferentially dehydrated by a synchronous mechanism, while the tertiary alcohols react *via* a carbonium ion. Neighboring-group effects leading to reorientation of the carbon skeleton are also possible, particularly in the case of alcohols of the neopentyl type. On dehydration of 2-butanol *(1)* and of 2- and 3-pentanol, 1- and *cis*- and *trans*-2-alkenes were obtained as primary products[7,38]. This *cis*-alkene is always favored in relation to the *trans*-alkene to a greater degree than that corresponding to thermal equilibrium. *Pines et al.* explain this result by a synchronous *trans*-elimination.

The intermediate proton-olefin complex *(2)* is thought to be responsible for the unusually high *cis*:*trans* ratio.



(1) *(2)*

Pines and *Manassen*[8] concluded that acidic and basic centers take part in the dehydration of alcohols on aluminum oxide. A carbonium ion mechanism appears to be favored in the dehydration of tertiary alcohols and a synchronous mechanism in the case of primary or secondary alcohols. If possible, the reaction proceeds as a simple 1,2-*trans*-elimination. Neighboring-group effects can lead to the migration of methyl groups. The reaction is thought to take place preferentially on steps, in pores, and in cracks in the oxide. Thus the aluminum oxide must surround the alcohol molecule in such a way that the acidic centers can act as proton donors (electron acceptors) and the basic centers as proton acceptors (electron donors). The catalyst is therefore regarded as a pseudosolvent, and the strong analogy with eliminations in the liquid phase is stressed.

Using these views as a basis, *Jain* and *Pillai*[39] proposed a mechanism (adsorbed phase substitution-elimination mechanism) that also embraces the ether formation.

If the aluminum oxide is assumed to have electrophilic (A) and nucleophilic (B) sites on its surface, there should also be two types of adsorbed alcohol molecules, *i.e.* carbonium ions *(3)* and alkoxide ions *(4)*. A nucleophilic attack by *(4)* on the positively charged C atom of *(3)* leads to ether formation (cf. homogeneous S_N2 reactions), while the abstraction of a β proton from the carbonium ion *(3)* by the alkoxide *(4)* (or by the basic site on the surface, as is now assumed) leads to the olefin. According to this view, therefore, the catalyst gives the reacting molecules the required polarity and fixes them in the correct arrangement. The adsorbed phase thus resembles a polar medium in which nucleophilic substitution and elimination compete with each other.

(3) *(4)*

The simultaneous dehydration of phenol and aliphatic alcohols, as well as poisoning experiments, carried out by the same authors[39a] lends support to the concept of two different species taking part in ether formation.

2. The Reaction Scheme in the Dehydration of Alcohols

The dehydration of simple alcohols on aluminum oxide leads mainly to ethers, olefins, and water, which may be formed in successive or parallel steps or else simultaneously. For the dehydration of methanol and ethanol up to about 200 °C, *Balaceanu* and *Jungers*[40] assume primary ether formation with possible equilibrium. In the dehydration of ethanol, ethylene is formed as a secondary product with re-formation of ethanol; it is also formed directly at higher temper-

atures. *Isagulyants et al.* [41, 42] reached the same conclusions on the basis of investigations on [^{14}C]-ethanol but assumed that the olefin is formed as a secondary product by the dehydration of ethers. *Stauffer* and *Kranich* [43], on the other hand, assumed that the primary aliphatic alcohols up to *n*-hexanol are dehydrated to the ether and the olefin in independent parallel steps. The results obtainable for other alcohols are not very extensive.

A good method for the determination of the reaction schemes of complex reactions is the study of the product distribution as a function of the catalyst temperature and the contact time. We used this method to study the reaction scheme for the dehydration of some unbranched and branched aliphatic alcohols [44, 45]. γ-Al_2O_3 was used as the catalyst for all the kinetic studies described.

Since the dehydration of methanol up to 320 °C yields only ether by the bimolecular reaction

$$2\,CH_3OH \rightleftarrows (CH_3)_2O + H_2O$$

with possible equilibration, the reaction scheme will be discussed for the case of ethanol. Figure 1 shows the partial pressures of the components occurring as a function of

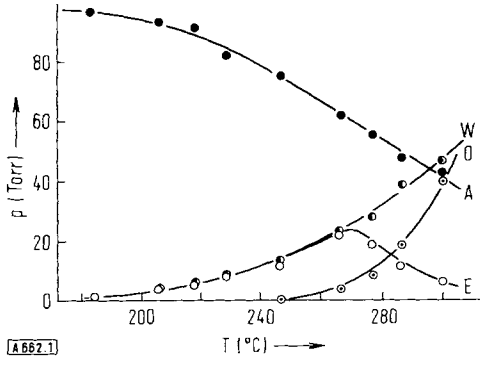

Fig. 1. Product distribution in the dehydration of ethanol on γ-Al_2O_3 as a function of the temperature [45].

A = alcohol, E = ether, O = olefin, W = water.

temperature. At low temperatures, only equimolar quantities of ether and water are obtained; the reaction therefore proceeds in accordance with:

$$2\,C_2H_5OH \underset{-1}{\overset{1}{\rightleftarrows}} (C_2H_5)_2O + H_2O \qquad (1)$$

Ethylene is formed only above 240 °C. The maximum in the ether-concentration curve points to secondary decomposition of the ether. Since ethylene formation begins in the immediate vicinity of the point of inflection in the ether curve, ethylene should be formed by the secondary decomposition of the ether. Diethyl ether on this catalyst does in fact give ethanol and ethylene (cf. Fig. 2). Both diagrams show that the secondary decomposition of ether on γ-Al_2O_3 begins

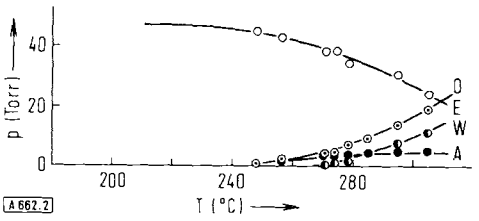

Fig. 2. Product distribution in the decomposition of diethyl ether on γ-Al_2O_3 as a function of the temperature [45].

A = alcohol, E = ether, O = olefin, W = water.

between 240 and 250 °C. The quantities of ethanol and ethylene in Figure 2 are initially equimolar

$$(C_2H_5)_2O \xrightarrow{2} C_2H_5OH + C_2H_4 \qquad (2)$$

Above 260 °C, the ethylene concentration increases more rapidly than the ethanol concentration, and at the same time water begins to appear as a result of secondary dehydration of ethanol in accordance with

$$(C_2H_5)_2O \xrightarrow{3} 2\,C_2H_4 + H_2O \qquad (3)$$

Even with long contact times, no ethylene is observed below 240 °C, while small concentrations that increase with the contact time appear at 256 °C (Fig. 3).

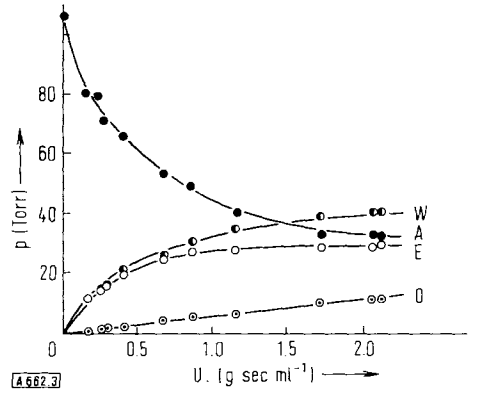

Fig. 3. Reaction isotherms for the dehydration of ethanol on γ-Al_2O_3 at 256 °C [45].

A = alcohol, E = ether, O = olefin, W = water, U = conversion.

Since the ethylene concentration does not exhibit the induction period (convex curvature with respect to the abscissa) characteristic of pure secondary reactions, direct olefin formation from ethanol must be superimposed on the

$$C_2H_5OH \xrightarrow{4} C_2H_4 + H_2O \qquad (4)$$

secondary ethylene formation from the ether. Two steps (3) and (4) leading to ethylene thus evidently proceed simultaneously and begin on γ-Al_2O_3 in approximately the same temperature range (240–250 °C).

At about 300 °C and above, the ethanol is not only dehydrated, but also dehydrogenated to acetaldehyde and hydrogen [45].

The unbranched primary alcohols up to *n*-hexanol behave in exactly the same manner. However, the temperature range for pure ether formation decreases as the number of carbon atoms increases, so that even for *n*-butanol, the reactions start almost simultaneously. Direct kinetic studies cannot therefore be carried out on any of these reactions for primary alcohols higher than *n*-propanol.

In the case of the higher homologs of the primary alcohols, isomerizations also occur in the initially formed 1-olefins. In agreement with *Pines* and *Haag* [7], we found isomeriza-

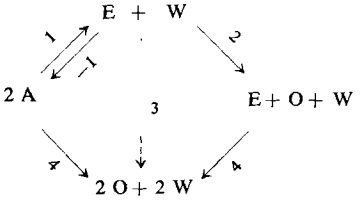
tion of 1-butene to *cis*- and *trans*-2-butene (with a clear preference for the *cis* product) in the dehydration of *n*-butanol, though no skeletal isomerization was detected [45].

Thus the steps corresponding to reactions (1) to (4) are observed for the primary alcohols containing two to six carbon atoms, and the ether formation can be clearly isolated for ethanol and *n*-propanol at low temperatures. As the temperature is raised, the primary olefin formation from alcohol and the secondary olefin formation from ether start in the same temperature range and steadily become more important. It is not certain whether the secondary olefin formation proceeds with regeneration of alcohol in accordance with step (2) or with dehydration of the ether in accordance with step (3). Step (2) should however be favored at low temperatures at least, since it is known from experience that the probability of the simultaneous participation of several bonds in the reacting molecule is very small. On the other hand, step (3) cannot be ruled out at about 300 °C (cf. [17]). The possible reaction directions for primary aliphatic alcohols are shown in Scheme 1, which is in agreement with the results obtained by *Balaceanu* and *Jungers* [40] as well as by *Bliss, Butt et al.* [46, 47, 47a]



Scheme 1.

Isopropanol, 2-butanol, isobutanol, and *tert*-butanol have also been investigated [44, 45]. The dehydration of isopropanol leads to the formation of propylene, and yields only small quantities of isopropyl ether. The dehydration of 2-butanol yields 1-butene and *cis*- and *trans*-2-butene, which, according to *Pines* and *Haag* [32] are formed as primary products in parallel steps. Isobutanol and *tert*-butanol give isobutylene in yields of more than 95 % (based on reacted alcohol).

Benzyl alcohol gives only dibenzyl ether up to 200 °C [48], while cyclohexanol gives cyclohexene [7, 49, 94]. A slow secondary skeletal isomerization of cyclohexene into methylcyclopentene was observed by *Pines* and *Haag* [7] only above 300 °C on strongly acidic oxides.

The alcohols suitable for kinetic studies are those in whose dehydration individual primary steps can be definitely isolated at least in narrow temperature ranges. Methanol, ethanol, *n*-propanol, and benzyl alcohol can be used as representative examples for the study of ether formation, and *tert*-butanol, isobutanol, and cyclohexanol for the study of olefin formation. Since the catalytic activity of a surface is strongly dependent on its structure and properties as well as on the surface compounds of the substrates and reaction products, the γ-Al_2O_3 surface and the adsorption structures of alcohols and their dehydration products will be considered before the kinetic studies are described.

3. The Surface Structure of γ-Al_2O_3

In the simplest model, the surface centers of aluminum oxide are regarded as incompletely coordinated aluminum and oxygen ions, the surface being assumed to be completely free from OH groups. Other models take into account cation defects and strained sites, which result from the dehydration of the originally hydrated surface [50, 51]. By investigation of the water-absorption and analysis of the IR spectra of water adsorbed on γ-Al_2O_3, *Peri* [52] developed a more detailed model based on the following considerations (cf. Fig. 4a).

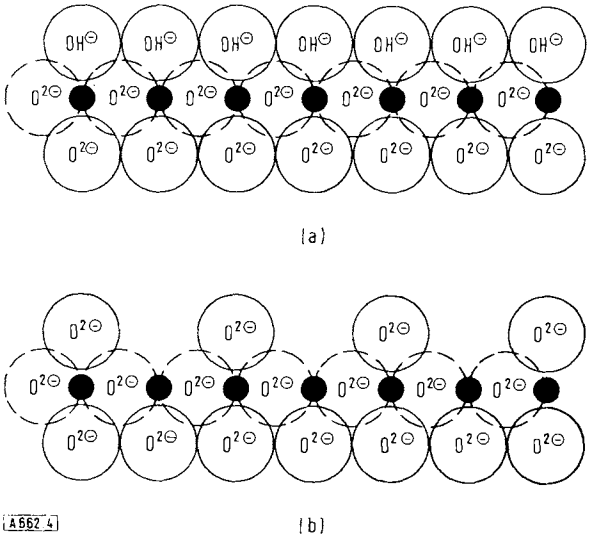


Fig. 4. Vertical section through an ideal γ-Al_2O_3 surface.
(a) hydrated surface, (b) dehydrated surface, ● = Al (after [52]).

The oxide is in the form of a defect lattice of the spinel type. Ionic surfaces are generally bounded by anions, which are more readily polarizable than cations. Though many authors (*e.g.* [53]) believe the [111] face of the oxygen sublattice to be energetically favored, *Peri* concludes that γ-Al_2O_3 is bounded by the [100] face. To reduce the surface energy, oxides of this type characteristically adsorb water, which leads whenever possible to the formation of OH groups. The liberation of water from a hydrated surface by condensation of two OH groups must expose oxygen ions. The re-

maining OH groups acquire different properties, which *Peri* explains by the change in their immediate surroundings. At the same time, aluminum ions in the second atomic position lose their full coordination and become accessible from the surface through oxygen vacancies (cf. Fig. 4b).

Aluminum oxide retains a part of its unimolecular surface coating of water even on dehydration for several hours under vacuum, the proportion retained depending on the heating temperature [54, 55]. This retained water is described as irreversibly adsorbed, and is partly in the molecular state and partly in the form of OH groups [52, 54, 56]. Adsorption isobars for a water partial pressure of zero, *i.e.* for the irreversibly adsorbed water, show that pure water does not give a unimolecular coating of OH groups in the temperature range for the catalytic dehydration of alcohols [55]. According to the Peri model, OH groups and oxygen ions as well as incompletely coordinated aluminum ions will therefore be accessible at the surface in this range. Since alcohols are also irreversibly adsorbed [57, 58], the distribution of these three types of centers will be modified by the adsorption of the alcohol.

It has been shown by gas chromatography that irreversibly adsorbed water on aluminum oxide is partly displaced by ethanol, and irreversibly adsorbed ethanol by water [59]. The aluminum ions whose coordination is disturbed by the condensation of two OH groups with formation and desorption of water may be regarded as acidic centers of the Lewis type [60, 61], which can be very selectively poisoned by organic bases [11, 12]. The OH groups are extremely weakly acidic Brønsted centers [11, 62]. Protons in cation vacancies have also been suggested as proton donors, but these would become effective only at temperatures above 400 °C because of their low activation energy [63].

4. IR Studies on the Adsorption Structures

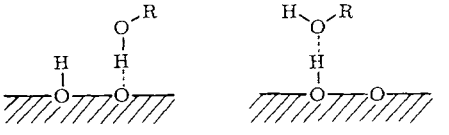
4.1. Adsorption of Alcohols

On adsorption of alcohols, particularly ethanol, IR studies showed three surface compounds:

1. molecular alcohol adsorbed *via* H bonds [67, 70];
2. alkoxide groups formed by dissociative adsorption [18, 19, 64–67, 75, 76];
3. carboxylate groups formed by oxidation of the alcohol [18, 19, 67, 76, 80, 81].

4.1.1. Molecular Adsorption of Alcohols

Whereas *Babushkin et al.* [64, 65] and *Boreskov et al.* [66] thought that they could still detect molecularly adsorbed ethanol even at high desorption temperatures, *Greenler* [18] (methanol and ethanol), *Treibmann* and *Simon* [19] (ethanol, *n*-propanol, and isopropanol) and *Kagel* [67] (*n*-propanol and *n*-butanol) found that alcohols are readily desorbed, even at room temperature. NMR studies showed that the hydroxyl group of the alcohols interacts directly with the oxide surface [68, 69]; it must therefore be assumed that H bonds are formed. *Kagel* [67] assumes without direct spectroscopic evidence, that the structures *(5)* and *(6)* are both present, *i.e.* that the alcohol forms both active and passive H bonds.



(5) *(6)*

However, the temperature dependence of the OH stretching bands on adsorption of methanol, ethanol, *tert*-butanol, isobutanol, cyclohexanol, and benzyl alcohol also indicates the presence of structures with two angular H bonds per alcohol molecule [70].

The absorption of the free OH groups of alcohols should be expected to appear at 3600 to 3650 cm^{-1}; the OH stretching vibrations of the chain associates formed by linear H bonds in the liquid phase occurs at 3350 cm^{-1} for all the alcohols in question. The shift of the OH stretching band is a measure of the strength of the H bonds. Linear H bonds are always stronger than angular bonds [71]. The pronounced frequency shift in liquid alcohols is thus explained by the formation of linear H bonds. All adsorbed alcohols give strong OH stretching bands centered around 3500 cm^{-1}. At low temperatures the bands are asymmetric, with a shallow gradient on the low wave-number side. As the temperature is raised, the bands decrease in intensity, starting at lower wave numbers, though the center still remains at 3500 cm^{-1}.

Thus at low temperatures there must be adsorption structures with relatively strong, probably substantially linear H bonds as well as weaker angular bonds, since the OH stretching band extends down to 3200 cm^{-1}. As the temperature is raised, the strong hydrogen bonds are broken while the weak-

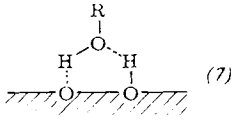
er bonds (absorption at 3500 cm^{-1}) remain intact. Since the absorption band of cyclic alcohol dimers with two non-linear H bonds in dilute solutions[72] and in N_2 matrices[73] was localized at 3500 cm^{-1} similar structures, such as *(7)* should be favored on adsorption of alcohols on aluminum oxide.



(7)

A structure such as *(7)* will be more stable and more heat-resistant than the singly H-bonded structures *(5)* and *(6)* if the energy of formation of each of the two angular H bonds is greater than half the energy of formation of singly H-bonded structures. Such energy relations have been found for the cyclic dimers of alcohols in dilute solution[74]. In the adsorption of alcohols on surfaces, steric factors must also be taken into account since, owing to the geometry of the alcohol molecules, the formation of a linear active H bond brings the alkyl group closer to the surface, this effect being particularly pronounced in the case of *tert*-butanol. The steric factors thus favor the formation of adsorption complexes of structure *(7)*, in which the alkyl groups are pushed farther away from the surface.

An adsorption *via* two passive H bonds to the surface by way of the two free electron pairs of the hydroxy oxygen atom cannot be dismissed categorically. In this case, the frequency of the free OH vibration of the alcohol should occur; however, this absorption would hardly be recognizable in the steep high-frequency flank of the band due to the perturbed OH-groups.

4.1.2. Alkoxide Structures

A comparison of the IR-spectra of adsorbed phases with those of solid alkoxides shows the presence of surface alkoxide groups on adsorption of methanol[18], ethanol[18,19,64–66,75], *n*-propanol[19,67], isopropanol[19], *n*-butanol[67], and benzyl alcohol[76]. In the Peri model of the aluminum oxide surface, there are two possible routes for the formation of alkoxide by dissociative adsorption:

1. A hydroxyl proton may be split off to form a surface OH group, while the alkoxide residue occupies an oxygen vacancy in the surface (Lewis center);

2. The C–O bond of the alcohol may be broken, the resulting hydroxyl group filling an oxygen vacancy on the surface, while the alkyl residue adds to an adjacent oxygen ion.

Though the somewhat lower energy of rupture of the C–O bond in the free alcohol[77] favors the second possibility, the lattice energy liberated on incorporation of the alkoxide or hydroxyl group decides in favor of the rupture of the O–H bond. *Treibmann* and *Simon*[19] concluded from displacement reactions that the alkoxide formation involves incompletely coordinated aluminum ions; *Kagel*[67] reached the same conclusion on the basis of mass-spectroscopic residual gas analyses after adsorption.

While dissociative adsorption with formation of a surface alkoxide has been substantially verified for the alcohols discussed so far, no analogous surface compound has been detected on adsorption of *tert*-butanol, isobutanol, and cyclohexanol[75,76]. This can be explained on the basis of the thermal stability of the corresponding alkoxides. The thermal stability of zirconium alkoxides decreases in the order $Zr(OC_2H_5)_4 \gg Zr[OCH(CH_3)_2]_4 > Zr[OC(CH_3)_3]_4 \approx Zr[OC(CH_3)_2C_2H_5]_4$[78]. The methoxides of aluminum and zirconium are stable up to 240 and 280 °C respectively, whereas *tert*-butoxides have an extremely poor thermal stability[79]. All the alcohols studied so far that can form a surface alkoxide give ethers on dehydration on aluminum oxide at low temperatures, while the others tend toward olefin formation.

4.1.3. Carboxylate Structures

Oxidation of the alcohols during adsorption or aluminum oxide above about 170 °C to give carboxylate structures with the aid of the oxygen ions on the surface has been observed for methanol[18], ethanol[18,19,75], *n*-propanol, and *n*-butanol[67,80]. Corresponding surface compounds have recently also been found on adsorption of isobutanol and benzyl alcohol on aluminum oxide above about 120 °C[81]. *Treibmann* and *Simon*[19] concluded from the occurrence of an acetate structure on adsorption of isopropanol that the carbon skeleton of the molecule is broken down. These carboxylate structures are observed up to 400 °C; the adsorption of water does not change their adsorption bands. In view of its high stability, this structure could hardly be important as an intermediate in surface reactions up to 250 °C. However, the dehydrogenation of ethanol observed above about 300 °C could proceed *via* an acetate structure[82].

4.2. Adsorption of Water

The adsorption of alcohols in the catalytic temperature range is always accompanied by the appearance of a band at about 1600 cm^{-1}, the intensity of which increases with rising temperature, and which is not due to the alcohol or any of its surface compounds[85].

Using the N_2 matrix technique, *van Thiel, Becker* and *Pimentel*[83] were able to show that the water molecules in the H-bonded clusters have a deformation band at 1633 cm^{-1},

[72] *L. P. Kuhn*, J. Amer. chem. Soc. *74*, 2492 (1952).

[83] *M. van Thiel, E. D. Becker*, and *G. C. Pimentel*, J. chem. Physics *27*, 486 (1957).

while the corresponding band for the free monomeric molecule occurs at 1600 cm^{-1}. Since the surface of aluminum oxide contains OH groups and oxygen ions, it must be assumed that molecular water is adsorbed by means of H bonds. The deformation band is a particularly suitable aid to the detection of such H bonds, as was shown by *Glemser* and *Hartert* [84] for the adsorption of water on aluminum oxide at room temperature. The temperature-dependence of the intensity and position of this band provides information about the structure of the H bonds [85].

Figure 5 shows the region around 1600 cm^{-1} for the rehydration of a sample of γ-Al_2O_3 that has been heated under vacuum at 520 °C. This oxide initially shows no absorption

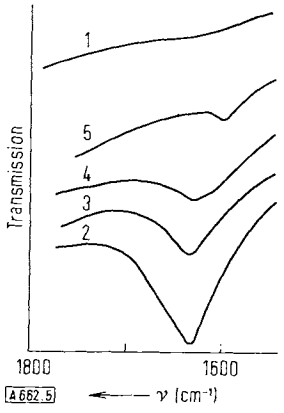

Fig. 5. Deformation bands of water adsorbed on γ-Al_2O_3.
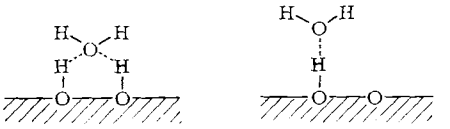
1: after evacuation for 60 min at 520 °C/10^{-3} torr, spectrum recorded at 80 °C, 2: water adsorbed at 80 °C, 3: at 130 °C, 4: at 168 °C, 5: water desorbed at 168 °C, evacuation for 70 min at 10^{-3} torr.

between 1630 and 1600 cm^{-1}. On rehydration (55 torr of water vapor), a strong band due to polymeric water associates with strong, substantially linear H bonds develops at 1630 cm^{-1}. It is conceivable that multilayer adsorption occurs, with incipient formation of liquid water in the form of cluster-like regions, at least in pores and cracks. With rising temperature and hence decreasing surface concentration, the intensity of the band at 1630 cm^{-1} decreases, while a band simultaneously develops at 1600 cm^{-1}; this latter band is assigned to the deformation vibration in quasimonomeric water molecules. (Molecules that are only passively involved in H bonds *via* free pairs of electrons exhibit the vibration frequencies of the free molecule [86, 87].) The band observed at 1600 cm^{-1} on adsorption of alcohols after catalytic dehydration has started must therefore be the deformation vibration of water molecules that are adsorbed on surface OH groups by passive H bonds and which do not undergo any further interactions. *Yates* [88] found a band at 1605 cm^{-1}, which he interpreted in a similar manner, on adsorption of water on titanium dioxide.

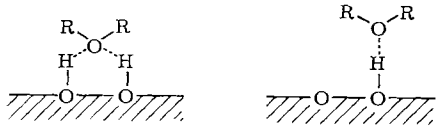
It is generally assumed that molecules containing oxygen and having two free pairs of electrons are preferentially adsorbed *via* two passive H bonds as in *(8)* [89]. This is thought to be the case in the adsorption of water on silanol groups [90]. This type of adsorption bonding *via* two H bonds requires two immediately adjacent OH groups on the surface, a condition that should be satisfied for the adsorption of pure water on aluminum oxide between 80 and 170 °C since up to 200 °C the surface of γ-Al_2O_3 still has a 50–80 % covering of OH groups [52, 55]. However, adsorption on isolated OH groups as in *(9)* should also be possible, at least when two adjacent OH groups are not available. This case is particularly probable when water is adsorbed in the presence of excess alcohol, *i.e.* under conditions that lead to the development of the band at 1600 cm^{-1} on adsorption of alcohol in the catalytic temperature range.



(8) *(9)*

4.3. Adsorption of Diethyl Ether

Diethyl ether is similar to the water molecule in that the oxygen atom has two free pairs of electrons, though ether cannot act as a proton donor and form active H bonds. However, the H-bond acceptor properties of the two molecules on adsorption on oxide surfaces having OH groups should be qualitatively similar. IR investigation of the adsorption of diethyl ether on aluminum oxide [85] shows that up to about 170 °C, it is bound only in a readily desorbable form. By analogy with the adsorption structures proposed for silicon dioxide [90–92] and the structures *(8)* and *(9)* for the adsorption of water on γ-Al_2O_3, it is assumed that diethyl ether is present in one of the forms *(10)* and *(11)*, depending on the surface concentration of OH groups.



(10) *(11)*

Bands indicating the formation of a surface ethoxide appear in the spectrum only above 200 °C [85]. This compound may be formed directly by dissociative adsorption of the ether or by secondary adsorption of the ethanol resulting from catalytic decomposition [*].

[*] *Note added in proof* (Sept. 19, 1968): In contrast to the results discussed here [85] no great shift of the OH stretching high-frequency bands of the surface hydroxyl groups after desorption of diethyl ether was observed by *Arai, Saito*, and *Yoneda* [92a]. The authors therefore rule out adsorption *via* H bonds. However, this conclusion does not necessarily apply when ether is also present in the vapor phase. On comparison of the desorption spectra with spectra of the $(C_2H_5)_2O$–$AlCl_3$ complex, the authors conclude that a coordinative adsorption bond is formed between ether and incompletely coordinated aluminum ions below 100 °C. This complex undergoes thermal decomposition to ethanol, diethyl ether, and ethylene. A surface ethoxide is observed at temperatures above 130 °C.

5. Kinetics and Mechanism of the Dehydration of Alcohols

Only a few intensive studies have been carried out on the kinetics of the dehydration of alcohols. The test reaction used in most cases was the formation of ethylene from ethanol at relatively high temperatures. However, the product distribution (cf. Section 2) shows no definite reaction steps. *Topchieva* and *Romanovskii* [93] described the kinetics of the formation of ethylene from ethanol by a simple Langmuir formula containing an inhibition term for water. According to *Kochloefl et al.* [94] the formation of olefins from some aliphatic and alicyclic alcohols at about 200 °C and at alcohol pressures of 70 to 80 torr is a zeroth order reaction. On the basis of kinetic data for the dehydration of 2-butanol and *n*-hexanol, *Kittrell* and *Mezaki* [95] proposed the participation of two types of centers. The same conclusion was reached by *de Mourges et al.* [96] for the dehydration of isopropanol, and by *Carrà et al.* for the dehydration of cyclohexanol [96a]. From the kinetic analysis of reaction isotherms for the dehydration of ethanol, on the other hand, *Solomon, Bliss*, and *Butt* [47, 47a] postulated a one-center mechanism, in which the simultaneous formation of ethylene and ether is assumed to take place *via* a common intermediate. The kinetics of the formation of olefins from *tert*-butanol, isobutanol, and cyclohexanol and of the bimolecular ether formation on dehydration of methanol, ethanol, *n*-propanol, and benzyl alcohol, *i.e.* of clearly isolable reaction steps, will now be discussed.

5.1. Olefin Formation

Under the conditions chosen for the measurements, *tert*-butanol [97] and cyclohexanol [76] are dehydrated above about 130 °C, whereas the reaction begins only above 160 °C in the case of isobutanol.

5.1.1. Influence of the Alcohol Pressure

At low conversions (<3 %), *i.e.* at low partial pressures of water, the reaction rate is independent of the alcohol pressure over a wide range; the reaction is thus zeroth order under the following conditions: Isobutanol up to 240 °C above 80 torr, *tert*-butanol up to 180 °C above 150 torr, and cyclohexanol up to 180 °C above 80 torr.

5.1.2. Influence of the Products

No decrease in the reaction rate due to the olefins formed could be observed in the cases of isobutanol, *tert*-butanol, and cyclohexanol, whereas water strongly inhibits dehydration to the olefin. Inhibition by water has also been observed in the formation of olefins from ethanol [93] and isopropanol [96]. The influence of water always decreases with increasing alcohol partial pressure and with rising temperature. The experimental results cannot be quantitatively described by the usual Langmuir formula for unimolecular decompositions with product inhibition. On the other hand, the reaction rates found can be excellently reproduced over the entire measuring range up to a water:alcohol concentration ratio of 15:85 at all temperatures by the empirical equation

$$r = r_0\Theta_A = \sqrt{p_A} \;/\; (\sqrt{p_A} + bp_W) \qquad (5)$$

(r = reaction rate, r_0 = reaction rate for zeroth order, both in mole/sec per g of catalyst, p_A, p_W = partial pressures of alcohol and water, b = constant). In linear form, equation (5) becomes:

$$r_0/r = 1 + bp_W \;/\; \sqrt{p_A} \qquad (6)$$

The validity of equation (6) is confirmed by Figure 6 for the formation of olefin from cyclohexanol. It has also been checked in the same way for *tert*-butanol [97] and isobutanol [76].

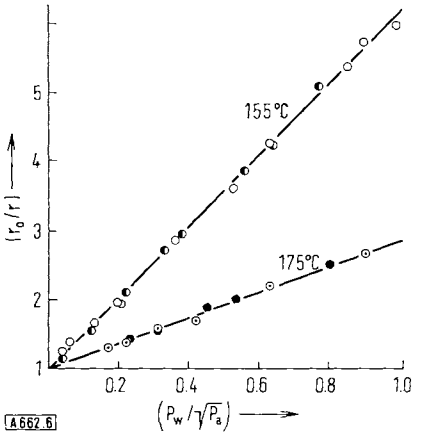

Fig. 6. Kinetics of olefin formation from cyclohexanol at alcohol pressures of 115 (○) and 155 torr (◐) (155 °C in each case), and 100 (●) and 160 torr (○) (175 °C in each case).

The expression Θ_A in equation (5) may be regarded as an adsorption isotherm. Θ_A then represents the relative coverage of the surface with alcohol in the presence of water. A similar equation with the pressure at powers less than one was derived by *Sips* [97a] for one-component adsorption exhibiting saturation properties at energetically heterogeneous surfaces; the validity of this equation has been established experimentally for a number of systems [97b, 97c]. IR spectra had shown that under the catalytic conditions, two-point adsorption in accordance with *(7)* is favored for alcohols, whereas a one-center adsorption in accordance with *(9)* must be assumed for water in the presence of an excess of alcohol.

5.1.3. Active Centers

The dehydration activity has repeatedly been found to exhibit an optimum value for a given pretreatment temperature of the aluminum oxide [9, 10, 98]. This optimum shows that a certain surface water content is essential to the reaction, but that other active centers besides OH groups must also be present on the surface. This is suggested by the adsorption structure *(7)*, which requires the presence of oxygen ions. If aluminum hydroxide (bayerite) is used as the catalyst, the dehydration of *tert*-butanol does not begin below 180 °C, *i.e.* about 50 °C higher than on the oxide [82]. Aluminum hydroxide has only OH groups on the surface, and in this form it is evidently inactive for the dehydration of *tert*-butanol. Above about 150 °C, the trihydroxide loses water to form the monohydroxide, with the result that oxygen ions and aluminum ions become accessible on the surface as well as OH groups, and the dehydration of *tert*-butanol can gradually begin.

A decision as to whether oxygen and/or aluminum ions are involved as active centers in the dehydration can be obtained by poisoning the aluminum oxide with pyridine. This strong Lewis base is very selectively adsorbed on the incompletely coordinated aluminum ions at the surface, which are Lewis-acid centers, with formation of an electron donor-acceptor complex [11]. The activity of the catalyst in olefin formation is not affected by modification with pyridine [75, 99, 100]. The (Lewis) acidic aluminum ions in the surface, which are responsible *inter alia* for isomerization [8] and polymerization [99], thus play no part in the formation of olefins from alcohols, and the OH groups and oxygen ions may be regarded as the active centers [*].

5.1.4. Mechanism of Olefin Formation

Olefin formation begins with an adsorption complex *(7)*. The water inhibiting the reaction blocks only the OH groups by a passive H bond. If, in accordance with *Peri* [52], the area required for an oxygen atom in the surface of γ-Al_2O_3 [see structure *(7)*] is assumed to be about 8 Å^2, the H–O···H angle between the H bonds is about 110 °, which is very close to the H–O–H angle in the water molecule. In agreement with the principle of least structural change [101], therefore, the water molecule may already be substantially formed in the adsorption structure *(7)* under the conditions of catalysis.

The further rearrangement could occur in two ways. With strongly polarized H bonds, *(7)* may approximate to an oxonium ion and change by charge migration into a carbonium ion, which allows the formation of an olefin by subsequent transfer of a proton to an adjacent surface oxygen ion. In this form the course of the reaction corresponds to the oxonium-carbonium mechanism of olefin formation [3–5]. However, a concerted E2-type mechanism is also possible, with simultaneous rupture of the C–H and C–O bonds in the alcohol. According to the results obtained by *Pines et al.* [8], it should be assumed that tertiary alcohols, which form relatively stable tertiary carbonium ions, are dehydrated to olefins by an ionic mechanism, and the other aliphatic alcohols by a concerted mechanism. β-Elimination always appears to occur if the molecule contains β-protons [8, 102]. In both mechanisms the water molecule is preformed in the adsorption complex, and the hydrogen exchange with the surface observed by *Eucken* and *Wicke* [10, 13, 14] must necessarily take place.

The rate-determining step can be established by measurement of the kinetic isotope effect. Investigations of this type have so far not been published for the dehydration of *tert*-butanols on γ-Al_2O_3 [103]. No primary isotope effect was observed in the dehydration of $(CH_3)_3COD$, in which heavy water is formed on deuterated surfaces; the rate cannot therefore be determined by the desorption of the water or the cleavage of the RO–H bond. On the other hand, a high primary alcohol effect is found in the dehydration of $(CD_3)_3COD$. Below 200 °C, removal of the β-proton must therefore be the slowest step also with *tert*-butanol.

Only a secondary isotope effect would be expected in the case of a pure carbonium-ion mechanism. An E2-type mechanism must therefore also be assumed for the dehydration of *tert*-butanol at temperatures below 200 °C. The investigations by *Pines* were all conducted at considerably higher temperatures. At low temperatures, olefin formation from aliphatic alcohols over aluminum oxide should therefore proceed fundamentally by an E2-type mechanism, the transition state – determined by the ionization potential of the alkyl group – containing ionic contributions. These ionic contributions should become more important as the temperature increases, so that when the temperature is sufficiently high for olefin formation from

[*] *Note added in proof* (Sept. 19, 1968): The participation of basic centers has recently been established by poisoning experiments with tetracyanoethylene [100a]. Formation of radical ions when this compound is adsorbed on aluminum oxide has been observed by means of electron spin resonance. Modification of aluminum oxide catalysts by tetracyanoethylene causes a considerable inhibition of the formation of not only ethylene but also ether. Since steric effects can be ruled out, active participation of basic centers in dehydration is thus proved.

tertiary alcohols an E1-type transition state will be present, as was observed by *Pines*. This concept is further supported by the strong temperature dependence of the isotope effect.

Olefin formation by dissociation of short-lived alkoxide groups has also been discussed [17]. The alkoxide would be formed by dissociative adsorption of alcohol on incompletely coordinated aluminum ions in the surface [19, 67]. However, since poisoning of these Lewis centers with pyridine does not decrease the activity of the aluminum oxide catalyst in the olefin formation [75, 99, 100], a mechanism of this type must be rejected, at least at low temperatures [*].

5.1.5. Reaction Rates of the Alcohols

Dohse [104] and *Bork* and *Tolstopja-Tova* [105] found a definite relationship between the activation energy for olefin formation on bauxite and the methyl substitution. According to *Dohse*, a methyl group in the α-position decreases the activation energy by 5.5 kcal/mole, in the β position by 2.5 kcal/mole, and in the γ position by 0.5 kcal/mole. *Stauffer* and *Kranich* [43] report a constant activation energy of 30.8 kcal/mole for the formation of olefins from linear alcohols from ethanol to *n*-hexanol on γ-Al_2O_3. *Kraus*, *Kochloefl et al.* [49, 94] showed that steric effects are much more important than electronic effects in the dehydration of aliphatic and cyclic secondary alcohols and of stereoisomeric alkylcyclohexanols on aluminum oxide. The authors conclude that the rate of reaction of organic compounds in heterogeneously catalyzed reactions is determined mainly by the steric arrangement of the reacting molecule and particularly of the chemisorbed species.

Kraus and *Kochloefl* [106] also detected electronic effects in the rate of dehydration of *meta*- and *para*-substituted phenylethanols. However, these effects are less important than the steric effects. Since the styrenes formed do not polymerize, the authors rule out the possibility of an ionic dehydration mechanism. A Hammett relationship between the logarithm of the rate constant and the σ* constant can be verified for these reactions (Fig. 7).

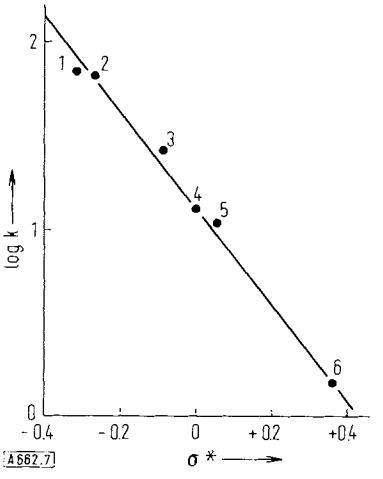

Fig. 7. Correlation of the rate constants (200 °C) for the dehydration of substituted phenylethanols with the Hammett equation (after [106]). 1: 2-(*p*-tolyl)-ethanol, 2: 2-(*p*-tert-butylphenyl)ethanol, 3: 2-(*p*-fluorophenyl)ethanol, 4: 2-phenylethanol, 5: 2-(*m*-methoxyphenyl)ethanol, 6: 2-(*m*-fluorophenyl)ethanol.

The "true activation energies" for the dehydration of aliphatic alcohols to olefins show a marked dependence on structure [106a] in the series $q_{primary} > q_{sec} > q_{tert.}$ If the E2-type mechanism represented in Section 5.1.4 is assumed to be valid, this order can be interpreted in terms of the structurally dependent ionic contributions to the transition state and of the inductive effect of the alkyl groups adjacent to the β-C atom. A comparison of the dehydration of *tert*-butanol (q = 25.5 kcal/mole [97]) and that of isobutanol (q = 30 kcal/mole [76]) may be cited as an example. The ionic contributions to the transition state are low for isobutanol compared to *tert*-butanol. Furthermore, the partial positive charge on C_β in isobutanol is compensated to some extent by the inductive effect of the two methyl groups in the γ position. Consequently, in the transition state the acidity of the β protons in isobutanol is much lower than in *tert*-butanol, so that the activation energies for dehydration fall as the acidity of the β protons increases. Comparison of the activation energies for the different possible reactions of alcohols that afford a number of olefinic products on dehydration clearly shows that not only the inductive effect but also an inductometric effect must come into play. On dehydration, 3-methyl-2-butanol and 2-methyl-2-butanol yield comparable amounts of "Hofmann" and "Saytzeff" products. If the inductive effect alone were to operate, the lower activation energy would be expected for the "Hofmann" product. In fact, however, the activation energy for the formation of this product from 3-methyl-2-butanol and from 2-methyl-2-butanol is lower by 2.5 kcal/mole and about 1 kcal/mole, respectively, than for the forma-

[*] *Note added in proof* (Sept. 19, 1968): Confirmation of the alkoxide mechanism has recently been attempted by investigations of the thermal desorption of ethanol [103a] and diethyl ether [92a] adsorbed on aluminum oxide. In this case olefin formation is desribed as a concerted decomposition of the alkoxide-type surface species, whereas ether formation is regarded as proceeding *via* condensation of two neighboring alkoxide groups. Using the same experimental technique, *Makarov* and *Shtschekotshichin* [103b] arrived at similar results. However, these authors assume direct or indirect participation of the surface carboxylate (cf. 4.1.3) in olefin formation. In view of the high stability of these surface compounds, such a route seems questionable, particularly since *tert*-butanol does not form a compound of this kind. Moreover, it does not appear certain whether conclusions regarding the mechanism of heterogeneously catalyzed dehydration of alcohols from the gaseous phase can be drawn from investigations of thermal desorption, since the experimental conditions differ greatly. In the reaction from the gaseous phase, molecules are necessarily also present that are physically adsorbed *via* H bonds; such molecules can also play a role in the reaction.

tion of the "Saytzeff" product. The relatively low differences in the true activation energies are nevertheless well outside the limits of experimental accuracy. Nor can they be due to lateral interactions in the adsorbed phase, since in each case two possible reactions of one alcohol, and not of substrates having different structures, are being compared. This result is in accord with the assumption of an E2-type mechanism, because inductometric effects can only play a role when the double bond of the incipient olefin is already present in the transition state; this is the case with transition states of the E2 type but not with those of the E1 type.

5.2. Ether Formation

The bimolecular ether formation from methanol [107], ethanol [108], *n*-propanol [75, 76], and benzyl alcohol [76] begins on γ-Al_2O_3 at about 130–140 °C. In the reaction

$$2\,ROH \underset{-1}{\overset{1}{\rightleftarrows}} ROR + H_2O \qquad (1)$$

the equilibration is fundamentally possible. However, since the equilibrium lies on the side of ether and water, the rate of the reverse reaction r_{-1} at low product concentrations, *i.e.* at low conversions in the dehydration, will be low in relation to the rate of ether formation r_1. This can be confirmed by thermodynamic estimations and by measurement of the rate of reformation of the alcohol (–1) [75, 107, 108]. Thus the ether formation from the four alcohols in question can be followed kinetically at low conversions independently of the equilibrium reaction.

5.2.1. Effect of Alcohol Pressure

The rate of the ether formation from methanol, ethanol, *n*-propanol, and benzyl alcohol becomes independent of pressure above about 160 torr at the highest measuring temperatures (about 200 °C), *i.e.* the bimolecular ether formation is a zeroth order reaction in the limiting case of high partial pressures of alcohol [76, 107, 108]. This behavior must be expected if the Langmuir-Hinshelwood mechanism is valid. The ethers should thus be formed from alcohols over aluminum oxide in a bimolecular reaction from the adsorbed phase, since a reaction oder of 1 should be obtained in the limiting case of high substrate partial pressures if the Eley-Rideal mechanism were valid. *Balaceanu* and *Jungers* [40] reached the same conclusion on the basis of kinetic studies. *de Boer et al.* [109, 110], on the other hand, propose the superposition of two independent mechanisms for the formation of ether from ethanol, the principal mechanism being an Eley-Rideal mechanism, with a smaller contribution by a Langmuir-Hinshelwood mechanism. However, these authors worked at conversions of up to 20 % and temperatures at which the secondary decomposition of the ether and the olefin formation probably cannot be neglected. Moreover, at the high conversions and relatively low alcohol partial pressures used, the inhibition of the reaction by the water formed may be appreciable, and the equilibrium reaction may falsify the rate of formation of the ether.

5.2.2. Influence of the Products

No inhibition of the reactions by the ethers formed has been observed in any case, whereas the ether formation is strongly inhibited by water. The inhibiting action of water decreases with rising temperature and increasing alcohol partial pressure [76, 107, 108]. As in the formation of olefins, the rate of ether formation can be satisfactorily described by the empirical equation (5) (in the form (6)) (Fig. 8). The quotient Θ_A may again be interpreted as an adsorption isotherm, which

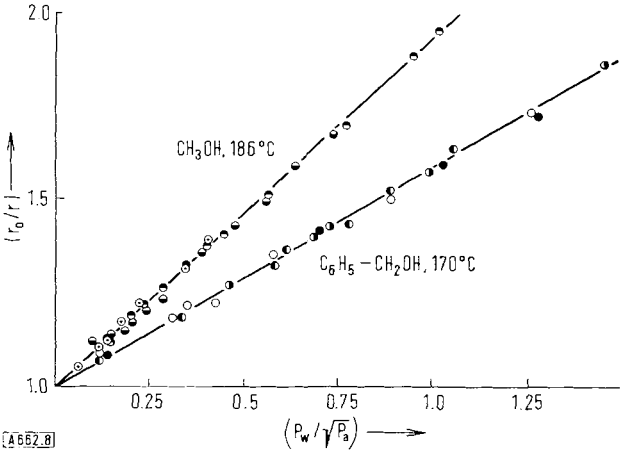

Fig. 8. Kinetics of ether formation from methanol at 109 (◓), 180 (◒), and 225 torr (○) (186 °C in each case) and from benzyl alcohol at 25 (●), 40 (◑), 50 (◐), and 78 torr (○) (170 °C in each case).

expresses the relative coverage of the surface with alcohol in the presence of the inhibiting water. Alcohol is molecularly adsorbed in the structure *(7)*, while water blocks only one surface OH group [structure *(9)*]. A limiting form of equation (5) for low surface coverages and negligible inhibition

$$r = r_0 \sqrt{p_A} \qquad (7)$$

was also found by *Meye* [31] for the formation of ether from methanol on γ-Al_2O_3. It is unusual for an equation (5) having the typical form of the kinetic equation of a unimolecular decomposition to be valid for a bimolecular reaction. For the ether formation one would expect an expression containing the square of the surface concentration of the alcohol. At least one reactive surface compound having a finite life must be assumed for ether formation [82], since the probability of a bimolecular surface reaction would otherwise be extremely small. Since a surface alkoxide has been de-

[110] *J. H. de Boer, R. B. Fahim, B. G. Linsen, W. J. Visseren*, and *W. F. N. M. de Vleesschauwer*, J. Catalysis *7*, 163 (1967).

tected in the catalytic temperature range for all the ether-forming alcohols that have been studied spectroscopically (cf. Section 4.1.2), this species must be regarded as the intermediate in question. The rate constant for the reaction is proportional to the surface concentration of the ethoxide [110a]. Because of its finite life and its relatively high stability, its concentration may be assumed to remain constant during the reaction. The rate equation therefore only explicitly contains the concentration of a second reactant Θ_A, *i.e.* an alcohol molecule adsorbed as such by means of two nonlinear H-bonds. The rate equation for the bimolecular ether formation must consequently be of the same form as that for the unimolecular olefin formation.

5.2.3. Active Centers

As in the olefin formation (cf. Section 5.1.3), it can be shown that OH groups are also necessary as active centers for the ether formation. Activity measurements on aluminum hydroxide, on the other hand, show that the catalytic activity is not due to OH groups alone, since aluminum hydroxide is at first totally inactive for ether formation. The ether formation begins with increasing conversion of the trihydroxide into monohydroxide, though only at higher temperatures than on γ-Al_2O_3 [75, 82]. In the Peri model of the oxide surface, therefore, oxygen ions and/or incompletely coordinated aluminum ions must take part in the reaction as well as OH groups. On blockage of the Lewis centers with pyridine, in contrast to the olefin formation, formation of ether from ethanol is strongly retarded. Figure 9 shows a plot of the relative rate of ether formation on a catalyst modified with pyridine at 320 °C with respect to the rate on pure γ-Al_2O_3 against the reaction time.

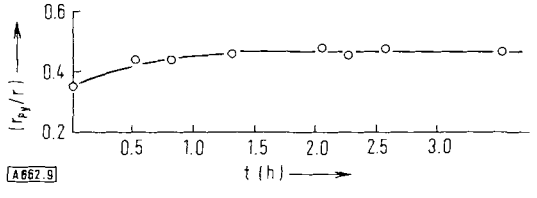

Fig. 9. Blockage of the surface of γ-Al_2O_3 in the formation of ether from ethanol. r_{Py}/r = relative reaction rate of a γ-Al_2O_3 catalyst modified with pyridine at 320 °C.

After a build-up period of about 70 minutes, the relative activity remains constant. As a result of the poisoning by pyridine, however, the rate of ether formation decreases by more than 50 %, and the activity does not regain its original value even after several hours. This shows that the ether formation, unlike the olefin formation, involves the active participation of Lewis centers. The oxygen ions must also be concluded to be involved on the basis of the structure *(7)* assumed for the adsorption of molecular alcohol, so that three types of centers, *i.e.* OH groups, oxygen ions, and incompletely coordinated aluminum ions, are necessary for ether formation (cf. also the note added in proof, p. 800).

5.2.4. Mechanism of Ether Formation

The formation of ethers from alcohols is assumed to result from the reaction of surface alkoxide groups with molecularly adsorbed alcohol molecules. A mechanism of this type is suggested by the fact that all the ether-forming alcohols examined so far can form a surface alkoxide that can be detected by IR spectroscopy, whereas no analogous surface compound is found for the olefin-forming alcohols. Since the alkoxides of the ether-forming alcohols are thermally more stable than those of the olefin-forming alcohols [78, 79], the direction followed by the reaction may be determined by the thermal stability of the alkoxide. The temperature range for the undisturbed ether formation thus becomes narrower with decreasing thermal stability of the alkoxide (cf. Section 2). Thus for isopropanol and *n*-butanol, olefin and ether formation and secondary decomposition of the ether begin at roughly the same temperature.

This naturally does not conclusively prove the active participation of surface alkoxides in the ether formation and the special reaction-directing effect of this group. However, since no opposing evidence has yet been found, a course of this type may be assumed, particularly since these views are indirectly reinforced by the form of the kinetic equation and the active participation of the Lewis centers, on which the alkoxide formation must occur [19, 67]. Ether formation by condensation of two adjacent alkoxide groups has been discussed by *Topchieva, Yun-Pin*, and *Smirnova* [17], but this would not explain the active participation of the three types of centers (cf. also the note added in proof, p. 801).

The rate determining step in the ether formation could in principle be the desorption of the water formed. However, since the formation of ether from deuteriomethanols on a deuterated oxide surface, which yields heavy water, shows no primary isotope effect [111], the rate cannot be determined by the desorption of water. There are two routes by which the reaction could proceed, but no definite decision as to which is actually followed is possible at present:

1. The R–OH bond of the molecularly adsorbed alcohol and the RO–Al bond in the alkoxide group are broken. No primary isotope effect is to be expected in this case, in agreement with the experimental observations [111]. The rate of ether formation may be determined by the cleavage of one of these two bonds, though it is not known which. Since the separation energies for homolysis are much lower than those for heterolysis [112, 113], the reaction would have to be assumed to be substantially nonionic.

2. Alternatively, the RO–H bond in the alcohol molecule and the R–OAl- bond in the alkoxide group

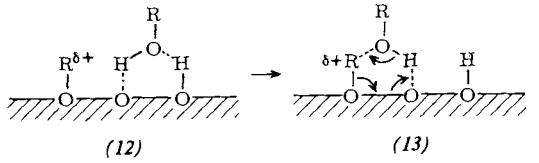
[110a] *H. Knözinger* and *H. Stolz*, unpublished.

[111] *H. Knözinger, A. Scheglila*, and *A. M. Watson*, J. physic. Chem. *72*, 2770 (1968).

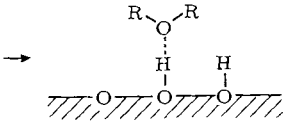
[112] *Landolt-Börnstein*: Zahlenwerte und Funktionen, Vol. 1: Atom- und Molekularphysik, Part 2: Molekeln I. Springer-Verlag, Heidelberg 1951, p. 36.

[113] *V. J. Vedeneyev, L. V. Gurvich, V. N. Kondratyev, V. A. Medvedev*, and *Ye. L. Frankevich*: Bond Energies, Ionization Potentials and Electron Affinities. Arnold Publ. Comp., London 1966.

may be broken. This route could be favored on steric grounds. The α-C atom in the alkoxide group may be positively charged because of the electron-attracting action of the aluminum, and, as an electrophile, attack the hydroxyl oxygen of the alcohol. This will cleave the passive H-bond between the hydroxyl oxygen of the alcohol and the surface proton. Rearrangement of the molecule then leads readily to a structure *(14)*



(12) *(13)*



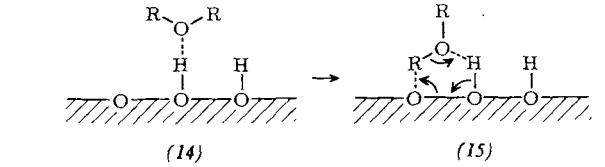
(14)

postulated on the basis of spectroscopic observations for the physically adsorbed ether [85]. The second reaction product, water, must be formed in this case by condensation of two adjacent surface OH groups. Thus hydrogen exchange with the surface must also occur in the ether formation.

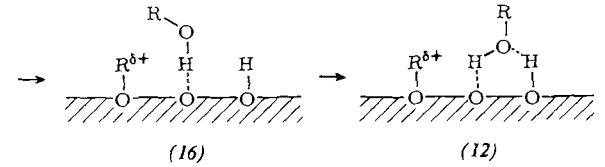
These views on mechanism can also be used to describe the equilibrium reaction (−1), *i.e.* the hydration of ethers

$$ROR + H_2O \xrightarrow{-1} 2\,ROH \qquad (-1)$$

while obeying the principle of microscopic reversibility. Starting with a surface area in which two adjacent OH groups have been formed by dissociative adsorption of a water molecule (*i.e.* reversal of the desorption of water during dehydration), the reaction can be schematically rerpesented as proceeding *via* the stages *(14)*, *(15)*, *(16)*, and *(12)*.



(14) *(15)*



(16) *(12)*

This brings us to the starting state *(12)* chosen in the dehydration of alcohols. In the following, final step, the second alcohol molecule must be formed by condensation of an alkoxide group with an OH group. This act of desorption corresponds, in the sense of microscopic reversibility, to the dissociative adsorption of alcohol with formation of the required surface alkoxide. According to these views, different intermediates would be required for the formation of ethers and of olefins.

Brey and *Krieger* [4], on the other hand, proposed the same intermediate, *i.e.* a carbonium ion, for both reactions. *Topchieva, Yun-Pin,* and *Smirnova* [17] deduced the same scheme, but replaced the common ionic intermediate by an alkoxide, as did *Solomon, Bliss,* and *Butt* [47].

If the second mechanism is correct, the cleavage of the RO–H bond may be ruled out as the rate-determining step for the ether formation, since no primary isotope effect is observed [111]. The slowest step in the ether formation should therefore be the cleavage of the AlO–R bond. The rate could in principle also be determined by the combination of the two groups to form the ether molecule, but this is unlikely in view of the high separation energies of the bonds to be broken.

5.2.5. Rate of Reaction of the Alcohols

The "true" activation energies for the formation of ethers from methanol, ethanol, *n*-propanyl, and benzyl alcohol are given with their maximum errors in Table 1.

Table 1. Reaction rates r_0 and "true" activation energies of some alcohols in ether formation on γ-Al_2O_3.

	q (kcal/mole)	$r_0 \cdot 10^7$ (mole/g sec) at 183 °C
Methanol [107]	25.9 ± 0.6	3.8
Ethanol [108]	25.9 ± 0.6	2.6
n-Propanol [76]	25.1 ± 0.6	1.5
Benzyl alcohol [76]	25.5 ± 0.6	17.2

To within the limits of accuracy, the true activation energies are the same, irrespective of the substrate alcohol. The zeroth order rates of formation r_0 of the ether decreases from methanol to *n*-propanol, while the ether formation from benzyl alcohol is 4.5 times as fast as from methanol. These observations can be explained by the reaction of a surface alkoxide group with a molecularly adsorbed alcohol molecule, with cleavage of the AlO–R bond as the rate-determining step. No data are available for the separation energy of this bond; the separation energy of the homolysis of the C–O bond in alcohols is independent of the alkyl residue R [77, 112, 113]. The separation energy of the Ti–O bond in titanium alkoxides is also substantially independent of the alkyl group [114]. It may therefore be assumed that a similar state of affairs exists for the separation energy of the C–O bond in aluminum alkoxides; this would explain the constancy of the activation energy. The rates of ether formation, on the other hand, vary with the substrate. The relative reaction rates based on that for methanol are plotted in Fig. 10 against the Taft constant σ*. They exhibit good agreement with the Taft equation. The differences in rate must therefore be due to inductive effects of

[114] *D. C. Bradley* and *M. J. Hillyer*, Trans. Faraday Soc. *62*, 2374 (1966).

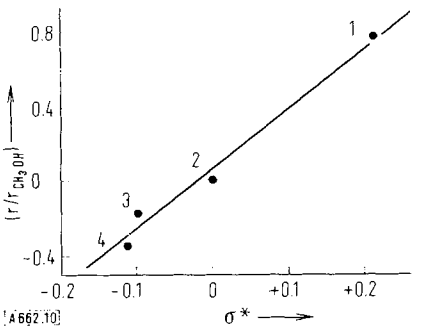


Fig. 10. Correlation of the relative rates of ether formation with the Taft equation.
1: benzyl alcohol, 2: methanol, 3: ethanol, 4: *n*-propanol.

the alkyl residues R. The straight line in Figure 10 has a positive gradient, *i.e.* the reaction constant ρ^* of the Taft equation is positive. Since this quantity becomes increasingly negative with increasing ionic character of the transition state[115], the transition state in the proposed ether formation mechanism (electrophilic substitution) must be assumed to be only weakly ionic.

I am grateful to my colleagues Dr. H. Bühl, G. Clement, G. Kinshofer, R. Köhne, W. Meye, E. Ress, A. Scheglila, Dr. H. Spannheimer, and H. Stolz for their enthusiastic cooperation, and to Prof. Dr. G.-M. Schwab for his interest in and encouragement of our work. Special thanks are due to the Deutsche Forschungsgemeinschaft and the Stiftung Volkswagenwerk for their generous support.

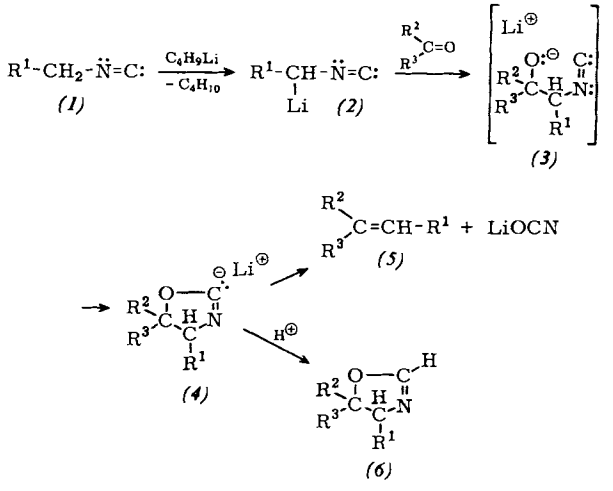
Carbonyl Olefination with α-Metalated Isocyanides

By *U. Schöllkopf* and *F. Gerhart*[*]

Dedicated to Professor H. Brockmann on the occasion of his 65th birthday

As is shown by the success of the Wittig reaction[1], the organic chemist is in urgent need of a process for the positionally specific conversion of carbonyl compounds into olefins.

We have now found that the reaction of α-metalated isocyanides *(2)* with aldehydes and ketones yields olefins *(5)* with their double bond in the position originally occupied by the carbonyl group. The olefination reagents *(2)* are obtained from isocyanides *(1)*[2] and bases such as butyllithium. The metalated oxazolines *(4)* are important intermediates; they result from the cyclization of the carbonyl adducts *(3)* and fragment to give the olefin *(5)* and metal cyanate. The readiness with which this decomposition occurs depends on the nature of the groups R_1, R_2, and R_3. The intermediates *(4)* and *(3)*, respectively, can be intercepted with protons with formation of the oxazolines *(6)*[3].



R¹	R²	R³	T (°C) [a]	Product	Yield %
H	C_6H_5	C_6H_5	−65	1,1-Diphenylethylene [b]	40
C_6H_5	C_6H_5	C_6H_5	−70	1,1,2-Triphenylethylene [c]	74

[a] Decomposition of *(4)*; metalation and carbonyl addition at −70C°; tetrahydrofuran as solvent.

[b] Together with 2-(diphenylhydroxymethyl)-5,5-diphenyloxazoline.

[c] Together with small quantities of 2-(diphenylhydroxymethyl)-4,5,5-triphenyloxazoline.

[d] Together with 5-(β-styryl)oxazoline.

[e] Together with 2-(diphenylhydroxymethyl)-5,5-diphenyl-4-vinyloxazoline.

The metalated isocyanides *(2)* are more reactive than the alkylidenetriphenylphosphoranes. For instance, α-lithiobenzhydrylisocyanide reacts even at −70 °C smoothly with benzaldehyde to 1,1,2-triphenylethylene (yield 30%), whereas diphenylmethylenetriphenylphosphorane is unreactive towards aldehydes and ketones[1].

1,1,2-Triphenylethylene:
A solution of 50 mmole of butyllithium in 45 ml of pentane was diluted with 150 ml of dry tetrahydrofuran. A solution of 5.85 g (50 mmole) of benzyl isocyanide in 30 ml of tetrahydrofuran was added dropwise at −70 °C. 9.1 g (50 mmole) of benzophenone dissolved in 50 ml of tetrahydrofuran was then added dropwise to the intensely yellow-red solution at −70 °C. The mixture was allowed to warm up to room temperature and evaporated to dryness under vacuum on a

rotary evaporator. 100 ml of water was added to the residue, the solution was extracted with 400 ml of ether, and the extract was dried over magnesium sulfate. Small quantities of 2-(diphenylhydroxymethyl)-4,5,5-triphenyloxazoline crystallized out on standing, and this was filtered off. Removal of the ether under vacuum left 13.3 g of residue. 3.5 g of this was chromatographed on 300 g of silica gel. 2.5 g (74%) of 1,1,2-triphenylethylene could be eluted with chloroform.

α-Methylstyrene:

Starting from methyl isocyanide and butyllithium, 50 mmole of isocyano-methyllithium was prepared at −70 °C (analogously to the above procedure). To the suspension was added with stirring at −70 °C 6.0 g (50 mmole) of acetophenone. The mixture was refluxed (under nitrogen) for 40 hours and subsequently poured into 600 ml of water. The olefin was extracted five times with 100-ml portions of pentane and dried over magnesium sulfate. The usual workup yielded 3.8 g of α-methylstyrene with b.p. 60–61 °C/18 torr.

Structure of Nitroso- and Nitro-dimethylamine

By *P. Rademacher*[*], *R. Stølevik*[**], and *W. Lüttke*[*]

Dedicated to Professor H. Brockmann on the occasion of his 65th birthday

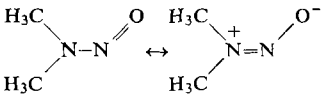
Continuing our systematic study of donor-acceptor molecules D–A, we have determined the structure of molecules of medium size containing an electron donor D linked directly to an electron acceptor A; we have used electron diffraction, IR, Raman, and NMR measurements as well as quantum-mechanical calculations. The structure recently published[1] for dimethylnitrosoaminecopper(II) chloride $(CH_3)_2N{-}NOCuCl_2$ induced us to report our results for the molecular geometry of nitrosodimethylamine *(1)* and nitrodimethylamine *(2)*.

	 *(1)*	 *(2)*
Symmetry	C_s	C_{2v}
Bond lengths (Å):		
N–O	1.235 (2)	1.223 (2)
N–N	1.344 (2)	1.382 (3)
C–N	1.461 (2)	1.460 (3)
C–H	1.129 (3)	1.121 (5)
Bond angles (°):		
N–N–O	113.6 (2)	114.8 (7)
O–N–O		130.4 (1.3)
C′–N–N	120.3 (3)	116.2 (3)
C″–N–N	116.4 (3)	116.2 (3)
N–C–H	109.6 (8)	101.9 (1.9)

Electron diffraction of *(1)* and *(2)* was measured in the usual way[2]. The molecular parameters (bond distances, angles, root mean squares of the vibrational amplitudes, shrinkage parameters) were determined from the scattering intensity curves by the method of least squares. No significant deviation from a planar skeleton was indicated for either molecule; and this finding was supported by quantum-chemical calculations and spectroscopic measurements[3].

The following results (standard deviations in parentheses) were obtained for the molecular geometries:

In a comparison of the structural data for gaseous *(1)* with those for the molecule bound in the $CuCl_2$ complex *(3)*[1] it is remarkable that both have the same C–N bond length, but that the N–N and the N–O bonds of the ligand in the complex are appreciably shorter (by 0.08 and 0.02 Å, respectively) while the N–N–O and the C′–N–N angles are larger (by about 4 °). The greatest shortening from the free molecule *(1)* to *(3)* occurs with the N–N bond length, which indicates an electronic influence of the type



in which the influence of the dimethylamino group on the nitroso group strengthens the complex bonding in the sense that the ligand becomes more firmly attached to the central atom. The compound *(1)* differs sharply from azomethane in this respect, since the molecular dimensions of azomethane are the same in the gaseous state[4] as when a ligand in the $CuCl_2$ complex[5].

The difference in the N–N distances for *(1)* and *(2)* (0.04 Å) can be interpreted as showing that the dimethylamino group is a stronger electron acceptor than the nitro group.

A detailed report of the electron diffraction study will appear elsewhere shortly[6].

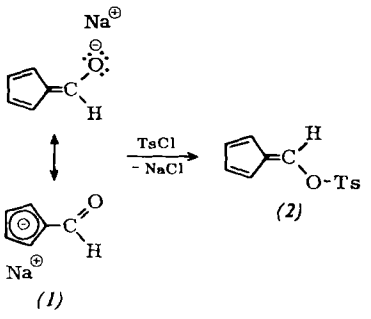
A Simple Synthesis of Substituted Fulvenes from 6-Fulvenyl *p*-Toluenesulfonates

By *K. Hafner*, *W. Bauer*, and *G. Schulz*[*]

6-Dimethylaminofulvene[1] and its derivatives are useful starting materials for the preparation of non-benzenoid, cyclic, conjugated π-electron systems[2]. In the treatment of 6-fulvenyl *p*-toluenesulfonates with nucleophilic reagents we have found a simple process for the introduction of functional groups at the 6-position of the fulvenoid system.

While reaction of sodium formylpentadienide *(1)*[3] with the Vilsmeier complex from dimethylformamide and dimethyl

sulfate[4] or with carbon dioxide affords 6-dimethylaminofulvene-2-carbaldehyde or 6-hydroxyfulvene-2-carboxylic acid, respectively, by *C*-acylation, we observed formation of *O*-acylation products[5] in the reaction with acyl halides. *p*-Toluenesulfonyl chloride and *(1)* in ether at −5 °C give

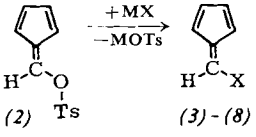


(1) *(2)*

6-fulvenyl *p*-toluenesulfonate *(2)* [yield 60 %; yellow needles (from ether), decomp. 47–48 °C; UV spectrum (*n*-hexane), λ_{max} = 226 nm (log ε = 4.11), 261 (4.34), 358 (2.51); NMR spectrum (CCl_4), τ = 2.25 (2H), d, τ = 2.70 (3H), d, τ = 3.80 (4H), m, τ = 7.64 (3H), s].

Analogously sodium 1-formylindenide and potassium 9-formylfluorenide[6] afford, respectively, 1-indenylidenemethyl *p*-toluenesulfonate (benzofulvenyl *p*-toluenesulfonate) [yield 63 %; pale yellow leaflets (from ethanol), m.p. 97–99 °C; UV spectrum (*n*-hexane), λ_{max} = 227 nm (log ε = 4.53), 305 (3.82), 314 (3.90), 326 (4.79); NMR spectrum ($CDCl_3$), τ = 2.75 (11H), m, τ = 7.67 (3H), s] and 9-fluorenylidenemethyl *p*-toluenesulfonate (dibenzofulvenyl *p*-toluenesulfonate) [yield 50 %; pale yellow crystals (from ethanol), m.p. 103–105 °C; UV spectrum (*n*-hexane), λ_{max} = 223 nm (log ε = 4.69), 228 (4.71), 247 (4.47), 257 (4.72), 274 (4.18), 283 (4.19), 300 (4.12), 313 (4.15); NMR spectrum ($CDCl_3$), τ = 2.4 (13H), m, τ = 7.65 (3H), s[7]].

6-Fulvenyl *p*-toluenesulfonate *(2)* reacts with secondary amines, alkoxides, carbanions, or sodium azide below 0 °C with C–O fission, presumably involving an addition-elimination mechanism, yielding the fulvenes *(3)–(8)* that are substituted at C-6.



(2) *(3)-(8)*

Benzo and dibenzo derivatives of *(2)* react with nucleophilic reagents analogously to the parent compound. 1-Indenylidenemethyl *p*-toluenesulfonate and sodium azide in aqueous methanol, acetonitrile, or acetone affords 1-indenylidenemethyl azide (azidobenzofulvene) [yield 21 %; pale yellow needles (from light petroleum), m.p. 76–78 °C (decomp.); UV spectrum (*n*-hexane), λ_{max} = 236 nm (log ε = 3.97), 274 (4.40), 283 (4.49), 333 (4.25), 346 (4.12)]; and 9-fluorenylidenemethyl *p*-toluenesulfonate affords the corresponding azide (azidodibenzofulvene)[9] [yield 57 %; yellow needles (from light petroleum), m.p. 88–90 °C (decomp.); UV spectrum (*n*-hexane), λ_{max} = 227 nm (log ε = 4.55), 233 (4.60), 246 (4.43), 253 (4.47), 263 (4.59), 280 (3.99), 290 (4.14), 302 (4.22), 325 (4.41), 337 (4.36)].

6-Fulvenyl p-toluenesulfonate (2):

A solution of *p*-toluenesulfonyl chloride (16 g) in ether (150 ml) is added dropwise to a suspension of sodium formylcyclopentadienide *(1)* (11.6 g) in ether (100 ml) at −5 °C with exclusion of oxygen and moisture. After 5 h the insoluble residue is filtered off under nitrogen, and the red ethereal solution is washed with water and dried over previously ignited Na_2SO_4. The solvent is removed under nitrogen at reduced pressure and the red, oily residue is then chromatographed on Al_2O_3 (neutral, activity grade III) with ether, whereupon a yellow zone can be eluted. The eluate is concentrated under nitrogen and cooled to −50 °C. Compound *(2)* (15 g, 60 %) is obtained as yellow needles that are sensitive to heat and to autoxidation and that decompose at 47–48 °C.

6-Fulvenyl azide (8):

A solution of sodium azide (6.5 g) in water (30 ml) is added to a solution of 6-fulvenyl *p*-toluenesulfonate *(2)* (12.8 g) in methanol (120 ml) at 0 °C, and the mixture is stirred for 4 h at −5 °C. After addition of water, the mixture is extracted with ether. The ether is removed under nitrogen at reduced pressure and the red, oily residue is chromatographed on Al_2O_3 (neutral, activity grade III) with light petroleum (40 to 60 °C). A red oil is obtained that affords 6-sulvenyl azide *(8)* (3 g, 50 %), as a yellow-red compound that is crystalline up to about −40 °C, on condensation in a low-temperature trap. *(8)* decomposes at room temperature and is characterized by its photolabile nature and by its sensitivity to air.

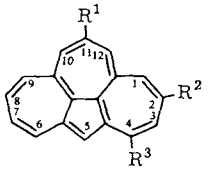
[9] 9-Fluorenylidenemethyl azide was recently prepared by *G. Smolinsky* and *C. A. Pryde* (J. org. Chemistry *33*, 2411 (1968)) from 9-fluorenylidenemethyl bromide and sodium azide.

Azuleno[8,8a,1,2-*def*]heptalene

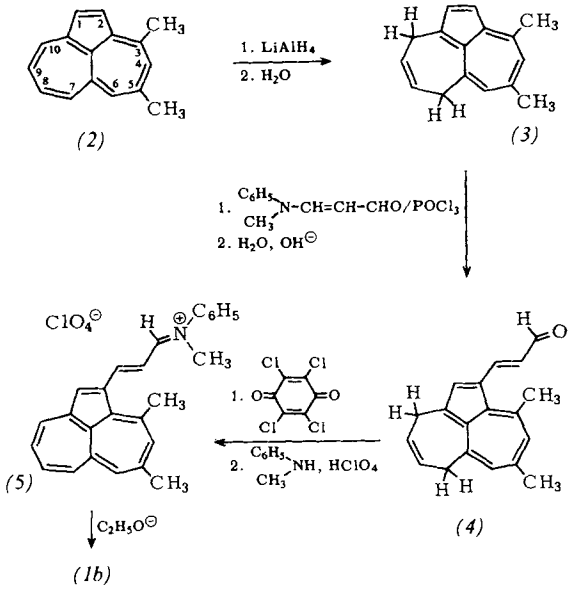
By *K. Hafner, G. Hafner-Schneider,* and *F. Bauer* [*]

Methyl derivatives of the still unknown hydrocarbon *(1a)* azuleno[8,8a,1,2-*def*]heptalene (dicyclohept[*cd-ij*]azulene) can be prepared by a simple process that has already repeatedly proved its value for preparation of polycyclic condensed



(1a), $R^1 = R^2 = R^3 = H$
(1b), $R^1 = CH_3$, $R^2 = R^3 = H$
(1c), $R^1 = R^2 = R^3 = CH_3$

non-benzenoid systems [1]. 11-Methylazuleno[8,8a,1,2-*def*]-heptalene *(1b)* is accessible from 3,5-dimethylaceheptylene *(2)* [2] by base-catalyzed intramolecular cyclization of the aldimmonium perchlorate *(5)*. The salt *(5)* cannot be prepared from *(2)* by the Vilsmeier reaction with 3-(*N*-methylanilino)acrolein and $POCl_3$ [3], since *(2)* is preferentially substituted in the 1- and 4- or 9-, and 6- or 7-positions by electrophiles. It can, however, be obtained by way of 7,10-dihydro-3,5-dimethylaceheptylene *(3)*, which is formed in



(2) *(3)* *(5)* *(4)* *(1b)*

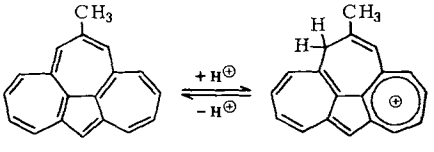
65–70% yield on partial reduction of *(2)* by $LiAlH_4$ in boiling tetrahydrofuran [dark blue crystals of m.p. 74–76 °C (from light petroleum) [4]].

As a derivative of azulene, compound *(3)* is substituted exclusively at C-2 by electrophilic reagents. On reaction with 3-(*N*-methylanilino)acrolein and $POCl_3$ in tetrahydrofuran and subsequent alkaline hydrolysis, *(3)* affords the propenal *(4)* [yield, 81%; dark green needles of m.p. 150 to 151 °C (from ethyl acetate) [5]], dehydrogenation of which by chloranil in boiling benzene gives 3-(3,5-dimethyl-2-aceheptylenyl)acrolein [yield, 68%; reddish-brown needles of m.p. 109–110 °C (from ethyl acetate) [5]]. Treatment with *N*-methylaniline and 70% perchloric acid in tetrahydrofuran leads to a 98% yield of the aldimmonium perchlorate *(5)* (black crystals, decomp. > 230 °C), which in the presence of sodium ethoxide in boiling ethanol condense to the thermally stable hydrocarbon *(1b)* [yield 7%; dark green needles of m.p. 115–116 °C (from light petroleum); trinitrobenzene adduct, black needles of m.p. 182–184 °C (from ethanol)].

Elemental analysis, molecular-weight determination, and UV and NMR spectra prove the constitution of *(1b)*.

The banded electronic spectrum of *(1b)* in *n*-hexane shows absorption maxima at 233 nm (log ε = 4.40), 276 (4.53), 299 (4.88), 337 (3.88), 398 (3.67), 507 (sh) (2.44), 539 (2.27), 583 (2.24), 638 (2.10), 930 (1.64), 1075 (1.74), 1275 (1.72), and 1630 (1.40). The unusually long-wave absorption of this 18 π-electron system accords satisfactorily with the result of an SCF calculation [6]. In the NMR spectrum of *(1b)* in CS_2 the proton signals are at notably high field: as well as the singlet of the five-ring proton H^5 at $\tau = 5.42$, there is the ABCD spectrum of the eight protons of the two unsubstituted seven-rings (H^1–H^4, H^6–H^9) at $\tau = 5.46$, 6.31, 6.04, and 7.12; a broadened singlet at $\tau = 8.02$ is to be ascribed to the two equivalent protons H^{10} and H^{12}, and a triplet at $\tau = 9.68$ (allylic coupling with H^{10} and H^{12}; $J = 0.6$ Hz) to the methyl protons. The positions of the signals indicate a strong paramagnetic ring current in the three seven-membered rings and a weak diamagnetic ring current in the five-membered ring [7].

Compound *(1b)* is strongly basic. The reversible protonation, occurring even in 2N H_2SO_4, leads to the reddish-violet conjugated acid *(6)* [UV spectrum of *(1b)* in CH_2Cl_2/



(1b) *(6)*

CF_3COOH: $\lambda_{max} = 326$ nm (log ε = 4.71) 402 (3.92), 423 (3.91), 551 (4.05), 645 (3.05), and 715 (2.52)], which is formally a combination of the azulene with the heptalenium cation [8]. The NMR spectrum of *(6)* [H^1–H^9, 2 multiplets centered at $\tau = 1.62$ (7H) and $\tau = 0.90$ (2H); H^{12}, broad singlet at $\tau = 2.66$; CH_2 (in position 10), singlet at $\tau = 6.12$; CH_3, doublet at $\tau = 7.32$ (allylic coupling with H^{12}, $J = 1.2$ Hz] confirms the protonation at position 10 (≡ 12), as does the SCF calculation [6] for *(1b)* according to which these positions have the highest electron density.

2,4,11-Trimethylazuleno[8,8a,1,2-*def*]heptalene *(1c)* can be prepared analogously to *(1b)* from 3,5,8,10-tetramethylaceheptylene [9] [yield, 7%; dark green cuboids of m.p. 106 to 107 °C (from light petroleum); trinitrobenzene adduct, black needles, decomp. > 190 °C (from ethanol)] by intramolecular cyclization of the aldimmonium perchlorate corresponding to *(5)* (yield, 97%, bluish-black crystals of m.p. 200 to 202 °C). This product *(1c)* has the same chemical and physical properties as hydrocarbon *(1b)*.

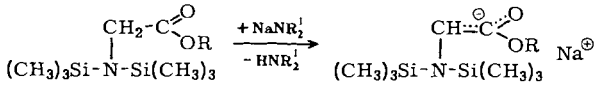
[9] *K. Hafner* and *G. Hafner-Schneider*, unpublished work; 4,6,8-trimethylazulene and 4-diethylamino-3-penten-2-one afforded 3,5,8,10-tetramethylaceheptylene in a synthesis analogous to that of *(2)* [2]. This aceheptylene derivative reacts preferentially with substitution in positions 4 and 6 on treatment with 3-*N*-methylanilinoacrolein/$POCl_3$; 3-(3,5,8,10-tetramethylaceheptylen-1-yl)acrolein is formed only as a by-product (25%).

Synthesis of Amino Acids from *N,N*-Bis(trimethylsilyl)glycine Esters[1]

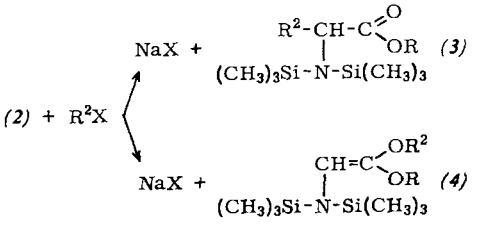
By *K. Rühlmann* and *G. Kuhrt*[*]

During our work on *N,N*-bis(trimethylsilyl)amines[2] we have found a very convenient and general synthesis of amino acids. *N,N*-Bis(trimethylsilyl)glycine esters *(1)* are first converted into the sodio derivatives *(2)* (not isolated) by means of Na bis(trimethylsilyl)amide or another base. The compounds *(2)* can undergo nucleophilic substitution or addition. The



(1a), R = C_2H_5 R^1 = H, $Si(CH_3)_3$ *(2a)*, R = C_2H_5
(1b), R = $Si(CH_3)_3$ *(2b)*, R = $Si(CH_3)_3$

C-substitution products *(3)* are obtained on reaction with alkyl halides, and *O*-substitution products *(4)* on reaction with trimethylsilyl chloride (see Table 1).

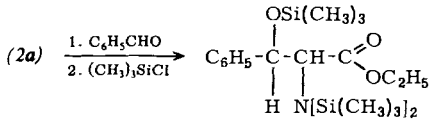


All the Si–O and Si–N bonds in compounds *(3)* and *(4)* are rapidly and completely cleaved by dilute aqueous or ethereal HCl. Thus ethyl amino-ester hydrochlorides are obtained from *(3a)–(3d)*, glycine ethyl ester hydrochloride from *(4a)*, and glycine from *(4b)*.

Table 1. Ethyl *N,N*-bis(trimethylsilyl)amino esters *(3)* and *N,N*-bis(trimethylsilyl)aminoketene acetals *(4)*.

Cpd.	R	R^2	X	B.p. (°C/torr)	n_D^{20}	Yield (%)
(3a)	C_2H_5	CH_3	I	110/111	1.4422	55
(3b)	C_2H_5	C_2H_5	I	115–117/12	1.4460	65
(3c)	C_2H_5	C_6H_5–CH_2	Br	179–181/10	1.4952	70
(3d)	C_2H_5	$(CH_3)_2HSi$–CH_2	I	133–134/10	1.4518	52
(4a)	C_2H_5	$(CH_3)_3Si$	Cl	118/9	1.4430	77
(4b)	$(CH_3)_3Si$	$(CH_3)_3Si$	Cl	122–126/10	1.4397	67

On treatment with aldehydes, *(1a)* loses hexamethyldisiloxane to afford imines, and *(2a)* gives salts of ethyl α-amino esters which can be converted into *N,N,O*-tris(trimethylsilyl) derivatives by trimethylsilyl chloride. As an example we



(5)

report the reaction with benzaldehyde yielding 3-phenyl-*N,N,O*-tris(trimethylsilyl)serine ethyl ester *(5)*, b.p. 115 °C/0.5 torr, n_D^{20} = 1.4703. This product, which is accessible in good yield, is hydrolyzed by dilute HCl to phenylserine ethyl ester hydrochloride, m.p. 170 °C[3].

N,N-Bis(trimethylsilyl)glycine ester (1):
Glycine ethyl ester or glycine is heated with an excess of (trimethylsilyl)diethylamine in the presence of a catalytic amount of $(NH_4)_2SO_4$ at *ca.* 120 °C until no more diethylamine distils off. For purification the residue is distilled in a vacuum. *(1a)*, b.p. 100 °C/10 torr, n_D^{20} = 1.4369, is formed in 75 % yield from glycine ethyl ester, and *(1b)*, b.p. 106–108 °C/10 torr, n_D^{20} = 1.4341, in 90 % yield from glycine.

Ethyl N,N-bis(trimethylsilyl)amino esters (3):
0.055 mole of Na bis(trimethylsilyl)amide in 100 ml of ether is added to 0.05 mole of *(1a)* in 50 ml of ether at −10 ° to 0 °C with stirring and the mixture is kept at room temperature for a short time. 0.05 mole of R^2X is then added dropwise and the whole is heated at the b.p. for 10–15 h, then filtered and distilled. *(4a)* is formed under analogous conditions; the synthesis of *(4b)* is carried out at −60 °C.

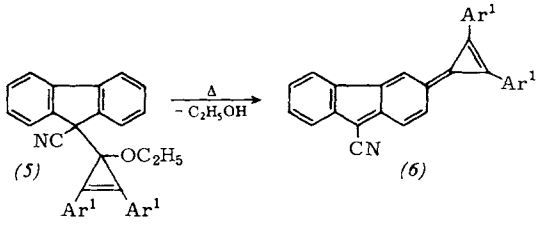
[a] In CH_2Cl_2.

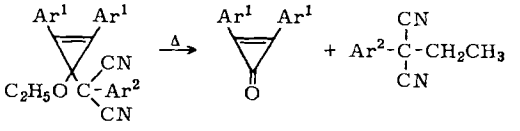
The 1:1 adduct *(5)* from *(1b)* and 9-cyanofluorene, when heated, gives the *p*-quinonoid system *(6)* [*(5)*, m.p. 219 to 220 °C (decomp.), 81 % yield; *(6)*, m.p. >340 °C, 38 % yield, λ_{max} (CH_2Cl_2) = 582 nm, $\varepsilon = 3.0 \cdot 10^4$]. The product *(6)* was obtained pure only as solvate with 1 mole of CH_3COOH of crystallization (from acetic acid/acetic anhydride).

The structure of the quinodimethanes *(4)* is supported by IR and NMR spectroscopic results. The IR spectra show absorption characteristic of the methylenecyclopropene grouping[4] at *ca.* 1850 cm^{-1}, and the NMR spectra show only aromatic protons (where Ar^1 = *p*-methoxyphenyl, also CH_3O). The *p*-quinonoid arrangement in *(4a)* and *(4b)* is favored by the fact that no quinodimethanes, but instead ethylated arylmalononitriles *(7a)* and *(7b)*, are formed when the *p*-position to the malononitrile group is blocked, *i.e.*, from the adducts of 4-methyl-1-naphthyl- *(3g)* and 4-biphenylyl-malononitrile *(3h)*, respectively and *(1a)*. The structure of the products *(7)* was proved by independent syntheses. Ethylation is also the main reaction when *(3c)* is heated.



(5) *(6)*

The *o*-quinonoid structure of *(4c)* and *(4d)* is made most probable by, *inter alia*, the UV-spectroscopic finding that the long-wavelength maxima differ relatively little in position from those of the *p*-quinonoid *(4b)*; so that an "*amphi*-quinonoid" system is improbable in *(4c)*, as is a vinylogous *p*-quinonoid system in *(4d)*.



(3g),(3h) *(7a),(7b)*

2-(1-Ethoxy-2,3-di-p-anisyl-2-cyclopropenyl)-2-phenylmalononitrile (3e):

A solution of diisopropylethylamine (2.60 g ≈ 20 mmole) in 1,2-dichloroethane (5 ml) was added dropwise to a suspension of *(1b)* [1] (20 mmole) and phenylmalononitrile (2.8 g ≈ 20 mmole) in anhydrous 1,2-dichloroethane (35 ml) over a period of 5 min; the mixture became warm, an orange coloration was observed, and the solids dissolved. After 45 min the solvent was removed in a rotary evaporator and the residue was digested with benzene (100 ml); diisopropylethylammonium tetrafluoroborate (4.36 g ≈ 20 mmole) remained behind. After removal of the solvent from the benzene solution, a red oil remained that crystallized on rubbing with ethanol (20 ml): 3.70 g (42%) *(3e)*, m.p. 180 °C (decomp.); pure on thin layer chromatography (benzene).

2-[4-(2,3-Di-p-anisyl-2-cyclopropenylidene)-2,5-cyclohexadienylidene]malononitrile (4e):

(3e) (1.00 g ≈ 2.3 mmole) was heated to 160 °C for 10 min, whereupon the substance turned carmine red and ethanol was evolved. On cooling the product was taken up in ether/CH_2Cl_2 1:1 and chromatographed on a silica gel column (150 g of "Kieselgel Merck", 0.05–0.2 mm). After elution of traces of *(3e)* with ether/CH_2Cl_2 1:1, the red substance remaining at the start was eluted with CH_2Cl_2/methanol 9:1: 0.85 g (95%) *(4e)*, m.p. 230–235 °C; carmine red needles from glycol monomethyl ether, m.p. 240 °C (decomp.).

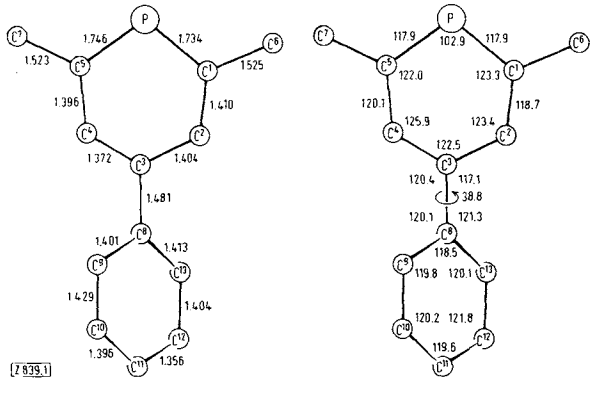
The Structure of 2,6-Dimethyl-4-phenylphosphabenzene

By *J. C. J. Bart* and *J. J. Daly* [*]

Märkl [1] has described an ingenious synthesis of 2,4,6-triphenylphosphabenzene *(1)*. The ^{31}P–NMR spectrum of this compound showed a large chemical shift of $\delta = -178.2$ ppm (in pyridine, $\delta H_3PO_4 = 0$) indicating considerable deshielding of the phosphorus nucleus. The compound is the first containing an apparently aromatic ring with phosphorus as a constituent. A triphenylphosphaindan (1,2,3-triphenyl-1,2,3-triphosphaindan) has been described [3] but its structure [2] shows no short P–C or P–P bonds; the phosphorus valences are not coplanar, so the five-ring system cannot be described as aromatic.

We have now determined the structure of 2,6-dimethyl-4-phenylphosphabenzene [4]. The crystals melt at 62–63 °C and are orthorhombic, space group $P\,2_12_12_1$ with $a = 7.312$, $b = 14.333$, $c = 10.820$ Å. There are four molecules of $C_{13}H_{13}P$ (M.W. = 200.2) in the unit cell. The intensities of the diffracted X-rays were measured on a Hilger and Watts linear diffractometer [5] and reflections with counts not significantly above the background were omitted from the analysis. The structure was solved by three-dimensional Patterson and two-dimensional (0*kl* projection) Fourier methods. The structure was refined by least squares with individual anisotropic temperature factors and the current value of *R* for 925 planes is 0.077. The hydrogen atoms have not yet been included in the analysis.



Projection along *a* of a 2,6-dimethyl-4-phosphabenzene molecule. Left: bond lengths (Å); maximum error ±0.0012 Å. Right: bond angles (°); maximum error ±0.8 °.

The results of the analysis are summarized in the Figure. The molecule possesses the approximate symmetry 2 (C_2), the axis running through the phosphorus atom and C(11). The two six-membered rings are both planar within the limits of error of the analysis. The dihedral angle between the least squares ($w = Z$) planes through these rings is 39 °, close to the value found for biphenyl [6] in the vapor phase (42 °). The CPC angle is quite small (103 °) and may be compared with the values found [7] in $P(C_6H_5)_3$ (103 °) and in a phosphamethinecyanine [8] cation (105 °). A phosphabenzene ring with a CPC angle of 103 ° and the remaining angles of 120 ° would not be planar. The planarity of this ring is achieved by an expansion of the PCC and CCC angles to about 123.3 °. A similar distortion is found in pyridine [9], but there only the NCC angles are greater than 120 °C. The P–C lengths are essentially equal (1.740 Å) and lie between the shorter [10, 11] values given for P=C (1.65 and 1.68 Å) and the length found in $P(C_6H_5)_3$ (1.83 Å). The carbon-carbon lengths in the phosphabenzene ring have an average value of 1.396 Å with no significant deviations. The bond joining the two rings is 1.48 Å, in agreement with the value given [12] (1.47–1.48 Å) for a $C(sp^2)$–$C(sp^2)$ single bond.

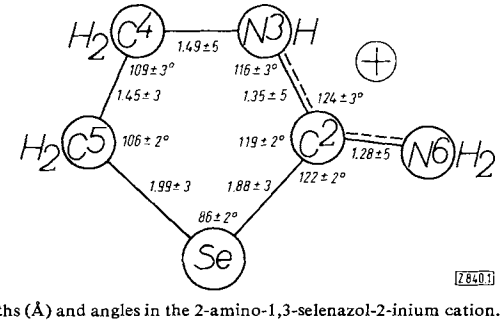
The Crystal Structure of 2-Amino-1,3-selenazol-2-inium Bromide

By *Louise Karle* [*]

The crystal structure of the anti-radiation drug 2-amino-1,3-selenazol-2-inium bromide [1] has been determined by means of X-ray diffraction with the help of a Patterson synthesis. The molecule is planar except for atom C^5 (see Fig.), which is displaced 0.43 Å from the plane. (The best plane through all the atoms except C^5 and Br is $7.01x-0.39y-7.11z-0.07 = 0$.) Both C···N distances are short. The shorter carbon-amine nitrogen bond, C^2···N^6, is only 1.28 Å while the C^2···N^3 bond in the ring is 1.35 Å. These distances indicate that the



Bond lengths (Å) and angles in the 2-amino-1,3-selenazol-2-inium cation.

positive charge is not localized on one of the nitrogen atoms, but shared between the two, with the greater charge concentration on the amine nitrogen atom. Furthermore, the ring nitrogen atom has only one Br^- neighbor (N···Br^- = 3.31 Å), whereas the amine nitrogen atom has three (N···Br^- = 3.27 Å, 3.46 Å, and 3.53 Å resp.). Each bromide ion in turn neighbors four co-planar nitrogens. The molecules pack in a close packing of the $(10\bar{1})$ planes, the distance between successive $(10\bar{1})$ planes being 3.52 Å. Interactions between a bromide ion and nitrogen atoms in adjacent planes are minimal because the interatomic distances involved are greater than 3.6 Å. Noteworthy are the unequal C^2–Se and C^5–Se distances (1.99 Å and 1.88 Å resp.) and the C–Se–C bond angle of 86 °. These values fall within the range of reported values for other organoselenium heterocycles [2]. Of particular similarity is the compound 3,3'-dioxo-2,2'-bibenzoselenolenylidene (C–Se–C = 80 °, Se–C = 1.97 or 1.75 Å) [3].

The substance crystallizes in space group $P\,2_1/c$ with four molecules per unit cell. The lattice constants are $a_0 = 7.606$ Å, $b_0 = 6.516$ Å, $c_0 = 13.574$ Å, $\beta = 99$ °; $D_m = D_x = 2.28$ g/cm³.

1056 intensities of independent reflections (245 unobserved) were estimated from Weissenberg photographs. Only the observed intensities were used for the computation of a Patterson map, on which just the Br–Br, Br–Se, and Se–Se peaks occurred with any intensity. Thus the co-ordinates of the Br and Se atoms were immediately determined. The resulting Fourier electron density map determined all but the hydrogen atom co-ordinates. An *R*-factor of 13.9% between observed and calculated structure factors was obtained by a least squares refinement using individual isotropic temperature factors.

The atom co-ordinates, the absolute standard deviation of the atom co-ordinates, and the temperature factors are given in the Table.

atom	*x*	*y*	*z*	Δ(10^{-3} Å)	B(Å^{-2})

Crystal Structure of "$Ir(CO)_3Cl$" = $Ir(CO)_{2.93}Cl_{1.07}$[1]

By *K. Krogmann*, *W. Binder*, and *H. D. Hausen*[*]

Compounds with linear chains of metal atoms, in which the central atom has a somewhat higher oxidation number than the corresponding planar d^8-complexes (*e.g.* $Mg_{0.82}[Pt(C_2O_4)_2]\cdot 5.3\ H_2O$[2]), have been known hitherto, but only with Pt as chain atoms. In the search for Ir(d^8) compounds suitable for the synthesis of analogous chains, we came upon "$Ir(CO)_3Cl$", which was first described with this formula by *Hieber et al.*[3], as a representative of this class of compounds with Ir as central atom.

According to *Fischer et al.*[4] the substance results from reaction of $IrCl_3\cdot xH_2O$ (adsorbed on silica gel) with CO at 180 °C; the product is in the form of brown-violet needles having a metallic luster. An X-ray determination of the crystal structure reveals chains with Ir–Ir distances of 2.85 Å. This distance is the same as that in the above mentioned Pt compound and corresponds to a partially oxidized chain, whereas non-oxidized Ir(*I*) complexes such as $Ir(CO)_2acac$ have distances of 3.20 Å[5]. We therefore examined the composition of the compound and obtained reproducible analyses consistent with the formula $Ir(CO)_{2.93}Cl_{1.07}$ *(1)*, thus confirming the partially oxidized character of the iridium.

The crystal structure contains orthorhombic unit cells with $a = 5.69$ Å, $b = 15.20$ Å, $c = 12.93$ Å. The cell volume (1118.3 Å^3), the formula weight (312.2), and the measured density (3.63 g/cm^{-3}) indicate the number of formula units per cell as being $Z = 7.83 \approx 8$. The space group is Cmcm or $Cmc2_1$. Strong intensities appear in layers of the reciprocal lattice with $h = 2n$ only, proving a subcell for Ir with $a' = a/2 = 2.845$ Å, which is also the period of the Ir chain. 316 reflections were strong enough to be measured on Weissenberg photographs with CuK_α radiation. The positions of the light atoms were found by Patterson and Fourier syntheses and refined to $R = 11\%$.

In the structure there are staggered planar complexes, stacked in columns parallel to the *a*-axis (A). Most complexes are $Ir(CO)_3Cl$, one Cl coordination site interchanging ligands with one CO-site (A, B). The analytically proven "surplus" Cl might be found random in this position, leading to *cis*-$Ir(CO)_2Cl_2$ complexes in the chain (C).

(A)	(B)	(C)
$(OC)_2Ir(CO)Cl$	$(OC)_2IrCl(CO)$	$(OC)_2IrCl_2$
$Cl(OC)Ir(CO)_2$	$Cl(OC)Ir(CO)_2$	$Cl(OC)Ir(CO)_2$

One would expect a normal $Ir(CO)_3Cl$ complex to be volatile, soluble in many organic solvents, chemically reactive, and to show only weak absorption in the visible region of the spectrum. Compound *(1)* sublimes in streaming CO, but not *in vacuo*. It is only soluble in solvents which attack the coordination sphere, *e.g.* aqueous KCN or pyridine (CO evolution); it is stable in air and inert. Absorption of visible light is strong for all wavelengths if the light is polarized parallel to the needle (*a*-)axis, but weak if polarized perpendicular to it. The compound exhibits a small temperature independent paramagnetic component $\chi_p = +71.0\cdot 10^{-6}$, if the molar susceptibility of $\chi_{mol} = -31.0\cdot 10^{-6}$ is corrected for diamagnetic increments of the atoms concerned.

According to the structure, relatively strong bonds between Ir atoms exist in the chains. From the similarity of the properties of *(1)* and those of the partially oxidized Pt compounds[2,6] it may be assumed that delocalized charges occur in the chains; however, in contrast to the Pt compounds the charge balance in these compounds is maintained in the coordination sphere itself by $Ir(CO)_2Cl_2$ groups. The degree of partial oxidation in Ir^I (+0.07) is remarkably small compared to that in Pt^{II} (0.3).

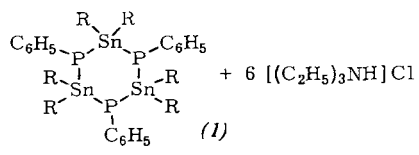
Cyclic Organostannylphosphines[**]

By *H. Schumann* and *H. Benda*[*]

Continuing previous work[1,2] we have found that cyclic organostannylphosphines of the type $(R_2Sn{-}PR)_3$ are formed on interaction of tetraphenyltin with phosphorus (P_4). The same type of compound arises also in reactions between triphenylstannyllithium and phenylphosphorus halides or phosphorus trichloride. Some of these reactions are not readily reproducible and their precise course has not yet been clarified.

Attempts to obtain such cyclic organostannylphosphines in an unambiguous manner from diorganotin dichlorides and phenylphosphine with thermal removal of HCl were unsuccesful until the following procedure was used: dimethyl-, dibutyl-, or diphenyl-tin dichloride and phenylphosphine are added (simultaneously at room temperature under nitrogen, during 2 h) to a benzene solution of triethylamine present in stoichiometric amount to act as complex-former and HCl-acceptor; this method, which accords with the dilution principle, leads to polymeric and trimeric *(1)* diorganostannylphenylphosphines.

$$3\ R_2SnCl_2 + 3\ C_6H_5PH_2 + 6\ (C_2H_5)_3N$$



$$\rightarrow \quad (1) \quad + 6\ [(C_2H_5)_3NH]Cl$$

	R	Yield (%)	M.p. (°C)	νSnP (nujol suspension)
(1a)	CH_3	73	134	388, 365, 318, 310, 284
(1b)	C_4H_9	61	Oil	388, 347, 307, 298, 289
(1c)	C_6H_5	53	155–160	372, 361, 335, 308, 297

Triethylammonium chloride and insoluble polymers are filtered off and the filtrate is concentrated in a vacuum, the products *(1)* being then precipitated on addition of pentane, and recrystallized from hot methylcyclohexane. They were shown to be homogeneous by thin-layer chromatography under argon[3]. Structures were proved by complete elemental analysis, cryoscopic determination of molecular weight, and IR and ^1H–NMR spectroscopy. In the IR spectra the vibrations due to alkyl and phenyl groups attached to tin and phosphorus were accompanied in all cases by five bands that are assigned to the Sn–P stretching vibrations. In accord with observations for dialkylsilicon sulfide[4] this indicates a chair form of the ring skeleton, having symmetry C_s and analogous to that for cyclohexane. The ^1H–NMR spectrum[5] of *(1a)* contains, as well as the multiplet of phenyl protons, the expected triplet for the protons of the two methyl groups bound to tin, namely at $\delta = 398.5$ Hz ($J_{^1H-C-Sn-^{31}P} = 4.4$ Hz, $J_{^1H-C-^{117}Sn} = 46.5$ Hz, $J_{^1H-C-^{119}Sn} = 51.5$ Hz).

(1a) is not very stable thermally: it decomposes above 175 °C into stoichiometric amounts of pentaphenylcyclopentaphosphane, bis(trimethylstannyl)phenylphosphine, and tin:

$$5\ [(CH_3)_2Sn\text{-}PC_6H_5]_3 \xrightarrow{\Delta}$$
$$(1a) \qquad 2\ [C_6H_5P]_5 + 5\ [(CH_3)_3Sn]_2PC_6H_5 + 5\,Sn$$

Ethereal hydrogen chloride cleaves *(1a)*, *(1b)*, and *(1c)* with liberation of phenylphosphine and formation of dimethyl-, dibutyl-, and diphenyl-tin dichloride, respectively, which also proves the constitutions.

closo-Tetrakis(phenylstannylphosphine), an Organostannylphosphine with a Cubane Structure[**]

By *H. Schumann* and *H. Benda*[*]

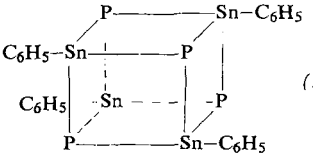
Among the oxidation products of the organostannyl phosphines formed on reaction of tetraphenyltin with phosphorus (P_4) in a sealed tube at 300 °C we have found a polymeric organotin phosphate that was apparently formed from a polymeric phenylstannylphosphine $(C_6H_5SnP)_n$[1]. The last-mentioned compound was not isolated under the conditions used at the time; it is also formed from anhydrous tin(II) chloride and diphenylphosphinolithium but this reaction is also not readily reproducible and its course is not clarified[2]:

$$n\ SnCl_2 + 2n\ LiP(C_6H_5)_2 \rightarrow (C_6H_5SnP)_n + nP(C_6H_5)_3 + 2nLiCl$$

We have now determined the structure of this organostannylphosphine by a clear synthesis.

If benzene solutions of phenyltin trichloride and triethylamine are added simultaneously under argon to benzene into which phosphine is being passed, the red solution obtained contains a resinous brown precipitate of triethylammonium chloride and polymeric products. These materials are removed, the filtrate is concentrated and freed from newly precipitated polymers, then methylcyclohexane is added; this leads to a yellow precipitate from which fractional precipitation by pentane affords tetrameric phenylstannylphosphine *(1)* in *ca.* 10% yield.

$$4\ C_6H_5SnCl_3 + 4\ PH_3 + 12\ (C_2H_5)_3N \longrightarrow$$



$$(1) \quad + 12\ [(C_2H_5)_3NH]Cl$$

Compound *(1)* decomposes above 160 °C (blackening) without melting; it cannot be kept for long, even in an inert atmosphere; it is largely polymerized to insoluble products even after two days. The homogeneous condition of the freshly prepared material is proved by thin-layer chromatography[3]. Complete elemental analyses, cryoscopic determinations of molecular weight, and the IR spectrum containing few lines indicate unambiguously that it has a cubane structure. In the infrared spectrum (Nujol) the vibrations of the phenyl groups bound to tin are accompanied by essentially only the Sn–P stretching vibration required for T_d symmetry at 328 cm^{-1}. The two infrared-active deformation bands lie in the longer-wavelength and no longer measurable region.

The reaction of methyl- or butyl-tin trichloride with phosphine leads, however, like that of methyl-, butyl-, or phenyltin trichloride with sodium phosphide in benzene, only to insoluble polymeric compounds.

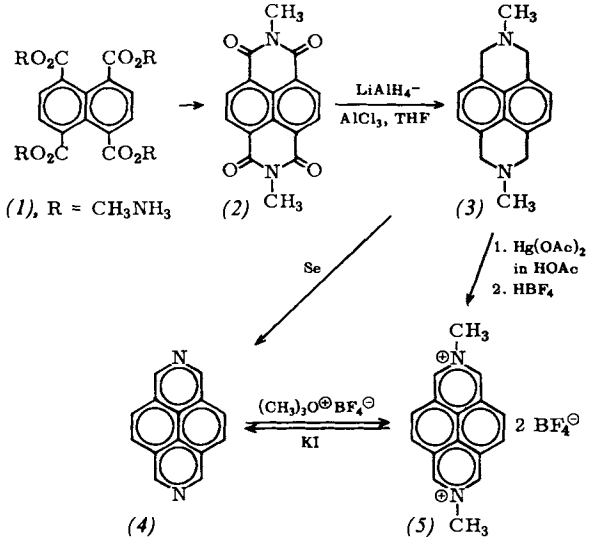
2,7-Diazapyrene and its Bis(*N*-methyl) Quaternary Salt

By *E. F. Lier*, S. *Hünig*, and *H. Quast* [*]

2,7-Diazapyrene *(4)*, which was recently synthesized [2] for the first time and by a theoretically interesting route, together with its bis(*N*-methyl)quaternary salt *(5)* were required for a study of the redox behavior of quaternary polynuclear heteroaromatic compounds [1]. We now report a synthesis giving good yields of both compounds.

1,4,5,8-Naphthalenetetracarboxylic acid, which is readily accessible commercially, was converted into the tetrakis(*N*-methylammonium) salt *(1)* by evaporating its solution in aqueous methylamine. When heated for 1 h at 150–203 °C in 1-methylpyrrolidone (500 ml), this salt *(1)* (0.1 mole) changes to the bis(*N*-methylimide) *(2)* [3], which can be isolated from the solution at 80 °C in 89% yield. Adding this imide (0.1 mole) with ice-cooling to a suspension of $LiAlH_4$ (0.7 mole) + $AlCl_3$ (0.235 mole) in tetrahydrofuran (600 ml) and then heating the mixture under reflux for 3.5 h yields 70% of the diamine *(3)*. This has the required equivalent weight, and its UV spectrum resembles that of 1,4,5,8-tetramethylnaphthalene [4].



Heating *(3)* (20 mmoles) with selenium (0.13 mole) at 260 to 265 °C for 3 h and then at 300–310 °C for 1 h, with subsequent chromatography on basic Al_2O_3 in benzene/chloroform (20:1), affords an 80% yield of nearly pure *(4)* as pale-yellow crystals. This product is obtained analytically pure by recrystallization from benzene and gives the NMR and UV values reported in the literature [2].

Trimethyloxonium fluoroborate in dichloromethane converts *(4)* smoothly into *(5)* (yield, 84%). *(5)* (1 mmole) is reconverted into *(4)* when heated with potassium iodide (16 mmoles) in triethylene glycol (100 ml) under nitrogen (yield, 50% after chromatography).

Boiling *(3)* (10 mmoles) for 30 min with mercury(II) acetate [5] (41 mmoles) in glacial acetic acid (200 ml) affords *(5)* directly. The cooled and filtered solution is treated with water (100 ml) and tetrafluoroboric acid ($d = 1.22$; 25 ml). On fractional concentration under reduced pressure an orange substance of unknown constitution (m.p. 274–276 °C) is first precipitated, and thereafter *(5)* in 20% yield. The electronic spectrum of *(5)* shows three bands with fine structure, the band of longest wavelength being shifted by 32 nm in comparison with that of *(4)*. The blue fluorescence of *(4)* is appreciably increased on conversion into *(5)*. As expected, three singlets appear in the NMR spectrum. In acetonitrile or dimethylformamide, compound *(5)* accepts one electron reversibly at −0.43 volt [6]. The green radical cation exhibits an ESR spectrum with hyperfine structure [7].

Data for new compounds (NMR spectral data in ppm, tetramethylsilane = 0): *(1)* (decomp. from 130 °C), NMR (D_2O) 2.55 (12H, S), 7.70 (4H, S); *(2)* (m.p. > 350 °C), NMR (trifluoroacetic acid) 3.28 (6H, S), 8.52 (4H, S), IR (Nujol) 1670, 1660, 1583 cm^{-1}; *(3)* (m.p. 237–239 °C, closed tube), NMR (trifluoroacetic acid) 4.52 (8H, M), 7.22 (4H, S), 8.18 (broad, 2H); *(4)* m.p. 283–284 °C (closed tube) [2], 304–306 °C; *(5)*, (m.p. > 330 °C), NMR (D_6-dimethyl sulfoxide) 4.95 (6H, S), 8.97 (4H, S), 10.37 (4H, S).

Use of the INDOR Technique in the Solution of Structural Problems in Organophosphorus Chemistry

By *R. Kosfeld*, *G. Hägele*, and *W. Kuchen* [*]

The reaction of thiophosphoryl halides of the types $PSCl_3$ and $RPSX_2$ (R = alkyl; X = Cl, Br) with Grignard reagents R'MgX' (R' = alkyl; X = Cl, Br, I) leads mainly to tetraalkyldiphosphine disulfides or trialkylphosphine sulfides, depending on the substituents R, X, R', and X' and the reaction conditions [1, 2].

By reaction of 1.76 mole of *tert*-C_4H_9MgCl with 0.43 mole of CH_3PSBr_2 in ether at 0 to 5 °C, followed by hydrolysis, we obtained a complex mixture which contained neither bis(methyl-*tert*-butyl)diphosphine disulfide $[CH_3(tert\text{-}C_4H_9)P(S)]_2$ nor methyldi-*tert*-butylphosphine sulfide $CH_3(tert\text{-}C_4H_9)_2PS$ in detectable quantities.

By means of the INDOR (internuclear double resonance) technique, heterospin decoupling, and ^{31}P- and ^1H–NMR spectroscopy, we were able to identify the individual components without prior physical or chemical separation.

As far as we know the INDOR technique [3] has not previously been applied to mixtures of structurally similar compounds. It offers two advantages over normal NMR spectroscopy:

1. For compounds having almost identical NMR spectra, all the nuclei in each molecule that couple with each other can be selectively identified.

2. The sensitivity is considerably increased, so that spectroscopic measurements on hetero nuclei coupled with protons can be carried out with specimens 5 mm in diameter.

In the analysis of highly resolved NMR spectra, the observed transition frequencies are used to find a set of constants which describe the system with sufficient accuracy; these constants are the chemical shift δ_{ij} and the coupling constant J_{ik}, the sign of which must be determined for coupling of several nuclei.

Further information can be obtained by double or multiple resonance measurements. In the case of double resonance there are five parameters: H_0, ω_1, H_1, ω_2, and H_2. H_0 is the homogeneous constant magnetic field, H_1 is the observation field, and H_2 is the irradiation field, while ω_1 and ω_2 are the frequencies [in our measurements: $\omega_1/2\pi = 90$ MHz (^1H); $\omega_2/2\pi = 36.431$ MHz (^{31}P)]

Table: Components identified with the aid of the INDOR technique in the reaction mixture from the reaction of *tert*-C_4H_9MgCl with $CH_3P(S)Br_2$. The values in parentheses are the corresponding data [4] for the pure substances [5].

	δ_{PCH_3} (ppm)[3]	$^2J_{PH}$ (Hz)	δ_{PCCH_3} (ppm)[3]	$^3J_{PH}$ (Hz)	δ_P [a] (ppm)	δ_P [b] (ppm)	δ_P [c] (ppm)	
CH_3(*tert*-C_4H_9)P(S)Br	2.36 (2.37)	11.4 (11.5)	1.38 (1.38)	21.6 (20.8)	−102.9 (−103.1)	−101.8 (−)	−103.2 (−)

CH_3(*tert*-C_4H_9)P(S)OH	1.93 (1.83)	11.8 (12.3)	1.25 (1.25)	17.8 (17.3)	− (−)	− (−)	− (−)	δ_{OH} = 7.4 (7.2) ppm

[a] ^{31}P-Resonance; [b] P—H-decoupling; [c] ^{31}P-INDOR.

In the INDOR technique, the ratio $\omega_1/\gamma H_0$ is kept constant and ω_2 is varied. If the condition for the Overhauser effect $(\gamma H_1)^2 T_1 T_2 = 1$ is satisfield [this condition is more rigorous than that for the tickling experiment $\gamma H_2/2\pi \approx \Delta\nu$ ($\Delta\nu$ = line width)], the radiation of H_2 leads to a change in the difference in occupancy of the energy levels, and hence to a change in the multiplet lines.

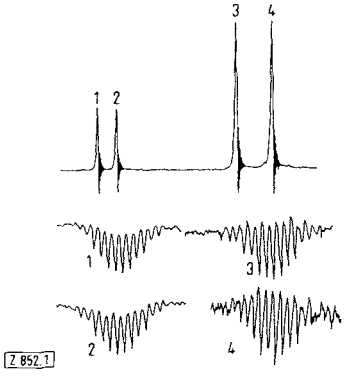

Fig. 1. ^{1}H—NMR (90 MHz) of CH_3(*tert*-C_4H_9)P(S)Br (top) and four INDOR spectra (bottom) of the proton resonance signals.

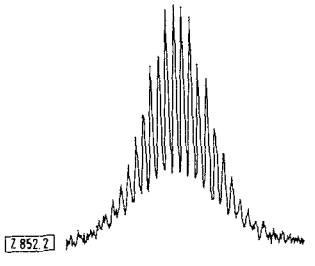

Fig. 2. ^{31}P—NMR spectrum (36.431 MHz) of CH_3(*tert*-C_4H_9)P(S)Br.

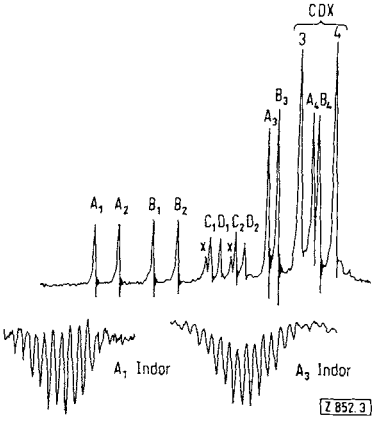

Fig. 3. ^{1}H—NMR spectrum (90 MHz) of the reaction mixture (top) and two INDOR spectra (bottom) recorded with the proton resonance signals A_1 and A_3 of the component CH_3(*tert*-C_4H_9)P(S)Br. The signals of the individual components are indicated by capitals.

The principle of this procedure is shown in Fig. 1 for the case of pure methyl-*tert*-butylthiophosphoryl bromide CH_3(*tert*-C_4H_9)P(S)Br. Figure 2 shows the ^{31}P NMR spectrum of this substance. By this method, which is demonstrated in Figure 3 for the component CH_3(*tert*-C_4H_9)P(S)Br, the compounds listed in Table 3 were identified in the reaction mixture mentioned earlier.

Volatile Transition Metal Alkanefluorodithiophosphonates [1]

By *H. W. Roesky* [*]

We recently reported the preparation of alkanefluorodithiophosphonic acids R(F)P(S)SH (R = CH_3, C_2H_5) [2]. These compounds react with transition metals with liberation of hydrogen, *e.g.*

$$2\,Cr + 6\,HS{-}\underset{F}{\overset{S}{P}}{-}C_2H_5 \rightarrow 2\,Cr(S{-}\underset{F}{\overset{S}{P}}{-}C_2H_5)_3 + 3\,H_2$$

The resulting alkanefluorodithiophosphonates (cf. Table) are characterized by considerable volatility under vacuum, and dissolve in acetone without decomposing.

The IR spectra of the metal compounds (in Nujol or capillary film) show mainly the absorption bands of the alkanefluorodithiophosphonic acids, apart from the ν(SH) vibrations, in the NaCl and KBr ranges. The absorptions around 300 cm^{-1} have been tentatively assigned to metal-sulfur stretching vibrations.

The ^{19}F—NMR spectrum of the zinc compound (melt) shows a double triplet with δ_F = 49.7 ppm (against CCl_3F; external), $J_{F\text{-}P}$ = 1111.7 Hz, $J_{CH_2\text{-}F}$ = 6.5 Hz. The ^{1}H—NMR spectrum contains a double triplet for the methyl group: δ_{CH_3} = −2.00 ppm (against TMS; external), $J_{CH_3\text{-}P}$ = 25.5 Hz, $J_{H\text{-}H}$ = 7 Hz, and a multiplet for the methylene group: δ_{CH_2} = −3.11 ppm.

Procedure

Acid is added dropwise to excess metal powder under purified and dried nitrogen. Some reactions (Mn, Ni, Zn) are exo-

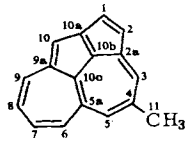
Crystal and Molecular Structure of 4-Methylpentaleno[6,6a,1,2-*def*]heptalene

By *H. J. Lindner* [*]

To obtain further information about 4-methyl-pentaleno-[6,6a,1,2-*def*]heptalene [1] $C_{17}H_{12}$ *(1)*, a polycyclic conjugated non-benzenoid system containing $4n$ π electrons ($n = 4$), by determination of its molecular geometry, an X-ray structural analysis was carried out.



(1)

(1) crystallizes in black monoclinic needles: the space group is P 2_1, with the lattice constants $a = 8.04 \pm 0.02$, $b = 6.67 \pm 0.02$, $c = 10.94 \pm 0.02$ Å; $\beta = 106.9 \pm 0.1°$. The unit cell contains two molecules. The intensities of 986 symmetry-independent reflections of the $h\,0\,l$ and $h\,4\,l$ layers were measured by means of an automatic, punched-tape-controlled Weissenberg diffractometer (Stoe-Güttinger system) with $Cu_{K\alpha}$ radiation and corrected in the usual manner.

The phases of 165 reflections with E values > 1.2 were determined by the *Karle* and *Karle* [2] symbolic addition method for non-centrosymmetric crystals. The Fourier synthesis with the E values of these reflections led to a structural model that was refined to within an R factor of 0.096 by further Fourier syntheses and by the method of least squares with isotropic temperature factors.

The molecule is planar. The bond lengths and angles are shown in Figures 1 and 2.

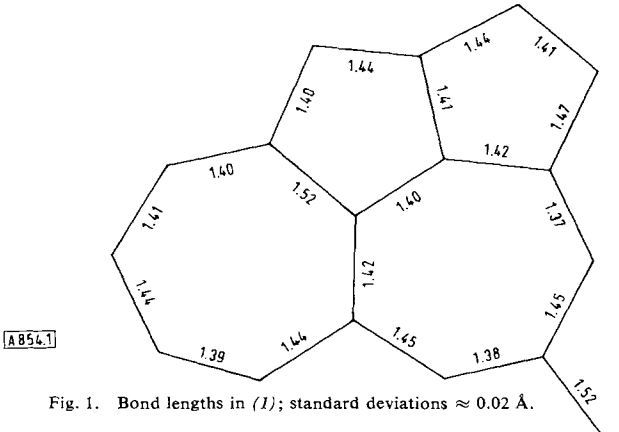


Fig. 1. Bond lengths in *(1)*; standard deviations ≈ 0.02 Å.

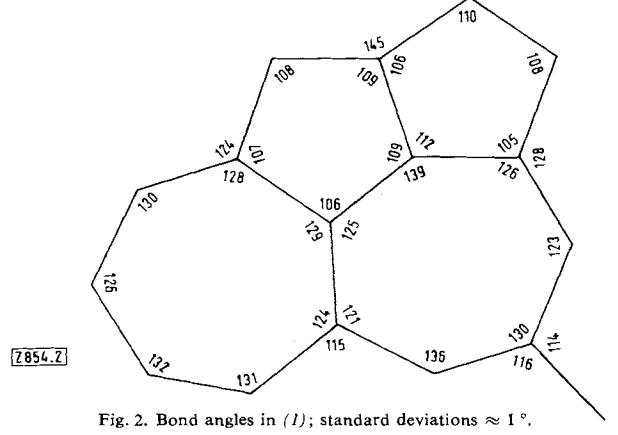

Fig. 2. Bond angles in *(1)*; standard deviations ≈ 1 °.

The alternance of the bond lengths agrees well with the results of quantum-chemical calculations [3].

Trithiomolybdates

By *A. Müller, E. Diemann, B. Krebs,* and *M. J. F. Leroy* [*]

Whereas the preparation of dithiomolybdates and tetrathiomolybdates by the introduction of H_2S into molybdate solution presents no difficulties, crystalline trithiomolybdates have not so far been obtained in this way [1]. We have now found a simple method for the preparation of crystalline Cs_2MoOS_3 and Tl_2MoOS_3.

H_2S is passed into a mixture of 15 ml of water and 15 ml of NH_3 solution ($d = 0.94$) containing 5 g of ammonium molybdate after addition of an excess of aqueous CsCl solution and acetic acid (up to pH 10). Orange to red crystals of Cs_2MoOS_3 *(1)* separate out. The less soluble Tl_2MoOS_3 *(2)* can be prepared from a solution of *(1)* by addition of $TlNO_3$.

(1) and *(2)* have been characterized by analysis, by their electronic and vibration spectra, and by X-ray investigation. *(1)* crystallizes in columns or plates with (100), (010), and (001) as the surface planes. Space group: D_{2h}^{16}, (Pnma); lattice constants: $a = 9.72 \pm 0.02$, $b = 7.21 \pm 0.02$, $c = 12.20 \pm 0.03$ Å, $V = 855.0$ Å^3. It is found from the measured density $d_{py} = 3.66$ g/cm^3 that $Z = 4$ formula units ($d_{X-ray} = 3.681$ g/cm^3). It seems certain from the similarity of the cell dimensions and the distribution of the reflection intensities in comparison with Cs_2MoS_4 [2] and other substances that crystallize in the β-K_2SO_4 type that *(1)* also belongs to this type.

The IR spectrum of solid *(1)* in Nujol contains the following bands, which conclusively demonstrate the presence of $MoOS_3^{2-}$ with approximately C_{3v} symmetry: 859 (ν_1 (A_1) $\triangleq$ νs (MoO)), 465 (ν_2 (A_1) $\triangleq$ νs (MoS)), 200 (ν_3 (A_1) $\triangleq$ δ_s (MoS_3)) and ν_6 (E) $\triangleq$ δ_{as} (MoS_3)), 475 (ν_4 (E) $\triangleq$ ν_{as} (MoS)), and 265 cm^{-1} (ν_5 (E) $\triangleq$ ρ_r (MoS_3)). The stretching vibrations of *(2)* are strongly displaced toward longer wavelengths (838), 460, and 440 cm^{-1}). Assuming a diagonal MVFF [3] F-matrix, one obtains the following force constants: $f_{MoO} = 5.89$ (5.85), $f_{MoS} = 3.11$ (3.18), $f_{MoS/MoS} = 0.30$ (0.27), $f_{SMoS} = 0.24$ (0.23), $f_{OMoS} = 0.21$, and $f_{SMoS/SMoS} = 0.00$ (0.00) mdyne/Å (corresponding values for MoO_4^{2-} and MoS_4^{2-} in parentheses [4]). The similarity of the force constants shows that the metal chalcogen bond orders are the same and the bond lengths similar in all three ions.

The electronic absorption spectrum of $MoOS_3^{2-}$ contains characteristic maxima at 21500 ($\varepsilon = 2.3 \times 10^3$), 25500 ($\varepsilon = 8.7 \times 10^3$, $f = 0.10$), 32000 ($\varepsilon = 6.6 \times 10^3$, $f = 0.09$), 38500 (shoulder), and 44100 cm^{-1} ($\varepsilon = 1.5 \times 10^4$ l·mole^{-1}·cm^{-1}, $f = 0.3$). The first bands are due to electronic reduction transitions S $\rightarrow$ Mo [5]. The high values of the oscillator strength f point to strong covalent Mo–S and Mo–O bonds. The reflection spectrum of *(1)* in the visible region is identical with the solution spectrum. This shows that isolated $MoOS_3^{2-}$ ions are present both in solution and in the solid state.

(1) gives a neutral reaction in aqueous solution. The parent acid is thus strongly dissociated. The equivalent conductivity of the $MoOS_3^{2-}$ ion is $\Lambda_{25}^{\infty} = 77\ \Omega^{-1}$ cm^2 eqt^{-1} (MoO_4^{2-}: 74.5 Ω^{-1} cm^2 eqt^{-1}).

Kinetics of the Aminolysis of Methoxyphenylcarbenepentacarbonylchromium(0) [1,2]

By *B. Heckl, H. Werner,* and *E. O. Fischer* [*]

Methoxyorganylcarbenepentacarbonylchromium complexes $Cr(CO_5)C(OCH_3)R'$ (*(1a)*: $R' = CH_3$, *(1b)*: $R' = C_6H_5$ [3]) react as analogs of esters with amines. For example, in the reaction of *(1a)* with NH_3 [4] and NH_2R [5], the methoxy group is substituted and aminocarbene complexes are formed.

We have now found that aminolysis also occurs when primary amines are allowed to act on *(1b)* in solvents such as *n*-hexane, ether, or dioxane at ~30 °C:

$$(1b) + NH_2R \rightarrow Cr(CO)_5C(NHR)C_6H_5 + CH_3OH$$

(2a): $R = C_6H_{11}$
(2b): $R = n\text{-}C_4H_9$
(2c): $R = CH_2C_6H_5$

The compounds *(2)* form yellow diamagnetic crystals, which are very readily soluble in organic solvents and are only slightly affected by oxidizing agents.

The rate of aminolysis can be determined by spectrophotometric methods (*(1b)*: $\lambda_{max} = 406$ nm, *(2a)–(2c)*: $\lambda_{max} = 362$–366 nm; in hexane [6]). The pseudo-first order rate constants for $R = C_6H_{11}$ are shown in Table 1.

Table 1. Pseudo-first order rate constants of the reaction of $Cr(CO)_5C(OCH_3)C_6H_5$ *(1b)* with $NH_2C_6H_{11}$ at 32.5 ± 0.1 °C.

[*(1b)*] (mmol/l)	[$NH_2C_6H_{11}$] (mmol/l)	Solvent	$k_{ps} \cdot 10^3$ (sec^{-1})
0.33	60	*n*-Decane	0.46
0.33	80	*n*-Decane	1.10
0.33	90	*n*-Decane	1.86
0.33	100	*n*-Decane	2.79
0.33	110	*n*-Decane	4.29
0.33	120	*n*-Decane	5.13
0.33	16.6	Dioxane	0.58
0.33	20.0	Dioxane	0.80
0.33	23.3	Dioxane	1.28
0.33	26.6	Dioxane	1.65
0.33	30.0	Dioxane	2.11
0.33	36.6	Dioxane	3.34
0.33	43.3	Dioxane	4.79

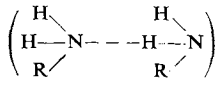
Plots of k_{ps} against [NH_2R] always lead to exponential curves, so that second order kinetics (*i.e.* first order with respect to the concentrations of complex and of amine) can be definitely ruled out. On the other hand, a very good linear relationship is found for k_{ps} and $[NH_2R]^3$ in *n*-decane and for k_{ps} and $[NH_2R]^2$ in dioxane.

$$n\text{-Decane: } \frac{d[(2)]}{dt} = k\,[(1b)][NH_2R]^3$$

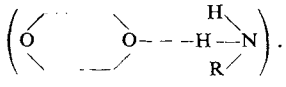
$$\text{Dioxane: } \frac{d[(2)]}{dt} = k'\,[(1b)][NH_2R]^2$$

In view of these unexpected and at first sight very surprising results, the following mechanism is suggested: The first step is the formation of an adduct (*A*) from one molecule of carbene complex and one of amine. The existence of hydrogen bonds between the NH protons and the oxygen atom of the OCH_3 group is shown by ^1H–NMR measurements[7]. The hydrogen bonding weakens the double-bond component between O and $C_{carbene}$ and so facilitates nucleophilic substitution on the carbene carbon atom.

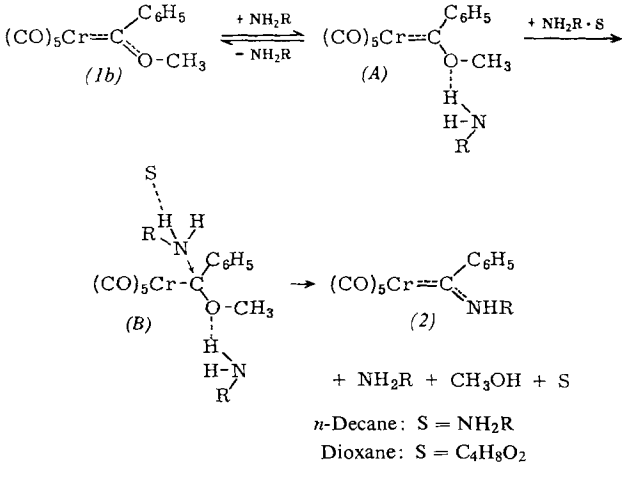
The attacking agent in *n*-decane could be an amine polarized by a second NH_2R molecule



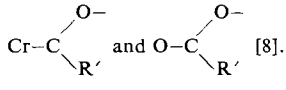
or an ion pair ($NH_3R^+ \cdot NHR^-$), and that in dioxane an amine molecule polarized by the solvent



In our view, this assumption provides a plausible explanation for the difference in the reaction order in these solvents and the higher reaction rate in dioxane (cf. Table 1).



The indicated mechanism for the aminolysis of *(1b)* again indicates the analogy between the groupings



[8].

The much greater reactivity of the former suggests less resonance stabilization and supports the view expressed earlier[3] that the $Cr-C_{carbene}$ back-bonding is only weak.

Elementary Steps in Acid-Base Catalysis. Proton Transfer Reactions in Aqueous Solutions.

By *M.-L. Ahrens* and *G. Maass*[*]

Proton transfer reactions characterized by the simple mech-

$$X + YH \underset{\overleftarrow{k}}{\overset{\overrightarrow{k}}{\rightleftharpoons}} XH + Y \qquad (1)$$

anism are described by a generalized Brønsted equation[1]:

$$\frac{d \log \overrightarrow{k}}{d \Delta pK} = \alpha \text{ (2a) and } \frac{d \log \overleftarrow{k}}{d \Delta pK} = -\beta = -(1-\alpha) \qquad (2b)$$

$\overrightarrow{k}$ and $\overleftarrow{k}$ are the rate constants for the proton transfer from the donor YH to the acceptor X and for the reverse reaction respectively. ΔpK is defined by $\Delta pK = pK_X - pK_Y$. The proton transfer is represented in a simplified form in Scheme (1). In the general case it is necessary to consider the protolysis and hydrolysis of XH and YH and the possibility that the proton transfer takes place *via* one or more water molecules. The latter point may be neglected, whereas a correction for hydrolysis is necessary in some cases in the calculation of the rate constants.

The coefficient α defined in equation (2a) is restricted to values $0 \leqslant \alpha \leqslant 1$. For $\Delta pK \gg 0$, *i.e.* $pK_X \gg pK_Y$, the proton transfer is diffusion-controlled, *i.e.* the rate cannot be increased further by increasing the pK difference. This gives the limiting value of $\alpha = 0$, and β is accordingly equal to 1. The situation is reversed for $\Delta pK \ll 0$. In this case the reverse reaction proceeds at its maximum rate (diffusion controlled), so that $\beta = 0$ and $\alpha = 1$. When the acidities of X and Y are nearly equal, so that $\Delta pK \approx 0$, the probabilities of recombination of the proton with each of them will be approximately the same, so that α will be different from 0 or 1. In the ideal case, this transition is restricted to a relatively narrow range around $\Delta pK = 0$. Actually this range extends over several orders of magnitude in most systems. This is understandable in view of the fact that the proton transfer takes place in a hydrogen bridge between the acceptor and the donor. It is therefore to be expected that the rate of the proton transfer will vary in the same way as the tendency of the reactants to form hydrogen bonds. The rate constants should accordingly decrease in the order

$$OH\ldots O > OH\ldots N > NH\ldots N > SH\ldots X > PH\ldots X > CH\ldots X$$

and the transition range $0 < \alpha < 1$ should become wider. In addition to these effects, steric hindrance or charge delocalization as a result of resonance stabilization in the reactants can lead to a further decrease in the rate of proton transfer and cause deviations from ideal behaviour. In general, a value $\alpha \neq 0$ or 1 is expected whenever the proton transfer between the donor and the acceptor in both directions is associated with the crossing of a fairly high activation barrier. The validity of the generalized Brønsted equation (2a, b) was confirmed by earlier investigations[2]. The present measure-

ments are an extension to proton transfer reactions in systems having a low tendency toward H-bond formation, as in transitions between mercapto groups. Each acceptor X was tested with a series of chemically similar donors YH having different acidities.

The very fast reactions were followed by ultrasonic relaxation methods in the frequency range of 0.3 to 100 MHz[2,3]. The rate constants $\vec{k}$ and $\overleftarrow{k}$ are listed in Tables 1 to 5. The ionic strength μ and the temperature t were constant for all the experiments.

Tables 1 to 5. Rate constants for the proton transfer between acceptor X and donor YH. μ = 1M, t = 20 °C.

3-Mercapto-propionic acid	−2.7	$6.6 \cdot 10^{5}$	$3.3 \cdot 10^{8}$

The results show that the transfer range with α values between 0 and 1 increases from the system O···H···O through N···H···N to S···H···N and S···H···S. This is in agreement with the above-mentioned relation between the reaction rate and the tendency toward hydrogen bond formation.

Deviations due to individual molecular structure effects are particularly noticeable in a comparison of Tables 4 and 5. Though both tables refer to S···H···S transfers, the log $\vec{k}$ (or log $\overleftarrow{k}$) values cannot be represented by a single curve in a log $k-\Delta pK$ diagram. The values for the methyl mercaptoacetate systems are displaced by a constant factor in relation to those for the 2-hydroxyethylthiolate systems, though the general form of the curve remains unchanged. The difference exceeds the experimental error, and suggests that the introduction of the hydrophobic methyl group in the ester leads to increased structure in the water and hence to an increase in the reaction distance, which may result in an acceleration of the reaction.

Diphthalocyaninato-thorium(IV) and -uranium(IV) [1]

By *F. Lux*, *D. Dempf*, and *D. Graw* [*]

During investigations on the separation of fission products from nuclear fuels in nonaqueous solutions [2–5], a sublimable phthalocyanin complex of neptunium was detected by radiochemical means [2]; this was the first volatile neptunium complex known. Neptunium and uranium were found in this work to differ in behavior, so that a thorough preparative study of phthalocyanin complexes of actinoids became desirable; this would be the more interesting in that a large majority of the actinoid complexes previously known contain ligands that are bonded to the central atom by oxygen.

Results reported previously [6–11] are in part contradictory [7,8]; in no case has the isolation of a phthalocyaninatoactinoid been proved unambiguously.

Thorium tetrachloride and phthalodinitrile (molar ratio 1:1 or 1:2) at 230–250 °C interact with evolution of HCl [6,10]. After extraction of the blue-black solidified melt with acetone, a solution of the residue in quinoline gives an electronic spectrum characteristic of phthalocyanin-metal complexes [11]; this contains only one absorption band between 700 and 600 nm, in this case at 685 nm. The thorium:chlorine ratio and the evolution of HCl indicate that some of the benzene rings of the phthalocyanin complex are chlorinated. The chlorinated product does not sublime: it decomposes with formation of metal-free phthalocyanin derivatives.

To prevent halogenation of the ligand, we treated thorium tetraiodide with phthalodinitrile at 240 °C. After extraction of the excess of nitrile, sublimation at 550 °C/10^{-5} torr, which involved evolution of iodine, yielded dark violet crystals of diphthalocyaninatothorium(IV) *(1)*. Dark violet diphthalocyaninatouranium(IV) *(2)* is formed analogously from uranium tetraiodide and phthalodinitrile.

These products are very stable thermally and resistant to air. *(1)* can be sublimed at 600 °C in a N_2 stream at atmospheric pressure with formation of needle-shaped crystals. *(1)* and *(2)* are sparingly soluble in benzene or tetrahydrofuran but more soluble in pyridine, quinoline, 1,2,4-trichlorobenzene, 1-chloronaphthalene, or the hexamethyltriamide of phosphoric acid; neither compound can be recrystallized from concentrated sulfuric acid.

The IR spectra (KBr disks; 2000 to 400 cm^{-1}) of *(1)* and *(2)* are almost identical with each other and very similar to the IR spectrum[12] of the analogous tin complex[13]; *(1)* and *(2)* show three bands between 1380 and 1280 cm^{-1} at 1329, 1307 or 1304, and at 1281 cm^{-1}, whereas the tin complex has only two bands in this region at 1335 and 1287 cm^{-1}. The IR spectra of *(1)* and *(2)* are characteristic of phthalocyanin-metal complexes[11].

(1) (cm^{-1}): 1608 (w), 1497 (sh), 1471 (m), 1450 (vw), 1402 (w), 1381 (w), 1329 (s), 1307 (m), 1281 (m), 1180 (vw), 1160 (w), 1112 (s), 1069 (s), 999 (w), 941 (vw), 880 (m), 866 (vw), 811 (w–m), 790 (w), 771 (m), 740 (m), 725 (vs), 625 (w), 560 (vw), 492 (w).

(2) (cm^{-1}): 1606 (w), 1481 (m), 1471 (m), 1405 (w), 1370 (w, broad), 1329 (s), 1304 (m), 1281 (w), 1160 (w), 1112 (s), 1066 (s), 999 (w), 940 (vw), 881 (m), 865 (w, sh), 810 (w–m), 790 (vw), 771 (m), 740 (m), 724 (vs), 625 (vw), 495 (w).

The electronic spectra (in pyridine: 700 to 300 nm) also accord with expectation[11]. *(1)*: λ_{max} = 650, 339 (Soret band) (log ε = 5.16, 5.03). *(2)*: λ_{max} = 647, 339 nm (Soret band) (log ε = 5.28, 5.20).

As expected, *(1)* is diamagnetic (at room temperature) and *(2)* is paramagnetic (*ca.* 3.1 B.M. between 100 and 239 °K)[14].

Mass-spectrometric molecular weights[15]: *(1)*, 1256 (±1); *(2)*, 1262 (±1). The molecules are barely fragmented at an electron energy of 50 eV, which confirms the very great stability of the compounds disclosed already by the behavior on sublimation.

Only one diphthalocyanin complex was previously known, namely, diphthalocyaninatotin(IV)[13].

Compounds *(1)* and *(2)* should have antiprismatic or bipyramidal structures, as previously proposed[16] for the tin compound. The mutual steric hindrance between the two ligands would be less in the archimedian antiprismatic arrangement. Magnetochemical results[14] also favor such structures. X-ray structure analysis is in progress.

Experimental:

A mixture of thorium iodide (1.83 g) and phthalodinitrile (6.3 g) (molar ratio 1:20) was stirred in an atmosphere of inert gas at 240 °C for 30 min, iodine being evolved and the melt becoming dark green. After cooling to room temperature, the solidified melt was powdered and extracted with benzene. The residue was dried in a high vacuum, enclosed in a platinum net, and heated in a quartz sublimation apparatus at 10^{-5} torr; at *ca.* 200 °C a rise in pressure and evolution of iodine were observed; the temperature was then raised to 550 °C. The material separating in the lower zone of the sublimate formed was similarly sublimed twice more for purification. Yield: 43%.

There is no need to use pure UI_4[17,19] in the analogous preparation of the uranium compound. Uranium turnings (1.3 g) were converted into uranium hydride. After decomposition of the hydride at 350 °C, iodine (4.2 g) was added to the uranium powder produced and the whole was heated in a closed vessel at 530 °C for 1 h. After cooling, the sublimed iodine was scratched off the walls of the vessel, and the mixture was heated for a further 12 h at 530 °C. The product was then treated with phthalodinitrile. Yield: 38%.

Enclosure of the substance in platinum gauze is particularly necessary for good yields in the first sublimation, and sublimation from a platinum crucible is necessary to afford a pure product. The layer of material in the sublimate attached directly to the wall of the vessel is discarded, to avoid products with too high a metal content; presumably at high temperatures the compounds react to some extent with the oxygen of the quartz, as was observed in the preparation of protactinium tetraiodide[18].

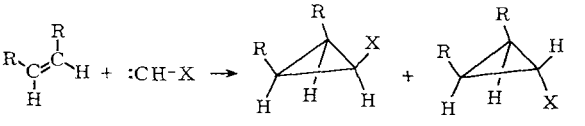
Monofluorocarbene and its *syn/anti* Selectivity[**]

By *M. Schlosser* and *G. Heinz*[*]

It has hitherto remained unexplained why addition of a carbene[1] to an olefin generally affords the thermodynamically less stable *syn*-substituted cyclopropane *(1)*[2].



R = H, Alkyl *syn-(1)* *anti-(1)*
X = Alkyl, Aryl, OR, Cl, Br

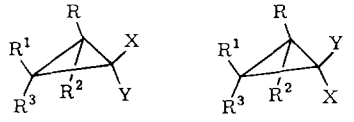
Attempts have been made to explain this stereoselectivity by assuming that in the transition state the London dispersion forces bring the alkyl groups of the olefin and the carbene ligands as close together as possible[3]. If this hypothesis were correct, then monofluorocarbene should add quite unselectively to olefins because of the small polarizability of the fluorine atom[4], and the *syn/anti* selectivity of a doubly substituted carbene :CXY should be the sum of the individual selectivities of X and Y[5].

We found that these expectations are not fulfilled. We were able to produce fluorocarbene[1,6] from dibromofluoromethane and *n*-butyllithium and to add it stereospecifically to several olefins, yielding fluorocyclopropanes (see Table 1). The *syn/anti* selectivity was then seen to be similar to that for chlorocarbene. The directive powers of carbene substituents are not additive, *i.e.*:

Table 1. Fluorocyclopropanes obtained by addition of fluorocarbene to olefins, and comparison of the observed *syn/anti* proportions thereof with those in the corresponding chloro- and chlorofluoro-cyclopropanes.

Reaction conditions: To 0.6 mole of olefin and 0.2 mole of halomethane ($CHBr_2F$, CH_2Cl_2, or $CHCl_2F$ [9]) at +15 °C was added, dropwise with stirring, 0.1 mole of *n*-butyllithium in 65 ml of hexane.

Structure determined by C, H analyses, mass spectra, and proton resonance.



syn *anti*

R	R^1	R^2	R^3	X = F, Y = H Yield (%)	*syn:anti*	X = Cl, Y = H Yield (%)	*syn:anti*	X = Cl, Y = F Yield (%)	*syn:anti*

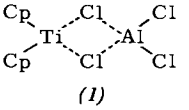
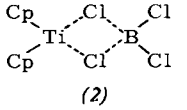
ESR-Investigation of a New Titanium-Boron Complex [1]

By *G. Henrici-Olivé* and *S. Olivé* [*]

The Ti(III)-Al complex *(1)* [2–4] has been investigated in some detail in connection with Ziegler-Natta catalysis; its ESR signal is shown in Fig. 1 (left) [2]. The six equivalent lines of the signal are due to interaction of the unpaired electron of the Ti^{III} with the Al nucleus (nuclear spin $I = 5/2$). It appears that, in this complex, the Ti^{III} species acts as an intramolecular electron donor towards the acceptor $AlCl_3$. Even better acceptor properties are exhibited by boron trihalides [5]; we therefore decided to prepare the boron analog of the complex *(1)*.



(1)



(2)

Dicyclopentadienyl-propyl-titanium chloride was reduced with alkali metal (Na, K) in toluene and in presence of an excess of BCl_3. The reaction solution showed, after having been stirred for *ca.* $^1/_2$ h, a strong ESR signal (Fig. 1, right). The four equivalent lines are clearly due to a nucleus of $I = 3/2$. Since identical signals are obtained with Na or K, an interaction of the unpaired electron of the Ti^{III} with the alkali metal [1] can be excluded in the present case; the quartet is thus obviously due to ^{11}B (natural abundance 81%). A further seven lines should be expected for ^{10}B (natural abundance 19%, $I = 3$). However, the hyperfine splitting is reduced by a factor $g(^{10}B)/g(^{11}B) \approx 0.3$; hence these weaker lines are lost under the four major lines.

On increasing the signal level, the ^{47}Ti and ^{49}Ti satellite lines can be observed which also split into quartets (Fig. 2). The bulk diagram has been constructed for both magnetic iso-

topes using $a(^{47,49}Ti) = 10.8$ and $a(^{11}B) = 5.9$ gauss. The upfield satellite lines are less resolved in the measured spectrum; the inner lines are masked by the lines of the main signal.

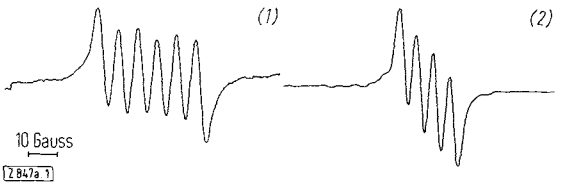


Fig. 1. ESR signal of $Cp_2TiCl_2AlCl_2$ *(1)* and $Cp_2TiCl_2BCl_2$ *(2)*.

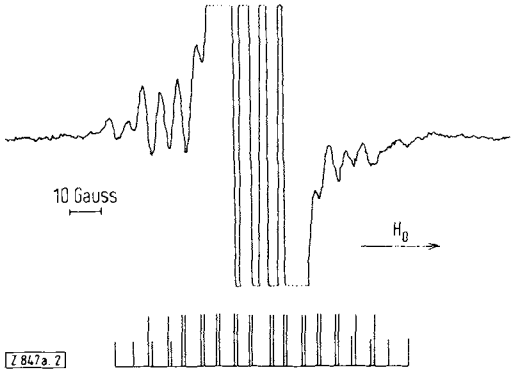

Fig. 2. ^{47}Ti and ^{49}Ti satellites in the ESR signal of $Cp_2TiCl_2BCl_2$ *(2)*. Above: recorded lines. Below: calculated bulk diagram.

As far as the accuracy of the ESR quantitative determination can be relied upon, it would seem that all, or the greater part, of Ti was present in the signal-producing form.

The spectroscopic parameters of complex *(2)* are similar to those of complex *(1)* (see Table 1), thus suggesting that both complexes have the same structure. It is possible, with the aid of the isotropic coupling constants of the free atoms B and Al [6], to estimate the density of the unpaired spin at the B and Al nucleus, ρ_M. The greater spin density at the B in *(2)* than at the Al in *(1)* confirms the greater acceptor ability of BCl_3, also toward the donor Cp_2TiCl. In perfect agreement with this statement the spin density at the Ti nucleus is smaller in the case of complex *(2)* (see column 3 of the Table).

Table 1. Comparison of ESR spectroscopic data of $Cp_2TiCl_2AlCl_2$ *(1)* and $Cp_2TiCl_2BCl_2$ *(2)*.

Cpd.	g-Value	$a(^{47,49}Ti)$ (gauss)	a(M) [a] (gauss)	Isotropic coupling (MHz) [b]	ρ_M (%)

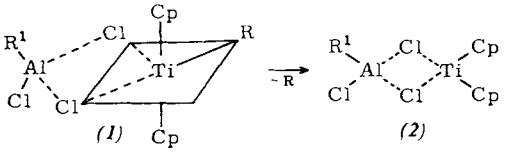
ESR-Investigation on the Stability of the Titanium-Carbon Bond in Soluble Ziegler-Natta Catalysts [1]

By *G. Henrici-Olivé* and *S. Olivé* [*]

The stability of the transition metal-carbon bonds is often decisive for homogeneous catalysis on these metals [2]. Soluble Ziegler-Natta catalysts of type *(1)* [3–5] represent a



(1a), R = C_2H_5, R^1 = C_2H_5
(1b), R = CH_3, R^1 = C_2H_5
(1c), R = C_2H_5, R^1 = CH_3
(1d), R = CH_3 R^1 = CH_3
(2a), R^1 = C_2H_5
(2b), R^1 = CH_3

Cp = cyclopentadienyl

very convenient model for the study of the Ti–C stability and the possibilities of influencing it. The reaction rate of the reduction $Ti^{IV} \rightarrow Ti^{III}$, as a consequence of the loss of R [3,4], can be measured magnetically and is a direct function of the stability of the relevant bond.

Figure 1 shows the ESR spectra observed during reduction of *(1a)–(1d)*. The hyperfine structure (six equivalent lines, not quite resolved; cf. [3]) is due to the interaction of the unpaired electron of the Ti^{III} with the Al nucleus. The last two spectra clearly differ from the first two; they show greater distance between lines and therefore appear better resolved. The splitting constant a_{Al} is determined by the ligands on

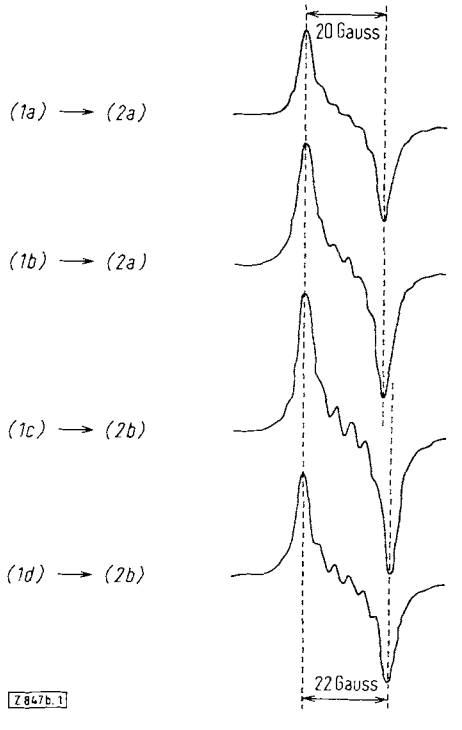


Fig. 1. The spectra observed on reduction *(1)*→*(2)*. $[Ti^{IV}]_0$ = 20×10^{-3} mol·l^{-1}; Al/Ti = 2; T = 20 °C. Solvent: toluene. The spectra were recorded after about 20% reduction.

the Al, as has been shown for similar complexes [4]. No noticeable exchange between R′ on the Al and R on the Ti occurs before relatively slow reduction reactions take place.

The methyl group is a weaker donor than the ethyl. This difference may cause great changes in transition metal complexes [6,7]. In *(2a)* $R' = C_2H_5$ is more effective than $R' = CH_3$ in *(2b)* against the delocalization of the unpaired electron of the Ti^{III}: consequently there is a lower spin density at the Al nucleus with $R' = C_2H_5$ (lines in the spectra are closer together). The donor ligands on the Al thus influence the electronic distribution in the whole complex; this influence is also to be expected for the Ti^{IV} species, and has in fact been detected. The higher the donor ability of R′ the higher the electron density on the Ti, and the higher the instability of the Ti–R bond. Such behavior is well illustrated by the reduction rate curves shown in Fig. 2, for the systems *(1a)* → *(2a)* (uppermost curve) and *(1c)* → *(2b)* (middle curve). This result confirms the hypothesis [5] that the stability of a carbon-metal bond can be varied at will by varying the ligands. The

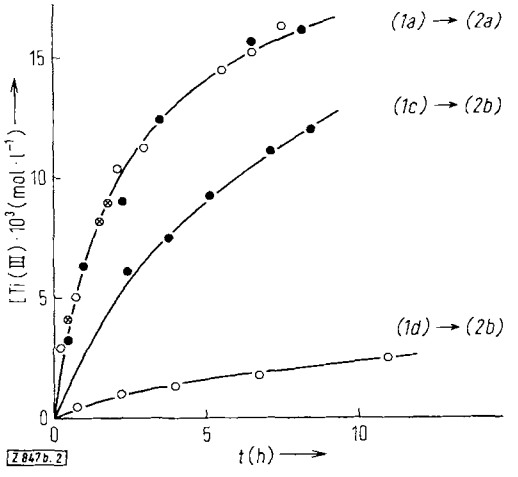

Fig. 2. Concentration of Ti(III) as a function of time.
• : from the magnetic susceptibility.
○ ⊗: from the ESR spectra (two series of experiments).

observed higher stability of the $Ti-CH_3$ bond in the system *(1a)* → *(2b)* (Fig. 2, lowest curve) can be interpreted according to the Mulliken model of the CH_3 group [8]. This model considers the methyl as a triply bonded $-C\equiv H_3$ species, and "H_3" as a heteroatom. The two bonding π-MO's perpendicular to the axis of $-C\equiv H_3$ (and the corresponding antibonding MO's) have the right symmetry to match with the d–π-Ti orbitals (d_{xz}, d_{yz}). This convenient configuration is obviously not available in the case of other alkyls.

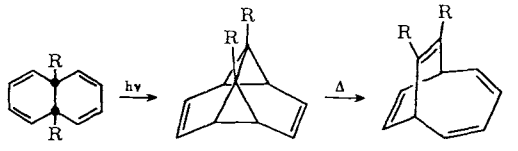
Degenerate Thermal Valence Isomerization of the Bicyclo[4.2.2]deca-2,4,7,9-tetraene Skeleton

By *W. Grimme, H. J. Riebel*, and *E. Vogel* [*]

The photochemical isomerization of *cis*-9,10-dihydro-9,10-naphthalenedicarboxylic anhydride *(1a)* to an anhydride with the bicyclo[4.2.2]deca-2,4,7,9-tetraene structure [1] disclosed a rearrangement that has since been demonstrated also for the parent hydrocarbon *(1b)* [2], the ester *(1c)* [3], and the compounds *(1d)* and *(1e)* [4]. The isolation and/or detection of the tetracyclo[4.4.0.0^{2,10}.0^{5,7}]deca-3,8-diene intermediates *(2d)* [4], *(2e)* [4], and *(2b)* [5] suggested that the rearrangement took the course shown in Scheme 1.



(1) *(2)* *(3)*

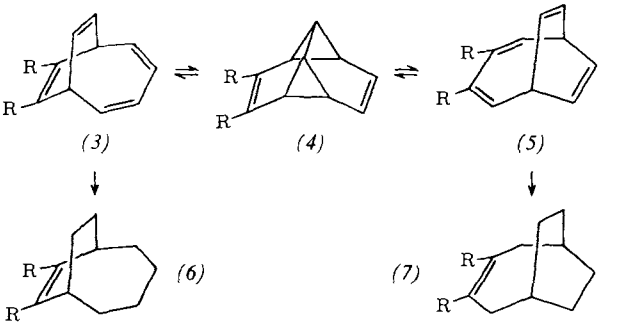
(a), R-R = -C(=O)-O-C(=O)- *(d)*, R-R = $-CH_2-O-CH_2-$

(b), R = H *(e)*, R-R = -C(=O)-N(CH_3)-C(=O)-

(c), R = CO_2CH_3 *(f)*, R = CO_2H

Scheme 1.

The bicyclo[4.2.2]deca-2,4,7,9-tetraene photoisomer obtained from *(1a)* should then have structure *(3a)*, in which the anhydride group is attached to one of the isolated double bonds. However, chemical degradation of the photoisomer showed that it has structure *(5a)* with the anhydride group attached to the diene system.



(3) *(4)* *(5)*

(a), R-R = -C(=O)-O-C(=O)- *(c)*, R = CO_2CH_3 *(f)*, R = CO_2H

Scheme 2.

On catalytic hydrogenation over platinum in glacial acetic acid the photoanhydride gives a hexahydro compound [m.p. 143 °C; UV spectrum, λ_{max} = 257 nm (ε = 5000) in dioxane], from which *cis*-1,4-cyclohexanediacetic acid [6] (identified by means of the dimethyl ester prepared with diazomethane) is formed on ozonolysis and subsequent oxidation by peracetic acid. Thus the hydrogenation product is *(7a)* and accordingly the photoanhydride itself must be *(5a)* [7].

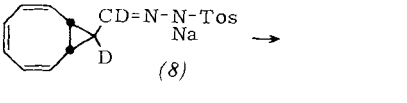
The mode of formation of the photoanhydride is clarified by the structure and properties of the acid obtained on its hydrolysis. The spectra of the acid and of its dimethyl ester [m.p. 49 °C; UV spectrum, λ_{max} = 214 nm (ε = 10300) with shoulders at 259 (2900), 267 (2900), and 277 nm (2200) in methanol; NMR spectrum, three separate groups of signals at τ = 3.82, 4.14, and 4.33 (each 2 H) and a multiplet at τ = 6.30 (8 H) superimposed by the signal of the methyl groups, in $CDCl_3$ at 100 MHz] can be interpreted only if the substituents in these compounds are attached to one of the isolated double bonds, according to *(3f)* and *(3c)*. This assignment was substantiated chemically as follows. Hydrogenation

of the acid *(3f)* affords a hexahydro acid to be considered as *(6f)*, from which an anhydride *(6a)* [m.p. 114 °C; UV spectrum, λ_{max} = 262 nm (ε = 4100) in dioxane], isomeric with *(7a)*, is formed by acetyl chloride. If *(6f)* is oxidatively degraded in the way used for *(7a)* (see above), then on treatment of the oxidation product with diazomethane an ester can be isolated that is shown to be dimethyl 1,4-cyclooctanedicarboxylate[8].

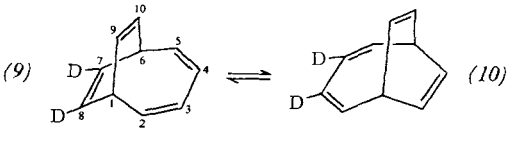
It is interesting that two different anhydrides can be obtained from *(3f)*, depending on the conditions of the dehydration. Heating at 180 °C or the action of acetyl chloride at room temperature regenerates *(5a)*, whereas treatment with ethoxyacetylene[10] at −30 °C yields an isomeric anhydride that is readily rearranged thermally to *(5a)*. The unstable anhydride must be *(3a)*, since its catalytic hydrogenation over platinum in methanol at −10 °C yields *(6a)*. Irradiation of *(1a)* at 0 °C leads, as expected, also to *(3a)*. The kinetics of the thermal isomerization of *(3a)* to *(5a)* in $CDCl_3$ was followed by NMR spectroscopy[11]; the reaction is of the first order, its rate constants being in accord with the Arrhenius equation: $k = 5.5 \cdot 10^{13} \cdot \exp.\ [(-24.5 \pm 2.7)\ \text{kcal}/RT]\ \text{sec}^{-1}$.

The reversible exchange of positions of functional groups observed on hydrolysis of *(5a)* or dehydration of *(3f)* is explained without difficulty by assuming a sequence of intramolecular diene and retro-diene reactions in which the tetracyclo[4.4.0.0^{2,10},0^{5,7}]deca-3,8-dienes *(4f)* or *(4a)* occurs as intermediate (Scheme 2).

The degenerate valence isomerization of the bicyclo[4.2.2]deca-2,4,7,9-tetraene skeleton established for the anhydride *(3a)* was detected by deuterium labeling for the parent compound *(3b)* also.



(8)



(10)

[9,10-D$_2$]-cis-Bicyclo[6.1.0]nona-2,4,6-triene-*anti*-9-carboxaldehyde tosylhydrazone *(8)* was obtained from ethyl [α-D]-diazoacetate and $LiAlD_4$ in analogy to the synthesis of the unlabeled compound[12]. It was converted into its sodium salt, which on thermolysis in diethylene glycol dimethyl ether (90 °C) gave dideuterated bicyclo[4.2.2]deca-2,4,7,9-tetraene (deuterium content determined by mass spectrometry = 97.5%). NMR spectroscopy was used to determine the position of the deuterium in the thermolysis product, which according to the mechanism assumed for decomposition of *(8)* should be *(9)*[13]. The product was purified by gas chromatography (column temperature 130 °C); its spectrum then consisted of four groups of signals, which can be assigned by spin decoupling as shown in Table 1.

Table 1. NMR signals of D$_2$-bicyclo[4.2.2]deca-2,4,7,9-tetraene (measured in CCl_4 against tetramethylsilane as internal standard at 100 MHz).

[a] For a 2:1 mixture of *(9)* and *(10)* with 97.5% labeling.

The relative intensities of the signals show the presence of a 2:1 mixture of *(9)*[14] and *(10)*. The proportions of *(9)* and *(10)* correspond to the statistical weight of the two labeled isomers after equilibration as in Scheme 2. The formation of *(9)* on thermal decomposition of *(8)* and its degenerate valence isomerization under the conditions of the synthesis are thus proved.

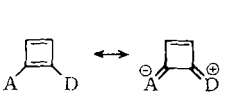
[14] The presence of a D$_2$-bicyclo[4.2.2]deca-2,4,7,9-tetraene in which one deuterium atom is attached at each of the isolated double bonds is excluded because the signal for H^7—H^{10} shows no H—D coupling.

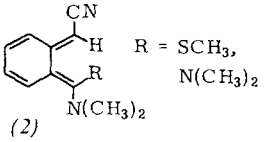
A Stable Cyclobutadiene

By *R. Gompper* and *G. Seybold*[*]

Cyclobutadiene[1] and its alkyl, aryl, and halogen derivatives have hitherto been detected only indirectly. *Roberts*[2] predicted a greater stability for 1-(*p*-dimethylanilino-2-(*p*-nitrophenyl)cyclobutadiene by reason of a "push-pull" effect of the substituents D (electron donor) and A (electron acceptor) in accord with *(1)*. An HMO calculation[3] for



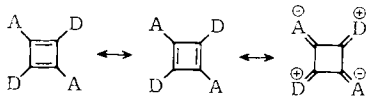
(1)



(2)

2-amino-1,3-cyclobutadiene-1-carbonitrile supports this view. How strong the stabilizing action of D and A actually is has been shown for the six-membered ring by the synthesis of *o*-quinodimethane *(2)*[4] which is stable at room temperature. All attempts to prepare cyclobutadienes *(1)* have, however, hitherto failed[5]. The stabilizing effect of D and A must be stronger in the cyclobutadienes *(3)* than in *(1)*.

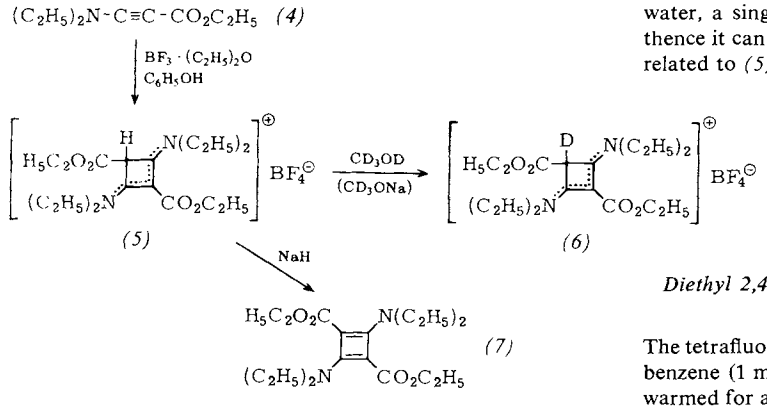
As *Viehe*[6] showed (see also ref. 7), ynamines can be "dimerized" to cyclobutenecyanines. – If ethyl (diethylamino)-propiolate *(4)* (prepared from ethyl 2-bromo-3-(diethylamino)acrylate by means of sodamide in liquid ammonia[8])



(3)

in dichloromethane is treated slowly, under nitrogen, with a solution of boron trifluoride-ether and phenol in dichloromethane (as described experimentally in ref. 7), subsequent evaporation of the solvent, chromatography of the residual yellow oil (silica gel/chloroform), and two recrystallizations of the resulting crystals from ethanol/ether yield colorless needles of m.p. 64–65 °C (yield, *ca.* 35%). In view of the data for "dimerization" of ynamines [6,7] this product must be the cyclobutenecyanine salt *(5)*.

Elemental analysis, the IR spectrum (1725, 1685, 1600, 1450, and 1080 cm^{-1}), the UV spectrum (λ_{max} = 286.5 nm, log ε = 4.51, in $CHCl_3$), the 60-MHz ^1H–NMR spectrum [in tetrahydrofuran: τ = 4.9 (1H, S); τ = 5.7 (4H; OCH_2; split quadruplet); τ = 5.93 (4H; NCH_2; Q); τ = 6.35 (4H; NCH_2; Q); τ = 8.69 (18H, split triplet)], the ^{19}F–NMR spectrum (in $CDCl_3$: singlet at −13.7 ppm relative to external C_6F_6; cf. the value for $NaBF_4$ [9]), and the ^{11}B–NMR spectrum (in $CHCl_3$: singlet at 0.09 ppm relative to external BF_3-ether) are in agreement with structure *(5)* and with the data for related compounds [6,7]. The mass spectrum contains, besides the peak at *m/e* = 339 (75%) for the cation of *(5)*, the peak



at 338 for the molecule ion of *(7)* as the most intense feature. If a catalytic amount of CD_3ONa is added to a solution of *(5)* in CD_3OD at room temperature the singlet for the tertiary proton at τ = 4.9 disappears within less than 2.5 min. Since the remaining signals of the NMR spectrum are not changed, there can be no change in the molecular structure of *(5)* except for an H–D exchange by which *(6)* is formed [*(6)* has not been isolated as yet]. The simplest explanation for the formation of *(6)* from *(5)* is intermediate occurrence of *(7)* which is rapidly deuterated to give *(6)*.

Solutions of *(5)* in tetrahydrofuran (THF) or D_8–THF or benzene assume a yellow color on addition of sodium hydride, and hydrogen is evolved. If the solutions are filtered from the excess of NaH the yellow color is retained for some time at room temperature, so that an NMR spectroscopic study can be made. The spectra are then only explicable on the basis that the symmetrically substituted cyclobutadiene *(7)* is present. In D_8–THF: τ = 6.0, Q; τ = 8.7, T (the high-resolution spectrum shows that the signals of the quadruplet are more strongly and those of the triplet less split); intensity ratio 2:3. In C_6D_6: τ = 5.84 (OCH_2); τ = 6.08 (NCH_2; M); τ = 8.93 (T); intensity ratio 2:3. The two quadruplets of the OCH_2 and NCH_2 protons of *(7)* overlap, so that a six-line spectrum arises (intensity ratios 1:3:5:7:6:2).

If trifluoroacetic acid is added to a solution of *(7)* in D_8–THF the yellow color disappears almost completely, and the NMR spectrum then shows in the CH_2 and CH_3 region once more the splitting picture of the spectrum of *(5)*. Only the singlet due to the tertiary proton is shifted, from = 4.9 to 5.2. This shift is ascribed to the difference in anion ($CF_3CO_2^-$) and the change of solvent due to the excess of trifluoroacetic acid; this shift (to τ = 5.05) occurs also in the NMR spectrum of *(5)* in D_8–THF/CF_3CO_2H.

If solutions of *(7)* in anhydrous benzene or THF are evaporated at 0 °C in a rotary evaporator, a yellow oil remains that crystallizes either spontaneously or when rubbed. It affords yellow leaflets, which rapidly liquefy in the air. The IR spectrum (strongest bands at 1610, 1560, and 1140 cm^{-1}) are distinctly different from those of the starting product *(5)*. UV spectrum: λ_{max} = 309 nm in benzene, 295 nm in THF. The most intense peak in the mass spectrum [10] is at *m/e* = 338 [≡ molecule-ion of *(7)*]; it is accompanied by an appreciably weaker peak at *m/e* 356, which is ascribed to the molecule ion of a "hydrate" of *(7)*. The high-resolution mass spectrum [10] gives for the peak at *m/e* = 338 an analytical composition $C_{18}H_{30}N_2O_4$, confirming the presence of *(7)*. For the peak at *m/e* = 356 the result is $C_{18}H_{32}N_2O_5$ [≡ *(7)*·H_2O].

Decomposition (thermal or under electron impact) of the "hydrate" to the cyclobutadiene *(7)*, which seems a possibility and could have falsely indicated the occurrence of *(7)*, is excluded by the mass spectrum of the pure "hydrate" (*m/e* = 356, 311, 284, 283, 256, 238, 210, 184, 100, 72); the fragmentation patterns of the two compounds differ fundamentally; in particular, the peak at *m/e* = 338 is missing from the mass spectrum of the "hydrate".

If the solution of *(7)* in D_6-acetone is treated with a little water, a singlet appears in the NMR spectrum at τ = 4.85; thence it can be concluded that the "hydrate" is a compound related to *(5)*.

Diethyl 2,4-bis(diethylamino)-1,3-cyclobutadiene-1,3-dicarboxylate (7):

The tetrafluoroborate *(5)* (100 mg) is suspended in anhydrous benzene (1 ml), NaH (100 mg) is added, and the mixture is warmed for a short time at *ca.* 40 °C, then cooled and filtered through a small fritted filter (G 3) into a Schlenk tube. The yellow filtrate is frozen and the benzene removed by means of an oil pump at 0 °C (duration *ca.* 2 hr). Pale yellow crystals from the residue, m.p. 50–52 °C. According to the mass spectrum [10] [*m/e* = 338 (100%), 309 (65%), 293 (30%), 249 (40%), 72 (40%), 29 (40%)] the "hydrate" content of this product is < 0.3%. The ^1H–NMR spectrum of this preparation in D_6-acetone [τ = 6.0 (NCH_2); τ = 5.7 (OCH_2)] is in accord with structure *(7)*. – All operations were carried out under very pure nitrogen.

Tris(*o*-arylenedioxo)- and Bis(*o*-arylenedioxo)-organosilicic Acids Containing Hexacoordinated and Pentacoordinated Silicon

By *H. Meyer, G. Nagorsen*, and *A. Weiss*[*]

The reaction of molten pyrocatechol with halogenosilanes under nitrogen leads to the formation of complex *o*-phenylenedioxosilicic acids containing hexacoordinated and pentacoordinated silicon:

$$3\ C_6H_4(OH)_2 + SiCl_4 \rightarrow \underset{(1)}{H_2[Si(O_2C_6H_4)_3]} + 4\ HCl$$

$$2\ C_6H_4(OH)_2 + RSiCl_3 \rightarrow H[SiR(O_2C_6H_4)_2] + 3\ HCl$$

(2a) $R = CH_3$
(2b) $R = C_6H_5$

Other *o*-dihydroxyarenes, such as 2,3-dihydroxynaphthalene, can react similarly.

The structure of tris(*o*-phenylenedioxo)silicic acid *(1)* is found from the molecular weight (370; cryoscopically in camphor) and the ^1H–NMR spectrum, which contains 2 singlets at $\tau = 3.08$ and 4.14 (in $DCCl_3$; TMS as external standard; the acid protons appear at $\tau = 4.14$), and so indicates that the three pyrocatechol residues are equivalent. *(1)* differs characteristically in its ^1H–NMR spectrum from the product first obtained by *Rosenheim et al.*[1] from $SiCl_4$ and pyrocatechol in ether; the latter product gives three signals at $\tau = 2.85$, 3.14, and 7.68 (in $DCCl_3$; TMS as external standard). *(1)* is dibasic, appears to be trimeric in benzene as a result of hydrogen bonding, and reacts with 2 moles of alkylamine to form a salt.

The ^1H–NMR spectra of bis(*o*-phenylenedioxo)methyl- and bis(*o*-phenylenedioxo)phenylsilicic acids, (2a) and (2b), show that the two pyrocatechol residues are again equivalent in these cases. These compounds also form salts with alkylamines[2]. Powder diagrams show that *(1)* and *(2)*, unlike the alkylammonium salts, are amorphous.

Procedure:

Preparation of *(1)*:

6.6 g (60 mmole) of pyrocatechol are melted under dry nitrogen. 3.4 g (20 mmole) of silicon tetrachloride are added dropwise to the melt with vigorous stirring at a bath temperature of 140 °C and over a period of 30 minutes. After a further 30 minutes, unreacted pyrocatechol and other volatile components are removed at ≈ 120 °C/10^{-2} torr. After cooling, the residue is dissolved in the minimum quantity of boiling absolute benzene and *(1)* is precipitated with absolute petroleum ether. Removal of the remaining solvent at 100 °C/10^{-2} torr leaves a red, vitreous mass that is sensitive to moisture. Yield ≈ 4 g (57%).

Preparation of *(2)*:

11 g (0.1 mole) of pyrocatechol are reacted as described above with 10.6 g (0.05 mole) of freshly distilled phenyltrichloro-silane or 7.74 g (0.05 mole) of freshly distilled methyltrichlorosilane. Yield without reprecipitation: 13 g (82%) of *(2a)* or 8.8 g (68%) of *(2b)*.

Detection of Open-Chain Intermediates in the Formation of β-Lactams from Ketenes and Azomethines

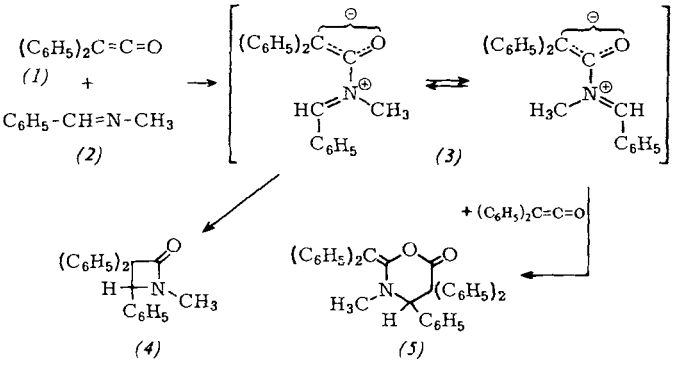
By *R. Huisgen, B. A. Davis*, and *M. Morikawa*[*]

β-Lactams were first obtained by *Staudinger* on cycloaddition of ketenes to *N*-aralkylidene-arylamines[1,2]. Other types of azomethines as well as heteroaromatic bases preferentially formed adducts with two equivalents of dimethylketene[3], which have recently been found to be hydrogenated 2-methylene-1,3-oxazin-6-ones[4,5].

We observed that in the system diphenylketene *(1)* + benzylidenemethylamine *(2)*, the 1:1 adduct *(4)* or the 2:1 adduct *(5)* is preferentially formed according to the reaction conditions. We therefore conclude that a common intermediate *(3)* is involved.

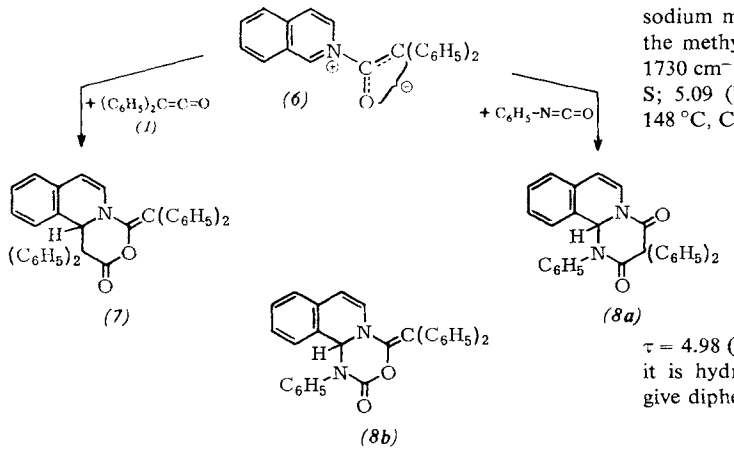
When 10.5 mmole of *(1)* in 15 ml of acetonitrile were added dropwise to a solution of 135 mmole of *(2)* in 85 ml of acetonitrile at room temperature, the rapid disappearance of the yellow ketene color showed that the ketene was quickly consumed. After removal of the excess of *(2)* by high-vacuum distillation, the NMR analysis indicated 82% of the β-lactam *(4)* together with 6% of the 2:1 adduct *(5)*.

On the other hand, when 6.8 mmole of *(2)* in 35 ml of acetonitrile were added dropwise to 55 mmole of *(1)* in 50 ml of acetonitrile, the yields were 81% of the 1,3-oxazinone derivative *(5)* and 19% of *(4)*[6]. When these two procedures were carried out in benzene with the same proportions, 71% of *(4)* + 17% of *(5)* were obtained in the first case and 95% of *(5)* in the second.



The β-lactam *(4)* did not form the 2:1 adduct *(5)* with excess diphenylketene *(1)* even after 6 hours at 140 °C. Thus the above reactions evidently involved an open-chain intermediate, presumably the 1,4-dipole *(3)*[7], which either closes the lactam ring or undergoes cycloaddition with a second molecule of diphenylketene to form *(5)*.

(1) and isoquinoline in ether at 20 °C gave 89% of a 2:1 adduct, which we assume to have the formula *(7)*, by analogy with the dimethylketene-quinoline adduct[5]. On the other hand, when isoquinoline and excess phenyl isocyanate were dissolved in benzene (the components do not react with each other in the cold) and diphenylketene slowly added, 30% of

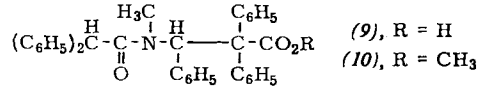


(7) (8a) (8b)

the 1:1:1 adduct *(8)* were isolated[8][**]. Thus the second ketene molecule can be replaced in its role as the dipola rophile and the intermediate 1,4-dipole *(6)* is intercepted by phenyl isocyanate.

Gomes and *Joullié*[9] recently reacted benzylideneaniline with ketene in SO_2 and obtained a thiazolidone 1,1-dioxide as a five-membered cycloadduct. *Kagan* and *Luche*[10] stopped the reaction of *(1)* with benzylideneaniline by the addition of methanol, and isolated 10% of an open-chain methanol adduct of the 1,4-dipole.

Properties and proof of structures of new compounds[11]: 1-Methyl-3,3,4-triphenyl-2-azetidinone *(4)*, m.p. = 118 °C, C=O 1752 cm^{-1}; NMR ($CDCl_3$, 60 MHz): τ = 7.17 (CH_3), S; 4.73 (*tert.*H), S. 3-Methyl-4,5,5-triphenyl-2-diphenylmethyleneperhydro-1,3-oxazin-6-one *(5)*: m.p. = 208–209 °C (dec.), C=O and C=C 1757 and 1630 cm^{-1}; NMR ($CDCl_3$): τ = 7.67 (CH_3), S; 5.08 (*tert.*H), S. When shortly boiled in 80% dioxane, *(5)* was converted into *(9)*: m.p. = 201–203 °C, amide-I 1616, acid C=O 1727 cm^{-1}. *(9)* is insoluble in aqueous sodium hydroxide solution, but can be titrated in dimethyl sulfoxide with NaOH.



(9), R = H
(10), R = CH_3

NMR (CD_3SOCD_3): τ = 7.31 (CH_3), S. The singlet at τ = 4.82 corresponds to the benzhydryl proton, since this signal is absent in the case of the product from *(5)* + D_2O; the signal of the second *tert.*H lies below the phenyl signals. *(5)* and sodium methoxide/methanol or *(9)* and diazomethane gave the methyl ester *(10)*: m.p. = 142–143 °C, C=O 1650 and 1730 cm^{-1}; NMR ($CDCl_3$) τ = 7.21 (NCH_3), S; 6.43 (OCH_3), S; 5.09 (benzhydryl H), S. *(7)*: 93% yield, m.p. = 146 to 148 °C, C=O and C=C 1635 and 1758 cm^{-1}; NMR ($CDCl_3$): τ = 4.98 (*tert.*H), S. *(7)* does not react with aqueous dioxane; it is hydrolyzed by dioxane/aqueous hydrochloric acid to give diphenylacetic acid and isoquinoline.

CONFERENCE REPORTS

Preparation and Properties of the Diastereoisomeric 1,3,5-Triglycidyl-*s*-triazinetriones

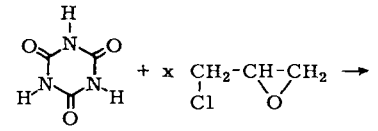
By *M. Budnowski*[*]

Interaction of epichlorohydrin *(2)* and cyanuric acid *(1)* above 60 °C leads to the *N*-alkyl compounds *(3)* in a thermodynamically controlled reaction. A relatively small excess of *(2)* favors formation of the addition product *(3c)*, whereas a large excess converts *(3c)* to the desired *(3f)*. Thus epichlorohydrin functions as both alkylating agent and base. The intermediates *(3d)* and *(3e)* were detected by thin-layer chromatography.

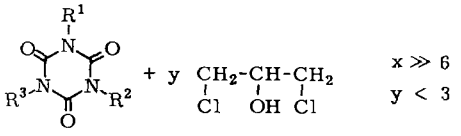
Fractional crystallization of the product *(3f)* gives two stereoisomers α-*(3f)* and β-*(3f)*, which were considered, on account of the chirality of the glycidyl group, to be racemates with the configurations (R,R,R/S,S,S) or (R,R,S/S,S,R) [m.p. 105 °C(α), 156 °C(β)].

In order to assign configurations to α-*(3f)* and β-*(3f)* and to the products therefrom suitable additive and degradative reactions were performed.

Among reagents of the type H^+A^- used for addition, *O*-Aryl, *S*-Aryl, *S*-Alkyl, and NR_2 act as anions. Treatment with aequeous alkali leads to partial or total hydrolysis. The adduct *(4)* is formed in almost quantitative yield on addition of 3 moles of HA to 1 mole of *(3f)*. Presence of a base leads, again almost quantitatively, to the oxazolidone *(5)*, which is also accessible by heating *(4)* with bases. The isomers α-*(3f)* and β-*(3f)* yield different adducts *(4)* but the same oxazolidone *(5)*.



(1) (2)



(3)

(a), $R^1 = R^2 = H$, $R^3 = CH_2\text{-}CHOH\text{-}CH_2Cl$

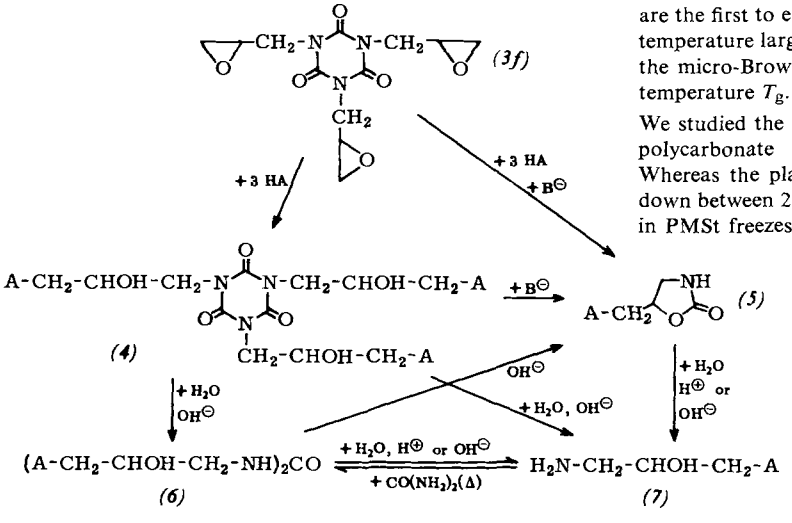
(b), $R^1 = H$, $R^2 = R^3 = CH_2\text{-}CHOH\text{-}CH_2Cl$

(c), $R^1 = R^2 = R^3 = CH_2\text{-}CHOH\text{-}CH_2Cl$

(d), $R^1 = R^2 = CH_2\text{-}CHOH\text{-}CH_2Cl$, $R^3 = CH_2$-(epoxide)

(e), $R^1 = R^2 = CH_2$-(epoxide), $R^3 = CH_2\text{-}CHOH\text{-}CH_2Cl$

(f), $R^1 = R^2 = R^3 = CH_2$-(epoxide)



A = *O*-Aryl, *S*-Aryl, *S*-Alkyl, NR_2

Partial hydrolysis degrades the products *(4)* to the urea derivatives *(6)*, α-*(4)* giving a mixture of two isomers *(6)*, but β-*(4)* giving only one urea derivative *(6)*, namely that formed in lower yield from α-*(4)*.

Total hydrolysis of *(4)*, *(5)*, and *(6)* leads to 1-amino-2-propanol derivatives *(7)*, independently of the isomer *(4)* or *(6)* used. Acylation of *(7)* with urea regenerates both isomers *(6)* in approximately equal yield.

These results identify α-*(3f)* and β-*(3f)* as racemates with the configurations (R,R,S/S,S,R) and (R,R,R/S,S,S) at the asymmetric centers. The ring-opening reactions, which occur with complete retention, require the same assignments of configuration for the adducts *(4)*. For α-*(4)* the three possibilities of ring fission lead to two moles of (*R,S*)-*meso* and one mole of (R,S/S,S)-racemic urea derivative *(6)*. β-*(4)* can give only one racemate for *(6)*. Synthesis of *(6)* from racemic *(7)* and urea yields the *meso*-*(4)* and the *rac*-*(4)* in about equal amounts.

Since the product distribution found for the diastereoisomers approximates to that calculated statistically, intramolecular interaction of the chiral groups is probably small. By variation of the anion in the reactant HA, this method can be modified so as to open new possibilities for preparation of derivatives of the above classes of compound which shall have predetermined configurations.

Hindered Rotation in Macromolecular Solids, Investigated by Nuclear Magnetic Resonance

By *R. Kosfeld*[*]

Nuclear magnetic resonance and nuclear magnetic relaxation are used as well as the mechanical-dynamic and dielectric methods for the study of molecular movements and their relation with the structure of amorphous and semicrystalline macromolecular solids.

The evaluation of investigations of this type are based on the fact that thermal molecular motion always occurs above absolute zero. These transpositions are strongly temperature-dependent. Owing to the complicated structure of high polymers, different types of movement can take place simultaneously or (depending on the temperature) successively. Thus at low temperatures, smaller groups such as the CH_3 group are the first to exhibit recognizable mobility. With increasing temperature larger parts of the molecule become mobile, and the micro-Brownian movement begins only above the glass temperature T_g.

We studied the freezing-in of the rotation of CH_3 groups in polycarbonate (PC) and poly-α-methylstyrene (PMSt). Whereas the planar rotation of the CH_3 groups in PC die down between 216 and 64 °K, the rotation of the CH_3 groups in PMSt freezes at temperatures between 320 and 80 °K.

If a classical jump process is assumed for the rotation of the CH_3 groups, the activation energies for rotation as found from NMR measurements are 1.2 kcal·mole^{-1} for PC and 1.5 kcal·mole^{-1} for PMSt. The limiting frequencies for this process would then be in the MHz range, *i.e.* they would be too low by a factor of 10^6.

Another model discussed instead of classical movement for the CH_3 groups is a quantum-mechanical rotator with a three-fold axis of symmetry, which can overcome the potential opposing rotation by the tunnel effect. This model gives a low-temperature potential barrier of 5.4–5.5 kcal·mole^{-1} for both polymers. At higher temperatures, the values of the correlation frequencies ν_c, which are equal to the tunnel frequencies for the quantum-mechanical rotator, differ considerably from those expected from the quantum-mechanical model. This is understandable, in view of the fact that the neighboring groups, which are responsible for the hindrance of the CH_3 rotation, also become more mobile with rising temperature. As the temperature rises, therefore, the rotation of the methyl groups approximate more closely to a rotation diffusion capable of being described in the classical theory. This result shows that the movement behavior of the methyl groups on transition from the frozen-in to the "freely mobile" state cannot be described merely by the model of a quantum-mechanical rotator, and points to a correlation spectrum.

Correlation functions are very difficult to determine. The amount N_{ME} of frozen CH_3 groups in relation to the total number N_M was determined as a function of the temperature by separation of the nuclear magnetic absorption curve. Hence it is possible to calculate the number of methyl groups that pass from the frozen state into rotational motion as a result of a temperature increase δT for PC and PMSt.

It is thus possible, from the nuclear magnetic resonance experiment, to find the number of CH_3 groups that are forced by a temperature change δT from a rotational movement below ν_c to a rotational movement above ν_c. This number is related to the number of CH_3 groups found in a frequency range δ_c around a frequency ν_c that is fixed by the temperature.

Electrical Excitation of the Axon Membrane as Co-operative Ion Exchange

By *G. Adam* [*]

The widely accepted theory proposed by *Hodgkin* and *Huxley* [1] for nerve stimulation fails to explain the mechanism of regulation of the state of the axon membrane by the membrane potential or the cation activities.

If, on the other hand, the axon membrane is regarded as a two-dimensional cation exchanger interacting with the internal and external electrolyte reservoirs, a physico-chemical mechanism can be advanced for the control of the electrical state of the membrane [2]. In this mechanism, calcium ions are bound in the lattice sites of the cation exchanger in the resting state. On depolarization or on lowering of the calcium activity in the outside medium, the resting state becomes thermodynamically unstable, and calcium is co-operatively displaced from the lattice sites by monovalent cations. The movements of the ions during this cation exchange give rise to an ion current flowing inward, as observed *e.g.* in the voltage-clamp experiment.

This co-operative cation exchange is described as a two-dimensional phase transition. Its kinetics can be theoretically described for small depolarizations on the basis of the concept of nucleation and nuclear growth.

The resulting kinetic theory has been applied to the measurements of *Cole* and *Moore* [3] of the ion current in the voltage clamp experiment. Within the range of validity of the theory, *i.e.* for small depolarizations, the experimentally determined dependence of the ion current on time and on the membrane potential, particularly the threshold behavior that characterizes axon stimulation, is quantitatively described by the equations derived.

Three parameters must be matched. Two of these have simple molecular meanings, and have the following numerical values: $a_o = 21 \times 21$ Å^2 = area per binding site for the co-operatively exchangeable cations; $w = 5.1$ kcal/mole = interaction energy between two binding sites in the two different bonding states.

It is probable, from the order of magnitude of these parameters, that the structural units responsible for the axon stimulation are membrane-bound proteins, as was suggested by *Tasaki et al.* [4].

High-Pressure Properties and Structure of Liquids

By *E. Kuss* [*]

In contrast to solids, compressed gases and liquids can be studied at pressures up to 10 kbar over a wide range of densities and hence valuable information about the intermolecular forces and the structure of liquids, which is still largely unknown, can be obtained from the physical properties. Properties of interest in this connection are the pVT data, the equations of state, the thermal conductivity, the viscosity, the spin-lattice interaction of the nuclear magnetic resonance, and the electric birefringence.

The theoretical calculation of the second, third fourth, and higher virial coefficients from fundamental potential functions leads to very complicated mathematical expressions and in some cases to very different constants for the potential functions. Owing to the mathematical difficulties, the potential $U(r)$ is always taken to be spherically symmetrical, *i.e.* the effect of the shape of the molecule is not yet theoretically expressible.

The effect of the molecular structure on the pVT data of liquids has been studied experimentally up to 2000 atm, and in some cases even up to 5000 atm. A piezometric method and a buoyancy method have been developed for this purpose. Since no suitable material was available for use as a float, the test substance was introduced into a hollow body and the buoyancy was measured in mercury. Measurements that have not yet been completed show that some substances whose viscosities are extremely pressure-dependent have a very low compressibility (*e.g.* 2,4-bis-(1-phenylethyl)methoxybenzene).

The viscosity measurements were carried out in a falling sphere viscometer (accuracy $\pm 2\%$) and a capillary viscometer (accuracy $\pm 1\%$), both of which are suitable for fully automatic operation. The effects of chain length, "degree of branching", and other parameters of the molecular structure on the viscosity-pressure behavior were determined for numerous substances. On the basis of the relationships found, it was possible to synthesize substances whose viscosities at 2000 atm are up to 8×10^6 times as great as at atmospheric pressure [1]. According to *Benedek* and *Purcell* [2], a comparison of measurements of the pressure-dependence of the viscosity and the nuclear magnetic relaxation leads to the conclusion that the translational degrees of freedom are more strongly reduced than the rotational degrees of freedom by rising pressure.

The very small measured effect in the electric birefringence requires the complete elimination of parasite birefringence of the high pressure windows in high-pressure measurements. Benzene showed a marked anomaly in the pressure dependence of the Kerr constant [3], which suggests a modification of the π-electron cloud or an unusual change in the liquid structure under pressure.

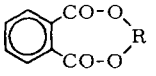
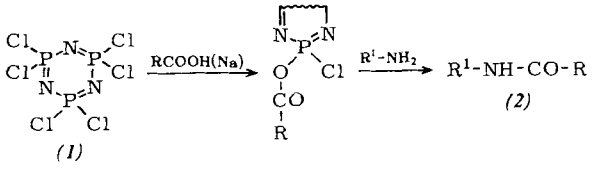
Synthesis of macrocyclic *o*-phthalate esters from the corresponding polyesters is reported by *W. A. Ehrhart*. Esterification of phthalic anhydride with glycols in the presence of catalysts such as tetrabutyl orthotitanate yields polyesters, from which the corresponding macrocyclic *o*-phthalic esters are obtained



(1), R = $-(CH_2)_2-O-(CH_2)_2-$
(2), R = $-(CH_2)_2-O-(CH_2)_2-O-(CH_2)_2-$
(3), R = $-(CH_2)_5-$
(4), R = $-(CH_2)_6-$

by distillation at 220–260 °C/1–4 torr. The polyesters of diethylene and triethylene glycol, as well as those of 1,5-pentanediol and 1,6-hexanediol, yield the macrocyclic compounds *(1)–(4)* in almost quantitative yields. / J. org. Chemistry *33*, 2930 (1968) / –Ma. [Rd 894b IE]

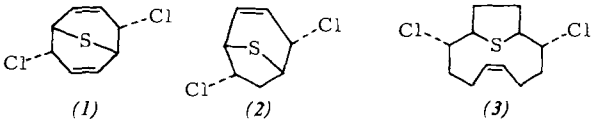
Phosphorus nitride-chloride *(1)* as an activator of carboxylic acids was investigated by *L. Caglioti, M. Poloni* and *G. Rosini*. *(1)* reacts with carboxylic acid salts, and on subsequent treatment with an excess of primary or secondary amine forms the amide *(2)* in yields of 60–83%. The reaction proceeds in benzene, cyclohexane, THF, THF/water, ethyl acetate, *etc.* Amine salts can be used in place of the alkali metal salts. *(1)* is used in amounts of 0.35–1 equivalents, and the amine in 6- to 10-fold excess. Hydrazides are obtainable in the same manner. The reaction takes about 20 min and presumably proceeds as follows:



(1) *(2)*

/ J. org. Chemistry *33*, 2979 (1968) / –Ma. [Rd 895 IE]

The reaction of SCl_2 with cyclic polyolefins was investigated by *F. Lautenschlaeger*. SCl_2 adds with the formation of new S-containing ring systems. 31, 35, and 69% yields of the bicyclic sulfides *(1)*, *(2)*, and *(3)*, m.p. 101–102 °C, 47.5 to

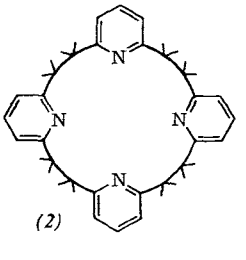


(1) *(2)* *(3)*

49 °C, and 139.5–141.5 °C respectively, were obtained from cyclooctatetraene, cycloheptatriene, and *trans,trans,cis*-1,5,9-cyclodecatriene, in CH_2Cl_2 at –10 to –20 °C. / J. org. Chemistry *33*, 2627 (1968) / –Ma. [Rd 896 IE]

Macrocyclic compounds with 2,6-bridging pyridine rings were synthesized by *W. Jenny* and *H. Holzrichter* by cyclization of 1,2-bis(6-chloromethyl-2-pyridyl)ethane *(1)* with Na and tetraphenylethylene in THF. Tetrameric [2.2.2.2]-(2,6)pyridinophane *(2)*, m.p. 205–206 °C and hexameric [2.2.2.2.2.2]-(2,6)pyridinophane, m.p. 160–161 °C, were isolated chromatographically in 4.2 and 2.1% yields, respectively. The compounds are colorless. The octamer was detected spectroscopically (< 1%). / Experientia *22*, 306 (1968) / –Ma. [Rd 897 IE]

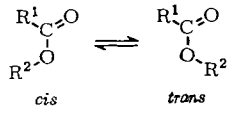
(1)



(2)

The reactions of methyl radicals with ethanol were examined mass-spectroscopically by *P. Gray* and *A. A. Herod*. The methyl radicals were generated by photolysis of acetone ($\lambda > 3000$ Å) and D_6-acetone at 130–250 °C. By comparing the reactions of CH_3CH_2OH, CH_3CD_2OH, and CH_3CH_2OD it was established that at 150 °C 75% of the hydrogen derived from the ethanol originates from the methylene group, 20% from the hydroxyl, and 5% from the methyl group. As the hydroxyl H undergoes an exchange reaction with acetone, D_6-acetone must be used for investigating the reaction of CH_3CH_2OD, as a source of the radicals. / Trans. Faraday Soc. *64*, 1568 (1968) / –Hz. [Rd 898 IE]

The ultrasonic absorption of alkyl esters in the 1–30 MHz region was studied by *J. Bailey* and *A. M. North*. The results were used to obtain an indication of the equilibrium between the isomers



cis *trans*

The activation energy is independent of R^1 and R^2 in the conversion of *trans* into *cis*, 8.8 ± 1.4 kcal/mole; in contrast, the energy content of the *cis*-form depends on the sum of the C-atoms in R^1 and R^2. It was concluded from this that the energy difference between the two isomers depends essentially on the steric interaction of the alkyl groups in the *cis*-form. The higher dipole moment of the *cis*-form or a stabilization of the *trans*-form by hydrogen bridges, on the other hand, are not suitable for the interpretation of the experimental results. / Trans. Faraday Soc. *64*, 1499 (1968) / –Hz. [Rd 899 IE]

Cleavage surfaces of silicon single crystals prepared under a high vacuum exhibit an ESR signal (g = 2.0055, width 6 G) according to *D. Haneman*. This corresponds to a spin density of 8.10^{13} cm^{-2} at the surface, which is not affected by addition of oxygen at 10^{-3} torr·min; with addition of more oxygen (about 10^{-1} torr·min) the spin density increases by some 20%. Hyperfine structure and g-anisotropy are not evident. Comparison with measurements of the electron work-functions and the conductivity in the neighborhood of the surface show that the spins lie in the surface itself. A model is proposed for the silicon surface, which shows the atoms arranged in alternate rows, running in the direction of cleavage. Each alternate row lies at a higher level and has unpaired electrons of preponderantly s-character, which are freely mobile within the row; these are responsible for the ESR signal. The other rows of atoms lie at a lower level, the single electrons have a preponderantly p-character, and overlap with their neighbors within the low-lying series. / Physic. Rev. [2] *170*, 705 (1968) –Hz. [Rd 900 IE]

Kinetics of the ring-opening in liquid cyclooctasulfur were investigated by *T. K. Wiewiorowski, A. Parthasarathy* and *B. L. Slaten*, It is known that an equilibrium is set up in molten sulfur (at a moderate temperature) between S_8 rings and S_8 chains. This reaction was followed by measurement of the freezing point of liquid sulfur in relation to the time of

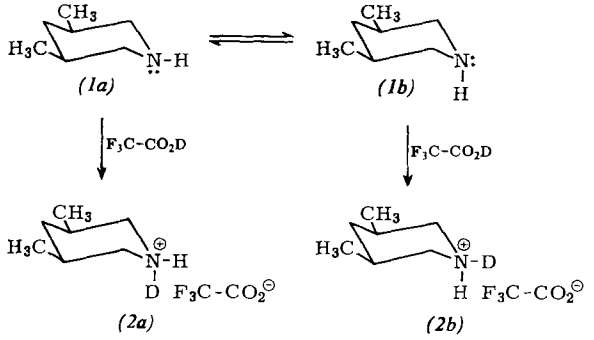
heating and temperature. The S_8 chains "dissolved" in the cyclooctasulfur bring about a freezing point depression. From the freezing point depressions after preheating to 130–150 °C, the rate constants of the ring opening reaction were calculated as 0.5×10^{-2} to 3.34×10^{-2} min^{-1}, and from their temperature dependence, the dissociation enthalpy of the S–S bond in cyclooctasulfur was obtained as 32 kcal/mole. / J. physic. Chem. *72*, 1890 (1968) / –Hz. [Rd 901 IE]

A mechanism for the chlorine dioxide explosion was proposed by *E. T. McHale* and *G. von Elbe*. The reaction is characterized by long induction periods; these were measured in relation to temperature (54–134 °C), pressure (0.2–40 torr), vessel size, irradiation, and addition of foreign gases. The reaction shows chain branching and proceeds *via* a relatively stable intermediate, identified as Cl_2O_3. The results of the measurements and known enthalpy data permit the postulate of the following reaction mechanism:

Start	$2\ ClO_2$	$\xrightarrow{\text{wall}}$	$ClO + ClO_3$
Intermediate product	$ClO_2 + ClO$	$\longrightarrow$	Cl_2O_3
	$ClO + Cl_2O_3$	$\longrightarrow$	$ClOOCl + ClO_2$
Branching	$ClOOCl$	$\longrightarrow$	$ClOO + Cl$
	$ClOO$	$\longrightarrow$	$Cl + O_2$
	$Cl + ClO_2$	$\longrightarrow$	$2\ ClO$
	$Cl + ClO_2$	$\longrightarrow$	$Cl_2 + O_2$
Chain termination	Cl	$\longrightarrow$	$1/2\ Cl_2$

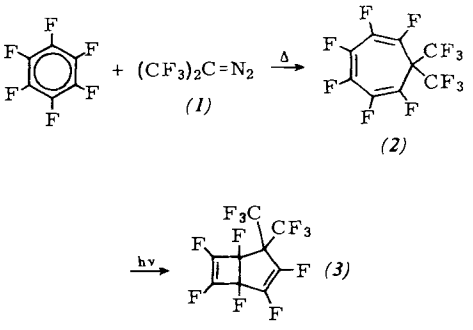
Cl_2O_3 is formed together with Cl_2O_6 by the photolysis of ClO_2 at –45 °C and can be separated readily from Cl_2O_6 because of its substantially greater volatility. The structure $O_2Cl–ClO$ is assigned to it. / J. phys. Chem. *72*, 1849 (1968) / –Hz. [Rd 902 IE]

The conformation equilibrium in *cis*-3,5-dimethylpiperidine *(1)* was examined by *H. Booth* by means of the ^1H–NMR spectra in deuterotrifluoracetic acid and in trifluoracetic acid. The 2,6-axial protons appear as a quartet in the spectrum of *cis*-3,5-dimethylpiperidinium trifluoracetate, *(1)*. CF_3CO_2H, at $\tau = 7.30$. The spectrum of the mixture of *(2a)* and *(2b)* shows a triplet at $\tau = 7.30$, and a quartet (2,6-axial protons of *(2a)* or *(2b)*). Under the conditions of the reaction exceptionally little H^+ or D^+ is split off from *(2a)* and *(2b)*. The spectrum was still unchanged after two days. The ratio of the areas of the triplet and the quartet shows that 54% of *(2a)* and 46%

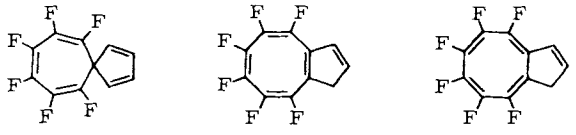


of *(2b)* are present. The energy difference between the two forms is only 0.1 kcal/mole. Obviously the H-atom and the free electron pair on the nitrogen require about the same space. / Chem. Commun. *1968*, 802 / –Kr. [Rd 903 IE]

Carbenes undergo addition to hexafluorobenzene, according to *D. M. Gale* and *M. Jones jr.* As a result hexafluorobenzene cannot be used as an inert solvent for carbene reactions. *Gale* obtained the perfluorinated *(2)* (b.p. ≈ 125 °C) by the

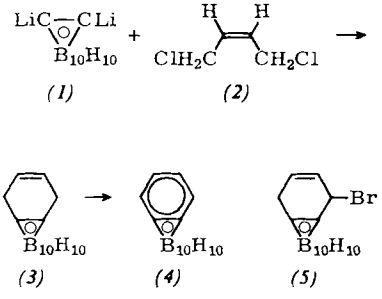


thermolysis of hexafluoro-2-diazopropane *(1)* in C_6F_6, in 20% yield; on irradiation, ($\lambda > 3100$ Å) *(2)* is converted into the bicyclic compound *(3)* (99% yield). *Jones jr.* was



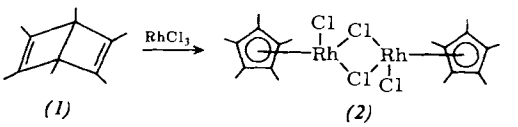
able to isolate the spirane *(4)* after irradiation of diazocyclopentadiene in C_6F_6, the former being converted on heating-probably into *(5)* or *(6)*. / J. org. Chemistry *33*, 2536, 2538 (1968) / –Kr. [Rd 905 IE]

The synthesis of benzo[a]-1,2-dicarba-*closo*-dodecarorane (benzocarborane) *(4)* was successfully carried out by *N. K. Hota* and *D. S. Matteson* by the reaction of 1,2-dilithiocarborane *(1)* with *cis*-1,4-dichloro-2-butene *(2)* and dehydrogenation of the reaction product with *N*-bromosuccinimide to *(4)*.



After chromatography, recrystallization and sublimation, *(4)* is obtained in 30% yield. According to the ^1H–NMR and UV spectra it has a partially aromatic character. It is not attacked by conc. H_2SO_4 at 100 °C, does not react with bromine in CBr_4, but is decomposed by $KMnO_4$ in acetone. The monobromo compound *(5)* may be obtained as a by-product of the dehydrogenation. / J. Amer. chem. Soc. *90*, 3570 (1968) / –Kr. [Rd 906 IE]

A new type of ring contraction was observed by *J. W. Kang* and *P. M. Maitlis*. $RhCl_3 \cdot 3\ H_2O$ in methanol is converted almost quantitatively with excess hexamethyl (Dewar)benzene *(1)* into the dimeric pentamethylcyclopentadienylrhodium-(III)chloride *(2)*, which forms very stable, dark red crystals

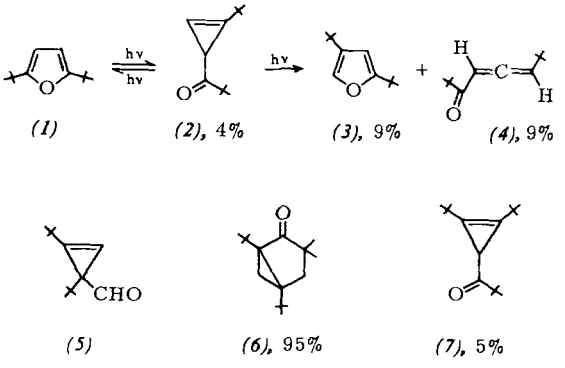


earlier regarded as $[(CH_3)_6C_6RhCl]_2^{4+}$ 4 Cl^- [11]. Hexamethylbenzene is also formed. The structure of *(2)* was checked by mass spectroscopy and other methods. The chlorine bridges

in *(2)* are broken by triphenylphosphine, pyridine, and other reagents. (π-1,5-cyclooctadiene) (π-pentamethylcyclopentadienyl)rhodium(I) is formed with 1,5-cyclooctadiene in the presence of Na_2CO_3. / J. Amer. chem. Soc. *90*, 3259 (1968) / –Kr. [Rd 907 IE]

[1] *B. L. Booth, R. N. Haszeldine,* and *M. Hill,* Chem. Commun. *1967*, 1118.

The photolytic isomerization of poly-*tert*-butylfurans was examined by *E. E. van Tamelen* and *T. H. Whitesides*. After irradiation of *(1)* in pentane (1.2×10^{-3} M) under nitrogen for 1 hour, *i.e.* after about a half of *(1)* had been converted, it was possible to isolate *(2)*, *(3)*, and *(4)* (residue: probably oligomers). *(2)* is converted on irradiation into *(1)*, *(3)*, and

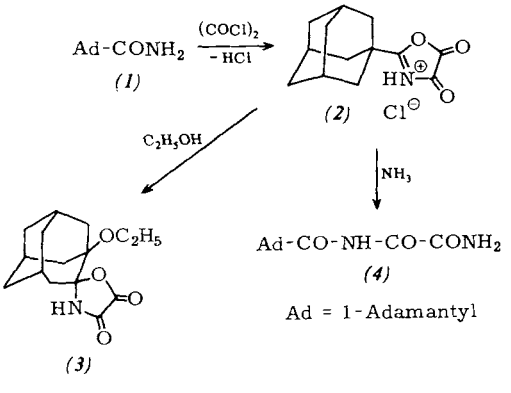


(1) *(2)*, 4% *(3)*, 9% *(4)*, 9%

(5) *(6)*, 95% *(7)*, 5%

(4), while *(3)* forms the cyclopropenecarbaldehyde *(5)*. 2,3,5-Tri-*tert*.butylfuran rearranges under analogous conditions mainly into the bicyclic compound *(6)*, and into the cyclopropyl ketone *(7)*. / J. Amer. chem. Soc. *90*, 3894 (1968) / –Kr. [Rd 908 IE]

A spirohomoadamantane *(3)* has been obtained by *T. Sasaki, S. Eguchi,* and *T. Toru* in the reaction of 1-adamantanecarbonamide *(1)* with oxalyl chloride by treatment of the primary adduct *(2)* with anhydrous ethanol at room temperature. The structure of the rather unstable compound *(2)*,



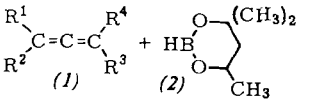
m.p. = 98–100 °C (dec.), yield ≈ 70 %, was determined *inter alia* by its ammonolysis to form *(4)*. The spirane *(3)* forms colorless crystals, m.p. = 194–195 °C (dec.), yield 62 %, which are insoluble in anhydrous ethanol. 1-Adamantane-carbanilide reacts in a similar manner. / Tetrahedron Letters *1968*, 4135 / –Kr. [Rd 909 IE]

Tris(diethylamino)phosphine has been suggested by *D. N. Harpp, J. G. Gleason,* and *J. P. Snyder* for the partial desulfurization of organic disulfides.

$$R^1\text{–S–S–}R^2 + [(C_2H_5)_2N]_3P \rightarrow R^1\text{–S–}R^2 + [(C_2H_5)_2N]_3PS$$

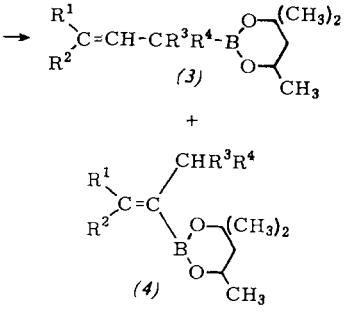
The method can be applied to many organic disulfides. No rearrangements take place. Examples: $R^1 = R^2 = n$-pentyl (yield 63 %); $R^1 = p$-tolyl, R^2 = benzyl (86 %), $R^1\text{–S–S–}R^2$ = 1,2-dithiacyclohexane (100 %). The formation of $R^1\text{–S–}R^1$, $R^2\text{–S–}R^2$, and $R^1\text{–S–}R^2$ in yields of 22, 11, and 38 % on partial desulfurization of $p\text{-Br–}C_6H_4\text{–}CH_2\text{–S–S–}CH_2\text{–}C_6H_5$ has not yet been explained. / J. Amer. chem. Soc. *90*, 4181 (1968) / –Kr. [Rd 910 IE]

The addition of 4,4,6-trimethyl-1,3,2-dioxaborinane *(2)* **to allenes** has been studied by *R. H. Fish*; this reaction, unlike the addition of B_2H_6 to allenes, proceeds in one step. If one of the terminal allene C atoms is unsubstituted, the principal product is the adduct *(3)*; on the other hand, the attack on the middle carbon atom to give *(4)* is favored in the other allenes. Thus allene *(1a)* gives the adducts *(3a)* and *(4a)* in a ratio of



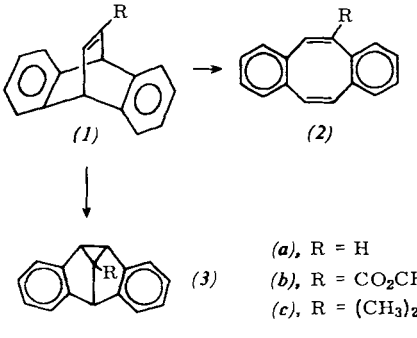
(1) *(2)*

(a), $R^1 = R^2 = R^3 = R^4 = H$
(b), $R^1 = R^2 = CH_3$, $R^3 = R^4 = H$
(c), $R^1 = R^2 = R^3 = R^4 = CH_3$
(d), $R^1 = R^4 = H$, $R^2\text{–}R^3 = -(CH_2)_6-$



86.5:13.5; *(1b)* gives 78 % of *(3b)* and 22 % of *(4b)*, and *(1c)* gives 100 % of *(4c)*. 1,2-Cyclononadiene *(1d)* gives the *cis* and *trans* adducts in a ratio of 85:15. 2,3-Pentadiene [*(1e)*, $R^1 = R^4 = H$, $R^2 = R^3 = CH_3$] forms 81 % of *(4e)*, but unlike the other allenes, it also yields 19 % of 4,4,6-dimethyl-2-(*trans*-3-penten-1-yl)-1,3,2-dioxaborinane, which is not formed by rearrangement from *(3e)*. / J. Amer. chem. Soc. *90*, 4435 (1968) / –Kr. [Rd 917 IE]

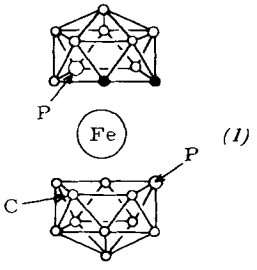
The photoisomerization of mono- and dibenzobarrelene *(1a)* by direct irradiation at 2537 Å is regarded by *P. W. Rabideau, J. B. Hamilton,* and *L. Friedman* as a convenient synthesis of mono- and *sym*-dibenzocyclooctane *(2a)*, which are formed almost without by-products. Irradiation > 3000 Å in the presence of acetophenone, or acetone, on the other hand, leads to semibullvalene *(3a)*, also in high yields.



(a), R = H
(b), R = CO_2CH_3
(c), R = $(CH_3)_2COH$

Direct irradiation of *(1b)* leads only to *(2b)*, whereas *(1c)* rearranges to give only *(3c)*. These results support the view of *Brewer* and *Heaney* that the cyclooctatetraenes are formed *via* the excited singlet state and the semibullvalenes *via* the excited triplet state. / J. Amer. chem. Soc. *90*, 4465 (1968) / –Kr. [Rd 918 IE]

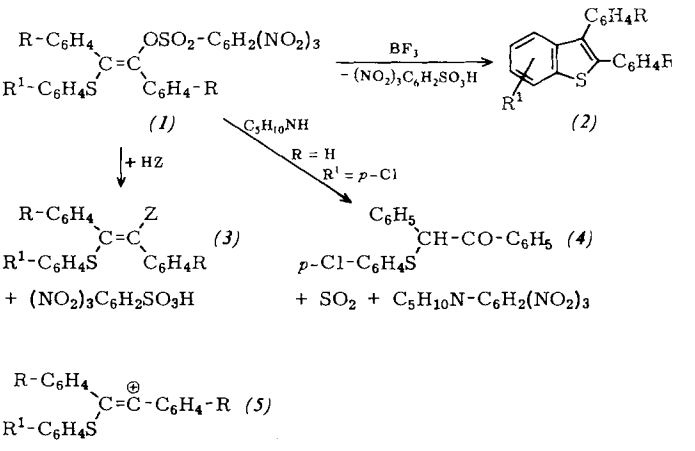
New transition metal complexes with the carbaphosphollide ion (3)-1,7-$B_9H_9CHP(CH_3)^-$ are described by *L. J. Todd, I. C. Paul, J. L. Little, P. S. Welcker*, and *C. R. Peterson*. When 1,7-$B_{10}H_{10}CHP$ is heated in piperidine it forms the piperidinium salt of (3)-1,7-$B_9H_{10}CHP^-$, the tetramethylammonium salt of which reacts with NaH and then with $FeCl_2$ to give the red-violet anion $[(3)\text{-}1,7\text{-}B_9H_9CHP]_2Fe^{2-}$. This anion can be alkylated with CH_3I to give $[(3)\text{-}1,7\text{-}B_9H_9CHP(CH_3)]_2Fe$ *(1)* (brown isomer, m.p. = 239.5–240.5 °C; red isomer, m.p. 233–234 °C). A cocrystallite containing both isomers forms deep red orthorhombic prisms (a = 13.66, b = 13.96, c = 20.36 Å, space group Pbca) on sublimation. The unit cell of the brown form has a = 14.44, b = 13.79, c = 19.51 Å.



(1)

According to the X-ray structural analysis of a cocrystallite of *(1)* (formula shown without substituents), the C atom in one of the polyhedra probably statistically occupies one of the two positions marked in black. Similar complexes are formed with Co^{2+} and Ni^{2+}. / J. Amer. chem. Soc. *90*, 4489 (1968) / –Kr. [Rd 919 IE]

1,2-Diaryl-2-arylthiovinyl-2,4,6-trinitrobenzenesulfonate *(1)* has been obtained by *G. Capozzi, G. Melloni, G. Modena*, and *M. Piscitelli* by addition of arylsulfenyl 2,4,6-trinitrobenzenesulfonates to tolan and 4,4′-dimethyltolan. The arylsulfenyl derivatives were prepared from arylsulfenyl chlorides with silver 2,4,6-trinitrobenzenesulfonate, and were not isolated. Examples of *(1)*: R = R^1 = H, m.p. = 109–110 °C; R=H, R^1 = *p*-Cl, m.p. 139–140 °C; R = R^1 = CH_3,



m.p. = 104–105 °C. *(1)* gives orange-red crystals, which can be recrystallized *e.g.* from chloroform/pentane and decompose in many inert solvents, particularly in the presence of BF_3, to give the free sulfonic acid and a 2,3-diarylbenzo[b]-thiophene *(2)*. Reaction with weak nucleophiles gives products such as *(3)*, while strong nucleophiles form acetophenone derivatives such as *(4)* as well as SO_2 and trinitrophenyl derivatives. The authors believe that a vinylcarbonium ion *(5)* is formed as an intermediate in the decompositions. / Tetrahedron Letters *1968*, 4049 / –Kr. [Rd 920 IE]

BOOK REVIEWS

Chemical Reactions at High Pressures: By *K. E. Weale, E.* and *F. N. Spon* Ltd., London 1967. 1st Edit., xiii, 350 pp., numerous illustrations and tables, 70 s.

The chemistry of reactions at moderately high and very high pressures has developed so vigorously in the last few years that it is now hardly possible for one person to write a really comprehensive monograph covering the whole field. At the same time, the meaning of the term "high pressure" becomes more and more blurred. From this point of view it must be recognized that, in spite of its comprehensive title, the present monograph deals thoroughly with only a part of the field of high-pressure chemistry – reactions in fluid phases at pressures up to 15 kbar.

A short historical introduction is followed by chapters on the influence of high pressures on the physical properties of single-phase systems and on the pressure dependence of phase equilibria. This is followed by a survey of the experimental methods of high-pressure chemistry, including a few sections on the possible sources of danger of work at high pressure.

The main part of the book is made up of chapters on equilibria and reaction rates in liquids at high pressures. After a rather theoretically oriented introduction to reaction kinetics at high pressures, which establishes the concept of activation volumes, many examples of the influence of high pressures on organic reactions are given. Polymerizations are treated particularly thoroughly. This chapter should be stimulating even to the specialist in the field.

Gas reactions at high pressures are also dealt with. The end of the book comprises a 19-page section entitled "Reactions at very high pressures" which deals with pressures above 15 kbar. In a later edition this section should either be omitted entirely or so expanded that the fundamentals of the chemistry of the solid state at very high pressures are at least indicated. In the present form it merely presents a distorted picture.

Weale cites about 1000 references to the literature, some as recent as 1966. In the main chapters, on the high-pressure reactions of organic systems in particular, the recent literature has been considered extensively. The book will be of greatest value to those wishing to familiarize themselves with the fluid state reactions at pressures up to 15 kbar, the basic information on instrumental aspects, theoretical foundations and experimental results. The book also provides a good introduction to the original literature. It will also be of interest to workers already concerned with high-pressure problems. *K.-J. Range* [NB 729 IE]

Aromatic Amine Oxides. By *E. Ochiai*. Elsevier Publishing Company, Amsterdam-London-New York 1967. 1st ed., x, 456 pp., 31 figures, 87 tables, bound Dfl 85.00 / £8.15.0.

The author of this book started his studies on the aromatic amine oxides, which had been discovered in 1925 by *J. Meisenheimer*, as early as 1940. It was only many years later, with the general growth of interest in the mechanism of

nucleophilic reactions and *H. J. den Hertog*'s independent investigations in this field after 1950, that *Ochiai*'s early work became known outside Japan. The literature has greatly increased in volume since then, an important cause of this growth being interest in biological aspects (iodinin had been known since 1938 as a metabolite of micro-organisms). *Ochiai* recognized *e.g.* the difference between the true aromatic amine oxides, *i.e.* the *N*-oxoaza aromatic compounds, and the *N*-oxides of trimethylamine, dimethylamine, *etc.*, and reached certain conclusions concerning the charge distribution in these compounds, which is roughly the reverse of that in the parent bases.

This field was dominated by Japanese workers for many years, and since most of the publications were in Japanese, it was some time before the results became known outside Japan. It is therefore all the more pleasing to find a thorough, competent review of work carried out up to the beginning of 1964 from the pen of the most successful worker and the foremost expert in the field. The book contains over 1100 references. However, the clear layout and style and the intelligent use of formulas ensure that even in the English translation by *D. U. Mizoguchi*, the reader will have no trouble in finding his way through the book.

The introduction is followed by a chapter on preparation, which contains a number of examples. The physico-chemical properties such as dipole moment, polarographic behavior, dissociation constant, NMR, IR and UV spectra, and the electronic structure from the point of view of MO theory are discussed in Chapter 4 (100 pages). Other chapters deal with reactivity, electrophilic and nucleophilic substitution, and the effect of the *N*-oxide groups substituents. The last chapter is devoted to the biological properties of the aromatic amine oxides, such as their antibacterial, carcinogenic, and carcinostatic activities, and reference is made to the possible pharmacological uses, which are still in their infancy.

Despite the broad picture presented by the book, the greatest care has been taken with details. In view of the rapid growth of knowledge in every field of organic chemistry really reliable monographs of this type are invaluable.

Ullmanns Encyklopädie der technischen Chemie (Ullman's Encyclopedia of Industrial Chemistry). Vol. 18: Uranium (continued) to Rayon Staple (Zellwolle). Chief editor *W. Foerst*, editor: *Hertha Buchholz-Meisenheimer*. Verlag Urban & Schwarzenberg, München-Berlin 1967. 3rd, completely revised Edit., xii, 792 pp., 261 figures, DM 182.– per volume (sold only as the complete work).

The penultimate volume of the encyclopedia [*] contains long articles on water (100 pp.), washing and detergents (95 pp.), vitamins (79 pp.), viscose rayon, fibers, and sponges (46 pp.), wine (46 pp.), uranium (continued) (45 pp.), wax (44 pp.), cellulose (41 pp.), and hydrogen (39 pp.). Of the shorter articles, mention should be made of viruses, growth factors spices, plasticizers, wool, bismuth, and tungsten.

The article on water is a condensed monograph. Nine authors from universities, industry, the Ministry of Health, the Vereinigung der Grosskesselbesitzer, and other institutions deal with structure, physical properties (with comprehensive tables), drinking water and water for industry (with good water consumption statistics and quality standards), boiler feed water, cooling water, demineralization of sea water (technical and economic comparison of the methods), general aspects of water supply, water legislation, and finally the production of heavy water (processes and economic comparison). The article shows an excellent combination of expert and editorial co-operation.

The article on cellulose gives a clear picture of modern digestion and purification processes. Many of the articles in this volume refer back to earlier articles, and efforts have been made in the treatment of new key words to include further information on topics discussed earlier. Thus the article on washing and detergents is closely related, *via* detergent raw materials, to the surfactants (Vol. 16). The question of biological degradation and tolerance by fish is considered at some length. The article also contains a good theory of washing, as well as a description of modern washing machines and the demands that they place on detergents and washing. In the article on wine, one is impressed by the progress in the field of foods and beverages. Total analyses of wines, listing more than 200 constituents, are given. We learn from the article on hydrogen that the liquid hydrogen consumption for rockets in the USA was 60000 t in 1966. The growing experience of the editorial staff becomes increasingly evident with each new volume of the encyclopedia that appears. We therefore look forward eagerly to the final volume, which will contain the general index.

Oligophenyls, Oligophenylenes, and Polyphenyls, a Class of Thermally Very Stable Compounds

BY W. RIED AND D. FREITAG[*]

Dedicated to Professor W. Schultheis on the occasion of his 65th birthday

The classical and modern syntheses of oligophenyls and polyphenyls are compared to illustrate the value and the range of applications of the preparation methods described. The investigations showed a relationship between the number, arrangement, and substitution of the aromatic rings and the physical properties of the products. The melting point of the p-polyphenyls rises with increasing degree of condensation. Methylation, and linkage in the m-positions lowers the melting point and at the same time improves the solubility. o-Oligophenyls melt at lower temperatures than the p-isomers. The highest-melting substance in this class is p-septiphenyl, which melts at 545 °C.

1. Introduction

Modern industry and space research in particular require new, and, above all, heat-resistant materials. The rapid development[1–3] of macromolecular organic chemistry has resulted in the development of innumerable new organic constructional and manufacturing materials. It has become possible to improve the natural properties of many polymers, *e.g.* their thermal and electrical insulating properties and their elasticity. Important progress has been made in particular in the synthesis of heat-resistant polymers, and products of this type with melting points[1] above 900 °C are no longer uncommon.

The laborious preparation of the starting materials, which often requires several costly reaction steps, has hindered the wide application of these substances. For this reason the strenuous efforts that have been made in recent years, particularly in the USA[4], to obtain thermally stable polyphenyl directly from benzene seem very promising.

The nature and number of linkages formed between rings in the polymerization of benzene are largely known from model reactions. The methods for the synthesis of oligo- and polyphenyls will now be described with special reference to their physical properties and the relation between the arrangement of the benzene units and the thermal stability of the products.

2. *p*-Oligophenyls

2.1. Nomenclature

The oligomeric lower members of the series benzene, biphenyl, *p*-terphenyl, *etc.* were referred to by *Kern* and *Wirth*[5] as "*p*-oligophenylenes". These compounds are now named in accordance with IUPAC Rule A-54[6], according to which the prefix for the number of linked rings (ter-, quater-, quinque-, sexi-, septi-, octi-, novi-, deci-, *etc.*) is placed in front of the radical name "phenyl". Substances of this class must therefore be named *p*-oligophenyls. An ex-

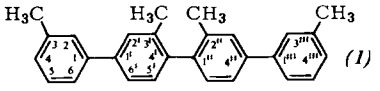
ample of the numbering of the carbon atoms is given in formula *(1)* [6a,7] (for other suggestions see [8]).



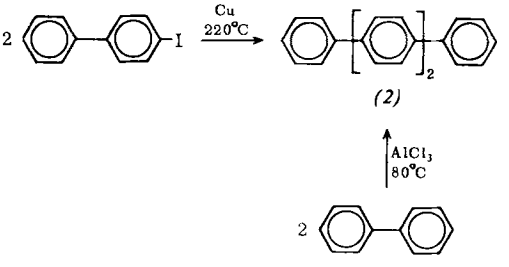
(1)

3,3′,2″,3‴-Tetramethyl-*p*-quaterphenyl

2.2. Syntheses

The Gattermann [9] synthesis of biphenyl is well known. A modification [10] of this reaction, the reduction of the diazonium salt with 78.5 % formic acid followed by decomposition with copper powder, led in 1924 not only to biphenyl, but also to ter-, quater, and the previously unknown quinquephenyl, with predominance of *p*-linkages.

Ullmann [11] prepared *p*-quaterphenyl *(2)* by reaction of *p*-iodobiphenyl with copper powder at 220 °C. *Dayal* and *Rao* [12] very recently discovered a simpler synthesis in which *p*-quaterphenyl is obtained in good yields from biphenyl and $AlCl_3$ in nitrobenzene at 80 °C.



(2)

p-Sexiphenyl [6b] has been obtained by a reaction similar to the Ullmann reaction from *p*-iodoterphenyl and silver powder at 330 °C. *Busch* and *Weber* [13] obtained *p*-oligophenyls with degrees of condensation up to $p = 7$ (Table 1) by hydrogenation of *p*-dibromobenzene under pressure with hydrazine hydrate as the source of hydrogen and palladium as the catalyst. The structure of *p*-septiphenyl could not be verified because of its poor solubility.

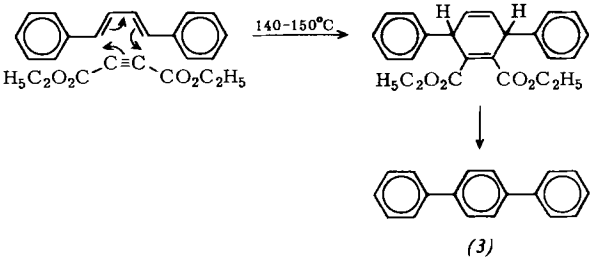
[a] The absorption bands were calculated by *Kuhn*'s root law [23].
[b] In chloroform. [c] Molecular weight not yet determined.

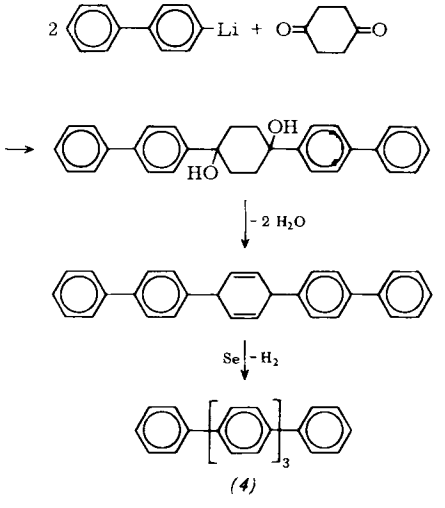
Most of the syntheses described so far are not very specific. They very often yield a mixture of several products, which can be separated only with difficulty and with considerable loss of material by fractional sublimation and crystallization.

A rather laborious, but specific, synthesis of *p*-terphenyl *(3)* was devised by *Lohaus* [14]. The intermediate product was hydrolyzed, decarboxylated, and oxidized.



(3)

An equally specific synthesis of *p*-terphenyl, the organometallic-carbonyl reaction [15], was first used by *Mayer* and *Schiffner* [16]; this method was later used by *Müller* and *Töpel* [17] for the preparation of *p*-quinquephenyl *(4)*.



(4)

Kern et al. [18] were able to obtain a large number of substituted *p*-oligophenyls having specific constitutions in yields of 40–50 % by a mixed Ullmann reaction. The organometallic-carbonyl reaction, which involves several steps, rarely gives higher yields than this process, in which a monofunctional aromatic halogen

$$n\,A\text{–}X + m\,ArX_2 \xrightarrow{Cu} \sum_{q=0}^{q=\infty} \nu_i\,A\text{–}[\text{–}Ar\text{–}]_q\text{–}A \qquad (1)$$
$$(q=0,1,2,3\ldots)$$

compound (A–X) is allowed to react with a bifunctional aromatic halogen compound (ArX_2) in accordance with eq. (1). The degree of polymerization q is determined by the molar ratio of the starting materials. When A–X is present in a sufficiently large excess, practically the only products are the first two members of the series with $q = 0$ and $q = 1$. The optimum molar ratio AX: ArX_2 found by *Kern et al.* [18] for the compound having $q = 1$, which is of considerable preparative interest, is about 10:1.

2.3. Properties

Owing to the linear arrangement of the *p*-phenylene units, the *p*-oligophenyls have rod-shaped molecules [5]; like the cumulenes, they differ in this respect from the linear aliphatic compounds. The single bonds allow free rotation of the rings about the longitudinal axis of the molecule, but no change in shape [19]. As can be seen from Table 1, the solubility of the *p*-oligophenyls decreases rapidly with increasing degree of condensation p, while the melting point rises very rapidly. Even the members with $p = 5$, 6, and 7 exhibit an unusually high thermal stability for organic molecules. It is even thought [1] that *p*-polyphenyl whose crystal lattice is free from defects could be infusible and stable up to 800 or 900 °C.

Dissolution and melting are strongly dependent on the lattice energy, since both processes involve the destruction of the lattice. In a search for a relationship between solubility and thermal stability in *p*-oligophenyls, *Kern et al.* [5, 18, 19a] synthesized 29 methylated *p*-oligophenyls with degrees of condensation up to $p = 12$ resp. 16 [19b] as models. It was found that the solubility of the *p*-oligophenyls is considerably improved by methylation, but the melting point is simultaneously lowered. The only exceptions to this rule are the initial members of the durene series with $p = 2$ and $p = 3$ [20]. *Kern et al.* [21] attribute this effect mainly to the disturbance of the molecular symmetry. Owing to the possibility of rotation of the substituted rings about the longitudinal axis of the molecule, it becomes fully evident in the *p*-oligophenyls only beyond $p = 3$.

The electronic spectra of the members from biphenyl to *p*-sexiphenyl, unlike that of benzene, show no fine structure splitting. The absorption maximum is displaced toward red with increasing degree of condensation p, and the intensity simultaneously increases.

The values calculated in accordance with *Kuhn*'s root law [23] (see eq. (2)) agree well with those found experimentally.

$$\lambda = \frac{2.08 \times 10^3}{\sqrt{1 - 0.634 \cos \frac{\pi}{p+1}}} \quad (2)$$

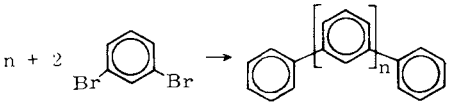
In 1939, *Gillam* and *Hey* [24] concluded from their measurements that all the nuclei of the *p*-oligophenyls are coplanar and that the entire molecule is in a state of resonance. These authors used the continuous conjugation, as a result of which quinoid formulations also contribute to the structure, to explain their observed electronic spectra. It was later shown by *Dale* [25], however, that biphenyl is not planar either in solution or in the crystalline state. As was found from an MO calculation by *Murrel* and *Longuet-Higgins* [26], the angle of twist between the ring units and the conjugation need not be considered in the interpretation of the electronic spectra of the *p*-oligophenyls. The formula used for the calculation of the excitation energies is simply based on π-electron repulsion between adjacent rings.

Special mention should be made of the fluorescence properties of the methyl-substituted *p*-oligophenyls. For example, 3,3′,2‴,3‴′-tetramethyl-*p*-quinquephenyl and 3,3′,2‴′,3‴′′-tetramethyl-*p*-sexiphenyl [5] fluoresce so strongly that their solutions must be described as blue. *p*-Oligophenyls, and particularly the methyl-substituted members, are used as scintillators [27].

3. Acyclic *m*-Oligophenyls

3.1. Syntheses

Mention has already been made of the linear linking of benzene rings into chains by hydrogenation of *p*-dihalogenoaromatic compounds under pressure [13], which leads to products up to *p*-septiphenyl. Using a



n = 1,3,7-14

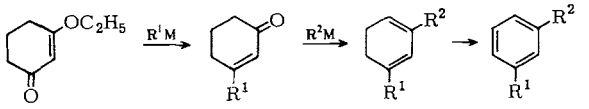
modified process (Pd/hydrazine hydrate, methanolic potassium hydroxide solution, 140 °C, 10 atm, 2.5 hours), *Busch* and *Weber*[13] condensed the rings in the *m*-position to give products up to *m*-sedeciphenyl ($p = 16$). The reaction led to ten acyclic *m*-oligophenyls in a total yield of 86 %. These were separated by fractional distillation and fractional dissolution and crystallization.

Woods et al. described the first specific synthesis of *m*-terphenyl, *m*-quaterphenyl, and *m*-quinquephenyl[28,29]. This is a two-step method involving the reaction of 3-ethoxy-2-cyclohexen-1-one *(5)* (the monoethyl ether of dihydroresorcinol) with organometallic compounds (R–M) to give the dihydroaromatic compounds, which are then dehydrogenated with palladium/animal charcoal.

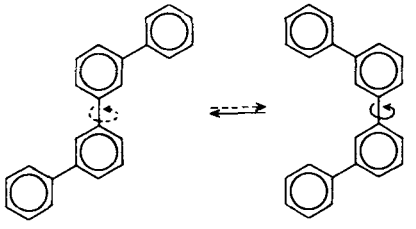


(5) R^1, R^2 = Aryl

Alexander[31] prepared *m*-sexiphenyl and *m*-octiphenyl by a similar method, and so completed the acyclic series of *m*-phenyls up to a degree of condensation $p = 16$, with the exception of *m*-septiphenyl.

3.2. Properties

Owing to the angular arrangement of the benzene rings, acyclic *m*-oligophenyls do not have a rigid molecular shape. Thus for *m*-quaterphenyl, rotation about the bond between the middle rings leads to an extended transoid form *(6)* and a ring-like cisoid form *(7)*.



(6) *(7)*

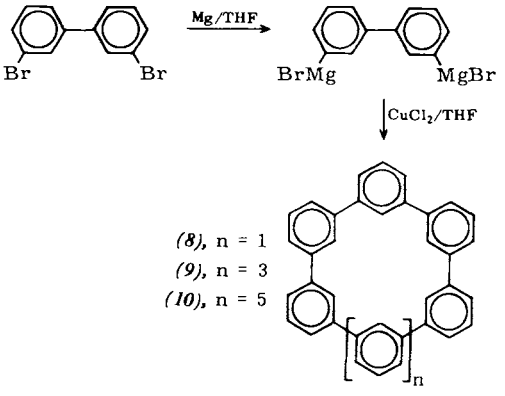
The disturbance of the molecular symmetry by rotation, like the substituent effect (cf. Section 2.3), results in a marked improvement in solubility and a considerable depression of the melting point in relation to those of the *p*-oligophenyls. This difference is very clear from a comparison of members of the *p*- and *m*-series (cf. Tables 1 and 2).

The UV spectra of the acyclic *m*-oligophenyls, in contrast to those of the *p*-oligophenyls, contain a practically constant absorption maximum at 250 nm. However, the molar extinction steadily increases with the number of units in the chain.

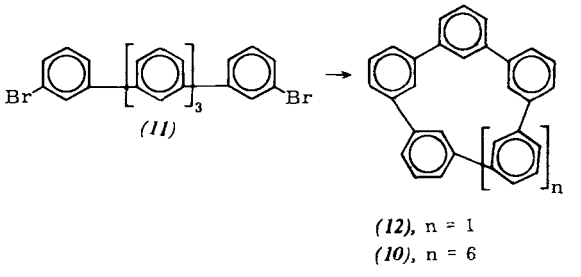
4. Cyclic *m*-Oligophenylenes[*]

4.1. Syntheses

On reaction of the di-Grignard compound of 3,3′-dibromobiphenyl in tetrahydrofuran with anhydrous copper(II) chloride, *Staab* and *Binnig*[32] obtained the cyclic *m*-oligophenylenes *(8)* (11 %), *(9)* (1.8 %), and *(10)* (≈0.1 %), which were separated by fractional precipitation and crystallization. Mass-spectrometric examination of the products showed that higher acyclic oligophenyls had also been formed.



3,3′′′′-Dibromo-*m*-quinquephenyl *(11)* was obtained by the organometallic-carbonyl reaction principle[33]. Conversion into the di-Grignard compound and reaction with copper(II) chloride gave *(12)* (3.2 %) and *(10)* (2.5 %).



(11)

(12), n = 1
(10), n = 6

4.2. Properties

Staab and *Binnig*[32,33] gained considerable information from investigations on the properties of the cyclic *m*-oligophenylenes and presented an interpretation of the results of physical measurements.

It is known from the structural analyses carried out so far that, at least in *m*-hexaphenylene *(8)* and *m*-octa-

phenylene *(9)*, the rings are turned through about 30° with respect to one another. On the other hand, the NMR spectrum of *m*-pentaphenylene *(12)* shows that the inside five protons are equivalent, from which it may be assumed that all the nuclei in *(12)* should be coplanar. However, a planar arrangement of the rings would give an H–H distance of 1.5 Å, for which no analogy is known. Information on this point should be provided by an X-ray structural analysis that has now been started.

The melting points of the cyclic *m*-oligophenylenes are much higher than those of the open-chain *m*-oligophenyls. In addition to its thermal stability, *m*-hexaphenylene has a remarkable stability to radiation, no change in physical properties being detected after exposure to extreme doses. The electronic spectra contain an absorption maximum at about 251 nm (except in the case of *m*-octaphenylene, the maximum of which is situated at 243 nm), comparable to that of biphenyl. The molar extinction increases with the number of nuclei.

Table 3. Properties of the cyclic *m*-oligophenylenes.

Degree of condensation *p*	M.p. (°C) corr.	λ_{max} (nm)	$\varepsilon_{max} \cdot 10^{-3}$
5	344	250 [b]	89.25
6	510–511	251 [c]	119
8	449–451	243 [b]	125
10	385–386 [a]	251 [c]	187

[a] According to mass-spectrometric analysis, the compound is not completely free from solvent and open-chain *m*-polyphenyls.

[b] In cyclohexane. [c] In tetrahydrofuran.

5. Acyclic *o*-Oligophenyls

5.1. Syntheses

Bachmann and *Clarke* [34] obtained *o*-terphenyl and *o*-quaterphenyl in low yields by the action of sodium on boiling chlorobenzene. To verify their structures, the two substances were prepared under the conditions of the Ullmann reaction from *o*-iodobiphenyl and iodobenzene with natural copper C and from *o*-iodobiphenyl with natural copper C. Two more recent methods giving higher yields of *o*-terphenyl have been described by *Kern et al.* [35]. *Wittig* and *Lehmann* [36] obtained *o*-sexiphenyl and *o*-octiphenyl by the decomposition of organometallic compounds.

5.2. Properties

A comparison of the acyclic terphenyls having different types of linkage shows that the melting point decreases in the order $p > m > o$. For the quater-, sexi-, and octiphenyls, on the other hand, the melting point changes in the order $p > o > m$ (cf. Tables 1, 2, and 4, and Fig. 1). The differences in thermal stability are undoubtedly due to the linearity or angularity of the structure. Stuart-Briegleb models of *o*-oligophenyls show [36] that no stereoisomers can be formulated for *o*-quaterphenyl, two for *o*-sexiphenyl, and more for *o*-octiphenyl. The observation that *o*-octiphenyl has a melting range of 8 °C (312–320 °C), whereas the lower homologs melt within 1–2 °C, agrees with the assumption that *o*-octiphenyl is a mixture of isomers.

The UV spectrum of *o*-terphenyl contains an absorption maximum [37] at 233 nm. The hypsochromic effect observed in relation to *m*-terphenyl is the more remarkable in that conjugation should occur more readily in *o*-terphenyl than in *m*-terphenyl. The relatively short distance between the two *o*-hydrogen atoms of the phenyl rings leads to twisting [38] of the rings, so that the conjugation extends over a shorter distance in *o*-terphenyl than in *p*-terphenyl. The absorption maximum for oligophenyls in the UV resulting from the energy difference between the ground state and the excited state can thus hardly be explained purely by the conjugation effect (cf. Section 2.3.).

6. Cyclic *o*-Oligophenylenes

6.1. Syntheses

Mannich [40] obtained dodecahydrotriphenylene on condensation of cyclohexane with methanolic sulfuric acid; subsequent dehydrogenation yielded triphenylene. The theoretically interesting biphenylene was first prepared by *Lothrop* [41] by dehalogenation of 2,2'-

dibromobiphenyl with copper oxide. *Rapson et al.*[42] synthesized *o*-tetraphenylene by reaction of the di-Grignard compound of 2,2′-dibromobiphenyl with anhydrous copper chloride. *o*-Hexaphenylene and *o*-octaphenylene were first synthesized by *Wittig* and *Lehmann*[36] from 2,2′-dilithiumbiphenyl with metal chlorides *via* the organometallic complexes.

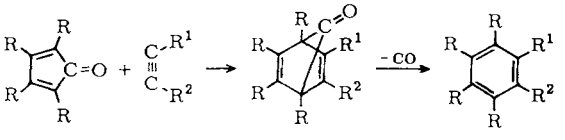
6.2. Properties

On the basis of models, *Wittig* and *Lehmann*[36] were able to show that the cyclic *o*-oligophenylenes have no stereoisomers. *o*-Hexaphenylene and *o*-octaphenylene have tube-like structures. In contrast to *o*-triphenylene, in which the outer rings are coplanar, the inner ring is not planar in *o*-tetra-, *o*-hexa-, and *o*-octaphenylene. (The conformations were deduced from the UV spectra[36, 39].) The relatively high melting points of the cyclic *o*-oligophenylenes are remarkable in comparison with those of the open-chain analogs. The melting point increases with increasing molecular size, while the solubility decreases.

7. Highly Arylated Oligophenyls

7.1. Synthesis from Monoalkynes with Mono- and Biscyclopentadienones

A simple, specific method for the preparation of branched oligophenyls is based on the Diels-Alder reaction. In this way *Dilthey et al.*[43] obtained arylated oligophenyls of the terphenyl series from tetracyclone and acetylene, phenylacetylene, or tolan.



R = C_6H_5
R^1, R^2 = H or C_6H_5

Whereas the double bonds of butadiene each react with a tetracyclone molecule to give hexaphenyl-*p*-quaterphenyl[44], only one of the triple bonds in compounds of the diphenyldiacetylene type reacts under the usual conditions[44, 45]. It was later found[46] that the reaction of two moles of tetracyclone with one mole of diphenyldiacetylene to give octaphenyl-*p*-quaterphenyl *(16a)* could be brought about under much more forcing conditions (bomb tube, 315 °C).

Becker et al.[46, 47] synthesized ten of the deeply colored "bistetracyclones" *(13a)–(13i)* and *(15)*, which react with tolan[46, 47] to give the analogs of hexaphenylbenzene *(14a)–(14i)* and *(16b)* (see Table 6).

Table 6. Properties of the *p*-ter-, *p*-quater-, *p*-quinque-, and *p*-sexiphenyl derivatives *(14)* and *(16)*.

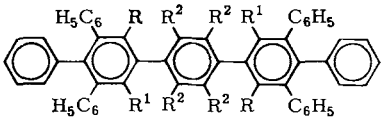
[a] In 1,2-dichloroethane. [b] Shoulder. [c] Prepared earlier by *Ried* and *Bönnighausen* [45] from tetracyclone and 1,4-bis(phenylethynyl)-benzene.

7.2. Synthesis from Dialkynes and Trialkynes with Mono- and Biscyclopentadienones

By heating one mole of aromatic diethynyl compound[48–50] with two moles of substituted cyclopentadienone in the high-boiling inert solvent β-decalol, we obtained[45] the products *(17)–(20)* in very good yields.



(17)

(a) R = C_6H_5; $R^1 = R^2$ = H; m.p. = 417–418 °C
(b) R = CH_3; $R^1 = R^2$ = H; m.p. = 311–312 °C
(c) R = $R^1 = C_6H_5$; R^2 = H; m.p. = 478–479 °C (sinters above 448 °C)
(d) R = $R^1 = C_6H_5$; R^2 = Cl; m.p. = 492–495 °C (sinters above 480 °C)

The *o*- and *m*-diethynylaromatic compounds also react to give the compounds *(21)–(24)*.

The constitution of the compounds *(17)–(24)* was readily verified by elementary analysis and from the IR spectra[52]. The formulation was based on the most favorable steric arrangement of the rings as found from models.

(17c) and *(17d)* have no stereoisomers while several conformations are conceivable for *(17a)* and *(17b)* as well as

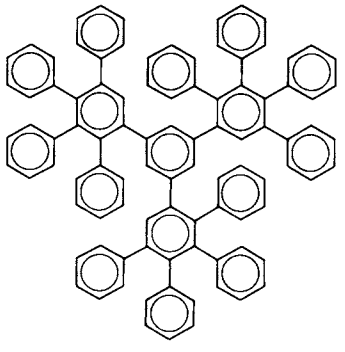
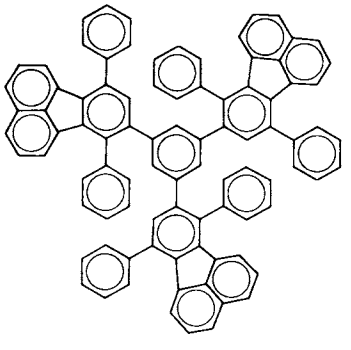
(16), R = *p*-C_6H_4

for *(18)–(24)*. However, the differences are evident only if rotation is restricted. An X-ray analysis[53] that has been started for *(17c)* and *(25)* should provide information about the steric arrangement.

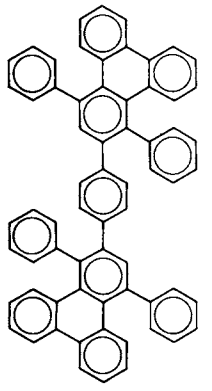


(25), m.p. = 374-375°C

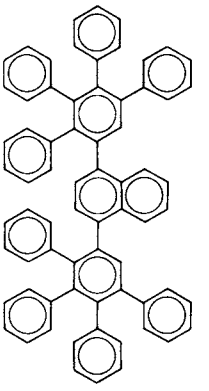


(26), m.p. = 296-301°C

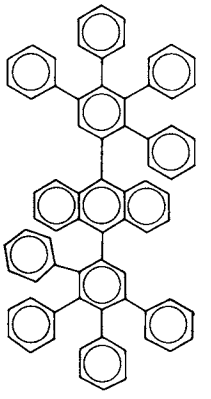
[53] *G. Habermehl*, Organisch-chemisches Institut der Technischen Hochschule Darmstadt.



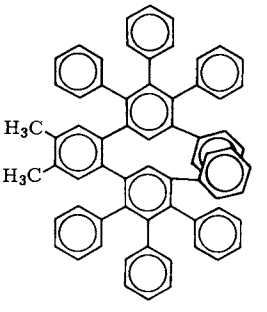
(18), m.p. = 411-413°C



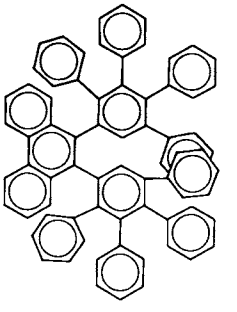
(19), m.p. = 368-370°C



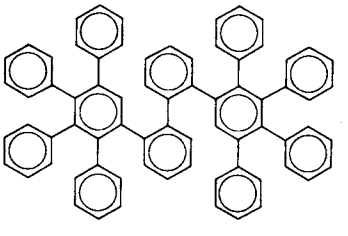
(20), m.p. = 404-406°C



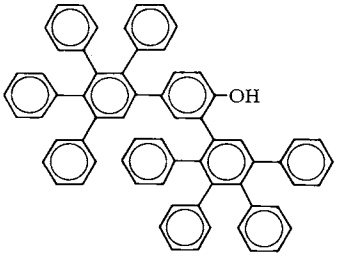
(21), m.p. = 377-379°C



(22), m.p. = 295-296°C



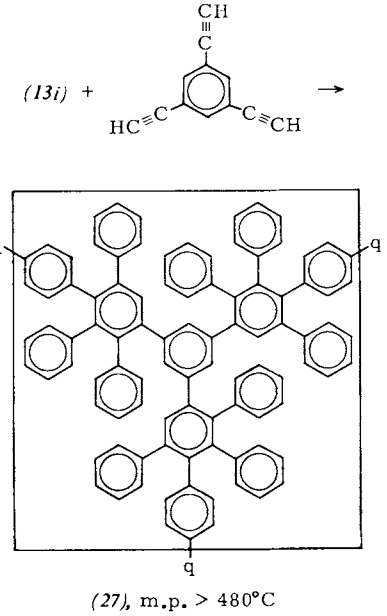
(23) [51], m.p. = 238-240°C



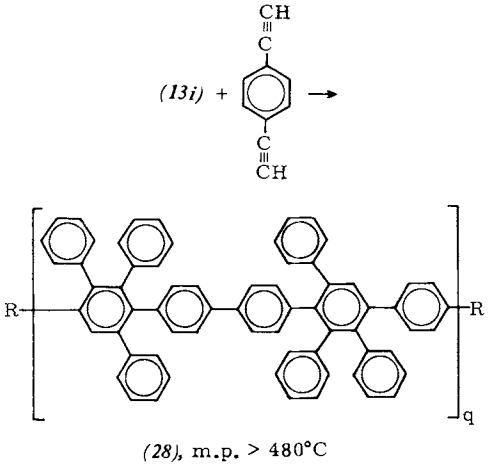
(24), m.p. = 393-396°C

Kern et al. [54] have already reported the preparation of branched oligophenyls by cyclotrimerization. We obtained the oligophenyls *(25)* and *(26)* quantitatively by Diels-Alder reactions of 1,3,5-triethynylbenzene [55] with cyclopentadienones. Both products [56] have a specific, star-shaped structure. The structures indicated are verified by elementary analysis, molecular weight determinations, and their IR spectra.

2,2′,4,4′,5,5′-Hexaphenyl-3,3′-bicyclopentadienyl-1,1′-dione *(13i)* reacts with diethynylbenzene and triethynylbenzene with elimination of CO and formation of the oligo- and polyphenyls respectively [56] *(28)* and *(27)*.



(27), m.p. > 480°C

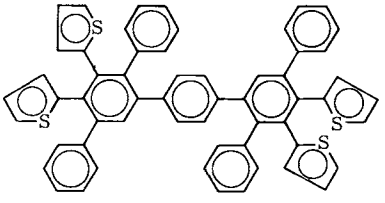


(28), m.p. > 480°C

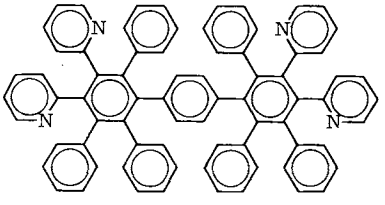
The IR spectrum of *(28)* still shows a weak carbonyl band at 1689 cm^{-1}, but no C≡C band at ≈2200 cm^{-1}; the end groups are therefore assumed to be *(13i)* groups. Nonlinear linkage of the benzene rings in *(28)* is thought to be unlikely because of its extremely high melting point (> 480 °C). *Stille et al.* [56a] have also synthesized *(28)* and found the molecular weight of the polymer to be ≈40000. Clear films, which are stable in air up to 550 °C, were prepared from *(28)*. The good agreement of the IR spectra of *(25)* and *(27)* supports the formulation *(27)*, particularly since the constitution of the model substance *(25)* has been definitely established. Further methods for the preparation of polyphenyls will be discussed in Section 8.

7.3. Preparation of Oligophenyls with Hetero Atoms

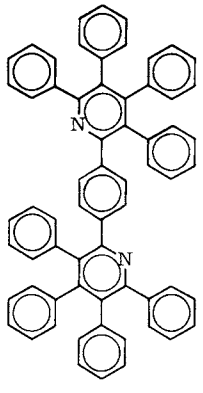
The oligophenyls *(29)* [57] and *(30)* [58], which contain hetero atoms, have recently been prepared by classical diene syntheses from heterocyclically substituted cyclopentadienones or their hydrates.



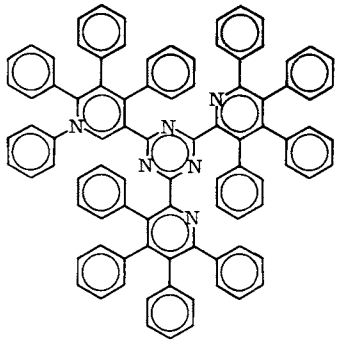
(29), m.p. = 395-397°C



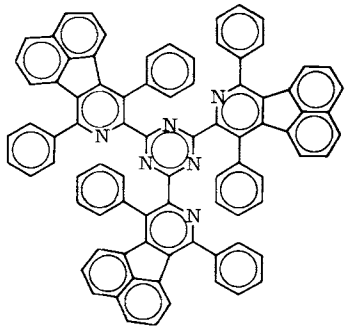
(30), m.p. = 488-490°C



(31), m.p. = 366-369°C



(32), m.p. = 208-213°C



(33), m.p. = 472°C (decomp.)

[58] *P. Bergmann* and *H. Paul*, Chem. Ber. *100*, 828 (1967).

Tetracyclone reacts in the same manner[59] with terephthalodinitrile to give *(31)* and with tricyano-*s*-triazine to give *(32)*. *(33)* has been prepared from acecyclone (diphenylnaphthopentalenone) and tricyano-*s*-triazine[59].

7.4. Properties

As expected, the melting point decreases with increasing aliphatic content in the series of highly arylated systems *(14a)–(14f)*. The compound *(16a)*, in which the rotation of the outer rings is largely blocked by the substituents, has a particularly low melting point. The electronic spectra of the oligophenyls *(14a)–(14h)* show no fine-structure splitting, and like the spectrum of hexaphenylbenzene, they have a principal absorption band at 247 nm. The molar extinction coefficient of the oligophenyls is about double that of hexaphenylbenzene. These observations[46] show that the spectral properties of the molecules *(14a)–(14h)* are almost additively those of two unconjugated hexaphenyl units.

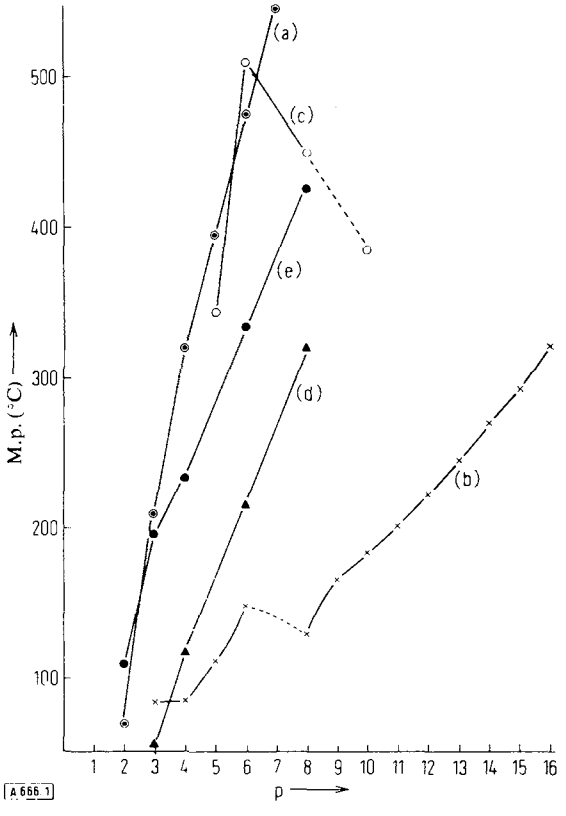

Fig. 1. Melting points of the oligophenyls and oligophenylenes as a function of the degree of condensation *p*.

(a) *p*-oligophenyls; (b) acyclic *m*-oligophenyls; (c) cyclic *m*-oligophenylenes; (d) acyclic *o*-oligophenyls; (e) cyclic *o*-oligophenylenes.

It can be seen from Figure 1 that the melting points of the oligophenyls and oligophenylenes depend mainly on the nature of the linkage, and less on the number of rings. The highest values are found for the *p*-oligophenyls.

An additional increase is obtained by symmetrical arylation, as is shown by a comparison of the melting points of hexaphenyl- and octaphenyl-*p*-quinquephenyl *(17a)* and *(17c)* (417–418 and 478–479 °C respectively) and of *p*-quinquephenyl (395 °C). A further, though small, improvement is achieved by halogenation [tetrachlorooctaphenyl-*p*-quinquephenyl *(17d)* melts at 492–495 °C].

With increasing steric hindrance [cf. octaphenyl-*p*-quaterphenyl *(16a)* and hexaphenyl-*p*-quinquephenyl *(17a)*], the increased bulk of the molecule leads to a decrease in the packing density in the lattice, and hence to a decrease in the enthalpy of fusion $(\Delta H)_f$, so that the melting point is lower. The relationship[20] between the melting point T_f, the enthalpy of fusion $(\Delta H)_f$, and the entropy of fusion $(\Delta S)_f$ can be expressed by equation (3):

$$T_f = (\Delta H)_f/(\Delta S)_f \qquad (3)$$

This equation shows that a disturbance of symmetry due to substitution [compare *(17a)* with *(29)* and *(31)*, *(17c)* with *(30)*, *(25)* with *(32)*, and *(26)* with *(33)*] results in an increase in entropy $(\Delta S)_f$ and hence to depression of the melting point at constant $(\Delta H)_f$. However, since $(\Delta H)_f$ changes, the melting point can be predicted only if the enthalpy and entropy terms are accurately known.

The oligo- and polyphenyls *(27)* and *(28)* are extremely heat-resistant for organic molecules (m.p. > 480 °C). The ready solubility of *(28)* in benzene is also interesting.

The UV spectra of the compounds *(17a)*, *(23)*, and *(25)* (in 1,2-dichloroethane) show a hypsochromic shift of the absorption bands from 255 through 248 to 244 nm. *(28)* has two absorption maxima at 250 and 310 nm, which probably result from the superposition of the electronic spectra of the hexaphenyl-*p*-quinquephenyl unit and the end groups R.

The arylated oligophenyls have proved to be very useful in gas chromatography[60]. Separating columns with solid (*e.g.* graphitized carbon black) as the stationary phase, when coated with less than a unimolecular layer of octaphenyl-*p*-quinquephenyl *(17c)*, are more reliable and more efficient than uncoated graphitized carbon black for the separation of gas mixtures. Strongly polar substances such as aniline derivatives and esters of fatty acids can also be separated at much lower temperatures. The thermal stability of the resulting columns is extremely good. Their properties were unchanged after a long test period (more than two months) at an analysis temperature of 450–480 °C.

8. *p*-Polyphenyls

It can be seen from Figure 1 that *p*-polyphenyls should be very suitable where maximum thermal stability is required. This conclusion has led to attempts to synthesize them in various ways.

Edwards and *Goldfinger*[61] obtained a "*p*-polyphenyl" having a molecular weight of 2700–2800 by condensation of *p*-dichlorobenzene in the presence of a liquid sodium-potassium alloy (KNa_2); however, the physical properties of the polymer showed that the rings were linked only predominantly, but not entirely, in the *p*-position. Despite these defects, the polyphenyl does not melt below 550 °C.

Kern et al. tried to obtain methyl-substituted *p*-polyphenyls having uniform structures from methylated

[59] *A. Göbel*, Dissertation, Universität Frankfurt/M., 1967.

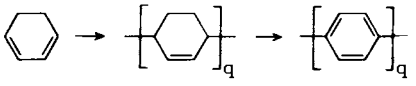
[60] *F. A. Holdinghausen, D. Freitag, W. Ried*, and *I. Halász*, Angew. Chem. *80*, 754 (1968); Angew. Chem. internat. Edit. *7*, 724 (1968).

[61] *G. A. Edwards* and *G. Goldfinger*, J. Polymer Sci. *16*, 589 (1955).

dihalogenoaromatic compounds by the Ullmann synthesis with copper [62], by the Wurtz-Fittig synthesis with sodium [19], and by the Kharasch synthesis with magnesium and anhydrous heavy metal chlorides [63].

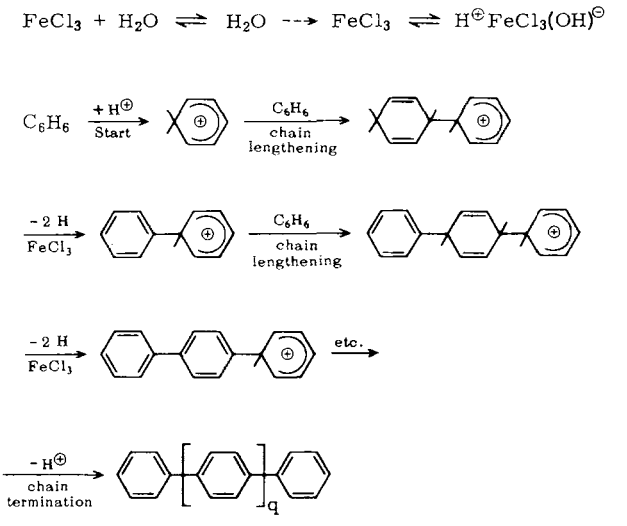
The reactions led [64] to soluble macromolecular products, but in addition to the desired *p*-linkages these also contained other linkages and exhibited branching. The methylated polyphenyls obtained by the Ullmann method had the highest melting point (290–310 °C).

Marvel et al. [65, 66] obtained polycyclohexene by polymerization of 1,3-cyclohexadiene with Ziegler catalysts or with cationic initiators; treatment with chloranil or halogenation followed by pyrolysis then gave *p*-polyphenyl (molecular weight 7000–8000) containing some incompletely aromatized units.



The polymeric products are dark brown to black (depending on the experimental conditions), infusible, and stable up to about 530 °C.

Kovacic and *Koch* [67] obtained a *p*-polyphenyl having similar properties in a single reaction step by oxidative cationic polymerization of benzene. The authors assumed that the reaction proceeds in accordance with Scheme 1.



A very recent method [4] that has proved a convenient route to *p*-polyphenyls is the oxidative coupling of benzene with chlorine. Natta-Ziegler catalysts react with benzene in this process to give a complex. The subsequent treatment with chlorine gas yields a yellow-brown *p*-polyphenyl having a softening point higher than 500 °C. Investigations on the stabilization of the complex with suitable co-catalysts and on the processing of the polymeric products are being carried out at present.

The author is grateful to the Fonds der Chemischen Industrie, the Deutsche Forschungsgemeinschaft, Farbwerke Hoechst AG, Farbenfabriken Bayer AG, and Badische Anilin- und Soda-Fabrik for their support of his work in this field.

Trends in Radiation Polymerization

BY R. C. POTTER, CHRISTEL SCHNEIDER, M. RYSKA, AND D. O. HUMMEL[*]

Dedicated to Professor K. Ziegler on the occasion of his 70th birthday

Previously it was generally assumed that high energy radiation could only initiate radical polymerization in solutions of monomers. However, examples of radiation-induced polymerization have recently become known that proceed via an ionic mechanism. Thus, solutions of a monomer can be polymerized ionically, preferably in the presence of a solid, at low temperatures. Surprisingly, this may also be accomplished with ultra-pure, mainly anhydrous systems, even at room temperature. The nature of the ions has not yet been fully elucidated.

1. Introduction

Probably going largely unnoticed by the community of polymer chemists has been the progression of the startling and exciting developments over the last ten years in the area of radiation-initiated polymerization. New instruments, refined techniques, inspired research, and an occasional sprinkling of serendipity have produced a renaissance in what was once thought to be a thoroughly explored field.

By 1957, most of the common monomers had been polymerized using high energy radiation. In order to determine the mechanism of reaction, the kinetics of radiation-initiated processes were compared with the kinetics of conventionally initiated free radical and ionic polymerization. For instance, since the dose rate of radiation, (I), is exactly analogous to catalyst concentration, (C), one would expect that for a radiation-induced free radical mechanism, the rate (R_p) and the average degree of polymerization ($\overline{DP}$) would obey the following relationships.

$$R_p \sim I^{0.5}$$

$$\overline{DP} \sim I^{-0.5}$$

Indeed it was observed that such was the case. Furthermore, experimentally determined temperature coefficients conformed to those predicted for a free radical process in which the formation of active species in the initiation step was independent of temperature. Additional evidence favoring a radical mechanism was obtained from scavenger studies and copolymerization experiments. Without exception, it appeared that a free radical mechanism could be ascribed universally to radiation polymerizable monomers.

Throughout the course of these studies, there gradually developed a picture of the events which take place in the interaction of ionizing radiation with covalently bonded molecules. This scheme of events remains valid today, although the importance of some of the reactions has had to be re-evaluated. Bearing this in mind, let us now consider this chain of reaction events.

2. Introduction to Radiation-Chemical Mechanisms

An incident photon may cause either ionization or excitation of a molecule AB.

$$AB + h\nu \rightarrow AB^+ + e^- + h\nu' \quad (1)$$

$$AB + h\nu \rightarrow AB^+ + e^- \quad (2)$$

$$AB + h\nu \rightarrow AB^* + h\nu'' \quad (3)$$

Equation (1) depicts classical Compton scattering, wherein the photon imparts sufficient kinetic energy to an orbital electron so that it is ejected from the molecule. Emerging from this encounter with a somewhat longer wavelength and a different direction of travel, the photon may interact further with AB by either additional Compton scattering or photoelectric absorption [eq. (2)]. In the case of photoelectric absorption, the energy of the photon is so low that it is all imparted to the electron. However, most experimental work utilizes γ rays from ^{60}Co, and since these transfer their energy [*] primarily by Compton scattering (in materials of low atomic number), reaction (2) is of relatively little importance as a primary process. Also the dimensions of experimental samples are usually smaller than the mean free path of a 1 MeV γ ray [as, for instance, might result from reaction (1)], which is of the order of 15 cm in material of unit density. Therefore, multiple interactions of a given γ ray within the sample are rather improbable.

[*] 1.33 and 1.17 MeV.

In some cases the energy transferred by the incident photon is insufficient to cause the ejection of an electron. Instead, the energy level of the molecule is raised above the equilibrium level to an excited state [eq. (3)]. However, since the reaction can involve no more than 3 to 4 eV per reaction step without rupturing covalent bonds, as contrasted with energies of the order of MeV involved in reaction (1), it is relatively unimportant as a means of depositing energy in the sample.

Compton "recoil electrons" usually possess sufficient energy to cause further ionization and excitation, according to the following reaction scheme:

$$AB + e_i^- \rightarrow AB^+ + e_{i'}^- + e_j^- \quad (4)$$

$$AB + e_i^- \rightarrow AB^* + e_{i''}^- \quad (5)$$

e_i^- is an incident, high energy electron formed in reaction (1); $e_{i'}^-$ is the same electron now of lower energy owing to ionization of the substrate molecule AB; e_j^- is the electron ejected in the ionization process; and $e_{i''}^-$ is also a lower energy state of the incident electron e_i^- resulting from an inelastic collision with a substrate molecule, and forming an excited molecule AB*.

If electrons $e_{i'}^-$, $e_{i''}^-$, or e_j^- have sufficient kinetic energy to escape Coulombic interaction with AB^+, they may produce further ionization and excitation, their energy approaching the thermal level more closely on each interaction. On the other hand, a scattered or ejected electron of low energy will be captured by AB^+. Thus, depending on the environment of the electron when it reaches thermal energy and on other factors, such as electron affinity of the substrate molecule, the following processes are possible:

$$AB^+ + e_{thermal}^- \rightarrow AB^{**} \quad (6)$$

$$AB + e_{thermal}^- \rightarrow AB^- \quad (7)$$

The absorption coefficients of γ rays and electrons of about the same energy are in the approximate ratio of 1:100 to 1:1000. When this fact is considered in conjunction with reactions (1) through (7), it may be seen that the vast majority of the energy deposited by γ rays from ^{60}Co in a small sample of almost unit density and low atomic number will result from reactions (4) and (5), which in turn are initiated by reaction (1).

The excited molecules produced by the above reactions are unstable and may decompose into molecular species, normal (or excited) radicals, or ions (AB* and AB** now being equally depicted as AB*):

$$AB^* \rightarrow A^\cdot + B^\cdot \quad (8)$$

$$AB^* \rightarrow A + B \quad (9)$$

$$AB^* \begin{cases} \nearrow A^+ + B^- \\ \searrow A^- + B^+ \end{cases} \quad (10)$$

However, reactions (8) and (9) are favored because less energy is required for homolytic scission [eq. (8)] than for heterolytic scission [eq. (10)]. Also the available energy is usually insufficient to prevent immediate recombination of the ion pair generated by reaction (10).

In summary, then, ions may be produced both directly and indirectly by radiation. However, free radicals are strictly an indirect product from the interaction of radiation with matter.

The very earliest theoretical arguments[1] supported a free radical mechanism of polymerization by advancing the view that large ions would probably be unstable and, further, by emphasizing that free radicals are an important by-product from the decay of excited molecules. The observation that thermalized recoil electrons [from reactions (1) and (4)] do not, on the average, escape recombination with positive ions, even in a solvent of such high dielectric constant as water[2] not only seemed to preclude the formation of free ions by reactions (1) and (4), but also minimized the formation of free ions by reactions due to electron solvation [eq. (7)]. Furthermore, calculations showed that the time required for thermalization followed by charge neutralization is short (*ca.* 10^{-13} seconds in water[2]). Thus, after a primary radiation event a population of excited molecules arises rapidly and exclusively through charge neutralization and direct excitation. As has already been mentioned, these excited molecules preferentially decay into free radicals.

Seemingly, then, there was no fundamental question in the field of radiation polymerization remaining to be investigated. An indication of the prevailing consensus is conveyed very well by *Chapiro*. He notes in the preface to his volume on the radiation chemistry of polymeric systems that his original manuscript contained a detailed argument which "not only showed that ionic processes had never been observed under irradiation but also conclusively demonstrated why radiations could not initiate ionic polymerization"[3].

3. Low-Temperature Polymerization

In 1957, *Magat* commented on the paradox that "ionizing" radiation seemed to be incapable of initiating ionic polymerization[4]. He challenged the idea that electron-neutralization times would be as short as 10^{-13} sec, especially if the irradiation were to be conducted at low temperature. Employing the Platzman-Frohlich model[5, 6], he calculated that a reduction in temperature from 300 to 100 °K corresponds to a thirty-fold increase in the distance between the parent ion and its thermalized electron. The increased ion-lifetimes under such conditions were deemed sufficient to sustain long-chain ionic propagation.

At just this time, the radiation-induced cationic polymerization of isobutene at low temperature[7] was

discovered. A great deal of evidence was amassed in support of an ionic mechanism, including a linear dose rate dependence[8], ionic copolymerizations[9,10], and inhibition by diisobutene[11] (which also inhibits the conventional ionic reaction). Although other scavenger studies did lead to some conflicting results (*e.g.*, retardation by benzoquinone[12]), these results were, nevertheless, reconcilable with an ionic reaction.

Magat also predicted that the presence of electrophilic solvents and/or inorganic solids in a reaction system would further facilitate ion propagation[4,13]. Thus he necessarily emphasized the importance of reaction (7) (electron solvation with monomer or solvent molecules) and the possibility of electron entrapment in a crystal defect:

$$e_{thermal} + \text{Solid} \rightarrow \text{F-center} \qquad (11)$$

Such strategems did, indeed, enhance the low-temperature polymerization rate (R_p) of isobutene[3]. The addition of zinc oxide to the system was especially successful in increasing R_p[14,15]. When the same reasoning was extended to styrene, similar results were obtained. For instance, when styrene was irradiated at −78 °C, it polymerized rapidly in methylene chloride[16,18], ethyl chloride[9], and 1,1- or 1,2-dichloroethane[17]. The polymerization rate was directly proportional to the dose rate ($R_p \sim I^{1.0}$) and the presence of oxygen or benzoquinone did not affect the reaction[17,18]. In addition, the reaction was accelerated by the presence of such solid additives as silica or zinc oxide[19].

Since these initial discoveries, the same techniques have been used to ionically polymerize and copolymerize some fifty monomers. In most cases, the investigators were content to merely establish the fact that one could induce an ionic mechanism in a certain monomer. Thus, one frequently encounters the statement in the literature that "monomer X polymerizes by an ionic mechanism at low temperature in the liquid phase but the normal free radical mechanism predominates at room temperature". Typically such

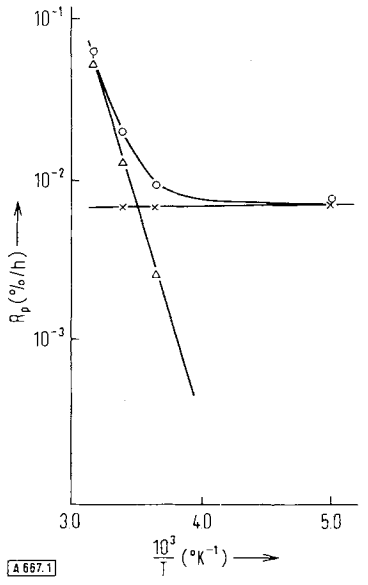

Fig. 1. Radiation polymerization of isoprene [20]: Radical and ionic contributions to the rate were distinguished by means of diphenyl picryl hydrazyl (DPPH): × — × experiments with DPPH; ○ — ○ experiments without DPPH; Δ — Δ experiments with pyridine. In this system radical polymerization is faster than ionic polymerization.

behavior is illustrated by a two-segment Arrhenius diagram (*e.g.*, see Fig. 1). Another frequent illustration is provided by the difference in copolymerization parameters between −78 and 0 °C (*e.g.*, see Table 1).

Table 1. Monomer reactivity ratios in copolymerization of isobutene (r_1) and vinylidene chloride (r_2) [9].

T (°C)	r_1	r_2
−78	25	0
−40	1.27	0.21
0	0.03	1.3

With few exceptions little has been done in the way of truly enlightening kinetic studies.

On γ-irradiation of the novel system of acrylonitrile in liquid ethylene at −78 °C[21,22], a maximum in R_p was observed at the highest acrylonitrile concentration and the reaction is completely inhibited by a radical scavenger such as pyrogallol.

The infrared spectrum of the resultant polymer corresponds to a reaction through the vinyl group as in *(1)*. The reaction

(1)   *(2)*

rate passes through a minimum at the equimolar concentration of the monomers and then reaches a second maximum at a very low concentration of acrylonitrile. In this region of low acrylonitrile concentration, pyrogallol has no appreciable effect on the reaction, the acrylonitrile polymerizing through the nitrile group to yield *(2)*.

Although the role of ethylene (mere solvent or reactive component) and the extent to which it influences the reaction is not clear, it is apparent that the presence of ethylene facilitates a changeover in reaction mechanism. Thus, it is believed that at low acrylonitrile concentration the reaction proceeds by an anionic mechanism. As the concentration increases, however, the reaction becomes progressively free-radical in character.

Despite the implications of *Magat*'s reasoning, many workers have assumed that the propagating ions in these systems are associated with some type of gegenion as in a normal catalytic polymerization. However, *Geymer* has suggested that free ions are the participating species [23]. He points out that a carbonium ion-electron pair in close proximity would be rapidly neutralized by quantum mechanical tunneling. It is then inconceivable that the lifetime of such a pair would permit a DP of 10^5, as has been observed for isobutene [8]. Furthermore this is an irreversible reaction since the neutralization of a polymeric carbonium ion releases about 5 eV of energy.

In another study relating to free ions, the effect of a strong electric field has been examined for the low-temperature cationic polymerization of styrene in methylene chloride [24]. It was found that the electric field increases R_p and has no effect on DP, which seemed to indicate that the number of initiating sites is increased. This phenomenon was explained by assuming a free ion mechanism wherein the population of stable propagating carbonium ions is increased because of the comparatively easy migration of electrons or solvated electrons towards the anode. On the other hand, the radiation-initiated anionic polymerization of methyl methacrylate in isopropylamine and acrylonitrile in triethylamine (at $-78\,^{\circ}C$) is retarded by the application of an electric field. Since the formation of propagating anions would depend upon electron solvation, this result gives further indication that there are fewer electrons available for reaction.

These studies have provided more evidence for the existence of ions in radiation polymerization. Also, on the basis of subsequent conductivity measurements it has been estimated that the lifetime of the styryl cation in the system is from 10^{-1} to 10^{-2} sec, which is quite sufficient for a long chain reaction to take place [25].

Some work has been done to investigate the role of solid additives. It has been found that during irradiation the conductivity of zinc oxide increases when isobutene is adsorbed on its surface [26]. This is believed to be due to the formation of positive "holes" within the zinc oxide as a consequence of irradiation. By means of the semiconductor effect these holes can then travel to the surface of the solid and abstract electrons from the isobutene molecules. Contrary to this idea, *Charlesby* has suggested that the carbonium ions are formed in the liquid phase and then become propagation sites by adsorption on the zinc oxide surface [27]. There is also the third possibility of electron trapping, which was the original proposal of *Magat*.

Interestingly, the addition of nickel oxide or magnesium oxide (which, just as zinc oxide, are p-type semiconductors) sharply increases R_p for the low-temperature anionic polymerization systems of methyl methacrylate and acrylonitrile [28]. Also, the rate of copolymerization of acrylonitrile with methyl methacrylate at $-50\,^{\circ}C$ is increased by about an order of magnitude by addition of magnesium oxide. The explanation of such results would require yet another hypothesis regarding the working of solid additives.

As might be expected, the use of various solvents in these ionic polymerizations yields varying results. Thus the rate of acrylonitrile polymerization is much higher in electron donating solvents than in electron withdrawing solvents [29]. However, the results are not always so predictable. For example, an equimolar feedstock of styrene and methyl methacrylate yields an equimolar copolymer in bromoethane, while one containing 91 mole-% styrene was obtained in dichloromethane [30]. Also the copolymerization of formaldehyde and styrene takes place in bulk and in dichloromethane, whereas in diethyl ether there is only homopolymerization of the formaldehyde [31].

4. Ultra-pure Systems

Without exception, the ionic polymerizations mentioned in Section 3 were carried out under "extreme" conditions. That is, they were performed at very low temperature (to favor ionic over free radical propagation), and sometimes with an added second phase (to act as an electron trap) or a homogeneously distributed second component of reasonably high dielectric constant (to promote ion stabilization). At normal temperatures, one could always rely upon the species of propagation as being free radicals.

However, in 1960 even this inviolable rule was put to rest by a remarkable discovery made at Brookhaven National Laboratory. *Metz*, having need of very pure polystyrene, turned to the catalyst-free technique of radiation preparation. In particular, special precautions were taken so that the monomer was extremely pure and dry before irradiation. The subsequent polymerization gave the astounding indications of proceeding, not by a radical mechanism, but by an ionic mechanism at *room temperature*, as evidenced by enhanced rates of reaction (as high as thirty times the previously observed free radical reaction rate), independence of molecular weight of dose rate, and extreme sensitivity to impurities, especially traces of water [32, 33].

During the early 1960's *Metz*[34], *Williams*[35,36,38], and *Hirota*[37] independently investigated pure, anhydrous α-methylstyrene, which was believed to polymerize conventionally only by an ionic mechanism. Normally under irradiation at room temperature, this monomer had polymerized very slowly and yielded a low molecular weight polymer. However, under the conditions of extreme purity the rate increased considerably and a material of much higher molecular weight was formed.

Only in the last two years has this field truly matured. The schools of *Metz*, *Williams*, and *Okamura* have provided the literature with a great outpouring of papers which have probed the subject at depth. The most detailed research efforts have been concerned with the further investigation of styrene[39–46,60]. However, a number of other highly purified monomers have been shown to be susceptible to ionic polymerization at room temperature, including β-pinene[35,36,38], isobutyl vinyl ether[47], 1,2-epoxycyclohexane[48,67], nitroethylene[49,51], and molten trioxane[50,66].

4.1. Techniques of Purification

Generally, the various purification schemes for preparing these ultrapure monomers have four steps in common, all of which are performed in a vacuum environment: distillation of monomer; vacuum bake-out of apparatus; degassing of monomer; and contacting of monomer with a drying agent such as activated silica gel, Na-K alloy, or barium oxide. As might be anticipated for an ionic polymerization these elaborate schemes do not always yield reproducible results. However, for the styrene and α-methylstyrene systems, reproducibility has ultimately been attained[41–45,60]. For this case, it is interesting to note that styrene at 0 °C, when exposed to ^{60}Co γ-rays at a dose rate of 1 Megarad/h, polymerizes at a rate of 940 %/h, compared to the classical free radical value of 0.2 %/h for these conditions (see Fig. 2).

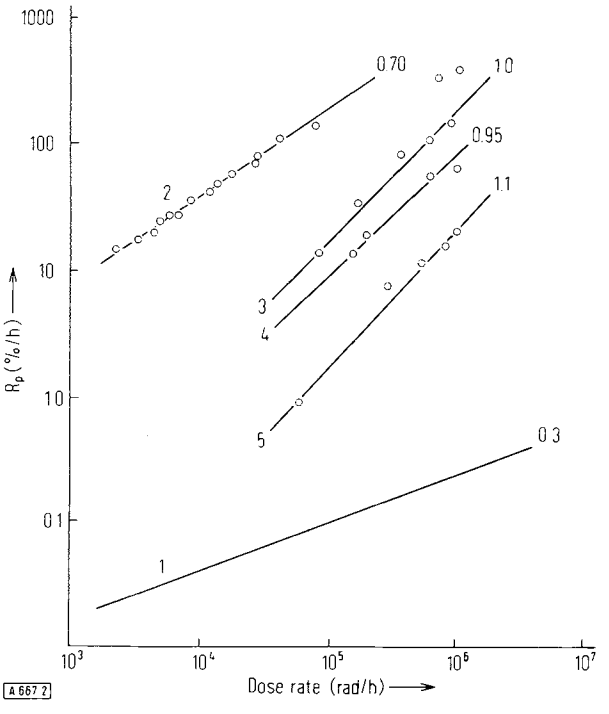

Fig. 2. γ-Induced polymerization of styrene at 0 °C. Curve 1: classical inverse-power radical polymerization (calculated); curve 2: reproducible results from four independent dilatometer determinations [41]; curves 3–5: previous non-reproducible results from three independent dilatometer determinations [40]. Values of x for the relation $R_p \sim I^x$ are given on the right-hand side of each curve.

4.2. Evidence for the Formation of Ions

At this point, it is worthwhile to conjecture as to the reasons for the sudden appearance of such enormous and unsuspected ionic activity. Certainly, the relatively recent discovery of the hydrated electron[52,53] forces a re-evaluation of the importance of electron solvation. The production of hydrated electrons during the radiolysis of water demonstrates that some electrons are not only capable of avoiding recapture [eq. (6)], but during the thermalization process may undergo solvation [eq. (7)].

Other recent evidence supporting a high degree of charge separation has been obtained by *Allen et*

al.[54,55] from measurements in irradiated media of low dielectric constant. Yields of free ions have been determined from the ion mobilities and zero-field conductivity induced by irradiation of insulating liquids with either X-rays or fast electrons. Surprisingly, although these yields [from reaction (1), (4), and (7)] are small, they are not negligible as had been supposed previously. For example, for "normal" purity hexane at 23 °C the yield of ion pairs was found to be 0.10 per 100 eV of absorbed radiation[54]. Using this value, it was then shown that an electron of 57 eV could travel a mean distance of 87 Å from its parent ion[55]. It had previously been estimated that the range of such an electron was only 9 Å[56]. Since the values of dielectric constants for hexane and for many monomers are similar, it would not be unusual to encounter a small but measurable yield of ions in an irradiated monomer. In fact, the low temperature ionic polymerization of cyclopentadiene (again, a "normal" purity system) has been shown to have an ion yield of 0.2 pairs per 100 eV[57]. It can be concluded, then, that the ionic contribution to a "normal" purity monomer had been overlooked because most of the growing chains are terminated as oligomers (or monomers) by means of a very efficient reaction with water and any other ion-inhibiting substances that might be present. The elimination of ions thus allows the free radicals generated [from reaction (8)] to act as the chain-sustaining species. It would follow that as the water concentration was reduced the contribution of the ionic species to the over-all polymerization would steadily increase.

4.3. The Influence of Water

It has already been mentioned that, for styrene, the earliest (and, thus, the least refined) drying and purification techniques of *Metz* produced reaction rate increases above the free-radical values by a factor of about one order of magnitude. Later work by *Metz*[40] and *Okamura*[39] resulted in an increase of about two orders of magnitude. Finally, *Metz et al.* reached the limiting and reproducible rates which correspond to an increase of approximately three orders of magnitude over the dose rate range studied[41]. Both groups have conclusively demonstrated that the re-introduction of small amounts of water into the ultra-pure reaction system results in an immediate reduction of rate to the free-radical level[43,46].

In view of this situation, it might seem paradoxical that for many conventional cationic polymerizations there can be no reaction at all without water being present as a co-catalyst. It must be remembered, though, that in a highly purified monomer system there is no chemical catalyst present with which the water can form an active complex:

$$BF_3 + H_2O \rightarrow [BF_3OH]^-H$$

Thus all the highly polar water molecules are free to act as ionic scavengers. *Pinner* has speculated that this reaction – in the case of carbonium ions – may consist of abstraction of a proton to form a hydrated hydronium ion[61] ($H_3O^+ \cdot n\,H_2O$). From a thermodynamic standpoint, such a reaction should occur spontaneously. Whatever the nature of this scavenging process, it must account for the regeneration of water, since no acceleration of rate corresponding to a depletion of water has ever been observed. As this reaction has a fundamental bearing on the course of polymerization, it should be included in our reaction scheme. Therefore, in lieu of additional data, this reaction will, for a monomer ion, be written simply as:

$$MH^+ + H_2O \rightarrow M + H_3O^+ \qquad (12)$$

(Any water of hydration has been omitted.) An analogous scheme can be written for the reaction of a polymer cation with water.

As yet, no one has reliably determined the maximum value of water concentration that still allows a detectable ionic propagation. Although *Okamura* has attempted quantitative measurements in this area[46], he failed to allow for the adsorption of deliberately-added water by the baked glass surface of the apparatus. It is known, however, that the critical water concentration lies below the limits detectable by Karl Fischer analysis (5 ppm)[58]. The maximum allowable water concentration may well be in the $1:10^9$ range.

Williams has pointed out that the phenomenon of low-temperature ionic polymerization may be intimately connected with a reduced activity of water[59], that arises from increased aggregation under the conditions of reaction. Further, the effects arising from the addition of "electron-trapping" substances in low temperature experiments may have been observed solely because of the adsorbing power of these substances. To put it somewhat differently, the low-temperature polymerization proceeded ionically because of conditions reducing the efficiency of reaction (12).

4.4. Radicals in Ultra-pure Systems

Another point of interest can be raised: namely, is the role of the free radical species during the irradiation of a monomer affected by removal of impurities? (Assuming, of course, that the monomer is susceptible to free-radical radiation polymerization in the first place.) An *a priori* conclusion would be that the ionic contribution is simply superimposed on the free-radical contribution. That is, increased purity merely serves to introduce ionic species and has no effect on the normal production of free radicals. This would

imply, however, that on a graph of R_p versus I there is a critical dose rate at the intersection of the classical free radical curve with the ionic curve, and below which there would only be free radical behavior. For the case of styrene, at least, there are some data which may refute this idea [41].

A dilatometer assembly was prepared of just sufficient purity to show a slight deviation ($R_p \sim I^{0.60}$) from the square root line. Thus, there was a definite, albeit small, ionic contribution. At dose rates below the point of intersection, the order dependency did not suddenly revert to 0.5 but, instead, remained constant. This can only occur if the free radical contribution has been reduced. Most of the styryl cations which are initially formed in a "wet" system are either destined to ultimately become free radicals [reaction (6) followed by reaction (8)] or else are inactivated as a consequence of eq. (12). Thus, the implication is that whenever some propagating ions are stabilized in a "dry" system, the result is the net loss of some potential free radicals.

4.5. Polymeric Ions

As already mentioned, it is clear that free ions are active in the systems rather than the "paired" ions prevailing in a conventional ionic system. An experimental argument supporting this comes from the observation that the propagation rate constants which have so far been determined for these radiation ionic reactions are very much higher than those for the corresponding catalytic ionic reactions [62]. The idea of the enhanced reactivity of a free ion over a paired ion is not only in accord with absolute rate theory, but also finds agreement with *Szwarc*'s work on "living" polystyrene [63].

Generally these ions are believed to be cationic, although there is no real evidence indicating whether they are carbonium ions or carbonium radical ions. An exception occurs in the radiation polymerization of ultra-pure nitroethylene at room temperature, which is believed to proceed by an anionic mechanism [49, 51]. This is not surprising, considering the well-known polymerizability of this monomer by basic reagents. Furthermore, it has been shown that nitroethylene polymerizes anionically in low-temperature systems [68].

The "cationic *status quo*" may have a much more intriguing exception in the case of styrene. Factors such as reaction retardation by ammonia [39], the observed relations $R_p \sim I^{1.0}$ [33, 40] and $\overline{DP} \sim I^0$ [43, 44], copolymerization results (see Fig. 3) [46], and previous results from low temperature polymerization combine to make a strong argument favoring a simple cationic polymerization mechanism. However, at the very highest rates of polymerization of styrene the relation $R_p \sim I^{0.70}$ holds (see Fig. 2). At these high

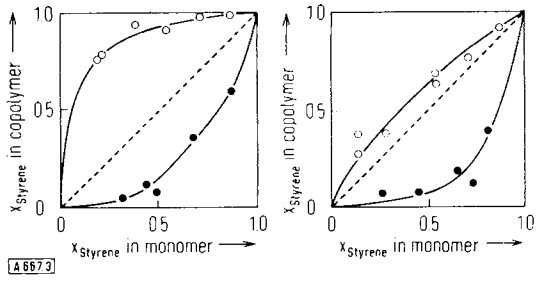

Fig. 3. a) Copolymerization of styrene and isobutyl vinyl ether, temperature 30 °C, dose rate 3800 rad/min; ○ normal purity r_1 (St) = 17.0 ± 8.0, r_2 (VE) = 0.1 ± 0.1, • anhydrous, r_1 (St) = 0.3 ± 0.3, r_2 (VE) = 10.0 ± 4.0 [46].
b) Copolymerization of styrene and α-methylstyrene, temperature 30 °C, dose rate 3800 rad/min, ○ normal purity r_1 (St) = 2.2 ± 0.2, r_2 (αMST) = 0.6 ± 0.2; • anhydrous r_1 (St) = 0.25 ± 0.25, r_2 (αMST) = 8.5 ± 4.0 [46].

rates (or, put another way, at this level of purity), species which are unusually sensitive to any protonic impurity, such as water, would begin to emerge. The styrene anion is such a species. Further, the propagation of the anion in addition to the cation would introduce the possibility of a remarkable mode of termination: termination by combination of oppositely charged polymeric ions. If this bimolecular termination occurred to an appreciable extent then a square-root dependency would be competing with the already established linear dependency. The result would be a dose rate dependence intermediate between these two extremes, which may account for the observed value of 0.70. Similar behavior has also been noted for α-methylstyrene [43, 60].

4.6. Influence of Temperature

Except for the thoroughly studied case of styrene, the influence of temperature in any of these systems has hardly been investigated. For styrene of a purity corresponding to a first order termination process ($R_p \sim I^{1.0}$), parallel isotherms have been obtained which correspond to a slightly negative overall temperature coefficient, E, on an Arrhenius diagram (*e.g.*, −1.5 kcal/mole) [43, 44]. It has also been shown that at higher purity levels the higher values of R_p result in isotherms corresponding to lower values of E (*e.g.*, −4 kcal/mole) [43, 44]. Such values of E are not in disagreement with those which would be predicted for ionic radiation polymerization. Interestingly, the isotherms obtained for the highest purity styrene ($R_p \sim I^{0.70}$) are skewed and therefore cross over one another [43, 44]. This behavior may be a consequence of the appearance of a second species (see Section 4.5.).

Other temperature investigations reveal a slight inverse relationship between temperature and $\overline{DP}$ [43, 44]. Again this is the theoretical expectation for an ionic polymerization initiated by radiation.

4.7. Chain Transfer

One further deduction may be made concerning the kinetics of these ionic systems. Simple calculations show that chain transfer occurs to a great extent dur-

[62] *F. Williams* [50].

[63] *D. R. Bhattacharyya, C. L. Lee, J. Smid,* and *M. Szwarc,* Polymer (London) *5*, 54 (1964); J. physic. Chem. *69*, 612 (1965).

ing the irradiation of ultra-pure monomers. To begin with, the values of $G_{(-m)}$ which are encountered are extraordinarily large[*]. For instance, in the case of styrene, values of $G_{(-m)}$ in the order of 10^5 are typical (as compared to free radical values of approximately 10^3). Assuming an ionic mode of termination and the total absence of chain transfer, the yield of chains initiated is given by:

$$G_i = G_{(-m)}/\overline{DP}$$

Since the $\overline{DP}$ for styrene is in the order of 10^3, the resulting value of G_i is in the order of 10^2. However, about 32 eV are required to form one ion pair in the gas phase, which corresponds to a G_i of about 3. For a condensed system, the corresponding result should be similar. In fact we have already made mention of the low G_i values ($\approx 10^{-1}$) for cyclopentadiene and hexane. A G_i of 10^2 is unreasonably high, and thus the presence of chain transfer is necessitated. When chain transfer occurs, the calculated value of G_i is reduced to a more reasonable value according to:

$$G_i = [k_t/(k_t + k_{tr})] \cdot [G_{(-m)}/\overline{DP}]$$

where k_t is the rate constant for termination and k_{tr} is the rate constant for transfer.

4.8. Synopsis on Ultra-pure Systems

Upon irradiation of an ultra-pure monomer, free ions arise immediately, primarily as a consequence of reactions such as (4) and (7). Provided that the concentration of water is low enough to preclude a substantial contribution from reaction (12), these ions permit rapid propagation of a relatively small number of kinetic chains. The primary mode of termination of the polymeric ions is effected by chain transfer to monomer. Transfer maintains R_p at a constant value and creates a distribution of low average molecular weight, while the termination of a kinetic chain by neutralization, although a relatively rare event, determines the dose rate dependency of the reaction. Under such conditions, the population of radical species is probably diminished to some extent, but, in any event, these free radicals propagate so slowly, that they make no appreciable contribution to the overall polymerization. For certain monomers, such as styrene, one may encounter the simultaneous propagation of carbonium ions [eq. (4)], carbanions [eq. (7)], and free radicals [eq. (8)]. The relative concentration of each chain-sustaining species is determined by the purity of the system.

One definite area of interest is the re-investigation of those monomers which previously exhibited a free radical mechanism, or even a total absence of polymerization, under irradiation. The polymerization of methyl methacrylate[44, 64] and acrylonitrile[65] have not yet responded to ultra-purification. Possibly, more stringent drying techniques are required for the complete removal of water from such highly polar monomers. Copolymerization results for styrene-methyl methacrylate tend to confirm this idea[64].

The primary source of impurities in a monomer system is the water adsorbed on the surfaces of the preparative and reaction apparatus[41, 46]. Since the thorough vacuum baking of apparatus has produced so many new developments in radiation polymerization, one might well ponder the impact of ultra-purity on other areas of chemistry. Studies on conventionally initiated ultra-pure styrene have, however, failed to produce any revolutionary findings (see Fig. 4).

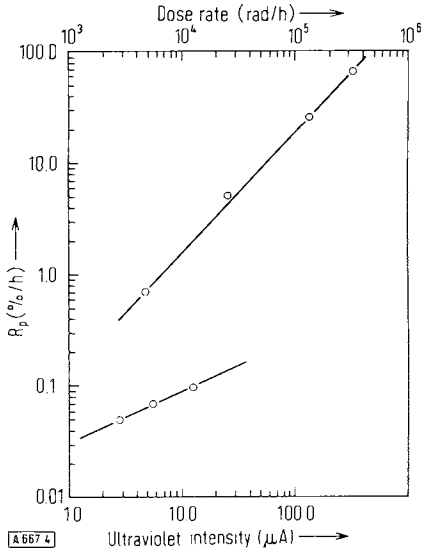

Fig. 4. Polymerization of styrene at 0 °C. Both curves represent the same dilatometer. The upper curve corresponds to γ-initiation, slope 1.1. The lower curve is the result of UV-initiation (using a solar cell to determine relative UV intensities) [40], slope 0.45.

A dilatometer assembly which exhibited the characteristics of the ionic reaction unter γ irradiation exhibited the characteristics of a free radical polymerization[40] when exposed to UV light. The same system also polymerized by a free radical mechanism when initiated thermally.

5. Pulse Radiolysis

Over the last few years, techniques have been perfected for the detection of transient species formed after a high current, microsecond burst of electrons. This analog of flash photolysis, aptly dubbed pulse radiolysis, has proved to be an immensely powerful method for studying the excited molecules, ionic species, and free radicals that are produced in irradiated aqueous solutions and organic systems[69]. Indeed the existence of the hydrated electron was revealed by this method[52, 53].

In all our previous remarks, the arguments for the existence of ions in radiation polymerization have

[*] $G_{(-m)}$ is the number of monomer units consumed per 100 eV of absorbed energy.

[69] *L. M. Dorfman* and *M. L. Matheson* in *G. Porter*: Progress in Reaction Kinetics. Vol. III, Pergamon Press, London 1965, p. 238.

been predicated upon indirect inferences from kinetics. However, pulse radiolysis has recently provided direct evidence for the existence of ions. The technique was first applied by *Burrell*[70] in 1964 to investigate the original example of ionic radiation polymerization: isobutene at low temperature. Using ultraviolet absorption spectroscopy, he observed a species absorbing at 297 nm which disappeared by a first order process. This species was identified as a carbonium ion, possibly the trimethylcarbonium ion.

Styrene and α-methylstyrene have also been examined. Three research groups, each of them using optical methods for the detection of transients, have made independent studies. *Katayama* briefly reported on the pulse radiolysis of anhydrous α-methylstyrene[71]. A transient was observed having absorption maxima at 366 and 546 nm, which was ascribed to the α-methylstyrene radical anion. The absorption disappeared by a first order process with a half-life of ~25 μsec.

Metz applied the pulse technique to ultra-pure styrene[72]. The absorption spectrum obtained after a 1 μsec pulse of 15 MeV electrons showed the existence of at least three species. While two of the absorptions had long lifetimes and were suggested to be due to a radical species and a relatively stable permanent product, the third species, which exhibited an absorption maximum at 370 nm, decayed according to first order kinetics with a half-life of about 4 μsec. This species is very sensitive to traces of water. Also, the addition of oxygen reduced the initial height of the absorption maximum. (Oxygen had already been shown to be an inhibitor for the γ-initiated polymerization of ultra-pure styrene[42, 44].) The authors tentatively identified this short-lived species with the styrene radical anion formed through electron capture by styrene monomer [eq. (7)]. Thus, a comparison of the effect of water and oxygen on R_p with their effect on the 370-nm absorption reinforces the previous suggestion that anions are partially responsible for the polymerization kinetics of ultra-pure styrene. Similar conclusions, based on similar observations, have been made for α-methylstyrene[43, 60].

A disturbing point raised by previous remarks concerns the failure to observe a cationic styryl species with pulse radiolysis? The simple constraint of overall charge neutrality assures the presence of a positively charged species. Moreover, there are reasons to believe that the carbonium ion-radical may absorb in the 600-nm region, which has not yet been investigated because of technical obstacles[72]. There is also the distinct possibility that the carbonium ion absorption overlaps that of the anion radical.

The most serious criticism which can be raised in this area is that intermittent high dose rate studies may not, perhaps, be validly compared with continuous irradiation, low dose rate studies. Unfortunately, there is as yet no answer to this question, although there is an encouraging shred of evidence that the same kinetic processes are operative under both modes of irradiation. R_p was determined for a dilatometer with ultra-pure styrene which had been polymerized by repetitive pulsing. By the admittedly hazardous expedient of extrapolating the limiting data of Fig. 2 across several orders of magnitude, the value of R_p from intermittent irradiation was within a factor of three of the continuous irradiation value[76].

Schneider has applied pulse radiolysis to monomers purified under normal conditions, without taking special precautions to remove traces of water[73–75]. Investigation of the polymerization rate and of the molecular weight of the polymer formed in experiments with repetitive pulsing showed that, under these conditions, the polymerization is caused by radicals. Unstable species were observed on irradiation of styrene and α-methylstyrene in bulk and in solutions of these monomers in benzene, cyclohexane, hexane, carbon tetrachloride, aliphatic alcohols, and water. While the absorption of the propagating styryl radical can be observed in each of these solutions, an additional, very short lived absorption with a maximum at about 390 nm appears in the bulk monomers and in solutions in hexane and cyclohexane (Fig. 5). The species responsible for this

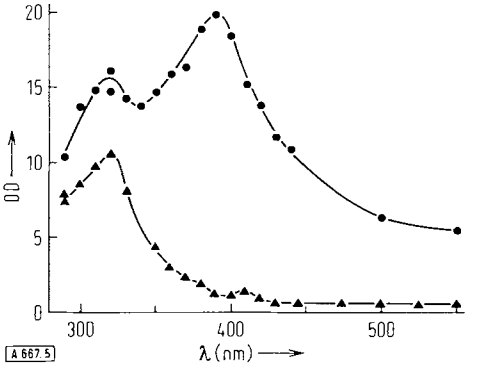

Fig. 5. Absorption spectra of a de-aerated solution of styrene (10^{-3} M) in cyclohexane. Upper curve: immediately after a 2 μsec pulse of 4 MeV electrons. Lower curve: 50 μsec later. Dose rate: 5000 rad/pulse. The free-radical species (left-hand peak) is relatively stable compared to the short-lived ionic species (right-hand peak) [75].

absorption was shown to be very sensitive to electron scavengers such as N_2O and halogen compounds. Water also had a strong effect on the 390 nm absorption. Contrary to the results obtained by *Metz*, the decay of this species was found to obey second-order kinetics, with a termination constant of about 10^{11} l mole^{-1} sec^{-1} and a first half-life of 3 μsec. Because of the effect of additives and the high decay

constant, it was concluded, in agreement with *Katayama* and *Metz*, that the 390 nm absorption is due to the styrene and α-methylstyrene radical anion. There also seems to be some evidence that the cation indeed absorbs in the same region of wavelength as the anion. A 30 % decrease in the absorption intensity at 390 nm was observed after a small amount of *n*-butylamine had been introduced into a dilute solution of styrene in cyclohexane [77]. In solutions of the monomers in aliphatic alcohols and in water, the solvated electron again reacts with the monomer to form the styrene anion, but due to rapid protonation no absorption at 390 nm can be observed. Certainly these findings are in accord with the previous remark that ions are probably always produced in substantial number under irradiation, regardless of the purity of the monomers, but that the successful propagation of these ions requires extreme purity.

Although there is still uncertainty and even contradiction in some of the pulse radiolysis results obtained so far, the results nevertheless indicate that the technique can provide direct information about the role of ions in polymerization processes. Now that the "second generation" of pulse radiolysis apparatus has arrived, in the guise of nanosecond machines, we may confidently look forward to further contributions toward the elucidation of radiation-induced ionic polymerization.

6. Solid-State Polymerization

Fidelity to theme requires a concluding section on ionic polymerization in the solid state. It is with considerable hesitation that such a section is included, since there has been so much confusion and controversy as to the mechanisms involved. Indeed, radiation polymerization constitutes one of the few areas of science in which the liquid phase is better understood than the solid phase.

One of the earliest expectations was that solid state polymerization for monomers at low temperature would be initiated by ionic species. Unfortunately, this *a priori* attitude did much to becloud the early literature. Contrary to fluid-phase kinetics, it has turned out to be extremely difficult to find clear-cut criteria for identifying the mechanism of the solid-state reaction.

The usual kinetic criteria are simply not unrestrictedly applicable to the solid state, and for several reasons: diffusion processes have a strong influence on the reaction, inhibitors will either act exclusively on the crystal surface or else produce defects in the crystal lattice, and copolymerization parameters are certainly more strongly affected by crystal structure than by monomer reactivity. Also, it is not possible to draw an analogy between radiation and catalytically initiated solid-state polymerization because the effect of the catalyst is confined to the crystal surface, whereas irradiation produces a uniform distribution of active species throughout the entire sample. In considering the mechanism of radiation-induced solid-state polymerization, then, one must use great caution in making statements about the role of ions or radicals. It has been known for some time that crystal structure plays a decisive part in these reactions. Until this influence of morphology is more clearly defined it is clear that any postulated mechanisms are highly speculative.

In the solid state classification scheme of *Chapiro* [78], the Group II monomers are those which are radiation polymerizable only in the solid state. Numbered among these monomers are 1,3,5-trioxane [*], the corresponding eight-membered ring, diketene, β-propiolactone, and 3,3-bis(chloromethyl)oxetane [*], which can be conventionally polymerized only by cationic catalysts. For the radiation initiated polymerization of these monomers, the temperature coefficient is small and the resulting polymer is highly crystalline. Thus, a cationic mechanism has been proposed [79]. This view is further supported by the findings of *Naruse* for trioxane, wherein the rate of reaction is increased by electron acceptors [83]. According to a recent theory, however, the trioxane reaction proceeds by a "radical-initiated ionic mechanism" [54].

The occurrence of post-polymerization introduces additional difficulties in the interpretation of these systems. This phenomenon has been thoroughly investigated for trioxane [80]. If oxygen is present during the in-source irradiation, then peroxides are formed which can initiate post-polymerization. However, post-polymerization occurs even in the absence of oxygen, and this may be due to the presence of trapped ions or radicals. However, little work has been performed *in vacuo* and this second possibility has been largely ignored.

Other investigations have shown that the presence of oxygen has no effect on the in-source polymerization, but that it greatly accelerates the rate of post-polymerization (a consequence of the above-mentioned peroxy radicals [79]). The in-source temperature coefficient has been found to be only 5 kcal/mole, whereas the post-polymerization temperature coefficient is more than 40 kcal/mole (near the value for the decomposition of peroxides). In addition, the reaction can be inhibited by the addition of a radical scavenger such as hydroquinone [82].

Trioxane that has been irradiated at low temperatures exhibits thermoluminescence with rising temperature, which is due to the release of trapped electrons. Also on the basis of ESR studies it has been suggested that the initiating species arises from a radical ion formed by irradiation, and that the polymerization probably proceeds by a cationic mechanism [100, 101].

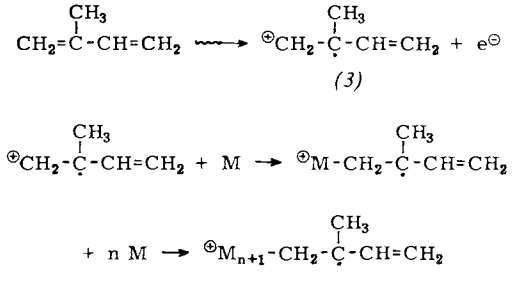
[83] *T. Naruse* and *M. Haga*, J. chem. Soc. Japan, ind. Chem. Sect. (Kōgyō Kagaku Zasshi) *69*, 527 (1966).

Clearly no consensus has been reached in this area. Thus, the identity of the long-lived species (*ca.* 10^4 to 10^5 sec [81]) participating in post-polymerization remains a mystery, waiting to be solved.

A cationic mechanism has also been proposed for the solid-state polymerization of 1,2-epoxycyclohexane [84]. The presence of water has been shown to drastically reduce the yield. Likewise, cations seem to be the initiators for 1,2,3,4-diepoxybutane [85]. Supporting evidence comes from a low temperature coefficient (0.4 kcal/mole) and a linear dependence of reaction rate on the dose rate.

Dienes have also been assumed to polymerize by an ionic mechanism, although free radicals have been detected *e.g.* by *Hirschberger* for isoprene [86]. Additional investigations have been made to clarify this anomaly, utilizing the low-temperature solid-state polymerization of isoprene, 1,3-pentadiene, and 2,3-dimethyl-1,3-butadiene [98]. The ESR-detected radicals (from electron irradiation) seemed to be of the propagating type attributable to addition of an alkyl radical to the terminal carbon atom of diene monomers. In order to confirm this assignment, several different types of radicals were generated by using ultraviolet irradiation: hydroxyl radicals were produced by the addition of *tert*-butyl hydroperoxide, methyl radicals were produced from methyl iodide, and radicals of undetermined structure were produced in the pure monomers. However, none of these radicals was capable of adding to an unsaturated bond. For instance, isoprene suffered abstraction of a hydrogen atom from its methyl group. Consequently, it seems unlikely that the free radicals from electron irradiation participate in the polymerization. Probably, the reaction proceeds *via* a radical ion *(3)* that reacts further with the monomer. (The sites chosen for the positive charge and for the unpaired electron are arbitrary.)



(3)

The chain would grow only from the ionic terminus, whereas the radical terminus is resonance-stabilized and inactive at low temperature. Similar mechanisms have been ascribed to the other dienes.

A few monomers are believed to polymerize by anionic mechanisms. Included among these are acrylonitrile [87–90] and methacrylonitrile [91], neither of which are polymerizable by cationic initiators. The temperature coefficient for acrylonitrile is −3 kcal/mole; that for methacrylonitrile, 0.3 kcal/mole. *Hardy* has proposed an anionic mechanism for cetyl methacrylate, although radical scavengers hinder the reaction [92]. In this connection it must be pointed out that methyl methacrylate undergoes almost negligible polymerization in the solid state. Nevertheless, mixtures of methyl methacrylate and paraffin oil yield large amounts of polymer by a reaction which is believed to be free radical in nature [99]. Since cetyl methacrylate, which, because of its long side-chain, may be considered analogous to a mixture of methyl methacrylate and paraffin oil, one should approach an anionic assignment with circumspection.

There have been several theories over the last few years proposing mechanisms which involve neither ionic nor radical species and which, in fairness, must be presented here. *Tabata* claims that the polymerizations of acrylonitrile, methacrylonitrile, isoprene, butadiene, and acetylene proceed according to an "electronic" mechanism [93]. Whereas the polymerization of acetylene in the liquid state leads to a *cis* structure by a cationic mechanism, the irradiation of solid acetylene results in a *trans* polymer [94]. This effect cannot be satisfactorily explained in terms of any of the usual theories. According to the "electronic" mechanism, the excitation of a single monomer entity collectively excites its neighboring molecules in the crystalline state. The corresponding polymer then forms spontaneously. The mechanism finds support in the fact that so many solid-state polymerizations have such extraordinarily small temperature coefficients. The mechanism is also in accord with the observation that, at low temperature, polymerization rates are controlled by crystal structure and that, in many instances, stereoregular polymers have been obtained.

A similar mechanism had been proposed earlier by *Semenov* [95] and was further elaborated upon by *Barkalov* [96]. According to the "hot" mechanism of *Semenov*, a highly excited monomer molecule attacks an adjacent molecule and the reaction then proceeds by stepwise excitation from molecule to molecule. This theory was applied by *Barkalov* to explain the polymerization of acrylonitrile, formaldehyde, isobutene, and phenylacetylene. In his view, along the tracks of primary and secondary electrons one would encounter molecular recoil from electron impact, de-freezing of rotation, and excitation of vibration. All these processes create excited species, which are much more reactive than radicals or ions [97]. The polymerization could begin in the "hot" zone of a spur and proceed either along the electron track or along a crystal axis. The excited

molecules would at first form metastable polymer molecules. These intermediate species may then either undergo "depolymerization" or be transformed into stable polymer. Perhaps this type of mechanism may be extended to explain the phenomenon of post-polymerization. It has been noted that the application of pressure before the post-polymerization of trioxane completely inhibits the reaction [102]. This effect may be due to the destruction of trapped, unstable intermediates, such as excited molecules.

This type of theory is gaining wide support and helps to cast even more doubt on previous discussions of ionic mechanisms in the solid state. Indeed, if these excitation theories are substantially correct, one can no longer consider ions as playing any significant part in solid-state polymerization.

We are grateful to the Bundesministerium für wissenschaftliche Forschung and the Deutsche Forschungsgemeinschaft for granting fellowships to two of us (M. R. by BMwF and R. C. P. by DFG). R. C. P. would also like to thank the Society of Sigma Xi for the award of RESA Grant-in-Aid of Research. Finally we wish to thank I. Denaxas and D. Widdershoven for their valuable assistance.

New Methods of Preparative Organic Chemistry [**]

Preparation, Properties, and Reactions of Polychloroamine Derivatives

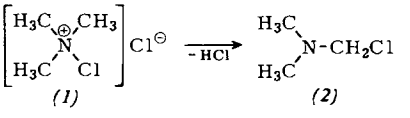
BY H. HOLTSCHMIDT, E. DEGENER, H.-G. SCHMELZER, H. TARNOW, AND W. ZECHER [*]

Highly chlorinated amine derivatives can be prepared by the high-temperature chlorination of amines and amine derivatives. Essential for the success of this reaction is an adequate temperature control suited to the constitution of the amines. In many cases the chlorination products achieve stability by cleavage reactions with formation of the imidic acid chloride or isocyanide dichloride grouping. Cyclic compounds are formed under special conditions. The chlorination process described can be used to obtain e.g. polychloroaryl and polychloroalkyl isocyanide dichlorides, polychloroaryl and polychloroalkyl imidic acid chlorides, and polychloroheterocyclic compounds.

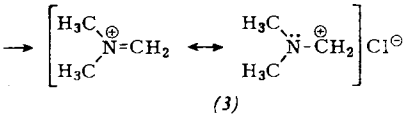
1. Introduction

1.1. Chlorination of Amines at Low Temperatures

The early chlorinations of amines and amine derivatives were all characterized by low reaction temperatures. The products were mostly very unstable, and sometimes decomposed very violently when heated. Primary and secondary amines yield the unstable and explosive *N*-chloro compounds [1]. Tertiary aliphatic amines give thermally unstable salt-like adducts. The product *(1)* obtained from trimethylamine and chlorine, for example, decomposes very vigorously and often explosively when heated above 35 °C [2]. The salt-like adducts of the type *(1)* give, with formal elimination of hydrogen chloride and migration of a chlorine cation, α-halogenated amines *(2)*, which are not stable as free bases, but quaternize with themselves.



(1) *(2)*



(3)

The α-halogenated amines may be regarded as resonance-stabilized immonium-carbonium salts *(3)*.

[**] Earlier contributions to this series are collected in five volumes, available in English and German, published by Verlag Chemie, Weinheim/Bergstr.

[1] *R. Stroh* in *Houben-Weyl-Müller*: Methoden der organischen Chemie. 4th Edit., Thieme-Verlag, Stuttgart 1962, Vol. V/3, p. 796.

[2] *H. Böhme* and *W. Krause*, Chem. Ber. *84*, 170 (1951).

They are among the most reactive of all electrophiles, and smoothly alkylate *e.g.* aromatic compounds [3].

An elegant route to the aliphatic α-halogenoamines *(2)* in solution, *i.e.* the chlorination of methylenediamines *(4)*, was discovered by *Böhme* [4].

$$\underset{(4)}{(CH_3)_2N{-}CH_2{-}N(CH_3)_2} \xrightarrow{Cl_2} \underset{(2)}{(CH_3)_2N{-}CH_2Cl} + Cl{-}N(CH_3)_2$$

Ammundsen and *Pitts* [5] obtained a mixture of β- and γ-monochloroalkylamines on chlorination of dimethylpropylammonium chloride at −75 °C with UV irradiation. No further chlorination was observed under these conditions.

1.2. High-Temperature Chlorination of Amines

The high-temperature chlorination of aliphatic amines was for a long time ignored by investigators, since such reactions were regarded as dangerous and without utility, as amine salts were reputed to be very resistant to further chlorination [6].

Consequently the observation [7] that amines and amine derivatives can be smoothly chlorinated in the alkyl and aryl residues at high temperatures, such as are normally used in the chlorination of hydrocarbons, came as quite a surprise. The success of the high-temperature chlorination was due to the development of specific techniques that avoided the formation of explosive halogen adducts and resin-forming intermediates. Careful temperature control is essential, particularly in the first phase of the reaction, owing to the high reactivity of the primary products. The basicity of the amine nitrogen and the reactivity of the chlorine atoms in the products decrease with increasing extent of chlorination. The products therefore gain thermal stability and get more resistant to resinification, so that the temperature can be continuously raised to complete the reaction, and can ultimately be elevated very rapidly to the level of 190–250 °C that is often necessary.

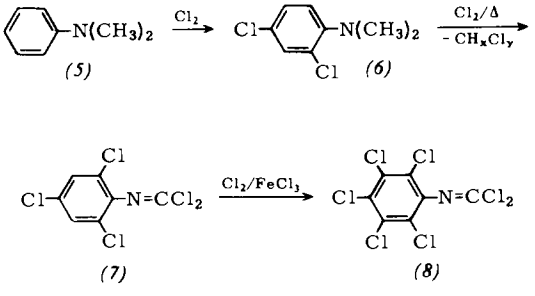
1.3. High-Temperature Chlorination with Dealkylation and Deacylation

During the chlorination of tertiary amines containing at least two suitable aliphatic groups and of disubstituted amides containing at least one alkyl group, a characteristic degradation takes place at high temperatures. Compounds of both classes achieve stability by formation of isocyanide dichlorides [*] or imidic acid chlorides, an alkyl residue being split off as the polychloroalkane in the case of the tertiary amines (high-temperature chlorination with dealkylation) and an acyl residue as the acyl chloride in the case of the amides (high temperature chlorination with deacylation).

2. High-Temperature Chlorination of Tertiary Amines

2.1. *N,N*-Dimethylaniline

The possibility of obtaining polychloroamine derivatives by chlorination of tertiary amines was first realized in 1962 [7]. A typical example is the chlorination of *N,N*-dimethylaniline *(5)*. The procedure found to be best is one in which the temperature is raised by approximately 10 °C per hour. At the same time an adequate supply of chlorine must be provided at all times. The chlorination of *(5)* begins with substitution of the benzene ring in the *o* and *p* positions [*(6)*] [8]. As the temperature is raised, the methyl groups are also chlorinated. The dealkylation with elimination of polychloromethane then begins above 180 °C, and 2,4,6-trichlorophenyl isocyanide dichloride *(7)* is formed at 200–230 °C in 90 % yield. On addition of a catalytic quantity of iron(III) chloride to *(7)*, the remaining hydrogen atoms can also be replaced by chlorine to give pentachlorophenyl isocyanide dichloride *(8)*.



Many derivatives of dimethylaniline and dimethylaminonaphthalene can be converted into highly chlorinated isocyanide dichlorides by the same method [9].

2.2. Intermediates in the High-Temperature Chlorination of *N,N*-Dimethylaniline

N-Dichloromethyl-*N*-trichloromethyl-2,4,6-trichloroaniline *(9)* has been isolated in substance as an intermediate in the high-temperature chlorination of *N,N*-dimethylaniline *(5)* [10]. Rather surprisingly, *(9)* is stable for long periods even at 240–250 °C.

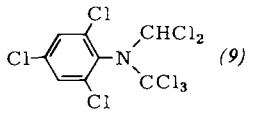
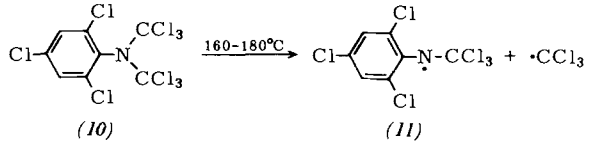
[10] *K. Grohe,* unpublished.



(9)

If the temperature is not allowed to exceed 140 °C, *N,N*-bis-(trichloromethyl)-2,4,6-trichloroaniline *(10)* can be obtained in good yields as the end product of the chlorination of *(5)* [11]. *(10)* decomposes at 160–180 °C into *(7)* and carbon tetrachloride. According to ESR-spectroscopic results, this decomposition proceeds *via* the nitrogen radical *(11)* and a trichloromethyl radical.

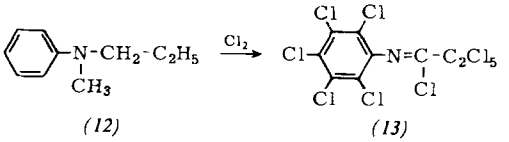


(10) *(11)*

(7)

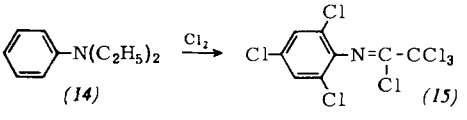
2.3. *N,N*-Dialkylarylamines

If the nitrogen carries higher alkyl residues, the chlorination leads to highly chlorinated imidoyl chlorides. In the case of the *N*-methyl-*N*-alkylanilines, the methyl group is predominantly eliminated as polychloromethane. *N*-Pentachlorophenylpentachloropropionimidoyl chloride *(13)* is formed in 62 % yield from *N*-methyl-*N*-propylaniline *(12)*.



(12) *(13)*

High alkyl groups can also be split off as polychloroalkanes during the high-temperature chlorination. For example, the chlorination of diethylaniline *(14)* results in the elimination of hexachloroethane and formation of 2,4,6-trichlorophenyltrichloroacetimidoyl chloride *(15)*.



(14) *(15)*

Cyclization of the alkyl groups occurs as a side reaction (cf. Section 10.3.3.).

Aromatic substituents on aromatic rings are also chlorinated in the high-temperature chlorination, while nitro groups and bromine atoms are largely replaced by chlorine.

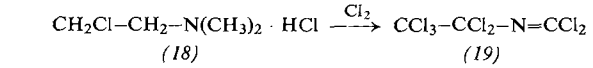
2.4. Trialkylamines

In the aliphatic series, the high-temperature chlorination of tertiary amines also leads to polychlorinated imidoyl chlorides, that of *N*-alkyldimethylamines yielding polychlorinated isocyanide dichlorides. In this case, however, the chlorination often proceeds less uniformly than in the aromatic series, since none of the N–C bonds is preferentially cleaved, and the side reactions of partly chlorinated intermediates are enhanced. This is understandable, since the ease of transition to the mesomeric immonium structure increases with the basicity of the nitrogen atom.

The aliphatic tertiary amines can also be chlorinated as hydrochlorides and ammonium chlorides, preferably suspended in trichlorobenzene, to give the imidoyl chlorides or isocyanide dichlorides. Owing to the heterogeneous nature of the reaction, the reaction times are very long and the yields are not particularly good.

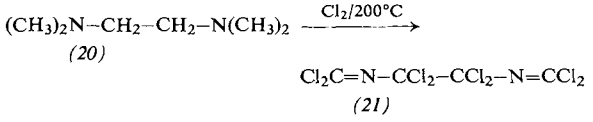
Trimethylammonium chloride *(16)* gives moderate yields of trichloromethyl isocyanide dichloride *(17)*. *N*-(2-Chloroethyl)dimethylammonium chloride *(18)* is chlorinated to pentachloroethyl isocyanide dichloride *(19)*.

(16) *(17)*



(18) *(19)*

The most successful chlorination observed so far is that of tetramethylethylenediamine *(20)* which leads to tetrachloroethylene-1,2-bis(isocyanide dichloride) *(21)* (yield 30–71 %).



(20) *(21)*

3. High-Temperature Chlorination of Acyl Derivatives of Secondary Amines

The high-temperature chlorination of acyl derivatives of secondary amines is another generally applicable method for the preparation of polychloroamine derivatives. This reaction is also accompanied by a characteristic cleavage. The most suitable acyl derivatives are *N*-chlorocarbonyl compounds and amides of carboxylic acids, though amides of phosphoric and sulfuric acids may also be used.

The aliphatic and aromatic residues are chlorinated first. At higher temperatures the *N*-acyl bond is broken and the acyl residue eliminated as acyl chloride, with formation of an imidoyl chloride grouping [12]. Dialkylamides containing at least one methyl group give isocyanide dichlorides, while higher *N*-alkylamides give polychlorinated imidoyl chlorides.

The chlorination of acyl derivatives of secondary amines has certain advantages over the chlorination of tertiary amines. The reaction solution is homogeneous, since no sparingly soluble hydrochlorides precipitate out. The amide nitrogen is much less basic than the nitrogen of the tertiary amines, so that optimum reaction conditions can be reached more readily, and resinification reactions become less important.

[11] *K. Grohe, E. Klauke,* and *H. Holtschmidt,* German Pat. Appl. F 48901 Vb/qu (April 7, 1966), Farbenfabriken Bayer AG.

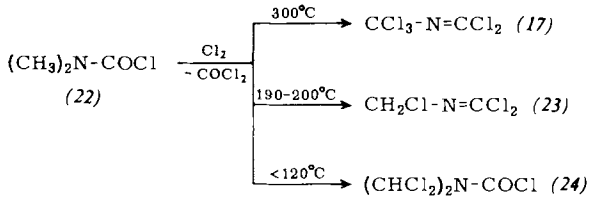
[12] *H. Holtschmidt* and *W. Zecher,* Belg. Pat. 622381 (Sept. 12, 1962), Farbenfabriken Bayer AG; Chem. Abstr. *59,* 11526c (1963).

Moreover, the reaction products are more uniform, since cleavage is almost totally confined to the *N*-acyl bond. The deacylation can be catalyzed by Lewis acids.

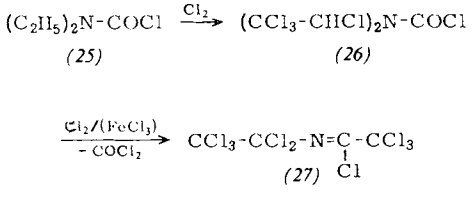
3.1. Chlorocarbonyl Derivatives of Secondary Amines

The use of chlorocarbonyl compounds is particularly advantageous, since the acyl chloride split off in this case is a gas and no chlorine is lost by chlorination of the acyl residue. Low-boiling chlorocarbonyl compounds can be readily chlorinated in the gas phase (preferably on catalysts such as activated charcoal) to give polychloroalkyl isocyanide dichlorides and polychloroalkyl imidoyl chlorides.

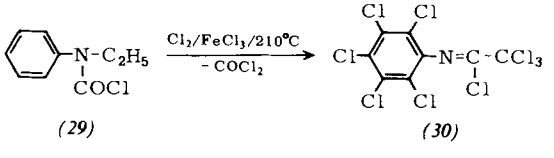
Whereas the gas-phase chlorination of dimethylcarbamoyl chloride *(22)* [13] gives trichloromethyl isocyanide dichloride *(17)* in 87 % yield, monochloromethyl isocyanide dichloride *(23)* can be obtained in 62 % yield by chlorination at 190 to 200 °C with simultaneous distillation [14]. If the reaction is carried out below 120 °C, no deacylation takes place, and bis(dichloromethyl)carbamoyl chloride *(24)* is formed in good yields.



Diethylcarbamoyl chloride *(25)* is first chlorinated to bis(tetrachloroethyl)carbamoyl chloride *(26)* which, at high temperatures, slowly loses phosgene in a current of chlorine to form *N*-pentachloroethyltrichloroacetimidoyl chloride *(27)*. To obtain *(27)* in preparative quantities, the deacylation is best catalyzed with iron(III) chloride.



The high-temperature chlorination proceeds particularly smoothly in the case of the *N*-alkyl-*N*-arylcarbamoyl chlorides, *e.g. (29)*, which gives *N*-pentachlorophenyltrichloroacetimidoyl chloride *(30)* [15].



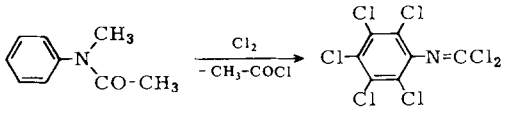
[13] *W. Zecher* and *H. Holtschmidt*, German Pat. 1222917 (Aug. 14, 1963) = Netherlands Pat. Appl. 6409122 (Feb. 15, 1965), Farbenfabriken Bayer AG; Chem. Abstr. *63*, 8327d (1965).

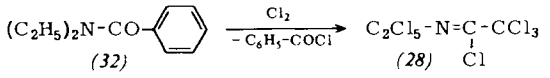
[14] *H. Holtschmidt*, German Pat. 1141278 (May 10, 1961), Farbenfabriken Bayer AG; Chem. Zbl. *1964*, 1–2415.

[15] *H. Tarnow*, *H. Holtschmidt*, and *G. Unterstenhöfer*, German Pat. 1197078 (Nov. 27, 1963), Farbenfabriken Bayer AG; Chem. Abstr. *63*, 14774c (1965).

3.2. *N,N*-Disubstituted Carbonamides

N,N-Disubstituted carbonamides behave in the same way as the chlorocarbonyl compounds on high-temperature chlorination. The acyl residues are split off in the chlorinated form. For example, *N*-methylacetanilide *(31)* gives pentachlorophenyl isocyanide dichloride *(8)*, and *N,N*-diethylbenzamide *(32)* gives *N*-pentachloroethyltrichloroacetimidoyl chloride *(28)* [16]. The chlorination of cyclic amides is discussed in Section 10.2.

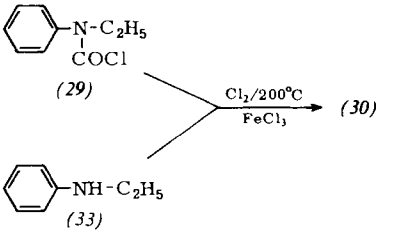




4. High-Temperature Chlorination of Secondary Amines

Instead of the acyl derivatives of secondary amines it is possible to chlorinate the secondary amines themselves [17]. It is surprisingly found that no *N*-chloro compounds accumulate under the conditions of the high-temperature chlorination. Since the secondary amines, as strong bases, form hydrochlorides exothermally at the beginning of the reaction, and in some cases even react with the less chlorinated alkyl residues, it is recommended that the hydrochlorides should be used from the outset to avoid side reactions. The end products are again polychloroamine derivatives containing the stable imidoyl chloride grouping. This grouping is formed even at 80 °C, *i.e.* under much milder conditions than are required for the dealkylation and deacylation. One disadvantage of this process, however, is that the reaction mixtures are inhomogeneous at the beginning of the chlorination because of the low solubility of the amine hydrochlorides.

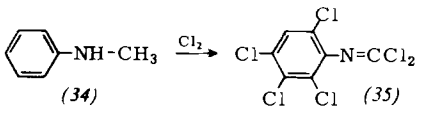
The compounds formed are generally the same as in the chlorination of the corresponding *N,N*-disubstituted carbonamides. Thus *N*-ethylaniline *(33)* like its chlorocarbonyl derivative *(29)*, reacts at 200 °C in the presence of iron(III) chloride to give *N*-pentachlorophenyltrichloroacetimidoyl chloride *(30)* in 85 % yield.



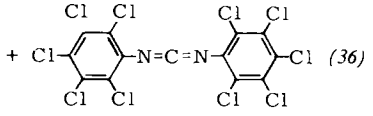
[16] *G. Dankert*, unpublished.

[17] *W. Zecher*, *H. Tarnow*, and *H. Holtschmidt*, German Pat. 1222918 (Dec. 21, 1964), Farbenfabriken Bayer AG.

A special case is the high-temperature chlorination of *N*-methylaniline *(34)*, in which considerable quantities of bis-(pentachlorophenyl)carbodiimide *(36)* and polymeric highly chlorinated diphenylcarbodiimides are obtained as well as 2,3,4,6-tetrachlorophenyl isocyanide dichloride *(35)*.

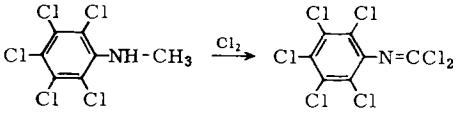


(34) *(35)*



(36)

The high-temperature chlorination of the less basic *N*-methylpentachloroaniline *(37)*, on the other hand, leads almost exclusively to the isocyanide dichloride *(8)* in very good yield [18].



(37) *(8)*

5. High-Temperature Chlorination of Derivatives of Primary Amines

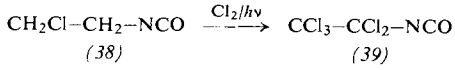
The chlorination of aryl and alkyl isocyanates, *N*-alkylcarbonamides, isocyanide dichlorides, and imidoyl chlorides, as well as of Schiff bases of aromatic and aliphatic amines, have been investigated. The alkyl and aryl residues can be readily polychlorinated in every case. The imidoyl chloride grouping is often formed either by rearrangement, dehydrochlorination, or chlorination of the azomethine group.

5.1. Alkyl Isocyanates and *N*-Alkylcarbamoyl Chlorides

The chlorination of alkyl isocyanates results in substitution in the alkyl chain. The alkyl residues of longer-chain alkyl isocyanates are largely randomly chlorinated, but the first chlorine atom is preferentially attached in an exothermic reaction to the α position with respect to the isocyanate group [19].

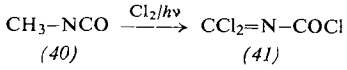
The complete chlorination of longer alkyl chains requires relatively high temperatures and long reaction times. Good yields are generally obtained only when the reaction is carried out in an inert solvent, since intramolecular condensation otherwise often leads to resinification.

The perchlorination of ethyl isocyanate or 2-chloroethyl isocyanate *(38)* leads to a product whose IR spectrum indicates that it consists mainly of pentachloroethyl isocyanate *(39)*.

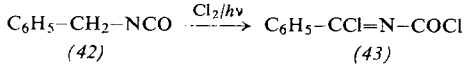


(38) *(39)*

Methyl isocyanate *(40)* and benzyl isocyanate *(42)*, on the other hand, give, not the expected chlorinated isocyanates, but the isomeric chloroalkylidenecarbamoyl chlorides *(41)* and *(43)* [7].



(40) *(41)*



(42) *(43)*

Instead of the alkyl isocyanates, the corresponding alkylcarbamoyl chlorides may also be chlorinated. The chlorinations of alkyl isocyanates and of alkylcarbamoyl chlorides are practically indistinguishable, since the hydrogen chloride formed adds to the isocyanate group to form the carbamoyl chloride. To avoid this exothermic reaction, it is often advantageous to convert the isocyanates into the carbamoyl chlorides before the chlorination. The fact that the carbamoyl chlorides boil at higher temperatures than the isocyanates is frequently also an advantage in the high-temperature chlorination.

5.2. Aryl Isocyanates and *N*-Arylcarbamoyl Chlorides

The chlorination of phenyl isocyanate in the cold, which has been known for a long time, leads to single or multiple ring chlorination, the hydrogen chloride formed adding to the isocyanate group to form the carbamoyl chloride [20].

Difficulties were encountered in the preparation of perchlorinated aryl isocyanates, since the use of high temperatures and metal catalysts is necessary for the substitution of the less active ring hydrogen atoms. Considerable losses result in this case from Friedel-Crafts condensations and carbodiimide formation. Perchlorinated aryl isocyanates such as pentachlorophenyl isocyanate can, however, be obtained in good yield by a two-step process [21]. The aryl ring is first chlorinated at or slightly above room temperature in the absence of metal catalysts to give a mixture of mono-, di-, and trichloro compounds. In the second step the chlorination is continued in the presence of *e.g.* iron(III) chloride at 210–250 °C, the perchlorinated aryl isocyanate ultimately being formed in very good yields.

Aromatic mono- and polyisocyanates with alkyl side chains can be chlorinated in the ring and/or in the side chain [22]. The chlorination of the side chain can be stimulated by light, free radical generators, or by

[18] *G. Beck*, unpublished.

[19] *H. Holtschmidt* and *E. Degener*, DAS 1122058 (Aug. 26, 1960), Farbenfabriken Bayer AG; Chem. Zbl. *1962*, 13945.

[20] *F. Gumpert*, J. prakt. Chem. *32*, 278 (1885).

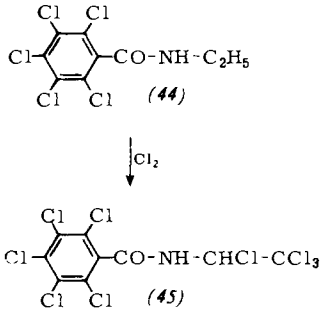
[21] *H. Holtschmidt*, *O. Bayer*, and *E. Degener*, German Pat. 1157601 (May 10, 1962), Farbenfabriken Bayer AG; Chem. Zbl. *1965*, 35–2659.

[22] *H. Holtschmidt*, German Pat. 947470 (April 9, 1953), Farbenfabriken Bayer AG; Chem. Zbl. *1957*, 3664.

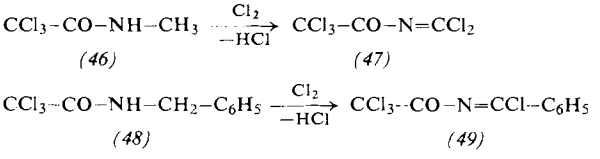
heat. The normal Friedel-Crafts catalysts are used for the ring chlorination. The aliphatic side chains can be chlorinated stepwise in a fairly uniform manner.

5.3. *N*-Alkylcarbonamides

The chlorination of *N*-alkylcarbonamides proceeds first with progressive substitution in the alkyl residue. At 160 °C, for example, *N*-ethylpentachlorobenzamide *(44)* gives *N*-(1,2,2,2-tetrachloroethyl)pentachlorobenzamide *(45)* [10, 18].



As in the chlorination of secondary amines, hydrogen chloride is frequently eliminated and acyl isocyanide dichlorides [such as *(47)*] or acylimidoyl chlorides [such as *(49)*] are formed [10]. Thus the chlorination of *N*-methyltrichloroacetamide *(46)* leads to very good yields of *N*-dichloromethylenetrichloroacetamide *(47)*, and that of *N*-benzyltrichloroacetamide *(48)* to *N*-(α-chlorobenzylidene)trichloroacetamide *(49)*.

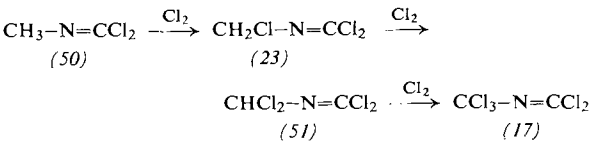


5.4. Isocyanide Dichlorides and Imidoyl Chlorides

The high-temperature chlorination of isocyanide dichlorides and imidoyl chlorides [23,24] proceeds particularly smoothly, since the energetically favored functional groups are already present in these cases. Aromatic isocyanide dichlorides and *N*-arylimidoyl chlorides behave in the same way as aryl isocyanates on chlorination. Partly chlorinated isocyanide dichlorides and imidoyl chlorides are intermediates in some of the high-temperature chlorinations described already.

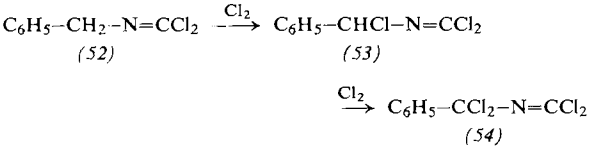
5.4.1. Alkyl Isocyanide Dichlorides

Methyl isocyanide dichloride *(50)* can be chlorinated in steps to give mono-, di-, and trichloromethyl isocyanide dichloride *(23)*, *(51)*, and *(17)*. However, this chlorination is very slow, even in the light. Rapid perchlorination in 80 % yield can be achieved in the gas



phase by passing methyl isocyanide dichloride or methyl isothiocyanate over activated charcoal in a current of chlorine and nitrogen at 350–390 °C.

The activated α-hydrogen atoms in benzyl isocyanide dichloride *(52)* are particularly readily replaced with formation first of α-chlorobenzyl isocyanide dichloride *(53)* and then of α,α-dichlorobenzyl isocyanide dichloride *(54)* in very good yields. With very long chlorination times the phenyl ring is also perchlorinated [18].

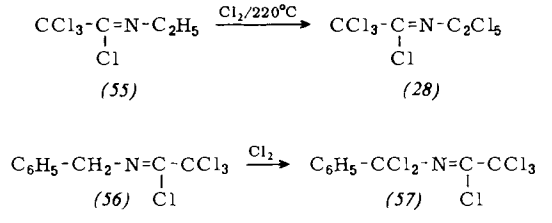


The isothiocyanates [25] and the formimidoyl chlorides [24, 26], which can be obtained from the formamides, can also be chlorinated directly. The primary product in both cases is the isocyanide dichloride, which need not be isolated (for the desulfurization of the isothiocyanates, see Section 9.1.).

5.4.2. *N*-Alkylimidoyl Chlorides

The *N*-alkyltrichloroacetimidoyl chlorides [23, 24], which are readily obtainable from *N*-alkylacetamides with phosphorus pentachloride, are particularly suitable for chlorination.

The chlorination of *N*-ethyltrichloroacetimidoyl chloride *(55)* at temperatures rising to 220 °C gives a 96 % yield of *N*-pentachloroethyltrichloroacetimidoyl chloride *(28)*, the same compound as is obtained on high-temperature chlorination of *(25)* and *(32)* with deacylation. *N*-Benzyltrichloroacetimidoyl chloride *(56)* leads, again in almost quantitative yield, to *N*-(α,α-dichlorobenzyl)trichloroacetimidoyl chloride *(57)*.



The chlorinations can also be applied to bifunctional imidoyl chlorides and to trichloroacrylimidoyl chlorides.

[23] *H. Holtschmidt, E. Degener*, and *H.-G. Schmelzer*, Liebigs Ann. Chem. *701*, 107 (1967).

[24] *E. Degener, H.-G. Schmelzer*, and *H. Holtschmidt*, German Pat. 1193033 (April 25, 1963), Farbenfabriken Bayer AG; Chem. Zbl. *1965*, 50–2453.

[25] *E. Degener, H. Holtschmidt*, and *H.G. Schmelzer*, German Pat. 1163803 (Dec. 14, 1962), Farbenfabriken Bayer AG; Chem. Zbl. *1965*, 5-2424.

[26] *E. Kühle*, Angew. Chem. *74*, 861 (1962); Angew. Chem. internat. Edit. *1*, 647 (1962).

5.4.3. Rearrangement of the N=C Double Bond

The N=C double bond of the imidoyl chlorides can rearrange during the high-temperature chlorination, as was observed in the case of *N*-alkylbenzimidoyl chlorides. The chlorinations of *N*-methyl- and *N*-ethylbenzimidoyl chloride *(58)* and *(59)* lead to the products *(54)* and *(57)*, which are also formed on chlorination of the isocyanide dichloride *(52)* and the imidoyl chloride *(56)*. The constitution of *(54)* is confirmed by independent synthesis from benzoyl isocyanide dichloride *(60)* and phosphorus pentachloride [27] and by the formation of benzoyl isocyanide dichloride *(60)* on partial hydrolysis with formic acid [23].

$$C_6H_5\text{-}\underset{Cl}{C}\text{=}N\text{-}CH_3 \xrightarrow{Cl_2} C_6H_5\text{-}CCl_2\text{-}N\text{=}CCl_2$$
(58) *(54)*

$$C_6H_5\text{-}\underset{Cl}{C}\text{=}N\text{-}C_2H_5 \xrightarrow{Cl_2} C_6H_5\text{-}CCl_2\text{-}N\text{=}\underset{Cl}{C}\text{-}CCl_3$$
(59) *(57)*

$$C_6H_5\text{-}CO\text{-}N\text{=}CCl_2 \underset{HCOOH}{\overset{PCl_5}{\rightleftharpoons}} \textit{(54)}$$
(60)

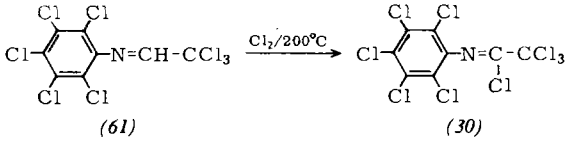
The IR spectrum of *(54)* also contains the characteristic absorptions of an isocyanide dichloride. The corresponding bands are absent from the spectrum of the chlorination product of *N*-methylpentachlorobenzimidoyl chloride, so that it is possible that the benzimidoyl chloride structure is retained in this case [28]. Steric factors appear to play some part in determining the position of the double bond.

5.4.4. Schiff Bases

The chlorination of Schiff bases generally begins with the hydrogen atom of the azomethine group. This yields imidoyl chlorides, so that the further chlorination proceeds as in these compounds.

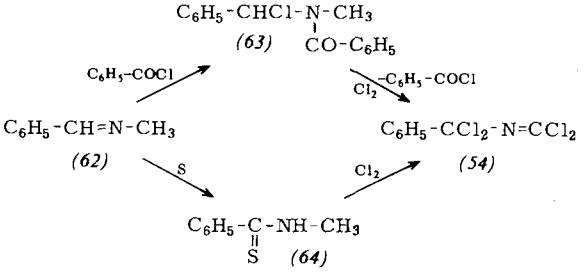
The Schiff bases from chloral and aniline derivatives are particularly suitable starting materials [29–31].

The acaricidally active pentachlorophenyltrichloroacetimidoyl chloride *(30)* can be obtained in practically quantitative yield by chlorination of *N*-(2,2,2-trichloroethylidene)pentachloroaniline *(61)* at 200 °C [32].

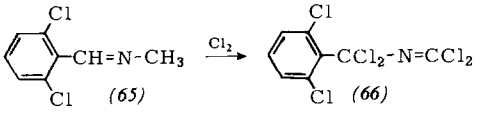


(61) *(30)*

Some Schiff bases, such as *N*-benzylidenemethylamine *(62)* cannot be chlorinated directly, since they polymerize under the chlorination conditions. However, these azomethines can be readily converted into chlorinatable intermediates either by addition of an acyl chloride [33] or by reaction with sulfur to form the thioamides [34]. The adduct *(63)* of *(62)* and benzoyl chloride, for example, can be smoothly chlorinated with deacylation to form α,α-dichlorobenzyl isocyanide dichloride *(54)*. The same product is obtained from *(62)* *via* *N*-methylthiobenzamide *(64)* by chlorolytic removal of the sulfur.



N-(2,6-Dichlorobenzylidene)methylamine *(65)*, on the other hand, does not polymerize so readily owing to steric hindrance, and can be chlorinated directly to form 2,6,α,α-tetrachlorobenzyl isocyanide dichloride *(66)* [35].



6. High-Temperature Chlorination of Alkylamino Nitrogen Heterocycles

The high-temperature chlorination of alkylamino nitrogen heterocycles leads first to substitution in the alkyl residue and sometimes also in the ring. The molecule is then stabilized by cleavage to form the imidoyl chloride or isocyanide dichloride grouping.

6.1. *N,N*-Dialkylamino Nitrogen Heterocycles

N,N-Dialkylamino nitrogen heterocycles behave in basically the same manner as the *N,N*-dialkylarylamines on high-temperature chlorination. If the dialkylamino group is in the α-position with respect to a doubly-bonded nitrogen atom, removal of the chloroheterocycle after the fashion of a deacylation can occur together with the principal dealkylation reaction.

An interesting example of this is the chlorination of 2-dimethylamino-4,6-dichloro-*s*-triazine *(67)* [36], which leads

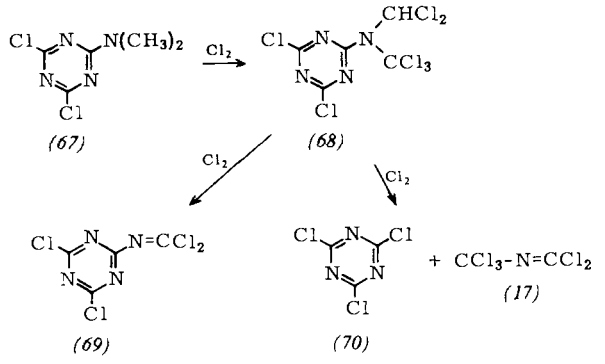
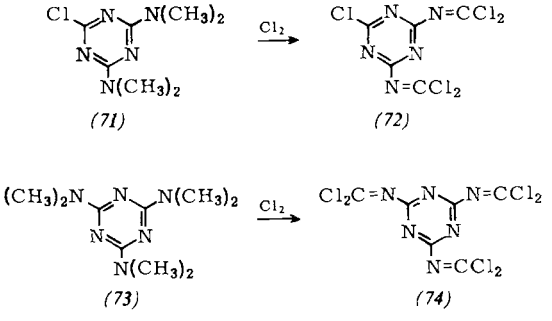
[35] *E. Roos*, unpublished.

[36] *H. Holtschmidt* and *W. Zecher*, German Pat. 1179214 (Sept. 13, 1961) = Belg. Pat. 622382 (Sept. 12, 1962), Farbenfabriken Bayer AG; Chem. Abstr. *59*, 11534f (1963).

via the isolable intermediate *(68)*[10] to a 72% yield of "tetrameric cyanogen chloride" *(69)*. Small quantities of cyanuryl chloride *(70)* and trichloromethyl isocyanide dichloride *(17)* are also formed by deacylation.

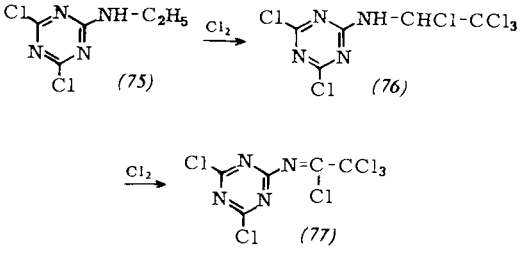


Similarly, though in much poorer yields, the bis(isocyanide dichloride) *(72)* (pentameric cyanogen chloride) is obtained from *(71)* and the tris(isocyanide dichloride) *(74)* (hexameric cyanogen chloride) from *(73)*.

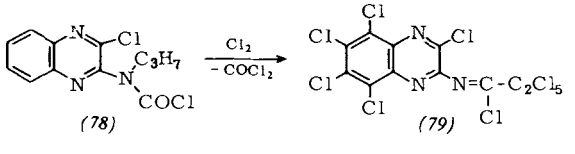


6.2. *N*-Alkylamino Nitrogen Heterocycles and their Acyl Compounds

Monoalkylamino nitrogen heterocycles lose hydrogen chloride in the same way as the secondary amines. The chlorination of 2-ethylamino-4,6-dichloro-*s*-triazine *(75)* leads *via* the isolable tetrachloroethylamine *(76)*[10] to a 90% yield of the imidoyl chloride *(77)*[17].

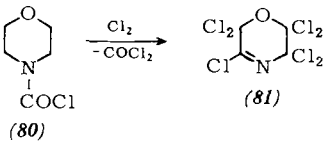


N-Acyl-*N*-alkylamino nitrogen heterocycles are deacylated on high-temperature chlorination; for example, the quinoxaline derivative *(78)* gives the perchlorinated imidoyl chloride *(79)* in 73% yield.



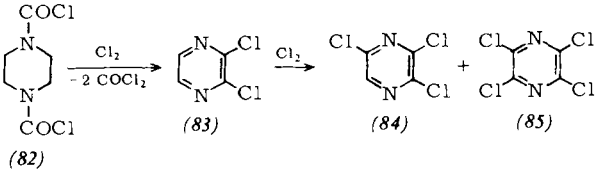
7. High-Temperature Chlorination of Cyclic Aliphatic Amines and their Acyl Compounds

The high-temperature chlorination of cyclic aliphatic amines and their acyl compounds proceeds similarly to the chlorination of open-chain amines, usually with formation of a cyclic imidoyl chloride grouping. Thus the chlorination of *N*-chlorocarbonylmorpholine *(80)* leads in good yield to the cyclic imidoyl chloride *(81)*[12].

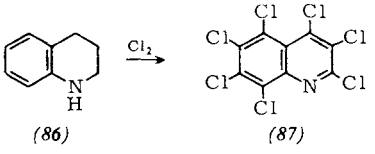


7.1. Aromatization

Five- and six-membered rings can be aromatized during the high-temperature chlorination[7]. Thus *N,N'*-bis(chlorocarbonyl)piperazine *(82)* is first doubly deacylated with formation of 2,3-dichloropyrazine *(83)*[12], which can be further chlorinated to tri- and tetrachloropyrazine *(84)* and *(85)*[37,38].



An example of a secondary cyclic amine is 1,2,3,4-tetrahydroquinoline *(86)* which gives perchloroquinoline *(87)* in moderate yield on high-temperature chlorination[39].



N-Methylpyrrolidine *(88)* first gives the chlorinated pyrroline *(89)*. On prolonged heating, *(89)* loses carbon tetrachloride to form pentachloro-2*H*-pyrrole *(90)*. This product can also be synthesized from dichloromaleimide and phosphorus pentachloride[41].

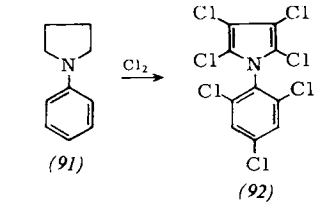
[38] *G. Palamidessi* and *P. Luini,* Farmaco (Pavia), Ediz. sci. *21,* 811 (1966).

[39] *W. Zecher, H. Tarnow,* and *H. Holtschmidt,* German Pat. 1222918 (Dec. 21, 1964), Farbenfabriken Bayer AG.

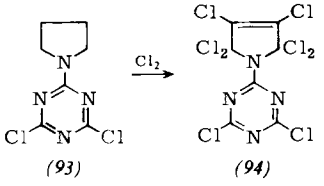
[40] *H. Holtschmidt,* Angew. Chem. *74,* 848 (1962); Angew. Chem. internat. Edit. *1,* 632 (1962).

[41] *R. Anschütz* and *G. Schroeder,* Liebigs Ann. Chem. *295,* 67 (1897).

If the nitrogen atom of the pyrrolidine carries an aryl or heterocyclic residue as in *(91)* and *(93)*, the substituent is not removed. Thus *(91)* aromatizes to give the pyrrole derivative *(92)* [40], while *(93)* gives the pyrroline derivative *(94)*.



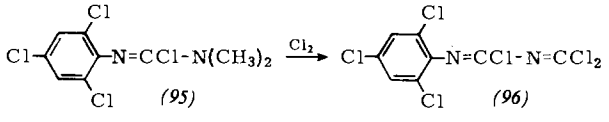
(91) *(92)*



(93) *(94)*

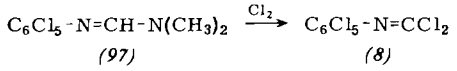
8. High-Temperature Chlorination of *N,N*-Dialkylamidines

The high-temperature chlorination of *N,N*-dialkylamidines leads either to dealkylation or, corresponding to the deacylation of *N,N*-dialkylcarbonamides, to cleavage of the amidine grouping. *N,N*-Dimethyl-*N'*-(2,4,6-trichlorophenyl)chloroformamidine *(95)* is converted in 58 % yield into the isocyanide dichloride *(96)*, *i.e.* the chloroformamidine grouping is retained [7].

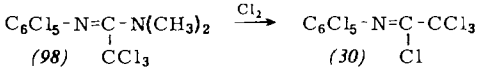


(95) *(96)*

On chlorination of *N,N*-dimethyl-*N'*-(pentachlorophenyl)formamidine *(97)* and of the corresponding trichloroacetimidine *(98)*, on the other hand, the amidine grouping is cleaved to give pentachlorophenyl isocyanide dichloride *(8)* or *N*-pentachlorophenyltrichloroacetimidoyl chloride *(30)* and chlorinated methyl isocyanide dichlorides.



(97) *(8)*

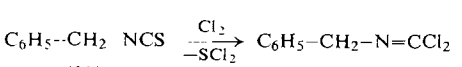


(98) *(30)*

9. High-Temperature Chlorination of Thioamides

9.1. Isothiocyanates

The chlorination of alkyl and aryl isothiocyanates leads even at low temperatures, and generally in an exothermic reaction, to removal of sulfur chlorides and formation of alkyl and aryl isocyanide dichlorides [42, 43]. Benzyl isothiocyanate *(99)*, for example, gives benzyl isocyanide dichloride *(52)* in almost quantitative yield [25].



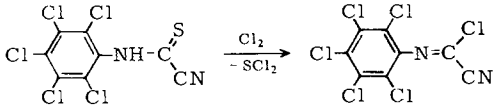
(99) *(52)*

The high-temperature chlorination of isocyanide dichlorides has already been described in detail in Section 5.4.1. If these reactions are carried out as a one-reactor process starting with the isothiocyanates, it is often advantageous to remove the sulfur after the first chlorination stage to avoid side reactions.

9.2. *N*-Monosubstituted Thioamides

The chlorination of *N*-alkylthioamides, which are readily obtainable by sulfurization of Schiff bases [34], has already been described in Section 5.4.4.

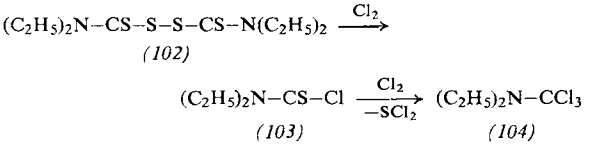
The adducts of hydrocyanic acid and isothiocyanates, *e.g.* *(100)*, are thioamides of cyanoformic acid [44]. They give cyanoformimidoyl chlorides *(101)* on chlorination [45].



(100) *(101)*

9.3. *N,N*-Disubstituted Thioamides

The behavior of the *N,N*-disubstituted thioamides on high-temperature chlorination differs from that of the corresponding carbonamides. *N,N*-Disubstituted thiocarbamoyl chlorides such as *(103)*, which can be prepared *e.g.* by chlorolysis of thiouram disulfides *(102)* [46], give tertiary amines *(104)* containing a trichloromethyl group on chlorination under mild conditions [47, 48].



(102) *(103)* *(104)*

The high-temperature chlorination of *(103)*, on the other hand, leads to a mixture of the isocyanide dichloride *(19)* and the imidoyl chloride *(28)*.

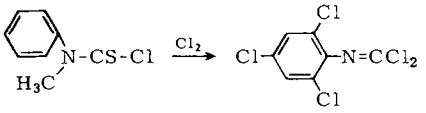
(103) (19) (28)

2,4,6-Trichlorophenyl isocyanide dichloride *(7)* is formed from *N*-methyl-*N*-phenylthiocarbamoyl chloride *(105)*.

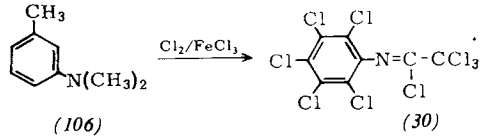


(105) (7)

10. Peculiarities of High-Temperature Chlorination

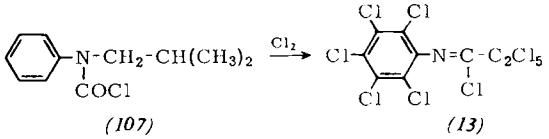
10.1. Cleavage and Formation of C–C Bonds

Under the vigorous conditions of high-temperature chlorination, the normal reaction products are frequently accompanied by substances which are formed by cleavage or formation of C–C bonds. In the chlorination of *N*,*N*-dimethylaniline *(5)* (see Section 2.1.), 3–5 % of *N*-pentachlorophenyltrichloroacetimidoyl chloride *(30)* are formed as a by-product. This compound surprisingly becomes the principal product in the chlorination of *N*,*N*-dimethyl-*m*-toluidine *(106)* in the presence of iron(III) chloride. Both reactions could involve a free-radical mechanism, in which a trichloromethyl radical is responsible for the formation of the C–C bond.



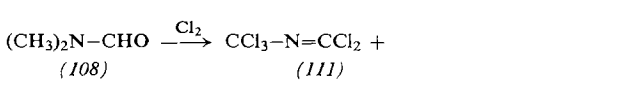
(106) (30)

In the high-temperature chlorination of *N*-isobutylanilinium hydrochloride or of *N*-isobutyl-*N*-phenylcarbamoyl chloride *(107)*, a methyl group is removed, and the product formed is *N*-pentachlorophenylpentachloropropionimidoyl chloride *(13)*.



(107) (13)

Dimethylamino compounds in particular tend to dimerize with formation of C–C bonds on high-temperature chlorination. Thus dimethylformamide *(108)* in suitable solvents gives, not only trichloromethyl isocyanide dichloride *(111)*, but also (formally by dimerization of the fragment $-CCl_2-N=CCl_2$) tetrachloroethylene-1,2-bis(isocyanide dichloride) *(21)*. Attempted chlorination of *(108)* in the absence of solvent generally resulted in explosive decomposition.



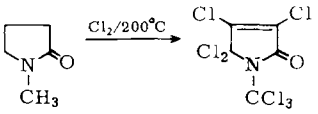
(108) (111)

$Cl_2C=N-CCl_2-CCl_2-N=CCl_2$

(21)

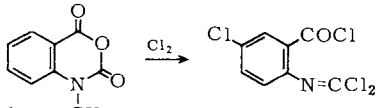
10.2. Cleavage of Cyclic Amides with Chlorination

Peculiarities are found in the chlorination of cyclic *N*-substituted amides[7], since deacylation in this case leads to ring opening. However, the cyclic structure has a certain stabilizing effect, so that the tendency toward cleavage is expected to be lower. Accordingly, the cyclic substitution product *(110)* is obtained as main product on high-temperature chlorination of *N*-methylpyrrolidone *(109)*.



(109) (110)

The chlorination of the less stable *N*-methylisatoic anhydride *(112)* on the other hand, leads to ring cleavage and formation of 2-chlorocarbonyl-4-chlorophenyl isocyanide dichloride *(113)*.



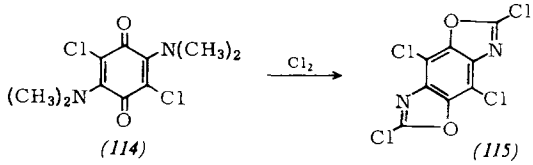
(112) (113)

10.3. Ring Closure Reactions

With favorable steric arrangements, ring closures with formation of C–O, C–N, and C–C bonds are possible under the conditions of high-temperature chlorination.

10.3.1. Oxazole Ring Closure in *N*,*N*-Dialkylaminoquinones

Double ring closure with formation of C–O bonds to give the oxazolobenzoxazole *(115)* occurs on chlorination of 2,5-bis(dimethylamino)-3,6-dichloro-*p*-benzoquinone *(114)*[7].

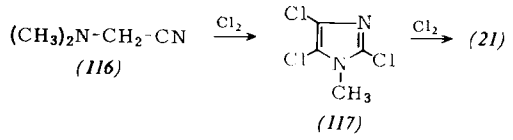


(114) (115)

10.3.2. Ring Closure Reactions of Dialkylaminonitriles

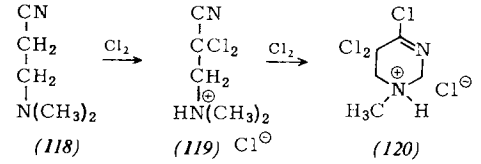
If the amino and nitrile groups in alkylaminonitriles are separated by one or two carbon atoms, the high-temperature chlorination is accompanied by cyclization to form five- or six-membered heterocycles.

The chlorination of dimethylaminoacetonitrile *(116)* leads first, at low temperatures, to cyclization and formation of 2,4,5-trichloro-1-methylimidazole *(117)* which undergoes practically quantitative ring opening on further chlorination at 180–200 °C to give tetrachloroethylene-1,2-bis(isocyanide dichloride) *(21)*[18].

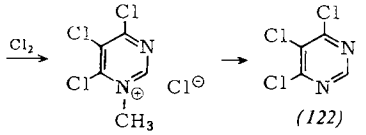


(116) (117) (21)

The chlorination of 3-dimethylaminopropionitrile (118) leads *via* the isolable intermediates (119)–(121) to 4,5,6-trichloropyrimidine (122)[49].

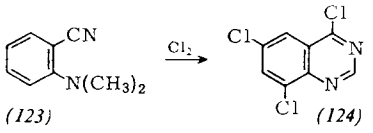


(118) (119) (120)



(121) (122)

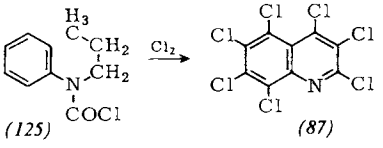
In a similar ring closure reaction, 2-dimethylaminobenzonitrile (123) gives 4,6,8-trichloroquinazoline (124)[18].



(123) (124)

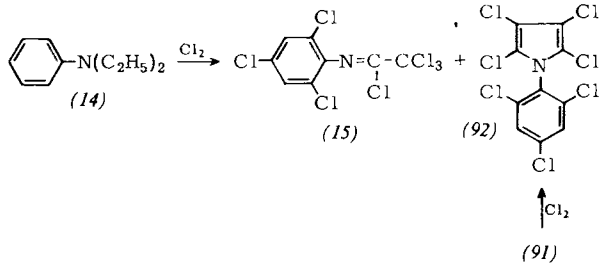
10.3.3. Ring Closure with Formation of C–C Bonds

Ring closure with formation of C–C bonds is observed in the high-temperature chlorination of *N*-chlorocarbonyl-*N*-propylaniline (125), which gives heptachloroquinoline (87) in a yield of approximately 50 %[50].



(125) (87)

In the high-temperature chlorination of *N,N*-diethylaniline (14), cyclization to form the pyrrole derivative (92) competes with the normal dealkylation to form (15); (92) is also formed from *N*-phenylpyrrolidine (91)[51].



(14) (15) (92) (91)

[50] *H. Tarnow, H. Holtschmidt*, and *O. Bayer*, German Pat. 1186859 (Oct. 20, 1962), Farbenfabriken Bayer AG; Chem. Zbl. *1965*, 39–2688.

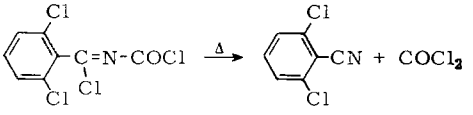
[51] *H. Tarnow, H. Holtschmidt*, and *I. Ugi*, German Pat. Appl. F 37066 IVd/12p (June 14, 1962), Farbenfabriken Bayer AG.

11. Thermal Cleavage of the Polychloroamine Derivatives

As can be seen from the conditions of their preparation, the polychloroamine derivatives obtained by high-temperature chlorination generally have a very high thermal stability. Repeated reference has already been made to the stability of the imidoyl chloride grouping. Imidoyl chlorides and isocyanide dichlorides can, however, undergo thermal cleavage under more forcing conditions.

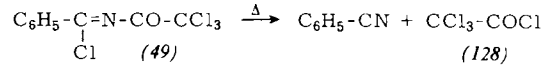
11.1. *N*-(1-Chloroalkylidene)amides

N-(1-Chloroalkylidene)carbamoyl chlorides and *N*-(1-chloroalkylidene)amides (acylimidoyl chlorides), which may be formally regarded as adducts of acyl chlorides with nitriles, decompose into these components even below 200 °C. The cleavage is catalyzed by Lewis acids. Thus 2,6-α-trichlorobenzylidenecarbamoyl chloride (126) gives 2,6-dichlorobenzonitrile



(126) (127)

(127) and phosgene, while *N*-(α-chlorobenzylidene)-trichloroacetamide (49) decomposes into benzonitrile and trichloroacetyl chloride (128).



(49) (128)

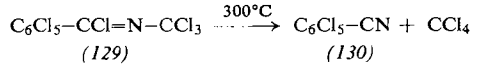
11.2. Perchloroalkyl Isocyanide Dichlorides and *N*-Perchloroalkylimidoyl Chlorides

Perchloroalkyl isocyanide dichlorides and *N*-perchloroalkylimidoyl chlorides are much more stable than the unchlorinated compounds, the decomposition of which into alkyl halide and nitrile is well known[52]. The perchloro compounds generally decompose only above 300 °C into perchloroalkane and nitrile.

Trichloromethyl isocyanide dichloride (17) decomposes in the gas phase above 350 °C into cyanogen chloride and carbon tetrachloride; similarly, pentachloroethyl isocyanide dichloride gives cyanogen chloride and hexachloroethane.

(17)

Pentachlorobenzonitrile (130) and carbon tetrachloride are formed in quantitative yield from *N*-trichloromethylpentachlorobenzimidoyl chloride (129) at about 300 °C[18].



(129) (130)

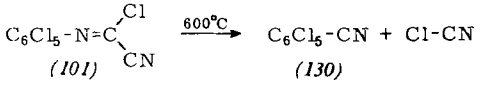
[52] *J. v. Braun*, Angew. Chem. *47*, 611 (1934).

11.3. Perchloroaryl Isocyanide Dichlorides and *N*-Perchloroarylimidoyl Chlorides

Pentachlorophenyl isocyanide dichloride *(8)* is thermally extremely stable. It is broken down into hexachlorobenzene and cyanogen chloride only on prolonged heating at 400 °C, or more rapidly on passage through a quartz tube heated to 700 °C. Pentachlorobenzonitrile *(130)* and chlorine are formed in rather smaller quantities [18].

$$\underset{(8)}{C_6Cl_5\text{-}N{=}CCl_2} \xrightarrow{400\text{–}700^\circ C} C_6Cl_6 + Cl\text{-}CN + \underset{(130)}{C_6Cl_5\text{–}CN} + Cl_2$$

The *N*-arylcyanoformimidoyl chlorides give the nitriles in very good yields on passage over quartz at 600 °C [53]. *N*-Pentachlorophenylcyanoformimidoyl chloride *(101)* gives pentachlorobenzonitrile *(130)* and cyanogen chloride in 91 % yield.



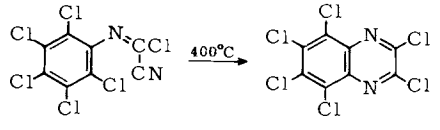
(101) *(130)*

12. Thermal Ring Closure of Polychloroamine Derivatives

Degradation to nitriles is not the only manner in which polychloroamine derivatives can change on pyrolysis. Another possibility is stabilization by ring closure.

12.1. Ring Closure with *N*-Arylation of the Nitrile Group

With suitable steric arrangements, cyclization with *N*-arylation of the nitrile group is possible under extreme thermal conditions. *N*-Pentachlorophenylcyanoformimidoyl chloride *(101)*, which gives pentachlorobenzonitrile at 600 °C in the gas phase (see Section 11.3), cyclizes at 400 °C in the absence of diluents to give hexachloroquinoxaline *(131)* [54].



(101) *(131)*

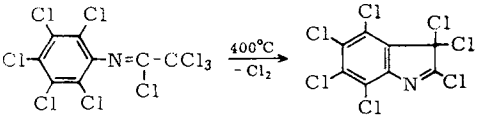
The reaction is confined to the perchlorinated compound.

[53] *G. Beck, E. Degener,* and *H. Holtschmidt*, German Pat. Appl. F 50630 IVb/12o (Nov. 9, 1966), Farbenfabriken Bayer AG.

[54] *H. Holtschmidt* and *E. Degener*, German Pat. Appl. F 49914 IVd/12n (Aug. 10, 1966), Farbenfabriken Bayer AG.

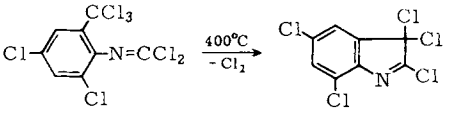
12.2. Ring Closure with Formation of C–C Bonds

Some polychlorinated *N*-arylimidoyl chlorides or aryl isocyanide dichlorides having a steric arrangement such that the formation of five- or six-membered rings is possible react at 300–400 °C with elimination of chlorine and formation of new C–C bonds to give condensed aromatic ring systems [55]. Thus *N*-pentachlorophenyltrichloroacetimidoyl chloride *(30)* loses chlorine at 400 °C to give heptachloro-3*H*-indole *(132)*.



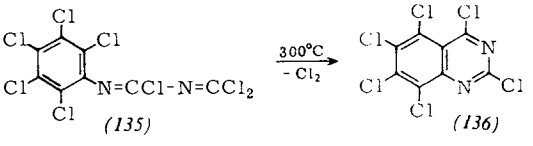
(30) *(132)*

2,3,3,5,7-Pentachloro-3*H*-indole *(134)* is formed under the same conditions from 2,4-dichloro-6-trichloromethylphenyl isocyanide dichloride *(133)* by cyclization of the *o*-trichloromethyl group with the isocyanide dichloride group.



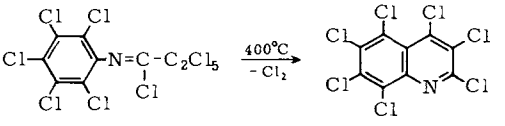
(133) *(134)*

Hexachloroquinazoline *(136)* is obtained in a yield of about 40 % when the isocyanide dichloride *(135)* is heated at 300 °C.



(135) *(136)*

N-Pentachlorophenylpentachloropropionimidoyl chloride *(13)* cyclizes at 400 °C with loss of chlorine to give heptachloroquinoline *(87)* in 81 %.



(13) *(87)*

We are grateful to Dr. Beck, Dr. Dankert, Dr. Grohe, and Dr. Roos for their cooperation. We also thank Dr. Pestemer, Dr. Lauerer, and Dr. Heitzer for carrying out numerous spectroscopic examinations.

Chalcogenocarbonic Acids and Their Anions

BY M. DRÄGER AND G. GATTOW [*]

Carbonic acids in which the oxygen has been wholly or partly replaced by sulfur, selenium, and/or tellurium are known as "chalcogenocarbonic acids". The aim of the present article is to review existing knowledge of these acids and so establish a basis for further systematic syntheses. The anions required for the synthesis of chalcogenocarbonic acids will also be briefly characterized.

1. Introduction

The known derivatives of "free carbonic acid $OC(OH)_2$" and its sulfur, selenium, and tellurium analogs are numerous, and have been widely studied[1]. Information on derivatives with acidic hydrogen bound to O, S, Se, or Te, with few exceptions, is unsatisfactory, and these compounds have often been dismissed as unstable without further discussion.

2. Possible Syntheses

There are theoretically four simple possibilities for the synthesis of chalcogenocarbonic acids.

1. Addition of two molecules to form the desired chalcogenocarbonic acid, *e.g.*:

$$H_2S + CS_2 \rightarrow SC(SH)_2 \qquad (1)$$

2. Addition of protons to the appropriate anion, *e.g.*:

$$CS_3^{2-} + 2\,H^+ \rightarrow SC(SH)_2 \qquad (2)$$

3. Cleavage of ester linkages in an ester of a chalcogenocarbonic acid, *e.g.*:

$$SC(SR)_2 + 2\,H_2O \rightarrow SC(OH)_2 + 2\,HSR \qquad (3)$$

4. Transchalcogenation of an existing chalcogenocarbonic acid, *e.g.*:

$$S{=}C(SH)_2 + H_2O \rightarrow S{=}C\begin{matrix}\diagup\,OH\\ \diagdown\,SH\end{matrix} + H_2S \qquad (4)$$

Reaction (1) is thermodynamically possible in some cases, but is sufficiently fast only in alkaline media. Similarly, reactions (3) and (4) can only be carried out as direct substitutions in alkaline media; a primary addition to form an orthocarbonic acid derivative followed by elimination has for some time been regarded as conceivable, but no conclusive proof of this course has yet been found[2,3]. In acidic media, on the other hand, the primary step is generally cleavage to form the starting materials of reaction (1).

Reactions (1), (3), and possibly (4) thus yield the anion of the acid, so that the only reaction that might be truly acid-forming is (2). This is the route that has been taken in all definite preparations of chalcogenocarbonic acids so far. The main problem in further syntheses of this type is to use a temperature and a medium such that reaction (2) is sufficiently fast and the resulting acid thermodynamically stable, or if this is impossible, to provide a device that rapidly converts the acid into a thermodynamically stable, or at least metastable, state. Another problem is the purification of a "crude acid" obtained in this way.

The anions required for the preparation of the acid are generally obtained by reaction (1) in alkaline media, *e.g.*:

$$CS_2 + HS^- \rightarrow HCS_3^- \xrightarrow{-H^+} CS_3^{2-} \qquad (1a)$$

3. Unsubstituted Trichalcogenocarbonic Acids

3.1. Simple Anions

The only trichalcogenocarbonate ions that have been definitely detected are those listed in Table 1, dashes indicate other possible combinations. Salts of the ions CO_3^{2-}, CS_3^{2-}, CSe_3^{2-}, and CS_2Se^{2-} can be obtained in the pure state; CO_2S^{2-} has been detected polarographically in aqueous solution, COS_2^{2-} by UV spectroscopy in aqueous solution, and $CSSe_2^{2-}$ by IR spectroscopy in solid solutions with CSe_3^{2-}.

Table 1. Trichalcogenocarbonate ions CX_3^{2-}.

[3] *B. Philipp* and *C. Fichte*, Faserforsch. u. Textiltechn. *11*, 118, 172 (1960).

All these ions are formed in accordance with eq. (1a) from CO_2, COS, CS_2, or CSe_2 and OH^-, SH^-, or SeH^-[14]; corresponding reactions with COSe, CSSe, CSTe, and HTe^- have evidently not yet been attempted.

Carbonates and trithiocarbonates[7–14] have been known for a long time. The barium[15–17] and potassium[15] salts of the CSe_3^{2-} ion and the barium[15,16,18], potassium[15], and sodium[15] salts of the CS_2Se^{2-} ion have been prepared. Barium salts can be prepared in aqueous media, while alkali metal salts are obtainable only in alcoholic solution, with subsequent precipitation by ether. CS_3^{2-} occurs, not only in simple salts with a metal cation, but also frequently as a ligand in complex transition metal anions[19,20]. The only crystal structure determination of a trithiocarbonate that has been reported so far is that of bis(tetraphenylarsonium) bis(trithiocarbonato)niccolate(II)[21]; like CO_3^{2-} and CSe_3^{2-}, CS_3^{2-} is planar.

Apart from the thermal degradation of some trithiocarbonates[8–10,22] and of $BaCSe_3$[23], from which the stability limits of phases having various degrees of hydration and some enthalpies of formation have been obtained, and the behavior of the chalcogenocarbonate ions in aqueous solution (cf. Section 3.3), the main sources of structural information have been the vibration[24–26] and electronic excitation spectra[27] of the ions CO_3^{2-}, CS_3^{2-}, and CSe_3^{2-}. In the free state these ions have D_{3h} symmetry, but their symmetry is decreased in the crystal because of the "site effect". Spectra of complex salts[20,28] and lattice vibrations[29] have also been studied. The fundamental vibrations of the ions are given in Table 2.

Table 2. Fundamental vibrations (cm^{-1}), valence force constants f_r (mdyne/Å), bond numbers N of the C-chalcogen bonds, according to *Siebert* [33], bond lengths $r_{spectr.}$ (Å) according to *Badger* [35], and bond lengths $r_{X\text{-ray}}$ (Å) [21, 36, 37] of CO_3^{2-}, CS_3^{2-}, and CSe_3^{2-} [38].

	ν_S	γ	ν_{as}	δ
CO_3^{2-}	1063	880	1415	680
CS_3^{2-}	520	505	905	320
CSe_3^{2-}	316	420	802	185

	f_r	N	$r_{spectr.}$	$r_{X\text{-ray}}$
CO_3^{2-}	7.66	1.42	1.30	1.294
CS_3^{2-}	3.72	1.16	1.68	1.68–1.70
CSe_3^{2-}	3.36	1.17	1.78	1.82

Complete sets of force constants and mean vibration amplitudes[32] have been calculated from the spectra for a general valence force system[26,30] and for a Urey-Bradley potential[26,31]. Values for the valence force constant f_r, which is linearly related to the Pauling electronegativities of the atoms O, S, and Se, are also shown in Table 2. The table also contains the bond numbers N found from f_r for the C-chalcogen

[4] Contrary to earlier views, *Hovenkamp* [5] has now been able, on the basis of a recalculated value of about 10^{-20} for the second dissociation constant of H_2S, definitely to assign the role of the acting ion to HS^-. For H_2Se ($K_2 \approx 10^{-15}$ [6]), on the other hand, reaction *via* the more active Se^{2-} ion cannot be ruled out.

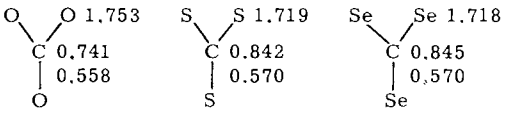
bonds[33,34], as well as the bond lengths $r_{spectr.}$[35] found from f_r, which can be compared with $r_{X\text{-ray}}$ for C–O in calcite[36], C–S in the bis(trithiocarbonato)niccolate(II) ion[21], and C–Se in *N*-benzoyl-*N'*-phenylselenourea[37].

The bands in the electronic excitation spectra of the ions CO_3^{2-}, CS_3^{2-}, and CSe_3^{2-} in aqueous solution have been assigned on the basis of an MO scheme and a simple HMO calculation[27]. The π-electron densities and π-bond orders obtained from the HMO calculation are shown in Scheme 1.

The π-bond orders vary in the opposite direction from *Siebert*'s bond number *N*.



Scheme 1.

Attempts to prepare $BaCSSe_2$[18] always lead to a substance whose IR spectrum points to a mixture of $BaCSe_3$ and $BaCSSe_2$[39], since the bands remaining on elimination of the CSe_3^{2-} spectrum show a logical relationship to the corresponding bands of the CS_2Se^{2-} ion, and all the bands for both ions can be assigned without difficulty to the six fundamental vibrations expected for an ion CX_2Y having C_{2v} symmetry[18]; these are shown in Table 3.

Table 3. Fundamental vibrations of the ions CS_2Se^{2-} and CSe_2S^{2-} (cm^{-1}).

CX_2Y	CS_2Se^{2-}	CSe_2S^{2-}
ν(CY)	842	930
ν_s(CX)	478	455
δ_s	299	193
γ	443	421
ν_{as}(CX)	930	898
δ_{as}	335	315

The ions CO_2S^{2-} and COS_2^{2-} are the primary products of the reactions of COS and CS_2 with OH^- ions in aqueous solution[40,41]; COS_2^{2-} is also formed on decomposition of simple xanthates in strongly alkaline media[3]. COS_2^{2-} can be detected by its characteristic UV absorption at 272 nm, and CO_2S^{2-} by its polarographic behavior. Dilute (10^{-4} M) solutions of COS_2^{2-} in 5 N sodium hydroxide solution have an average lifetime of about 50 hours (at room temperature). More concentrated solutions cannot be prepared, since COS_2^{2-} reacts rapidly with an excess of CS_2 to form CS_3^{2-}. Dilute solutions of CO_2S^{2-} in 5 N sodium hydroxide solution, on the other hand, have a half-life of only about 5 min at room temperature, but can be stabilized for a few hours by cooling to −30 °C (the freezing point of the aqueous solution being lowered by addition of $NaClO_4$). Both ions decompose rapidly in more weakly alkaline solution. COS_2^{2-} first forms COS, which reacts with OH^- to form CO_2S^{2-}; CO_2S^{2-} decomposes to form SH^- and CO_3^{2-}. CS_2 is not regenerated[40,41].

3.2. Hydrogen Anions HCX_3^-

Aqueous solutions of the anions listed in Table 1 or the corresponding acids always contain the monoprotonated anion in the dissociation equilibrium (cf. Section 3.3). However, since the decomposition of CO_2S^{2-}[40] and CS_3^{2-}[42], and probably also of CS_2Se^{2-}[18], proceeds *via* the hydrogen anions HCX_3^-, it is not surprising that no salts of any of these ions have been obtained.

Hydrogen carbonates have been known for a very long time. However, these do not contain free HCO_3^- groups, but infinite chains[43] or dimers[44] held together by hydrogen bonds. The stability of these salts is therefore primarily due to the strong O–H···O bond. HCO_3^- groups that are no longer held together by hydrogen bonds occur in the crystalline state when samples of hydrogen carbonate in alkali metal halide disks are heated to 480 °C[45]; these groups are retained when the disks are quenched to room temperature, and can be detected by their IR spectrum, which contains all nine fundamental vibrations of the HCO_3^- ion. A force constant determination gave values of 9.12 mdyne/Å for the valence force constant f_r[45], 1.53 for the Siebert bond number *N*[33], and 1.27 Å for the length $r_{spectr.}$ of the two free C–O bonds[38].

3.3. Acids

The anions of Table 1 are all fairly stable in strongly alkaline aqueous solution and in an atmosphere of nitrogen, whereas they rapidly decompose in acidic

solution *via* the undissociated acid or the hydrogen anion. *e.g.*:

$$H_2CO_3 \rightarrow H_2O + CO_2 \quad (5)$$

$$HCO_2S^- \rightarrow HS^- + CO_2 \quad (6)$$

$$H_2COS_2 \rightarrow H_2S + COS \quad (7)$$

$$HCS_3^- \rightarrow HS^- + CS_2 \quad (8)$$

$$HCS_2Se^- \rightarrow HSe^- + CS_2 \quad (9)$$

$$H_2CSe_3 \rightarrow H_2Se + \text{polymeric C–Se products} \quad (10)$$

(5) is a very fast reaction, which, like the slow reverse reaction of the hydration of CO_2, has been very extensively studied because of its practical importance[46]. Reactions (6) and (7), which are also very fast, have not yet been followed in acidic solution[40,41]. The rapidity of reactions (5) to (7) makes it impossible to obtain these acids from the aqueous phase.

The same is true of H_2CSe_3, which has a half-life of 15 sec in 10^{-3} M solution at 0 °C and so permits conductivity measurements, but decomposes very rapidly in more concentrated solutions to form C-Se polymers that have not yet been studied in detail [reaction (10)][17,47]. Thus H_2CSe_3 also cannot be obtained from aqueous solution. H_2CS_3[42] and H_2CS_2Se[18], on the other hand, decompose *via* their hydrogen anions, and are therefore so stable in fairly concentrated strongly acidic solution that the free acids can be precipitated from aqueous solutions of their salts owing to their low solubility in water.

Extensive measurements on aqueous solutions of the salts and the free acids have led to the values given in Table 4 for the electrolytic dissociation constants; the constants for perthiocarbonic acid H_2CS_4[49] are also given for comparison.

Table 4. Dissociation constants K_1 at 0 °C and K_2 at 25 °C.

	H_2CO_3 [48]	H_2CS_3 [42]	H_2CSe_3 [47]	H_2CS_2Se [18]	H_2CS_4 [49]
K_1	1.55×10^{-4}	1.2 [a]	6.9×10^{-2}	1.2×10^{-5}	2.8×10^{-4} [b]
K_2	4.69×10^{-11}	1.2×10^{-7} [a]	6.9×10^{-8}	1.0×10^{-11}	5.75×10^{-8}

[a] Value for 20 °C. [b] Value for 2 °C.

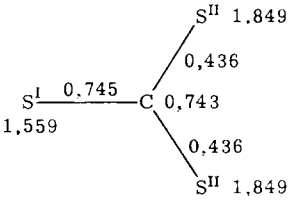
Free H_2CS_3 is formed on reaction of an aqueous suspension of $BaCS_3$ with hydrochloric acid at 0 °C. It occurs as a red oil, which can be separated from the aqueous phase without appreciable decomposition, dried, and stored at −78 °C[50]. Many physical and thermodynamic constants of the substance, which solidifies at −26.9 °C, have been determined[50,51].

An X-ray structural analysis at −100 °C showed that solid H_2CS_3 exists in the form of isolated molecules, which are joined by hydrogen bonds to form double spirals with alternating left-hand and right-hand twists. The CS_3 group is planar, and the various C–S distances are given in Table 5.

Table 5. C–S distances in solid H_2CS_3 at −100 °C [52].

C=S	S as H-bond acceptor	1.69–1.70 Å
C–S–H	S as H-bond donor	1.75–1.77 Å
C–S–H	S not bound by H bond	1.71–1.73 Å

The hydrogen bonds in solid and liquid H_2CS_3 are indicated in the IR system[50,53] by an S–H stretching band at about 2500 cm^{-1}, which is replaced by a sharp split band at 2550 cm^{-1} in dilute solutions of H_2CS_3 in CCl_4, in which the H bonds are broken. The other IR bands have been assigned to the fundamental vibrations of the $SC(SH)_2$ molecule[54]. HMO calculations[54,55] for the CS_3 skeleton of the acid give the π-electron densities and π-bond orders shown in Scheme 2.



Scheme 2.

H_2CS_3 is of little importance as a reagent in preparative chemistry. The only known reactions in which the CS_3 grouping is retained are the reaction with oxalyl chloride to form 4,5-dioxo-2-thioxo-1,3-dithiolane[56], the reaction with chlorosulfanes S_xCl_2 to form $(CS_{3+x})_n$ (n about 10, x = 1 to 6)[57], and the oxidation by bromine at −30 °C to give $(CS_3)_n$[58] (n about 9). The products obtained in all other cases are also obtainable by similar reactions with H_2S[62]. However, H_2CS_3 is frequently more reactive[59]. Heavy metal

trithiocarbonates can be readily obtained in the pure state by reaction of the acetates with H_2CS_3 in dimethyl sulfoxide [14].

Like H_2CS_3, free H_2CS_2Se can be obtained by reaction of an aqueous suspension of the barium salt with hydrochloric acid [18]. It is a bluish-red oil, which cannot be obtained in the pure state owing to rapid decomposition, but can only be separated by dissolution in a stabilizing organic phase. It is stable at low temperatures in this phase after drying. H_2CS_2Se probably exists in the asymmetric form *(1)*, since only H_2Se and CS_2 can be detected when it decomposes, and methylation of CS_2Se^{2-} yields the asymmetric dimethyl ester *(2)* [64].

(1) *(2)*

The other trichalcogenocarbonic acids, on the other hand, can be prepared only in nonaqueous solution, *i.e.* from the anhydrous salts, so that H_2CO_2S and H_2COS_2, whose anions are known only in aqueous solution, have not yet been obtained.

Free carbonic acid is formed as the dimethyl ether monoadduct $H_2CO_3 \cdot O(CH_3)_2$ on reaction of dry Na_2CO_3 with HCl in dimethyl ether at −35 °C; the excess of dimethyl ether is evaporated off under vacuum at −80 °C [65, 66]. The white crystalline adduct melts at −47 °C with polymerization, and decomposes at temperatures >−26 °C to give H_2O, CO_2, and $O(CH_3)_2$. ^{1}H-NMR studies have shown the presence of C−O−H protons [66]. A number of thermodynamic constants have been determined from vapor pressure measurements [65–67]. A monoadduct with diethyl ether reported earlier [68] could not be definitely confirmed by other investigators [66]. The description of the experiment [68] suggests the presence of an addition compound having a variable composition [69].

Similar experiments on a suspension of $BaCSe_3$ in diethyl ether with HCl at −30 °C lead to the formation of a dark red, highly viscous oil, which decomposes very rapidly above −10 °C [17]. Owing to low solubility in organic solvents, it has not yet been possible to separate H_2CSe_3 from $BaCl_2$ formed at the same time.

4. Monoalkylated Trichalcogenocarbonic Acids

The various types of monoalkyl trichalcogenocarbonic acids and trichalcogenocarbonates are listed in Table 6. The alkyl group may be bound to different chalcogen atoms. The most extensively studied of these compounds are the ethyl derivatives.

Table 6. Monoalkyl trichalcogenocarbonic acids and trichalcogenocarbonates; existence of compounds in brackets still doubtful (examples of R : C_2H_5, CH_3).

CSe_2−OR$^-$	

4.1. Anions

Monoalkyl trichalcogenocarbonates are generally prepared by reaction of CO_2, COS, CS_2, CSSe, and CSe_2 with alkoxides or thiolates [1]; reactions with selenolates or tellurolates have not yet been examined. Transesterifications and partial hydrolyses of dialkyl compounds can also be used.

Alkyl carbonates in aqueous solution exist in the equilibrium

$$R{-}O{-}CO_2^- + H_2O \rightleftharpoons HCO_3^- + R{-}OH$$

The equilibrium constant at 0 °C is $K = 12$ for the methyl compound and $K = 23$ for the ethyl compound [70]. Salts can therefore only be obtained in alcoholic solutions. In acidic and in alkaline media, the equilibrium is strongly displaced toward the decomposition products; equilibrium is reached very rapidly in acidic solution, but slowly in alkaline solution [70]. Whereas alkaline earth metal alkyl carbonates have high CO_2 partial pressures, dry alkali metal salts are very stable [70]. Alkyl carbonates are used as carboxylating agents [71, 72].

O-Alkyl monothiocarbonates are formed when COS is passed into alcoholic alkoxide solutions [1]; the best known of these compounds is potassium *O*-ethyl monothiocarbonate (Bender's salt) [73]. These compounds decompose rapidly in aqueous solution *via*

the free *O*-ethyl monothiocarbonic acid. The rate of decomposition consequently decreases steadily above pH ~ 9, while it rapidly increases below this pH value [3, 74]. IR spectroscopic data for the alkyl monothiocarbonates are given in Table 7 [75]. *S*-Alkyl monothiocarbonates are much less stable, and have so far been obtained only in solution. They are formed from alkyl carbonates on transesterification with thiolates [71].

O-Alkyl dithiocarbonates, which are generally known as xanthates, are the most extensively studied and the (technically) most important group of alkyl chalcogenocarbonates. They are formed by reaction of CS_2 with alkoxides [11, 76]. Xanthates are relatively stable in aqueous solution between pH 7 and pH 14 [3], but decompose rapidly outside this range [77, 78]. The decomposition in acidic solution [77] proceeds *via* the free xanthic acid with formation of alcohol and CS_2 (cf. Section 4.2), while that in alkaline solution [78], proceeds *via* a dithiocarbonate to give sulfide and carbonate.

Crystal structure determinations [79] have shown that the ionic alkali metal xanthates consist of isolated cations and xanthate groups, while the xanthates of arsenic and antimony, as well as of the transition metals, have complex molecules in which the xanthate sulfur has a square-planar arrangement around M^{II} or a distorted octahedral arrangement around M^{III} [80]. The two C–S bonds in the ionic xanthates are equivalent (C–S = 1.68 Å), whereas the complex xanthates contain one short (1.56–1.65 Å) and one long (1.70–1.79 Å) C–S bond. The CS_2O portion is planar in all the xanthates. On examination of the IR spectrum [80, 81] (see Table 7), no definite distinction could be made between C=S and C–O–C vibrations, which couple strongly with one another. The electronic excitation spectrum contains strong absorption maxima at 301 and 226 nm [82].

Table 7. IR bands of alkyl chalcogenocarbonates.

ν (cm⁻¹)	COS–OR [75]	CS_2–OR [80, 81]	COS–SR [84]	CS_2–SR [81]	CSe_2–OR [88]

νCS	1025–1040	1020–1070	950–960	1000–1050	
νCSe					940–950
νCOC	1090–1120	1100–1280			

The *S*-alkyl dithiocarbonates are also much less stable than the *O*-alkyl compounds. They are formed on careful hydrolysis of *O*,*S*-dialkyl dithiocarbonates with tertiary amines in organic solvents below room temperature [83], and decompose in aqueous solution into COS and alkanethiols.

The alkyl trithiocarbonates, which are obtained by reaction of alkanethiolates with CS_2 [1], form salts that are relatively stable even in aqueous solution [81, 82].

Alkyl selenocarbonates corresponding to the xanthates, *i.e.* *O*-alkyl thioselenocarbonates [85] and *O*-alkyl diselenocarbonates [86] have been obtained in the form of their alkali metal salts by reaction of alkoxides with CSSe or CSe_2. These salts form yellow crystals, and are stable only under nitrogen, in the absence of light, and at low temperatures. CSe_2 reacts vigorously with cellulose to give cellulose selenoxanthate, the rapid formation of which is followed by equally rapid decomposition [87].

4.2. Acids

The xanthic acids [89] and the trithiocarbonic acids [90] can be precipitated from aqueous solutions of salts

of alkyl trichalcogenocarbonic acids by dilute hydrochloric acid or sulfuric acid. They separate out as oily liquids or even in the crystalline form, and can be isolated without difficulty. The rate of decomposition of the other alkyl chalcogenocarbonates in acidic media is so high, on the other hand, that the free acids cannot be obtained from aqueous solution.

Distillation of liquid CO_2 into alcohols at −50 °C under pressure yields compounds having the empirical formulas of alkyl esters of carbonic acid[69] (the methyl, ethyl, propyl, *tert*-butyl, and amyl compounds have been prepared). However, these are probably addition compounds rather than free alkyl carbonic acids, since a reaction between CO_2 and alcohol under these conditions is very unlikely. Equally improbable is the formation of a stable solid *S*-ethyl thiocarbonic acid by oxidation of ethylthioacetylene with 30% H_2O_2 in glacial acetic acid on heating[91]. *O*-Ethyl selenocarbonic acid is reported to be formed on reaction of ethyl chloroformate and magnesium hydrogen selenide bromide as colorless needles having m.p. 122–123 °C[92].

Free selenoxanthic acid is formed on acidification of aqueous monoselenoxanthate solution as an oil that decomposes rapidly with formation of selenium[85].

Xanthic acids are very stable in the perfectly pure state or in apolar solvents even at 50 °C[89, 93]. Even traces of polar substances, however, cause decomposition into CS_2 and alcohol, which further accelerates the decomposition autocatalytically. Extensive measurements on the decomposition kinetics[77] have shown that the first step in the decomposition of the acid is the formation of an active zwitterionic complex. The rate of decomposition of the xanthic acids decreases again in strongly acidic solution, since they are then present in the protonated form. The dissociation constant of ethylxanthic acid is 0.023 at 0 °C and 0.027 at 25 °C[77].

Pure xanthic acids and alkyl trithiocarbonic acids contain intermolecular hydrogen bonds[53], which are broken in solutions of the acids.

High molecular weight cellulosexanthic acid is formed as the initial product in the reaction of cellulose xanthate with acids in aqueous solution[94]. The decomposition can be followed by measurement of the UV absorption at 270 nm; the dissociation constant is about 0.05.

5. Chalcogenocarbonic Acids Containing Nitrogen

Known chalcogenocarbonic acids containing nitrogen are carbamic acids, carbazic acids, and isocyanic acids.

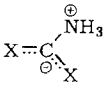
[94] *H. Jost* and *J. Ludwig*, Faserforsch. u. Textiltechn. *17*, 29, 194 (1966); *18*, 274 (1967).

Chalcogenocarbamic acids in general are prepared by reaction of their salts, the chalcogenocarbamates[95], with acids. Ammonium or alkylammonium salts are readily obtained by reaction of CO_2, COS, CS_2, or CSe_2 with ammonia or amines[1, 86, 96–99]. In addition to a number of IR[81, 100] and UV[82, 101] spectroscopic studies, special mention should be made of the numerous crystal structure determinations of a wide range of dithiocarbamate complexes[102]. In these complexes, in contrast to the xanthate complexes, the two C–S bonds generally appear, to a close approximation, to be equivalent (C–S ≈ 1.68–1.71 Å).

This tendency to form equivalent C-chalcogen bonds in the form of a zwitterion is also found in the free acids. However, extensive decomposition measure-



ments in aqueous dithiocarbamate solutions have shown[103] that their decomposition begins with a zwitterionic form of this type, so that the rate of decomposition of the chalcogenocarbamic acids increases rapidly with increasing *N*-alkylation (and

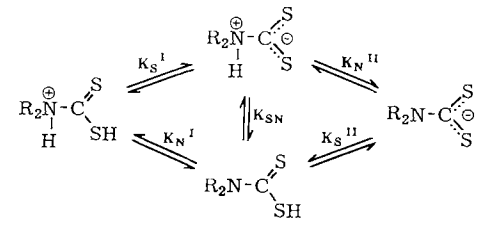
hence increasing basicity of the amide group), while carboxyl or phenyl groups on the amide nitrogen stabilize the free acids. Apart from unsubstituted dithiocarbamic acid[104], therefore, all the known[109] chalcogenocarbamic acids are stabilized in this way, *i.e.* *N*-(2-acetyl-2-ethoxycarbonylthioacetyl)-, *N*-[2,2-bis(ethoxycarbonyl)thioacetyl]-, *N*-(2,2-diacetylthioacetyl)-, and *N*-(2-ethoxycarbonyl-2-cyanothioacetyl)-carbamic acids[105] and *N*,*N*-diphenyl-[106], *N*-cyano-[107], and *N*-thiocarbamoyldithiocarbamic acid[108].

Dithiocarbamic acid itself is formed as colorless needles when concentrated hydrochloric acid is added dropwise to an aqueous solution of its ammonium salt at 0 °C[104]. It is stable below 0 °C, but decomposes rapidly at higher temperatures to give CS_2 and ammonium dithiocarbamate[110]. The crystals melt at about 35 °C. According to its IR spectrum[104], unsubstituted dithiocarbamic acid in the crystalline state also consists of unionized acid molecules, which are joined in pairs by strong S–H···N bonds. The resulting double molecules are linked to one another by weaker S–H···S bonds. The decomposition of the acid in the double molecule begins with the transfer of the bridge proton from the sulfur to the nitrogen, the acceptor molecule then breaking down into CS_2 and NH_4^+.

The recently described preparation of the liquid compounds[111] *N*-β-hydroxyethylcarbamic acid (perfectly stable up to 120 °C) and *N*,*N*-dimethylcarbamic acid (distils at 60 to 61 °C without decomposing), both of which appear to exist as zwitterions, is contrary to all other experience with carbamic and dithiocarbamic acids. Spectroscopic methods were not used in the elucidation of the structures of these compounds.

Depending on the pH range, aqueous dithiocarbamate solutions contain *S*-anions, free acids in the neutral and zwitterionic forms, or *N*-protonated cations. The situation is shown in Scheme 3[103].



Scheme 3.

An equilibrium constant K_2 of 1.13×10^{-3}[104] has been found for dithiocarbamic acid at 20 °C; for *N*,*N*-diethyldithiocarbamate, $K_1 = 1.6 \times 10^{-8}$ and $K_2 = 1.0 \times 10^{-8}$ (both at 20 °C)[112]. These constants have not yet been assigned to S- or N-dissociation.

A carbamic acid containing selenium, *i.e.* *N*,*N*-dimethyldiselenocarbamic acid[98], has also been prepared. The above stability considerations based on the tendency to form a zwitterion with equivalent carbon-chalcogen bonds do not apply to this acid. A similar conclusion is indicated by the results of a crystal structure determination on nickel bis(*N*,*N*-diethyldiselenocarbamate)[113], according to which there are two different C–Se distances in *N*,*N*-diselenocarbamate (C–Se = 1.84 and 1.97 Å[114]). The C–S distances in the corresponding dithio compound are approximately equal (1.68 and 1.70 Å)[115].

5.2. Chalcogenocarbazic Acids

Hydrazinium salts of the chalcogenocarbazic acids are formed on reaction of hydrazine with CO_2[116], COS[117], CS_2[118], CSSe[119], or CSe_2[118,120]. In addition to the hydrazinium salts, a number of transition metal complexes are also known[118,121].

The free carbazic acids are found only as β-protonated zwitterions, owing to the strong basicity of their β nitrogen. This strongly hinders the α-protonation required to initiate the decomposition. At the same time there is a substantial gain in lattice energy

in the crystalline state. The carbazic acids are consequently much more stable than corresponding carbamic acids. The zwitterionic character has been conclusively demonstrated by IR spectroscopy [118].

Carbazic acid is formed as a white powder by way of a hydrazinium salt [122] when CO_2 is passed into hydrazine for several days [116]. Dithiocarbazic acids (*N,N*-dimethyl-, *N,N*-diethyl-, *N,N*-diisopropyl-, *N,N*-pentamethylene- [*], and *N*-phenyldithiocarbazic acids) and diselenocarbazic acids (*N,N*-dimethyl- and *N*-phenyldiselenocarbazic acids) are formed as white or orange-red crystals on dropwise addition of aqueous solutions of their salts to an equimolar quantity of 6 N hydrochloric acid [118a]. *N,N*-Diisopropylthioselenocarbazic acid is formed by reaction of *N*-isothiocyanatodiisopropylamine with H_2Se; an analogous reaction with H_2Te yielded only ditelluride [118b]

5.3. Chalcogenoisocyanic Acids

Anions of chalcogenoisocyanic acids are formed by addition of O, S, Se, or Te to cyanide [1]. Salts of OCN^-, SCN^-, and $SeCN^-$ [123] have been known for a long time; $TeCN^-$, on the other hand, has only been detected in small concentrations in aqueous solution by its UV spectrum [124], whereas all attempts to prepare it as such have so far been unsuccessful [125].

The simple linear shape of the chalcogenocyanates, their interesting formation conditions, and their pronounced tendency to form complexes have led to numerous investigations on their vibration [126] and electronic excitation spectra [124] as well as to crystal structure determinations [126] and theoretical calculations [127, 128]. The metal complexes can contain X-metal or N-metal bonds, or even metal-XCN-metal bonds with an XCN bridge. The fundamental vibration frequencies of the anions accordingly differ widely [126].

Of the free acids, isocyanic acid can be obtained by pyrolysis of its trimer, cyanuric acid, at red heat [129] or by passage of HCl gas through dry NaNCO [130] and collection of the escaping gas at −78 °C; the acid obtained by the second of these methods contains less impurity [130]. In the pure state it is a colorless liquid that polymerizes readily (m.p. −86 °C, b.p. 23.5 °C, formation of macromolecular cyamelide below 150 °C and of trimeric cyanuric acid above 150 °C [129]), which is stable only at −78 °C and occurs in the solid state in a high-temperature and a low-temperature modification (transition point about −100 °C) [131]. In all aggregation states and in apolar solvents it exists only as isocyanic acid molecules H−N=C=O [131, 132]. In the crystal lattice of the solid acid, the molecules of the high-temperature modification are held together by N−H···N bonds, and those of the low-temperature modification by N−H···O bonds [131]. Isocyanic acid is a medium-strong acid in aqueous solution ($K_a = 3.4 \times 10^{-4}$ at 25 °C) [134].

Isothiocyanic acid is formed as a colorless gas on careful reaction of KSCN with $KHSO_4$ [135]; it can be condensed at −190 °C to form a white solid, which melts at −110 °C and trimerizes above −90 °C; extensive polymerization takes place above 0 °C [135]. The gas phase and solutions in apolar solvents again contain only isothiocyanic acid molecules H−N=C=S [136]; in polar solvents, on the other hand, an equilibrium probably occurs with the thiocyanic

[122] The compound is reported to be distillable [116]. No structural investigations have been reported.

acid form $N\equiv C-S-H$[136]. Isothiocyanic acid is a strong acid in aqueous solution (K = 69 at 25 °C)[137].

Dilute aqueous solutions of selenocyanic acid, which rapidly decompose with separation of selenium, are formed by the action of H_2S on lead selenocyanate[138]. No attempt has yet been made to prepare this acid again in nonaqueous media.

6. Chalcogenocarbonic Acids Containing Phosphorus

The phosphinochalcogenoformic acids $H_2P-CXXH$, which would correspond to the chalcogenocarbamic acids, have not yet been prepared. Metal complexes of *P,P*-diphenylphosphinomonothioformic and -dithioformic acids are formed on reaction of phenyldiphenylphosphinozinc[139], triphenyldiphenylphosphinotin[140], and tetrakis(diphenylphosphino)tin[140] with CS_2 or COS. According to their IR spectrum these last complexes contain covalent Sn–S and Sn–O bonds[140].

When CS_2 or CSe_2 is brought into contact with tertiary phosphines, zwitterions of the phosphinoformic acids are formed[141]. Corresponding carbamic acids are unknown.

The betaines are much more stable than the rapidly decomposing zwitterions of the *N,N*-dialkylcarbamic acids, but react as a mixture of tertiary phosphine and CS_2[141,142]. Their structure has been confirmed by IR spectroscopic studies[141,143] and a crystal structure determination[144] on the triethylphosphine–CS_2 compound ("triethylscarphan").

CS_2 reacts with Pt(0)- or Pd(0)-triphenylphosphines to give addition compounds having the formulas $Pt[P(C_6H_5)_3]\cdot CS_2$ and $Pd[P(C_6H_5)_3]\cdot CS_2$. These compounds do not contain C–P bonds; on the contrary, an angular CS_2 molecule (136 and 139.7 °) is bound to Pt or Pd by C and an S atom[145]. Similar complexes with CS_2 and COS are known for other transition metals[145].

7. Chalcogenocarbonic Acids Containing Halogen and Pseudohalogen

Halogen derivatives of the chalcogenocarbonic acids YCXXH (where X = chalcogen, Y = halogen) are named as halogenoformic acids. Only the esters are known so far as stable solid compounds. Free chloroformic acid[67] is formed in the photochemical reaction of Cl_2-formic acid mixtures as a short-lived intermediate having a half-life of 50 to 70 μsec[146]; it has been detected by means of its C–Cl absorption at 768 cm^{-1} with a fast-recording instrument in a mixture ignited by flash photolysis. Chloroformic acid decomposes into CO_2 and HCl. Chlorothioformic acid is reported to be formed on careful hydrolysis of thiophosgene[147]. Halogenoformic acids are also postulated as active substances in the corrosion of metals by halogens[148].

On the other hand, cyanodithioformic acid, which contains the pseudohalogen CN, and which precipitates out as a colorless solid on dropwise addition of hydrochloric acid to a nonaqueous solution of one of its salts, is surprisingly stable[149]. Its salts are formed on reaction of CS_2 with cyanides in dimethylformamide[149–151]. The sodium salt changes readily into the disodium salt of dimercaptomaleonitrile[149,150].

Salts of cyanodiselenoformic acid are formed in a vigorous reaction of CSe_2 with cyanide, again in dimethylformamide[149].

8. Chalcogenocarbonic Acids in the Ortho Form

Very stable tetraalkyl esters of chalcogenocarbonic acids with four chalcogen atoms directly bonded to the C atom can be prepared [1]. On the other hand, neither the free acids nor any of their salts can be obtained as such, or even detected indirectly, though ortho compounds of this type are frequently postulated as intermediates in the hydration of carbon dioxide [152] and in the formation and decomposition of trithiocarbonate [2, 153], xanthate [2, 3, 154], and carbamate [155]. Though plausibility considerations are very convincing, particularly in the xanthate reactions [3], there is still absolutely no proof of the occurrence of such intermediates.

The same is true of the silver salts that are reported to be formed from xanthate and $AgNO_3$ [2] and of a nickel orthocarbonate [156] whose occurrence has been postulated in the thermogravimetric degradation of basic nickel carbonates.

9. Perchalcogenocarbonic Acids

In this context the term "perchalcogenocarbonic acids" will be taken to mean compounds that contain the grouping X–X instead of a single chalcogen atom X.

9.1. Peroxocarbonic Acid and Peroxocarbonates [157]

Peroxocarbonates can be obtained by three methods:

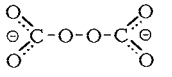
1. Anodic oxidation of concentrated carbonate solutions [158];

2. Action of CO_2 on peroxides or hydrogen peroxides [159];

3. Reaction of carbonate or ethyl carbonate with H_2O_2 [160].

Only the products obtained by methods 1 and 2 are true peroxocarbonates with C–O–O bonds. The third reaction yields carbonates containing H_2O_2 of crystallization [161].

The composition of the peroxocarbonates varies widely with the preparation conditions, and whereas extensive studies have provided considerable information on the kinetics of their anodic formation [158], nothing definite is yet known about the structure of individual peroxocarbonates. Suggestions [157] include the formulas of a simple peroxocarbonate CO_4^{2-}, a dimer [162],



and a hydrogen peroxocarbonate HCO_4^-.

Free peroxocarbonic acid is reported to be formed on reaction of peroxocarbonates with phosphoric acid as a substance that can be extracted with ether [163], as well as from CO_2 and H_2O_2 in aqueous solution [164] and on irradiation of water containing CO_2 with X rays [165]. These data are based more on assumptions than on accurate identification of the acid formed, and have in some cases been definitely refuted [163, 164]. On the other hand, polarographic studies have shown that the hydrolytic decomposition of peroxocarbonates in aqueous solution proceeds *via* a free acid [166].

9.2. Perthiocarbonic Acid and Perthiocarbonates

Solutions of the supposed trithioperoxocarbonate ion CS_3O^{2-} are formed when dilute aqueous trithiocarbonate solutions are left in air for several days [2, 167]. The solutions give UV absorptions at 308 and 378 nm, whereas the absorption bands of the CS_3^{2-} ion have completely disappeared. Solutions exhibiting the same UV absorption are also formed on saturation of dilute hydrogen sulfide solutions with COS and O_2 [2].

The tetrathiocarbonate ion CS_4^{2-} (referred to as perthiocarbonate in the following discussion) is formed on reaction of disulfides with CS_2 in alcohol; crystalline or initially oily salts can be precipitated with ether [7, 49]. Solutions of CS_4^{2-} are also formed on treatment of trithiocarbonate solutions with sulfur [2, 168]. The known salts include alkali metal salts,

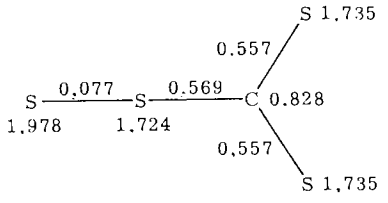
in some cases with widely differing contents of water of crystallization[169], calcium salts having widely varying compositions[170], and a few transition metal complexes[120,171].

Analysis of the vibration spectrum of the CS_4^{2-} ion shows that it has a true perthiocarbonate structure[172]. An elementary HMO calculation gave the π-electron densities and π-bond orders shown in Scheme 4[172].



Scheme 4.

Free perthiocarbonic acid H_2CS_4 is formed on reaction of equimolar quantities of ammonium perthiocarbonate and HCl gas in dimethyl ether at −78 °C[49]; filtration of the solution and evaporation of the dimethyl ether at −78 °C under vacuum yields H_2CS_4 as a yellow crystalline substance melting at −36.5 °C to give a red oil, which rapidly becomes cloudy owing to the separation of sulfur. The acid is stable at −190 °C; at −78 °C, it decomposes slowly into H_2S, CS_2, and sulfur. The IR spectrum of H_2CS_4 in CCl_4 contains two S–H stretching bands at 2575 and 2395 cm^{-1}; H_2CS_4 thus has the unsymmetrical structure HS–C(S)–S–S–H. This structure explains why H_2CS_4 cannot be obtained from H_2CS_3 and sulfur[168], whereas its anion can be obtained by reactions of this type. The thermodynamic data obtained by vapor pressure measurements over the decomposing acid[49], in conjunction with the corresponding data for trithiocarbonic acid[51], show that the formation of the perthio acid from H_2CS_3 and S would be thermodynamically possible above 57 °C. However, neither H_2CS_4 nor H_2CS_3 is stable at this temperature. Dissociation constants of perthiocarbonic acid in aqueous solution are given in Table 4.

9.3. Peroxocarbonates Containing Selenium

CSe_3^{2-} solutions do not react with selenium[117]. Concentrated aqueous Na_2CS_3 solutions take up 0.6 g-atom of selenium per mole of CS_3^{2-}, but there is no evidence of compound formation corresponding to the formation of CS_4^{2-} from CS_3^{2-} and sulfur; Na_2CS_3 and selenium are precipitated separately on addition of alcohol and ether[173].

On the other hand, when a suspension of sulfur in an aqueous $BaCS_2Se$ solution is vigorously stirred, the UV bands of the CS_2Se^{2-} ion (325, 365, and 535 nm) disappear, to be replaced by a spectrum containing absorption bands at 319 and 397 nm, which (apart from a small shift toward longer wavelengths) is of the same form as the spectrum of the CS_4^{2-} ion[23]. It may therefore be assumed that an ion $^{\ominus}Se-C(S)-S-S^{\ominus}$ is formed.

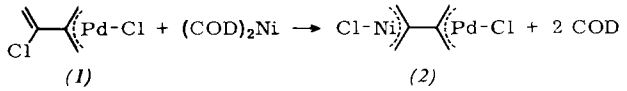
Bimetallic π-Allyl Complexes of Nickel and Palladium

By *W. Keim*[*]

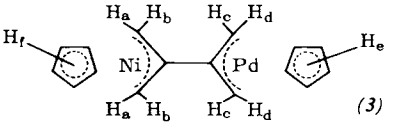
Dedicated to Professor K. Ziegler on the occasion of his 70th birthday

If, in accord with the method of *G. Wilke et al.*[1] for the preparation of π-allylnickel halides, bis(1,5-cyclooctadiene)-nickel is treated with *(1)*[2] in toluene for 24 h at 0 °C, the complex 2,2'-bis(π-allyl)dichloronickelpalladium *(2)* is formed in 70–80% yield. The precipitation of metallic nickel during the reaction suppresses the formation of *(2)*.



(1) *(2)*

The brown insoluble compound *(2)* reacts with cyclopentadienylsodium, forming 2,2'-bis(π-allyl)dicyclopentadienylnickelpalladium *(3)*, which is readily soluble in organic solvents, sublimes at 90 °C/10^{-4} torr, and forms red needles that decompose at 150–160 °C. Hydrogenation of *(3)* affords metallic nickel and palladium, 2,3-dimethylbutane, and cyclopentane. Its mass spectrum[3] is in accord with structure *(3)*. The ^1H–NMR spectrum shows six sharp signals (see Table 1).



(3)

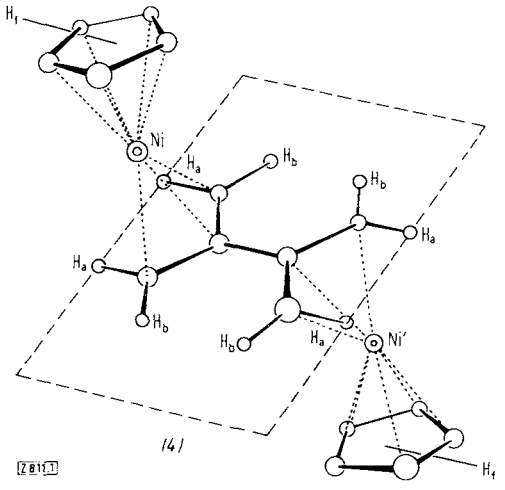
Table 1. ^1H–NMR spectral bands of *(3)* and *(4)* in C_6D_6 at ~ 30 °C (internal reference tetramethylsilane; Varian A 60).

Proton	*(3)* (ppm)	*(3)* relative intensity	*(4)* (ppm)	*(4)* relative intensity
H_a	1.15	2	1.3	2
H_b	2.75	2	3.05	2
H_c	3.65	2	—	—
H_d	2.15	2	—	—
H_e	5.75	5	—	—
H_f	5.15	5	5.30	5

If a tetrahydrofuran/hexane solution of *(3)* is kept for three months at 25 °C, deep red crystals of composition $C_{16}H_{18}Ni_2$ separate, apparently owing to the transmetalation:

$$2\ C_{16}H_{18}NiPd \rightarrow C_{16}H_{18}Ni_2 + C_{16}H_{18}Pd_2$$
(3) *(4)* *(5)*

The mass spectrum [3] of the complex *(4)* shows the expected signals. The ^1H–NMR spectrum shows three sharp signals (see Table 1).



(4)

An X-ray structure analysis confirms the π-allyl structure assigned to *(4)*, the nickel atoms and the cyclopentadienyl rings being in *trans*-positions to one another [4]. The complex *(5)* has not yet been isolated with complete spectral and analytical purity.

Hydrogenation of Polyenes by Tricarbonylcyclopentadienylhydrido-molybdenum and -tungsten

By *A. Miyake* and *H. Kondo* [*]

Dedicated to Professor K. Ziegler on the occasion of his 70th birthday

Tricarbonylcyclopentadienylhydridochromium *(1)* hydrogenates polyenes [1]. We have now found that the corresponding complexes of Mo [*(2)*] and W [*(3)*] react analogously.

If a solution of isoprene *(4)* (0.23 g, 3.4 mmoles) and tricarbonylcyclopentadienylhydridomolybdenum *(2)* [2] (1.54 g, 6.3 mmoles) in *n*-heptane (10 ml) is warmed to 59 °C, the solution at once becomes red and bis(tricarbonylcyclopentadienylmolybdenum) *(5)* soon separates as red crystals. After 4.7 h the reaction mixture was analyzed by gas chromatography; it contained 2-methyl-2-butene, 2-methyl-1-butene,

$$2\ C_5H_5(CO)_3MoH + CH_2{=}CH{-}C(CH_3){=}CH_2 \rightarrow$$
(2) *(4)*

$$[C_5H_5(CO)_3Mo]_2 + CH_3{-}CH{=}C(CH_3)_2$$
(5)

$$2\ C_5H_5(CO)_3WH + CH_2{=}CH{-}(CH{=}CH)_2{-}CH{=}CH_2 \rightarrow$$
(3) *(6)*

$$[C_5H_5(CO)_3W]_2 + CH_3{-}(CH{=}CH)_3{-}CH_3$$
(7) *(8)*

$C_5H_5(CO)_3CrH$ *(1)* $[C_5H_5(CO)_3Cr]_2$ *(9)*

3-methyl-1-butene, and unchanged *(4)* in the molar ratio 82:6:3:9.

1,3,5,7-Octatetraene *(6)* [3] (0.5 g, 4.1 mmoles) in *n*-pentane (20 ml) was treated with tricarbonylcyclopentadienylhydridotungsten *(3)* [3] (3.2 g, 9.6 mmoles); red crystals of bis(tricarbonylcyclopentadienyltungsten) *(7)* separated at once. After 4.7 h the reaction mixture was analyzed by gas chromatography. It contained 2,4,6-octatriene *(8)* and unidentified products (three components) in the ratio 89:11. The tetraene *(6)* was completely consumed. The triene *(8)* was gas-chromatographically identical with a sample obtained by another route [4].

Table 1. Half-reaction time for hydrogenation of polyenes by hydrido complexes.

Hydrido-complex	Polyene	Temp. (°C)	$t_{1/2}$ [a] (hr)	Products
(1)	2,4-Hexadiene	20	6	[b]
(2)	2,4-Hexadiene	59	20	[c]
(2)	4-Methyl-1,3-pentadiene	20	10	[d]
(2)	4-Methyl-1,3-pentadiene	59	0.2	[d]
(2)	2,4,6-Octatriene	20	0.1	[e]
(2)	1,3,5-Hexatriene	20	0.03	[f]
(3)	4-Methyl-1,3-pentadiene	60	70	[g]
(3)	1,3,5-Hexatriene	20	9	[h]
(3)	1,3,5,7-Octatetraene	20	0.2	[i]

[a] Half-reaction time for the polyene in a mixture with initial concentrations: polyene 0.5 mole/l; hydrido complex 1 mole/l. Hydrogenation products:

[b] *trans*-2- and -3-Hexene 89%, *cis*-2- and -3-hexene 11%.

[c] *trans*-2- and -3-Hexene 79%, *cis*-2- and -3-hexene 21%.

[d] 2-Methyl-2-pentene 76%, 4-methyl-2-pentene 24%.

[e] Two products (probably 3,5-octadiene and 2,4-octadiene) in the ratio 83:17.

[f] 2,4-Hexadiene, *trans,trans* 66%, *trans,cis* 31%, *cis,cis* 3%.

[g] 2-Methyl-2-pentene 72%, 4-methyl-2-pentene 28%.

[h] 2,4-Hexadiene, *trans,trans* 67%, *trans,cis* 30%, *cis,cis* 4%.

[i] See text.

As shown in Table 1, the reactivity of the hydrido complexes decreases in the series *(1)* > *(2)* > *(3)*. *(1)* reacts 10^2 to 10^3 times faster than *(2)*, and *(2)* reacts 10^2 to 10^3 times faster than *(3)*. The reactivity of the polyenes increases with increasing number of conjugated double bonds.

The Mo–Mo and W–W bonds in *(5)* and *(7)* are much more stable than the readily fissile Cr–Cr bond in bis(tricarbonylcyclopentadienylchromium) *(9)* [5]. Whereas hydrogenation of *(9)* to *(1)* proceeds smoothly [1,2], reduction of *(5)* or *(7)* by hydrogen to *(2)* or *(3)*, respectively, is not to be expected; and our attempts to reduce polyenes catalytically by means of *(5)* or *(7)* were unsuccessful. When compared with hydro-

genation catalyzed by *(9)*, the stoichiometric hydrogenation by the readily accessible complexes *(2)* and *(3)* has the advantage that conjugated polyenes can be reduced stepwise.

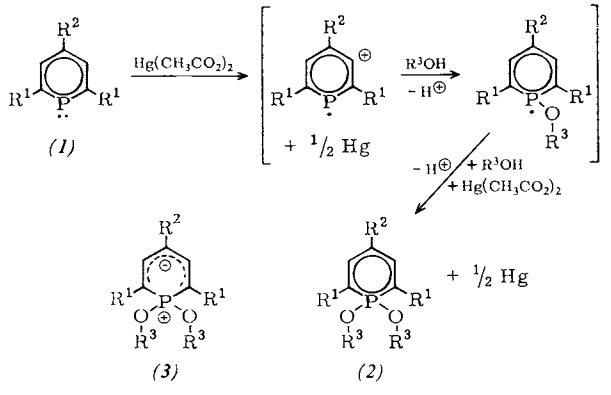
1,1-Dialkoxy- and 1,1-Diaryloxy-phosphorins, a New Class of Organophosphorus Compounds

By *K. Dimroth* and *W. Städel*[*]

Dedicated to Professor K. Ziegler on the occasion of his 70th birthday

2,4,6-Trisubstituted phosphorins *(1a)–(1f)* are oxidized to stable radical cations by, *inter alia*, mercury(II) acetate[1,2]; in the presence of alcohols or phenols the reaction proceeds with separation of mercury to form the novel, strongly fluorescent 1,1-dialkoxy- or 1,1-diaryloxyphosphorins *(2a)* to *(2f)* as highly stable crystalline compounds. The reaction probably proceeds *via* the cation radical stage, which can be detected by ESR spectroscopy.

The new compounds *(2)* (for examples, see Table) are only weakly basic. We were not able to alkylate them with oxonium salts, nor acylate them with acyl chlorides. They are insoluble in dilute acids and are protonated only by strong acids such as trifluoroacetic acid, whereupon their fluorescence disappears; compounds *(2)* are regenerated on treatment with bases. ^{1}H–NMR-spectroscopic observations on *(2b)* and deuteriotrifluoroacetic acid showed that C-2 and C-4 are protonated in the ratio of 3:1. The low basicity of compounds *(2)* and comparison of the dipole moments [*(1a)*: μ = 1.54 D; *(2a)*: μ = 1.28 D (both in benzene)] indicate structure *(2)* rather than *(3)*.



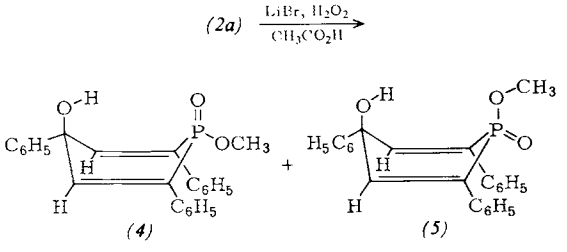
(1) *(3)* *(2)*

The symmetrical structure of compounds *(2)* is proved by ^{1}H–NMR measurements on *(2b)* in $CDCl_3$. The protons attached to C-3 and C-5 give rise to a doublet at $\delta = -7.93$ ppm ($J_{P-C-C-H} = 36.5$ Hz); the signal of the methoxy protons ($\delta = -3.40$ ppm) is split to a doublet by coupling with the phosphorus ($J_{P-O-C-H} = 13.5$ Hz). TMS as internal reference.)

The ^{31}P–NMR signals of *(2a)–(2d)* in benzene lie between −58 to −65 ppm and show only a slight shift in trifluoroacetic acid [*(2a)* in benzene: $\delta = -65.2$ ppm, in trifluoroacetic acid: $\delta = -62.2$ ppm; *(1a)* in benzene: $\delta = -178.2$ ppm; measured with respect to 85% H_3PO_4 as external reference].

Compounds *(2)* can be both oxidized to novel stable phosphorus radical cations [coupling constant for *(2a)* $a_P = 20.1$ gauss] and reduced to radical anions that are likewise new. During the latter process, a doublet having $a_P = 31.6$ gauss is first observed, which changes to a broad singlet, having a suggestion of a fine structure, on further reduction[3].

Treatment of *(2a)* in dimethoxyethane with LiBr, acetic anhydride, and H_2O_2 affords the isomers *(4)* and *(5)* of 1-methoxy-2,4,6-triphenyl-4-hydroxy-1-phospha-2,5-cyclohexadienone (m.p. 198 °–200 °C and 194–198 °C). Their OH groups can be acetylated without isomerization with acetic anhydride in pyridine. However, with trifluoroacetic acid, *(4)* and *(5)* give the same deep blue salt *(6)* [λ_{max} in trifluoroacetic acid = 335 nm ($\varepsilon = 0.46 \times 10^4$), 394 ($0.49 \times 10^4$), 560 ($3.54 \times 10^4$), and 695 ($2.53 \times 10^4$)] (cf. reference[4]). *(6)* affords *(7)* and *(8)* when treated with alcohols, and regenerates *(4)* and *(5)* with aqueous acetic acid.



(4) *(5)*

The NMR data recorded for compounds *(2)* show a marked similarity to those of 1-alkyl-1-phenyl-2,4,6-triphenylphosphorins, which were obtained by *Märkl et al.*[5] and for which an "aromatic" bonding state with contributions from d_π-p_π bonds comes into consideration – as is the case with our compounds *(2)*.

	R^1	R^2	R^3	*(2)* M.p. (°C)	λ_{max} (nm) [c] 1.	2.	$\varepsilon \times 10^{-4}$ 1.	2.

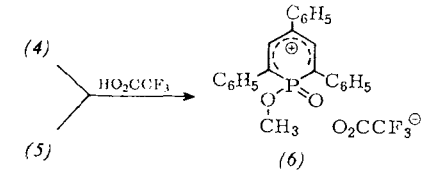
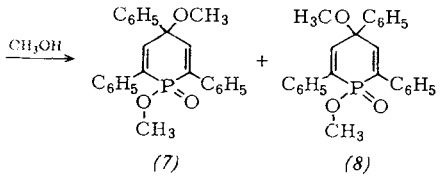
[a] Fluorescence maximum at 490 nm (in methanol).

[b] No fluorescence (in dichloromethane).

[c] In cyclohexane.





1,1-Dimethoxy-2,4,6-triphenylphosphorin (2a):

2,4,6-Triphenylphosphorin *(1a)* (0.84 g, 2,6 mmole) and mercury(II) acetate (0.83 g, 2.6 mmole) are stirred for 15 h at 20 °C in a mixture of dry benzene/methanol (1:1) (100 ml). Column chromatography on silica gel in benzene affords analytically pure *(2a)* (0.78 g, 77% yield) having m.p. 112 °C.

Stereoisomeric 4-hydroxy-1-methoxy-2,4,6-triphenyl-1-phospha-2,5-cyclohexadien-1-one (4) and (5):

30% hydrogen peroxide (2.5 g) and acetic anhydride (2.5 g) are added to *(2a)* (2.5 g, 6.5 mmole) and LiBr (3.0 g, 34 mmole) in dimethoxyethane (50 ml) with ice-cooling and stirring; the mixture is then stirred for 15 h at 20 °C. Column chromatography in benzene/acetic ester (4:1) on silica gel yields *(4)* [0.3 g, m.p. 198–200 °C (decomp.)] and *(5)* [0.08 g, m.p. 194–198 °C (decomp.)] (yields 12% and 2%, respectively), alongside other unidentified substances. ^{1}H–NMR spectra (in [D_6]-dimethyl sulfoxide): *(4)* and *(5)*, respectively: δ = −6.8 to −7.4 and −6.8 to −7.3 ppm, resp. (15 phenyl protons), m; δ = −6.35 and −6.31 ppm, resp. (H attached to C-3 and C-5), d, J_{P-H} = 32 and 33 Hz, resp.; δ = −6.37 and −6.40 ppm, resp. (hydroxyl proton), s; δ = −3.16 and −3.24 ppm, resp. (methoxy protons), d, J_{P-H} = 12 and 11 Hz, resp.; TMS as internal reference.

Stereoisomeric 1,4-dimethoxy-2,4,6-triphenyl-1-phospha-2,5-cyclohexadien-1-one (7) and (8):

(4) (0.30 g, 0.77 mmole) is dissolved in trifluoroacetic acid (5 ml) and stirred for 1 h. Methanol (100 ml) is then added dropwise to the deep blue solution. Column chromatography over silica gel in benzene/acetic ester (5:1) affords a mixture (0.15 g, 50% yield) of the isomers *(7)* and *(8)* in the approximate ratio of 1:1 and having m.p. 98–101 °C. ^{1}H–NMR spectra (in $CDCl_3$): δ = −6.8 to −7.3 ppm (2 × 15 phenyl protons), m; δ = −6.16 ppm (H attached to C-3 and C-5), d, J_{P-H} = 33 Hz; δ = −6.11 ppm (H attached to C-3 and C-5), d, J_{P-H} = 33 Hz; δ = −3.30 ppm (2 × methoxy protons), s; δ = −3.26 ppm ($POCH_3$ protons), d, J_{P-H} = 12 Hz; δ = −3.24 ppm ($POCH_3$ protons), d, J_{P-H} = 12 Hz; TMS as internal reference.

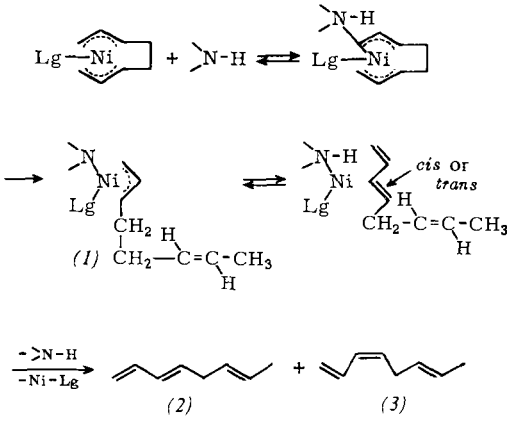
cis,trans- and *trans,trans*-1,3,6-Octatriene from Butadiene

By *P. Heimbach*[*]

Dedicated to Professor K. Ziegler on the occasion of his 70th birthday

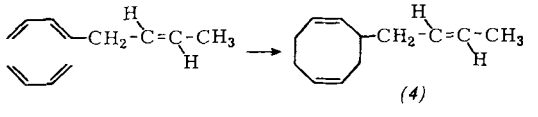
In the presence of morpholine (or another dialkylamine) butadiene is dimerized almost exclusively to *cis,trans-* and *trans,trans*-1,3,6-octatriene *(3)* and *(2)*, respectively, at a nickel-triethyl phosphite catalyst[1–3]; the yield is 90% at 50% conversion. (Molar proportions at the beginning of the reaction Ni: $P(OC_2H_5)_3$: morpholine: butadiene = 1:1:50:800.)



Scheme 1. Lg = phosphite or phosphine.

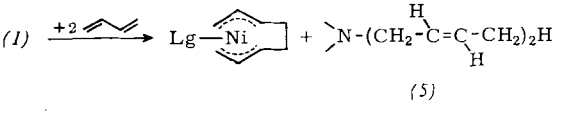
Evidence for the reaction's proceeding according to Scheme 1 is provided by the following observations:

1. When *o*-substituted triaryl phosphites are present as ligands (Lg), which screen the higher coordination positions of the Ni[4], they lead to formation mainly of eight-membered rings that otherwise arise only in the absence of amines. In addition, codimerization of butadiene with 1,3,6-octatriene occurs [up to 25% of the reaction product consists of *(4)*].

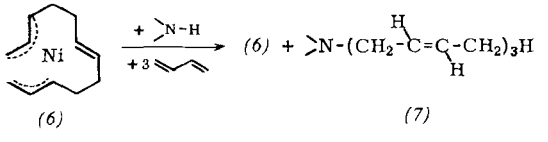


2. If *cis*-1,2-divinylcyclobutane, which rearranges to the bis-(π-allyl) chain at the nickel[5], is used in place of butadiene, then compounds *(2)* and *(3)*, as well as C_{16} olefins, are formed alongside *cis,cis*-cyclooctadiene at almost quantitative conversion. Under the same conditions, butadiene affords C_{12} and C_{16} olefins (see below).

3. The formation of trialkylamines in a side reaction is in accord with the proposed course of the reaction. This aminoalkylation, which yields *(5)*, becomes the main reaction at 20 °C (>75% yield calculated with respect to reacted amine).



In the absence of additional phosphorus-containing ligands, three butadiene molecules are joined to one amine molecule in the presence of nickel to form *(7)*. *(5)* and *(7)* can be hydrogenated to the saturated tertiary amines[6].



4. The reaction course proposed in Scheme 1 corresponds to the dimerization of butadiene to methylheptatriene in the presence of cobalt catalysts[7,8]; "Co–H" and "N–Ni–H" would be comparable with each other as "active principle". If the conversion of butadiene is too high, compounds *(2)* and *(3)* react further as 1,3-dienes with butadiene to form mainly the butenyloctatrienes 4(2-*trans*-butenyl)-1,3,6-*trans*-octatriene, 5-(2-*trans*-butenyl)-1,3-*trans*, 6-*trans*-octatriene, 5-(2-*trans*-butenyl)-1,3-*cis*, 6-*trans*-octatriene.

Similarly to butadiene, substituted butadienes can also be dimerized. A 1:1 mixture of *(2)* and *(3)* yields 61% of 5,6-dipropyldecane, 38% of 5-propyltridecane, and 1% of hexadecane (after hydrogenation).

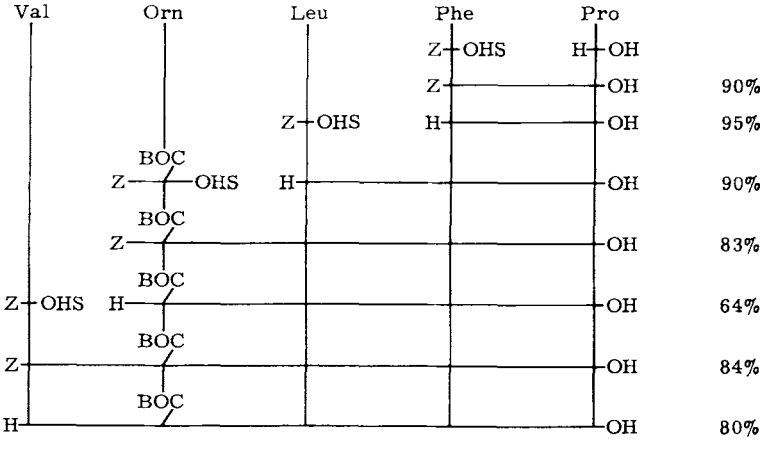
Synthesis of all-L-Gramicidin S[1][**]

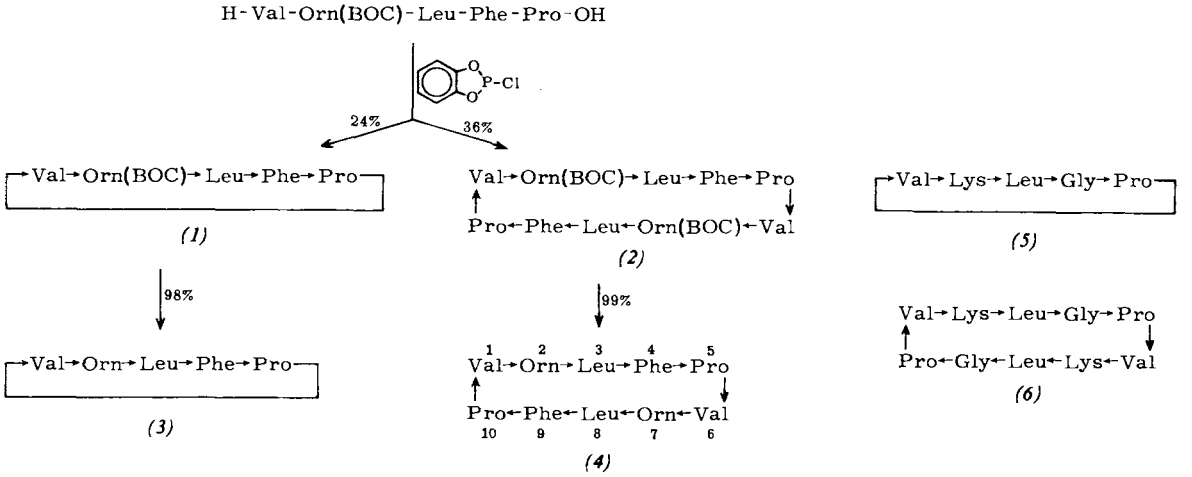
By *M. Rothe* and *F. Eisenbeiss*[*]

We have synthesized the long sought[3] cyclodecapeptide all-L-gramicidin S *(4)*, in which the two D-phenylalanine groups of gramicidin S (from *Bacillus brevis*) are replaced by the L-isomer[2].

We first prepared the linear pentapeptide Val-Orn(BOC)-Leu-Phe-Pro by stepwise synthesis from the carboxyl end by the hydroxysuccinimide ester method[4]. The path of the synthesis is shown in Schemes 1 and 2. The ring closure proceeded in 60% yield by the phosphite method[5] with *o*-phenylene chlorophosphite[6] in 5×10^{-3} M solution in diethyl phosphite at 100 °C. The reaction led, not only to the 15-membered cyclopentapeptide *(1)*, but also by dimerization to the desired 30-membered cyclodecapeptide *(2)* (ratio about 2:3); the products were separated on Sephadex LH 20 in methanol solution. The ring sizes were established by



Scheme 1. Synthesis of Val-Orn(BOC)-Leu-Phe-Pro. The values on the right are the yields of recrystallized TLC-pure products. BOC = *tert*-butyloxycarbonyl, Z = benzyloxycarbonyl, OHS = hydroxysuccinimide ester.



Scheme 2. Synthesis of cyclosemi-all-L-gramicidin S *(3)* and all-L-gramicidin S *(4)*. *(5)* and *(6)* were prepared in a similar manner.

molecular weight determinations [*(1)*: calc. 670.9, found 671 by mass spectrometry; *(2)*: calc. 1341.7, found 1275 by vapor pressure osmometry]. The δ-BOC protective group of the ornithine was removed with N HCl/glacial acetic acid at room temperature.

The dihydrochloride of *(4)* crystallizes as rods from ethanol/2 N HCl; the analytical data point to a tetrahydrate. The quantitative amino-acid analysis[7] after total hydrolysis (6 N HCl, 110 °C) gave the following values: Val 0.92, Orn 1.14, Leu 1.01, Phe 1.05, Pro 1.00 (reference value).

Lys^2, Gly^4-cyclosemigramicidin S *(5)* and Lys^2, Gly^4, Lys^7, Gly^9-gramicidin S *(6)* could be obtained in a similar manner as the hydrochloride and the dihydrochloride respectively. Some physical data for compounds *(1)–(6)* are given in Table 1.

Table 1. Physical data for *(1)–(6)*.

Cpd.	M.p. (°C)	$[\alpha]_D^t$ (°)	*t* (°C)	*c*	Solvent
(1)	136	−111.8	26	0.8	Methanol
(2)	185–190 decomp.	−82.1	26	1.54	Methanol
(3) [b]	184	−91.4	25	0.33	Methanol
(4) [a]	246–247	−76.8	24	0.66	60%Ethanol
(5) [b]	204–206	−156.1	25	0.92	Ethanol
(6) [a]	275 decomp.	−191.9	23	0.6	Methanol

[a] Dihydrochloride; [b] Hydrochloride.

All-L-gramicidin S and the cyclopeptides *(5)* and *(6)* have no antibiotic activity toward gram-negative bacteria (*E.coli*); *(6)* shows growth inhibition > 40 μg/ml [10^6 organisms], glucose broth, against gram-positive bacteria (*Staph. aureus*); gramicidin S (synthesized according to *Merrifield* and cyclized as described above) gives a value of < 1 μg/ml[8]. This shows that in addition to the known factors (basic amino acids, hydrophobic side chains, minimum ring size), the D-amino acids are also essential to the activity of cyclopeptide antibiotics (specific conformation, resistance to enzymatic cleavage).

The ring closure to form *(1)* and *(2)* is a new example of the concentration- and solvent-dependent formation of homologous rings in the cyclization of oligopeptides[2,9].

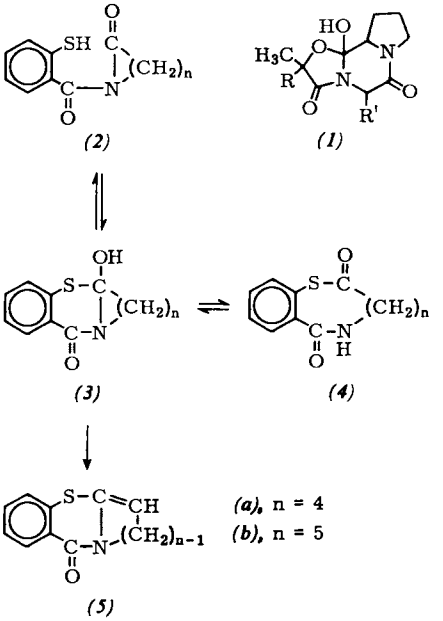
Thiacyclols and Cyclothiodepsipeptides[1][**]

By *M. Rothe* and *R. Steinberger*[*]

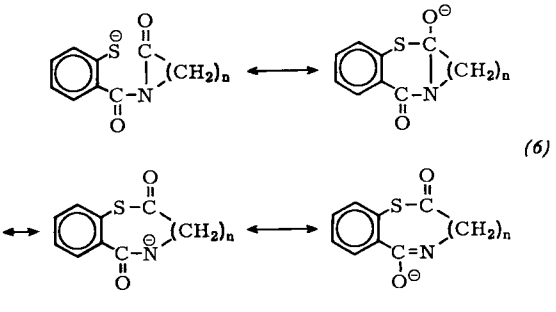
Orthocarboxylic acid derivatives containing a free OH group are stable only in exceptional cases, *e.g.* in the form of the cyclol grouping[2], which occurs in the peptide part of the ergot alkaloids *(1)*.

We have synthesized the first thiacyclols *(3)*[***], *N*-acylated orthoacid monothioester monoamides, from *N*-(ω-mercaptoacyl)lactams *(2)* which can be obtained from *S*-protected mercaptoacyl chlorides and *N*-trimethylsilyllactams by elimination of trimethylchlorosilane followed by removal of the protective group[3]. Aromatic *o*-mercaptoacyllactams, *e.g.* *N*-(*o*-mercaptobenzoyl)-δ-valerolactam *(2a)* and -ε-caprolactam *(2b)*, are unstable, and react spontaneously to form the thiacyclols *(3a)* and *(3b)* or to give the cyclothiodepsipeptides *(4a)* and *(4b)*, which have also been unknown until now.



The structures of *(3)* and *(4)* are clearly shown by their IR spectra (Table 1). Cyclothiodepsipeptides give the characteristic thioester and amide-II bands, which do not appear in the spectra of the thiacyclols. As expected, the thiacyclols give only one a carbonyl band and the OH band, while the mass spectrum contains a weak molecular peak, together with a strong peak at M − 18 corresponding to dehydrothiacyclol *(5a)*, m.p. 60.5–61.5 °C, whose double bond can be detected by NMR spectroscopy (one vinyl proton at τ = 4.92 in CCl_4, TMS as internal reference). This dehydration can also be detected in the mass spectrum of the cyclothiodepsipeptides, and shows the ease of cyclol formation with transannular amide-thioester interaction in ten- and eleven-membered rings. *(5a)* was synthesized from *(3a)* by dehydration with acidic Al_2O_3 (activity I).

The existence of the equilibrium *(2)* ⇌ *(3)* ⇌ *(4)* is shown by the conversion of *(3b)* into *(4b)* in acetone/water, which can



(6)

be accelerated by the addition of catalytic quantities of $OH^{\ominus}$, and by the methylation of *(3b)* with CH_3I under S_N2 conditions, the ambident anion *(6)* giving the *S*-methyl ether of *(2b)*, m.p. 88–89 °C. All the compounds were pure on thin layer chromatography and on analysis.

Table 1. Melting points and IR spectra of thiacyclols and cyclothiodepsipeptides.

	M.p. (°C)	ν (cm⁻¹) OH	NH	Amide I	Amide II	C=O (thioester)	C=O (thiazinone)

5a-Hydroxy-6,7,8,9-tetrahydro-5aH,11H-pyrido[2,1-b]benzo-[e]-[1,3]thiazin-11-one (3a)

Ag acetate (955 mg, 5% excess) is added under nitrogen to a solution of (*S*-acetyl-*o*-mercaptobenzoyl)valerolactam (1.50 g, 5.40 mmole) [m.p. 99–100 °C, synthesized according to ref. [3]] in methanol (30 ml) and pyridine (2 ml). The mixture is stirred for 30 min at room temperature, poured into water, and the colloidally dissolved Ag thiolate is salted out with HNO_3. The solid thus obtained is filtered off, dissolved in acetone/water (5:1) (50 ml), and H_2S is introduced into the solution with stirring. After the AgS has been filtered off and the acetone removed under vacuum, 950 mg (75%) of the crystalline thiacyclol *(3a)* (m.p. 129–130 °C) is obtained. Compound *(3a)* rapidly turns yellow to form *(5a)*, but is stable at −15 °C. *(3a)* (10.0 g) is recrystallized from a mixture of acetone (150 ml), water (75 ml), and triethylamine (0.5 ml). 75 mg of *(4a)* (m.p. 195–196 °C, from acetic acid) in the crystalline state is obtained at room temperature.

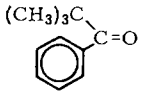
Energy Differences in the Inner Molecular Orbitals of *tert*-Butyl and Trimethylsilyl Phenyl Ketones[1]

By *H. Bock, H. Alt*, and *H. Seidl* [*]

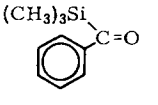
In contrast to the colorless alkyl ketones, monosilyl ketones are yellow [2,4] and disilyl ketones are violet [3]. The following interpretations are offered in the literature for the reduced excitation energy of the n → π* transition responsible for the color: (a) "Through space" interaction d_{Si}/n_0 between the free electron pair n_0 of the carbonyl oxygen, which is orthogonal to the CO π-system, and unoccupied 3d atomic orbitals of the silicon leads to a "superchromophore" Si–C=O [4]. (b) The π^*_{CO} molecular orbital is lowered by d_{Si}/π^*_{CO} splitting [5]. (c) The σ-donor and π-acceptor properties of R_3Si groups stabilize the n → π* excited state of the ketone π system relative to the ground state [6]. (d) The strong inductive effect of R_3Si groups increases in particular the level $E(n_0)$ of the free electron pair on the oxygen [7]. It should be possible to decide between these interpretations on the basis of additional energy data for alkyl and silyl ketones.

Investigations on the substituent effects of R_3C and R_3Si groups on linear and cyclic π-electron systems have shown that the following values can be used to determine the energy differences between the inner molecular orbitals π, n, and π*: According to *Koopmans'* theorem [8], vertical ionization energies IE found by mass spectroscopy correspond to the energy of the highest occupied molecular orbital $E(n)$ or $E(\pi)$ in the ground state [9]. Charge-transfer excitation energies $\tilde{\nu}_m^{CT}$ of suitable donor-acceptor complexes are proportional to the energy $E(\pi)$ of the highest occupied π molecular orbital [9,10]. Half-wave reduction potentials $E_{1/2}^{Red}$ can be correlated with the energy $E(\pi^*)$ of the lowest unoccupied π molecular orbital [11]. With the aid of the electronic excitation energies $\tilde{\nu}_m^{n\to\pi^*}$ and $\tilde{\nu}_m^{\pi\to\pi^*}$, these energy values can be used to construct approximate energy level diagrams for the inner molecular orbitals [12] by introduction of simplifying assumptions concerning the differentiation of molecular orbitals and electronic states.

The approximate energy level diagrams (Fig. 1) for *tert*-butyl *(1)* and trimethylsilyl phenyl ketone *(2)* may be deduced from the experimental values (Table 1).



(1)



(2)

Table 1. Experimental values for *tert*-butyl *(1)* and trimethylsilyl phenyl ketones *(2)*.

	IE (eV)	$\tilde{\nu}_m^{n\to\pi^*}$ (cm⁻¹)	$\tilde{\nu}_m^{\pi\to\pi^*}$ (cm⁻¹)	$E_{1/2}^{Red}$(V)	$\tilde{\nu}_m^{CT}$ (cm⁻¹) [a]
(1)	9.04	31250	42000	−1.57	19700
(2)	8.20	23650	40000	−1.30	21700
Δ	0.84	7600	2000	−0.27	−2000

[a] Measured for methyl and trimethylsilyl β-naphthyl ketone [13].

ΔIE is due to the different energies $E(n_0)$ of the free electron pair on the carbonyl oxygen, and is also reflected in the different p*K* values [14] of the two compounds. The lowering of the π* level in the silyl ketone *(2)* deduced from the large difference in the n → π* excitation energies $\Delta\tilde{\nu}_m^{n\to\pi^*}$ is confirmed by the fact that the half-wave reduction potential $E_{1/2}^{Red}$ of *(2)* is more positive. A similar lowering of the π level suggested by the smaller difference in the π → π* excitation energy $\Delta\tilde{\nu}_m^{\pi\to\pi^*}$ is confirmed by the different charge-transfer excitation energies $\tilde{\nu}_m^{CT}$ of tetracyanoethylene complexes of methyl and trimethylsilyl β-naphthyl ketone [13].

The fact that the n → π* excitation energy of the yellow silyl ketone is lower than that of the colorless *tert*-butyl ketone can be explained (on the basis of a σ/π separation) as follows: The strong inductive effect of the trimethylsilyl group $+I_{SiR_3} > +I_{CR_3}$ raises all the inner molecular orbitals. However, this becomes observable only in the free electron pair of the carbonyl oxygen, which is orthogonal to the π

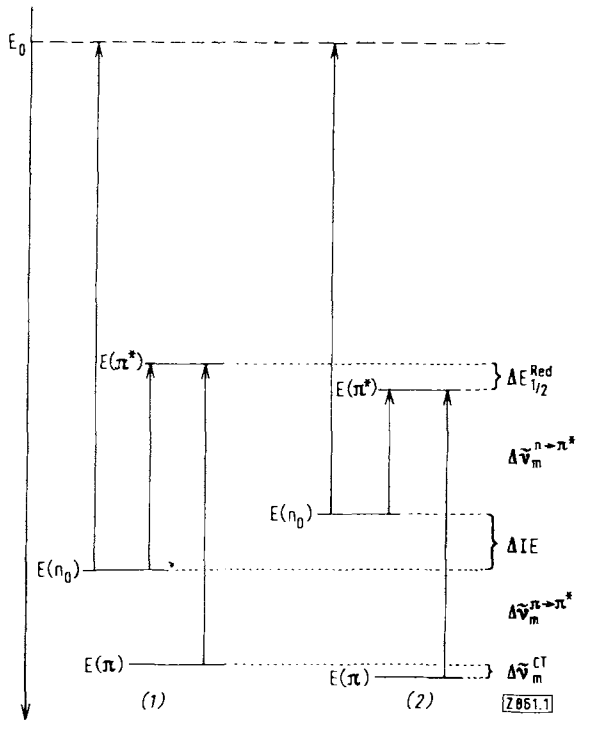


Fig. 1. Approximate energy level diagrams for *tert*-butyl *(1)* and trimethylsilyl phenyl ketone *(2)*.

system and is situated in the β position with respect to the silicon. The energies of the ground state and the excited states, on the other hand, are lowered by the possibility of back-donation Si ← C_π from the π system into empty atomic orbitals of the silicon, which is in the α-position in this case. As expected, this interaction is greater in the excited states because of the smaller energy difference in relation to the unoccupied Si acceptor orbitals. The acceptor function of trimethylsilyl groups, which must be of π symmetry, may involve unoccupied 3d atomic orbitals of the silicon.

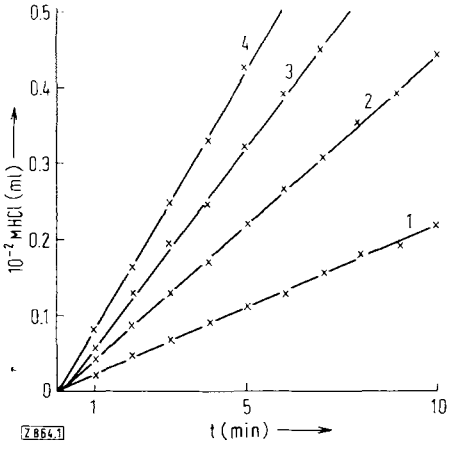
A New Test for the Determination of Pyruvate Decarboxylase Activity

By *A. Schellenberger, G. Hübner*, and *H. Lehmann* [*]

The hydroxide ions formed in the pyruvate decarboxylase reaction(PDC, 2-oxoacid carboxylase, EC 4.1.1.1) in accordance with

$$CH_3\text{–}CO\text{–}COO^\ominus \xrightarrow[+\,H_2O]{(PDC)} CH_3CHO + CO_2 + OH^\ominus$$

permit the accurate determination of the reaction rate by pH-stat titration. It can be seen from Figure 1 that the acid consumption increases linearly with time and that the slope of the curves is proportional to the enzyme concentration.



Owing to the sensitivity of the test, the pyruvate conversion is low, so that there is no inhibition of the reaction by the acetaldehyde formed. The fact that investigations can be carried out in buffer-free media, thus eliminating salt and foreign-ion effects, represents a further advantage. The enzyme activities found in the optical test described by *Holzer* [1] and in the Warburg test agree to within a good approximation with those found in the pH-stat test (Table 1).

Table 1. Comparison of enzyme activity measurements.

pH	Enzyme activity (I.U.)/0.05 ml standard (*ca.* 2 mg PDC/ml)		
	pH-stat test	optical test	Warburg test
5.2	0.29		
5.6	0.70		
6.0	0.88	0.90	0.82
6.4	0.79	0.80	
6.8	0.62	0.62	
7.5	0.16	0.16	

The pH-stat test can be used between pH = 5.2 and 7.5. The enzyme activities found at various pH values exhibit good agreement with those reported by *Singer* and *Pensky*[2].

The pH-stat test can also be used to measure the decarboxylation rate of substrate analogs such as aliphatic α-keto acids and substituted phenylglyoxylic acids, which cannot be measured by the optical test. Since no auxiliary enzyme system is required, the determination can also be carried out in the presence of product.

Friedel-Crafts Reactions of Octachlorocyclotetra(phosphazene)

By *V. B. Desai, R. A. Shaw*, and *B. C. Smith*[*]

Friedel-Crafts reactions of octachlorocyclotetra(phosphazene) have been attempted, but no pure products have been isolated[1]. The preparation of two crystalline compounds from the reaction with benzene is reported here.

A mixture of octachlorocyclotetra(phosphazene) (14.1 g), anhydrous aluminum chloride (30.9 g), and triethylamine (9.2 g) in benzene (620 ml) was boiled under reflux (48 h). The product was divided into two portions.

1. Hydrolysis by cold dilute hydrochloric acid, extraction with benzene, and filtration through short alumina and silica columns gave 2,2,4,4-tetrachloro-6-phenyl-6-(2,2,2-triphenylphosphazenyl)cyclotri(phosphazene) *(1)* (yield 0.6%, m.p. and mixed m.p. 181 °C)[2]. The product was isolated by recrystallization from light petroleum (b.p. 40–60 °C)/methylene chloride (1:1).

This is the first reported example of a ring contraction resulting from Friedel-Crafts reactions in the phosphazene series of compounds.

2. An excess of dimethylamine was added at 0 °C, and the mixture was boiled under reflux (1 h). Filtration through a short silica column gave dichlorodimethylaminopentaphenylcyclotetra(phosphazene) *(2)*, which was isolated by recrystallization from light petroleum (b.p. 40–60 °C)/methylene chloride (1:3) (yield 0.6%, m.p. 171 °C).

The dimethylamino ^{1}H–NMR spectrum of this product ($^3J_{P-H}$ 11.6 Hz) confirms the presence of a $P(C_6H_5)N(CH_3)_2$ group. The mass spectrum exhibits a peak at *m/e* 680 corresponding to the molecular ion $[N_4P_4(C_6H_5)_5Cl_2N(CH_3)_2]^+$, but no peak occurs at *m/e* 262 corresponding to the fragment $[P(C_6H_5)_3]^+$. The broad P=N stretching band in the infrared spectrum occurs at *ca.* 1240 cm^{-1}, *i.e.* at a higher (*ca.* 80 cm^{-1}) wave-number range than in *(1)*, thus confirming the presence of a cyclotetra(phosphazene) ring[1]. The positions of the remaining substituents are not yet known.

Dimethyl Pentacyclo[5.2.0.0^{2,9}.0^{3,5}.0^{6,8}]nonane-1,7-dicarboxylate[1]

By *H. Prinzbach, W. Eberbach*, and *G. Philippossian*[*]

Compounds with the tetracyclo[4.2.0.0^{2,8}.0^{5,7}]octane skeleton *(3)*, the next higher homolog in the series prismane *(1)*, quadricyclane *(2)*, have often been postulated as intermediates but their existence has not yet been directly proved[2].

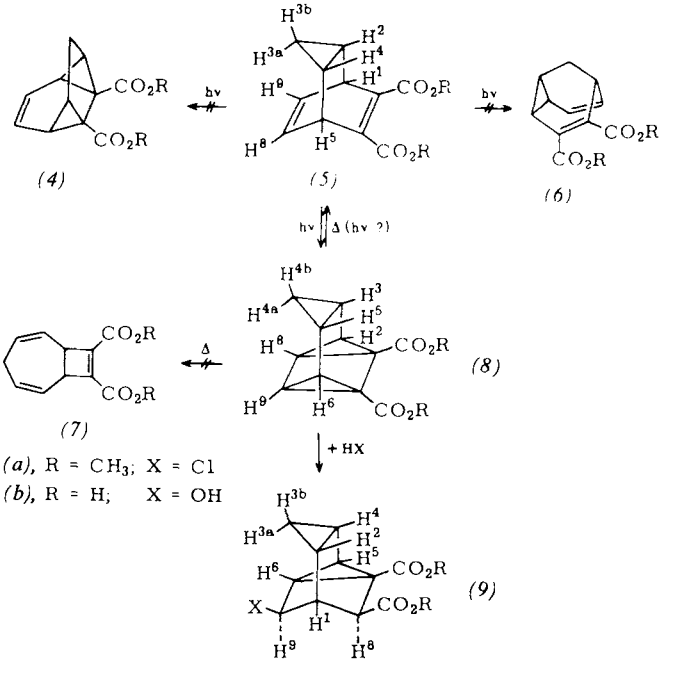
(1) *(2)* *(3)*

We have now isolated the system *(8a)* that is very closely related to the tetracycle *(3)*.

Compound *(8a)* is formed in at least 80% yield[3] on direct irradiation (Hanau Q-81 lamp, Pyrex filter, 2 h) of an ethereal solution (100 mg/300 ml) of "monohomobarrelene" *(5a)* [λ_{max} (ether) = 257 nm (ε = 2060; $\varepsilon_{280\,nm}$ = 800)] cooled to −20 °C.

Apparently this ($2\pi + 2\pi$) cycloaddition *(5)* → *(8)* is not detectably (NMR analysis) accompanied by ($2\pi + 2\sigma$) addition *(5)* → *(4)* in spite of the stereoelectronically favorable[4] *exo*-arrangement of the three-membered ring[5] to the substituted (excited) C=C double bond. Moreover, there was no indication that *(6a)* was formed, although this product would be the one most expected on triplet sensitization[6].

The photoproduct *(8a)* is very unstable thermally. When the photosolution is warmed, *(8a)* rearranges quantitatively (NMR accuracy) to *(5a)*, the half-life ($CHCl_3$) at 21.5 °C



(4) *(5)* *(6)* *(7)* *(8)* *(9)*

[a] In $CDCl_3$. [b] In $C_6H_6/CDCl_3$ (3:1).

being *ca.* 90 min. Compound *(8a)* is isolated by concentration of the solution at low temperature; it can be obtained in at least 95% purity [5% of *(5a)*] as colorless fine needles (m.p. 49–50 °C on rapid heating) by recrystallization from ether at −60 °C.

In this temperature range the fission *(8a)* → *(7a)*, *i.e.*, the reverse of the thermally "allowed" (2 + 2 + 2) addition *(7a)* → *(8a)*, does not compete with the thermally "forbidden" [7] isomerization *(8a)* → *(5a)*.

Whilst it was impossible [9] to effect cycloaddition to the bishomocyclobutadiene system of *(8a)* by the dienophilic reagents usually valuable [8] for polycycles of type *(2)*, the compound *(8a)* can be converted into the chloride *(9a)* (m.p. 87–89 °C) by addition of HCl (passage of gaseous HCl into a CH_2Cl_2 solution at −20 °C). This reaction is quantitative and stereospecific; the stereochemical details are proved by the NMR data (Table 1) [10]. We had previously identified the alcohol *(9b)* as the sole product of photolysis of the dicarboxylic acid *(5b)* in water and had determined the configuration at the centers C-8 and C-9 by an independent synthesis [11]. The thermal lability of *(8a)* and the ease of addition of HCl to *(8a)* raise again the question of the mechanism of the hydration *(5b)* → *(9b)* [2].

According to preliminary results, irradiation of dimethyl bicyclo[2.2.2]octadiene-2,3-dicarboxylate under the conditions used for the reaction *(5a)* → *(8a)* (Vycor filter) causes *ca.* 50% isomerization to *(11)*; NMR ($CHCl_3$), τ = 6.22 (6 H), 7.69 (2 H), 7.88 (4 H), 8.37 (2 H). Having a half-life of *ca.* 12 min. at 19 °C in $CHCl_3$, *(11)* is even less stable than *(8a)*; the reverse reaction *(11)* → *(10)* occurs quantitatively. Addition of HCl at −25 °C leads to *(12)*.

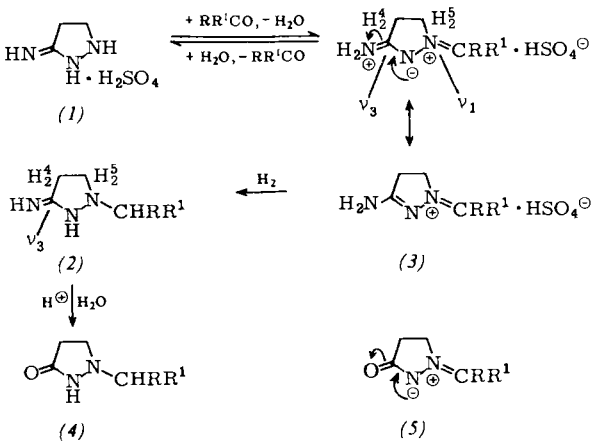
1-Alkylidene- and 1-Arylalkylidene-3-iminopyrazolidine *N,N*-Betaine Salts, a New Type of Azomethine Imine Stabilized by Mesomerism

By *H. Dorn* and *A. Otto* [*]

The reaction of 3-pyrazolidone and other cyclic acylhydrazines with carbonyl compounds provides a general route to "carbonyl-stabilized azomethine imines" *(5)* [1,2] in which the more electronegative oxygen acquires part of the charge from N-2. We have now isolated "imino-stabilized azomethine imines" as the salts *(3)*, in which the electronegativity of the imino-N atom has been raised sufficiently by salt formation.

3-Iminopyrazolidine·H_2SO_4 *(1)* [3] is readily accessible from hydrazine, acrylonitrile, and sulfuric acid; if 1 equivalent of *(1)* is heated with 1 equivalent of any desired carbonyl compound in methanol until dissolution is complete, then, on cooling, the azomethine imine salt *(3)* separates in *ca.* 100% yield; these products are mostly colorless and can be recrystallized from alcohols. When warmed, their aqueous solutions regenerate free RR^1CO quantitatively.

Catalytic hydrogenation of *(3)* (suspension in methanol, Adams Pt, 20 °C, 1 atm.) affords 100% yields of crystalline salts of 1-substituted 3-iminopyrazolines *(2)* from which the bases *(2)* are generated by methanolic NaOH [yield 92–96%; identical with authentic *(2)* [2,4]]. Salts of *(2)* are also obtained when equimolar mixtures of *(1)* and RR^1CO are catalytically hydrogenated in water or methanol-water. If aqueous solutions of salts of *(2)*, *e.g.*, *(2)*·H_2SO_4 are heated for a further 3–4 h, best after addition of a further equivalent of H_2SO_4, then 1-substituted 3-pyrazolidones *(4)* (identical with authentic specimens) are obtained in yields of 80–90%. The last mentioned reactions not only prove the position of CRR^1 in *(3)* but also afford new, very simple, and general syntheses of compounds of types *(2)* and *(4)*.



(a), $CRR^1 = (CH_3)_2C=$

(b), $CRR^1 =$

(c), $CRR^1 = C_6H_5CH=$

Compd.	M.p. (°C)	^{1}H–NMR [b]	τH-5[a]	τH-4[a]	IR (cm^{-1}) ν_3 (C=N)	ν_1 (C=N)	δ (NH_2)
(3a)	215–218	A	5.58 [c]	6.88	1600 [d]	1689 [d]	1658 [d]

(2a)		B	6.82–7.58 [e]				
(2b)	104–105	B	7.00 [g]	7.42	1652 [h]		
(2c)	78–79	B [i]	7.10 [g]	7.47	1652 [k]		

[a] Referred to tetramethylsilane as internal standard. [b] A: In $(CD_3)_2SO$. B: in $CDCl_3$ (Varian A 60A). [c] A_2X_2 system, signal for CH_2–N broadened. [d] In KBr. [e] Signals for both ring-CH_2 appear together with the signals for $CH(CH_3)_2$ as a multiplet. [f] In $CHCl_3$. [g] $\tau_{H\text{-}5}$ refers to the most intense signal of the AA′ portion, $\tau_{H\text{-}4}$ to the most intense signal of the BB′ portion of the AA′BB′ system; the position of these signals is representative for τ_A and τ_B, since $\nu_A - \nu_B$ [25 Hz for *(2b)* and 22 Hz for *(2c)*] is about three times as large as J_{AB} or $J_{A'B'}$. [h] In $CHCl_3$; after H/D exchange with D_2O, 1651 cm^{-1} without change of intensity; 1665/1650 in KBr. [i] In $(CD_3)_2SO$ the corresponding signals are shifted by *ca.* 0.1 τ to higher field. [k] In $CHCl_3$; 1665 cm^{-1} in KBr.

The NMR spectra of the azomethine imine salts *(3)* contain an A_2X_2 system for the protons at C-4 and C-5; the NMR spectra of the iminopyrazolidines *(2)* contain an AA′BB′ system for these protons. $\tau_{H\text{-}5}$ for *(3)* is shifted to lower field from its position for *(2)* as a result of the lesser shielding by N^+ (see Table). The same is true for *(5)* in comparison with *(4)*. For *(3a)* $\tau_{NH_2} = 2.05$ and $\tau_{HSO_4} = 1.40$, and for *(3b)* these values are 2.07 and 1.75, respectively.

Stabilization of the charge on N-2 can be recognized in the IR spectra of the azomethine imine salts *(3)*. These spectra include three intense bands between 1580 and 1690 cm^{-1}, of which one, namely $\delta(NH_2)$, disappears on H/D exchange with D_2O; of the other two (see Table), ν_3(C=N) is shifted by *ca.* 50 cm^{-1} towards the red in comparison with ν_3(C=N) of the iminopyrazolidines *(2)* as a result of the decrease in the C···N bond order.

10-Phenyldibenzo[*b*,*e*]phosphorin

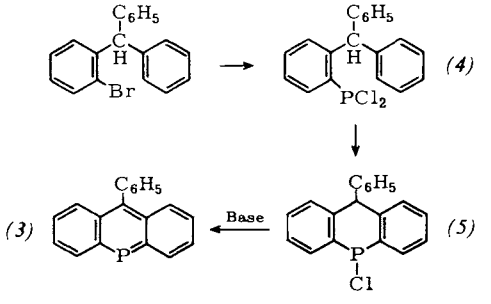
By *P. de Koe* and *F. Bickelhaupt* [*]

The tricyclic heteroaromatic phosphorus compounds *(1)* [1] and *(2)* [2] are unstable, so that their occurrence in solution has been only indirectly proved, mainly by spectroscopy. On the contrary, the monocyclic phosphorin derivatives are quite stable, isolable compounds [3–5].

One of the possible causes of this difference might be the stabilizing action of substituents, which are in the 2-, 4-, and 6-position for all the monocyclic phosphorins described so far.

(1)   *(2)*

For investigation of this problem we have prepared 10-phenyldibenzo[*b*,*e*]phosphorin *(3)*. In contrast to unsubstituted dibenzo[*b*,*e*]phosphorin *(1)*, this derivative *(3)* is a stable compound and can be sublimed at 160 °C/10^{-3} torr, but it reacts with oxygen faster than do the monocyclic phosphorins [6].



Synthesis of *(3)* was carried out by a method analogous to that used for *(1)* [1] (all reactions under nitrogen): The Grignard compound from 2-bromotriphenylmethane (30 g) in tetrahydrofuran was added to a solution of chlorobis(diethylamino)phosphine (17.6 g) in tetrahydrofuran cooled to −80 °C. The mixture was then heated at the b.p. for 16 h and the solvent was removed. The residue was extracted with cyclohexane and the extract was saturated with gaseous HCl. Finally, distillation under vacuum gave dichloro[*o*-(diphenylmethyl)phenyl]phosphine *(4)* [7], b.p. 161 °C/10^{-3} torr, m.p. 76.5–79 °C. When boiled for 10 h with a small excess of

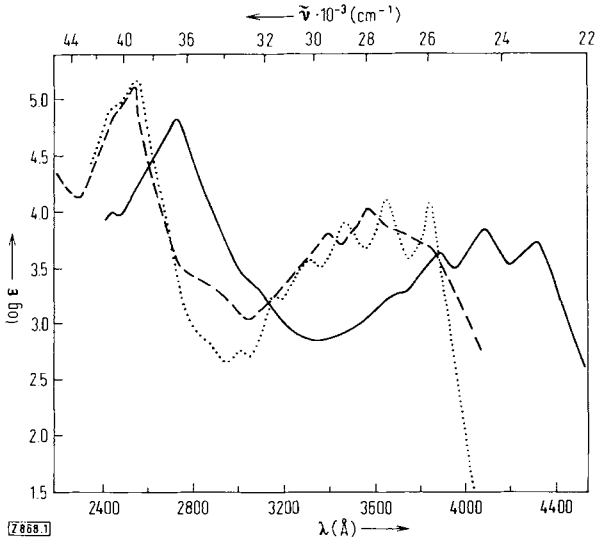


Figure 1. UV spectra of 9-phenylanthracene (in ethanol) (·····) [9], 9-phenylacridine (in ethanol/water, 20:8 v/v) (— — — —) [10] and *(3)* (in diethyl ether) (————).

aluminum chloride in carbon disulfide, this product *(4)* afforded a 41% yield of 5-chloro-5,10-dihydro-10-phenyldibenzo[*b,e*]phosphorin *(5)*[7], b.p. 131 °C/10^{-3} torr, m.p. 94–101 °C.

For removal of HCl, compound *(5)* (592 mg) in 40 ml of dimethylformamide was treated with 1,5-diazabicyclo[5.4.0]-undec-5-ene (357 mg) in a high-vacuum system. After about 12 h the solution was evaporated and the residue was purified by dissolution in cyclohexane, crystallization from toluene, and sunlimation in a vacuum. Yellow crystals of *(3)*, m.p. 173–176 °C, were obtained.

The structure of *(3)* follows from the elemental analysis, the mass spectrum[8] (molecular ion at m/e = 272, 100%), the ^{1}H–NMR spectrum [in CS_2 with tetramethylsilane as external standard: multiplets at δ = 7.7–8.5 (11 H) and 8.72 to 9.25 ppm [2 H, presumably those on C-4 and C-6], and the UV spectrum Fig. 1). The UV curve is largely similar to that of the unsubstituted parent *(1)* and in comparison with this shows a bathochromic shift of 6 nm for the longest-wavelength absorption [λ_{max} = 432 nm (ε = 7970) in diethyl ether], as is to be expected in analogy to the carbon and nitrogen analogs.

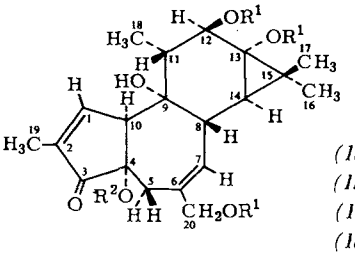
Lumiphorbol Triacetate, a Cage-like Derivative of the Diterpene 4α-Phorbol

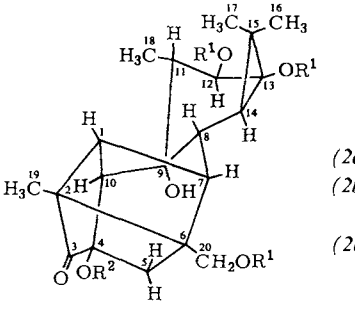
By *E. Hecker*, *E. Härle*, *H. U. Schairer*, and *P. Jacobi*
also *W. Hoppe*, *J. Gassmann*, *M. Röhrl*, and *H. Abel*[*]

During the isolation of the tetracyclic diterpene phorbol[1,2] [***] by alcoholysis of its esters that occur in croton oil[3] a mother-liquor was obtained[4] which, on acetylation by acetic anhydride and pyridine, afforded not only phorbol 12,13,20-triacetate[4] but also a triacetate *(1a)* with somewhat lower R_F value (0.55 and 0.30, respectively, ether/petroleum ether 10:1). The new triacetate has m.p. 165 to 166 °C, λ_{max} = 195, 238, 339 nm (ε_{max} = 11800, 6700, 65; in methanol), and it was also obtained when phorbol 12,13,20-triacetate was treated with sodium methoxide in methanol and then with acetic anhydride/pyridine. Isomerization is hindered by methylation of the ketol hydroxyl[5] at C-4 of phorbol. The analytical and physical data for the new compound show that it must be an isomer of phorbol 12,13,20-triacetate [*(1a)*, tentatively designated isophorbol triacetate].

In contrast to isophorbol triacetate *(1a)*, the free isophorbol *(1b)* could not be induced to crystallize. With acetic anhydride/pyridine the alcohol *(1b)* also gave a 4,12,13,20-tetraacetate *(1c)*, m.p. 164–167 °C, in contrast to phorbol[4], and with benzoyl chloride/pyridine it gave a 4,12,13,20-tetrabenzoate *(1d)*, m.p. 150–154 °C. With acetic anhydride/pyridine *(1a)* can be further acetylated to *(1c)*.



(1a), R^1 = $COCH_3$, R^2 = H
(1b), R^1 = R^2 = H
(1c), R^1 = R^2 = $COCH_3$
(1d), R^1 = R^2 = COC_6H_5



(2a), R^1 = $COCH_3$, R^2 = H
(2b), R^1 = $COCH_3$, R^2 = *p*-Br-C_6H_4-CO
(2c), R^1 = R^2 = H

Irradiation of *(1a)* by UV light (254 nm) affords almost quantitatively a new substance *(2a)*, m.p. 130–137 °C, λ_{max} = 194, 297 nm (ε = 2300, 50; in methanol), which we designate lumiphorbol triacetate. Analysis and mass, UV, IR, and particularly ^{1}H–NMR spectra show that it is a 12,13,20-triacetate and they accord with the cage-like structure *(2a)* in which the five- and the seven-membered ring must be *cis*-linked (4α,10α), *i.e.*, differently from the linkage in phorbol. Isophorbol *(1b)* is thus a 4-epimer of phorbol. Like *(1a)*, the triacetate *(2a)* can also be acylated on C-4. A 4-(*p*-bromobenzoate) *(2b)*, m.p. 182 °C, λ_{max} = 198, 246 nm (ε_{max} = 3800, 19600; in methanol), can be obtained by reaction of *(2a)* with *p*-bromobenzoyl chloride in pyridine.

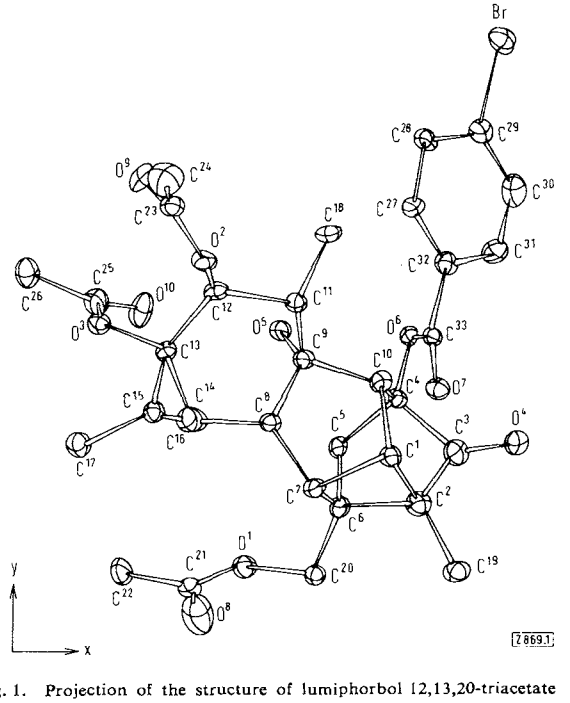


Fig. 1. Projection of the structure of lumiphorbol 12,13,20-triacetate 4-(*p*-bromobenzoate) *(2b)* [****].

X-ray analysis of the 4-(*p*-bromobenzoate) *(2b)* leads to the relative configuration of the molecule (Fig. 1) (space group $P\,2_1$, $Z = 2$, $a = 10.20$ Å, $b = 20.29$ Å, $c = 7.93$ Å, $\beta = 90.52°$). The structure was determined, fully automatically, by finding the position of the bromine atom from Patterson synthesis and subsequent treatment by phase-improvement methods. The pseudoasymmetry due to the position of the bromine could be overcome in that work [****].

This proves the structure *(2a)* of lumiphorbol triacetate, and shows isophorbol *(1b)* to be the 4α-phorbol (4α,9,12β,13,20-pentahydroxy-1,6-tigliadien-3-one). Accordingly, lumiphorbol *(2c)* is a 4α,9,12β,13,20-pentahydroxy-1,7:2,6-dicyclo-4α-tiglian-3-one or a 7,8β,10,12α-tetrahydroxy-14-(hydroxymethyl)-1,6,6,9-tetramethylhexacyclo[10.2.1.$0^{2,11}$.$0^{3,14}$.$0^{4,10}$.$0^{5,7}$]pentadecan-15-one [6].

Preparation of Titanyl and Vanadyl Mesoporphyrin IX Dimethyl Esters

By *M. Tsutsui, R. A. Velapoldi, K. Suzuki*, and *T. Koyano* [*]

The presence of titanium porphyrins in petroleum has been suggested but not proved, yet vanadyl porphyrins have been identified as constituents [1]. Moreover, titanium porphyrins have hitherto not been prepared whereas vanadyl porphyrins have been synthesized under severe reaction conditions [2]. General methods of metal insertion and reaction with metal carbonyls have not been successful or applicable for the preparation of titanium porphyrins [3].

We wish to report the synthesis of titanyl mesopophyrin IX dimethyl ester: Mesoporphyrin IX dimethyl ester (0.300 g) and diphenyltitanium (1.527 g) [4] *molar ratio (1:15)* were ground together in the solid state and then allowed to react for 1.5 h at 210 °C in either degassed, purified mesitylene (100 ml) (bath temperature 240 °C) or triethylbenzene (100 ml) (bath temperature 210 °C) under argon. The reaction mixture was cooled and filtered in the atmosphere. A chloroform extract of the precipitate was passed through a chromatographic column of basic alumina for purification. A deep purple solid (0.083 g) was isolated from the eluent by addition of *n*-hexane followed by centrifugation and drying under vacuum.

The absorption spectrum was similar to that of the corresponding vanadyl compound [2]; with chloroform, pyridine, or *n*-hexane as a solvent, the following visible spectrum was recorded: 407 nm (log ε = 5.60), 500 nm (shoulder), 536 nm (log ε = 2.35), 574 nm (log ε = 2.46).

The compound is diamagnetic, as shown by the Gouy and NMR methods, and thus contains Ti^{IV}. This can be attributed to oxidation of the Ti^{II} to the more stable titanyl moiety during isolation of the compound in the atmosphere.

No N–H stretching frequency was observed at 3319 cm^{-1} in the infrared spectrum, which proves metal insertion. A strong, broad absorption at 1038 cm^{-1} was assigned as the titanyl stretching frequency [5]. All other absorptions in the spectrum are similar to those of either metalloporphyrins or free porphyrins.

We further wish to report a simple method for the preparation of vanadyl mesoporphyrin IX dimethyl ester: A mixture of an excess of vanadium hexacarbonyl (0.140 g) and mesoporphyrin IX dimethyl ester (0.028 g) was heated at 170 °C for 1.5 h in *n*-decane (10 ml) under nitrogen. The product (0.011 g) was isolated and purified similarly to chromium mesoporphyrin IX dimethyl ester [3], and was identified by comparison with the previously prepared compound [2].

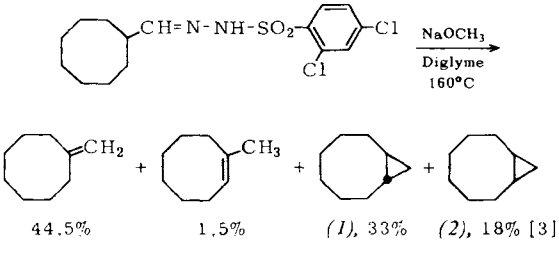
trans-Bicyclo[5.1.0]octane

By *W. Kirmse* and *Ch. Hase* [*]

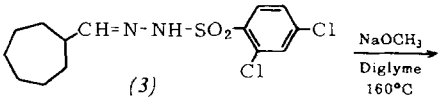
Intramolecular insertion reactions of *sec*-alkylcarbenes afford more *trans*- than *cis*-1,2-dialkylcyclopropanes [1], but because of ring strain cyclopentylcarbene and cyclohexylcarbene give only *cis*-bicyclo[*n*.1.0]alkanes ($n = 3$ or 4) [1,2]. We have



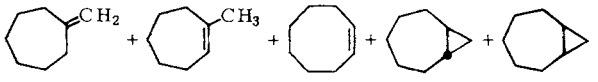
found that when $n = 6$ the *trans*-isomer *(1)* again preponderates.

The isomeric bicyclo[6.1.0]nonanes *(1)* and *(2)* can also be prepared from *cis*- and *trans*-cyclooctene[4,5] and the pairs of samples were identified by comparison.

We were able to prepare the strongly strained[6] *trans*-bicyclo-[5.1.0]octane *(7)* analogously by means of cycloheptylcarbene, although this product is not obtainable by any other route.



(3)



(4), 48% *(5)*, 2% *(6)*, 1% *(7)*, 12% *(8)*, 37%

All the products except *(7)* were identified by comparison with authentic specimens. After removal of the olefins *(4)* to *(6)* by ozonolysis, the isomers *(7)* and *(8)* were separated by gas chromatography. *(7)* was shown to be a cyclopropane derivative by its NMR spectrum (2 H at 0.08 ppm) and its IR spectrum (1013, 1037 cm^{-1}).

The increased ring strain in *(7)* is shown by catalytic hydrogenation to methylcycloheptane (glacial acetic acid-pentane 2:1, PtO_2, 1 atm of H_2, 22 h). During quantitative hydrogenation of the *trans*-compound *(7)*, 90% of the *cis*-isomer *(8)* remained unchanged. Thermal isomerization of *(7)* is only slow: under the conditions of its formation (diglyme, $NaOCH_3$, 160 °C) 11.5% of methylcycloheptene *(5)*, 9.5% of methylenecycloheptane *(4)*, and 1% of *(8)* were formed in 40 min; 78% of the *(7)* remained unchanged.

trans-Bicyclo[5.1.0]octane (7):

The sulfonylhydrazone *(3)* (decomp. 107 °C) was prepared (yield 43%) from cycloheptanecarbaldehyde[7] and 2,4-dichlorobenzenesulfonohydrazide (decomp. 108–110 °C) in methanolic hydrochloric acid. 11.2 g of the sulfonylhydrazone in 30 ml of diglyme was added during 6 min to a suspension of 8.9 g of sodium methoxide in 150 ml of boiling diglyme (85% total yield, determined by gas chromatography with cyclooctane as standard). The mixture was worked up by dilution with water, extraction with *n*-pentane, ozonolysis in methanol at −70 °C, cleavage of the ozonides with aqueous $Na_2SO_3/NaHSO_3$ solution, and extraction with *n*-pentane. On preparative gas chromatography (column 300 × 1 cm, 20% tricresyl phosphate on kieselguhr, 90 °C, 220 cc of H_2/min) we obtained *ca.* 180 mg of the bicyclooctane *(7)*.

Synthesis, on a Preparative Scale, of Ethanol Stereospecifically Labeled on Hydrogen[***]

By *H. Simon*, *M. Kellner*, and *H. Günther*[*]

Compounds, *e.g.*, ethanol[1–3], stereospecifically labeled on hydrogen are of interest in biochemistry[1] and for the study of reaction mechanisms[2]. Such ethanol preparations, made by chemical methods, have been hitherto only of moderate optical purity[2]. Biochemical methods are not practicable on a preparative scale because of the large amounts of enzyme required[3] and furthermore need substrates or cosubstrates labeled on hydrogen.

(1*R*)-[1-D]- and (1*R*)-[1-T]-ethanol of high stereospecific purity can be obtained surprisingly easily by incubating, *e.g.*, the yeast *Torulopsis utilis*[4] in D_2O or H_2O/HOT containing 10% of ethanol for 50–90 h.

Experimental:

Starved *Torula* yeast (153 g) was suspended in D_2O (80 ml) and centrifuged off, and this process was repeated twice more. The yeast was then stirred vigorously at 30 °C under an atmosphere of oxygen for 50 h in 300 ml of D_2O and 18 ml of citrate buffer (0.3 M, pH = 5.6) in D_2O to which 34 ml of ethanol had been added. 22.7 ml of ethanol remained in the supernatant liquor.

For determination of the D content and D distribution, several samples were converted into ethyl 3,5-dinitrobenzoate, and from a part silver acetate was prepared by Kuhn-Roth oxidation. For determination of the stereospecificity the ethanol was dehydrogenated by yeast alcohol dehydrogenase to acetaldehyde[3,5] and this aldehyde was precipitated in the form of its 2,4-dinitrophenylhydrazone or dimedone derivative. All the products were measured by mass spectrometry[6]. The 2,4-dinitrophenylhydrazone was also oxidized by the Kuhn-Roth method and the acetic acid was analyzed, since under the conditions of formation of the hydrazone hydrogen exchange between the methyl group and the medium takes place[7].

Typical results for 50 h reaction are: 0.98 gram atom of D per mole of ethanol, 0.085 being in the methyl group and less than 0.07 in the (1*S*)-position; after 96 h reaction, 1.16 gram atoms of D per mole of ethanol, 0.12 being in the methyl group and 0.11 in the (1*S*)-position.

(1*S*)-[1-D]- and (1*S*)-[1-T]-Ethanol can be obtained in this way by using CH_3-CD_2OH or non-stereospecifically labeled [1-T]ethanol, respectively, in H_2O. Since yeast alcohol dehydrogenase reacts also with other alcohols, these can also be labeled, but according to our experiments more slowly.

An Abnormal Ring Cleavage of 1α,2α-Epoxy-3-keto Steroids by Hydrogen Fluoride

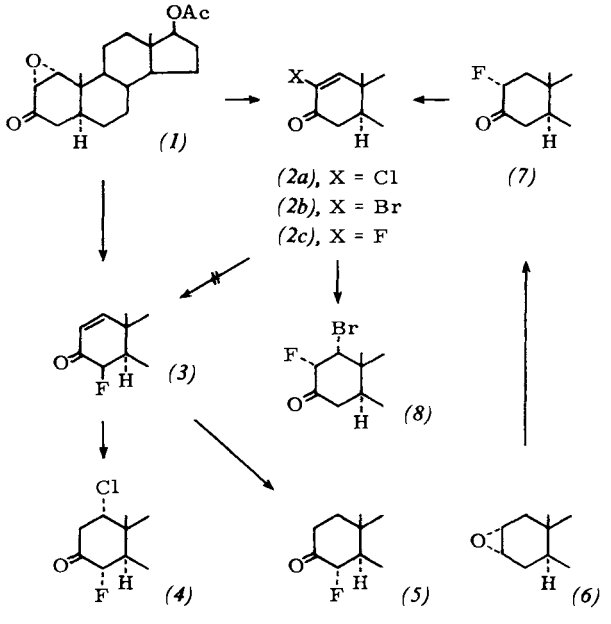
By *U. Kerb, G. Schulz,* and *R. Wiechert* [*]

2-Chloro- *(2a)* and 2-bromo-5α-androst-1-en-3-one *(2b)* have been obtained by treatment of 17β-acetoxy-1α,2α-epoxy-5α-androstan-3-one *(1)* [1] with hydrogen chloride and hydrogen bromide, respectively [2, 3].

However, hydrogen fluoride causes rearrangement, yielding, from *(1)*, 17β-acetoxy-4β-fluoro-5α-androst-1-en-3-one *(3)*, m.p. 173–174 °C (UV: $\varepsilon_{234} = 10960$) [4].

The characteristic signals in the NMR spectrum of this product *(3)* are the doublets of two olefinic protons ($\delta = 7.33$ and 6.00), the double doublet of the proton on C-4 ($\delta = 4.50$), and the signal of the 19-CH_3 group ($\delta = 1.20$) which is split to a doublet [5] by 1,3-diaxial interaction with the 4β-fluorine atom.

The 1α-chloro-4α-fluoro ketone *(4)* (m.p. 173 °C with decomp.) was obtained from *(3)* by means of hydrogen chloride in glacial acetic acid, isomerization at C-4 and addition of HCl occurring. Hydrogenation of *(3)* in presence of Pd/C in methanol and subsequent epimerization by hydrogen chloride in glacial acetic acid led to the 4α-fluoro ketone *(5)* (m.p. 187.5–188 °C). In the NMR spectra of *(4)* and *(5)* the signal of the 19-CH_3 group appears as a singlet, whence it follows that the fluorine is in the 4α position.



For further proof of the structure of *(3)*, 17β-acetoxy-2β-fluoro-5α-androstan-3α-ol (m.p. 205–206 °C) was prepared from the 2α,3α-epoxide *(6)* [6] and was oxidized to the 2β-fluoro ketone (m.p. 158–160 °C) and converted by acid isomerization into the known 2α-fluoro compound *(7)* [4] (m.p. 189–190.5 °C). The double bond was introduced into *(7)* by bromination and then removal of hydrogen bromide. The 17β-acetoxy-2-fluoro-5α-androst-1-en-3-one *(2c)* prepared in this way (m.p. 160.5–161.5 °C; UV: $\varepsilon_{238} = 10100$) gave a depression of the melting point on admixture with *(3)*. The NMR spectrum of *(2c)* contains the signal of only one olefinic proton.

We were unable to rearrange *(2c)* to *(3)* by hydrogen fluoride under the conditions of epoxide ring fission, in the way that *Djerassi* and *Scholz* [7] observed for the 17α-benzoyloxy-2-bromo-5α-androst-1-en-3-one system which was transformed into the 4-bromo isomer. Compound *(2c)* adds hydrogen bromide, yielding *(8)* (m.p. 159.5–160.5 °C).

17β-Acetoxy-4β-fluoro-5α-androst-1-en-3-one (3):

Compound *(1a)* (1 g) is added portionwise to a mixture of a) dimethylformamide (5 ml) and hydrogen fluoride (5 ml) or b) tetrahydrofuran (40 ml) and hydrogen fluoride (10 ml) and the mixture is stirred for 22 h or 48 h, respectively, at room temperature. The reaction mixture is then poured into ice-water and neutralized with K_2CO_3; the precipitate is filtered off and recrystallized from dichloromethane/isopropyl ether (yield 60%).

Formation of Adenosine Triphosphate (ATP) from Adenosine Diphosphate (ADP) and Phosphate during Oxidation of Mercaptoacetate by Bromine [1]

By *Th. Wieland* and *E. Bäuerlein* [*]

We have converted oxidation energy into the energy of the "energy-rich" diphosphate bond, *e.g.*, that in ATP, by oxidation of *S*-alkylmonothiohydroquinones [2], *N*-acetylhomocysteine thiolactone [3], thiazolidones [4], monoacetyldurohydroquinone [5], α-tocopherol [6], and *S*-*p*-tolyl thioacetate [6] by bromine in pyridine in the presence of ADP and phosphate (P). We have now found that under these conditions mercaptoacetate also gives ATP from the tetrabutylammonium (TBA) salts of ADP and P, and that yields exceed 30%.

In several batches, 13.33 ml of 0.1 N (TBA)·OH solution in 2-propanol/methanol (Merck, Darmstadt) was treated with 0.67 ml of 1 N solution of *ca.* 90% phosphoric acid in dioxane; 0.107 g of $ADPH_3 \cdot 3\,H_2O$ (C. F. Boehringer und Soehne, Tutzing) was dissolved therein, and then 0.016 ml of freshly distilled mercaptoacetic acid was added. The solution was evaporated under vacuum, and the residue was dried over P_4O_{10} for 20 min at 0.1 torr and then dissolved with stirring in 9 ml of anhydrous pyridine, whereupon a deep yellow color developed. (A solution of the TBA salt of mercaptoacetic acid in anhydrous pyridine is colorless.) The solution was then treated, by dropwise addition within a few minutes, with $^5/_9$ mmole (0.028 ml), $^2/_9$ mmole (0.011 ml), or 0.133 mmole (= $1.2 \times {}^1/_9$ mmole) (0.007 ml) of bromine, each amount in 1 ml of anhydrous pyridine.

This caused a color change from deep yellow through deep red to pale yellow; a precipitate was formed after a few minutes. After 1 h each batch (several repeats) was worked up for determination of ATP (results in Table 1).

No more than conjectures can be made at present about the mechanism of this coupled reaction. It may be that a sulfenyl bromide is first formed by bromination of the thiol and then combines with the phosphate ion to give a mixed sulfenic phosphoric anhydride $R-S-O-PO_3H^-$, which is the actual phosphorylating agent.

Table 1. Yields of ATP (calc. on the 84% ADP used on simultaneous oxidation of equivalent amounts of $(TBA)_2HPO_4$, $(TBA)_3ADP$, and TBA mercaptoacetate by 1.2, 2.0, and 5.0 equivalents of bromine.

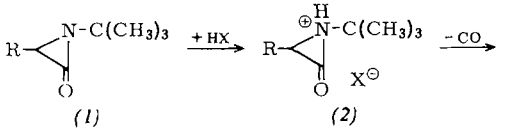
Synthesis of 1-Adamantanecarbaldehydes

By *K. Bott* [*]

According to a process described in the patent literature [1] free 1-adamantanecarbaldehydes can be prepared by reduction of 1-[1-(adamantanecarbonyl)]aziridines using $LiAlH_4$. We have now found that 1-adamantanecarbaldehydes *(4)* can be obtained in essentially higher yields (92–96%) by decomposition of the aziridinones *(1)* with aqueous mineral acids (Table 1). Compounds *(2)* and *(3)* are assumed to be intermediates because the aldimonium salts *(3)* can be isolated quantitatively on working in anhydrous ether [2].



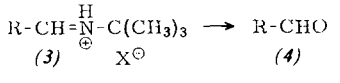


Table 1. Characterization of the aldehydes *(4)*.

Product	R	M.p. (°C)	$\tilde{\nu}$(CO) (cm^{-1})
Aldehyde [a]	1-Adamantyl	139–141 [b]	1722 [c]
Dimethyl acetal	1-Adamantyl	40–41	–
Aldehyde	3-Methyl-1-adamantyl	Colorless oil	1710
Oxime	3-Methyl-1-adamantyl	76–77	–
Aldehyde	3,5,7-Trimethyl-1-adamantyl	74–75	1710 [c]
Dimethyl acetal	3,5,7-Trimethyl-1-adamantyl	54–55	–

[a] First characterized as 2,4-dinitrophenylhydrazone [3].
[b] Described in ref. [1] as an oil; according to ref. [5], m. p. 195 to 197.3°C. [c] KBr disc.

Although 1-adamantanecarbaldehydes lose CO on heating under nitrogen, they are converted into stable dimethyl acetals when dissolved in methanol containing hydrogen chloride.

3,5,7-Trimethyl-1-adamantanecarbaldehyde:

1-*tert*-Butyl-2-(3,5,7-trimethyl-1-adamantyl)aziridinone [4] (1.50 g) is heated to 100 °C under nitrogen for a period of 15 min with a mixture of water (75 ml) and methane-sulfonic acid (7.0 g). The aldehyde formed is steam-distilled into an ice-cooled receiver, filtered off, and dried over P_2O_5 in a vacuum; yield 1.03 g (96%); m.p. 74–75 °C.

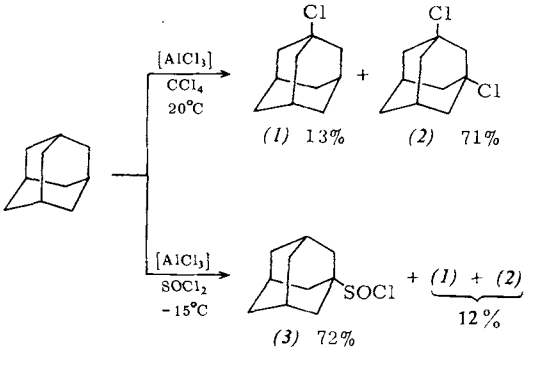
New Possibilities of Direct Substitution of Adamantane

By *H. Stetter, M. Krause*, and *W.-D. Last* [*]

An ionic mechanism has been proposed for halogenation of adamantane [1]; correspondingly, Friedel-Crafts catalysts catalyze this reaction. Adamantane can be halogenated also by halogenated hydrocarbons in the presence of such catalysts [2]. Thus treating adamantane with aluminum chloride in carbon tetrachloride at room temperature gives a mixture of 1-chloroadamantane *(1)* [1] and 1,3-dichloroadamantane *(2)* [3] in 84% yield.

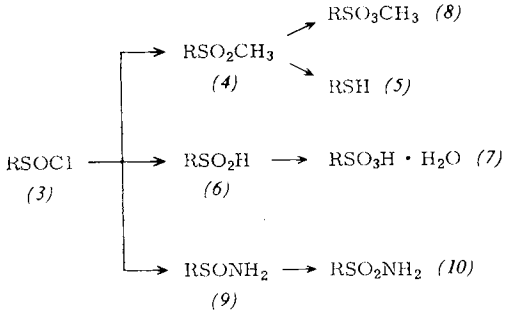


Using thionyl chloride instead of halogenated hydrocarbons also affords chlorinated adamantanes. However, surprisingly, at −15 °C 1-adamantanesulfinyl chloride *(3)* is formed in 72% yield. On increase in the temperature the proportion of *(3)* formed decreases, and 1,3,5-trichloroadamantane [3] is the main product at the boiling point. 1-Chloroadamantane *(1)* always gives a smaller proportion of the sulfinyl chloride *(3)* under comparable conditions. We assume that a chain reaction occurs in which the 1-adamantylium ion $R^{\oplus}$ participates.

$$R^{\oplus} + SOCl_2 \rightarrow RSOCl + Cl^{\oplus}$$
$$Cl^{\oplus} + RH \rightarrow R^{\oplus} + HCl$$

The chloride *(3)* can be converted into methyl 1-adamantanesulfinate *(4)* (colorless crystals, m.p. 44–46 °C) in 83% yield by means of boiling anhydrous methanol (6 h), and this ester is converted into 1-adamantanethiol *(5)* [4] in 90% yield by $LiAlH_4$ in anhydrous ether (17 h, 36 °C). Further, the acid

chloride *(3)* is converted by 5% sodium hydroxide at room temperature into 1-adamantanesulfinic acid *(6)* (yield 61%; m.p. 132–134 °C in a sealed tube), which is oxidized almost quantitatively by hydrogen peroxide to 1-adamantanesulfonic acid *(7)* [5]. The chloride *(3)* can also be used for preparation of esters and amides of 1-adamantanesulfonic acid that were not previously accessible. For this purpose *(3)* is treated with alcohols or amines, yielding 1-adamantanesulfinic acid derivatives, which can be oxidized in good yield by potassium permanganate in boiling acetone. For instance, oxidation of *(4)* gives methyl 1-adamantanesulfonate *(8)* (colorless crystals, m.p. 113–114 °C) in 85% yield. 1-Adamantanesulfonamide *(10)* (colorless needles, m.p. 197 to 198 °C) is obtained analogously in 95% yield, the 1-adamantanesulfinamide *(9)* (m.p. 141–142 °C) being prepared in 75% yield by treating *(3)* with concentrated aqueous ammonia for 2 h at 100 °C.



R = 1-adamantyl

1-Adamantanesulfinyl chloride:

$AlCl_3$ (40 g) and $SOCl_2$ (200 ml) are treated with adamantane (40.8 g) with exclusion of moisture at −15 °C over a period of 2 h; the mixture is then stirred for another 1 h at the same temperature. The clear solution is allowed to warm to room temperature, the excess of $SOCl_2$ is removed under vacuum, and the residue is taken up in CCl_4 (300 ml) and cautiously treated with water. The organic phase is separated off, dried over $CaCl_2$, and the solvent is removed. The oily residue is distilled at 130–136 °C/3–4 torr, the chloroadamantanes occurring in the first runnings. Yield 47 g (72%, m.p. 42 to 44 °C).

Single Crystals of Phenylalanine-Specific Transfer Ribonucleic Acid

By *F. Cramer, F. v. d. Haar, W. Saenger,* and *E. Schlimme* [*]

On the basis of the base-pairing rules and the results of chemical and biochemical experiments, suggestions have been made concerning the secondary [1] and tertiary [2] structures of transfer ribonucleic acid (tRNA), the validity of which, however, can only be proved by X-ray structural analysis. Recently, microcrystalline spherulites of $tRNA^{F.\ Meth}_{E.\ coli}$ and $tRNA^{Ser}_{yeast}$ have been obtained [3]; however, single crystals are essential for an X-ray structural analysis. In this communication we wish to report on the crystallization of a tRNA from brewers' yeast.

$tRNS^{Phe}_{yeast}$ was isolated from a commercially available (Boehringer, Mannheim) soluble yeast-RNA. The working-up involved a partition step, as described by *Khym* [4] and subsequent chromatography on benzoylated DEAE-cellulose [5,6]. The $tRNA^{Phe}_{yeast}$ (82% aminoacylatable) thus obtained was first dialyzed against 10^{-2} M EDTA and then against 10^{-3} M Mg^{2+} and 10^{-2} M K^+.

The non-bonded metal ions were subsequently removed by dialysis against distilled water. Dioxane, from a solution of dioxane/water (35:100 v/v) was distilled *via* the vapor phase into a 1.5% solution of tRNA in dioxane/water (20:100 v/v) at room temperature in a dessicator. Crystals of rhombohedral form (Fig. 1) were formed along the vessel wall at the surface. The crystals were about 0.15 mm in length, about 0.07 mm wide, and were considered to be of a thickness of 0.01–0.02 mm.

In polarized light extinction was observed at each 90° interval, thus suggesting an orthorhombic system. On excitation by light of 325 nm wavelength the crystals exhibited strong blue fluorescence, as does the $tRNA^{Phe}_{yeast}$ itself. After redissolution of the crystals, the $tRNA^{Phe}_{yeast}$ was aminoacylatable to the same extent as the starting material.

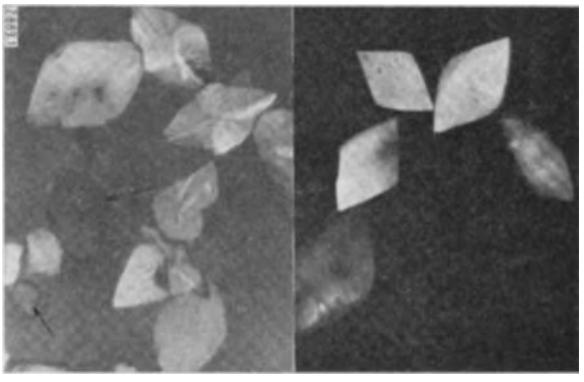

Fig. 1. Crystals of $tRNA^{Phe}_{yeast}$ yeast in polarized light.
The crystals were kept in the upper part of the Debye-Scherrer type crystallization tube (4mm diameter) for the photographic recording. The crystals situated at the places marked by arrows are oriented such that they do not rotate the plane of the polarized light. (Magnification approx 133×.) [**]

Fourth International Catalysis Congress[*]

The Moscow Catalysis Congress from June 23 to 29, 1968 was the fourth in a series of four-yearly international congresses on heterogeneous catalysis. The kinetics and mechanisms of special reactions, new research methods, and the properties of little-known catalysts were dealt with in six plenary lectures and 86 discussion lectures, but the principal topic was the relation between the chemical composition, crystalline and electronic structure, and the activity and selectivity of catalysts.

1. The Active Center

Though many systems are now known in which the entire catalyst surface is uniformly active, the particularly high activity of special centers on the surface of others is partly due to geometric or topochemical factors. Uniformly active surfaces have been found on metal oxides in simple combustions and on metals in simple hydrogenations. This is so *e.g.* according to *P. C. Aben, J. C. Platteeuw,* and *B. Stouthamer* (Netherlands) (31) in the hydrogenation of benzene on Pt, Pd, and Ni catalysts supported on SiO_2, Al_2O_3, Al_2O_3–SiO_2, and MgO–SiO_2, and according to *M. Kraft* and *H. Spindler* (Leuna) (69) in the dehydrogenation of cyclohexane with Pt on Al_2O_3. However, these authors also found that the surface of the same catalyst is not uniformly active in the dehydrocyclization reaction of *n*-heptane. *R. van Hardeveld* and *F. Hartog* (Netherlands) (70) also point out that a catalyst can have several types of centers, which can act differently in different reactions; nickel on aerosil is reported to have a uniformly active surface in the deuteration of benzene to give cyclohexane, but not in the H/D exchange between benzene and D_2. Apart from crystallite corners, edges, surfaces, and lattice defects, active centers in metal catalysts include crystallite steps of atomic height (B_5 sites), as was described by *G. C. Bond* (England) (67).

The importance of the topochemical factor was discussed by *G. Parravano* (USA) (11) for the $^{12}C/^{14}C$ exchange in CO_2/CO mixtures and for the decomposition of H_2O_2 and N_2O on cobalt ferrites having the composition Co_{3-x} Fe_xO_4 (x = 1.9 ... 2.1). Whereas the stoichiometric ferrite (x = 2.0) gives a minimum rate for the first reaction, it is found to be the optimum catalyst for the other two reactions; this is attributed to the change in the distribution of ion vacancies with the Co/Fe ratio. *B. V. Erofeev, N. V. Nikiforova, I. I. Urbanovich,* and *L. D. Dmitrieva* (USSR) (47) reported that Cu and Mo on Al_2O_3, MgO, SiO_2, BeO, ZnO, and some spinels are particularly effective in the dehydrogenation of cyclohexane or the dehydrocyclization reaction of *n*-hexane if the metals are atomically dispersed and situated in cation sites of supports with octahedrally arranged anions. According to *K. Tarama, S. Yoshida,* and *Y. Doi* (Japan) (13), Cr^{5+} ions, which are characterized by an unusual crystal field, are active in the copolymerization of ethylene on chromic oxide.

A geometric factor is particularly important for systems in which multi-point adsorption of the reacting materials occurs. For example, according to *O. V. Krylov* and *E. A. Fokina* (USSR) (64), the activity of metal oxides in the reaction of acrolein with methanol increases with the lattice constant. *O. N. Bragin* and *A. L. Libermann* (USSR) (27) showed that the hydrogenolysis of alkylcyclopentanes and cyclohexane on Ru, Rh, Os, and Ir, which proceeds by two-point adsorption, yields a large number of products, whereas on Pt, owing to six-point adsorption, only the alkylcyclopentanes, and not the cyclohexane, react. According to *H. Noller, P. Andréu, E. Schmitz, S. Serain, O. Neufang,* and *J. Girón* (Hannover and Venezuela) (81), two-point adsorption is also responsible for the stereospecific action of many catalysts in the dehydrochlorination and dehydrobromination of 2,3-dichloro- or 2,3-dibromobutane to form 2-halogenobutene. For example, while KBO_2 and K_2CO_3 give a high *cis-trans* ratio in the end products, $CaCl_2$ and $Ca_3(PO_4)_2$ give a low ratio; this is explained by differences in the adsorption of substrate halogen on the catalyst cation and of substrate hydrogen on the catalyst anion.

In most insulating catalysts and in reactions with uncharged adsorbed intermediates, acid groups on the catalyst surface act as active centers. This was shown by *T. Yamaguchi* and *K. Tanaba* (Japan) (80) in the hydrolysis of dichloromethane on $NiSO_4$, ZnS, SiO_2, and Al_2O_3–SiO_2, by *Y. Noto, K. Fukuda, T. Onishi,* and *K. Tamaru* (Japan) (37) and *J. M. Criado, J. Dominguez, F. González, G. Munuera,* and *J. M. Trillo* (Spain) (38) in the dehydration of formic acid on Al_2O_3, SiO_2, Cr_2O_3, and TiO_2 and by *B. D. Flockhart, S. S. Uppal, I. R. Leith,* and *R. C. Pink* (Ireland) (79) in the H/D exchange between *n*-propane and D_2 on Al_2O_3. According to *H. Bremer* and *K. H. Steinberg* (Merseburg) (76), *T. V. Antipina, O. V. Bulgakov,* and *A. V. Uvarov* (USSR) (77), and *T. Nishizawa, H. Hattori, T. Uematsu,* and *T. Shiba* (Japan) (55), acid groups also bring about the dehydrogenation of isopropanol on MgO–SiO_2 and cracking processes, as well as the polymerization of ethylene and propylene and double bond migrations in 1-butene on partly fluorinated or hydrofluorinated Al_2O_3 catalysts. In all these cases the activity increases with the concentration of Lewis- or Brønsted centers.

2. The Catalyst-Substrate Bond

A knowledge of the nature and strength of the chemisorption bond is particularly useful for the establishment of reaction mechanisms and for the estimation of reaction rates. As was emphasized by *J. L. Garnett, R. J. Hodges,* and *W. A. Sollich-Baumgartner* (Australia) (1), there is an analogy between homogeneous and heterogeneous catalysis, as a result of which the interaction between individual substrate molecules and isolated catalyst structural units also approximately describes the chemisorption on the surface of solid catalysts. In the H/D exchange of monohalogenobenzenes, alkylbenzenes, and polycyclic aromatic compounds with D_2O on Pt, for example, the analogy is attributed to the π-complex mechanism occurring in homogeneous and heterogeneous catalysis. *V. S. Feldblium* (USSR) (15) referred to the analogy in the dimerization and isomerization of α-olefins on Ziegler catalysts. *P. Cossee, P. Ros,* and *J. H. Schachtschneider* (Netherlands) (14) presented results of quantum-chemical calculations that give a detailed picture of the energy relationships of the catalyst-substrate complex in the first-mentioned case. *A. Cimino, V. Indovina, F. Pepe,* and *M. Schiavello* (Italy) (12) studied the action of isolated catalyst structural units on the decomposition of N_2O on solids containing atomically dispersed Cr_2O_3 as catalyst doped with

[*] In this report, the lecture number is given (in parentheses) in each review, cf. Proc. IV. Internat. Congress Catalysis, Moscow 1968, in press.

various amounts of Li_2O in a catalytically inactive MgO matrix.

H. H. Dunken and *C. Opitz* (Jena) (2) calculated the chemisorption bond of CO, HCN, OH, and hydrocarbons on metals by the MO–LCAO method. The authors did not examine only the interaction between substrate molecules and isolated metal atoms, but also considered small metal domains. The results correspond qualitatively to a number of important experimental results.

Some authors also examined the interactions between substrates and the solid's electrons. However, an electronic factor can be expected only with semiconducting catalysts and possibly with metallic catalysts, but not with insulators, and also only in reactions with complete electron exchange between substrate and catalyst (ionosorption). It is therefore not surprising *e.g.* that *F. Bozon-Verduraz* and *S. J. Teichner* (France) (6) found no change in the rate of hydrogenation of ethylene on ZnO whose electron concentration was varied by doping, since the rate-determining step in this case is not associated with an electron exchange. On the other hand, *T. Freund, S. R. Morrison,* and *W. P. Gomes* (USA) (4) found that in the oxidation of formic acid to H_2O_2 and CO_2 on ZnO exposed to light, the concentration of electrons and holes on the catalyst surface determines the reaction rate.

According to *J. M. Criado, J. Dominguez, F. González, G. Munuera,* and *J. M. Trillo* (Spain) (38), the rate of dehydrogenation of formic acid on Cr_2O_3 and on TiO_2 also increases with the electron concentration, which is varied by doping. *C. Borgianni, F. Cramarossa, F. Paniccia,* and *E. Molinari* (Italy) (7) found that p-semiconductors (Cr_2O_3, NiO) are more active than n-semiconductors (ZnO, Fe_2O_3) in the combustion of H_2. *E. G. Schlosser* and *W. Herzog* (Frankfurt/Main) (9) presented a semiquantitative interpretation of the electronic factor on the basis of the combustion of CO and H_2 on doped NiO catalysts. Taking into account the space-charge layers on the catalyst surface, they were able to show that both the increase in reaction rate with increasing hole concentration and the decrease in reaction rate with decreasing hole concentration are much smaller than expected. *J. Scheve* and *I. W. Schulz* (Berlin) (84) believe that the electronic factor is due to energetic excitation of adsorbed molecules as a result of collision with electrons of the solid. The best catalyst is accordingly characterized by maximum energy transfer with agreement between the thermal energy of the electrons and special energy term differences of the molecule, as was shown for the decomposition of N_2O on CuO/Cr_2O_3 mixed catalysts.

N. P. Keyer (USSR) (8) mentioned that the "field effect", in which changes in the electron concentration on the surfaces of solids are brought about by an electric field, should be particularly useful for the investigation of electronic factors, since the catalyst mixture does not change in this case. Results have already been obtained for the decomposition of isopropanol on TiO_2. On the basis of investigations on the hydrogenation of benzene on Cu/Ni alloys, *D. A. Cadenhead, N. J. Wagner,* and *R. L. Thorp* (USA) (26) warn against overestimation of the electronic factor. Whereas the decrease in the reaction rate observed in this case with increasing Cu content had previously been attributed entirely to the filling of the electron vacancies in the 3d band, the authors now believe that the only important factor is the Ni concentration on the catalyst surface, which can differ from that in the interior as a result of a separation effect.

3. Catalytic Activity and Thermodynamic Quantities

As was shown by *W. M. H. Sachtler, G. J. Dorgelo, J. Fahrenfort,* and *R. J. H. Voorhoeve* (Netherlands) (34) for the oxidation of benzaldehyde to benzoic acid on MnO_2, V_2O_5, and V_2O_5/SnO_2 mixed catalysts, by *V. E. Ostrovsky* and *N. N. Dobrovolsky* (USSR) (46) for the combustion of H_2 on Cu, Ag, and Au, and by *A. Cimino, V. Indovina, F. Pepe,* and *M. Schiavello* (Italy) (12) for the decomposition of N_2O on Cr_2O_3/MgO mixed catalysts doped with Li_2O, the activity of the catalysts increases as the chemisorbed oxygen becomes more loosely bound. This is not surprising, since the reaction consists essentially of two steps, *i.e.* the combination of the organic substrate or of hydrogen with chemisorbed oxygen and the re-chemisorption of oxygen on the catalyst, the first step being rate-determining. Similar relationships were found by *G. K. Boreskov, V. V. Popovsky,* and *V. A. Sazonov* (USSR) (33) in the $^{16}O/^{18}O$ exchange in oxygen isotope mixtures on oxides of the first series of transition metals and in the combustion of H_2 and methane on cobaltites and chromites. *D. G. Klissurski* (Bulgaria) (36) confirmed these findings in the oxidation of methanol to formaldehyde on transition metal oxides and on Sb_2O_3, WO_3, and SnO_2, and *K. Kochloefl, M. Kraus,* and *V. Bažant* (ČSSR) (85) mentioned in this connection the dehydration of secondary alcohols on SiO_2, TiO_2, ZrO_2, and Al_2O_3.

In all these cases there is a linear relationship between the logarithm of the reaction rate or the activation energy and the bonding energy of the surface oxygen *i.e.* the free energy of surface oxygen release. This linear relationship, which is also known as the linear free energy relationship (LFER), may according to *V. A. Roiter, G. I. Golodetz,* and *Y. I. Pyatnitzky* (USSR) be regarded as a solid analog of the Hammett or Taft relationship found for homogeneous organic reactions. The authors also showed in the combustion of H_2 and propane on transition metal oxides that the activity cannot be increased indefinitely by the use of catalysts having very low oxygen-binding energies; on the contrary, there is an optimum catalyst for which the oxygen-binding energy is roughly equal to half of the enthalpy of the overall reaction. If the oxygen-binding energy is further decreased the catalyst activity decreases again, since the oxidation of the catalyst now becomes rate-determining instead of its reduction. A plot of the activity against the oxygen-binding energy gives a diagram having the volcano shape described by *Balandin.*

R. A. Gardner (USA) (83) also assessed the catalytic activity from the strength of the catalyst-substrate bond by evaluation of special bond strengths of the intermediates, which affect the IR vibration frequency, as shown for the combustion of H_2 and the combination of H_2 and CO.

4. Statistical Methods for the Discovery of Catalysts

The work of *I. I. Joffe, V. S. Fyodorov, B. Y. Gurevitch, M. A. Ustrayh, I. S. Fux,* and *K. M. Muhenberg* (USSR) (63) may be of special practical interest. The authors use the parameter calculation method known from statistics to find active and selective catalysts, *e.g.* for the oxidation of hydrocarbons, and illustrated the process in the case of the combustion of CO on metal oxides. It was found that out of 20 tabulated physicochemical quantities of the catalysts, only eight are significant for the catalytic activity. These quantities in order of increasing influence, are density, color index, melting point, vacancy volume, electronic structure factor, susceptibility, concentration of d-electron vacancies, and ionization potential of the metal. On the basis of these quantities, a number of metal oxides that have not yet been tested were chosen as promising catalysts for the combustion of CO.

D. A. Dowden, C. R. Schnell, and *G. T. Walker* (England) (62) showed how active and selective catalysts for complicated reactions can be found by the use of an arrangement scheme by means of which a large volume of experimental data can be taken into account, *e.g.* catalysts for the steam reforming of paraffins.

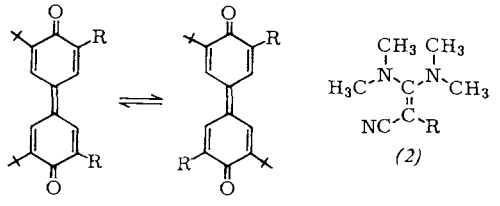
Use of Nuclear Magnetic Resonance to Detect Intramolecular Rotations

By *H. Kessler* [*]

Isomerizations at CC and CN double bonds have been followed by NMR spectroscopy.

Rotation about CC double bonds can take place *e.g.* in quinonemethides [1] and in *o*-diphenoquinones [2] *via* a diradical transition tate. This is also the case with *p*-diphenoquinones of the type *(1)* ($\Delta G^{\ddagger}_{144\,°C}$ = 23.6 kcal/mole for R = C_6H_5) [3].



(2)

R = CH_3, C_6H_5 *(1)*

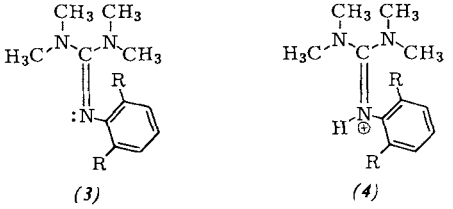
On the other hand, an ionic mechanism occurs in the rotation about the CC double bond in substances of the type *(2)* [4]. Hindrance of rotation about both CN single bonds is also observed (Table 1).

Table 1. Free enthalpies of activation $\Delta G_c^{\ddagger}$ for intramolecular rotations in 1,1-bisdimethylamino-2-cyanoethylenes *(2)*.

	R	$\Delta G_c^{\ddagger}$ (kcal/mole)			
		C=C	C–N [a]	C–N [b]	C-Aryl
(a)	CN	[c]	10.3	10.3	–
(b)	COC_6H_5	15.3	11.1	[d]	–
(c)	$COOC_2H_5$	13.5	13.9	[d]	–
(d)	C_6H_5	21.0	11.6	12.1	< 10
(e)	*p*-Cl–C_6H_4	20.1	11.8	12.3	< 10
(f)	*p*-Br–C_6H_4	20.2	12.0	12.4	< 10
(g)	*p*-CH_3CO–C_6H_4	17.8	12.9	13.2	10.3
(h)	*p*-NO_2–C_6H_4	16.2	13.9	13.8	10.9

[a] Methyl groups evaluated at low field. [b] Methyl groups evaluated at high field. [c] Not interpretable NMR spectroscopically for symmetry reasons. [d] Down to –60 °C the signal of the dimethylamino group at high field does not split.

The $\Delta G_c^{\ddagger}$ values of *(2d)–(2h)* can be correlated with the Hammett σ_p constants, two ρ values being obtained for the C–N rotations. It is therefore concluded that the *p*-substituent has different effects on the *cis* and on the *trans* positions. The *syn-anti* isomerization in phenylguanidines *(3)* proceeds



(3) *(4)*

Table 2. Free enthalpies of activation $\Delta G_c^{\ddagger}$ of the *syn-anti* isomerization of *(3)* and the rotation about C=N⊕ in *(4)*.

	R	Reaction	$\Delta G_c^{\ddagger}$ (kcal/mol)
(3a)	H	Inversion	12.1
(3b)	CH_3	Inversion	11.9
(4a)	H	Rotation	12.6
(4b)	CH_3	Rotation	14.4

via a linear transition state (inversion) [5]. This becomes particularly clear from a comparison of the steric effects of two *o*-substituents in the phenyl ring of *(3)* with the effect in the guanidinium salts *(4)*. In the salts, the free electron pair on the nitrogen is fixed by the protonation, so that only rotation is now possible. The steric effect hinders rotation, but facilitates inversion (Table 2).

Phenyllithium Complexes of Transition Metals

By *Brigitte Sarry* [*]

Either of two types of organometallic compounds may be formed on treatment of anhydrous transition-metal halides with an ethereal solution of phenyllithium.

In the case of iron(III) chloride reduction to Fe(0) occurs, with binding of five molecules of phenyllithium in a complex compound $Fe(C_6H_5Li)_5$ analogous – though only formally so – to iron pentacarbonyl. This product is readily soluble in benzene; it is black and extremely sensitive to oxygen and moisture; it is quantitatively decomposed by water, the course of the hydrolysis depending on the conditions used:

$$Fe(C_6H_5Li)_5 + 7\,H_2O \xrightarrow{a} Fe(OH)_2 + 5\,LiOH + H_2 + 5\,C_6H_6$$
$$\text{(1)} \qquad \xrightarrow{b} Fe(OH)_2 + 5\,LiOH + 7/2\,H_2 + 5/2\,(C_6H_5)_2$$

(a: below –80 °C; b: at room temperature).

Oxidation of *(1)* by iodine causes attack only at the ligands and separation of elemental iron occurs according to the equation:

$$(1) + 5/2\,I_2 \rightarrow Fe + 5\,LiI + 5/2\,(C_6H_5)_2$$

However, in the reaction of *(1)* with mercury(II) chloride for determination of the phenyl groups, the iron is also oxidized:

$$(1) + 6\,HgCl_2 \rightarrow FeCl_2 + Hg + 5\,LiCl + 5\,C_6H_5HgCl$$

On the contrary, reduction of the pentabromides of niobium, tantalum, and tungsten by phenyllithium proceeds only to oxidation state +2 of the transition metal. The resulting diphenylmetals bind additional phenyllithium in neutral complexes of the general formula

$$[M(C_6H_5)_2(C_6H_5Li)_4]\cdot n(C_2H_5)_2O.$$

Their IR spectra show the phenyl groups to be bound to the central atom by σ-bonds.

From comparative investigations of various reactions carried out under the same conditions with phenyllithium complexes on the one hand and with pure, solid, solvate-free isolated phenyllithium on the other, conclusions can be drawn about the nature of the bonding of the phenyllithium to the transition-metal atom. Oxidation of phenyllithium in ethereal solution by dry oxygen leads to phenol and bi-

phenyl; reaction in the solid state gives also *o*-, *p*-, and, in small amounts, *m*-terphenyl. After treatment of phenyllithium with benzophenone and subsequent hydrolysis, triphenylmethanol is the only detectable product.

In contrast thereto, the corresponding reactions of phenyllithium complexes lead in all cases to triphenylene as an essential product along with biphenyl and in some cases some *o*-terphenyl. Thence it is concluded that in the complexes the lithium and the transition metal are bound in *ortho*-positions to the benzene nucleus.

SELECTED ABSTRACTS

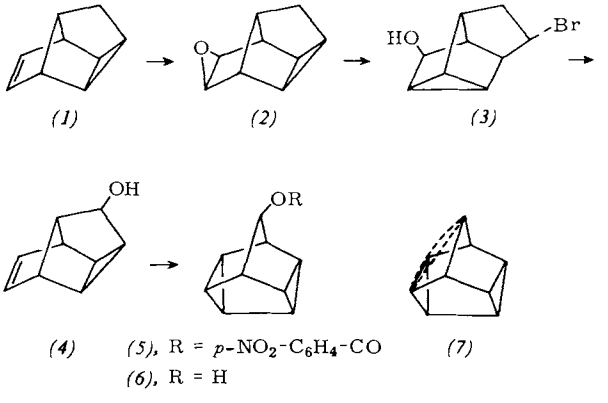
Some reactions of the species C_4 have been described by *R. F. Harris* and *P. S. Skell*. Small quantities of C_4 are present in carbon vapor, which can be produced with a high-vacuum arc. On co-condensation of the vapor with one of the substrates hexane, *cis*-2-pentene, *tert*-butyl chloride, methanol, ethanol, 1- and 2-propanol, and *tert*-butanol (all of which contain hydrogen) on a surface cooled with liquid nitrogen, a mixture of 1-butyne, 1,2- and 1,3-butadiene, and 1-buten-3-yne (vinylacetylene) is obtained from each substrate except pentene and *tert*-butanol, with which no vinylacetylene could be detected. The yields of C_4 hydrocarbons were around 1–2 %. Experiments with ^{14}C-enriched electrodes showed that the C atoms of the products all came from the electrode material. Carbon vapor from an electrically heated carbon filament, surprisingly, does not give the reactions described. / J. Amer. chem. Soc. *90*, 4172 (1968) / –Kr. [Rd 911 IE]

The decomposition of aromatic compounds in the focus of a laser beam has been studied by *R. H. Wiley* and *P. Veeravagu*. The impulse (3.5 ± 0.5 J or 10.0 ± 0.5 J) of a ruby laser was focused by means of a lens on an area of about 0.8 mm² of the sample, which had previously been frozen in liquid nitrogen. 1–3 mg of sample was decomposed. Gas-chromatographic analysis of the decomposition products showed mainly methane and acetylene, together with small quantities of ethane, ethylene, propane, propene, allene, diacetylene, and vinylacetylene, but no butadiene. Hydrogen and carbon monoxide were also detected in a few cases. Polycyclic hydrocarbons (naphthalene, anthracene, phenanthrene, biphenyl) gave a low methane/acetylene ratio (4:85), while monocyclic compounds (toluene, xylene, mesitylene) gave a higher ratio (40:10). Several observations indicate that plasma-like conditions prevail with excited carbon atoms in the reaction zone, *e.g.* the formation of large quantities of acetylene from entirely different substances and the substantial independence of the product distribution when the decomposition is carried out in the presence of nitrogen, oxygen, or hydrogen. / J. physic. Chemistry *72*, 2417 (1968) / –Hz. [Rd 922 IE]

Strongly exothermic heats of solution of palladium in molten tin have been found by *J. R. Guadagno* and *M. J. Pool*. This points to the formation of a compound even in the liquid state. The partial heat of solution of Pd does not change measurably in the concentration range from pure tin to the solubility limit (approx. 26 kcal/g-atom of Pd); it thus differs only slightly from the heats of solution of the known solid Pd–Sn compounds PdSn (–28.84 kcal/g-atom of Pd), $PdSn_2$ (–31.35), and $PdSn_4$ (–33.85). It can therefore be concluded that the bonding is similar and each Pd atom has four tin neighbors in the liquid state. It can be estimated from density measurements on a liquid alloy of 4 % of Pd in Sn that the Pd–Sn distance in a tetrahedral $PdSn_4$ molecule is practically the same as that found in the solid intermetallic compounds. / J. physic. Chemistry *72*, 2535 (1968) / –Hz. [Rd 924 IE]

The transfer of electronic excitation energy from a complex cation (hexaureachromium(III)) to an anion (hexacyanochromate(III)) has been observed by *H. Gausmann* and *H. L. Schläfer*. When the compound $[Cr(ur)_6][Cr(CN)_6]\cdot 3H_2O$ *(1)* [(ur)=$CO(NH_2)_2$] is irradiated with light of a wavelength that is absorbed practically only by the cation (*e.g.* 436 nm), the characteristic phosphorescence of the anion is emitted at 800–880 nm (at about 77 °K). The characteristic emission of the cation at 700–760 nm is not observed. Since the absorption spectrum of *(1)* is practically identical with the superimposed spectra of $K_3[Cr(CN)_6]$ and $[Cr(ur)_6]Cl_3$, there is only very weak coupling of the two chromium(III) centers in *(1)*. In this case it is possible to follow the path of the electronic excitation energy. It is absorbed by the cation (excited state, based on octahedral symmetry, $^4T_{1g}$) and passes nonradiatively into the lowest excited state of the system as a whole, *i.e.* the ^2E_g state of the anion, whence it is emitted as phosphorescence. / J. chem. Physics *48*, 4056 (1968) / –Hz. [Rd 923 IE]

9-Pentacyclo[4.3.0.0^{2,4}.0^{3,8}.0^{5,7}]nonyl *p*-nitrobenzoate *(5)* has been synthesized by *R. M. Coates* and *J. L. Kirkpatrick* from *(1)* ("deltacyclene") *via* the intermediates *(2)*–*(4)*. The solvolysis of *(5)*, m.p. 153.5–154.5 °C, in 65 % aqueous acetone at 125 °C exhibits first order kinetics with k = (7.0 ± 0.2)



(1) *(2)* *(3)* *(4)* *(5)*, R = *p*-NO_2-C_6H_4-CO *(6)*, R = H *(7)*

×10^{-5}sec^{-1} (for comparison, k for 7-norbornadienyl *p*-nitrobenzoate is (5.8 ± 0.1) × 10^{-4} sec^{-1}). On solvolysis of [9-D]-*(5)* with *(6)*, one third of the D content is retained on C-9, and the remainder is found in two equivalent positions. The result suggests that the solvolysis proceeds *via* the cation *(7)*. / J. Amer. chem. Soc. *90*, 4162 (1968) / –Kr. [Rd 912 IE]

The tetracyclo[4.3.0.0^{2,4}.0^{3,7}]non-8-en-5-yl cation *(7)* does not rearrange, as was found by *P. von R. Schleyer* and *R. E. Leone*. The cation occurs in the solvolysis of the *p*-toluenesulfonate *(5)*, which was obtained from 7-norbornadienyl *tert*-butyl ether *(1)* *via* the intermediates *(2)*–*(4)*. On solvol-

(7) (8)

ysis of [5-D]-(5) in buffered CH_3COOH (10% excess of CH_3COONa, 110 °C, 3 hours), only the [5-D]-acetate (6) was found. This result is all the more surprising in that a rearrangement of (7) into (8) is readily conceivable, and the corresponding saturated [8-D]-cation rearranges readily into the [4-D]-cation [1]. / J. Amer. chem. Soc. *90*, 4164 (1968) / –Kr. [Rd 913 IE]

Di-*tert*-butyl thioketene (1) and di-*tert*-butyl thioketene *S*-oxide (2) have been prepared by *E. U. Elam, F. H. Rash, J. T. Dougherty, V. W. Goodlett,* and *K. C. Brannock.* (1) is formed from di-*tert*-butyl ketene or 2-*tert*-butyl-3,3-dimethylbutyryl chloride with P_2S_5 in pyridine. (1) was obtained in yields of 41 and 64% respectively as a purple-red oil boiling at 59 to 60 °C/6 torr.

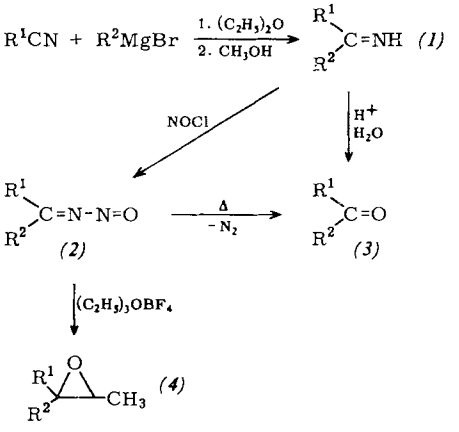
$$[(CH_3)_3C]_2C{=}C{=}O + P_2S_5 \rightarrow [(CH_3)_3C]_2C{=}C{=}S \quad (1)$$

$$[(CH_3)_3C]_2CH{-}COCl + P_2S_5 \rightarrow [(CH_3)_3C]_2C{=}C{=}S$$

Compound (1) does not dimerize or polymerize on storage at room temperature. It reacts with H_2O_2 or monoperphthalic acid to give the thioketene *S*-oxide $[(CH_3)_3C]_2C{=}C{=}S{=}O$ (2), which forms colorless crystals having m.p. 34–35 °C. Compound (2), which is the first known substance of this class, has roughly the same stability as aromatic thioketone *S*-oxides. / J. org. Chemistry *33*, 2738 (1968) / –Kr. [Rd 914 IE]

[1] *P. K. Freeman* and *D. M. Balls*, Tetrahedron Letters *1967*, 437.

N-Nitrosoketimines (*N*-nitrosoalkylidenamines) (2) have been synthesized by *C. J. Thoman* and *I. M. Hunsberger* from nitriles and Grignard compounds. The resulting alkylidenamines (1) were then treated with NOCl to form (2). Examples: $R^1 = R^2 = C_6H_5$, blue, m.p. 50–53 °C (25% yield); R^1 = *p*-tolyl, R^2 = *o*-tolyl, purple-red, m.p. 43 °C (68%); $R^1 = p$-Cl–C_6H_4, $R^2 = o$-Cl–C_6H_4, purple-red, m.p. 69 to 71 °C (76%).



Some nitrosoketimines could be kept only in solution. The compounds with bulky substituents or (in the case of the benzophenone derivatives) with electron-attracting substituents are more stable than the others. The decomposition to form the ketone (3) exhibits first order kinetics. Some nitrosoketimines can be converted by triethyloxonium tetrafluoroborate into oxiranes (4). / J. org. Chemistry *33*, 2852 (1968) / –Kr. [Rd 915 IE]

New adsorbents suitable for thin layer chromatography, according to *G. Hesse, H. Engelhardt,* and *R. Kaltwasser,* are polyacrylamide (1), *N*-acetylpolyacrylamide (2), and polyacrylonitrile (3). Suspensions of the finely divided materials in alcohol give strongly adhering layers on glass, on which water-soluble substances and substances containing hydrogen bonds can be separated. (1) and (2) have been found suitable for the separation of amino acids and dicarboxylic acids (both with alkaline eluents). Benzenesulfonic and toluenesulfonic acids were separated for the first time on (1) in *n*-butanol/water/methylamine (30% in H_2O) (80:6:15). (1), (2), and (3) can be successfully used for the separation of mono- and disaccharides. The separatory action is strongly dependent on the eluent. / Chromatographia *1*, 302 (1968)/ –Kr. [Rd 916 IE]

BOOK REVIEWS

Organometallic Compounds, Methods of Synthesis, Physical Constants and Chemical Reactions. Edited by *M. Dub.* Volume II: Compounds of Germanium, Tin and Lead. Including Biological Activity and Commercial Applications. Edited by *R. W. Weiss.* Springer Verlag, Berlin-Heidelberg-New York 1967. 2nd enlarged Edition. vii, 695 pp., 216 tables, DM 98.–.

The second edition of this meritorious book has been enlarged considerably and reviews the literature from 1937 to 1964 (1st Edition: 1937 to 1958). Thus, a complete survey of the literature concerning this important branch of organometallic chemistry, from the days of *E. Frankland,* is now available: Up to 1936 through the excellent critical treatment by *E. Krause* and *A. v. Grosse* (published by Borntträger, Berlin 1937, reprinted by Sändig, Wiesbaden 1965), from 1964 to 1966 through the annual literature surveys by *D. Seyferth* and *R. B. King* (published by Elsevier, Amsterdam), and finally through Part B of Organometallic Chemistry Reviews.

The book provides a complete collection of the literature. The seemingly overwhelming material has been presented in

a clear and readily usable form through skillful use of a system of tables and summaries. The tables, which are arranged according to groups of substances, provide information on methods of preparation and – as far as is known – yields; further, on physical properties and reactions, and in many cases also references to spectroscopic measurements, physiological effects, and proposed or actual technical applications of the individual substances. Critical evaluation of the subject matter is naturally left mainly to the reader himself – as is the case, for example, in "Beilstein". For instance, all the methods given for preparation of a substance in the literature of the period reported are listed alongside one another, complete with the often varying values for physical properties reported by the original authors. Since the work is not intended as a text book for students, but as a comprehensive, noncritical source of information for the specialist, this feature is certainly no drawback.

W. P. Neumann [NB 742 IE]

Strahlenchemie. Grundlagen – Technik – Anwendung. (Radiation Chemistry. Principles – Techniques – Applications.) Edited by *K. Kaindl* and *E. H. Graul*. Dr. Alfred Hüthig Verlag, Heidelberg 1967. 1st Edit., 645 pp., 236 figs., 95 tables, plastic cover, DM 92.–.

This book contains the contributions of seven well-known authors and is arranged in 12 chapters. Particular attention is given to the possibilities of quantitative treatment of radiation chemical processes, and the most important units and conversion factors are therefore discussed extensively. Another section shows the considerable progress that has been made in the last 20 years in the development of nuclear reactors, accelerators, and other sources of radiation. Only chemical dosimetry has been considered on the whole for the quantitative determination of the energy absorbed by a system that has been subjected to ionizing radiation.

The importance of radiation chemical reactions in water and aqueous solutions is clearly indicated. The main emphasis in the treatment of organic molecules has been placed on the polymerizations induced by irradiation – one of the main fields of radiation chemical research and of technical utilization – and it is satisfying to see that the kinetics of the processes have not been neglected. In addition, radiolysis of organic reactor coolants has been considered. A later edition should if possible indicate the possibilities of radiation chemical synthesis of low-molecular organic products.

Radiolytic effects in frozen solutions, important for the chemistry of radicals, are treated briefly. There are some excellent chapters on the radiation chemistry of solids and the influence of radiation on catalysts, outlining some possibilities of irradiated catalysts. The last chapter, written in English, deals with radiation-induced reactions in gases. All chapters have an index to the literature, arranged in alphabetical order of the authors' names.

In general, it can be said that the high standard of this work does credit to the authors and editors. The book fills a gap in an important field that has been somewhat neglected in Germany, and it can therefore be recommended to every scientist and engineer interested in radiation chemistry.

H. Drawe [NB 750 IE]

Comprehensive Biochemistry. Volume 26: "Extracellular and Supporting Structures". Parts A and B. Edited by *M. Florkin* and *E. H. Stotz*. Elsevier Publishing Company, Amsterdam-London-New York 1968. Part A: xvi, 295 pp., many figures and tables, Dfl. 47.50; Parts B: xii, 297 pp., many figures and tables, Dfl. 47.50.

Volume 26 of "Comprehensive Biochemistry"[1] deals with the molecular structure and the biochemical function of the extracellular supporting structures. Two of the planned total of three subvolumes have so far been published. The first one considers the substances and tissues occurring in microorganisms and plants, and the second one those found in vertebrates. In spite of their briefness, the various sections are treated thoroughly and are up to date. The complete volume will contain almost 1000 pages. This fact is an indication both of the great interest in this subject and of the biological importance of the cell-supporting structures, which are of paramount importance for contact with the environment.

Isolation, chemical and physical characterization, biosynthesis, and physiological function are treated in the individual sections, the literature up to 1966 having been reviewed in an excellent manner. The respective authors have either aimed at providing a complete bibliography or made an excellent choice of the most important publications. Once again it has proved possible to engage authors of international standing.

A terse and exhaustive account of the polysaccharides, polyuronides, and lignin of plant cells is given by *S. M. Siegel. J. M. Ghuysen, J. L. Strominger*, and *D. J. Tipper* display their mastery in a skillfully written review of the cell-wall structures of gram-positive bacteria; the same applies to *O. Lüderitz, K. Jann*, and *R. Wheat*, the authors of the extremely thorough, expert article on the antigenes of gram-negative cells. The interesting topic of shell formation by mussels, snails, and birds is summarized in a comparative manner by *K. M. Wilbur* and *K. Simkiss. A. J. Bailey* provides a detailed and scholarly guide through the broad and complex field of the collagens, and *B. J. Barrett* through that of cartilaginous tissue. In both these chapters the subject matter is viewed from the most varied aspects, starting from the structure and the biosynthesis and going through to aging, so that a unique review has resulted that is certainly worthy of the series. In their section on silk and other spun fibers, *F. Lucas* and *K. M. Rudall* consider all the available material from a number of different points of view. Fittingly, there follows a brief and yet exhaustive section on intracellular fibrous proteins and keratinization (*K. M. Rudall*).

Together, the two subvolumes cover the fields considered in a series of varied, competent, and contemporary articles. *M. Florkin* and *E. H. Stotz* have once again succeeded in bringing out a work that continues this remarkable monographic text- and hand-book in the expected manner. Without doubt these eminently successful volumes again deserve the highest praise; they maintain the excellent quality of their predecessors.

L. Jaenicke [NB 741a IE]

Comprehensive Biochemistry. Volume 27: Photobiology, Ionizing Radiations. Edited by *M. Florkin* and *E. H. Stotz*. Elsevier Publishing Company, Amsterdam-London-New York 1967. 1st Edit., xvi, 356 pp., 104 figures, 23 tables, Dfl. 55.00 / 114 s.

This extensive handbook of biochemistry now enters the realm of molecular biology proper with the fifth section, which is to embrace eight volumes. The present volume 27 shows that radiation effects of the most widely varying kinds are approachable from a biochemical angle and are no longer the exclusive domain of radiologists and physiologists, and analyzes the detection and biochemical and biophysical applications of radiations of all kinds. The first seven chapters, which deal with photobiology as such, are certainly of the standard expected of this competent work.

Photomechanical reactions of plants are described in the contributions on phototropism (*K. V. Thimann*), photosynthesis (*L. N. M. Duysens* and *J. Amesz*), phytochrome and photoperiodism (*S. B. Hendricks* and *H. W. Siegelman*); the treatment of photosynthesis is, however, rather categorical, this probably being attributable in part to a desire to avoid duplication of material in earlier volumes, and hardly considers the outstanding work of *H. T. Witt*. On the other hand, *J. K. Setlow* gives a detailed and most useful account of the

[1] Cf. Angew. Chem. *79*, 627 (1967); Angew. Chem. internat. Edit. *6*, 646 (1967).

effects of ultraviolet radiation on proteins, nucleic acids (pyrimidine dimerization), and nucleoproteins. However, a more rigorous treatment of fundamentals, and of photochemical and photophysical primary processes as an introduction, which will certainly be missed by the biologist, would have been welcomed. The other chapters are concerned with biochemistry of vision (*C. D. B. Bridges*), bioluminescence in various organisms (*F. H. Johnson*), and the photosensitization of biological material (*M. I. Simon*). One will miss references to the important work done on quinone-catalyzed photooxidation in this section.

In spite of the broad field covered in comparison with the preceding articles, the final chapter by *P. Alexander* and *J. T. Lett* on the effects of ionizing radiation on biological macromolecules gives more the impression of an appendix, and by no means provides an adequate treatment of the available knowledge in this field, particularly more recent work. However, one can always argue about how much space should be devoted to these things in such a comprehensive work: they could even occupy a separate volume. On the whole, this book gives a well balanced impression and summarizes a topic that has been the ground of various diverging disciplines for much too long. The literature has been covered up to 1966, thus making this volume a highly informative and desirable standard work. *L. Jaenicke* [NB 741b IE]

Atomic Absorption Spectroscopy and Analysis by Atomic Absorption Flame Photometry. By *J. Ramírez-Muñoz*. Elsevier Publishing Company, Amsterdam-London-New York 1968. 1st Edit., xii, 493 pp. 156 figs., 23 tables, bound, Dfl 80.—.

The analytical technique of atomic absorption spectroscopy, which has been described in four monographs in English within the space of two years, deserves special consideration. The present work is one of those four monographs and, from its size, the fullest. The author, who is a spectroscopist employed by a firm of instrument makers, divides his book into five chapters which are unfortunately very uneven in treatment. Within this framework, the fundamentally simple theory of atomic absorption spectroscopy is mentioned only briefly but quite sufficiently. Most of the space is taken up by description of instrumental details. It is in this section that the danger exists that, without a critical selection, which is lacking in this work, the details may obscure the whole. Light sources and burners are certainly important parts of the apparatus, but it is not justifiable to devote a fifth of the book to them. The very wide expositions on sensitivities and detection limits unfortunately do not clarify these important aspects of analysis. The experimental methods, so long as they deal with general details like solutions for calibration, preparation of diluted solutions, and calculation of the results, are treated very fully. On the other hand, there is no special reference to the possibility of interference and its avoidance.

The actual application of atomic absorption spectroscopy to the quantitative determination of particular elements in the presence of others is treated too briefly. The author often limits himself to a literature reference, without going further into the analytical directions or the relevant range of concentration. This last part, which deals specifically with applications (40 pp.), should be enlarged. The volume of literature quoted certainly justifies a wider treatment.

The bibliography, which comprises 950 citations up to about 1966, has been compiled very carefully. References that are difficult to obtain, and older reports of symposia, have been conscientiously recorded.

For those concerned with the apparatus side of atomic absorption spectroscopy, the present book with its ample collection of material will be an excellent aid. For the practising analyst confronted every day with new problems that he might wish to solve by this method, the present volume offers too little that would give information and advice in the laboratory.

In spite of these limitations, this is still the most comprehensive monograph on the subject. The rather one-sided emphasis or preference for some aspects does not diminish the great service that the author has rendered in making a considerable contribution to the further diffusion of a new analytical technique. *J. Ringhardtz* [NB 755 IE]

Clathrate Compounds. By *V. M. Bhatnagar*, S. Chand & Co., Delhi-New Delhi-Jullundur-Lucknow-Bombay-Calcutta-Madras 1968. 1st Edit., viii, 244 pp., many Figures and Tables, Rs. 20.00 / $ 8.00.

The book is a – not completely exhaustive – collection of the literature concerning inclusion compounds, in which the various types of inclusion compounds (urea, gas hydrates, deoxycholeic acids, cyclodextrins, *etc.*) are reviewed. Unfortunately, the extremely interesting theoretical aspects of bonding in these substances are not discussed at all. The division of the subject matter appears arbitrary. For instance, the term clathrate compound (title of the book) is not defined until page 60 of a total of 132 pages of text. The bonding, the essentially new feature of these compounds, is dismissed in a single sentence: ".....very weak forces like those of H bonds and of the van der Waals type, which are normally not capable of joining molecules together, may contribute to hold the two components in the inclusion compounds together". That is rather meager! The catalytic action of inclusion compounds, and inclusion compounds in biochemical reactions and in protein chemistry, are not considered at all. The claims made in the foreword – "This book is designed to gather together in one place the total literature pertaining to clathrate compounds", or "it will be the first book to give a detailed catalogue of all the work on clathrates from the origin to date" – appear to the reviewer to be at least unjustified. The book contains no subject and author index. Technical production is poor. The information that it contains can probably be obtained more readily and more cheaply from review articles written by competent researchers.

Olefin Alkylation in Biosynthesis

BY J. W. CORNFORTH [*]

Stereochemical studies, made possible by asymmetric labeling with hydrogen isotopes, have led to the hypothesis that enzymic association of C_5 units in polyisoprenoid synthesis is not a concerted process but proceeds in two steps: a trans 1,2-addition to an olefin followed by a trans 1,2-elimination. It is shown that similar mechanisms can also explain the cyclization of squalene epoxide to tetracyclic and pentacyclic triterpenoids.

1. Introduction

It is difficult, though perhaps not impossible, to imagine a chemical basis for life in which connected carbon atoms play no part. Recent experiments on the genesis of "life-like" molecules from substances, such as methane and hydrogen cyanide, which might be presumed to have been abundant on the prebiotic earth, have indicated several natural non-biotic mechanisms for carbon-carbon bond formation. The hypothesis underlying such experiments is that the first life on earth was organized from existing, complex chemical species, and a necessary consequence is that mechanisms for biosynthesis evolved before the available supply was exhausted: mechanisms for carbon-carbon bond formation along with the rest.

In the biosynthetic reactions leading to proteins, carbohydrates, nucleic acids, and most lipids, condensations of the aldol and Claisen type predominate: an enolate anion, formed by removal of hydrogen (or sometimes carboxyl) α to a carbonyl group, attacks another carbonyl group. The *alkylation* of enols, so common in organic synthesis, is curiously rare in biosynthesis; it is probably true that the nucleophilic carbonyl group and the electrophilic enolate ion generate, by reaction with each other, most of the carbon-carbon bonds found in nature.

This is one reason why the enzymes of terpenoid biosynthesis [1] are of especial interest: although (*R*)-mevalonic acid *(1)*, the starting-point for all terpenoid biosynthesis, is formed by Claisen condensation of three molecules of acetyl-coenzyme A, neither the aldol nor the Claisen condensation is of any further importance in forming the many additional carbon-carbon bonds of the terpenoids. Instead, we have a type of reaction which can be classed as olefin alkylation.

The "leaving" group for the first alkylation [*(4)* + *(3)* → *(7)*] is pyrophosphate ion. Mevalonic acid 5-pyrophosphate *(2)* is produced by two successive phosphoryl transfers to (*R*)-mevalonic acid *(1)* from adenosine triphosphate. The double bond required for further alkylation is then generated by a concerted elimination reaction, also requiring adenosine triphosphate; the four products obtained in this step are inorganic phosphate, adenosine diphosphate, carbon dioxide, and isopentenyl pyrophosphate *(3)*. The leaving group is then activated further by a prototropic exchange which produces dimethylallyl pyrophosphate *(4)*. The increased electrophilic activity of the allylic pyrophosphate *(4)*, compared with the homoallylic isomer *(3)*, is seen for example in its sensitivity to aqueous acid. Below pH 5 pyrophosphate ion is rapidly eliminated and water is alkylated; the major product is the alcohol *(5)* presumably formed from the intermediate allylic carbonium ion *(6)*. The sequence of enzymic reactions leading from *(1)* to *(4)* was first indicated in soluble preparations from yeast, and then from liver. The four enzymes responsible have been extensively purified. Each of them can be separated from the other three, though none of them has yet been obtained completely pure.

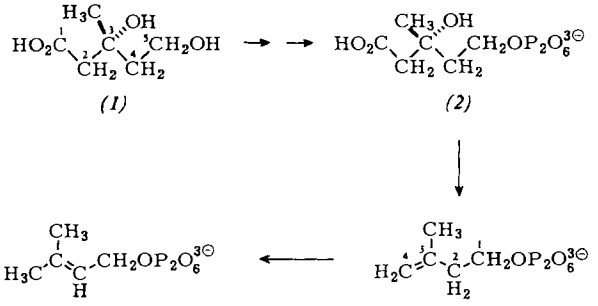
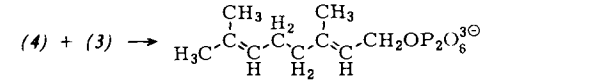
[1] An excellent review of terpenoid biosynthesis is that by *R. B. Clayton*, Quart. Rev. (chem. Soc. London) *19*, 168, 201 (1965).

Combination of the intermediates *(3)* and *(4)* is the first and characteristic step in the biosynthesis of polyisoprenoids. In this enzymic reaction, a molecule of dimethylallyl pyrophosphate and one of isopentenyl pyrophosphate react, with loss of a proton and of a pyrophosphate anion, to form a new allylic pyrophosphate. In the soluble liver and yeast preparations which so far have been the most extensively studied, the product is geranyl pyrophosphate *(7)*. This allylic pyrophosphate can then react, apparently on the same enzyme, with another molecule of isopentenyl pyrophosphate *(3)* to produce the C_{15}-derivative farnesyl pyrophosphate *(8)*. Further chain-lengthening to geranylgeranyl pyrophosphate does not proceed at a measurable rate with this enzyme system.

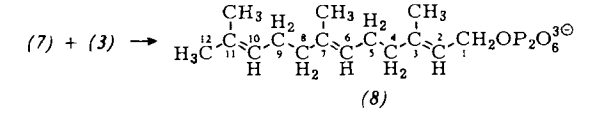


(1) *(2)* *(3)* *(4)*

(5) *(6)*



(7)



(8)

The formation of *(7)* can be interpreted as proceeding by way of two carbonium-ion intermediates, thus:

$$\underset{(4)}{\text{R–OPP}} \rightarrow \text{R}^+ + \text{OPP}^- \qquad (1)$$

$$\text{R}^+ + \underset{(3)}{\text{H}_2\text{C=C(CH}_3\text{)CH}_2\text{CH}_2\text{OPP}} \rightarrow \text{RCH}_2\overset{+}{\text{C}}\text{(CH}_3\text{)CH}_2\text{CH}_2\text{OPP} \qquad (2)$$

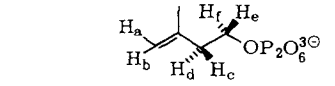
$$\text{RCH}_2\overset{+}{\text{C}}\text{(CH}_3\text{)CH}_2\text{CH}_2\text{OPP} \rightarrow \underset{(7)}{\text{RCH}_2\text{C(CH}_3\text{)=CHCH}_2\text{OPP}} + \text{H}^+ \qquad (3)$$

R = dimethylallyl

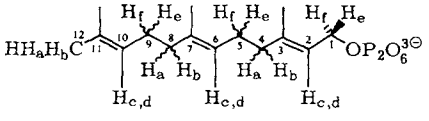
The isomerization of isopentenyl pyrophosphate to dimethylallyl pyrophosphate can also be interpreted by equations (2) and (3), if H^+ replaces R^+.

2. Stereochemical Considerations

To know what actually happens on the enzyme, more information is needed than is ascertainable by present methods. Some insight can be gained, however, by studying the stereochemistry of the condensation; and during the last few years *Popják* and the writer, at Milstead Laboratory, have examined the stereochemistry of polyisoprenoid, and particularly of squalene, biosynthesis.



(9)



(10)

It is not immediately apparent that anything can be learned in this way, for the optical asymmetry present in mevalonic acid and its phosphates is lost in isopentenyl and dimethylallyl pyrophosphate. However, in isopentenyl pyrophosphate there are three methylene groups. Assuming that it is possible to distinguish between the two hydrogen atoms on each methylene group, as in *(9)*, and also to trace the fate of each hydrogen atom in the products of the enzymic reactions leading, for example, to farnesyl pyrophosphate *(10)*, then several conclusions are possible concerning what happens on the enzymes. Let us suppose that in the stereochemical sequence rules [2] H_a ranks higher than H_b and H_e ranks higher than H_f. Then

1) If the hydrogen-ion eliminations in the isomerization and in the two coupling reactions are stereospecific, positions 2, 6, and 10 in *(10)* will be occupied by H_c or H_d according to the stereochemistry. Nonstereospecific reactions would lead to mixtures of H_c and H_d at these positions.

2) Displacement of pyrophosphate anion is necessary to form the carbon-to-carbon bonds between positions 4–5 and 8–9. If these displacements occur with inversion of configuration the absolute configurations at C-5 and C-9 in *(10)* will be (*S*); if retention of configuration is the rule, then these absolute configurations will be (*R*). If these displacements are nonstereospecific (as carbonium-ion reactions often are), then (*RS*)-configurations will result at C-5 and C-9.

3) The two sides (above and below the plane of the projection *(9)*) of the double bond in isopentenyl pyrophosphate are not equivalent in an asymmetric environment. If the new carbon-carbon bond is formed from *below* the plane of this double bond, the absolute configurations at C-4 and C-8 in *(10)* will be (*S*); if it

[2] *R. S. Cahn, C. K. Ingold,* and *V. Prelog,* Experientia *12,* 81 (1956).

is formed from *above* that plane, the absolute configurations will be (*R*).

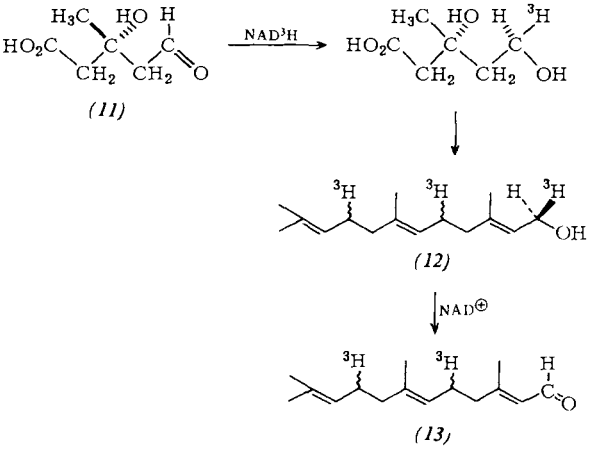
These three potentially stereospecific processes define the stereochemical behavior of all atoms in the substrates which undergo permanent changes in bonding as a result of the coupling reaction. The isomerization is not so completely defined, for the transformation of isopentenyl pyrophosphate *(3)* into dimethylallyl pyrophosphate *(4)* requires the uptake of a hydrogen ion. The terminal methylene group in *(3)* can take up the ion from above or below the plane of the double bond, but the resulting pattern of substitution (*e.g.* the C-12 methyl group in *(10)*) has no chirality unless the entering hydrogen can be distinguished from *both* H_a and H_b. Since the only practical way of distinguishing between the two hydrogen atoms in each pair (H_{ab}, H_{cd}, H_{ef}) is to label one of them with a hydrogen isotope, it follows that chirality could only be introduced at the methyl group of dimethylallyl pyrophosphate by using all three known isotopes of hydrogen, and the stereochemistry of hydrogen addition could only be solved by devising some method of recognizing this chirality.

2.1. Preparation of Isotopically Labeled Compounds

Experimentally, it is not convenient to label isopentenyl pyrophosphate *(3)* directly with hydrogen isotopes. Its precursor mevalonic acid *(1)* is a better subject, for the principal reason that mevalonic acid already possesses a center of asymmetry at C-3, and that only (*R*)-mevalonic acid is accepted as a substrate by the enzyme that phosphorylates it [3, 4].

If a hydrogen atom at the 4- or 5-position of mevalonic acid is replaced stereospecifically by deuterium or tritium, this configuration will persist at the corresponding position (2 and 1 respectively) of the isopentenyl pyrophosphate *(3)* formed from it enzymically, since at neither of these carbon atoms is the bonding altered. If, however, mevalonic acid is labeled stereospecifically at the 2-position with isotopic hydrogen, the relationship between the chirality at C-2 of mevalonate with the geometry at C-4 in isopentenyl pyrophosphate depends on the mechanism of the elimination reaction *(2)* → *(3)*. Therefore, it is necessary to determine the orientation of isotopic hydrogen at C-4 of the isopentenyl pyrophosphate – it is not sufficient, as it is with C-1 and C-2, to know the configuration of the parent mevalonate.

Introduction of labeled hydrogen (both deuterium and tritium) into C-5 of mevalonic acid was done enzymically [5]. An enzyme extractable from pig liver, mevaldate reductase [6], transfers hydrogen from NAD^2H and NAD^3H to mevaldic acid *(11)*, the aldehyde of mevalonic acid; NADH itself can easily be labeled with deuterium or tritium. Curiously, the enzyme reduced both the (*R*)- and the (*S*)-forms of mevaldic acid, but this lack of stereospecificity is at a site remote from the center of action. Tritium-labeled mevalonic acid, prepared in this way, was converted by a preparation of soluble enzymes from rat liver into



(11) *(12)* *(13)*

farnesyl pyrophosphate, which could be hydrolyzed enzymically (alkaline phosphatase) to farnesol. When this labeled farnesol *(12)* was oxidized to farnesal *(13)* by NAD^+ in the presence of liver alcohol dehydrogenase, one-third of the tritium, *i.e.* all the tritium at C-1, was lost.

The orientation of the hydrogen removed from primary alcohols by liver alcohol dehydrogenase has been determined, for ethanol, as pro-*R*. If the stereospecificity of alcohol dehydrogenase is the same for farnesol as for ethanol (as would be expected) then the isotopic hydrogen introduced into mevalonate by mevaldate reductase should also produce this (5*R*) configuration. Confirmation of this was obtained [7] from experiments with geraniol as a model for farnesol, showing that liver alcohol dehydrogenase removes the pro-*R* hydrogen from geraniol; later, a direct correlation of the specificities for geraniol and for ethanol was obtained [*] by chemical degradation of geraniol, labeled with tritium by reduction of geranial with NAD^3H in the presence of liver alcohol dehydrogenase, to ethanol containing the same primary hydroxyl group. On liver (or yeast) alcohol dehydrogenase this ethanol lost all its tritium.

For the stereospecific labeling at the 4- and 2-positions of mevalonic acid, chemical methods were used. The acid *(14)* and the lactone *(15)* [8] were first converted into the geometrically isomeric benzhydrylamides *(16)* and *(17)*. Each of these was epoxidized and subsequently reduced by $LiBD_4$ to give, after alkaline hydrolysis, two specimens of mevalonic acid labeled with deuterium at position 4.

Because of the method of synthesis, these two specimens of mevalonic acid must be composed of different molecular species. The epoxidation of a double bond by a peroxy-acid is a *cis* addition of oxygen; the

reduction of an epoxide by a metal hydride produces inversion of configuration at the center from which oxygen is displaced. Hence the benzhydrylamide *(16)* produced a racemic mixture of the enantiomeric epoxides *(18a)* and *(18b)*, and from this by reduction and hydrolysis the racemic mixture *(20a)* and *(20b)* was formed; whereas the benzhydrylamide *(17)* gave the racemic mixture *(21a)* and *(21b)* *via* the racemic epoxide *(19a)* and *(19b)*. Further, because mevalonic kinase phosphorylates only the (3*R*) form of mevalonic acid, the racemic mixtures *(20)* and *(21)* will behave enzymically as though each consisted exclusively of one molecular species *(20a)* and *(21a)*. When the sequence of enzymic reactions has proceeded as far as isopentenyl pyrophosphate, the asymmetry at C-3 of mevalonate is destroyed but the asymmetric labeling persists, *(20a)* giving exclusively the (2*S*) enantiomer *(22)* and *(21a)* giving exclusively the (2*R*) *(23)* [9].

The diastereoisomeric mevalonic acids *(20)* and *(21)* were also useful in solving the problem of labeling position 2 of mevalonic acid asymmetrically with hydrogen. For if the carboxyl and hydroxymethyl functions of mevalonic acid are exchanged, the product is still mevalonic acid with the difference that C-4 has become C-2 and a (3*R*)-mevalonic acid has become (3*S*). Thus the enzymically inactive component *(20b)* gives enzymically active (3*R*) [2*R*-2-D_1]mevalonic acid *(24)*. Similar treatment of the racemic mixture *(21)* will give *(25)* as the sole enzymically active molecular species.

The necessary inversion of functional groups was effected [10] in three stages: 1) C-4 labeled mevalonates were esterified by reaction of methyl iodide with the silver salts; 2) the methyl mevalonates were oxidized by zinc permanganate in cold acetone to methyl hydrogen 3-hydroxy-3-methylglutarates; 3) reduction of the lithium salts with lithium borohydride then gave C-2 labeled mevalonates.

The enzymic reaction leading from mevalonic acid 5-pyrophosphate *(2)* to isopentenyl pyrophosphate *(3)* is a *trans* elimination of water and carbon dioxide; so that (3*R*)[2*R*-2-D_1]mevalonate generates *cis*-[4-D_1]-isopentenyl pyrophosphate *(26)* and (3*R*)[2*S*-2-D_1]mevalonate generates *trans*-[4-D_1]-isopentenyl pyrophosphate *(27)*. However, this was not known *a priori* and the geometry of the two deuterioisopentenyl pyrophosphates, prepared enzymically from the two mevalonates, had to be ascertained [10]. This was done by enzymic hydrolysis of both compounds to isopentenol *(26a)* and *(27a)*, addition of

[9] *J. W. Cornforth, R. H. Cornforth, C. Donninger*, and *G. Popják*, Proc. Roy. Soc. (London), Ser. B *163*, 492 (1966).

bromine to the double bond, and elimination of hydrogen bromide by methanolic alkali in conditions favoring the E_2 reaction. The main product is a mixture of *trans*-4-bromoisopentenol with a lesser amount of the *cis* isomer. Since addition of bromine to a double bond is specifically *trans*, and the E_2 elimination preferentially *trans*, it follows that the deuterium in *cis*-[4-D_1]isopentenol will be retained in the *cis*-4-bromoisopentenol and absent from the *trans*; the converse will be true with *trans*-[4-D_1]isopentenol. By separation of the geometrically isomeric bromoisopentenols (by gas-liquid chromatography) and examination of each isomer for deuterium (by mass spectrometry) it could be shown that deuterium was retained in the *cis*-4-bromoisopentenol *(28)* derived, ultimately, from (3*R*)[2*R*-2-D_1]mevalonate *(24)* and in the *trans*-4-bromoisopentenol *(29)* derived from (3*R*)[2*S*-2-D_1]-mevalonate *(25)*. From the other two bromoisopentenols, the deuterium was largely lost. Thus the enzymic formation of isopentenyl pyrophosphate was established as a *trans* elimination, and the stereochemical correlation between C-2 labeled mevalonates and C-4 labeled isopentenyl pyrophosphates was secured.

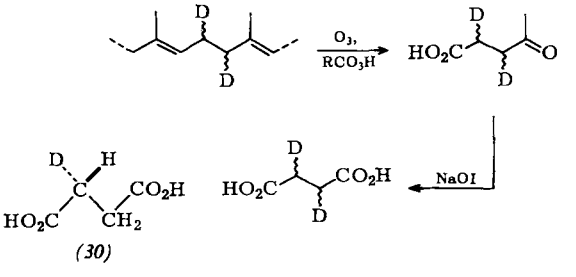
3. Formation of Polyisoprenoids from C_5 Units

The stereochemistry of the alkylation step leading to polyisoprenoids was defined by tracing the fate of deuterium or tritium when these stereospecifically labeled mevalonates were used as substrates for cell-free preparations of rat liver. Sometimes farnesyl pyrophosphate was chosen as the end-product for examination; sometimes squalene.

When farnesyl pyrophosphate is synthesized enzymically from three mevalonate units, three hydrogen atoms are eliminated which were originally attached to C-4 of mevalonate. By mass-spectrometric examination of farnesol derived by enzymic hydrolysis from biosynthetic farnesyl pyrophosphate, it was found[9] that when (3*R*)[4*R*-4-D_1]mevalonate was the precursor all three deuterium atoms were retained, but that deuterium-free farnesol was formed when (3*R*)[4*S*-4-D_1]mevalonate was the precursor. This result was confirmed by examination of squalene, biosynthesized from either C-4 deuteriated or C-4 tritiated mevalonates; the 4*R* hydrogen was completely retained and all of the 4*S* hydrogen was lost.

When mevalonates labeled at the 2- and 5-positions were the precursors, only deuterium could be used as the labeling isotope. Farnesol or squalene derived enzymically from these labeled precursors was degraded by ozonolysis; the levulinic acid, which contained the potentially asymmetric centers to be investigated, was oxidized by alkaline sodium hypoiodite to give as main products iodoform and succinic acid.

We had already prepared, for a different purpose, asymmetrically labeled monodeuteriosuccinic acid of known absolute configuration, and had shown that its optical activity in the ultraviolet is easily measurable by a modern spectropolarimeter; $[\alpha]_{250nm}$ is $\pm 18°$, so that a few milligrams of pure succinic acid suffice to determine the direction and extent of asymmetric labeling. Squalene made biosynthetically



(30)

from (3*R*)[5*R*-5-D_1]mevalonate[9], and farnesol from (3*R*)[2*R*-2-D_1]mevalonate[10], were degraded to succinic acid as described. Each of these succinic acids was found to consist essentially of [2*R*-2-D_1]succinic acid *(30)*, the optical activity corresponding to the deuterium content of the specimen, as measured by mass spectrometry of the methyl ester or the anhydride[11].

Assume that a molecule of isopentenyl pyrophosphate, which is to be alkylated by a molecule of a primary allylic pyrophosphate *(31)*, is oriented on the enzyme as represented in *(32)*. The two carbon atoms of the double bond and the four atoms attached to them are in the plane of the paper. Then our results show (i) that complete inversion of configuration occurs at the primary allylic carbon atom (C-2) when pyrophosphate ion is displaced and the new C–C bond is formed, (ii) that this bond is formed from *below* the plane of the double bond in isopentenyl pyrophosphate, and (iii) that the 2*R* hydrogen atom of the isopentenyl pyrophosphate is eliminated to form the new, *trans*, double bond.

[11] *G. Popják* and *J. W. Cornforth*, Biochem. J. *101*, 553 (1966).

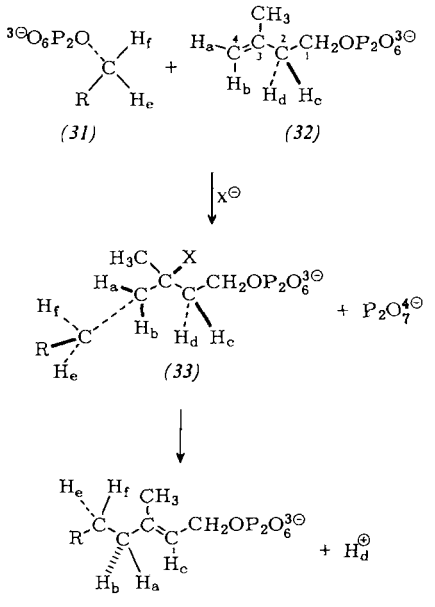
From (i) the conclusion may be drawn that the condensation cannot be initiated by formation of a carbonium ion from the allylic pyrophosphate, unless (a) the carbonium ion is spatially so restricted that rotation about the $C-CH_2^+$ bond is forbidden, or (b) formation of the new C–C bond occurs so rapidly that there is insufficient time for this rotation to occur. The simplest explanation, requiring no such special hypotheses, is that the new bond is formed as the old bond breaks: a reaction of S_N2 type where inversion of configuration is normal. This makes the C–C bond formation a concerted process.

Is it possible to extend this concept and to represent the whole condensation as a concerted process, a continuous drift of electrons starting from the $C-H_R$ bond at position 2 of isopentenyl pyrophosphate and ending with the departure of pyrophosphate anion? If the stereochemical requirements (ii) and (iii) are considered together, this appears unlikely. For since a *trans* double bond is being generated in the product, the entire isopentenyl pyrophosphate molecule must be oriented for a concerted reaction, as shown, with H_R on C-2 (that is, H_d) *below* the plane of the paper. Since the electrons of the $C-H_R$ bond are being used to form the new double bond, C-3 of the isopentenyl pyrophosphate is having electrons supplied to it (to form the new double bond) and withdrawn from it (to form the C–C bond) on the same side; effectively, a nucleophilic substitution with retention of configuration. This seems energetically far less favorable than a concerted mechanism in which electrons are supplied to, and withdrawn from, opposite sides of C-3; but in the present case this would lead either to a *cis* double bond or to the elimination of H_S: both contrary to experiment. Indeed, when rubber (which has *cis* double bonds) is biosynthesized, it is H_S which is eliminated, not H_R.

These considerations have led us to postulate a two-stage mechanism for the alkylation, in which an electron-donating group X is supposed to participate. This group might be part of the enzyme, but it might also be an enzyme-bound water molecule, or an oxygen atom of the pyrophosphate group in isopentenyl pyrophosphate (a hypothesis put forward by *Johnson* [12] before the stereochemical details were known). The first stage is then a *trans*-addition of the allylic group and of X to the double bond of isopentenyl pyrophosphate; the second stage is a *trans*-elimination of X and H_R from the intermediate *(33)* to generate the new double bond. If the group X has a formal negative charge, its binding to C-3 might not at any stage be more than that in a close ion-pair.

This mechanism accounts satisfactorily for the observed stereochemistry of the condensation. However, an alternative explanation is possible.

In a classical publication [13], *Eschenmoser*, *Ruzicka*, *Jeger*, and *Arigoni* showed how the cyclization of *trans*-squalene could lead without formation of stable intermediates to all known types of tetracyclic and pentacyclic triterpenes by a series of stereospecific steps. The cyclizations, which are all classifiable as olefin alkylations, were assumed to proceed by "antiparallel"

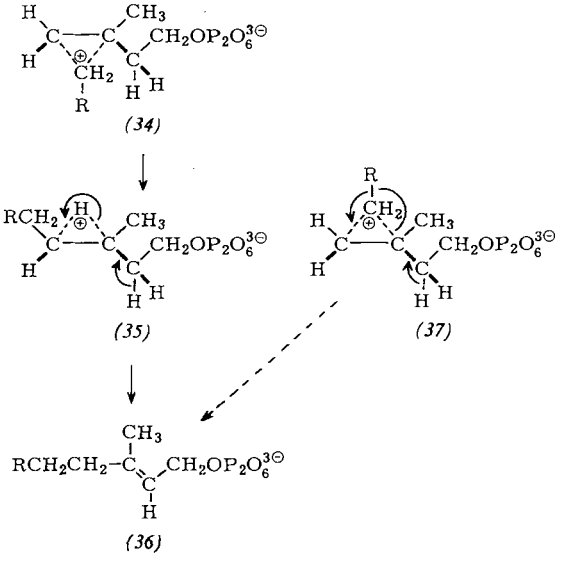


(31) *(32)* *(33)*

(*trans*) addition, to a double bond, of a carbonium ion and an electron-donating group (in this case the π-electrons of another double bond).

In order to derive the observed stereochemical arrangement of the final product, it was always necessary to postulate one or more stereospecific intramolecular rearrangements of non-classical carbonium ions. Sometimes, two successive stereospecific rearrangements of the same complex cation had to be assumed.

An analogous mechanism could account for the observed stereochemistry of alkylation of isopentenyl pyrophosphate. According to this, the first step would be the formation of the non-classical carbonium ion *(34)*; next, this would undergo intramolecular rearrangement to another non-classical ion *(35)* which would allow the now stereochemically favorable elimination of H_R to give the final product *(36)*. It is a logical disadvantage of this mechanism that formation of the non-classical carbonium ion from the other side of the double



(34) *(35)* *(37)* *(36)*

[12] *W. S. Johnson* and *R. A. Bell*, Tetrahedron Letters No. 12, 27 (1960).

[13] *A. Eschenmoser*, *L. Ruzicka*, *O. Jeger*, and *D. Arigoni*, Helv. chim. Acta *38*, 1890 (1955).

bond [as in *(37)*] would allow a mechanistically similar formation of *(36)* without need to postulate an intermediate rearrangement.

One might regard the mechanism *(34)* → *(36)* as equivalent to the "X-group" mechanism in which the electrons of a C–H bond act as an X-group. The essential difference between this and the true "X-group" mechanism is spatial. The rearrangement of *(34)* to *(35)* entails a large displacement in space of the allylic group R (or alternatively of the whole isopentenyl pyrophosphate molecule). This displacement must occur (since no stable intermediate is permitted) at the "active center" of the condensing enzyme, to which the substrates have already been bound for the initial stage of the reaction. When it is also considered that the group R may be large, and that its allylic double bond leaves it little flexibility at the point of attachment to isopentenyl pyrophosphate, the difficulty of postulating intramolecular rearrangement of *(34)* to *(35)* becomes obvious. This can be regarded as an argument in favor of the X-group mechanism, since the capacity of the active center of an enzyme to bind a specific substrate in a specific conformation favorable for reaction should be greater, the less movement of the substrate is necessary during the enzymic reaction. In the X-group mechanism, little movement is necessary.

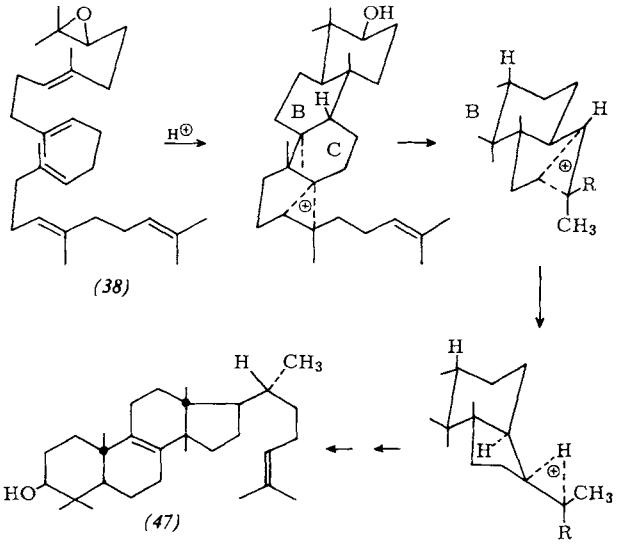
4. Cyclization of Squalene to Triterpenoids

It is instructive to examine whether the cyclization of squalene to tetracyclic and pentacyclic triterpenoids can be formulated with X-group mechanisms in place of the original concept of stereospecific intramolecular rearrangements of carbonium ions. This turns out to be possible. The first three postulates of the original scheme can be retained: that all-*trans* squalene is the starting-point, that the substrate molecules assume definite conformations for cyclization, and that (to paraphrase the third requirement) whenever electrons are abstracted from a particular substituted carbon atom, the deficiency is always made good from the opposite side. The fourth postulate, that no stable intermediate intervenes between squalene and the final product, is not acceptable for X-group mechanisms. It was an intellectual *tour de force* to show that every known type of triterpenoid could arise from squalene by a "non-stop" mechanism, but this view tends to require incompatible properties in the enzyme mediating a cyclization.

Since no stable intermediate is permitted, the whole process has to be supposed to occur on a single enzyme. This enzyme must be able, at the same active center, to impose a particular conformation on the squalene chain and to allow considerable freedom of movement in this chain during rearrangements; and to control stereochemically the intramolecular, space-demanding rearrangements of carbonium ions without participating in them chemically. If, in contrast, the formation of stable intermediates allows the participation of more than one enzyme, the spatial requirements of the active center of each enzyme can be less exacting.

4.1. Formation of Lanosterol from Squalene

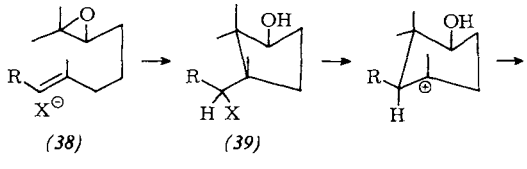
More evidence is available on the transformation of squalene to lanosterol than on the formation of any other cyclic terpenoid. This is not a "non-stop" reaction, since squalene epoxide *(38)* appears to be an obligatory intermediate[14,15]. The classical theme of cyclization, adapted to start from this intermediate, is as shown (Scheme 1).



Scheme 1.

We can consider whether it is useful to postulate an X-group mechanism for any of these ring-closures and subsequent rearrangements.

Formation of rings A and B: Here, the only way to involve an external X-group is to postulate that the initial cyclization leads to a cyclopentane ring [*(39)*, exemplified for ring A], and that rearrangement to a cyclohexyl cation precedes further cyclization.



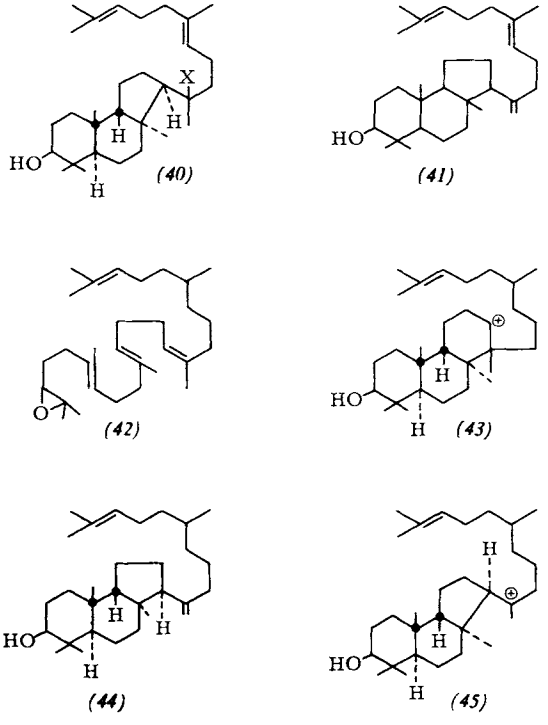
There seems to be no reason here why rings A and B should not be closed by a concerted process, the π-electrons of the next double bond playing the part of the X-group, and six-membered rings being formed *ab initio*. Moreover, the alternative is an anti-Markovnikov addition to the double bond and is to this extent energetically unfavorable.

Formation of ring C: Here, the intervention of an X-group does lead to a cyclization in the Markovnikov sense, and formation of the intermediate *(40)* would be favored (though rearrangement to the energetically

[14] *E. J. Corey, W. E. Russey,* and *P. R. O. de Montellano,* J. Amer. chem. Soc. *88*, 4750 (1966).

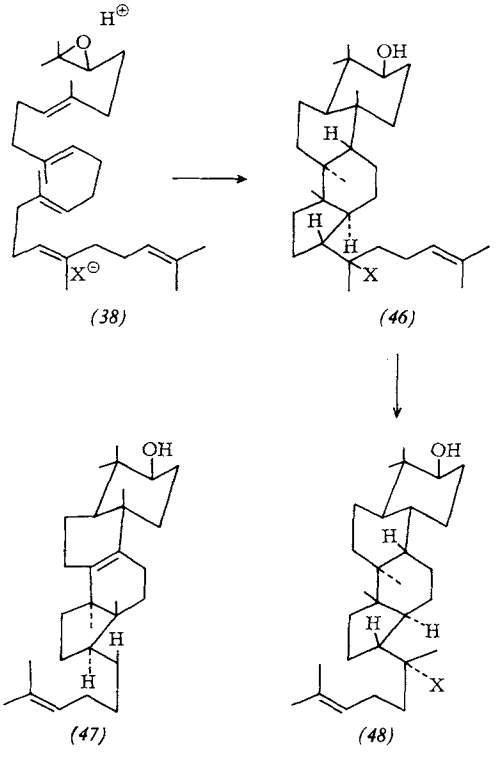
[15] *E. E. van Tamelen, J. D. Willett, R. B. Clayton,* and *K. E. Lord,* J. Amer. chem. Soc. *88*, 4752 (1966).

less favored cyclohexyl cation must still occur if the cyclization is to continue). Secondly, it has been shown that non-enzymic cyclization of squalene epoxide does yield as one product a cyclopentanonaphthalene derivative *(41)*, an indication that this mode of cyclization is energetically favorable[16]. Thirdly, the dihydrosqualene epoxide *(42)* can be partially cyclized enzymically to a mixture of products, a major component of which is probably the alcohol *(44)*[17]. This of course could arise from an intermediate *(40)* by simple elimination of HX.



To decide whether this finding is evidence for an intermediate such as *(40)*, we can consider the "normal" mechanism in which a six-membered ring C is formed directly by a continuation of the concerted cyclization that closed rings A and B. This is an anti-Markovnikov cyclization, but on the enzyme it might be promoted by the stereochemical arrangement of the substrate, the π-electrons of the next double bond being available to complete the addition only in the anti-Markovnikov sense. If these π-electrons were not available, as in the dihydrosqualene epoxide *(42)*, the cyclization may be assumed to proceed as far as the cation *(43)*. In the absence of an electron-donating group this cation would tend to rearrange to the more stable tertiary form *(45)*. Loss of a proton from this cation could well give mainly the olefin *(44)* since one hydrogen atom in the methyl group would always be in a stereochemically favorable position for the final elimination. One has to conclude that the intervention of an X-group in the closure of ring C, though quite possible, is not on the evidence a necessary postulate.

Formation of ring D: This is a cyclization in the Markovnikov sense and there is no incentive to suppose that a six-membered ring might be formed first and rearrange to a five-membered ring. (The objections to the sequential rearrangement of non-classical cations, as formulated in Scheme 1, have already been stated.) The alternative is to postulate an electron-donating group X which completes the addition. Accepting that the other cyclizations are concerted, one then has a multiplex electron-shift leading from squalene epoxide *(38)* to the intermediate *(46)*. Little displacement of any part of the molecule is required for this cyclization.



The rearrangement to lanosterol can proceed directly from the final non-classical cation pictured in Scheme 1, the four migrating groups and the proton finally to be eliminated already having the favorable *trans-anti-trans-anti-trans* arrangement. For analogous rearrangement of the intermediate *(46)*, a preliminary rotation through 120° is necessary about the single bond joining the side-chain to ring D. This gives the conformation *(48)* and might occur in one of three ways:

1) Rotation is confined to the side-chain and occurs without detachment of *(46)* from the enzyme on which it was formed. For example, the group X might be a water molecule attached to an anionic site on the enzyme; after cyclization, the resulting –OH group might swing to a cationic site where its separation, initiating rearrangement, would be facilitated. This mechanism would also require 120° movement of the rest of the side-chain; but this is a part of the molecule which does not need to be bound at the active center,

[16] *E. E. van Tamelen, J. D. Willett, M. Schwartz*, and *R. Nadeau*, J. Amer. chem. Soc. *88*, 5937 (1966).

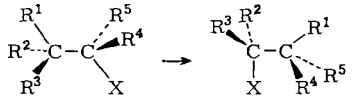
[17] *E. E. van Tamelen, K. B. Sharpless, R. Hanzlik, R. B. Clayton, A. L. Burlingame*, and *P. C. Wszolek*, J. Amer. chem. Soc. *89*, 7151 (1967).

and which apparently can be altered considerably without affecting the cyclization [18].

2) The intermediate *(46)* is held to the enzyme by its X-group while the rest of the molecule is reoriented, perhaps on an adjacent part of the enzyme, in the configuration favorable to rearrangement.

3) The intermediate *(46)* dissociates from the enzyme, and rearrangement with elimination of HX and formation of lanosterol *(47)* occurs on another enzyme.

Also in the case of pentacyclic triterpenoids, X-group mechanisms can explain the various structures and stereochemistry, but it is necessary to assume the intervention of two X-groups, and also to postulate double 1,2-rearrangements of the following type:



Several examples of this type of rearrangement are already known; *e.g.*, the rearrangement of 5α,6β-dibromocholestane and of other vicinally disubstituted steroids [19].

The postulated course of the cyclization can be represented as in Scheme 2 for the case of β-amyrin *(49)*. It is clear that this process could not be considered to take place on a single enzyme, and therefore that if the X-group mechanism is correct at least one intermediate between squalene epoxide and β-amyrin remains to be found. Recognition of such an intermediate will also decide between the "non-stop" mechanism originally proposed and the stepwise mechanism to which our stereochemical studies have led us.

Crystallization during Polymerization

BY B. WUNDERLICH[*]

This paper is dedicated to Prof. Dr. E. Husemann on the occasion of her sixtieth birthday

Simultaneous as well as successive polymerization and crystallization is possible. While crystallization after polymerization usually produces folded chain lamellar crystals, crystallization during polymerization frequently produces fibrillar extended chain crystals.

1. Introduction

A polymerization reaction leading from small monomer molecules to linear high polymer may be one of two types, a step reaction or a chain reaction[1]. A step reaction proceeds by random coupling of bifunctional molecules and results in a gradual increase in molecular weight (see Fig. 1).

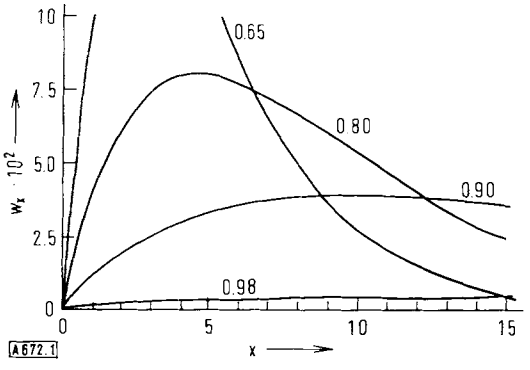

Fig. 1. Molecular weight distribution during a step reaction polymerization. The weight fraction of molecules made of x monomers is w_x. The degree of completion of the reaction is expressed by p which varies between 0 and 1. Mathematically the curves are represented by

$w_x = x(1-p)^2p^{x-1}$

An example of a step polymerization is the reaction of ε-aminocaproic acid in the molten state. The possible reactions are represented by equation 1:

$$\underset{x\text{-mer}}{H[-NH-(CH_2)_5-CO-]_xOH} + \underset{y\text{-mer}}{H[-NH-(CH_2)_5-CO-]_yOH} \rightarrow \underset{(x+y)\text{-mer}}{H[-NH(CH_2)_5-CO-]_{x+y}OH} + H_2O \quad (1)$$

x and y may take any value above zero. The step reaction is thus a typical chemical reaction. A chance of rearrangement of chemical bonds exists on any collision of the reactive partners. Any two steps contributing to the growth of the same polymer molecule are completely uncorrelated. If the reaction is speeded up by a catalyst, each step is catalyzed separately.

A completely different picture is presented by a chain reaction polymerization, which leads to linear high polymers in a one dimensionally cooperative process. The growth of a polymer molecule can proceed only after initiation and then goes sequentially by addition of one monomer unit at a time. Thus, the reaction mixture contains only monomer molecules and growing or completed polymer molecules. The termination or transfer of a growing chain determines, in conjunction with the initiation, the molecular weight. Ethylene polymerization (equation 2) is an example of free

$$\text{Initiation:} \quad R-O-O-R \rightarrow 2\,R-O\cdot \quad (2)$$

$$\text{Propagation:} \quad R-O\cdot + CH_2=CH_2 \rightarrow R-O-CH_2-CH_2\cdot$$

$$\underset{x\text{-mer}}{R-O(-CH_2-)_{2x-1}CH_2\cdot} + \underset{\text{monomer}}{CH_2=CH_2} \rightarrow \underset{(x+1)\text{-mer}}{R-O(-CH_2-)_{2x-1}CH_2\cdot}$$

radical chain reaction polymerization. Any two steps contributing to the growth of the same polymer molecule are correlated.

Crystallization is in principle a three dimensional cooperative polymerization reaction since any molecule of more than about 1000 atoms may be called a high polymer and any crystal grain can be looked upon as a single molecule. Most crystals studied in the past have bonds of similar strength in all three directions of space. All ionic crystals and all metals fall into this category. Crystals of linear high polymers represent an exception, for the bonds along the backbone chain are stronger by a factor of 10 to 100 than the secondary bonds which hold the crystal together. This difference in bond strength allows the separation of the formation of a linear high polymer crystal into two stages, the polymerization which sets the primary bonds, and the crystallization which sets the secondary bonds. Many of the presently common linear high polymers have a ceiling temperature[2] sufficiently above the melting temperature that on melting or dissolution no primary bonds are broken.

[2] The ceiling temperature is the temperature of the polymer-monomer equilibrium above which only monomer is thermodynamically stable.

2. Categories of Crystallization and Polymerization

Crystallization before the polymerization is completed may be separated into two categories, simultaneous and successive polymerization. Simultaneous polymerization and crystallization is indicated if the covalent primary and secondary bonds are set at the same time. The description of such a process is identical with ordinary crystallization. A pattern unit, which may be part or all of the monomer molecule, is positioned on a lattice point on the surface of an already existing crystal. Covalent bonds are rearranged simultaneously with the formation of secondary bonds which may be hydrogen bonds, dipole bonds, or van der Waals bonds. The heat of transition contains contributions from the heat of polymerization as well as the heat of crystallization. Analogously the entropy is the sum of two such contributions.

Successive polymerization and crystallization is the process in which crystallization occurs somewhat later than polymerization, but before the polymer molecule is completely formed. In this case a detailed kinetic description of the steps leading to crystal formation is necessary to understand the influence of the polymerization step on solidification and *vice versa*. If the reaction is carried out close to the ceiling temperature, it may be possible to distinguish between simultaneous and successive polymerization on the basis of purely thermodynamic arguments. For example, crystalline polyoxymethylene has a lower formaldehyde vapor pressure than the less ordered polymer. Determination of the formaldehyde vapor pressure or the formaldehyde equilibrium concentration during polymerization should thus indicate the physical state of the chain ends. The closer the polymerization and crystallization sites approach, the lower should be the vapor pressure or concentration of formaldehyde [3].

Simultaneous polymerization and crystallization was suggested as early as 1927 by *Staudinger et al.* [4] for the formation of fibrous polyoxymethylene from gaseous formaldehyde. Also an early suggestion was that in an ideal single crystal of polyoxymethylene grown during polymerization of formaldehyde the molecular length should be identical with the crystal dimension in the chain direction [5].

In addition to the two categories of crystallization during polymerization, one must consider the case in which the polymer molecule is completed in the dissolved or molten state before crystallization commences. The usual crystallization from polymer melt and solution [6,7] are such processes. There is no question about the separate treatment of polymerization and crystallization step. Complications, however, are still possible if the polymer molecules are produced in a special non-equilibrium conformation and crystallization begins before equilibration. Interesting examples are the formation of metastable, supersaturated solutions of polyamide in chloroform at low temperature using the Schotten-Baumann reaction [8], and of silk fibroin in the silk glands of *Bombyx mori* [9]. Both metastable solutions can be broken up by spontaneous precipitation. In such cases of very large supercooling, a crystallization different from crystallization close to the melting or dissolution temperature is to be expected.

The three categories of crystallization of flexible linear high polymers are summarized in Fig. 2.

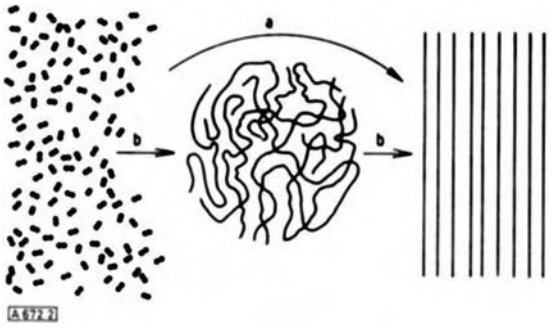

Fig. 2. Schematic representation of the paths from the monomer to the crystalline polymer. a) Simultaneous and successive polymerization and crystallization; b) separate polymerization and crystallization.

3. Nucleation and Crystal Growth

Crystal growth can occur only after a nucleus of sufficient size has been produced. The free energy of formation of a homogeneous nucleus of quadratic cross section normal to the chain direction can be estimated from equation 3:

$$\Delta\Phi = a^2 l \Delta f + 4al\sigma_s + 2a^2\sigma_e \qquad (3)$$

The free energy of crystallization is represented by Δf, a negative quantity below the melting or dissolution temperature. σ_s and σ_e are the positive surface free energies of the side and end surfaces respectively. The molecular chain length in the nucleus is l while a is the width of the quadratic cross section. Figure 3 shows the change of $\Delta\Phi$ as a function of a and l for a certain set of parameters. The path of minimum free energy to a large crystal goes across the saddle point at which the size of the critical nucleus is reached, further growth is accompanied by a decrease in free energy and is thus a spontaneous process.

From the different examples of crystallization during polymerization five nucleation paths have been derived [10]: A. an intermolecular nucleation followed by simultaneous polymerization and crystallization near

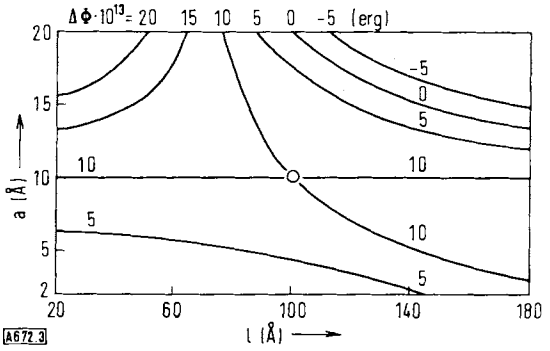

Fig. 3. Graph of the free energy of formation, $\Delta\Phi$, of a polymer crystal nucleus of length l in the chain direction and width a, assuming a quadratic cross section. Parameters assumed are σ_e = 50 erg/cm², σ_s = 5 erg/cm², $\Delta f = -2 \cdot 10^8$ erg/cm³ which corresponds to polyethylene 25—30 °C supercooled.

the ceiling temperature; B. an intermolecular nucleation followed by simultaneous polymerization and crystallization far from the ceiling temperature; C. an intermolecular nucleation followed by successive polymerization and crystallization; D. an intramolecular nucleation followed by simultaneous polymerization and crystallization; and finally E. an intramolecular nucleation followed by successive polymerization and crystallization. Only path A is close enough to the polymerization equilibrium that one may assume reversibility of the polymerization step. In all other cases the depolymerization reaction is probably small. If the ceiling temperature of a simultaneous polymerization and crystallization is below or at the melting or dissolution temperature of the crystal, and if the reaction is carried out close to the ceiling temperature, one can expect a perfect coupling of polymerization and crystallization (case A). Nucleation is then also a prerequisite for high molecular weight polymer. The examples best studied of such reactions are the formation of metaphosphate by dehydration of orthophosphate [11] and the polymerization of formaldehyde in aqueous or alcoholic solution [12].

The formation of lithium metaphosphate by dehydration of the acid orthophosphate is typical for all alkali metaphosphates and metaphosphoric acid [13].

$$x\ HO(-\overset{\overset{O}{\|}}{\underset{\underset{O^{\ominus}}{|}}{P}}-O-)H \longrightarrow HO(-\overset{\overset{O}{\|}}{\underset{\underset{O^{\ominus}}{|}}{P}}-O-)_xH + (x-1)\ H_2O \qquad (4)$$

Although the metaphosphate is stable at lower temperature it does not form below 210 °C on stepwise heating because of nucleation difficulties. At 210 °C, 0.65 moles of water are lost per mole of LiH_2PO_4, and oligomers up to nonaphosphate have been identified by thin-layer chromatography in the almost completely amorphous reaction product [13]. The oligomers were formed by a step reaction and one expects a distribution of molecular weights as shown in Fig. 1. The step reaction sequence is interrupted as soon as the crystalline linear high polymer phase is nucleated. At this moment further polymerization proceeds by addition of small molecules to the crystal surface, the step reaction pattern has changed to a chain reaction sequence. The chain reaction kinetics is a cooperative polymerization scheme and as such the only one compatible with crystallization.

The type A nucleation and crystal growth of metaphosphates by dehydration is thus a random step reaction to form oligomers of sufficient length to nucleate the crystalline phase, followed by simultaneous polymerization and crystallization. From the degree of polymerization at the temperature of first nucleation and the results of thin layer chromatography it can be estimated that the chain length of the critical nucleus is about ten PO_3-units [10]. The molecular weight distributions shown in Fig. 1 apply only for the prenucleation period. For the crystalline metaphosphates of potassium, molecular weights up to several million have been reported [14, 15]. The molecular weight was found to be quite uniform, increasing in uniformity with time of reaction [14].

A similar mechanism has been shown to govern the formation of polyoxymethylene from formaldehyde in aqueous or alcohol solution. In these solvents the monomer is largely present as diol or hemiacetal, respectively, where the C=O double bond is already replaced by two single bonds. This reduces the major driving force of polymerization of formaldehyde ($\Delta G = -3.7$ kcal/mole) to little more than the driving force for crystallization ($\Delta G = -0.4$ kcal/mole) [12]. The initial stages of the reaction are again a step reaction until oligomers of about ten monomer units are reached, then spontaneous nucleation of solid polyoxymethylene takes place and further growth occurs *via* chain reaction by simultaneous polymerization and crystallization [12]. All polymer produced is completely crystalline as in the case of metaphosphates. Polyoxymethylene precipitates spontaneously out of a clear formaldehyde solution if it reaches a supersaturation of 4 to 8 weight percent formaldehyde. High molecular weight has only been achieved by control of nucleation [12].

Both the metaphosphate and the polyoxymethylene can be crystallized close to equilibrium by properly adjusting concentration of monomer and temperature. The reversibility of polymerization and crystallization under these conditions allows a rejection of defects and generation of perfect crystals. Further from the ceiling temperature (case B) it is more difficult to achieve more perfect crystals. The polymerization rate must first be matched to the nucleation, then to the crystallization rate. Since any polymerization may be slowed down by concentration change, temperature variation, or even a moving temperature gradient [16], it should still be possible to grow good crystals. The polymerization of *p*-xylylene and cellulose may be examples for type B nucleation followed by simultaneous polymerization and crystallization.

The formation of poly-*p*-xylylene is an example of conversion of a gaseous monomer into a crystalline polymer [17]. The monomer can be produced in 100% yield by vapor phase pyrolysis of di-*p*-xylylene at 550—600 °C [18]. Solid polymer has only been observed on surfaces cooled below 30 °C [18],

despite a 420 °C melting point of the polymer [19]. Special nucleation difficulties exist because of the relative instability of the dimer and trimer diradicals with relatively weak central bonds [17]. In terms of equation 3, $\Delta\Phi$ must be particularly large for small values of l because of a large σ_e caused by the free radical ends. If nuclei are once formed, polymerization and crystallization is fast and the crystallinity is only about 80%, probably due to the large supercooling. Increasing the supercooling gives rise to even smaller crystallinity [19]. The more interesting experiment, to raise the temperature after nucleation to about 400 °C in order to carry out the crystallization more slowly, has not, as yet, been performed.

The biosynthesis of cellulose by *Acetobacter xylinum* is the other probable example of type B nucleation and crystal growth [10]. Simultaneous polymerization and crystallization has been assumed [20] when it was shown that no oligomers are present in the vicinity of actively polymerizing cellulose fibers [21]. Intermolecular nuclei have been observed after an initial induction period [22]. In cellulose, very little or no growth occurs in the direction normal to the molecular chain axis after nucleation. The measured diameter of the fibers is 100–250 Å [23]. This polymer is far from completely crystalline, probably as the result of a large degree of supercooling.

Type C nucleation and crystal growth differs from types A and B by showing successive polymerization and crystallization. The originally polymerized oligomers do not crystallize completely, but leave active chain ends in the amorphous phase. Such an intermolecular crystallization presents a number of problems: 1. On going from the crystallized to the amorphous portion of the molecule there is an increase in space requirement which can only be accommodated by a fibrous morphology. 2. Different polymerization rates of chains contributing to the same crystal should lead to defects and folds [24] (see Fig. 4.). 3. The distribution of active chain ends in solution or melt or on a solid surface should be of influence upon crystallization. 4. Solubility or crystallization temperature of chain ends, polymerization rate, density of chain ends, and molecular weight should be variables of the process.

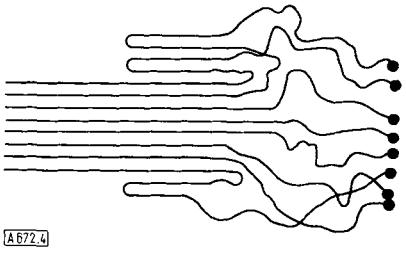

Fig. 4. Schematic representation of the fibrous habit caused by increased space requirement of the amorphous portion of molecules and the introduction of defects and folds by molecules of different polymerization rate (see also ref. [24]).

Many examples of type C nucleation and crystal growth are known [10]. Of particular interest have been the vinyl polymerizations involving Ziegler-Natta catalysts and ionic chain reactions.

A Ziegler-Natta catalyst usually consists of the reaction product of an organometallic compound (like triethylaluminum) and a transition metal compound (like titanium tetrachloride) slurried in a dry, oxygen free, inert hydrocarbon solvent (like heptane) along with the monomer to be polymerized. Such catalysts are capable of producing stereoregular (crystallizable) polymers so that conditions are set for crystallization during polymerization.

$$\text{Catalyst-CH}_2\text{-CHR}' + x\,\text{CH}_2\text{=CHR} \rightarrow \text{Catalyst}(-\text{CH}_2\text{-CH}(\text{R})-)_x\text{CH}_2\text{-CHR}' \quad (6)$$

Bulkiness of the catalyst in homogeneous catalysis and sparsity of reaction sites in the case of heterogeneous catalysis precludes simultaneous polymerization and crystallization. In all cases of high active site concentration fibrillar crystals have been observed. The best perfection was obtained by room temperature polymerization of ethylene on glass-supported $VCl_3/Al(C_2H_5)_3$ catalyst in heptane [25]. Intermediate perfection was found with $TiCl_3/Al(C_2H_5)_3$ catalyst in heptane and toluene between 0 and 40 °C [26]. The least perfect fibrils grew at the highest reaction temperature and the best solvents, 85 to 110 °C with $TiCl_3/Al(C_2H_5)_3$ catalyst in toluene and xylene [27].

Examples of homogeneous ionic polymerization and crystallization of the type C include the formaldehyde [12] and probably also the trioxane polymerization to polyoxymethylene [28, 29], the lactam polymerization to polyamide [30], and the decomposition of diazomethane to polymethylene [31]. In all these cases a complicated reaction intermediate precludes polymerization on a crystal surface. Very little is known in these cases about the crystal morphology, nothing is known about the nucleus size.

The polyamide crystallinity was varied by changing reaction conditions. If the reaction is carried out very fast an amorphous "virgin polymer without thermal history" can be produced [32]; in contrast, on careful slow zone polymerization, a highly crystalline polyamide was made [33]. A considerable reduction in crystallinity was found for polymethylene when the polymerization temperature of diazomethane was reduced to −50 °C. The amorphous polyamide was produced so fast, that even nucleation was avoided, while the low crystallinity polymethylene was probably less perfect because the polymerization rate exceeded the crystallization rate.

Nucleation and crystal growth of type A to C have an intermolecular nucleation step in common. Oligomers of short enough length must crystallize before high polymer can be produced. If the oligomer is formed *via* a chain reaction, it is possible to have such a low concentration of oligomers that intermolecular

nucleation becomes impossible. The oligomer grows into a high molecular weight polymer and after reaching sufficient size may nucleate a crystal intramolecularly. Figure 3 indicates that this is only likely in a folded chain conformation since both dimensions, *a* and *l*, must have a reasonable value, larger than several atomic diameters. Since chain folding ought to increase σ_e, an elongated nucleus, similar to the one assumed in calculation of the data given in Fig. 3, is expected. After nucleation, further crystal growth can occur by simultaneous polymerization and crystallization (type D) or by successive polymerization and crystallization (type E). The reaction site is at the surface of the crystal and since the nucleation difficulty has been overcome, further crystal growth should increase dimensions *a* and *l* following approximately the valley of Fig. 3. At later times oligomers can add to the growing crystal so that the molecular weight may be less than the crystal weight.

Type D or E nucleation and crystal growth should be of particular importance for free radical polymerization of crystallizable monomers since free radical oligomers would rather terminate than nucleate a crystal. Concentrations of free radicals of 10^{-8} to 10^{-9} M are common in such polymerizations, a concentration much too low to yield sufficient oligomer for intermolecular nucleation.

The most probable example of intramolecular nucleation is the free radical polymerization of tetrafluoroethylene[10]. The resulting polymer is recovered as a granular powder or as a dispersion. The molecular weight may be as high as 10^8 and the crystallinity is estimated to be 97%[35]. Single dispersion particles (diameter $\approx$ 0.2 μ about 200 molecules) have given rise to discrete electron diffraction patterns[7].

The main conclusions to be drawn here then are that the first nucleation and later crystallization steps must be matched to polymerization rate to yield a perfect crystal. The nucleus size for several polymers has been estimated to be about 20 Å in the chain direction. Five types of nucleation and crystallization seem to describe the presently known cases of crystallization during polymerization.

The importance of nucleation is illustrated by the polymerization of ε-aminocaproic acid from the gas phase[36]. In a closed vessel ε-aminocaproic acid crystals were shown to cover their surfaces with polymer. The monomer evaporates to build up the vapor pressure of 0.2 torr. From the gas phase ε-aminocaproic acid is able to polymerize after nucleation of the crystalline state. This nucleation is greatly enhanced on the monomer crystal surface, so that despite a much larger glass vessel surface the largest portion of polymer, crystallized during polymerization, is found on the surface of the monomer crystal. A direct polymerization of the crystalline monomer seems impossible probably because the monomer exists in the form of zwitterions. The polymerization of the gaseous monomer is a successive crystallization and polymerization[10].

Several problems of crystallization are connected with crystallization during polymerization. Besides the crystal perfection mentioned above the directiveness of polymer chains presents a major difficulty. Polymers like cellulose, polycaprolactam, and poly-β-hydroxybutyrate[37] can fit only in antiparallel arrangement onto an ideal crystal. If such polymer chains are produced from an active center such that it grows only in one direction, the most stable crystalline arrangement cannot be achieved. Experiments on caprolactam seem to bear out this fact, the X-ray diffraction diagram indicates a less perfect arrangement for crystals grown during polymerization than for antiparallel folded chain crystals grown from solution[33].

A special type of polymerization is the reaction of crystalline monomer[38]. The numerous examples studied can be separated into the categories, polycondensations, free radical reactions, and ring opening polymerizations. Polycondensations of amino acids and oligoamides[39] have led only to successive polymerization and crystallization with a loss of the initial orientation. Some of the reactions were topochemical since they followed a reaction path only possible for crystalline monomer, but none of the cases investigated demonstrated topotacticity, a solid state path from the crystalline monomer to the crystalline polymer.

Free radical polymerization from crystalline monomers is even more difficult. Besides the general conditions for a topotactic polymerization (to provide the proper geometry for monomer approach for reaction and to have a continuous path to the crystal structure of the polymer) an additional condition exists: the need to protect the radicals from mutual termination. Only in clathrates have all these conditions been fulfilled and simultaneous polymerization and crystallization has been achieved for 2,3-dimethylbutadiene and 2,3-dichlorobutadiene in thiourea[40], and for butadiene and vinyl chloride in urea[41]. Figure 5 represents schematically the

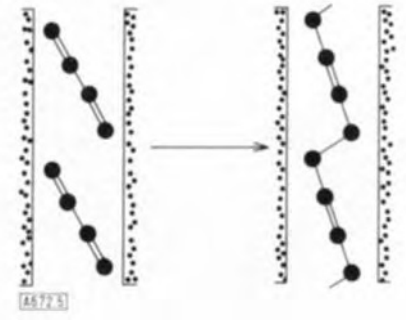

Fig. 5. Schematic representation of simultaneous polymerization and crystallization of butadiene urea clathrates. The reaction is free radical initiated by ionizing radiation.

reaction conditions. The geometry is just right for the parallel approach of the planar sp^2 hybrid of the double bond and the planar free radical, only a minimal adjustment of the position of the monomer is necessary to give polymer inside the urea

or thiourea channels. The final group of solid state monomers which have been polymerized are ring type monomers such as trioxane, trithiane, tetroxane, 3,3-bis(chloromethyl)-oxetane, and β-propiolactone[10]. In this group topotactic polymerization reactions seem to be possible (simultaneous polymerization and crystallization). The favorable factors are a small heat of reaction and a small volume change since the number of covalent bonds stays constant.

4. Comparison of Crystal Forms from Different Crystallization Paths

The discussion of nucleation and crystal growth has shown that crystallization during and after polymerization may be very different; as a consequence different crystal forms are expected. Crystal growth from the already polymerized melt or solution has been studied in great detail[6,7]. In all careful homopolymer crystallizations lamellar crystals similar to the one shown in Fig. 6 were found with the small dimension of the

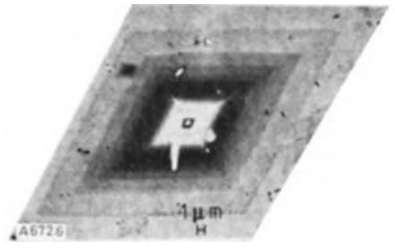

Fig. 6. Chain folded lamellar polyethylene crystal. The chain direction is normal to the plane of the micrograph, a growth spiral of many lamellae is shown.

lamellae being in the chain direction; the usually much longer chains are accommodated by chain folding. Typical lamellar thicknesses (chain fold lengths) on crystal growth from solution are 50 to 200 Å, from the melt 100–500 Å.

A lamellar crystal of only 100 Å thickness has a specific surface area of about 10^6 cm²/g. Such a large surface area makes the folded chain crystal lamellae metastable, they melt usually 5 to 30 °C below the melting point of extended chain crystals[33,42,43]. If the metastable lamella melts without reorganization[44], the melting temperature lowering, ΔT, can be described by the Thomson equation[45], first applied to melting of lamellae by *Tammann*[46]:

$$\Delta T = 2\,\sigma_f T_m^\circ / \Delta H_u \cdot \rho \cdot l \qquad (7)$$

σ_f is, as shown above, the surface free energy, in this case of the fold surface. T_m° is the melting point of a very thick lamella, H_u is the heat of fusion per cm³ of polymer, ρ is the crystalline density, and l the lamellar thickness, the fold length. From measurements of ΔT, values of 40 to 90 erg/cm² have been derived for some typical polymers[33,43,47].

The reason for the metastable lamellar habit is an intramolecular secondary nucleation for each new chain crystallizing. Figure 3 shows that after the saddle point has been overcome, the path of lowest free energy would call for an increase of both a and l. If, however, each new molecule must be nucleated anew on the growth face of the crystal, new folds with a small value of l are set up during crystal growth. Crystal growth in the l-direction is only possible as a second step going on in the solid state. It involves a rearrangement of folded chain portions of the crystals to larger fold lengths in a thickening process – a process which is often kinetically hindered.

Proof of this crystal growth sequence has come, *inter alia*, from direct experiments with extended chain polyethylene crystals. Lamellae of up to 10 µ in the chain direction and 100 µ at right angles were grown by crystallization from the melt at elevated hydrostatic pressure[48,49]. Under these conditions the

thickening after folded chain crystal growth is enhanced relative to the crystal growth. Figure 7 shows such an extended chain lamella viewed at right angles to the chain direction. Attempts to use these high melting crystals as seeds for crystallization of extended chain crystals failed, only folded chain lamellae grow on extended chain nuclei as is shown in Fig. 8[50,51]. Once folded chain lamellae were formed, they could be made to extend somewhat by annealing at the crystallization or higher temperature[51]. Crystallization of polyethylene over extended periods of time has led to crystals up to 2000 Å in fold-length[52].

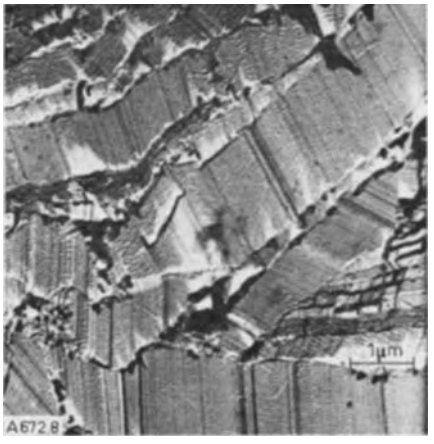

Fig. 8. Folded chain lamellae grown on the surface of extended chain polyethylene crystals. Electron micrograph of a surface replica. The chains are in the plane of the micrograph at rigth angles to the upper and lower lamellar surfaces.

All these difficulties do not exist in crystallization during polymerization if the random polymeric state is avoided before crystallization. The size of the nucleus for simultaneous polymerization and crystallization of polyoxymethylene, metaphosphates, and possibly also poly-*p*-xylylene seems to indicate that the surface free energy of the intermolecular critical nucleus is less than that of a folded chain polymer nucleus. After reaching the critical size, further growth in the chain direction by addition of more monomer units proceeds without difficulty. A problem might be the converse, growth of further layers parallel to the chain direction which calls for new, secondary nucleation. If this is the case, a fibrous habit as found in the Kurrol's salts [11], in cellulose (from *Acetobacter xylinum*) [53], in several differently polymerized polyoxymethylenes [54] and polytrithianes [55], and in the polyolefins from Ziegler catalysis [56], must be the natural result.

A comparison of density of extended chain crystals grown from the melt at varying pressures with folded chain crystals grown from solution at different temperatures is shown in Fig. 9. Both forms can show a high degree of perfection [48, 57]. A difference is seen, however, in the melting behavior, as predicted by equation 7. Crystals grown during polymerization of comparable or greater perfection than crystals grown after polymerization melt at higher temperatures. Measurements were performed on polytetrafluoroethylene [58], polyethylene [59], polycaprolactam [33], polytrithiane [55], and the clathrate polymers [40,41]. Even more characteristic seems to be the fact that extended chain crystals melt so slowly, that with standard thermal analysis heating rates temporary superheating beyond the melting point is possible [42].

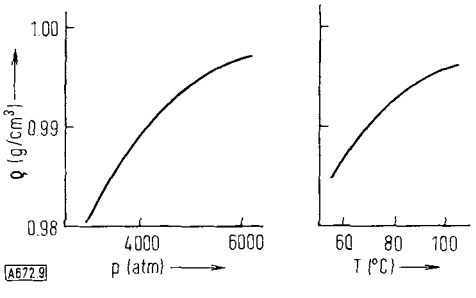

Fig. 9. a) The density of extended chain crystals of polyethylene approaches the X-ray density above 3000 atm crystallization pressure. b) The density of folded chains of crystals of polyethylene also approaches the X-ray density if the crystallization temperature is close to the dissolution temperature. (The ideal X-ray density of polyethylene at 23 °C is 1.000 g/cm³.)

Most of the comparison of different crystallization paths has been concerned with the two limiting cases: folded chain and extended chain crystals. The discussion of Ziegler type crystallization during polymerization has indicated that on successive polymerization and crystallization considerable distances may exist between the sites of polymerization and crystallization. In such cases chain folding may be induced because of introduction of randomized chain portions and because of unequal polymerization rates as was illustrated in Fig. 4.

Overall it seems possible to conclude that all chain conformations in solid polymers are schematically represented by the area of the triangle in Fig. 10.

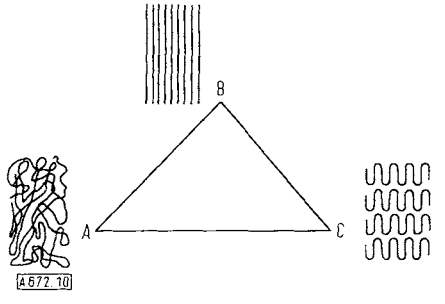

Fig. 10. Schematic representation of polymer chain conformations in the solid state. A, glassy (or molten) random chains. B, extended chains. C, folded chains.

For crystallizable polymers the chain conformations around A can be produced by quenching polymer melts or solutions as well as by very fast polymerizations into the glassy state. Crystals with more extended chain conformation can be produced by crystallization during polymerization or occasionally by special annealing after crystallization from the melt. Morphologies of folded chain conformation can be produced by separate polymerization and crystallization. On faster crystallization, usually at higher degrees of supercooling, poorer crystals with conformations tending toward A are produced.

A final note concerns the X-ray structure of polymer crystals grown during polymerization. Most examples reported seem to have the same crystal structure as the

polymer crystallized from melt or solution [10]. Occasionally a less stable or low temperature structure can be produced. An example is the polycaprolactam made by zone polymerization which has not the ideal orthorhombic crystal structure, but a paracrystalline structure which has a less perfect alignment of H-bonds [33]. The metaphosphates can be produced in a low temperature crystal form first which converts into the high temperature modification at higher temperature [13]. Polyoxymethylene may under certain conditions of crystallization during polymerization form orthorhombic instead of hexagonal crystals [12]. Poly-*p*-xylylene also crystallizes during polymerization first as a metastable orthorhombic structure, to change at about 240 °C into the stable, denser hexagonal crystal structure [19].

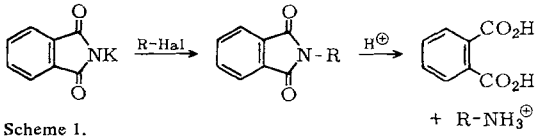
The Gabriel Synthesis of Primary Amines

BY M. S. GIBSON AND R. W. BRADSHAW[*]

Reaction of potassium phthalimide with halogenoalkanes and with a variety of other alkylating agents leads to the N-alkylphthalimide. N-Substituted phthalimides may be converted into the corresponding primary amine by hydrolysis or hydrazinolysis. The scope and limitations of these reactions, which together constitute the Gabriel Synthesis of primary amines, are reviewed.

1. Introduction

The Gabriel Synthesis of primary amines and amino compounds may be summarized schematically as follows:



Scheme 1.

Potassium phthalimide is generally used for the first stage but (a) sodium phthalimide and (b) phthalimide and potassium carbonate or sodium carbonate have been used to some extent; the second stage is normally accomplished by hydrolysis or hydrazinolysis [1]. The importance of the Gabriel Synthesis lies in (i) the absence of secondary or tertiary amine contamination of the primary amine, (ii) the toleration of a very wide range of other functional groups in the molecule, and (iii) the mild conditions now available for accomplishing both stages. High yields of primary amines are generally obtainable, rendering the synthesis attractive, *inter alia*, for the preparation of isotopically labeled amines and amino acids [2].

The successful conversion of methyl and ethyl iodides into the *N*-alkylphthalimides by reaction with potassium phthalimide at 150 °C was reported by *Graebe* and *Pictet* in 1884 [3]. It was already known that *N*-alkylphthalimides could be hydrolyzed to phthalic acid and the primary amine, but it was *Gabriel* who appreciated the significance of these reactions and formulated the Synthesis which bears his name [4]. The scope of the synthesis was explored by *Gabriel* and his colleagues in Berlin for over 30 years.

In the early days, examples slowly accumulated of the preparation of primary alkylamines and aralkylamines from alkyl bromides (including allyl bromide) [5] and aralkyl chlorides and bromides [4,6]. However, from the beginning, greater interest attached to applications of the reaction to bi- and poly-functional halogeno compounds (with potassium phthalimide) and to transformations, including hydrolysis, of the products. In the aralkyl series, early examples included the chloromethylnitro- and chloromethylcyano-benzenes [4,7]. Reaction occurred readily (with potassium phthal-

imide) and control of temperature was important; sometimes the reactions were necessarily moderated by diluting the reactants with sodium chloride [8] or (in one case) benzyl cyanide [9], but years were to elapse before the use of solvents became commonplace.

With the *N*-(cyanobenzyl)phthalimides, the vigorous treatment used for hydrolysis led to the corresponding amino acid [10]. In the aliphatic series, such bi- and poly-functional compounds as monochloroacetone, ethyl chloroacetate and 1,3-dichloro-2-propanol [11], 1-bromo-2-phenoxyethane [12] and 4-bromobutanenitrile [13] were examined; acidic hydrolysis gave the expected amino compounds, the ester and nitrile groups also undergoing hydrolysis.

Greatest interest attached to the particular cases of 1,2-dihalogenoethanes and 1,3-dihalogenopropanes in which, by choice of conditions, one or both halogen atoms could be displaced in Stage 1. If both halogen atoms were replaced, completion of the Gabriel Synthesis gave ethylenediamine and trimethylenediamine respectively [4, 14]. If one halogen atom were displaced, the resulting *N*-(halogenoalkyl)phthalimide could be subjected to hydrolysis, giving halogenoalkylamine salts, or to metathetical reactions with various nucleophiles. Thus, reaction of *N*-(2-bromoethyl)phthalimide with (a) aniline [15], (b) potassium hydrogen sulfide [16], and (c) sodium benzenesulfinate [17] gave (a) *N*-(monoanilinoethyl)- and *N*-(dianilinoethyl)-phthalimides, (b) the *N*-(mercaptoethyl)phthalimide and *N*,*N*'-thiodiethylenediphthalimide, and (c) phenylsulfonylethylphthalimide respectively, which could be hydrolyzed to the corresponding amino compounds. Again, use of sodio derivatives of diethyl malonate and its monoalkylated derivatives provided syntheses of amino acids [18].

Other useful developments hinged on the stability of the phthalimido group under a variety of conditions which permitted the modification of other functional groups. These may be illustrated by the use of 3-phthalimidopropionyl chloride in the Friedel-Crafts acylation of benzene [19], the α-bromination of ω-phthalimidoalkylmalonic esters in the preparation of α,ω-diamino acids [20], and the oxidation of *N*-(ω-hydroxyalkyl)- and *N*-(ω-mercaptoalkyl)phthalimides to the corresponding carboxylic and sulfonic acids [16, 21].

The general usefulness of the Gabriel Synthesis was thus established, though limitations were imposed by the reaction conditions in common use. Most of the alkylation reactions (Stage 1) were carried out by heating the reactants together at temperatures in the range 120–240 °C for periods of up to several hours, even though such conditions were recognized as undesirable or even dangerous in some cases [22]. In this context, it is perhaps remarkable that *Beck*'s demonstration in 1893 that 1-chloromethyl-2-nitrobenzene reacted readily enough with potassium phthalimide in boiling ethanol [23] should have been overlooked.

The vigorous conditions of acidic hydrolysis (Stage 2) used at this time prevented extension of the synthesis to compounds containing acid-sensitive groups, although preliminary alkaline hydrolysis to the *N*-substituted phthalamic acid, followed by milder acidic hydrolysis to phthalic acid and the amine, permitted some variation. Again, the significant observation that hydrazine readily cleaved the phthaloyl group from ethyl phthalimidoacetate as phthalhydrazide under quite mild conditions (*Radenhausen*, 1895) [24] had either been missed or insufficiently appreciated. Approximately 30 years were to elapse before hydrazinolysis was introduced as a technique for accomplishing Stage 2 of the Gabriel Synthesis [25].

2. Stage 1: Formation of the *N*-Substituted Phthalimide

2.1. Displacement Reactions

2.1.1. Alkyl Halides

The most commonly used alkylating agents in the Gabriel Synthesis are the alkyl halides. As indicated above, a wide range of other functional groups are tolerated as substituents within the molecule, although it may be necessary or desirable to protect some functional groups in order to facilitate reaction; *e.g.* it is standard practice to use halogenoalkanoic esters (not the acids), and it seems necessary to protect phenolic groups [26].

The consensus of opinion is that the alkylation stage is an S_N2 reaction, the ambident phthalimide ion reacting at nitrogen, though this view rests largely on analogy with other nucleophilic reactions of alkyl halides [27]. Whilst in the main

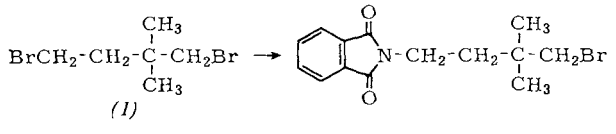
the products are those expected from the S_N2 mechanism, it is clear that this mechanism cannot apply in all cases.

There are indications that primary chloroalkanes are less reactive than the corresponding bromides or iodides in the Gabriel Synthesis (see *e.g.* [28–33]). However, since the reactions are carried out under such a wide range of conditions, the comparison must be interpreted cautiously. There is, nonetheless, a predisposition to accept this view of the relative ease of reaction of halides, borne out by the choice of bromide or iodide rather than chloride [34], the unreactivity of alkyl fluorides (illustrated by the preparation of 2-(fluoroethyl)phthalimide from 1-bromo-2-fluoroethane [35]), and the occasional use of iodide ion as additive [36] (for examples of other additives see Ref. [30a, 37–39]). Recently, the reactions of 1-chloro-, 1-bromo-, and 1-iodopropane with potassium phthalimide in dry dimethylformamide at 25 °C have been found to be first order, in halogenoalkane and in potassium phthalimide, the order of reactivity being RCl < RBr < RI; the rates of the first two reactions were not increased by addition of iodide ion [36c].

Primary halogenoalkanes not containing other functional groups, except sterically hindered compounds of the neopentyl type, react reasonably well with potassium phthalimide. Thus *(1)* shows very marked difference in reactivity of the two bromine atoms; a competing elimination reaction was noted in this case, although the by-product was not identified [40]. Examples in which this type of compound has been induced to react are provided by *(2a)*, *(2b)* [41] and



(1)

$H_3C-C(CH_2X)_3$ *(2a)*, X = *p*-$CH_3-C_6H_4-SO_3$
(2b), X = Br

$(CH_3)_2C(CH_2X)_2$ *(3a)*, X = $C_6H_5SO_3$
(3b), X = Br

$(CH_3)_nSi(CH_2X)_m$ *(4a)*, *n* = 3, *m* = 1, X = Cl
(4b), *n* = 2, *m* = 2, X = Cl

(3a) and *(3b)* [42]; in each case the reaction was carried out at high temperature. The analogous silicon compounds *(4a)* and *(4b)* have been successfully substituted using phthalimide and potassium carbonate [43a], and potassium phthalimide in dimethylformamide [43b].

Substitution has also been achieved with some secondary halogenoalkanes, though apparently with greater difficulty, and with attendant side reactions (elimination). 2-Bromopropane [5b] and 2-bromobutane [44] give the substituted phthalimide and apparently olefins; bromocyclohexane is reported to give cyclohexene [25]. Bromodiphenylmethane gives according to conditions, the substituted phthalimide or mainly tetraphenylethylene [45].

Systems involving differently environed halogen atoms react preferentially at the carbon which is more susceptible to S_N2 attack. An improved synthesis of the antimalarial drug primaquine, utilizes this idea in the treatment of 1,4-dibromopentane with potassium phthalimide in acetone to give 67% of the desired *N*-(4-bromopentyl)phthalimide [46]. In the case of 1,2,3-tribromopropane, the product is *N*-(2-bromoallyl)-phthalimide [47]. Elimination is also noted with 1,3-dichloro-3-methylbutane, which gives isopentenylphthalimide [48], and with 1,4-dibromopentane in ethanol, which gives polymeric material [46].

There are a considerable number of applications to cases of halogeno compounds bearing a ketonic [49], ester [49], or nitrile [50] function at the halogenated carbon atom; these relate to syntheses of aminoketones, amino-acids, or derivatives thereof. A particularly important case is that of diethyl bromomalonate, which gives the well-known diethyl phthalimidomalonate, starting point of the Sörensen amino-acid synthesis [51]. Scission of a benzoyl group has been reported during reaction of 2-bromo-1,3-diphenyl-1,3-propanedione with potassium phthalimide in ethanol (no cleavage is reported in benzene, or without solvent) [52]. Substances such as 2-chloropropionitrile give acrylonitrile and a small amount of the substituted

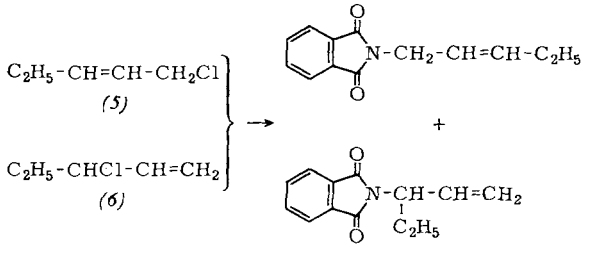
phthalimide when heated with potassium phthalimide[53]; however, acrylonitrile adds to potassium phthalimide under appropriate conditions[54].

Allylic halides react reasonably well with potassium phthalimide to give the corresponding substituted phthalimides[36a,55]. *N*-(*cis*-2-butenyl)- and *N*-(*trans*-2-butenyl)phthalimides have been made in this way[56]. *Meisenheimer* and *Link*[57] have investigated the allylic isomers *(5)* and *(6)* in this reaction, and obtained mixtures of virtually the same composition from each: the primary allylic phthalimide is the major component, and the overall yield of isomers was appreciably lower from the secondary halide. The reactions were conducted at 190–200 °C, and the absolute purity of the halides may perhaps be open to question. However,



the possibility of rearrangement remains, at least in some cases, and further investigation seems desirable. Propargylic halides have also been used in the Gabriel Synthesis[58], and are reported to give excellent yields of the derivative.

Gabriel occasionally utilized solvents in some of his reactions of halogenoalkanes with potassium phthalimide[9a,59], although he evidently preferred the absence of a diluent for most of his investigations in this field (see Ref.[9,23,25,45b,52a,55c,59–72] for examples of the solvents used and referred to in the older literature). Dimethylformamide is now widely employed as a solvent for Stage 1 of the Gabriel Synthesis[49] because potassium phthalimide is moderately soluble in this solvent, and relatively mild conditions suffice for the displacement of halogen by phthalimide ion. Moreover, yields are significantly enhanced[73,74], though again the presence of water may adversely affect some reactions[75]. However, other solvents continue to be employed, *e.g.* petrol[76], kerosene[42], acetamide[77], chlorobenzene[78], acetonitrile[79], amyl alcohol[80], diglycol[81], ethylene glycol[36b], and dimethylsulfoxide[82]. However, on occasions the absence of a solvent may still be preferred where yields are critical, as in the synthesis of $^{13}CH_3NH_2$, which proceeds in higher yield using the original method[83].

A recent preliminary account of the use of hexamethylphosphoramide (hexametapol)[84], indicates that Stage 1 of the Gabriel synthesis may be accomplished under conditions comparable with those reported for dimethylformamide. Indeed, it has been shown that sodium phthalimide can be generated *in situ* in this solvent, and that some reactions occur at room temperature with equally acceptable yields.

From the discussion in Section 2.1.4. it is clear that the first stage of the Gabriel synthesis does not always involve direct substitution of halogen by phthalimide ion in these reactions. It may be mentioned in passing, however, that the proposed S_N2 mechanism does involve definite stereochemical implications. In a rare case of substitution at an asymmetric carbon atom, *Fischer*[85] noted that (−)ethyl 2-bromopropionate, when treated with potassium phthalimide at 125 °C for 5 hours, gave the phthalimido derivative with approximately 42% racemisation. Mild conditions are now available for carrying out the Gabriel Synthesis, and this point clearly requires investigation with optically stable materials.

2.1.2. Aryl Halides and Vinyl Halides

In the early days of the Gabriel Synthesis, it was noted that picryl chloride reacted readily (70 °C) with potassium phthalimide to give *N*-picrylphthalimide; 2-chloroquinoline, however, was observed not to react even at temperatures as high as 230 °C[12]. Later authors have expressed the view that picryl chloride is the only aromatic halide to react in the Gabriel Synthesis[86], though this is not in fact the case.

1-Chloroanthraquinone has been reported to react with phthalimide and sodium acetate in the presence of copper at temperatures near 200 °C, hydrolysis with sulfuric acid yielding 1-aminoanthraquinone. Similar results were obtained with 1,5-dichloroanthraquinone and other substituted anthraquinones[87]. Again, 2-bromofluorene, 1- and 2-chloroanthracenes, and 9-bromoanthracene react with potassium phthalimide in nitrobenzene under similar conditions, though in indifferent yields[62].

A number of aromatic systems bearing halogeno substituents and capable of facilitating delocalization of the negative charge during attack by phthalimide ion (*e.g.* $-NO_2$, $-CN$), have also been noted to react. Examples are provided by 1-fluoro-2,4-dinitrobenzene[88], and (less readily) 1-chloro-2,4-dinitrobenzene[88], 1-chloro-2-nitrobenzene[89] (although 1-chloro-4-methoxy-2-nitrobenzene is said not to react under the same conditions[89]), 1,3,5-trichloro- and 1,3,5-trifluoro-2,4,6-tricyanobenzenes[79].

Cyanuric chloride reacts with potassium phthalimide (1 equivalent) in acetone to give *N*-(4,6-dichlorotriazin-2-yl)phthalimide[90]. Acetonylacetone condenses with *N*-aminophthalimide to give *N*-(2,5-dimethylpyrrol-1-yl)phthalimide[91].

ω-Bromostyrene (with copper catalysis)[92] and tetrafluorobenzoquinone[93] provide examples of unsaturated halogeno compounds which react with potassium phthalimide. *Nesmejanow* and his co-workers have investigated the reaction of copper phthalimide with bromo- and chloroferrocene[94], when fairly good yields of *N*-ferrocenylphthalimide were obtained.

Recently, work has been performed on the direct phthalimidation of unsubstituted aromatic systems. For example *N*-chlorosulfonylphthalimide has been shown to react with biphenyl[95]; however, the product yield is low. Without the use of any catalyst, the major product of the reaction is *N*-(4-biphenylyl) phthalimide, whereas in the presence of cuprous chloride, the three isomeric monophthalimido-derivatives are produced in approximately equal proportions. This suggests that the reaction proceeds *via* a free radical mechanism, a view supported by the isolation of phthalimide itself from the reaction mixture. Since *N*-chlorophthalimide reacts with biphenyl to give only a trace of *N*-(4-biphenylyl)phthalimide, it is thought that this possible intermediate is not formed. The reaction has been extended to halogenated benzenes using either cuprous chloride, or cuprous naphthenate as catalyst.

2.1.3. Other Displaceable Groups

Although the metathetical reaction of alkyl tosylates with phthalimide ion was discovered in 1928[96], it was nearly 20 years later before *Sakellarios*[97] developed the use of these derivatives as alternatives to halogenoalkanes in the Gabriel Synthesis. This author discussed the advantages of tosylates over halides with respect to their lower volatility and greater thermal stability. It may be added that these derivatives are also more accessible in the pure state than the corresponding halogenoalkanes. Coupled with the fact that yields are often enhanced when sulfonates rather than the bromides are employed[41,42], it is perhaps surprising that relatively few examples of this modification of the Gabriel Synthesis are reported. Moreover, the reaction with potassium phthalimide and 2-chloroethyl tosylate gives *N*-(2-chloroethyl)phthalimide in excellent yield[97], at least suggesting that sulfonates are more reactive than the corresponding chlorides.

Other typical examples include such tosylates as *(7)*[98] and *(8)*[82], the sultones *(9)*[68] and *(10)*[99], and the neopentyl sulfonates *(2)* and *(3)*[41,42]. A case of elimination has

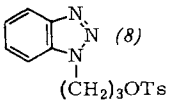
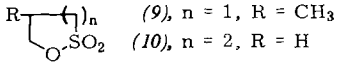
been noted with 2-cyanoethyl tosylate, when the main product of reaction is the volatile acrylonitrile[97], as with the corresponding 2-chloropropiononitrile under similar conditions[53]. Moreover, although *N*-(2-tosyloxyethylsulfonyl-*p*-phenyl)acetamide appears to react by displacement of the tosylate function[69], it is possible that this is an elimination-addition reaction.

(7) $n\text{-}C_{18}H_{37}OTs$ *(8)*

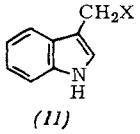




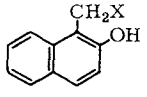
(9), n = 1, R = CH_3
(10), n = 2, R = H

Other types of ester have been occasionally employed. For example, potassium phthalimide and ethyl carbonate react to give *N*-(2-hydroxyethyl)phthalimide[100], as do γ-lactones[101,102], *e.g.* γ-butyrolactone affords 3-phthalimidobutyric acid[101]; trimethyl phosphate gives *N*-methyl-4-nitrophthalimide on treatment with potassium 4-nitrophthalimide[103]. *N*-Benzylphthalimide is formed from benzyl nitrate and potassium phthalimide in dimethylformamide[36c].

Mannich compounds and derived salts have also been employed in metathetical transformations involving the phthalimide ion. For instance, phthalimidomethyltrimethylammonium iodide and potassium phthalimide give diphthalimidomethane[104]. Base catalyzed reactions of phthalimide with *(11)* and *(12)* give the corresponding phthalimido derivatives[104,105]. Although *o*-nitro-β-(dimethylamino)propiophenone and β-(dimethylamino)propiophenone[106] may formally react by a displacement with phthalimide ion[107], the likelihood of an elimination-addition reaction still remains.



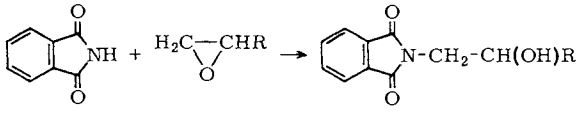
(11)



(12)

X = $N(CH_3)_2$, SC_2H_5

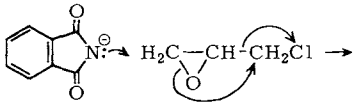
In 1917, *Gabriel* and *Ohle* demonstrated that epoxides could be used for direct alkylation of phthalimide itself[108]. In general, the product of reaction is the *N*-(2-hydroxyalkyl)phthalimide (see Scheme 2).



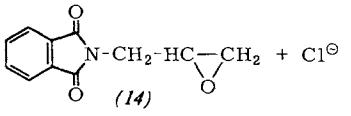
R = H, CH_3 [108], CH_2Cl [108,109], $CH_2OC_2H_5$, $CH_2OC_6H_5$ [110], $CH_2OC_6H_4NO_2$-(*p*) [111]

Scheme 2.

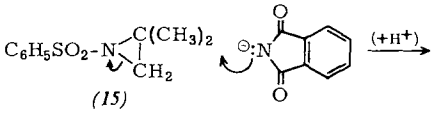
Although the reaction is usually conducted with phthalimide itself, it is evident that a small amount of phthalimide ion is required to initiate the process; pyridine can also be used as a base[111,112]. If potassium phthalimide is employed as the reagent, further reaction may occur. For example, epichlorohydrin *(13)* gives rise to the epoxy compound *(14)*[113], which may react further to give *N,N'*-(2-hydroxytrimethylene)-phthalimide as a by-product[11,109]. An analogous nitrogen heterocycle is the aziridine derivative (15), which on treatment with phthalimide and a catalytic amount of potassium phthalimide affords the sulfonamide *(16)*[114].



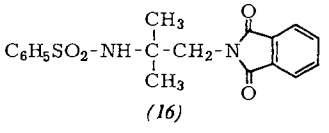
(13)



(14)



(15)



(16)

(Certain quaternary ammonium salts are also effective alkylating agents in the Gabriel Synthesis; these reactions are discussed in Section 2.1.4.[115].)

2.1.4. Neighboring Group Participation

In general, very few examples of genuine neighboring group effects in the Gabriel reaction have been investigated. Many cases where, in the light of present day knowledge[116], a participation would be expected to occur, are either qualitatively expressed as being fast, or no data concerning the relative rate of reaction are recorded. For example, compounds of the type

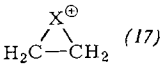
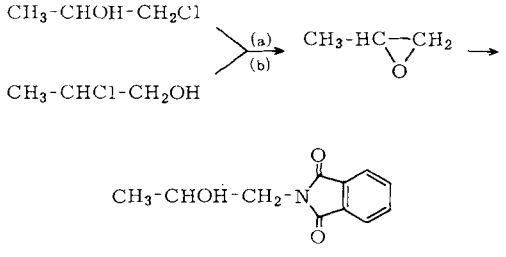
X–CH_2CH_2–Hal [where X is (substituted) nitrogen[117], sulfur[118], or possibly oxygen[29]], might be expected to react rapidly with phthalimide ion, as in fact do *N*-(2-bromoethyl)-*N*-methylaniline[119] and bis-(2-chloroethyl)amine[120]. The observed rapidity of reaction in these instances could well mean the involvement of intermediates of the general formula *(17)*, and the simple S_N2 mechanism may not apply.



(17)

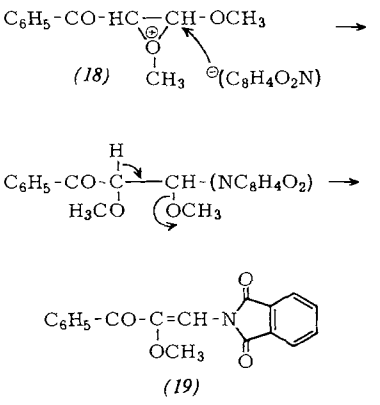
Halonium ions are also formally possible intermediates in certain cases of α,ω-dihalides. Participation may also arise with some substituted benzyl halides. Whereas the above examples must rest largely upon analogy, the following systems leave little doubt that participation is in operation.

Gabriel and *Ohle*[121] re-examined the product obtained from 2-chloro-1-propanol and potassium phthalimide, and found it to be identical with that from 1-chloro-2-propanol. The resulting material was identified as *N*-(2-hydroxypropyl)phthalimide, and it was concluded that the reaction proceeded *via* propylene oxide as an intermediate. Moreover, it was separately shown that phthalimide ion reacts with epoxides under similar conditions[108]. Even in the absence of further



information it is clear that reaction (a) involves neighboring group participation; this is probably true for reaction (b) also. However, not every reaction of a hydroxyalkyl halide with potassium phthalimide involves rearrangement even in cases where a cyclic ether intermediate may be formed; *e.g.* no rearrangement occurs in the case of 1-iodo-3-pentanol[122].

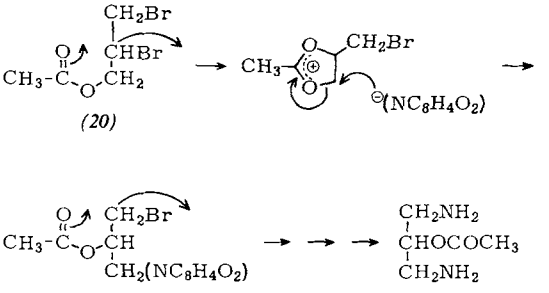
Reaction may also proceed *via* a three-membered ring in the case of 2,2′-diiododiethyl ether[29]. An interesting related example is provided by 2-bromo-3,3-dimethoxy-1-phenyl-1-propanone, which reacts readily with potassium phthalimide to give *(19)*[123]. Here, the oxonium salt *(18)* could function as intermediate.



(18)

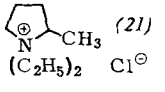
(19)

Philippi and *Seka*[124] examined the reaction between potassium phthalimide and 2,3-dibromopropyl acetate *(20)*, and suggested that 2 moles of potassium phthalimide were consumed, to give rise to the metathetical product, which on acid hydrolysis afforded the diamine. A parallel sequence with 2,3-dibromopropanol provided the same compound. However, *Fairburn* and *Cowdrey*[125] later examined the product from 1,3-dichloro-2-propanol, which they found to be identical with the compound examined by *Philippi* and *Seka*. In the light of present day knowledge, it is clear that the product is not the 1,2-diamine, but is the 1,3-analog, produced *via* at least one cyclic five-membered intermediate (cf. also[126, 73a]).



(20)

Similar effects are found in nitrogen- and sulfur-containing compounds; for instance, *N*,*N*-diethyl-*N*-(4-chloropentyl)amine gives only a trace of the metathetical product. The major component of the reaction with potassium phthalimide was found to be *N*-(4-diethylaminopentyl)phthalimide[115]. Here, the reaction was shown to proceed *via* the pyrrolidinium salt *(21)*.



(21)

Again, benzyl-2-chloro-2-cyanoethyl sulfide gave the metathetical product as the minor component of reaction, whereas the major product was found to be *N*-(2-benzylthio-2-cyanoethyl)phthalimide[127]. From the above examples of neighboring group

participation, it can be seen that where such an effect is liable to occur, due caution must be placed in interpreting the course of the phthalimidation reaction.

2.2. Addition Reactions

In the presence of basic catalysts, phthalimide has been found to add readily to a variety of α,β-unsaturated systems [54, 128–134]. Such α,β-unsaturated com-

$$X{-}CH{=}CH_2 + C_8H_4O_2NH \rightarrow X{-}CH_2CH_2(NC_8H_4O_2)$$

X = CN, CHO, CO_2CH_3, $COCH_3$
$C_8H_4O_2NH$ = phthalimide

pounds may be intermediates in reactions of halogeno-compounds with potassium phthalimide. This elimination addition mechanism seems certain to apply in the reactions of phthalimide ion with γ-bromo-β-methoxybutyrophenone [135], and β-bromo-β,β-dinitroethylacetate [136] which give respectively 1-(2-oxo-2-phenylethyl)-*N*,*N*′-ethylenediphthalimide) and *N*-(2,2-dinitroethyl)phthalimide as the sodium salt.

A novel, but slow addition of *N*-bromophthalimide to isolated double bonds (which competes with allylic abstraction) has recently been reported [137]. Thus, 3,3-dimethyl-1-butene (CCl_4, reflux 120 hours) gives a 1:1 adduct [137]. However, it is reported that ethyl vinyl ether adds to *N*-bromophthalimide at 50 °C in two hours [138].

2.3. Condensation Reactions

Whereas secondary aliphatic amines and primary and secondary aromatic amines condense with formaldehyde and phthalimide to give *N*-alkyl (or *N*-aryl) aminomethylphthalimides [139], primary aliphatic amines give the *N*,*N*′-(alkylamino)dimethylenephthalimide. It is somewhat surprising that primary and secondary alcohols react with phthalimide to give condensation products, with the elimination of water [140]. A typical example is provided by the reaction of 3-morpholino-1-propanol, which gives a good yield of the corresponding phthalimido derivative. The high pressure condensation of phthalimide with acetone in the presence of hydrogen and an Al_2O_3/Pt catalyst, to give *N*-isopropylphthalimide [141] is presumably an example of reductive alkylation, and as such could be a new route to this type of primary amine.

3. Stage 2: Formation of the Primary Amine

3.1. Hydrolytic Methods

3.1.1. Acidic Hydrolysis

Hydrolysis of *N*-substituted phthalimides by hydrochloric acid has been widely practised in the Gabriel Synthesis. At first, fuming or concentrated acid was used, often at temperatures as high as 200 °C in sealed tubes (*e.g.* [4, 6, 7a, 9b, 22]). Such extreme conditions are probably unnecessary in many cases, and more acceptable conditions involve the use of concentrated or 20% acid at reflux temperature for several hours (*e.g.*, [16, 21, 55d, 68, 83, 113, 115]). In some cases, acetic acid is employed as co-solvent (*e.g.*, [8, 17, 29, 58a]). Typical examples of acid hydrolyses are provided by (2-mercaptoethyl)phthalimide [16, 142], *N*-acetonylphthalimide [143], *N*-(2-diethylaminoethyl)phthalimide [117], *N*,*N*′-iminodiethylenephthalimide [120], a variety of phthalimidoalkyl heterocycles [82, 144], tetraethyloxydiethyl-2,2-diphthalimido-2,2,2′2′-tetracarboxylate [145].

Similar hydrolytic procedures involve the use of hydrobromic (*e.g.*, [14, 15, 19, 40, 97, 146]), hydriodic (*e.g.*, [26, 47b]), and sulfuric (*e.g.*, [13b, 14, 23]) acids. The choice of acid is perhaps significant in the hydrolysis of *N*-(halogenoalkyl)phthalimides, when it is preferable to use the halogeno acid corresponding to the halogen atom in the side chain, so as to avoid the possibility of exchange [113a, 147–149]. The conversion

of *N*-(4-bromobutyl)phthalimide to 4-iodobutylamine hydriodide by 55% hydriodic acid illustrates such exchange [150]. Sulfuric acid may also promote hydrolysis of the halogeno function in these cases [14].

A common complication is the hydrolysis of other functional groups, [13, 18–20, 36b, 39, 51c, 54, 69, 77, 124, 151, 152, 154–160]; although γ-lactone rings [153], and a number of ether bonds [145] survive. Moreover, electrophilic displacement of aryl iodine during acidic hydrolysis occurred in an unsuccessful attempt to prepare *p*-iodobenzylamine by the Gabriel method [161], and esterification of alcoholic functions may take place when concentrated halogen acids are used [73a, 108, 162]. Finally, some phthalimides resist acidic hydrolysis, or are decomposed under the reaction conditions (*e.g.*, [59c, 158, 163]). Whilst in such cases as amino-acid synthesis, the concomitant hydrolysis of *e.g.* ester and phthaloyl groups is convenient, the usefulness of acidic hydrolysis is otherwise limited by the susceptibility of other groups to attack.

3.1.2. Two Stage Hydrolysis

In this method the imide is hydrolyzed under alkaline conditions to the phthalamic acid, and the latter under acidic conditions to the amine. The first stage occurs very readily [50b, 164], and vigorous alkaline treatment is unnecessary unless other groups are to be hydrolyzed [51a]. Indeed, opening of the imide ring occurs to some extent under such mild conditions as are obtained in Schotten-Baumann acylations [165], and oxidations with $[Fe(CN)_6]^{3-}$ [160].

The second stage can usually be accomplished under milder acid conditions than those used for the substituted phthalimide [17, 166], a feature relevant where some of the more acid-sensitive groups are concerned [159a, 164a]. A major drawback is the loss of material through re-cyclization to the imide in the second stage (*e.g.*, [12, 159a, 160, 167]), though this can be recovered and re-cycled if necessary [168].

3.1.3. Alkaline Hydrolysis

Complete alkaline hydrolysis was advocated by *Putochin* [66, 169], particularly for the preparation of diaminoalkanes [170] from α,ω-diphthalimidoalkanes, and aminoalcohols [171] from ω-phthalimidoalkyl halides (with the reported exception of *N*-(4-chlorobutyl)-phthalimide which gives pyrrolidine [172]); the method was independently used for the preparation of certain allylic amines [61, 173]. More recent applications include syntheses of neopentyl type amines [41, 42]. The method has not been widely used, and is unsuitable for alkali sensitive molecules; for example, a Smiles rearrangement occurs during alkaline hydrolysis of *N*-[2-hydroxy-3-(*p*-nitrophenoxy)propyl]phthalimide [111], and its acetate [174].

3.2. Aminolytic and Hydrazinolytic Methods

3.2.1. Aminolysis

There were definite indications in early work on the Gabriel reaction that alkyl phthalimides reacted with primary amines with ring opening. Thus *Seitz* had noted *N*-phenylphthalimide as a product of reaction of *N*-(2-bromopropyl)phthalimide with aniline [31a], and *Ristenpart* had obtained the corresponding phthalimides from methylamine and ethylamine with *N*-(2-bromoethyl)phthalimide [175]. Alternative ring closure of such phthalamides will (a) regenerate the original phthalimide and (b) lead to the phthalimide derived from the amine reactant [176]. Such aminolytic reactions have led to complications in much of the synthetic antimalarial work based on reactions of *N*-(halogenoalkyl)phthalimides with primary amines [177]. Aminolysis of phthalimides either as the major [178] or

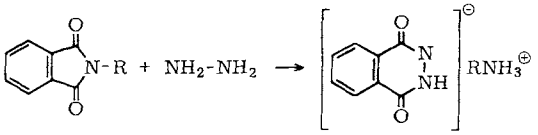
as the minor reaction [179] has been noted in other instances. Thalidomide (α-phthalimidoglutarimide) also apparently reacts with certain diamines, notably putrescine and spermidine, very readily [180].

3.2.2. Hydrazinolysis

Hydrazinolysis, introduced by *Ing* and *Manske* [25, 181] in 1926, has largely but not entirely superseded hydrolytic methods for accomplishing the second stage of the Gabriel Synthesis. In the original method, the substituted phthalimide was treated with hydrazine in hot ethanolic solution, when an uncharacterized (and incorrectly formulated) intermediate was readily produced. This was decomposed by heating with hydrochloric acid, when phthalhydrazide was precipitated and the amine hydrochloride usually remained in solution. The comparatively mild conditions of reaction and ease of separation of products presented obvious attractions and constituted an important advance, but it was not until nearly 20 years later that such technical innovations as conducting the hydrazinolysis [184] or acidic decomposition [70] stages at room temperature were employed in one or two cases, and that the intermediate was recognized as the amine salt of phthalhydrazide *(22)* [176b].



(22)

Manske applied the technique to the Curtius and related reactions [182]. Thus, substituted urethanes and ureas react with phthalic anhydride to give the corresponding phthalimides which can then be hydrazinolyzed; isocyanates can likewise be converted in two steps into the primary amine [183].

Inherent merits in the method were apparent in cases of difficult hydrolysis, for example *N*-(3-*p*-acetamidophenoxypropyl)phthalimide [163], and in avoidance of side reactions [159a, 185]. In 1946 *Mosher* [177] queried the necessity of boiling the hydrazinolysis intermediate with hydrochloric acid prior to isolation of the amine, and he illustrated an alternative procedure in which the intermediate was rendered alkaline and the expected amine isolated directly by solvent extraction. Independently, *Barber* and *Wragg* [176b] had recognized the hydrazinolysis intermediate in these reactions as *(22)*; formation of the amine or its hydrochloride, depending on whether *(22)* was treated with potassium hydroxide or hydrochloric acid, was thus immediately intelligible.

The use of an excess of hydrazine and the separation of the expected amine as the free base has been used occasionally [144b], and specifically recommended for some peptides where it would be otherwise difficult to remove residual hydrazine hydrochloride from the peptide hydrochloride [186]. However, the presence of residual hydrazine in some cases may pose problems of purification [187], requiring the use of *e.g.* salicylaldehyde for its removal [35, 73a].

The conditions available for hydrazinolysis are sufficiently mild to allow the preservation of many functional groups (*e.g.* [56, 73e, 189, 191, 192]), including most of those which are sensitive to hydrolysis. Thus, α,ω-aminoalkanenitriles are available through hydrazinolysis [193]. Carboxylic ester functions generally survive [49, 73b, 190], though there are indications that this group is somewhat sensitive [194], as indeed are xanthates [195].

Hydrazinolysis has frequently been practised in boiling ethanol, and under such conditions, reaction is likely to be fast. Nevertheless, reported reaction times vary considerably, and some quoted periods are probably excessive. Intermediate temperatures have also been employed [188], and occasionally necessitated by the sensitivity of another part of the molecule to attack, as for example with certain 2-aminothiazole derivatives [189]. Finally, hydrazinolysis has been accomplished for a considerable number of compounds, including peptides (which may be hydrazinolyzed in aqueous solution [190]), at room temperature [184, 191].

Moreover, the hydrazinolysis procedure cannot generally be applied to molecules containing (a) halogenoalkyl [196], or (b) aldehyde or ketonic groups, although the latter may often be protected by conversion into acetals and thioacetals [102, 197], or ketals and thioketals [132b, 198]. acid sensitive groups (*e.g.* acetal), isolation of the amine by basification may be necessary for the group to be preserved [102]. In this connection, use of an excess of hydrazine to permit direct isolation of amines may be used [144b]. If the expected amine is base-sensitive, a carefully controlled hydrazinolysis followed by acidic work-up may provide the only possibility of isolation of the hydrochloride [111] (for examples see [165, 199]).

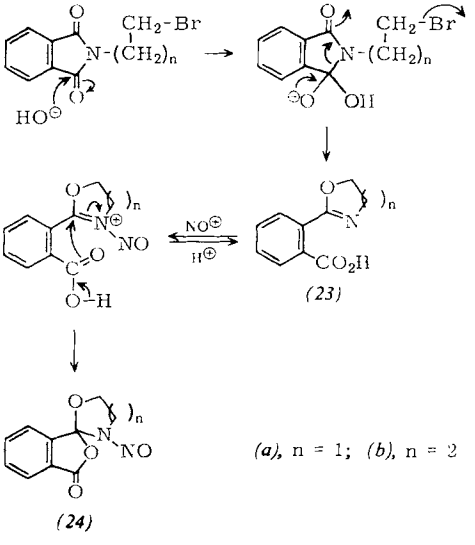
3.2.3. Phenylhydrazinolysis

Phenylhydrazinolysis was introduced for removing phthaloyl groups in one stage, particularly from peptide derivatives [200], so avoiding the final acid treatment of the Ing-Manske hydrazinolysis procedure. The technique has not been widely used and has been reported as unsuccessful when applied to *cis*-2-butenylphthalimide [56a] and *N*-(5-sulfamoyl-2-thienyl)-phthalimide [201]; the last compound is reported to suffer decomposition on attempted hydrazinolysis.

3.3. Neighboring Group Participation

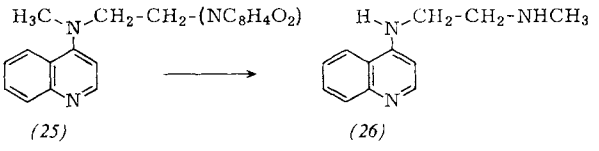
Neighboring group participation effects are observable in the alkaline hydrolysis of *N*-(2-bromoethyl)- and *N*-(3-bromopropyl)phthalimide, in which the *N*-nitroso compounds *(24a)* and *(24b)* resp. are formed [203]. *Gabriel* postulated the formation of intermediate products having 8- and 9-membered rings [202] respectively. These reactions have recently been reinvestigated, and the intermediate products recognized as the oxazolene *(23a)* and 1,3-oxazine derivative *(23b)* respectively, presumably in the zwitterionic form.

Similar considerations probably apply for example, in the reaction of *N*-(2-bromoethyl)phthalimide with



potassium pyrrole with subsequent hydrazinolysis, which leads not to *N*-(2-aminoethyl)pyrrole [204] but to pyrrole itself and a product that may be equated with that subsequently obtained by hydrazinolysis of *(23a)* [203a]. This apparently anomalous result is readily explained by assuming that pyrrole anion, like hydroxide ion, reacts with the phthalimide to give an intermediate product, which then reacts with hydrazine in the expected way (cf. also [205]).

Artefacts are frequently obtained in hydrolysis and hydrazinolysis reactions where the generated primary amino group can interact with other functional groups in the molecule. Examples are provided by the formation of pyrrolene derivatives in (a) the acidic hydrolysis of *N*-(4-oxo-4-phenylbutyl)phthalimide [154]



(25) *(26)*

and (b) the hydrazinolysis of methyl 3-phthalimidocrotonate [206]; formation of analogous six-membered rings has also been noted [207]. The involvement of cyclic transition states may also lead to rearranged products. Thus the alkaline hydrolysis of *N*-[2-hydroxy-3-(*p*-nitrophenoxy)propyl]phthalimide involves an O→N aryl migration [111, 174]; O→N acetyl migration has been noted during hydrazinolysis and work-up of 3-methoxy-1-(*p*-nitrophenyl)-2-phthalimidopropyl acetate [208]. An example of N→N migration is afforded by the reaction *(25)*→*(26)* [164d].

4. Conclusions

Finally a few limitations of the Gabriel Synthesis should be noted. For example, *sym*-dichloroacetone is reported to react with potassium phthalimide to give phthalimide itself [209]. Difficulties have also been noted with certain pentaerythritol derivatives such as *(27)*, which, with potassium phthalimide also produces phthalimide and probably an oxetane [73a]. Further *(28)* gives an unidentified compound rather than the metathetical product [210].

Most of the reported failures in the second stage of the synthesis are largely concerned with the inherent instability of either the generated amine, or some other sensitive part of the molecule. Examples of the former category are encountered in systems of the type *(29)–(31)*, which do not survive hydrolysis or hydrazinolysis, and usually decompose *inter alia* to formaldehyde and ammonia. The latter group includes some examples of *N*-thienylphthalimides, in which the heterocyclic ring decomposes, and gives rise to hydrogen sulfide [201].

$X(CH_2\text{–}NC_8H_4O_2)_n$

(29) X = RS–; n = 1 [211]
(30) X = N; n = 3 [212]
(31) X = NO_2; n = 1 [213]

Despite these minor limitations, the Gabriel Synthesis will doubtless continue to be exploited for the preparation of primary amines, but more complete understanding of the reactions involved must await further mechanistic studies.

The authors wish to thank Dr. E. M. Howells for reading the manuscript.

Kinetic Studies on Substitution Reactions of Carbonylmetal Complexes [1]

BY H. WERNER [*]

Kinetic studies of substitution reactions of carbonylmetals and of carbonylmetal derivatives in which other ligands (n or π donors) besides CO are bound to the metal atom have recently attracted great interest, and the results of these investigations throw a new light on theoretical and preparative problems. The substitution mechanism is determined mainly by steric and electronic factors.

1. Introduction

It is known from the classic work of *Hieber* and his school that metal carbonyls undergo substitution reactions of type (1) when thermal or photochemical

$$M(CO)_x + yL \rightarrow M(CO)_zL_y + (x-z)CO \qquad (1)$$

energy is supplied. The ligand L may be varied within wide limits, and may be either an n donor (*e.g.* amine, phosphine, arsine, stibine, isocyanide, thioether) or a π donor (*e.g.* olefin, aromatic compound). Carbonylmetal derivatives in which one or more other groups X (*e.g.* NO, H, halogen, alkyl) are bound to the metal atom besides CO also react readily with donors L. The course of the substitution is in many cases determined by the nature of the non-CO ligands, their donor and acceptor properties being particularly important.

General observations of this type were until recently based almost exclusively on the results of preparative studies [2]. Kinetic studies on the mechanism of substitutions of carbonylmetal compounds have only recently been initiated, and are now being carried out in rapidly growing numbers.

The first study in this field was reported in 1959 and was concerned with the kinetics of the reactions of carbonylphosphinenickel complexes which are important in industry [3]. This report referred to the use of spectrophotometric methods for the determination of the concentration of carbonylmetals, and so provided a decisive stimulus to further development.

Photochemical reactions will not be discussed in the present article, since a review of this topic has recently been published [4].

2. Possible Reaction Courses

There are two possible courses for the reaction [eq. (1)] of a carbonylmetal $M(CO)_x$ with a donor L (y = 1, $z = x-1$).

(a) The first step is the cleavage of an M–CO bond to form an intermediate in which the coordination number has been reduced by 1, which then reacts with L.

$$M(CO)_x \xrightarrow[-CO]{} M(CO)_{x-1} \xrightarrow{+L} M(CO)_{x-1}L \qquad (2)$$

[3] *L. S. Meriwether* and *M. L. Fiene*, J. Amer. chem. Soc. *81*, 4200 (1959).

[4] *W. Strohmeier*, Angew. Chem. *76*, 873 (1964); Angew. Chem. internat. Edit. *3*, 730 (1964); see also *E. O. Fischer* and *M. Herberhold*, Experientia, Suppl. *1964*, 259.

(b) The first step is a direct attack of L on the central atom of the original complex to give an activated complex and possibly also an intermediate in which the coordination number has been increased by 1, and from which the reaction product is formed by loss of a CO group.

$$M(CO)_x \xrightarrow{+L} M(CO)_xL \xrightarrow[-CO]{} M(CO)_{x-1}L \qquad (3)$$

If the first step is rate-determining, as is usual in substitution reactions of complexes, the rate equations are:

$$\text{for (a)} \quad \frac{d[M(CO)_{x-1}L]}{dt} = k[M(CO)_x] \qquad (4)$$

$$\text{for (b)} \quad \frac{d[M(CO)_{x-1}L]}{dt} = k[M(CO)_x]\,[L] \qquad (5)$$

According to the nomenclature established by *Ingold*[5], a reaction course of the type (a) is an S_N1 mechanism, while course (b) is S_N2.

Following a suggestion by *Langford* and *Gray*[6], an S_N1 mechanism might also be called a D mechanism ("dissociative mechanism") and an S_N2 an A mechanism ("associative mechanism"). This terminology avoids the use of the word "nucleophilic", which seems undesirable in view of the fact that very many donors L have not only electron donor, but also electron acceptor properties as complex ligands.

The substitution reactions of carbonylmetal compounds do not always obey the simple rate equations (4) and (5). It has been found that several parallel steps as well as several consecutive steps can be rate-determining. Such processes give rate equations of fractional order, the interpretation of which will be explained with the aid of some examples in Section 4.

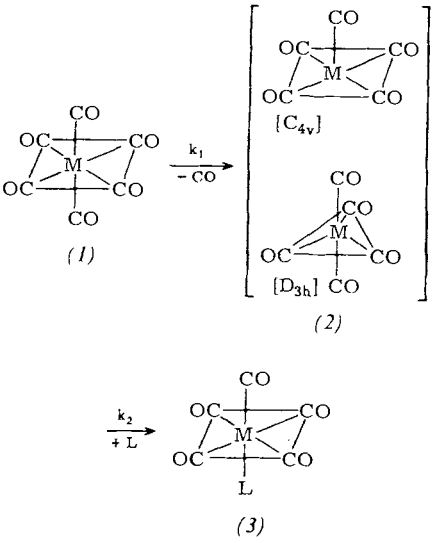
3. Methods of Investigation

As was mentioned above, the concentration determinations required for the calculation of rate data are mainly based on spectrophotometric methods in the reactions of carbonylmetal compounds. IR spectroscopy is particularly widely used, since the CO stretching frequencies are generally very intense, and so reflect accurately even relatively small concentration changes during the reaction. Absorption measurements in the visible region have also proved useful (*e.g.* in the reactions of the colorless hexacarbonylmetals, which generally lead to colored substitution products). In some cases the rate of evolution of CO was also followed by gas-volumetric measurements; small quantities of CO, however, are difficult to detect. With labeled donors L (*e.g.* ^{14}CO or $^{14}C_6H_6$), the substitution can be followed in the gas phase or in solution by the decrease in activity. Rate equations can be obtained from these investigations with the aid of *McKay*'s equations[7].

4. Results of Kinetic Studies

4.1. Carbonylmetals

Among the compounds $M(CO)_x$, those most extensively used in kinetic studies are the hexacarbonyls of chromium, molybdenum, and tungsten, owing to their chemical properties. Unlike other carbonylmetals, such as $Fe(CO)_5$, $Co_2(CO)_8$, and $Mn_2(CO)_{10}$, they never undergo disproportionation on reaction with n donors, but are always substituted. Extensive investigations by various research groups have shown that both the exchange reactions of $M(CO)_6$ *(1)* with ^{14}CO in the gas phase[8–10] and in solution[11] and the reactions with unidentate and multidentate n and π donors[12–16] proceed by an S_N1 mechanism ($k_2 > k_1$) over a wide concentration range.



(6)

The structures discussed for the intermediates *(2)* formed in the rate-determining step are the tetragonal pyramid and the trigonal bipyramid. The molecules $M(CO)_5$ formed on irradiation of *(1)* at −180 °C in a matrix have symmetry C_{4v} according to their IR spectra[17].

In the presence of a large excess of phosphine, the rate of formation of pentacarbonylphosphinemetals $M(CO)_5PR_3$ *(4)* from *(1)* satisfies the equation

$$\frac{d[(4)]}{dt} = k[(1)] + k'[(1)]\,[PR_3] \qquad (7)$$

The second order term, the importance of which increases with the size of the central atom[18,19], can be

explained by a direct attack of the phosphine on the metal atom or on the C atom of a CO group.

In the reactions of hexacarbonylmetals *(1)* with multidentate donors L, the compounds *(3)* are formed as intermediates. The rate of further intramolecular substitution

$$(3) \xrightarrow[-CO]{k_3} M(CO)_4L \quad \text{(L bidentate)} \tag{8}$$

$$(3) \xrightarrow[-CO]{k_3} M(CO)_4L \xrightarrow[-CO]{k_4} M(CO)_3L \quad \text{(L terdentate)} \tag{9}$$

$$(3) \xrightarrow[-CO]{k_3} M(CO)_4L \xrightarrow[-CO]{k_4} M(CO)_3L \xrightarrow[-CO]{k_5} M(CO)_2L \quad \text{(L quaterdentate)} \tag{10}$$

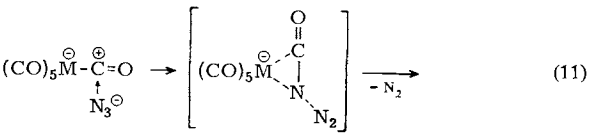
is strongly dependent on the nature of L[16]. For example, if L is a diamine, $k_3 > k_1$; in this case there is no evidence of the existence of intermediates under the conditions used. If on the other hand L is a diphosphine, k_1 and k_3 are comparable in magnitude[20]. With $L = C_2H_4[P(C_6H_5)_2]_2$, it is possible in the case of M = Mo to isolate a compound *(3)* in which only one of the two phosphorus atoms of the diphosphine is coordinately bound to the metal atom[21]; the formation of the chelate complex $M(CO)_4L$, as expected, proceeds with first order kinetics in this case.

The activation energies of the substitution reactions of the hexacarbonylmetals increase in the order Mo < Cr < W (see Table 1). This increase parallels the increase in the force constants for the M–C stretching vibration of the compounds $M(CO)_6$, which are 1.81, 2.03, and 2.15 mdyn/Å for M = Mo, Cr, and W respectively[22]. The kinetic measurements thus confirm numerically the experimentally observed higher reactivity of $Mo(CO)_6$ as compared with $Cr(CO)_6$ and $W(CO)_6$, and so confirm the general experience that complexes of elements of the second transition series are very often more reactive than the corresponding compounds of elements of the first and third transition series.

Table 1. Activation energies E_a of substitution reactions of the hexacarbonylmetals (kcal/mole).

	Cr	Mo	W	Ref.
$M(CO)_6$ + ^{14}CO (Vapor)	39.3	30.8	40.4	[8–10]
$M(CO)_6$ + ^{14}CO (Decalin)	39.0	31.6	40.6	[11]
$M(CO)_6$ + $P(C_4H_9)_3$ (Decalin)	40.8	32.3	40.5	[19]
$M(CO)_6$ + $P(C_6H_5)_3$ (*n*-Decane)	38.7	30.8	39.6	[16]
$M(CO)_6$ + C_7H_8 (*n*-Decane)	39.0	30.0		[14, 23]

$Cr(CO)_6$ and $W(CO)_6$ react with N_3^- without elimination of CO to form the anions $[M(CO)_5NCO]^-$ (M=Cr, W). Some recent investigations[24] have shown that the rate-determining step is bimolecular, and is probably a direct nucleophilic attack of the azide ion on the C atom of a CO group. The subsequent steps, *i.e.* removal of N_2 and formation of the M–N bond, appear to be synchronous as is assumed in the Curtius azide degradation.



$$[(CO)_5M\text{-}N{=}C{=}O]^-$$

A similar primary step must also be assumed for the reactions of *(1)* with carbanions[25], and the Hieber base reaction probably also begins with a nucleophilic attack of an OH^- ion on the CO group of the carbonylmetal[26].

$Fe(CO)_5$ is practically inert to labeled carbon monoxide[27,28] and phosphines[29] below its decomposition point (90 °C). In the presence of CF_3COOH, however, rapid exchange occurs with ^{14}CO even at −20 °C[30], with preferential substitution of the axial CO ligands. Since the exchange rate is independent of the ^{14}CO concentration, the rate-determining step must be assumed to be the removal of one CO from the protonated intermediate complex. The reactions of $Fe(CO)_5$ with nitrogen donors, such as *n*-butylamine or pyrrolidine, probably proceed by primary attack of the donor on the C atom of a CO group[31].

In contrast to $M(CO)_6$ and $Fe(CO)_5$, $Ni(CO)_4$ *(5)* reacts with ^{14}CO[28] and $P(C_6H_5)_3$[32] even at 0 °C in toluene. Both reactions are first order with respect to the $Ni(CO)_4$ concentration and zeroth order with respect to the ligand concentration. Nevertheless, the mechanisms of these reactions do not appear to be the same, since the activation parameters are quite different[33] (*(5)* + ^{14}CO in toluene: $\Delta H^{\neq} = 12$ kcal/mole, $\Delta S^{\neq} = -26$ cal/mole·deg; *(5)* + $P(C_6H_5)_3$ in toluene: $\Delta H^{\neq} = 21$ kcal/mole, $\Delta S^{\neq} = +2$ cal/mole·deg). The strongly negative activation entropy for the CO exchange is particularly surprising, and, according to general experience, is evidence against a "normal" S_N1 mechanism. The first step in this case may be, not a dissociation process, but a rearrangement of the tetrahedral $Ni(CO)_4$ to the square planar structure[34,34a].

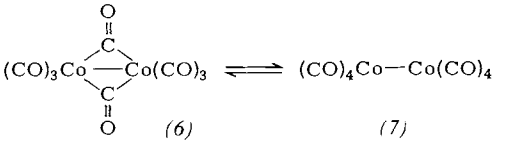
The reactions of $Co_2(CO)_8$ with labeled carbon monoxide [28, 34] and alkynes [35] is also thought to start with rearrangement of the complex, in this case with cleavage of one of the CO bridge bonds of *(6)*. This is supported by the results of IR measurements, which indicate that *(6)* and *(7)* exist in equilibrium in solution [36].



(6) *(7)*

$Co_2(CO)_8$ reacts much more rapidly with triphenylphosphine than with ^{14}CO or alkynes. The reaction rate is independent of the phosphine concentration at a molar ratio $Co_2(CO)_8:P(C_6H_5)_3 \leqslant 1:2$, but is directly proportional to this concentration at molar ratios $> 1:2$ [32]. The substitution could proceed *via* a primary 1:1 adduct, the decomposition of which, with liberation of CO, is rate-determining (k_1 and $k_3 > k_2$).

$$Co_2(CO)_8 + P(C_6H_5)_3 \xrightarrow{k_1} Co_2(CO)_8P(C_6H_5)_3 \xrightarrow[-CO]{k_2}$$

$$Co_2(CO)_7P(C_6H_5)_3 \xrightarrow[+P(C_6H_5)_3]{k_3} [Co(CO)_3[P(C_6H_5)_3]_2]^{\oplus}[Co(CO)_4]^{\ominus} \quad (12)$$

Different authors have different views on the mechanism of the reaction of $Mn_2(CO)_{10}$ with triphenylphosphine, which proceeds in accordance with a first order rate equation. Whereas *Wawersik* and *Basolo* [37] explain the formation of the substituted compounds by a reaction sequence:

$$Mn_2(CO)_{10} \underset{-CO}{\xrightarrow{k_1}} Mn_2(CO)_9 \xrightarrow[+P(C_6H_5)_3]{k_2}$$

$$Mn_2(CO)_9P(C_6H_5)_3 \underset{-CO}{\xrightarrow{k_3}} Mn_2(CO)_8P(C_6H_5)_3$$

$$\xrightarrow[+P(C_6H_5)_3]{k_4} Mn_2(CO)_8[P(C_6H_5)_3]_2 \quad (13)$$

($k_1 < k_2$), *Hopgood* and *Poe* [38] believe that the first step is homolysis of the Mn–Mn bond to give $Mn(CO)_5$ radicals, which can either recombine, decompose after diffusion out of the solvent cage, or react with the phosphine.

$$Mn_2(CO)_{10} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} [2 \cdot Mn(CO)_5]$$

$$[2 \cdot Mn(CO)_5] \xrightarrow{k_2} 2 \cdot Mn(CO)_5 \xrightarrow{\text{fast}} 2\,Mn + 10\,CO$$

$$[2 \cdot Mn(CO)_5] + P(C_6H_5)_3 \xrightarrow{k_3} \text{products} \quad (14)$$

The activation energy of 37 kcal/mole, which is considerably higher than the dissociation energy found for the Mn–Mn bond by mass spectrometry (19 kcal/mole), favors the first of the above suggestions. In the reactions of $Mn_2(CO)_{10}$ with amines, which lead *via* $[Mn(CO)_5L]^-[Mn(CO)_5]^-$ to the series of compounds $[MnL_6]^{2+}[Mn(CO)_5]_2^-$ (L = amine) [39], the first step in polar solvents is assumed to be amine-assisted heterolysis of the Mn–Mn bond [40].

In the dodecacarbonyls of iron, ruthenium, and osmium, all the CO groups are exchangeable with ^{14}CO; the exchange rate is independent of the ^{14}CO concentration [41, 42]. In the case of $Fe_3(CO)_{12}$, which contains both terminal and bridge CO ligands, a continuous rapid interconversion of the Fe–CO bonds is postulated to explain the kinetic data.

4.2. Carbonylnitrosylmetals

In contrast to the substitution reactions of $Ni(CO)_4$ *(5)*, the reactions of the "pseudo-tetracarbonylnickels" $Co(CO)_3NO$ *(8)*, $Fe(CO)_2(NO)_2$ *(9)*, and $Mn(CO)(NO)_3$ *(10)* (which also have tetrahedral configurations) with n donors L proceed by an S_N2 mechanism [32, 43–45]. A trigonal-bipyramidal arrangement of the ligands is conceivable in the transition state.

$$(8) + L \rightarrow Co(CO)_2(NO)L + CO \quad (15)$$

$$(9) + L \rightarrow Fe(CO)(NO)_2L + CO \quad (16)$$

$$(10) + L \rightarrow Mn(NO)_3L + CO \quad (17)$$

The reactions corresponding to equations (15) to (17) are particularly fast when L is readily polarizable; this means that the metal atoms in the carbonylnitrosylmetals may be regarded as typical "soft" acids [46]. In the reactions of *(8)* with $L = PR_3$, there is an almost linear relation between the second order rate constants and the polarizability of the phosphine [43].

(8) and *(9)* react with 1,2-bis(diphenylphosphino)-ethane (P–P) in tetrahydrofuran or toluene at 25 °C to form first the intermediates *(11)* and *(13)*, which can be detected by IR spectroscopy, and which lose CO at somewhat higher temperatures to form the chelate complexes *(12)* and *(14)* [44]. The rate of the monosubstitution (k_1 or k_1') is first order with respect to the diphosphine concentration, while the rate of the second (k_2 or k_2') is independent of this concentration.

[46] For the concept of "hard and soft acids and bases", see *R. G. Pearson*, J. Amer. chem. Soc. *85*, 3533 (1963); Science (Washington) *151*, 172 (1966); *R. G. Pearson* and *J. Songstad*, J. Amer. chem. Soc. *89*, 1827 (1967); *H. Werner*, Chemie in unserer Zeit *1*, 135 (1967); *B. Saville*, Angew. Chem. *79*, 966 (1967); Angew. Chem. internat. Edit. *6*, 928 (1967).

$$(8) + \text{P–P} \xrightarrow[-CO]{k_1} \underset{(11)}{Co(CO)_2(NO)P\text{–}P} \xrightarrow[-CO]{k_2} \underset{(12)}{Co(CO)(NO)P\text{–}P} \quad (18)$$

$$(9) + \text{P–P} \xrightarrow[-CO]{k_1'} \underset{(13)}{Fe(CO)(NO)_2P\text{–}P} \xrightarrow[-CO]{k_2'} \underset{(14)}{Fe(NO)_2P\text{–}P} \quad (19)$$

The reactions of the bridge complexes $P\text{–}P[Co(CO)_2NO]_2$ and $P\text{–}P[Fe(CO)(NO)_2]_2$ with P–P to form *(12)* and *(14)* follow a second order rate equation [44]. This is also true of the exchange reaction:

$$Co(CO)_2(NO)L + L' \rightarrow Co(CO)_2(NO)L' + L \quad (20)$$

The reaction rate in this case is determined mainly by the nature of the ligand L, and increases in the order $P(C_6H_5)_3 < P(OCH_3)_3 < P(OC_6H_5)_3 < As(C_6H_5)_3 \approx P(OCH_2)_3CCH_3 < CNC_6H_{11}$ for a given L'. For the same complex $Co(CO)_2(NO)L$, the reactivity of L' increases in the order $P(OC_6H_5)_3 < P(C_6H_5)_3 < P(C_6H_5)_2C_2H_5 < P(n\text{-}C_4H_9)_3$ [47]. The substitution of a second CO group (eq. (21)) proceeds more slowly in every case than the ligand exchange (20).

$$Co(CO)_2(NO)L + L' \rightarrow Co(CO)(NO)LL' + CO \quad (21)$$

The difference in the reaction behavior of carbonylmetals and carbonylnitrosylmetals can be seen not only on comparison of $Ni(CO)_4$ with $Co(CO)_3NO$ but also on comparison of $Fe(CO)_5$ with $Mn(CO)_4NO$ *(15)*. The compound *(15)*, which is the first in the series of "pseudo-pentacarbonylirons", reacts with phosphines, phosphites, and arsines at $\approx$ 50–70 °C by an S_N2 mechanism [45].

$$\underset{(15)}{Mn(CO)_4NO} \xrightarrow{+L} Mn(CO)_4(NO)L \xrightarrow[-CO]{} Mn(CO)_3(NO)L \quad (22)$$

The relatively low activation energy (*(15)* + $P(C_6H_5)_3$ in *p*-xylene: E_a = 20 kcal/mole), as in the case of $Co(CO)_3NO$ (*(8)* + $P(C_6H_5)_3$ in toluene: E_a = 15 kcal/mole), indicates that in these reactions the addition of a ligand L to the original complex is favored over the dissociation of an M–CO bond. This is probably because the metal atoms in the carbonylnitrosylmetals carry a formal negative charge as indicated in resonance formula *(16)*, with the result that M–CO backbonding is strengthened and dissociation therefore becomes more difficult. This argument is supported by the values of the force constants of the M–C stretching vibrations of $Ni(CO)_4$ (2.1 mdyn/Å) and $Co(CO)_3NO$ (2.92 mdyn/Å) [48,49].

$$\underset{(16)}{\overset{\ominus}{M}=\overset{\oplus}{N}=O} \leftrightarrow \underset{(17)}{M\text{–}\ddot{N}=O}$$

The resonance formula *(17)*, which makes little contribution to the ground state of the carbonylnitrosylmetals, could be more important in the transition state of a bimolecular reaction step. In *(17)*, the metal has a free low-energy orbital, which could explain why the addition of a donor ligand is favored.

4.3. Carbonylmetal Hydrides

The carbonylmetal hydrides $HMn(CO)_5$ and $HCo(CO)_4$ undergo substitution reactions much more readily than the corresponding metal carbonyls $Mn_2(CO)_{10}$ and $Co_2(CO)_8$. The rate of the exchange is independent

$$HMn(CO)_5 + 5\,{}^{14}CO \rightarrow HMn({}^{14}CO)_5 + 5\,CO \quad (23)$$

of the ^{14}CO concentration [30], and is much lower than the rate of reaction of the isoelectronic $[HFe(CO)_5]^+$ cation with labeled carbon monoxide, indicating a higher M=CO double bond character in the uncharged pentacarbonylhydridomanganese. The reactions

$$HCo(CO)_4 + P(C_6H_5)_3 \rightarrow HCo(CO)_3P(C_6H_5)_3 + CO \quad (24)$$

$$HCo(CO)_3L + L \rightarrow HCo(CO)_2L_2 + CO \quad (L = PO_3C_6H_{11}) \quad (25)$$

probably also follow an S_N1 mechanism [32, 50]. The formation of an intermediate $HCo(CO)_3$ by loss of CO from $HCo(CO)_4$ was assumed earlier in connection with studies on the mechanism of hydroformylation (oxo synthesis) [51].

4.4. Carbonylmetal Halides

The carbonylmetal halides used so far in kinetic studies nearly all have octahedral structures. It is therefore not surprising that their substitutions proceed mainly by an S_N1 mechanism.

The following reactions of pentacarbonylmanganese and pentacarbonylrhenium halides have recently been particularly extensively studied.

$$\begin{array}{ccc} M({}^{14}CO)_5X & & M(CO)_3LL'X \\ {\scriptstyle +\,{}^{14}CO}\uparrow{\scriptstyle (b)} & & {\scriptstyle +\,L'}\uparrow{\scriptstyle (e)} \\ M(CO)_5X & \xrightarrow[(a)]{+L} & M(CO)_4LX \\ {\scriptstyle (c)}\searrow & & \nearrow{\scriptstyle +\,L\ (d)} \\ & [M(CO)_4X]_2 & \end{array} \quad (26)$$

The rate of the monosubstitution (26a) is independent of the ligand concentration [L], but depends on X; at a given temperature it increases in the order X = I <

[51] *R. F. Heck* and *D. S. Breslow*, J. Amer. chem. Soc. *83*, 4023 (1961).

Br < Cl [52-54, 54a]. This variation of the reactivity is probably due to the differences in the electronegativities of the halogens; the greater the electronegativity, the smaller is the degree of M–CO back-bonding and hence the strength of the M–CO bond. There is as yet no satisfactory explanation for the contrary trends shown by the activation energies of the first step

$$M(CO)_5X \rightarrow M(CO)_4X + CO \qquad (27)$$

postulated for the substitution. For M – Mn, the E_a values increase with increasing atomic weight of the halogen [53], while for M = Re they decrease [54]. The pentacarbonylmanganese halides react appreciably faster than the corresponding rhenium compounds at the same temperature. In the exchange reaction of $Mn(CO)_5X$ with ^{14}CO in accordance with equation (26b), it appears, contrary to earlier findings [52], that the exchange rate for the four equatorial CO groups differs only slightly from that for the axial CO group [55].

The formation of the dinuclear complexes $[M(CO)_4X]_2$ (26c), like the substitution (26a), probably proceeds *via* an $M(CO)_4X$ intermediate [54]. The rate of the dimerization surprisingly changes with the concentration of the $M(CO)_5X$ solutions, just as is found in the reactions of hexacarbonylmetals with aromatic π donors [14]. The existence of equilibria is probably the deciding factor in both cases.

The reactions of the dimeric tetracarbonylrhenium halides *(18)* with $P(C_6H_5)_3$ and with pyridine and pyridine derivatives (eq. (26d)) obey a second order rate equation [56].

$$\frac{d[Re(CO)_4LX]}{dt} = k[(Re(CO)_4X)_2][L] \qquad (28)$$

The rate constant k is found to be approximately a function of the basicity of the substituent L. It is thought that either the first step is the formation of an intermediate with a 7-coordinate metal atom, or the bimolecular rate-determining step (k_1) is preceded by a rapid equilibrium between *(18)* and *(19)* [56] ($k_2 > k_1$).

[56] *F. Zingales, U. Sartorelli, F. Canziani*, and *M. Raveglia*, Inorg. Chem. *6*, 154 (1967).

The fact that only *cis*-$Re(CO)_4LX$ is formed is plausibly explained by the reaction sequence indicated.

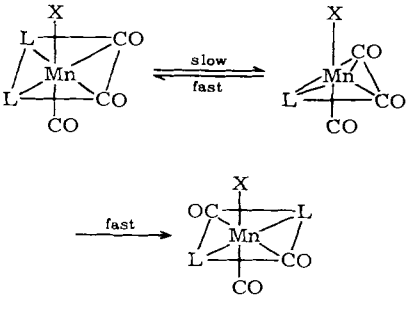
$$[Mn(CO)_4X]_2 + 4\,L \rightarrow \underset{(20)}{2\,Mn(CO)_3L_2X} + 2\,CO \qquad (30)$$

The reaction (30) (L = pyridine, γ-picoline, 3-chloropyridine) gives an additive rate equation [57]:

$$\frac{d[(20)]}{dt} = k'[(Mn(CO)_4X)_2] + k''[(Mn(CO)_4X)_2][L] \qquad (31)$$

The simultaneous occurrence of dissociation (k') and addition (k'') in this case could be explained by the fact that the Mn–X bond is weaker than the Re–X bond.

Like the monosubstitution (26a), the disubstitution (26e) proceeds under relatively mild conditions. The rate is again independent of the nature and concentration of L′, and increases in the order X = I to Cl [58, 59]. It is also strongly dependent on L; the bulkier and the "harder" this ligand is, the more strongly is the dissociation favored. For example, $Mn(CO)_4P(C_6H_5)_3Br$ in tetrachloroethane at 40 °C reacts about seven times as fast as $Mn(CO)_4P(n\text{-}C_4H_9)_3Br$ (phenyl is larger than *n*-butyl), and $Re(CO)_4(C_5H_5N)Br$ in CCl_4 at 60 °C reacts about six times as fast as $Re(CO)_4P(C_6H_5)_3Br$ (pyridine is "harder" than triphenylphosphine). The compounds $Mn(CO)_3LL'X$ (or $Mn(CO)_3L_2X$) formed in accordance with equation (26e) for M = Mn initially have the *cis* configuration, but rearrange slowly in solution to give the *trans* form [60]. The isomerization is probably intermolecular and begins with the removal of L.



(32)

A mechanism proposed by *Cohen* and *Basolo* [61] for the substitution reactions of tetracarbonyliron dihalides with n donors L (L = ^{14}CO, $P(C_6H_5)_3$, $P(OC_6H_5)_3$, $As(C_6H_5)_3$, $Sb(C_6H_5)_3$) should be viewed with caution.

When L is present in excess, the rate of formation of *(21)* is independent of the donor concentration; it is influenced by light and by free halogen. The obvious

[61] *I. A. Cohen* and *F. Basolo*, J. inorg. nuclear Chem. *28*, 511 (1966).

$$Fe(CO)_4X_2 + L \rightleftharpoons (CO)_4Fe\begin{matrix}X\\ \diagup\\ \diagdown\\ X\end{matrix}L$$

$$Fe(CO)_4X_2L \rightleftharpoons Fe(CO)_4 + LX_2$$
$$Fe(CO)_4 + L \rightarrow Fe(CO)_4L \qquad (33)$$
$$Fe(CO)_4L + LX_2 \rightarrow Fe(CO)_3LX_2 + L + CO$$
(21)

assumption suggested by the kinetic data, *i.e.* that the first step is loss of CO, is dismissed by the authors because of the low activation energy of 6.2 kcal/mole. However, their argument for the relationship between the E_a values and the position of the ν_{CO} absorptions should be critically checked.

The halogen exchange on $Fe(CO)_4X_2$ proceeds as follows

$$Fe(CO)_4X_2 + X_2^* \rightleftharpoons Fe(CO)_4X_2^* + X_2 \qquad (33a)$$

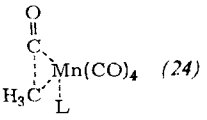
by an S_N1 mechanism [61a]. The activation energy is 28 kcal/mole when X = Br and 14 kcal/mole when X = I. Of the monocarbonylbis(triphenylphosphine) rhodium chlorides, the rhodium(III) compound $Rh(CO)[P(C_6H_5)_3]_2Cl_3$ reacts with ^{14}CO by an S_N1 mechanism [62], and the rhodium(I) compound $Rh(CO)[P(C_6H_5)_3]_2Cl$ by an S_N2 mechanism [63]. In general, a direct attack of the substituting ligand on the central atom appears to be favored in square planar neutral complexes.

4.5. Carbonylalkylmetals and Carbonylacylmetals

Unlike the halogen compounds $Mn(CO)_5X$ (X = Cl, Br, I), pentacarbonylmethylmanganese reacts with various n donors without elimination of CO to give acetylmanganese complexes.

$$CH_3Mn(CO)_5 + L \rightarrow CH_3COMn(CO)_4L \qquad (34)$$
(22) *(23)*

When L = ^{14}CO, the activity is found not in the keto group formed but quantitatively in the CO ligands attached to the metal [64,65]. In agreement with this, stereochemical studies show that *(23)* is formed not by direct insertion of CO into the H_3C-Mn bond but very probably by migration of the methyl group onto one of the *cis* CO ligands [65,66]. The fact that this migration is decisively assisted by the substituent L suggests a transition state *(24)* [67].



(24)

This agrees with the fact that for L = $C_6H_{11}NH_2$, the rate of the reaction (34) in apolar solvents such as *n*-hexane exhibits a first-order dependence on the concentrations of both reactants [68]. In polar solvents, the solvent evidently takes over the role of L; the course of the reaction can then be formulated as follows (S = solvent):

$$(22) + S \rightleftharpoons CH_3COMn(CO)_4S \underset{-S}{\overset{+L}{\longrightarrow}} CH_3COMn(CO)_4L \qquad (35)$$

The rate is independent of [L], since the first step is very much slower than the subsequent displacement of S by L [68,69]. It has been shown that the reaction of $CH_2FMn(CO)_5$ with the strongly nucleophilic iodide ion to form $[CH_2FCOMn(CO)_4I]^-$ is an S_N2 reaction in the presence of an excess of I^-, even in 2,2′-diethoxydiethyl ether [70].

Acylpentacarbonylmanganese compounds react with $P(C_6H_5)_3$ or I^- in accordance with a first order rate equation [69,70].

$$RCOMn(CO)_5 + L \xrightarrow{k} RCOMn(CO)_4L + CO \qquad (36)$$
(25) *(26)*

When R = $C_6H_5CH_2CH(CH_3)$, *i.e.* the manganese compound *(25)* is optically active, the direction of rotation is unchanged in the reaction product *(26)* [70]. For R = CH_3, the rate constant *k*, as expected, agrees with that (*k*′) of the decarbonylation

$$CH_3COMn(CO)_5 \xrightarrow{k'} (22) + CO \qquad (37)$$

In this case the dissociation of an Mn–CO bond is probably followed by fast migration of the CH_3 group onto the manganese atom.

The reactions of acyltetracarbonylcobalt compounds with $P(C_6H_5)_3$ or ^{14}CO, like the reactions of *(25)*, proceed by an S_N1 mechanism [34,71]. $CH_3COCo(CO)_4$ dissociates about 2250 times as rapidly as $CH_3COMn(CO)_5$ in ether at 25 °C. Comparison of $(C_6H_5)_3PAuCo(CO)_4$ with $(C_6H_5)_3PAuMn(CO)_5$ shows that the cobalt compound is much more reactive toward ^{14}CO than the manganese complex [34]. This confirms the observation made earlier on the unsubstituted carbonylmetals that the dissociation of an M–CO bond within a class of compounds becomes less favored with increasing coordination number of the metal atom.

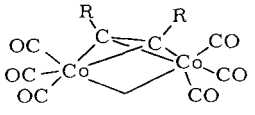
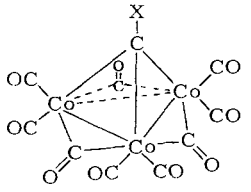
Two carbonylcobalt complexes having remarkable structures *(27)* and *(28)*, which, like the carbonylalkylcobalts and carbonylacylcobalts, contain Co–C σ bonds, readily undergo CO exchange reactions with ^{14}CO. The exchange rate always exhibits first-order dependence on the concentration of the complex, and is independent of the concentration of labeled carbon monoxide [27, 72, 73].



(27)



(28)

It has been suggested that the first step in the reactions of *(27)* is an intramolecular rearrangement introduced by the cleavage of a Co–C σ bond [73]. On variation of the substituents on the acetylenic C atoms, the first order rate constants decrease in the order $C_2(CH_3)_2 > C_2(C_6H_5)_2 > C_2H_2 > C_2(CH_2Cl)_2 > C_2(COOCH_3)_2 > C_2(CF_3)_2$. This sequence could reflect the difference in the strengths of the Co-alkyne bonds.

4.6. Amine-, Phosphine-, Arsine-, Stibine-, Isocyanide-, and Olefincarbonylmetals

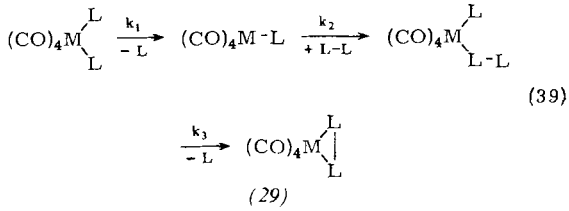
Substitution reactions of the amine-, phosphine-, arsine-, stibine-, isocyanide-, and olefincarbonylmetals $M(CO)_{n-m}L_m$ (which are mostly readily obtainable from carbonylmetals $M(CO)_n$) with n or π donors L′ can lead to displacement of CO, of L, or of CO and L. The principal factors affecting the course of the reaction, apart from the nature of the donor L′, are the number and nature of the ligands L. The effects of these factors are clear from the reactions of substituted carbonylmetals of chromium, molybdenum, and tungsten.

(a) The reactions of the compounds $M(CO)_5L$ (L = RNH_2, PR_3, CNR) with unidentate donors L′ lead predominantly to substitution of CO.

$$M(CO)_5L + L' \rightarrow M(CO)_4LL' + CO \qquad (38)$$

For M = Mo and L′ = $P(C_6H_5)_3$, the reaction rate in *n*-decane at 97.8 °C varies with L in the order $P(C_6H_5)_3 > P(OC_2H_5)_3 > CNC_6H_{11}$. The formation of $Mo(CO)_4[P(C_6H_5)_3]_2$ from $Mo(CO)_5P(C_6H_5)_3$ under these conditions takes place largely by an S_N1 mechanism [74]. A dissociation step (in this case the cleavage of an M–P bond) is also rate-determining in the reactions of the dinuclear complex $[M(CO)_5]_2L–L$ (M = Cr, Mo, W; L–L = $C_2H_4[P(C_6H_5)_2]_2$) with chelating groups L′–L′ [21, 75].

(b) The disubstitution products $M(CO)_4L_2$ readily undergo ligand exchange with bidentate donors L–L (L–L = $C_2H_4[P(C_6H_5)_2]_2$, dipy [*]), the exchange rate being independent of the concentration of L–L [76, 77]. The following reaction course therefore seems plausible (k_2 and $k_3 > k_1$):

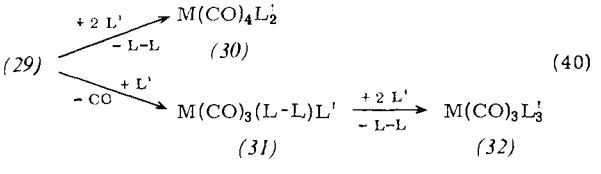


(39)

(29)

For M = Mo and L–L = dipy, the rate constant k_1 increases with changing L in the order $Sb(C_6H_5)_3 < PC_6H_5Cl_2 < P(C_6H_5)_3 < As(C_6H_5)_3 \ll$ pyridine $\ll PCl_3$ [77]. For M = Mo and L–L = $C_2H_4[P(C_6H_5)_2]_2$, the rate constant increases in the order $P(OC_6H_5)_3 \ll P(C_6H_5)_3$ and $PC_6H_5Cl_2 \ll PCl_3$ [76]. The reaction of *cis*-$Mo(CO)_4[P(C_6H_5)_3]_2$ with dipy is much faster than that of *trans*-$Mo(CO)_4[P(C_6H_5)_3]_2$, *i.e.* the dissociation of the Mo–P bond is facilitated, probably on steric grounds, by an adjacent $P(C_6H_5)_3$ ligand.

(c) The chelate complexes *(29)* with M = Cr and L–L = dipy, *o*-phenanthroline, or 1,2-diamino-2-methylpropane react with phosphines and phosphites L′ with exclusive substitution of CO. The reaction rate exhibits first-order dependence on [*(29)*] and is independent of [L′], so that the first step may be assumed to be a dissociation [78, 79]. The reactions of the corresponding compounds of molybdenum and tungsten with L′(=PR_3 or $P(OR)_3$) lead to both CO substitution and ligand exchange (eq. (40)).



(40)

(29) *(30)* *(31)* *(32)*

The kinetic data, which formally agree with an additive rate equation

$$-\frac{d[(29)]}{dt} = k[(29)] + k'[(29)][L'] \qquad (41)$$

(M = Mo, W), have been interpreted as indicating that simultaneously with the primary dissociation (*k*), L′ also directly attacks the metal atom of the original complex (*k*′) [80, 81]. The dependence of the rate on [L′] could however also be explained by the reaction sequence (42).

The reactions of the tetracarbonylmetal-diene complexes *(29)* (L–L = norbornadiene, 1,5-cyclooctadiene) with n [23,76,82] and π donors [20,83] very probably proceed by a mechanism of this type. The first step is the partial cleavage of the diene-metal bond; the coordination vacancies in the resulting intermediate *(33)* can be filled either by recombination (k_{-1}) or by addition of L′ (k_2). For the reaction (43)

$$(29) + L_\pi \rightarrow \underset{(36)}{M(CO)_3L_\pi} + L\text{–}L + CO \qquad (43)$$

the application of the Bodenstein theorem to a reaction sequence analogous to (42) gives the equation

$$\frac{d[(36)]}{dt} = \frac{k_1k_2[(29)][L_\pi]}{k_{-1} + k_2[L_\pi]} \qquad (44)$$

which is exactly satisfied for M = Cr, L–L = norbornadiene, and L_π = mesitylene, hexamethylbenzene, or naphthalene [23,83].

(d) The reactions of the cycloheptatrienetricarbonylmetals $C_7H_8M(CO)_3$ (M = Cr, Mo, W) with trimethyl phosphite lead even under very mild conditions to substitution of the triene and formation of $M(CO)_3[P(OCH_3)_3]_3$. Kinetic studies show that these reactions follow an S_N2 mechanism [84]. The activation energy increases in the order M = Mo (9.8) < W (11.3) < Cr (16.5 kcal/mole); the E_a values are about 10–15 kcal/mole lower than those of the reactions of the diene-tetracarbonylmetals with n and π donors.

The exchange reaction

$$\underset{(37)}{C_7H_8Cr(CO)_3} + {}^{14}C_7H_8 \rightarrow \underset{(38)}{{}^{14}C_7H_8Cr(CO)_3} + C_7H_8 \qquad (45)$$

gives an additive rate law [85]:

$$\frac{d[(38)]}{dt} = k[(37)] + k'[(37)][{}^{14}C_7H_8] \qquad (46)$$

The course of the substitution reactions of the compounds $M(CO)_{6-n}L_n$ (M = Cr, Mo, W) can be summarized as follows. If L is a phosphine, isocyanide [86], or olefin, *i.e.* a "soft" base, the ligand exchange evidently predominates over the CO substitution with increasing *n*; similarly, if the steric conditions remain approximately the same, nucleophilic attack of the donor L′ on the original complex is favored. If on the other hand L is an amine, *i.e.* a "hard" base, the tendency toward ligand exchange or CO substitution becomes less distinct. The reaction behavior appears to be determined by the interplay of the donor and acceptor character of the ligands L and CO.

The substitution and ligand exchange reactions of the carbonylphosphine complexes of iron and nickel proceed almost exclusively by an S_N1 mechanism. The activation energy for the removal of a CO group from *(39)*

$$\underset{(39)}{Fe(CO)_4P(C_6H_5)_3} \xrightarrow[-CO]{k_1} Fe(CO)_3P(C_6H_5)_3 \xrightarrow[+P(C_6H_5)_3]{k_2} Fe(CO)_3[P(C_6H_5)_3]_2 \qquad (47)$$

($k_2 > k_1$) (E_a = 43.5 kcal/mole) is remarkably high [29], and is comparable with that of the reaction of $Cr(CO)_5P(C_6H_5)_3$ with $P(C_6H_5)_3$ [74]. In the presence of CF_3COOH in 1,2-dichloroethane, three of the four CO groups in *(39)* are extremely labile and undergo rapid exchange with ^{14}CO even at −30 °C [30].

The CO exchange of the compounds $Ni(CO)_3P(C_6H_5)_3$ *(40)* and $Ni(CO)_2[P(C_6H_5)_3]_2$ *(41)* is much slower than that of $Ni(CO)_4$ *(5)*. The first order rate constants of the reactions of *(5)*, *(40)*, and *(41)* with ^{14}CO in toluene at 25 °C are related as 420:70:1 [28]. The rates of reactions (48), (49), and (50) are independent

$$Ni(CO)_3PR_3 + PR'_3 \rightarrow Ni(CO)_2(PR_3)PR'_3 + CO \qquad (48)$$

$$Ni(CO)_2(PR_3)_2 + PR'_3 \rightarrow Ni(CO)_2(PR_3)PR'_3 + PR_3 \qquad (49)$$

$$Ni(CO)_2(PR_3)PR'_3 + PR'_3 \rightarrow Ni(CO)_2(PR'_3)_2 + PR_3 \qquad (50)$$

of [PR′$_3$], but are strongly dependent on the nature of the coordinated phosphine; the variation of reactivity is found to be similar to that in reactions (38) and (39) [31].

4.7. Arenecarbonylmetals

In thermal substitution reactions of the arenetricarbonylmetals, the aromatic ligand is always displaced. According to *Strohmeier* [87–89], the ligand exchange

$$\underset{(42)}{C_6H_5XM(CO)_3} + {}^{14}C_6H_5X \rightarrow \underset{(43)}{{}^{14}C_6H_5XM(CO)_3} + C_6H_5X \qquad (51)$$

(M = Cr, Mo, W; X = H, Cl, CH_3) satisfies the rate equation

$$\frac{d[(43)]}{dt} = k[(42)]^2 + k'[(42)][{}^{14}C_6H_5X] \qquad (52)$$

The constants *k* and *k′*, which are functions of the Hammett σ parameter of X, increase in the order M = Cr < W < Mo at a given temperature. The first

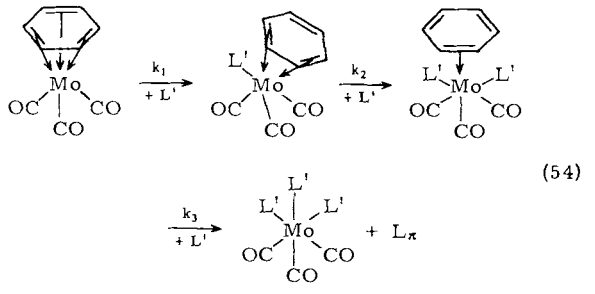
[89] *W. Strohmeier* and *R. Müller,* Z. physik. Chem. N.F. *40*, 85 (1964).

term in equation (52) is particularly interesting, and suggests the formation of an activated complex from two molecules of *(42)*. A rate equation analogous to (46) is found for the exchange reaction of $C_{10}H_8Cr(CO)_3$ with ^{14}C-labeled naphthalene.

The reactions of the arenetricarbonylmolybdenums *(44)* with phosphines [90] and phosphites [91] proceed by a "normal" S_N2 mechanism.

$$Mo(CO)_3L_\pi + 3\,L' \rightarrow Mo(CO)_3L'_3 + L_\pi \qquad (53)$$

Assuming an initial rate-determining attack of the substituent L′ on the metal atom followed by cleavage of the arene-molybdenum bond, the following reaction course is conceivable (k_2 and $k_3 > k_1$):



(54)

On substitution of the aromatic ring, the rate decreases as the number of methyl groups is increased, as is to be expected on the basis of bonding theory. Reversal of the reaction (54) is possible *e.g.* for L′ = $C_6H_5NH_2$ [92]; the formation of the compound *(44)* (L_π = mesitylene) in polar solvents such as dioxane or tetrahydrofuran then proceeds substantially by an S_N1 mechanism.

Kinetic studies [93–95] on substitution reactions on the cyclic ligands of arenetricarbonylchromiums such as

$$C_6H_5XCr(CO)_3 + OCH_3^\ominus \xrightarrow{(CH_3OH)} C_6H_5OCH_3Cr(CO)_3 + X^\ominus \qquad (55)$$
$$(X = F, Cl)$$

$$p\text{-}(m\text{-})XC_6H_4COOCH_3Cr(CO)_3 + OH^\ominus \xrightarrow{(Acetone/H_2O)} p\text{-}(m\text{-})XC_6H_4COOHCr(CO)_3 + OCH_3^\ominus \qquad (56)$$
$$(X = CH_3, Cl, NH_2, OCH_3, COOCH_3)$$

$$C_6H_5CH_2ClCr(CO)_3 + H_2O \xrightarrow{(Acetone/H_2O)} C_6H_5CH_2OHCr(CO)_3 + H^\oplus + Cl^\ominus \qquad (57)$$

clearly show that the reactivity of the coordinated aromatic ligand is always greater than that of the free benzene derivative. This means that in the nucleophilic substitution (55), the electron density on the electrophilic center of the ring is evidently decreased by complex formation, *i.e.* the $Cr(CO)_3$ group acts as an electron-attracting substituent, the influence of which is comparable to that of an NO_2 group in the *para* position [93].

4.8. π-Cyclopentadienylcarbonylmetals

Of the monomeric cyclopentadienylcarbonylmetals, the compounds $C_5H_5M(CO)_2$ (M = Co, Rh, Ir) react much more readily with n and π donors than the complexes $C_5H_5M(CO)_3$ (M = Mn, Tc, Re) and $C_5H_5V(CO)_4$. Reactions of the type

$$C_5H_5M(CO)_2 + L \rightarrow C_5H_5M(CO)L + CO \qquad (58)$$

(L = ^{14}CO, CNR, PR_3, $P(OR)_3$) are possible under relatively mild conditions, *e.g.* in toluene at 40 °C; they all proceed by an S_N2 mechanism [96,97,97a]. The reaction rate is a function not only of L but also of M; for L = $P(C_6H_5)_3$, the rate increases in the order Ir < Co ≪ Rh. Similar special behavior of the 4d metal was mentioned in connection with the hexacarbonylmetals (cf. Section 4.1.).

Replacement of the CO groups in $C_5H_5Mn(CO)_3$ by L has not so far been achieved by heating. On the other hand, CO is readily split off to form compounds of the type *(45)* on UV irradiation *e.g.* in *n*-hexane. If L is an olefin such as ethylene, propylene, cyclopentene, cycloheptene, or cyclooctene, ligand exchange takes place in the presence of L′ (= PR_3, $P(OR)_3$, or $S(C_6H_5)_2$)

$$C_5H_5Mn(CO)_2L + L' \rightarrow C_5H_5Mn(CO)_2L' + L \qquad (59)$$
(45)

The cleavage of the Mn–L bond is rate-determining in this reaction [98].

The CO exchange of $[C_5H_5Ni(CO)]_2$ depends on the concentration of labeled carbon monoxide [96]. In the reactions of the dicarbonylcyclopentadienyliron halides $C_5H_5Fe(CO)_2X$ with ^{14}CO, the rate is determined by the nature of the halogen, and increases under the same conditions in the ratio 1:25:500 for X = I, Br, Cl [52].

4.9. π-Allylcarbonylmetals

Like the π-cyclopentadienyl residue, the π-allyl residue may be formally regarded as an anionic delocalized π-electron system. The π-C_3H_5–M bond is generally very stable, and is not broken in reactions with Lewis bases. Of the π-allylcarbonylmetals prepared so far, the cobalt compounds *(46)* react by an S_N1 mechanism, while the isoelectronic iron complexes

[96] *A. Wojcicki* and *F. Basolo*, J. inorg. nuclear Chem. *17*, 77 (1961).

[97] *H. G. Schuster-Woldan* and *F. Basolo*, J. Amer. chem. Soc. *88*, 1657 (1966).

[97a] Note added in proof: An S_N2 reaction can also be assumed for the reaction of $C_5H_5V(CO)_4$ with $P(C_6H_5)_3$: see *W. Strohmeier* and *H. Blumenthal*, Z. Naturforsch. *22b*, 1351 (1967).

[98] *R. J. Angelici* and *W. Loewen*, Inorg. Chem. *6*, 682 (1967).

(47) (though the metal here has a higher coordination number than in *(46)*) react by an S_N2 mechanism [50,99,100] (R = H, CH_3, C_6H_5, Cl, Br, $COOCH_3$; L = $P(C_6H_5)_3$, $PO_3C_6H_{11}$).

$$\underset{(46)}{\pi\text{-}C_3H_4RCo(CO)_3} + L \rightarrow \pi\text{-}C_3H_4RCo(CO)_2L + CO \quad (60)$$

$$\underset{(47)}{\pi\text{-}C_3H_5Fe(CO)_3X} + L \rightarrow \pi\text{-}C_3H_5Fe(CO)_2(L)X + CO \quad (61)$$

The substituent R has relatively little influence on the rate of the reaction (60). The reactivity of *(47)* depends on X in the same manner as in the π-cyclopentadienyl compounds $C_5H_5Fe(CO)_2X$.

4.10. Carbene-Carbonylmetal Complexes

The compounds $M(CO)_5C(OCH_3)R$ [101] having a carbene residue as a ligand exhibit surprising reactivity toward nucleophiles. They react as analogs of the hexacarbonylmetals with tertiary phosphines, *i.e.* with substitution of a CO group.

$$\underset{(48)}{M(CO)_5C(OCH_3)R} + PR'_3 \rightarrow \underset{}{cis\text{-}M(CO)_4(PR'_3)C(OCH_3)R} + CO \quad (62)$$

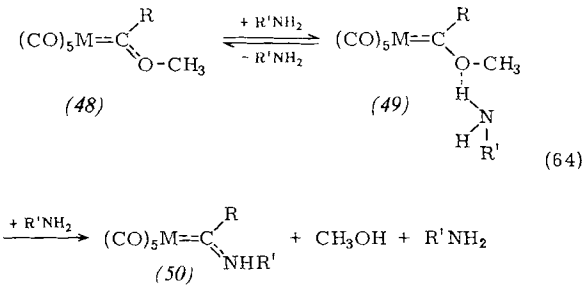
(M = Cr, Mo, W; R = CH_3, C_6H_5; R′ = C_2H_5, *n*-C_4H_9, C_6H_{11}, C_6H_5, *p*-$CH_3C_6H_4$). The dominating rate-determining step must be assumed to be the cleavage of an M–CO bond [102,103]. The activation energies for the CO substitution (M = Cr and R = CH_3: E_a = 28.2 kcal/mole; M = Cr and R = C_6H_5: E_a = 27.4 kcal/mole), which are relatively low in relation to those of the reactions of the hexacarbonylmetals, suggest that the carbene ligand can contribute considerably to the stabilization of the transition state involved in the dissociation. The reaction of tertiary aliphatic phosphines with *(48)* also leads to cleavage of the metal-carbene bond [103].

The kinetics of the "ester-like" reaction of (48) with primary amines $R'NH_2$ has also been studied [104]. For M = Cr, R = C_6H_5 and R′ = C_6H_{11}, *n*-C_4H_9, $CH_2C_6H_5$, the reaction in dioxane follows a third order rate equation

$$-\frac{d[(50)]}{dt} = k[(48)][R'NH_2]^2 \quad (63)$$

which suggests that the aminocarbene complex *(50)* is formed by a multi-step mechanism.

The existence of hydrogen bonds in the primary adduct *(49)* can be shown by NMR measurements.



(64)

5. Summary and Outlook

The results of the investigations described above show that the course of substitution reactions of carbonylmetal complexes is determined mainly by steric and electronic factors. Complexes having a relatively small central atom that is substantially screened by the surrounding ligands are not readily accessible to direct attack by a donor L, and so react preferentially by an S_N1 mechanism. An S_N2 mechanism is favored when the metal atom is large or when it is coordinated to ligands other than CO, such as NO, π-C_5H_5, or C_6H_6, which are capable of strong π back-bonding.

Generalizations of this type must for the present be treated with caution, since development is still in progress and the end is not yet in sight. Despite this limitation, however, the value of the kinetic studies is obvious; they provide an insight into the reaction mechanism, and so offer the possibility of controlling a given reaction by alteration of the conditions. The importance of the present results, however, goes much farther. They have excited new interest in the phenomenon of the bonding in carbonylmetals, and thrown doubt on several established ideas. As examples we may again consider the compounds $M(CO)_{n-m}L_m$ discussed in Section 4.6. It is generally argued that the ligands L, the majority of which are stronger donors than acceptors, cause an increase in the electron density on the metal atom; this leads to stronger back-bonding and hence to an increase in the M–CO bond strength. Application of this bonding concept to the reaction behavior suggests that the dissociation of an M–CO bond should be more difficult in the complexes $M(CO)_{n-m}L_m$ than in unsubstituted carbonylmetals $M(CO)_n$. This is so if L is a phosphine or phosphite, but not when L is an amine. To explain this, reference is often made to the HSAB concept [46]. Amines are "hard" bases, whereas phosphines are "soft", and form stronger bonds with "soft" acids (metal atoms having low oxidation numbers). However, this classification has little bearing on the difference in the strength of the M–CO bonds that is reflected in the substitution reactions of amine- and phosphinecarbonylmetals. The HSAB concept (which is based on thermodynamic considerations) appears to be overrated in this case.

Another point must be emphasized in a comparison of bond character and reactivity. The resonance formulas *(51)* and *(52)* considered in the description

(51) *(52)*

of the M–CO bond relate only to the ground state; however, the reaction behavior is determined by the energy of the transition state. It is possible that ligands such as amines contribute to the stabilization of the transition state, though the reason for this is still unclear. A fuller knowledge of the electronic structure of the excited states of carbonylmetals would be very useful.

Finally, it should be mentioned that the kinetic studies have also led to preparative successes. Thus the study of the mechanism of substitution reactions of hexacarbonylmetals and the application of the knowledge gained led to the preparation of the first hexamethylborazine–transition metal complex $B_3N_3(CH_3)_6$-$Cr(CO)_3$ [105], and other complexes of this type are now also known [106]. It is not difficult to predict that a combination of kinetic and preparative work in this field will continue to be fruitful in the future.

The work described here was carried out with the assistance in particular of Dr. R. Prinz, as well as of Dipl.-Chem. Edith Deckelmann, Dipl.-Chem. K. Deckelmann, Dipl.-Chem. B. Heckl, Renate Koneberg, and Hermine Rascher, to all of whom I am very grateful. The work was supported by grants from the Deutsche Forschungsgemeinschaft and the Verband der Chemischen Industrie. Thanks are also due to Prof. Dr. E. O. Fischer for his support of our investigations.

A New Synthesis of Isocyanates and Isothiocyanates

By *G. Greber* and *H. R. Kricheldorf* [*]

Dedicated to Professor E. Husemann on the occasion of her 60th birthday

Thermal cleavage of carbamoyl chloride and carbamic esters (urethanes) usually gives only poor yields of isocyanates because the high cleavage temperatures (200–300 °C) favor side reactions and the decomposition products undergo reverse reaction at slightly lower temperatures.

We have found that chlorides, anhydrides, and esters *(1)* of carbamic acids, when *N*-silylated to *(2)* [*e.g.*, by chlorotrimethylsilane/triethylamine or mono- or bis-(trimethylsilyl)-acetamide], decompose to isocyanate *(3)* and a silicon compound *(4)* even between −20 and +120 °C.

$$R^1\text{-}NH\text{-}\overset{\overset{O}{\|}}{C}\text{-}X \xrightarrow{+\,R^2Si(CH_3)_3} R^1\text{-}N(Si(CH_3)_3)\text{-}\overset{\overset{O}{\|}}{C}\text{-}X \xrightarrow{\Delta}$$

(1) *(2)*

$$R^1\text{-}N{=}\overset{\overset{O}{\|}}{C} + X\text{-}Si(CH_3)_3$$

(3) *(4)*

X = Cl, $OCOR^3$, OR^3; R^1, R^3 = alkyl, aryl, or cycloalkyl
R^2 = Cl, CH_3CON–, $CH_3CONSi(CH_3)_2$–

Since the products *(4)* and *(3)* undergo neither back-reaction nor, to an appreciable extent, side reactions, even sensitive or very reactive isocyanates can be obtained in yields of between 70 and 95%. For urethanes R^1–NH–$COOR^3$ the temperature for fission depends on the nature of R^3 if R^1 remains the same; it decreases rapidly with increasing stability of the anion R^3–$O^{\ominus}$ (examples: $R^1 = C_6H_5$; $R^3 = C_2H_5$, C_6H_5, *p*-Cl–C_6H_4, or *p*-NO_2–C_6H_4; fission at 80–110 °C, 50 to 70 °C, 10–30 °C, or −20–0 °C, respectively).

Preparative work starts with an amine, which is first acylated by a chloroformic or carbonic ester to the urethane and then silylated; for fission the reaction mixture is warmed. Instead of chlorotrimethylsilane, other chlorosilanes such as chlorotrialkyloxysilanes, and even $SiCl_4$ can be used. This method can also be used for amino alcohols and amino thiols which become disilylated on N and O or N and S. Cleavage of these compounds gives isocyanates of a new type, containing protected hydroxy or mercapto groups. For instance, from 2-aminoethanol we prepared (2-isocyanatoethoxy)trimethylsilane (b.p. 55–56 °C/14 torr) for the first time, the yield being about 70%.

Like urethanes, *S*-alkyl(aryl) thiocarbamate or *O*-alkyl(aryl) thiocarbamate can also be cleaved, after *N*-silylation, in good yield to isocyanates or isothiocyanates and a silicon-containing component.

Preparation of isocyanates from urethanes:

The urethane (1 mole) is heated to the b.p. with triethylamine (1.2 moles) in toluene (*ca.* 1 l), chlorotrimethylsilane (1.2 moles) is added, and the whole is heated for a further 2 h under reflux with stirring. After cooling, the precipitated triethylammonium chloride is filtered off and the filtrate is fractionated for isolation of the isocyanate.

Preparation of isocyanates from carbamoyl chlorides:

A solution of carbamoyl chloride (1 mole) in CCl_4 (*ca.* 1 l) is treated at −20 to 0 °C with a solution of trimethylsilylacetamide (1 mole) in CCl_4 (0.5 l) and kept at the reaction temperature for another hour. The mixture is then filtered from the precipitated acetamide, freed from solvent, and fractionated for isolation of the isocyanate.

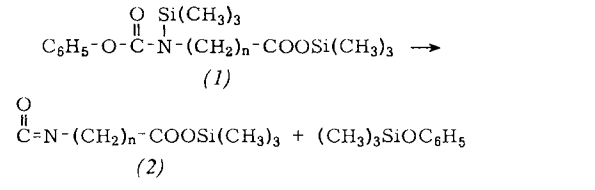
Preparation of Silyl Esters of Isocyanato Carboxylic Acids

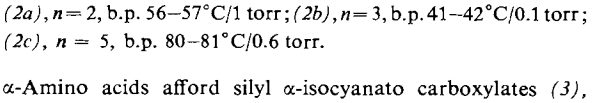
By *G. Greber* and *H. R. Kricheldorf*[*]

Dedicated to Professor E. Husemann on the occasion of her 60th birthday

On thermal fission of trimethylsilyl *N*-(phenoxycarbonyl)-*N*-(trimethylsilyl)amino carboxylates *(1)*[1] derived from β-, γ-, or ε-amino acids we obtained stable, distillable silyl β-, γ-, and ε-isocyanato carboxylates *(2)*.



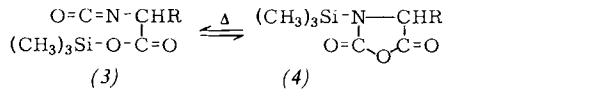
(1)



(2)

(2a), $n = 2$, b.p. 56–57°C/1 torr; *(2b)*, $n = 3$, b.p. 41–42°C/0.1 torr; *(2c)*, $n = 5$, b.p. 80–81°C/0.6 torr.

α-Amino acids afford silyl α-isocyanato carboxylates *(3)*, which however exist in equilibrium with the *N*-carboxy-*N*-(trimethylsilyl)amino acid anhydrides *(4)*; rise in temperature shifts the equilibrium in favor of *(3)*.



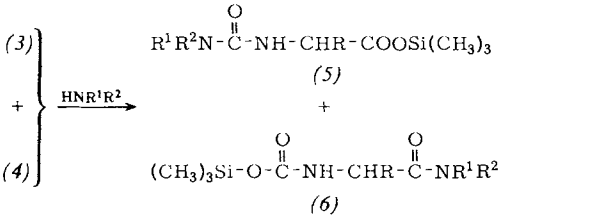
(3) *(4)*

R = H, CH_2–O–$Si(CH_3)_3$, CH_2–C_6H_5, or CH_2–C_6H_4–O–$Si(CH_3)_3$.

Silylation of α-*N*-carboxyamino acid anhydrides affords the same mixture.

Treating the mixture of *(3)* and *(4)* with primary or secondary amines affords the urea derivatives *(5)* and the carbamic acid derivatives *(6)*, which can be hydrolyzed to the substituted hydantoic acids or α-amino amides, respectively; these products can be separated readily and quantitatively. At high temperatures good yields (up to 90%) of the hydantoic acid derivatives, and at low temperature good yields (up to 90%) of α-amino amides, result.

Mixtures of *(3)* and *(4)* are stable over several hours only in dilute solution below 25 °C. It is interesting that, like one of these silyl esters of α-isocyanato carboxylic acids, trimethylsilyl *o*-isocyanatobenzoate exists in temperature-dependent equilibrium with *N*-carboxy-*N*-(trimethylsilyl)anthranilic anhydride.



(5) + *(6)*

R^1 = H, alkyl, aryl, or cycloalkyl

R^2 = alkyl, aryl, or cycloalkyl.

Asymmetric Catalytic Hydrogenation with an Optically Active Phosphinerhodium Complex in Homogeneous Solution[1]

By *L. Horner, H. Siegel,* and *H. Büthe*[*]

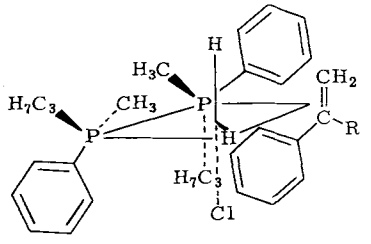
Dedicated to Professor Werner Schultheis on the occasion of his 65th birthday

In a recent publication[2] we pointed out that, with the use of optically active tertiary phosphines as ligands in complexes of univalent rhodium, an asymmetric hydrogenation of unsymmetrically substituted C–C double bonds should be possible.

Knowles and *Sabacky*[3] have used this method and optically active methylphenyl-*n*-propylphosphine[4] to prepare optically active hydratropic acid (15% optical yield) from atropic acid and methylsuccinic acid (3% optical yield) from itaconic acid.

We have found that α-ethylstyrene and α-methoxystyrene can be hydrogenated to (*S*)–(+)-2-phenylbutane *(1)* (7–8% optical yield) and (*R*)–(+)-1-methoxy-1-phenylethane *(2)* (3–4% optical yield) respectively, by use of a phosphinerhodium complex formed *in situ* from [Rh(1,5-hexadiene)Cl]$_2$ and (*S*)–(+)-methyl-phenyl-*n*-propylphosphine in benzene at normal pressure and room temperature.

Assuming an a-chloro-ef-dihydrido-d-olefin-bc-bisphosphinerhodium complex *(3)*[**] one finds from conformative reasoning (methyl and *n*-propyl groups of both phosphines in skew positions) that the olefin will be fixed to the complex in such a way that the *cis*-addition of hydrogen preferentially yields (*S*)–(+)-*(1)* from α-ethylstyrene and (*R*)–(+)-*(2)* from α-methoxystyrene. The preferential formation of (*S*)–(+)-hydratropic acid from atropic acid[3] agrees with this model.



(3)

Procedures:

$2.2 \cdot 10^{-4}$ moles of (*S*)–(+)-methylphenyl-*n*-propylphosphine are added to a solution of $0.5 \cdot 10^{-4}$ moles of [Rh-(1,5-hexadiene)Cl]$_2$[5] in 20 ml benzene under hydrogen in a shaking flask. 10^{-2} moles of olefin are then injected into the homogeneous yellow-orange solution. The reaction which takes 6–8 hours is checked by gas-chromatography. The hydrogenation products are separated from the rhodium complex by chromatography on Al_2O_3 (Woelm), fractionally distilled, and identified by NMR spectroscopy. Their configurations are determined through ORD measurements.

Synthesis of 2*H*-1,3,5,2-P^V-Thiadiazaphosphorine Derivatives[1]

By *A. Schmidpeter* and *N. Schindler* [*]

Owing to their high reactivity toward nucleophiles, dimeric thiophosphonic anhydrides *(1)* are suitable for use in the synthesis of phosphorus-nitrogen heterocycles both by cyclocondensation[2] and – as here – by cycloaddition. In the reaction of *(1)* with an excess of dialkylcyanamides we obtained quantitative yields of derivatives of a new ring system, 4,6-diamino-2*H*-1,3,5,2-P^V-thiadiazophosphorine-2-thiones *(2)*. The reaction probably begins with nucleophilic ring opening in *(1)*[3] by the cyanide nitrogen; it resembles the reaction of $[SO_3]$, which is isoelectronic with $[RPS_2]$, with nitriles[4].

The compounds *(2)* are colorless, crystalline, and stable to water and ammonia. Their structure is confirmed by their analytical composition, their molecular weight, the nonequivalence of the residues R^1 in the ^1H–NMR spectrum, the intensity ratio of the ^1H–NMR signals, and the uniformity of the ^{31}P signal. They react in molar proportions with methyl iodide to form *(3)*, X = I. These salts can be recrystallized from water, hydrolyze only very slowly with loss of methylthiol, and can be converted *e.g.* into *(3)*, X = $B(C_6H_5)_4$ by precipitation from aqueous solution.

[a] The chemical shifts for ^{31}P and ^1H signals were measured in CH_2Cl_2 against H_3PO_4 and TMS respectively in ppm; the negative sign indicates downfield shifts.

The methylation of the thiono sulfur of *(2)* results in a distinct decrease in the shielding of all the protons of the dialkylamino groups. This shows the distribution of the positive charge and the increased participation of phosphazene bond structures in *(3)*. The strengthening of the phosphazene ring bond, as expected[5], is generally accompanied by an upfield shift of the ^{31}P signal.

Procedure:

About 4 moles of a liquid dialkylcyanamide are added to 1 mole of *(1)*, which dissolves with strong evolution of heat. The solution is heated for a few minutes at 100–130 °C, and solidifies on cooling to give a crystal slurry. The product *(2)* is filtered off and recrystallized from a little benzene. The reaction of the solid dicyclohexylcyanamide is carried out in the stoichiometric quantity with dioxane as the solvent.

Unusual Formation of the Unusual 1,2,8,9-Tetraaza-1,8-cyclotetradecadiene-3,10-diol System and its 5,12-Dioxa Analog[1,2]

By *S. Hünig* and *J. Cramer* [*]

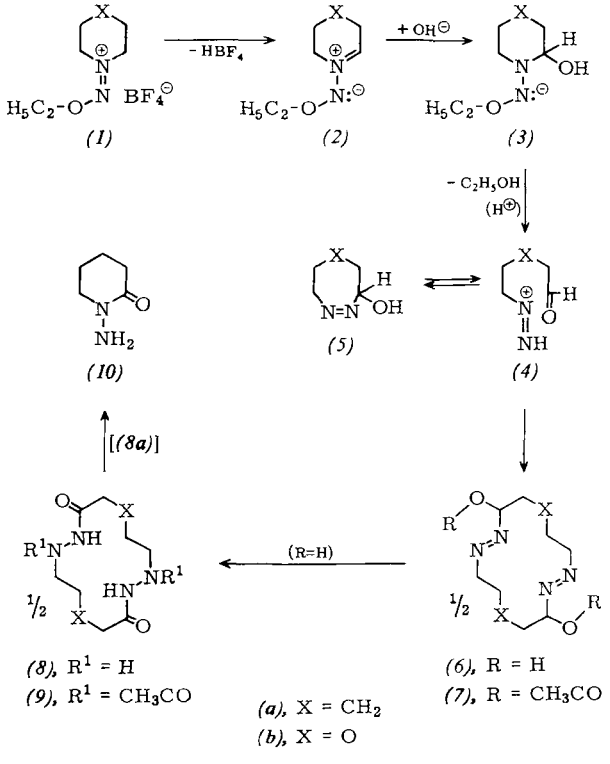
1,1-Pentamethylene-2-ethoxy-diazenium tetrafluoroborate (30.0 g)[3,4] is transformed into an ether extractable base [*ca.* 20% yield, m.p. 120 °C (decomp.)] when added to aqueous sodium carbonate solution (200 ml H_2O, 20 g Na_2CO_3, and 70 g NaCl) at −10 °C. This base has been characterized as 1,2,8,9-tetraaza-1,8-cyclotetradecadiene-3,10-diol *(6a)* on the basis of the following properties and an X-ray structure analysis[5]. Thus a six-membered ring is converted into a fourteen-membered ring that contains, in two positions, the hitherto rare combination[6,7] of an azo and an α-hydroxylalkyl group.

In confirmation of previous findings[3], *(6a)* has λ_{max} = 360 nm (CH_3OH) with ε = 27, as expected for aliphatic *trans*-azo compounds[8]. The fact that the IR spectrum is

clear between 1570 and 1500 cm^{-1} also excludes the presence of a *cis*-azo compound[9]. The sharp band at 3410 cm^{-1} (C_2Cl_4), independent of concentration, is assigned to an intramolecular bridging OH group: it disappears on acetylation of *(6a)* (by pyridine/acetic anhydride). The resulting *(7a)* now shows the ester-carbonyl band at 1750 cm^{-1} and unchanged UV absorption. The complicated NMR spectra[2] are also in accord with structures *(6a)* and *(7a)*. The largest masses found in the spectrometer are 210 ($M - H_2O$) for *(6a)* and 284 ($M - N_2$) for *(7a)*[10]. The molecular weight found for *(7a)* osmometrically in benzene was 319 (calc. 312).

Dilute HCl isomerizes *(6a)* to the very sparingly soluble *(8a)* (m.p. 261 °C), whose structure can be derived from the following results. Reduction of ammoniacal silver salt solution and absence of reaction with *p*-nitrobenzaldehyde indicate a secondary hydrazide[3]. This is supported by absence of UV absorption below 210 nm, and appearance of two NH bands at 3290 and 3250 cm^{-1} (KBr) and a low-frequency CO band (1630 cm^{-1}). Presence of the amide-II band at 1560 cm^{-1} requires a more than ten-membered ring since the amide group can be *transoid* only in large rings[11]. The mass spectrum[10] gives the required molecular weight of 228, which is increased to 232 on treatment with D_2O. Acetylation of *(8a)* affords a compound *(9a)* (m.p. 296 °C), isomeric with *(7a)* and giving one NH band (3170 cm^{-1}) and two CO bands (1695 and 1630 cm^{-1}), as well as the required molecular weight of 312. Concentrated HCl "halves" *(8a)* with renewed ring closure to the piperidine derivative *(10)*, which was identical with authentic material[3].

The transformations *(1)* → *(6)* → *(8)* occur also with the morpholine derivative *(1b)* (m.p. 97–98 °C): 1,8-dioxa-4,5,11,12-tetraaza-4,11-cyclotetradecadiene-3,10-diol *(6b)*, m.p. 150 °C (decomp.); *(7b)*, m.p. 218 °C (decomp.); *(8b)*,



m.p. 227 °C. These more readily soluble transformation products have the expected properties. The sequence *(1)* →→ *(6)*, as drawn, illustrates the reaction route that is at present the most probable[12]: deprotonation affords first the mesomeric zwitterion *(2)* and this readily adds nucleophiles at the α-carbon atom[1,3]; the OH adduct *(3)* loses ethanol, yielding, presumably by way of *(4)*, the "monomeric" intermediate *(5)*[13], that was earlier formulated in place of *(6)*[3]. Reaction of *(1)* with bases leads first to an absorption maximum at 375 nm with a higher extinction coefficient, indicating the presence of a *cis*-azo-compound[8]. The rate of transformation of *(5a)* into *(6a)* (356 nm in H_2O) decreases with increasing dilution, as expected for a dimerization.

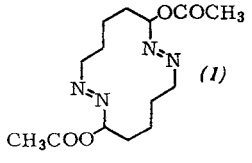
Crystal Structure of 1,2,8,9-Tetraaza-1,8-cyclotetradecadien-3,10-ylene Diacetate

By *R. Allmann* and *I. Kawada*[*]

A series of findings has led to ascription of a structure containing a fourteen-membered ring to the compound *(1)* that was prepared by *Hünig* and *Cramer*[1]. The X-ray structure analysis recorded below confirms this.

Well-formed colorless crystals of the diacetate *(1)* were available for the investigation. Boundary faces were {100}, {010,} {011}, and {11$\bar{1}$}. The short prismatic crystals used for measurement were of about 0.5 mm diameter. The following data were determined: Space group $P2_1/c$; $a = 8.18 \pm 1$, $b = 14.84 \pm 2$, $c = 7.50 \pm 1$ Å; $\beta = 116.1° \pm 1°$; $V = 817 \pm 3$ Å^3; $d_{py} = 1.265 \pm 2$, $d_{X\text{-ray}} = 1.270 \pm 4$ g·cm^{-3}; $Z = 2$; F_{000} (electrons/cell) = 336.



(1)

Using Cu–K_α radiation, 1448 independent reflections were measured with an automatic scintillation-counter diffractometer; of these, 77 lay below the limit of observation. Phase-determination of the 248 strongest reflections ($E > 1.4$) was achieved by the symbolic addition method[2]. A Fourier synthesis calculated with these values gave the positions of all eleven independent atoms except H [because of the centrosymmetry of *(1)*, only the atomic positions in one half of the molecule need to be determined]. After three cycles of refine-

ment of the coordinates by the method of least squares the R value fell to 16.8%. Then the ideal positions of the nine independent hydrogen atoms of the fourteen-membered ring were calculated and these were included in the subsequent calculations. In two further cycles of refinement, using isotropic temperature factors, the R value was lowered from 15.6 to 14.9%. The positions of the hydrogen atoms of the methyl groups have not yet been found. Figure 1 shows the projection of the nolecule on the x,y plane, with the calculated atomic distances and bond angles. The standard deviations of these values are somewhat less than 0.01 Å and 0.5 °, respectively.

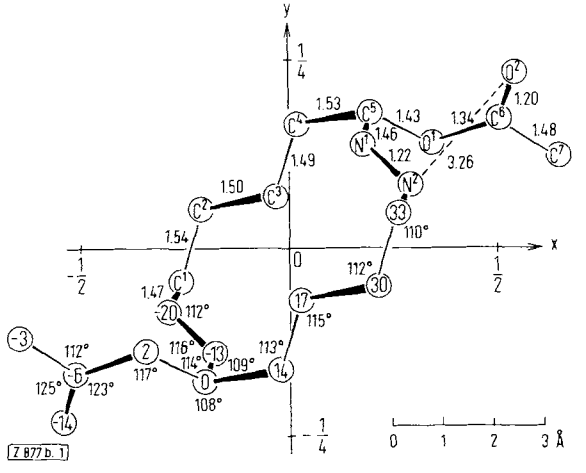


Fig. 1. x,y Projection of a molecule of 1,2,8,9-tetraaza-1,8-cyclodecadien-3,10-ylene diacetate *(1)*, with atomic distances and bond angles. Numbering of the atoms is shown in circles for one half of the molecule, and the heights (in 1/10 Å) above the plane of projection are shown in circles in the other half. The C—N bonds lie approximately in the direction of projection.

Each of the two sets of five carbon atoms (C^1—C^5) in the fourteen-membered ring forms a stretched zigzag chain (mean C—C distance 1.52 Å), these chains being joined by the two *trans*-azo groups (distances: C—N = 1.47; N=N = 1.22 Å). The acetoxy groups are approximately perpendicular to the plane of the ring with the carbonyl-oxygen atom approaching the azo group (separation: $O^2 \cdots N^2$ = 3.26 Å). The separations and angles are all normal, except for the short C—O bond in the acetoxy group (1.34 Å instead of 1.40 Å for a single bond $C(sp^2)$—O). The "hole" in the ring is completely filled by two hydrogen atoms (on C^3 and $C^{3'}$).

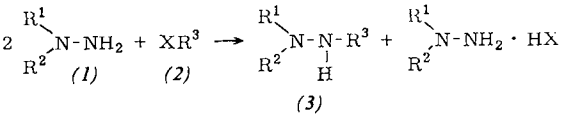
New Hydrazyls of Low Molecular Weight and Polymeric Hydrazyls[**]

By *D. Braun* and *G. Peschk*[*]

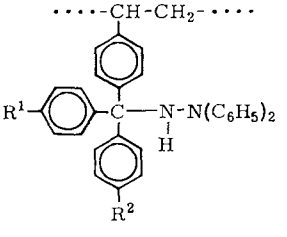
Almost all the stable hydrazyls known so far contain nitro groups[1]; the use of hydrazyls as radical traps in kinetic studies of polymerizations thus lead to uncontrollable side reactions. The only hydrazyl free from nitro groups known hitherto was 2,2-diphenyl-1-[2,4,6-tris(methoxycarbonyl phenyl]hydrazyl[2][***]. We have now prepared the hydrazines *(3a)*–*(3e)*, which contain no nitro group, by reaction of a hydrazine derivative *(1)* with a halogen compound *(2)* in the molar ratio 2:1 in ether or tetrahydrofuran. The hydrazines *(3a)*–*(3d)* can be oxidized by active PbO_2 to the hydrazyls, but these could not be isolated in solid form because they have, in general, a strong dehydrogenating action on the solvent.

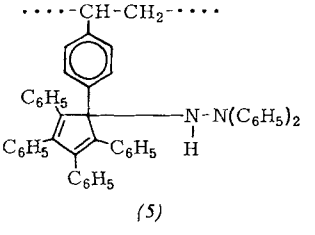


Cpd.	*(2)* X	*(3)*, name	*(3)*, M.p. (°C)	Hydrazyl $\tau_{1/2}$ [a]	Hydrazyl ESR lines
(a)	Cl	2,2-Diphenyl-1-[α-(4-biphenylyl)-benzhydrazyl]-hydrazine	85—86	≈ 3.5 h	7
(b)	Cl	2,2-Diphenyl-1-[α,α-bis(4-biphenylyl)-benzyl]hydrazine	124—126	≈ 3.5 h	7
(c)	Cl	9-[(Triphenylmethyl)-amino]carbazole	239—241	≈ 2.5 h	3
(d)	Br	9-[(Pentaphenylcyclo-pentadienyl)amino]-carbazole	218—219	45 min	3
(e)	F	9-[(2,4,6-Tricyano-phenyl)amino]-carbazole	157—159	—	—
(f)	Cl	Dodecahydro-9-(picrylamino)-carbazole	161—162	3.5 h	8

[a] Half-life determined by ESR measurements in benzene solution.

Dodecahydro-9-(picrylamino)carbazole *(3f)* was also prepared, as model substance. It could be oxidized by active PbO_2 to a relatively unstable radical.





(5)

(4a), $R^1 = R^2 = H$
(4b), $R^1 = H$, $R^2 = C_6H_5$
(4c), $R^1 = R^2 = C_6H_5$

The polyhydrazines *(4a)*–*(4c)* and *(5)* were obtained by treating diaryl(polyvinylphenyl)methyl chlorides[3] or tetraphenyl(polyvinylphenyl)cyclopentadienyl chloride[4] in tetrahydrofuran with 1,1-diphenylhydrazine (molar ratio 1:2 calculated on the chlorine content of the polymers). These products can be oxidized in benzene solution by active PbO_2 to polyhydrazyls that can be precipitated by dry light petroleum. The yellow-brown polymeric hydrazyls are stable in the solid state and are paramagnetic. They are soluble in benzene and tetrahydrofuran.

N-[(Pentaphenylcyclopentadienyl)amino]carbazole (3d):

N-Aminocarbazole (18.4 g, 0.1 mole) and pentaphenylcyclopentadienyl bromide[5] (26 g, 0.05 mole) in absolute tetrahydrofuran (*ca.* 150 ml) are refluxed gently for 5 h. The mixture is allowed to cool and precipitated hydrobromide is filtered off. The solution is concentrated and the substance remaining is dissolved in hot benzene and treated with an equal volume of hot ethanol, whereupon the hydrazine gradually crystallizes out. Pale yellow crystals [m.p. 218 to 219 °C, yield 25–27 g (80–85%)] are obtained after two recrystallizations.

To form the radical by oxidation, the substance is shaken with a ten-fold excess of active PbO_2 in benzene for 10 min. On rapid removal of the solvent, the reddish-brown solution affords an impure, reddish-brown paramagnetic product.

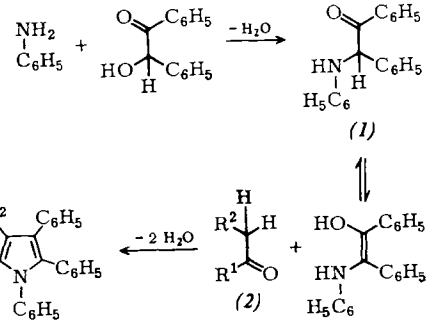
Simple Synthesis of Substituted 1,2,3-Triphenylpyrroles

By *H. J. Roth, H. George, F. Assadi*, and *H. J. Rimek* [*]

As simple as possible a synthesis of substituted 1,2,3-triphenylpyrroles was required in order that they might be precisely characterized when obtained photochemically [1]. For this purpose, benzoin was condensed with aniline under catalysis by traces of formic acid, yielding 2-anilino-2-phenylacetophenone (anilinodeoxybenzoin) *(1)* in almost quantitative yield. This was converted by reaction with CH-acidic



Cpd.	*(2)*	R^1	R^2	*(3)* Yield (%)	*(3)* M.p. (°C)
(a)	Acetophenone	C_6H_5	H	70	196

$Pb(H_2PO_4)_4 \cdot (C_6H_5)_3PO$, Lead(IV) Tetrakis(dihydrogen phosphate) Stabilized by Triphenylphosphine Oxide

By *F. Huber* and *M. S. A. El-Meligy* [*]

Binary lead(IV) phosphates have been hitherto unknown. In our experience earlier attempts to prepare such compounds failed because of insufficient knowledge of conditions and gave only indefinite products with a considerable Pb(II) content [1] or complex lead(IV) phosphate(V) compounds [2] (the possible occurrence of complex phosphorus-containing lead(IV) derivatives had already been considered by *Bode* and *Voss* [3]). Our attempts to obtain lead(IV) phosphates by treatment of $Pb(OCOCH_3)_4$ or PbO_2 with phosphoric acid of various concentrations led finally to phosphatolead(IV) acids, *e.g.*, $H_2[Pb(H_2PO_4)_6]$, in which the central atom achieves the minimum coordination number 6 [4].

We then tried to stabilize lead(IV) phosphates by neutral electron-donors, such as $(C_6H_5)_3PO$, in two ways, namely, first by trapping binary lead(IV) phosphates by simultaneous complex formation with the donor at the moment of their formation in the above-mentioned reactions and, secondly, by anion-exchange of lead(IV) coordination compounds. We had no success with the first method, because complex formation with H_3PO_4 to very stable lead(IV) acids (formally $H_2[PbX_4(H_2PO_4)_2]$) associated *via* hydrogen bridges occurred immediately on dissolution of lead(IV) compounds in phosphoric acid and ligand exchange then occurred only subsequently in a slow reaction. The second method, however, was successful:

When $Pb(OCOCH_3)_4$ (11.1 g) was added to a solution of $(C_6H_5)_3PO$ (13 g) in anhydrous benzene (100 ml), a yellow precipitate was at once formed, which was slowly decolorized on addition of anhydrous phosphoric acid (9.3 g). After 3 hours' stirring at 50 °C the precipitate was filtered off under reduced pressure and dried. Elemental analysis accorded with the composition $Pb(H_2PO_4)_4 \cdot (C_6H_5)_3PO$ (oxidation value 99%).

This white crystalline product, which is slightly soluble in methanol but insoluble in other solvents, is astonishingly insensitive to moisture and is hydrolyzed only slowly in cold water although rapidly in hot water with separation of PbO_2; it decomposes in a vacuum above 140 °C. It was found thermogravimetrically that $(C_6H_5)_3PO$ is first split off quantitatively, and that the donor-free residue, presumably $Pb(H_2PO_4)_4$, then at once decomposes forming lead(II) phosphate.

The behavior on decomposition shows the importance of the donor for stabilization of the oxidation state +4 of the central atom; immediately after removal of the $(C_6H_5)_3PO$ the change of oxidation state $Pb^{IV} \rightarrow Pb^{II}$ occurs with loss of oxygen. The yellow precipitate that is formed on addition of

$(C_6H_5)_3PO$ to solutions of $Pb(OCOCH_3)_4$ in benzene decomposes when its isolation is attempted. From the analytically determined atomic ratio Pb:P = 1.00:0.93 and ligand exchange with H_3PO_4 to give $Pb(H_2PO_4)_4 \cdot (C_6H_5)_3PO$, however, it can be concluded that the yellow primary product is the 1:1 adduct $Pb(OCOCH_3)_4 \cdot (C_6H_5)_3PO$, which also had not previously been described.

Structure of Molten Antimony[**]

By *H. U. Gruber* and *H. Krebs*[*]

The intensity distribution of Mo radiation scattered at a free surface of molten antimony has been measured with great accuracy by a Bragg-Brentano type camera followed by bent quartz crystal monochromator[1] and discriminator. The melt was placed in a quartz cuvette with a lustrous carbon window capable of being heated. The measured intensities were normalized by *Hosemann*'s empirical procedure[2].

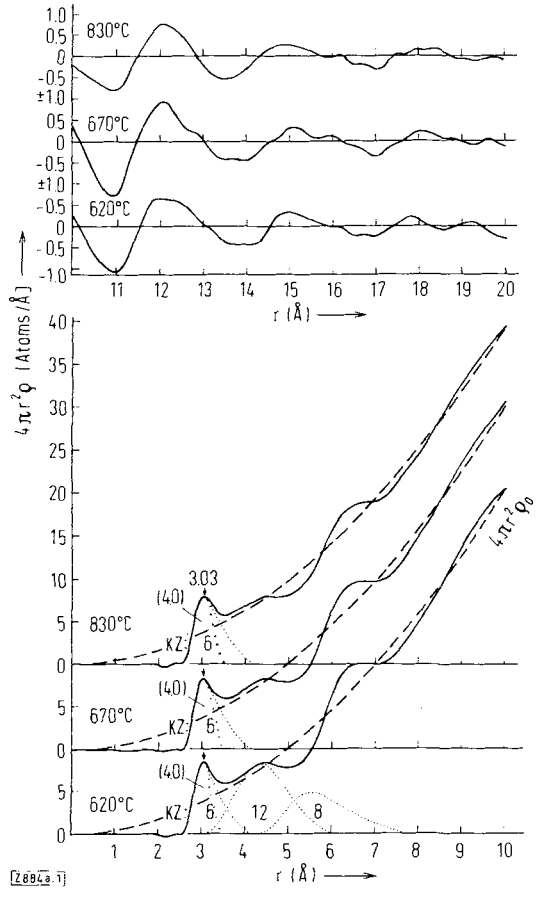

Fig. 1. Atom distribution curves for molten antimony. For r values > 10 Å only the deviation from the statistical distribution — the scale increased by a factor of 5 — is shown.

Figure 1 shows the atomic distribution curves at 620 (supercooled), 670, and 830 °C. Maxima can be recognized at $r \approx n \cdot 3.03$ Å where $n \approx 1, 2, 3, 4, 5$, and 6; there is also a well-developed maximum at $r \approx \sqrt{2} \cdot 3.03$ Å.

Hosemann[3] recently drew attention to the micellar structure of metallic melts. Accordingly antimony melts may be composed of double layers of limited extension as they can be cut out of a primitive cubic structure parallel to (100) (Fig. 2).

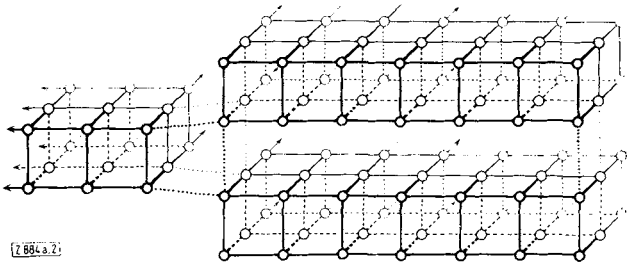

Fig. 2. Schematic representation of the atomic arrangement in molten antimony.

The atomatic distances are probably not equal within these double layers, but they alternate, as in the structures of black phosphorus or GeS[4]. The double layers may be arranged one on the other, as in GeS, since antimony has a strong tendency to take part in pσ bonds and sp hybridization is diminished[4]. In Figure 2 one possibility of lateral bonding of the double layers is indicated.

The great mobility of the atoms in the melt probably arises from the easy exchange between bilateral pσ bonding and unilateral sp hybrid bonding, so that a mesomeric bond is readily broken on one side and strengthened on the other[4].

Electrical Conductivity and Formation of Chalcogenide Glasses in Ge–As–Se and Ge–Sb–Se Melts[**]

By *R. W. Haisty* and *H. Krebs*[*]

A high-polymeric glass can be formed from a melt only if a large portion of bivalent atoms (*e.g.*, O, S, Se, or Te) or atomic groups (*e.g.*, CH_2) with a bond angle $< 180°$ is present, allowing an irregular type of bonding[1,2] and thus, together with slight thermal dissociation, a certain mobility of the atoms in a viscous melt. If the starting material contains too many tervalent (*e.g.*, P, As, or Sb) and quadrivalent atoms (*e.g.*, Si or Ge), dissociation processes do not lead to sufficient mobility of the atoms to permit a molten liquid state. In this case the melting process must be connected with a complete change in the bonding system. As in molten germanium, the coordination number 6 should be approached, since then, as with germanium, mesomeric pσ bonding is possible. As a result metallic conductivity should occur and, in addition, the atoms then would be highly mobile, since by

local conversion into unilaterally binding sp hybrid quantum states bonds can be broken easily while others are strengthened [2, 3]. The high mobility of the electrons, and thus of the atoms themselves, should lead to great reactivity of the atoms and hence to crystallization of the melt.

These relations were verified experimentally for the systems Ge–Sb–Se and Ge–As–Se. The electrical conductivity could be measured up to high temperatures by a new, very rapid, electrodeless method [4].

Figure 1 shows the glass-forming region for slow and rapid cooling in the system Ge–Sb–Se. Glass-forming melts are semiconducting, with a wide forbidden zone (symbol ○). Far

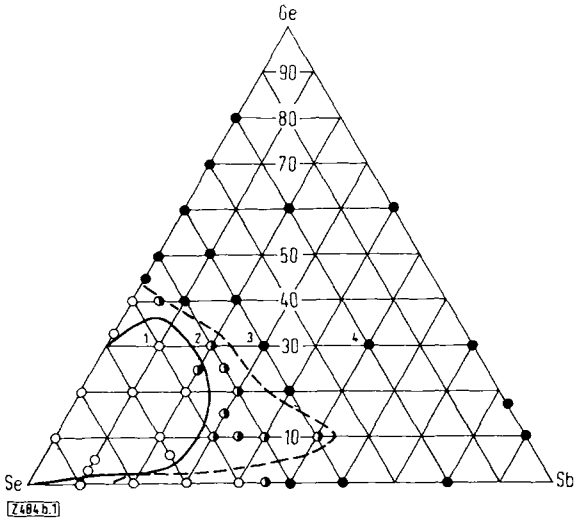

Fig. 1. Glass-forming region in the system Ge–Sb–Se on slow (——)[5] and rapid (- - -) cooling. Typical electrical conductivity curves for the compositions 1,2,3, and 4 are reproduced in Fig. 2.

outside the glass-forming region the melts have metallic conductivity (●). However, relatively high but non-metallic conductivity (◑) is found in a transition region; there the melts seem to be biphasic in microregions, containing metallic

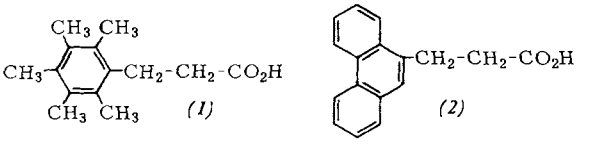
Formation of Electron-donor-acceptor Complexes as a Basis for Specific Adsorption

By *H. Stetter* and *J. Schroeder* [*]

We have begun a study of whether the formation of electron-donor-acceptor complexes can be used for specific adsorption in the chromatography of compounds of high molecular weight [1]. The most suitable substrates proved to be cellulose esters of 3-(pentamethylphenyl)- *(1)* and 3-(9-phenanthryl)-propionic acid *(2)* [2], which can be prepared from mercerized cellulose and the chlorides of the two acids [3]. Each glucose unit could be esterified with 2–3 equivalents of the acid.



The new cellulose esters permit appreciably better separation of aromatic nitro compounds and of quinones than is possible on commercial cellulose powder or silica gel (Figs. 1 and 2).

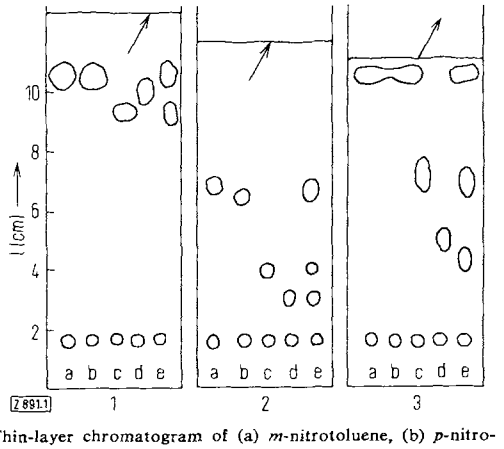


Fig. 1. Thin-layer chromatogram of (a) *m*-nitrotoluene, (b) *p*-nitrotoluene, (c) 2,4-dinitrotoluene, (d) 2,4,6-trinitrotoluene, (e) mixture. 1 = MN silica gel, 2 = cellulose ester of *(1)*, 3 = cellulose ester of *(2)*. Eluant: ether/light petroleum/acetone 50:40:10. Color of the complexes: yellow-red.

Moreover the position of the substances on the plate can be easily determined by the color of the donor-acceptor complexes formed. We consider this principle of specific adsorption to be capable of extension.

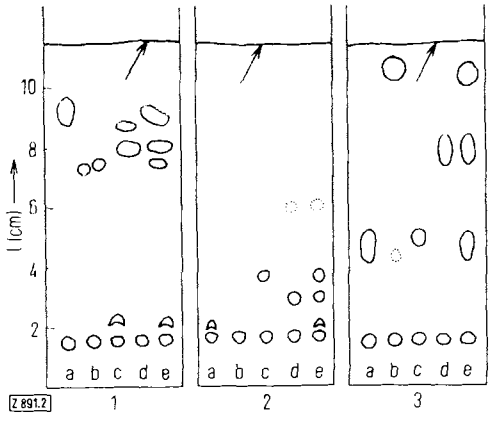

Fig. 2. Thin-layer chromatogram of (a) chloranil, (b) tetrachlorohydroquinone, (c) 1,2-naphthoquinone, (d) 1,4-naphthoquinone, (e) mixture. Adsorbant and eluant as for Fig. 1. Color of the complexes: yellow-red.

Cellulose ester of (1):

Mercerized cellulose[4] (10.6 g) is made into a slurry with pyridine (22 ml) and dioxane (78 ml). The acid chloride (56 g) of *(1)* in dioxane (200 ml) is added and the whole is heated at 95 °C for 24 h, and the ester is then precipitated by pouring the mixture into methanol (500 ml). The ester is isolated, boiled with acetone, triturated with a little methanol for 3 h in a ball mill, filtered off, and dried (yield 39.6 g; insoluble in alcohols, sparingly soluble in chlorinated hydrocarbons; sap. val: found 75.0% of acyl; calc. for diester 71.7% and for triester 79.3%).

Cellulose ester of (2):

Cellulose (11.3 g) in pyridine (23 ml) and dioxane (150 ml) is heated with the acid chloride (68 g) of *(2)* in dioxane (220 ml) as above for 48 h. The viscous solution is poured into methanol (1 l) + acetone (500 ml). The precipitated ester is filtered off, ground twice with methanol/acetone, and triturated with a little acetone in a ball mill for 2 h. It is insoluble in most organic solvents (yield 50 g; sap. val: found 75.3% of acyl; calc. 74.4% for diester).

For thin-layer chromatography 5 g of the cellulose ester of *(1)* is homogenized on a shaker with 0.3 g of gypsum, 8 ml of methanol, and 5 ml of water. For the ester of *(2)*, 4 g are similarly treated with 0.2 g of gypsum, 20 ml of methanol, and 5 ml of water. These materials are placed on plates, dried in the air, and heated at 90–100 °C shortly before use.

1,5,9-Cyclododecatriene Complexes of Nickel(0) [**]

By *K. Jonas, P. Heimbach*, and *G. Wilke* [*]

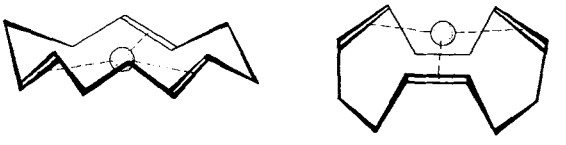
Cyclotrimerization of butadiene on 'naked' nickel leads to three isomeric cyclododecatrienes[1] (*cis,cis,trans*-CDT, *cis,trans,trans*-CDT, and all-*trans*-CDT). all-*cis*-CDT is not formed catalytically but can be prepared from all-*trans*-CDT[2]. Of the nickel complexes, so far only the deep red all-*trans*-CDT–Ni(0) *(1)* has been prepared[3]; its X-ray structure analysis[4] shows the nickel atom to occupy the center of the ring and to interact with all three double bonds. We have now studied the problem whether the other isomers can form defined complexes with nickel(0).

On treatment of bis(2,4-pentanedionato)nickel(II), $Ni(acac)_2$, with triethylaluminum (3:2; in ether) in the presence of *cis,cis,trans*-CDT or *trans,trans,cis*-CDT, red solutions are obtained from which $Al(acac)_3$ can be separated at −78 °C. If the filtrate therefrom is concentrated and cooled to −20 °C, pale red needles are precipitated whose composition corresponds approximately to $C_{12}H_{18}Ni$. The very soluble products decompose extremely easily so that attempts at further purification have so far failed.

However, all-*cis*-1,5,9-cyclododecatrienenickel(0) *(2)* can be very easily obtained in pure form by mixing the all-*trans*-complex *(1)* with all-*cis*-CDT in the molecular ratio 1:1 in ethereal solution at −78 °C and warming the whole slowly to room temperature. The color of the solution soon changes from deep red to yellow and on renewed cooling to −78 °C almost colorless needles of composition $C_{12}H_{18}Ni$ (mol. wt. 210, cryoscopic) in benzene are precipitated in 75% yield.

$$ttt\text{-CDT}\cdot Ni(0) + ccc\text{-CDT} \rightarrow ccc\text{-CDT}\cdot Ni(0) + ttt\text{-CDT}$$

This complex *(2)* reacts with CO, yielding $Ni(CO)_4$ and free all-*cis*-CDT. Its ^{1}H-NMR spectrum (in deuteriobenzene) shows two signals at τ = 5.24 (=CH–) and 7.68 ($-CH_2-$) with the intensity ratio 6:12, *i.e.*, all three *cis*-double bonds are bound to the nickel atom, as in *(1)*. It can be seen from the model that *cis*-CDT in *(2)* thus very probably occurs in the crown form.



(1) *(2)*

In the complex of this isomer there is maximum overlap of the metal orbitals with those of the double bonds, since both the bonding and the antibonding orbitals of all three *cis*-double bonds lie in one plane, whereas in the less stable complex *(1)* the three *trans*-double bonds are turned propellor-wise out of this plane[4].

There is clearly no relation between the stability of the individual complexes with nickel(0) and the isomer distribution of the cyclododecatrienes formed from butadiene on 'naked' nickel, since the isomer, all-*cis*-CDT, giving the most stable complex with Ni(0), is not formed catalytically.

The fourth coordination position of the nickel atom in *(2)* can be occupied by another ligand, as in *(1)*; but only tris-(*o*-biphenylyl) phosphite gives a stable 1:1 adduct with *(2)*, whereas phosphines also form stable 1:1 complexes with *(1)*.

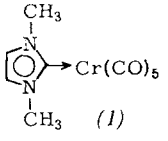
Pentacarbonyl(2,3-diphenylcyclopropenylidene)-chromium(0)

By *K. Öfele* [*]

All the stable transition-metal-carbene complexes known so far contain carbene ligands whose nucleophilic character is ascribed to delocalization of non-bonding electron pairs in hetero atoms to a vacant p-orbital of the carbene-carbon atom [1]. $(C_6H_5)_2C{=}CFe_2(CO)_8$, in which diphenylvinylidene occurs as carbene bridging ligand [2], represents an exception.

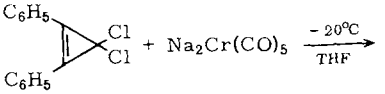
In pentacarbonyl(1,3-dimethylimidazolin-2-ylidene)chromium(0) [3] *(1)* and a series of analogous pentacarbonylchromium and tetracarbonyliron complexes with 1,2-dimethyl-

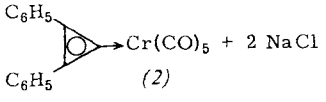


(1)

pyrazolin-3-ylidene, 3-methylthiazolin-2-ylidene, and 2,4-dimethyl-1,2,4-triazolin-3-ylidene as ligand [4], the nucleophilic character of the carbene ligands is particularly strongly developed because an aromatic 6π-electron system can arise by this delocalization. This may be the reason for the observed stability of the above-mentioned complexes and of the bis-(1,3-diphenylimidazolio)mercury salt prepared by *Wanzlick et al* [5].

To discover whether cyclic carbenes such as diphenylcyclopropenylidene [6] that contain an aromatic π-electron system but not any hetero atom would also form stable complexes with transition metals, 1,1-dichloro-2,3-diphenylcyclopropene was treated with $Na_2Cr(CO)_5$. A deep yellow, crystalline compound of m.p. 199–200 °C (decomp.), was formed, which was identified as pentacarbonyl(2,3-diphenylcyclopropenylidene)chromium(0) *(2)* by elemental analysis and by its mass spectrum.





(2)

The following ions occur in the mass spectrum [7] of *(2)*:

m/e	I_{rel}	Assignment
382	9.6	$(CO)_5CrL^+$
354	0.2	$(CO)_4CrL^+$
326	4.0	$(CO)_3CrL^+$
298	9.7	$(CO)_2CrL^+$
270	17	$(CO)CrL^+$
242	100	CrL^+
52	61	Cr^+

L = diphenylcyclopropenylidene.

A very weak peak occurs at *m/e* = 190 due to free carbene presumably split off thermally. The intensity distribution with the carbene-Cr fragment as base peak is similar to that observed for *(1)* [3] and other pentacarbonylchromium complexes with acyclic carbene ligands [8].

As in the case of *(1)*, the IR spectrum of *(2)* contains fewer ν(CO) bands than expected, namely, at 2061 (m) and 1938 cm^{-1} (vs) (in cyclohexane). In the ultraviolet region a solution of the compound in cyclohexane absorbs at 440 ($\log \varepsilon = 3.42$), 366 (4.16), and 248 nm (4.75). The ^{1}H-NMR spectrum of *(2)* in $CDCl_3$ shows two multiplets at $\tau = 1.68$ and 2.26 (intensity ratio 2:3) for the phenyl protons.

The new complex, with a carbene ligand but no hetero atom, is astonishingly stable. In the crystalline state it is stable to air; in an inert atmosphere it decomposes only above 192 °C, forming $Cr(CO)_6$, and in a vacuum it can be sublimed at 110 °C without decomposition. It dissolves readily in benzene, moderately in ether or acetone, and sparingly in light petroleum.

Experimental:

A solution of 1,1-dichloro-2,3-diphenylcyclopropene (1.5 g, 6.5 mmoles) in tetrahydrofuran (10 ml) was added dropwise to a solution of $Na_2Cr(CO)_5$ (1.6 g, 6.7 mmoles) in tetrahydrofuran (25 ml) at −20 °C with vigorous stirring and exclusion of air. After 1/2-hour's stirring at room temperature, the solvent was removed under reduced pressure, and the brown residue was taken up in ether (100 ml) and washed in a separatory funnel with two portions (each 20 ml) of water. The ethereal solution was then dried over sodium sulfate and filtered through Al_2O_3 on a G4 fritted filter. The ether was then distilled off in a vacuum and the residue was warmed for 1 h under high vacuum at 60 °C to remove $Cr(CO)_6$ and diphenylcyclopropenone. The crude product thus obtained was dissolved in benzene/ether (1:2) and freed from a dark brown impurity by chromatography with hexane and ether (column length 1 m; silica gel). The yield was 19.5%.

Dipotassium Hexaamidoplumbate(IV) [**]

By *O. Schmitz-Du Mont* and *W. Jansen* [*]

The only purely inorganic lead(IV)-nitrogen compound to have been discovered up till now was obtained by *Schwarz et al.* [1] on ammonolysis of $PbCl_4$ in liquid NH_3. The product, which still contains chlorine, was assigned the empirical formula $Pb_5N_6Cl_4$; nothing is known about its structure. On ammonolysis of $Pb(C_6H_5)_4$ in liquid NH_3 and in the presence of KNH_2, we obtained a black, insoluble Pb^{IV} compound as a by-product that was so explosive that it could not be isolated [2]. The main reaction product, which was formed in the course of a redox reaction with liberation of N_2, was $K[Pb(NH_2)_3]$ *(1)*. We assumed that complete ammonolysis of $Pb(C_6H_5)_4$ first leads to dipotassium hexaamidoplum-

bate(IV), $K_2[Pb(NH_2)_6]$ *(2)*, which is unstable at 20 °C and mainly decomposes to form *(1)* and N_2. Lowering of the reaction temperature could possibly permit isolation of *(2)*.

Since tetraphenyllead, which is insoluble in liquid NH_3, does not react below 5 °C, readily soluble $(C_6H_5)_2PbI_2$ was subjected to ammonolysis at −75 °C in the presence of KNH_2. On addition of KNH_2 to the colorless solution of $(C_6H_5)_2PbI_2$ (1.2 g, 1.9 mmole) in NH_3 (60 ml) a voluminous yellow precipitate of $[(C_6H_5)_2Pb]_3N_2$ is first formed which redissolves after a total of 0.55 g (10 mmole) of KNH_2 has been added. If the yellow solution is then warmed to −25 °C, lustrous, colorless crystals gradually separate, which are filtered off after 3 h, washed with liquid NH_3 at −50 °C, and are freed from retained NH_3 under reduced pressure at −75 °C. Hydrolysis in a moist stream of oxygen-free nitrogen at −20 °C (absorption of liberated NH_3 in 2% aqueous boric acid; NH_3 determined conductometrically[2]) affords a brownish black precipitate. The analytical data correspond to the formula $K_2[Pb(NH_2)_6]$.

We assume the following reaction scheme to apply in the formation of *(2)*:

$$3\,(C_6H_5)_2PbI_2 \xrightarrow[-6\,KI,\,-4\,NH_3]{+\,6\,KNH_2\,(-75\,^\circ C)} [(C_6H_5)_2Pb]_3N_2 \text{ yellow precipitate}$$

$$[(C_6H_5)_2Pb]_3N_2 \xrightarrow{+\,6\,KNH_2,\ +\,4\,NH_3} 3\,K_2[(C_6H_5)_2Pb(NH_2)_4] \text{ yellow solution}$$

$$3\,(2) \xrightarrow[-\,6\,C_6H_6]{+\,6\,NH_3\,(-25\,^\circ C)} 3\,K_2[(C_6H_5)_2Pb(NH_2)_4]$$

In contrast to the analogous, highly stable tin compound $K_2[Sn(NH_2)_6]$, which has been known for a long time, compound *(2)* decomposes at room temperature with a black coloration, and with liberation of NH_3 and partial reduction of Pb^{IV} to Pb^{II} as well as formation of a black, highly explosive substance. Discoloration also occurs under liquid NH_3 at 0 °C. At 10 °C the black precipitate disappears within 40 h, with simultaneous evolution of N_2. After filtration of the solution and evaporation of NH_3 there remains a colorless, crystalline precipitate, which could be identified as a mixture of *(1)* and KNH_2 (analysis, Debye photograph).

Hydrazine and diimine[3] are probably involved in the decomposition of *(2)* according to the equation:

$$3\,(2) \rightarrow 3\,(1) + 3\,KNH_2 + 4\,NH_3 + N_2$$

Fragmentation of Specifically Deuterated Tri-*n*-alkylchromium Compounds

By *R. P. A. Sneeden* and *H. H. Zeiss*[*]

Tri-*n*-alkylchromium compounds undergo fragmentation in tetrahydrofuran solution, on warming from −70 to +20 °C, to unequal quantities of *n*-alkane and 1-*n*-alkene plus a hydridochromium species capable of catalyzing the isomerization of the terminal olefins[1,2].

$$x\,(RCH_2CH_2)_3Cr(THF)_n \xrightarrow{-70\text{ to }+20^\circ} y\,RCH_2CH_3 + z\,RCH{=}CH_2 + x\,\text{"HCR"} (+\,m\,THF)$$

In order to determine the origin of the hydrogen atoms required for the formation of the alkane and hydridochromium species the fragmentation of the tris([2,2-D_2]-4-phenylbutyl)-chromium *(1)* and tris([1,1-D_2]-4-phenylbutyl)chromium *(2)* in tetrahydrofuran solutions has been studied[3,5].

At −40 °C both *(1)* and *(2)* are stable, undergoing methanolysis to essentially pure [2,2-D_2]- and [1,1-D_2]-4-phenylbutane [*(3)* and *(4)*] respectively.

After 0.5 h at 20 °C, *(1)* has undergone partial fragmentation (Table 1, exp. 1). The products, after hydrolysis, consist of hydrogen and hydrogen deuteride, *(3)* containing some [1,2,2-D_3]-4-phenylbutane *(5)*, plus [2-D]-4-phenyl-1-butene containing some [1,2-D_2]-4-phenyl-1-butene.

$$(C_6H_5CH_2CH_2CD_2CH_2)_3Cr(THF)_n \xrightarrow[2)\,H_2O]{1)\,0.5\text{ h at }20^\circ C} \begin{cases} C_6H_5CH_2CH_2CD_2CH_2(H, D) \\ C_6H_5CH_2CH_2CD{=}CH(H, D) \\ H_2 + HD \end{cases}$$

After 20 h at 20 °C, the organochromium compound has undergone complete fragmentation and the isomerization of the 1-alkene is complete. The products after hydrolysis (Table 1, exp. 2) now consist of hydrogen and hydrogen deuteride, *(3)*, and *(5)*, plus deuterated *cis*- and *trans*-2- and 3-alkenes.

Table 1. Fragmentation of tris([2,2-D_2]-4-phenylbutyl)chromium and tris([1,1-D_2]-4-phenylbutyl)chromium. Isotopic compositions of hydrolysis products.

	H_2/HD	0.5 [c]	97.4	2.6	0.0		

[a] Unless otherwise stated, these are the relative percentages present in the total hydrocarbon mixture.
[b] Expressed in relative percentages and corrected for natural isotopic abundances.
[c] Expressed in mmoles per mmole chromium.
[d] Not measured.

After 0.5 h at 20 °C, *(2)* has undergone extensive fragmentation and the resulting 1-alkene has been partially isomerized. The products after hydrolysis (Table 1, exp. 3) are hydrogen and hydrogen deuteride, *(4)* containing some trideuterated 4-phenylbutane, a complex mixture of non-deuterated 4-phenyl-1-butene and mono-, di- and tri-deuterated 4-phenyl-1-butenes, in which the deuterium is distributed over C^1, C^2, and C^3, plus *trans*- and *cis*-2-alkenes.

$$(C_6H_5CH_2CH_2CH_2CD_2)_3Cr(THF)_n \xrightarrow[2)\,H_2O]{1)\,0.5\text{ h at }20^\circ C} \begin{cases} C_6H_5CH_2CH_2CH_2CD_2H \\ C_6H_5CH_2CH(H, D)C(H, D) = CD(H, D) \\ \textit{trans}\text{- and } \textit{cis}\text{-2-alkene} \\ H_2 + HD \end{cases}$$

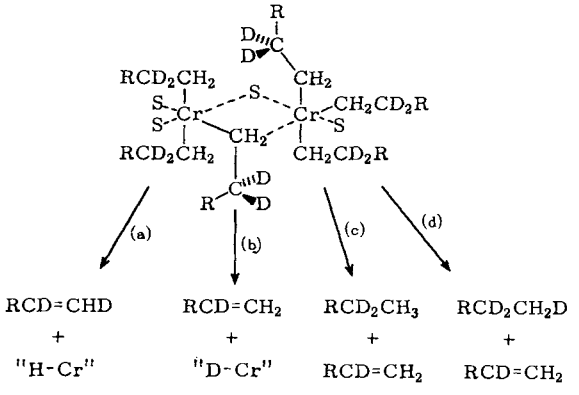
The present results prove that in the fragmentation of tri-*n*-alkylchromium compounds:

(i) the hydrogen (deuterium) atoms present on the carbon atoms α and β to the metal center are transferred to the metal[6] (HD on hydrolysis);

(ii) the hydrogen (deuterium) on the carbon atom β to the metal center is acquired by one of the alkyl groups originally bonded to the chromium (presence of trideuterioalkane);

(iii) prior to the isomerization process (and perhaps during it) there is transfer of hydrogen and deuterium over C^1, C^2, and C^3, this occurring without concomitant double bond migration.

It is now clear that the fragmentation of tri-*n*-alkylchromium compounds involves at least two fundamental processes, the first is a homolytic or one-electron transfer process in a monomeric or dimeric chromium species and the second is β-elimination of metal hydride[7]. These can be summarized, for the dimeric species, as follows: (R = $C_6H_5CH_2CH_2-$; S = THF):



(a): α-elimination of metal hydride. (b): β-elimination of metal hydride. (c): attack on solvent. (d): attack on alkyl group.

[3] The respective deuterioalkanes obtained by hydrolysis of the deuterioalkyl-Grignard used were shown by mass spectrometry to consist of 96.3% [2,2-D_2]-4-phenylbutane and 97.2% [1,1-D_2]-4-phenylbutane [4].

[4] All isotopic compositions were kindly determined mass spectrometrically by Dr. *W. E. Koerner* and his associates of Monsanto Company, Research Center, St. Louis, Mo. USA.

[5] The individual organic compounds were isolated by preparative scale gas chromatography and identified by comparing their infrared and ^{1}H-NMR spectra with authentic specimens. The isotopic compositions of the pure compounds were determined by mass spectrometry [4], the location of the deuterium atoms follows from the proton count of the ^{1}H-NMR spectra. The gaseous products were isolated using a vacuum line and their identities and compositions established by mass spectrometry [4].

[6] Similar conclusions have been reached by *J. Chatt, R. S. Coffey, A. Gough*, and *D. T. Thompson*, J. chem. Soc. (London) (A) *1968*, 190 for the fragmentation of alkylplatinum complexes.

[7] The present results also suggest, but do not prove, that α-elimination of metal hydride may also occur.

Ring Closure of 2-Hydroxyadipaldehyde

By *H. Mathais, J. P. Schirmann*, and *F. Weiss*[*]

Feichtinger and *Noeske*[1] recently reported that 1,2-cyclohexanediol *(8)* is formed on discontinuous pressure hydrogenation of aqueous solutions of 2-hydroxyadipaldehyde *(1)* to 1,2,6-hexanetriol, ring closure being assumed to occur with 1,6-linkage and elimination of the hydroxyl group from the α-position.

However, as we have found, the ring is closed before the hydrogenation occurs. 1,2-Cyclohexanediol *(8)* is formed by hydrogenation of 1,2-cyclohexanedione *(6)* or its enol *(3)* or hydrate *(5)* (see Scheme 1), which are formed by intramolecular aldol formation merely on warming an aqueous solution of *(1)*[2–5]. If, for instance, 200 g/h of a 20% aqueous, slightly acid (pH 5) solution of *(1)* is passed through a copper tube (length 500 mm, diameter 10 mm) at 140–170 °C in a stream of nitrogen (12 l/h), the aldehyde is completely cyclized. Several extractions with dichloromethane afford 1,2-cyclohexanedione *(6)* in 48% yield and 5-hydroxy-1-cyclopentene-1-carboxaldehyde *(4)* in 34% yield; if the experiment is conducted at about 80 °C, then only the dione is detectable by gas chromatography.

The reaction is extremely fast in the hot, *e.g.*, when a solution of *(1)* is injected into an evaporation cell for gas chromatography. A certain amount of *(6)* may be formed, as shown by thin-layer chromatography, when an aqueous solution of 3,4-dihydropyran-2-carbaldehyde is heated to prepare *(1)*.

The varying results of continuous and discontinuous pressure hydrogenation of *(1)* are thus explained as follows: in discontinuous experiments, *(1)* is exposed to heat for relatively long times and at relatively high concentrations and can thus cyclize partly before hydrogenation occurs. Experimentally, *cis*- and *trans*-1,2-cyclohexanediol *(8)* and 2-hydroxycyclopentanemethanol *(7)* are formed, which proves this stepwise process; further, 1,2-dihydroxycyclopentanemethanol – a hydrogenation product of *(2)* – was found on hydrogenation of *(1)* over copper at 200 °C[6]. However, in the continuous process the concentrations of *(1)* are kept so low by immediate hydrogenation that the ring-closure mechanisms cannot operate.

Ion Pair Formation in Benzene Radical Anion Solutions[**]

By *G. L. Malinoski jr.* and *W. H. Bruning*[*]

Our investigations of electron transfer effects on the ESR spectrum of benzenide ion produced by alkali metal reduction in tetrahydrofuran (THF), dimethoxyethane (DME), and mixtures of these two solvents lead us to believe that extensive ion pairing occurs with metal ions in solution[1].

However, our results do not agree with the spectra or discussion recently reported by *Köhnlein, Böddeker,* and *Schindewolf*[2]. These authors reported a spectrum of about 15 lines obtained after warming the solution (in THF/DME) to 0 °C and then recooling to −30 °C in the absence of alkali metal alloy. In addition, during this cycle they observed a color change from deep green to brown-yellow. They also reported that if alkali metal was visibly present in the solution the color remained deep green and the normal 7 line ESR pattern of $C_6H_6^-$ was obtained. They concluded that the 15 line pattern arose from interactions with metal ions causing the lifting of the orbital degeneracy in $C_6H_6^-$.

We have tried unsuccessfully to repeat their experiments. Great care was taken in our work to purify solvents and benzene. (A. R. grade solvents were exhaustively dried over Na–K alloy, distilled from the alloy, degassed and transferred from one vacuum storage bottle, containing Na–K alloy, to another several times. Spectroquality benzene was dried over Na–K alloy in vacuum storage bottles, for periods of months, until use.) In a given glass apparatus several preparations of anion radical were usually made and discarded *via* glass sidearms in an attempt to scavenge all possible impurities in the system before producing the final solution for ESR analysis. The resulting solutions were always blue or slightly blue green in color and repeated warming-cooling cycles, with or without metal present, caused no color changes and did not affect the ESR spectra obtained. (Warming and cooling without metal present did lead to some reduction of signal intensity, presumably due to decomposition of $C_6H_6^-$.)

Many different samples were prepared with initial neutral benzene concentrations in the range 0.1 M to 4 M using solvents from different sources. Reductions were carried out with either Na–K alloy in mixed solvents or with K in DME, THF, or the mixed solvents. Our spectra always gave the basic 7 line pattern of benzenide ion, often broadened due to electron transfer. (The spectra could be collapsed to the exchange narrowed limit depending on the concentration of neutral benzene and temperature.) Computer simulation of these spectra in the broadening limit could be accomplished using solutions to the density matrix equations[3]. An alkali metal coupling constant of approximately $a_M = 0.5–0.7$ gauss was included along with $a_H = 3.6$ gauss[4] (Figure 1).

Our experiments indicated that a_M depends on concentration of neutral benzene as well as temperature. (As $[C_6H_6]$ increases a_M seems to increase. The dielectric constant of benzene is ~3 times smaller than THF or DME[5] and the increase in a_M is not unreasonable.) At no time however, did we observe spectra attributable to a predominant interaction of the electron spin with the symmetrical E_{2u} state of benzene.

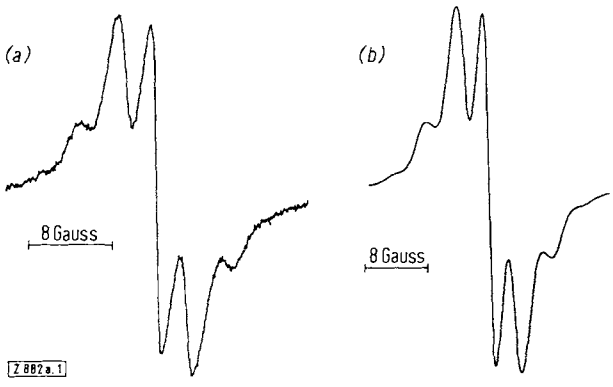

Fig. 1. (a) ESR spectrum of $C_6H_6^-$ produced by reduction of benzene (≈ 4 M in DME) with potassium. $T = -24$ °C.

(b) Computer simulation of the same spectrum: $a_H = 3.6$ gauss, $a_K = 0.7$ gauss, mean lifetime of species $\tau = 3.75 \times 10^{-7}$ sec. With $a_K = 0$, a completely different pattern results.

Alkali metal splitting was not observed at temperatures between −85 and +30 °C. Time dependent electron transfer, metal ion transfer, or rapid interconversion processes between various types of ion pairs may be responsible for this[6]. In addition, as temperature is lowered metal splittings generally decrease and relatively slow processes can still lead to averaging effects which wipe out small splittings[5]. (There is always neutral benzene present in these systems and electron transfer is important, even at −50 °C.)

We believe *Köhnlein et al.* did observe a species related to $C_6H_6^-$; however, our results indicate that their spectrum cannot be attributed to interaction with the gegenion. The warming-cooling cycle dependence they reported, with or without metal present, could perhaps be explained if $C_6H_6^-$ abstracted a proton from a trace impurity in their system. Protonation could lead to a depression in energy of the symmetric orbital and a 15 line pattern would result if the magnetic interaction of the extra proton was very weak. Subsequent contact with alkali metals could then destroy such a species, with evolution of H_2 in the system.

A Reinterpretation of the ESR Spectrum Attributed to a Non-degenerate State of the Benzene Radical Anion[**]

By *Pamela Wormington* and *J. R. Bolton*[*]

Köhnlein, Böddeker, and *Schindewolf*[1] recently reported a fifteen-line ESR spectrum which they attributed to the benzene anion confined in the symmetrical (E_{2u}) state[2] of the degenerate ground state of the benzene anion. They reported a large triplet (1:2:1) hyperfine splitting of 6.5 G and a smaller quintet (1:4:6:4:1) splitting of 1.7 G. Indeed these hyperfine splittings are close to those expected for a benzene anion confined to the symmetrical state.

On reinvestigation of this system ($C_6H_6^-$ in THF/DME[1]), we find that each line of the original fifteen-line spectrum splits into at least twelve components; this finding clearly demonstrates that the spectrum does not arise from any form of the benzene radical anion.

The ESR spectra were recorded on a modified Varian V 4502 spectrometer; a sample of *N,N,N',N'*-tetramethyl-*p*-phenylenediamine in methanol was used for field calibration[3]. The solvent (Mallenckradt Chromatographic spectro grade) was purified by distillation from CaH_2 and subsequent vacuum distillation from $LiAlH_4$ into a solvent vessel containing sodium and an involatile aromatic hydrocarbon such as perylene; the benzene (Coleman, Matheson and Bell "spectrograde") was used as received.

At −60 °C a "normal" 7-line benzene anion spectrum[4] was obtained. As the temperature was raised, the spectrum broadened and all but disappeared at 0 °C. At 20 °C a triplet structure began to appear which then resolved into three quintets. However, on reducing the microwave power below 1 milliwatt and using a very low modulation amplitude, each of the fifteen lines resolved into at least twelve components. We have been able to analyze this substructure as arising from a doublet (one proton), a triplet (2 protons), and a quintet (4 protons).

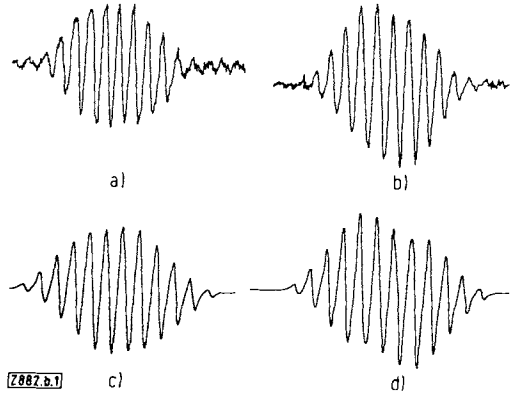

Table 1. Hyperfine splittings found for the ESR spectrum observed from the reaction of benzene with a Na—K alloy in THF/DME.

T(°C)	a_H (Gauss)				
	2 H	4 H	1 H	2 H	4 H
−65			0.413 ± 0.004	0.235 ± 0.002	0.116 ± 0.002
−63	6.505 ± 0.013	1.774 ± 0.011	0.407 ± 0.002	0.234 ± 0.001	0.119 ± 0.001
−60			0.386 ± 0.003	0.226 ± 0.002	0.114 ± 0.002
−37			0.383 ± 0.004	0.236 ± 0.002	0.119 ± 0.002
−36	6.432 ± 0.007	1.800 ± 0.007			
−34			0.363 ± 0.002	0.228 ± 0.001	0.117 ± 0.001
− 3	6.252 ± 0.001	1.774 ± 0.001	0.349 ± 0.003	0.232 ± 0.002	0.117 ± 0.002
+22	6.116 ± 0.003	1.758 ± 0.002	0.326 ± 0.006	0.231 ± 0.005	0.115 ± 0.005

The above Figure shows the resolution of the central line at +22 °C (a) and at −37 °C (b) as well as the corresponding computer simulations based on the coupling constants given in Table 1 [(c) and (d)].

The improved resolution of the original fifteen-line spectrum[1] provides clear evidence that the radical producing this spectrum is not the benzene radical anion since at least thirteen protons are contributing hyperfine splittings. The radical is obviously a product of some coupling reaction; however, we are not willing to speculate as to its identity at this stage.

Influence of Solvent Pretreatment and Electrolyte Addition on the ESR Spectra of Aromatic Radical Anions

By *K. W. Böddeker, G. Lang,* and *U. Schindewolf*[*]

In the ESR spectroscopic investigation of the benzene radical anion, $C_6H_6^-$, in tetrahydrofuran (THF)/dimethoxyethane (DME), the ESR septet occurring at low temperatures was found to give way on warming (up to ≈ 0 °C) to a new spectrum whose fine structure could be interpreted[1] as resulting from a preferred occupation of the symmetrical (E_{2u}) state of the two states contributing to the ground state of $C_6H_6^-$. Further experiments with and without addition of electrolyte, which have been extended to cover simple benzene derivatives, have shown that the behavior of the radical anions differs according to whether the solvent has been dried over $LiAlH_4$ or has been pretreated in some other way.

Preparation of samples: Each of the samples was prepared under vacuum conditions in a Pyrex vessel (Fig. 1) furnished with a suitable side-arm for the recording of ESR spectra (flat cell).

The K/Na alloy (0.1 ml; 3:1 or 5:1) was introduced into the apparatus by vacuum distillation *via* the side-arm A which subsequently was sealed off. 0.5 ml of the aromatic hydrocarbon to be investigated and 6 ml of THF/DME mixture (THF:DME usually 2:1) were then introduced into the reaction vessel through B. The ethers, which had been dried either over $LiAlH_4$ or over K/Na alloy, were first distilled into a measuring cylinder connected to the

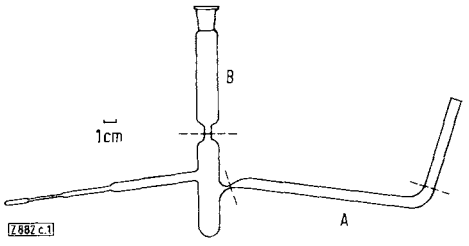

Fig. 1. Pyrex glass vessel for preparation and measurement of ESR samples; the tube is sealed off at the position marked — — — — —.

vacuum line and thence into the reaction vessel. After sealing off, the sample was thoroughly mixed at room temperature (as fine a division of the liquid alloy as possible) and then cooled in Dry-ice/methanol. Similarly, corresponding samples were prepared with addition of about 50 mg LiCl, which had been baked-out in the reaction vessel at 200 °C under vacuum before distillation of the other components.

Results: 1. THF and DME dried over $LiAlH_4$. — After warming the samples, or in the presence of LiCl typical ESR spectra were obtained of the radical anions formed with C_6H_6, C_6H_5D, and $C_6H_5CH_3$ (see Fig. 2). In LiCl-free solution these spectra only developed at temperatures above

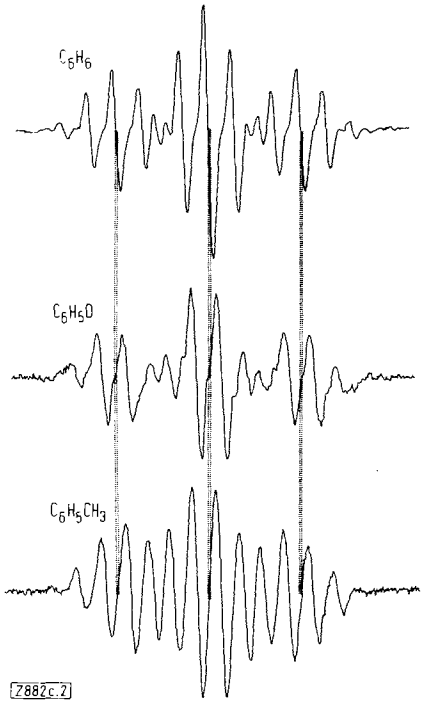

Fig. 2. ESR spectra of radical anions obtained in solvents pretreated with $LiAlH_4$ (the triplet structure is indicated by gray lines).

$\approx$ 0 °C from the "normal" spectra initially appearing at low temperatures; however in the presence of LiCl the new spectra were obtained immediately, even at low temperature, in the case of C_6H_6 and C_6H_5D [2].

The common feature exhibited by the spectra is the triplet structure with splitting of about 6.2 to 6.8 gauss (20 to −80 °C) that is indicated in Fig. 2 by gray lines and which points to a preferred occupation of the symmetrical state characterized by an increased spin density on two oppositely situated ring positions. According to this interpretation the radical anions are analogous to the radical anion of *o*-xylene which has similar triplet coupling constants and likewise exhibits a total splitting $Q < 22.5$ gauss [3]. A qualitatively similar charge distribution also occurs in the pyridine radical anion [4] whose tendency to form bipyridyl [5] finds a parallel in the formation of biphenyl in LiCl-containing benzene samples as observed by us.

The superhyperfine structure in the 15 line spectrum of benzene found by *Wormington* and *Bolton* [6] suggests that a complex structure is present in the case of these anion radicals [7] which, nevertheless must be intrinsically related to the original hydrocarbons.

2. THF and DME dried over K/Na alloy. — Whereas on increasing the temperature the ESR spectrum of the benzene radical anion in LiCl-free solution exhibits the behavior observed by *Malinoski* and *Bruning* [8], we obtained in the presence of LiCl, the spectrum shown in Fig. 3 which

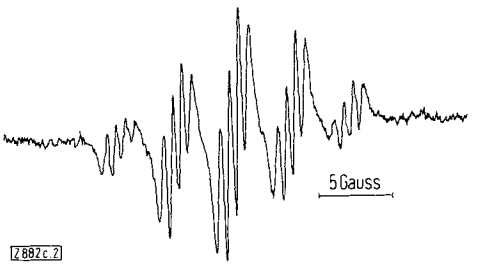

Fig. 3. ESR spectrum of the benzene radical anion in THF/DME (1:1) at −40 °C in the presence of LiCl; the solvent was dried over K/Na alloy. (The outermost groups of lines, intensity $^1/_{20}$ of that of the central groups, are just recognizable.)

indicates, by a quartet splitting of each of the seven lines of the "normal" $C_6H_6^-$ spectrum [9], an association with alkali metal cation.

In the presence of $LiAlH_4$, which was introduced into the reaction vessel under protective gas before the distillation of the residual components, we also observed in the case of benzene the 15 line spectrum shown in Fig. 2 when the temperature was raised.

Analysis of Foodstuffs with Particular Reference to Quality Control

The Foodstuff and Juridical Chemistry Group of the Gesellschaft Deutscher Chemiker and the Selskabet for Levnedsmiddelteknologi og -hygiejne, anerkendt selskab under Dansk Ingeniørforening, held a joint meeting in Kiel from 17 to 19 September 1968. Four of the fourteen lectures are reported below.

Recent Results concerning the Fate of Sulfurous Acid in the Organism

By *W. Diemair* (Lecturer) and *G. Pfleiderer* [*]

In order to follow the fate of sulfite in the organism we first prepared $^{35}SO_3^{2-}$, by *Griess*'s method, namely, by evaporating copper sulfate and carrier-free $Na_2{}^{35}SO_4$ solution on a water bath to complete dryness (87% yield). The yield measured with a Packard liquid scintillation spectrometer was 94%.

Sulfite can be determined in biological material by *Engelhardt*'s method, namely, distillation in a modified Reith-Willems apparatus with Tillmann's reagent. For determination of ^{35}S the organic tissues were freeze-dried. Combustion in pure oxygen and absorption of the radioactive gaseous combustion residues permits the very tedious chemical oxidation of the ^{35}S compound to be avoided. The apparatus described by *Kalberer* and *Rutschmann* was used.

It was observed that sulfite taken perorally is oxidized rapidly but not completely in the ileum. All ions resobed in the ileum proceed first to the liver; the rapid diminution in the amount of sulfite indicates a sulfite oxidase activity in *Lang*'s sense. The proportion of sulfite oxidized in the ileum is smaller the emptier are the stomach and ileum. After 40 min most of the sulfite in the jejunum is already oxidized to the extent of 40%. The residual sulfite is excreted almost wholly through the kidneys. Sulfite can be detected only in traces in the liver. At least in the liver the total activity is accounted for as sulfate; introduction of ^{35}S from sulfite is not observed.

Studies of the Occurrence of Aflatoxin B_1, Migration and Changes in Content in the Preparation of Some Foods

By *E. Hanssen* [*]

Aflatoxin B_1 can be formed by *Aspergillus* [1–4] and other types of mold [2], being contained both in the mycelium and in the spores of this mycotoxin. That means that foodstuffs may have toxic action even if not visibly contaminated with mold. *Penicillium* species seem particularly liable to form aflatoxin. In *Penicillium* species discovered on preserved gherkins, stored at a temperature of 4 °C, we found 0.150 ppm of aflatoxin B_1, and in orange peel on which *Penicillium* was growing we found 0.010 ppm.

The medium must fulfil definite requirements for growth of *Aspergillus flavus* [5]. We found that there is a minimum of vitamin B content necessary for its growth. It could not be grown on white bread dough or biscuit dough (vitamin B_1 content 0.50 ppm), though it grows very well on whole wheat dough (vitamin B_1 content 3.00 ppm). We have followed the separation of aflatoxin in the interior of the attacked material, in a foodstuff whose cell structure had been destroyed (whole wheat dough), and in a foodstuff with undamaged cell structure (opened coconut). After about one week the content of aflatoxin B_1 in the mycellium was 0.250 ppm; in the layer 7 mm below the mycellium it was about 0.085 ppm, both for cellular and non-cellular material. In the lowest layers (between 2 and 7 cm) we found a very high content of aflatoxin (about 0.800 ppm).

The aflatoxin B_1 content of peanuts is decreased by 40% on dry roasting (130 °C, 5 min); it is reduced by about 20% of the original content on oil roasting (120–150 °C, 6 min).

Fluorimetric Determination of Some Antioxidants

By *H.-P. Thier* [*]

Alkyle sters of gallic acid, dihydronorguaiaretic acid (NDGA), and the mixture of 2- and 3-*tert*-butyl-4-hydroxyanisole (BHA) (2- and 3-*tert*-butyl-4-methoxyphenol) are used in many countries as antioxidants for fats and fatty foodstuffs. Sensitive fluorimetric methods have been worked out for their quantitative determination.

Treatment in dimethylformamide/water (85:15) with 1% of ethylene diamine is suitable for the determination of 0.01 to 10 μg/ml of the gallic esters. A blue fluorescence (λ_{max} = 455 nm) is formed, which is measured after 2–3 h; its intensity is greatest for the propyl ester.

Condensing the guaiaretic acid with 5% of ethylene diamine in methanol/water (7:3) leads to a product that fluoresces green (λ_{max} = 530 nm). The intensity of fluorescence is measured after 7–24 h, enabling 0.1–5 μg/ml of the acid to be determined quantitatively. Gallic esters must be removed previously.

When dissolved in acetonitrile and oxidized with cerium(IV) sulfate in sulfuric acid, both the methoxyphenols gave 2-*tert*-butyl-*p*-benzoquinone. When taken up in chloroform, this quinone reacts with a 0.02% solution of potassium cyanide in dimethyl sulfoxide/water (96:4) in 20 min, yielding 5-*tert*-butyl-2,3-dicyanohydroquinone, which fluoresces blue (λ_{max} = 475nm), whence 0.5–5 μg/ml of total methoxyphenol can be determined.

Trypsin and Chymotrypsin Inhibitors in Foodstuffs

By *J. Weder* (Lecturer) and *H.-D. Belitz* [*]

Trypsin and chymotrypsin inhibitors have been shown to be present in a very large number of foodstuffs, *e.g.*, in milk, in egg-white, in some animal organs, and in legumes, potatoes, root crops, and cereals. Disturbances in which these inhibitors seem to have played a part have been observed from time to time when these materials were fed to animals or man. The inhibitors can be completely destroyed by sufficient heat treatment. Data in the literature and our own observation [1] show that, for instance in legumes, the thermal stability of the trypsin and chymotrypsin inhibitors can vary very greatly from species to species.

To obtain more precise information about this differing behavior, we have isolated the trypsin and chymotrypsin inhibitors from the legumes *Pisum sativum* var. *balticum*, *P. sativum* var. *Schneebergeri*, *Phaseolus vulgaris* var. *nanus*, *Ph. coccineus*, *Lathyrus odoratus*, and *Vicia faba*, by extraction of the ground seeds with H_2SO_4 and fractional precipitation with ammonium sulfate or, for *Vicia faba*, with acetone. The specific activities of these crude inhibitors were 0.2 to 1.6 TIE ^{cas}/mg [**] and 0.3 to 0.8 CTIE ^{cas}/mg, or, for *Vicia faba*, 83 TIE ^{cas}/mg and 54 CTIE ^{cas}/mg. The pure inhibitor obtained, as described by *Werle et al.* [2], from *Lathyrus odoratus* by use of an insoluble trypsin derivative had 30 times the activity of the crude preparation.

The following molecular weights were found by gel filtration on Sephadex G 50 (sequence as above): 10800 and 15800 (2 fractions), 10900, 17100, 14600, 11700, and 10200. No correlation could be found between thermal stability and molecular weight.

The pure inhibitor from *Lathyrus odoratus* had a strikingly high cysteine content, and an excess of acidic over basic amino acids, but methionine was absent.

SELECTED ABSTRACTS

The growth of anodic mercuric sulfide films on a mercury electrode in solutions containing sulfide and the effect of such films on the anodic dissolution of mercury have been studied by *R. D. Armstrong, D. F. Porter*, and *H. R. Thirsk* by measurement of potentiostatic switching curves. In the initial stage of film formation, black mercuric sulfide (metacinnabarite, identified by electron diffraction) is deposited on the electrode surface in two successive monolayers. Each of these layers considerably reduces the rate of dissolution of mercury to form HgS_2^{2-}. The current-voltage curve shows a discontinuity for the formation of each monolayer of HgS. It is mentioned that passivation processes on solid metal electrodes could be similar in nature. / J. physic. Chemistry *72*, 2300 (1968) / –Hz. [Rd 921 IE]

The reaction of mercury atoms with chlorine atoms has been investigated by *D. G. Horne, R. Gosavi*, and *O. P. Strausz*. The chlorine atoms were obtained by flash photolysis of CF_3Cl sensitized by mercury vapor; the kinetics of the reaction were deduced from the absorption of HgCl at 2790 Å. The extinction coefficient of HgCl at 2790 Å was determined as $(1.6 \pm 0.6) \cdot 10^5$ mole^{-1} cm^{-1}; the rate constant (second order) of the reaction amounts to $3 \cdot 10^{10}$ mole^{-1} sec^{-1} in 720 torr CF_3Cl and $0.9 \cdot 10^{10}$ mole^{-1} sec^{-1} in 10 torr CF_3Cl + 710 torr Ar, and it is temperature-independent between 110 and 170 °C. The rate constant (second order) of dimerization of HgCl in the gas mixtures named has the value $(3.0 \pm 1.8) \cdot 10^{11}$ or $(1.9 \pm 1.3) \cdot 10^{11}$ mole^{-1} sec^{-1}. / J. chem. Physics *48*, 4758 (1968) / –Hz. [Rd 925 IE]

The superconducting properties of ternary intermetallic compounds having a β-tungsten structure were studied by *G. Otto*. The samples, which all had the composition $Nb_3(X_{1-x}M_x)$ with X = Al, Sn, or Ga and M = Ga, Ge, In, or Sn, were obtained by melting the powder-form elements under argon in an electric arc and were studied in the quenched and in the tempered state. In order to relate the transition temperature to other quantities that were not directly dependent on superconductivity, the lattice constants and micro-hardness of the samples were measured. The highest transition temperature was found for $Nb_3(Al_{0.7}Ge_{0.3})$ at 20.05 °K. As x varies in a mixed-crystal series the transition temperature passes through a maximum when a valence electron density of 0.26 Å^{-3} is reached. Further, the lowest micro-hardness and the highest transition temperature occur together in one mixed-crystal series. Tempering raises the transition temperature over that of the quenched sample by a maximum of 1.3 °C. / Z. Physik *215*, 323 (1968) / –Hz. [Rd 926 IE]

The course of the synthesis of cyclooctatetraene by tetramerization of acetylene in the presence of nickel compounds has been the subject of attempted quantum-chemical explanation by *E.-A. Reinsch*. As well as fixing the geometrical relations of the four acetylene molecules in a complex *cis*-$[Ni(C_2H_2)_4X_2]$ where X is a further unidentate ligand, the nickel has the function of orienting two unpaired electrons spatially to two acetylene ligands in such a way that a new C–C bond can be formed. The orbitals necessary for this catalytic assistance are singly occupied only in magnetically normal d^8 complexes (high spin); other electron configurations do not come into consideration for this purpose. The special feature of paramagnetic nickel complexes in catalysis of this reaction is thus explained. / Theor. chim. Acta *11*, 296 (1968) / –Hz. [Rd 927 IE]

Amide ions NH_2^- as color centers in crystalline KCl, KBr, and KI were investigated by *R. Windheim*. In an electric field or under uniaxial mechanical strain the crystals show peculiarities due to the fact that the color centers are not centrosymmetric; the oscillator strengths of the UV bands at 295 nm are larger in the HNH plane than perpendicular to it. The NH_2^- ions orient themselves, so far as possible, with their dipoles in the (100) direction. The orientation favored under uniaxial strain is that where the protons are separated as

widely as possible from their nearest K^+ neighbor. The dipole moment of NH_2^- in KCl and KBr is 0.23 D (that of the amide radical 0.26 D), but in KI it is 0.44 D. The large difference is explained by assuming that in the large I^- anion holes the NH_2^- is not central but lies towards the edge, thus creating an addition to the dipole moment. / Z. Physik *215*, 152 (1968) / –Hz.

[Rd 928 IE]

The reaction cross-section of ammonium salts for scattering of subthermal neutrons (wavelength 8.5 Å) as a function of temperature has been evaluated by *P. S. Leung, T. I. Taylor,* and *W. W. Havens jr.* The increase S_T in the reaction cross-section, calculated for each hydrogen atom and for unit change of temperature, does not change appreciably in the region of the lambda transformations, which correspond to the change from ordered to disordered spatial orientation of the NH_4 ions; on the other hand, for the chloride, bromide, and iodide the reaction cross-section per H atom increases as much as 18–20 barn (1 barn = 10^{-24} cm^2) at the transformation point of first order, where the torsional vibration of the NH_4 ions passes into relatively free rotation and, in this connection, the CsCl structure is substituted by the NaCl structure. S_T increases in a defined manner with decreasing torsional frequency or rotation potential threshold. Calibration of the values for the halides enabled the hitherto unknown rotation-potential thresholds for ammonium sulfate (3.4 kcal/mole) and perchlorate (0.4 kcal/mole) to be determined. For the halides, hindrance to free rotation in the NaCl phase decreases in the order Cl, Br, I. / J. chem. Physics *48*, 4912 (1968) / –Hz.

[Rd 929 IE]

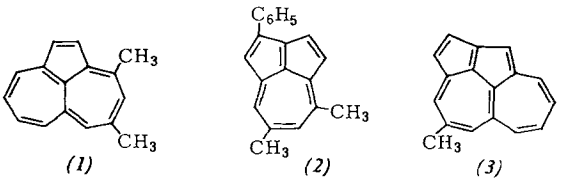
Shifts in the fluorescence bands at different wavelengths of excitation were observed by *A. N. Fletcher* for the following organic compounds: 2-aminopurine, biphenyl-2,2'-diol, 6-methoxy- and 6-ethoxy-quinaldine, 3-aminophthalhydrazide, 6-methoxyquinoline, and quinine. The effect depends on the presence of rotatable auxochromic groups in the molecule and on the solvent; shifts of up to 50 nm in the emission maximum can occur. To explain the effect it is assumed that the molecule can exist in at least two conformations which are stabilized or destabilized by the solvent to different extents in the ground and the excited state. A change in the wavelength of excitation then leads to a change in the distribution of the excitation energy between the two conformers and thus to a shift in the emission. It should be noted that quinine, which is used as a fluorescence standard, also shows this effect! / J. physic. Chemistry *72*, 2742 (1968) / –Hz.

[Rd 930 IE]

Proof of the existence of I_4 in iodine vapor has been provided by *A. A. Passchier* and *N. W. Gregory*. The temperature- and pressure-dependence of the absorption band at 265 nm, to which both I_2 and I_4 contribute, was used to determine the equilibrium constants of the reaction $2\ I_2 \rightleftharpoons I_4$ between 150 and 420 °C, and thence the bond enthalpy $\Delta H^\circ_{605\,°K} = -2.9 \pm 0.4$ kcal/mole and the bond entropy $\Delta S_{605} = 123 \pm 2$ cl/mole. These values are those to be expected if only van der Waals forces are effective between the two iodine molecules. As an example of how little I_4 is formed it is stated that at 240 °C and 2.5 atm total pressure, only 1.4% of the vapor exists as I_4. / J. physic. Chem. *72*, 2697 (1968) / –Hz.

[Rd 931 IE]

The fluorescence of *peri*-condensed non-alternant polycyclic hydrocarbons has been studied by *R. C. Dhingra* and *J. A. Poole*. Like azulene, *(1)* and *(2)* show fluorescence from the second excited singlet state. The absorption spectrum of *(3)*

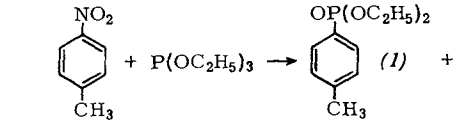


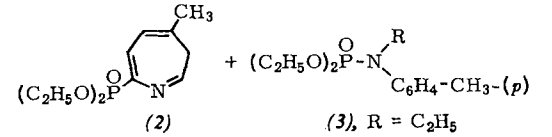
(1) *(2)* *(3)*

is not wholly assigned, but the fluorescent state is in this case also at least the second, and perhaps a still higher, singlet state. Normal fluorescence from the first singlet state was not found in a single case. / J. chem. Physics *48*, 4829 (1968) / –Hz.

[Rd 934 IE]

A new possibility of removing nitro groups from non-activated nitro compounds such as *p*-nitrotoluene is described by *J. I. G. Cadogan, D. J. Sears,* and *D. M. Smith*. Reaction of boiling triethyl phosphite with *p*-nitrotoluene gives 5% of diethyl *p*-toluenephosphonate *(1)* together with 6% of diethyl 4-methyl-3*H*-azepine-7-phosphonate *(2)*, 24% of diethyl *N*-ethyl-*N*-*p*-tolylphosphoramide *(3)*, and 26% of diethyl *N*-*p*-

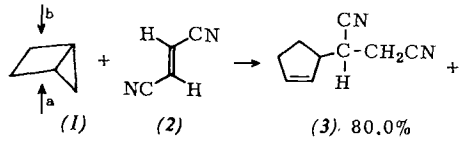




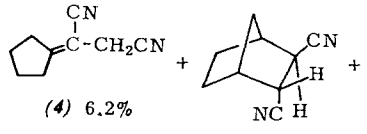
tolylphosphoramide *(4)*. *p*-Nitroanisole and *p*-ethylnitrobenzene behave analogously. *o*- and *m*-Nitro analogs cannot be converted into diethyl arylphosphonates. / Chem. Commun. *1968*, 1107 / –Ma.

[Rd 936 IE]

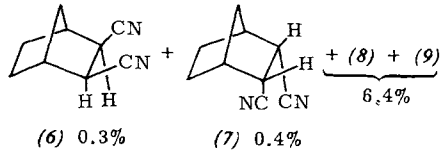
The mechanism and stereochemistry of the addition of olefins to bicyclo[2.1.0]pentane *(1)* were studied by *P. G. Gassman, K. T. Mansfield,* and *T. J. Murphy*. On using fumarodinitrile *(2)* they obtained compounds *(3)*–*(7)* in the relative yields



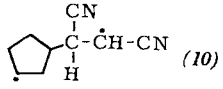
(1) *(2)* *(3)* 80.0%



(4) 6.2% *(5)* 6.7%



(6) 0.3% *(7)* 0.4%



(10)

shown, together with two unidentified products *(8)* and *(9)*. Use of maleodinitrile afforded the same compounds, yields being 88.7, 2.2, 1.2, 2.1, 3.0, and 2.8% [for *(8)* + *(9)*], respectively. This can be explained only by assuming an intermediate stage that permits rotation. Since *(3)*–*(7)*, as well as fumaro- and maleo-dinitrile are stable under the reaction conditions and a zwitterionic intermediate was previously excluded, the intermediate product must be the diradical *(10)*. The question whether the olefin approaches the bicyclic system from "below" (a) or "above" (b) could be answered by studying addition of maleic anhydride to [2,3-D_2]bicyclo[2.1.0]pentane *(1)*; the olefin approaches from "below". / J. Amer. chem. Soc. *90*, 4746 (1968) / –Kr.

[Rd 940 IE]

The adsorption of trace elements from sea water on to the surface of containers has been studied by *D. E. Robertson* for the radioactive isotopes ^{46}Sc, ^{59}Fe, ^{60}Co, ^{65}Zn, ^{85}Sr, ^{86}Rb, ^{110}Ag, ^{114}In, ^{124}Sb, ^{134}Cs, and ^{235}U, when these are added to the sea water as soluble salts. After storage for 20 days at the normal pH (8.0) of sea water in polyethylene flasks, indium, scandium, and iron were adsorbed to the extent of about 95, 45, and 40%, respectively; losses of the other elements remained below 20%. Except for scandium and iron, the losses on Pyrex glass were less than 10%. Polyethylene containers came off best when the sea water was acidified to pH = 1.5; then, after 20 days, only about half of the scandium had been adsorbed, while the amounts for other elements were less than 10%. / Analyt. Chim. Acta *42*, 533 (1968) / –Kr.

[Rd 937 IE]

Bis(triphenylstannyl)mercury *(1)*, the first compound containing a Hg–Sn linkage, was obtained by *C. Eaborn, A. R. Thompson,* and *D. R. M. Walton,* as a yellow solid, on treatment of triphenylstannane with bis[bis(trimethylsilyl)amido]-mercury at room temperature:

$$2\,(C_6H_5)_3SnH + Hg[N(Si(CH_3)_3)_2]_2 \rightarrow Hg[Sn(C_6H_5)_3]_2 + 2\,[(CH_3)_3Si]_2NH$$

(1)

(1) is stable for several months in the dark at room temperature, but decomposes rapidly in light, in solution, or when heated. The Hg–Sn bond is not formed from triethylstannane and dibenzylmercury at 100 °C or from bromotriphenylstannane and sodium amalgam, the analogy to Hg–Si and Hg–Ge bonds failing. / Chem. Commun. *1968*, 1051 / –Kr.

[Rd 938 IE]

BOOK REVIEWS

Chromatographisches Praktikum (Practical Chromatography). By *G. Hesse*. Vol. 6 in the series "Methoden der Analyse in der Chemie" (Methods of Analysis in Chemistry) edited by *F. Hecht, R. Kaiser, H. Kriegsmann,* and *W. Simon*. Akademische Verlagsgesellschaft, Frankfurt/M. 1968. 1st Edit., 1967, 244 pp., 50 figs., 28 tables, linen. DM 39.–.

This book gives an introduction to the most important chromatographic procedures and describes in the two main chapters the chromatography of solutions (column, thin-layer, and paper chromatography) and gas chromatography. The above procedures and their variants are described with the aid of numerous easily reproducible examples. The author addresses himself predominantly to chemistry and biology students in their final year at school or the first year at university. The comprehensive presentation of chromatographic methods and the emphasis laid on their essential similarity are particularly welcome. Theoretical explanations are only given insofar as they are necessary for the solution of examples. Anyone who has worked through the experiments should have no difficulty in solving problems of separation in analogous cases.

With this selected class of readers in mind, it is of course understandable that various methods important in research (such as exchange chromatography of amino acids and nucleotides, countercurrent distribution, *etc.*) are mentioned only briefly or not at all. In conjunction with the connection between the activity of the adsorbent and the polarity of the substances and the eluent, so very important in practice, one would have liked to see – besides the eluotropic series (p. 27) – a reference to the 'microcircular technique' (*E. Stahl*) which often allows one to determine from TLC the proper conditions for separation on a column. The ninhydrin reaction (p. 103) is not solely a means for the detection of α-amino acids.

In accordance with the subtitle 'Introduction to the Critical Performance of Chromatographic Procedures' the possible pitfalls are clearly indicated in each chapter, especially in the section on 'Changes in Materials During Chromatography'. The convincing critical assessment of R_f values is particularly pleasing.

The reviewer finds the book very suitable as an introduction to the field of chromatographic separation.

W. Barz [NB 752 IE]

Fortschritte der Arzneimittelforschung. (Progress in Drug Research). Volume 10. Edited by *E. Jucker*. Birkhäuser Verlag, Basel-Stuttgart 1966. 1st Edit., 603 pp., DM 128.–.

The introductory article, "Drug Research – Whence and Whither", to this new volume[2] has been written by *R. G. Denkewalter* and *M. Tishler*. After a short historical introduction, the authors attempt to sketch out the position of pharmaceutical research in the present day and in the future, and to fathom and establish the factors that could play an important role. In so doing, they point to the uncertainty of all predictions: "The true nature of a discovery is that it is unexpected" (31 pages). – The article by *G. Ehrhart* "Considerations on the Development of Medicaments" deals with a number of examples; the author refers to the fact that "significant advances can only be made when new territory is opened up by new fundamental discoveries" (13 pages). – *J. H. Beil* and *B. K. B. Lum* give a 36-page review of "The β-Andrenergic Blocking Agents, Pharmacology and Structure-Activity Relationships". After a critical discussion of the receptor theory, relationships are considered between chemical constitution and exciting or blocking action, a number of relevant compounds are listed, and their clinical pharmacology is briefly touched upon (165 references).

[1] Angew. Chem. *79*, 911 (1967); Angew. Chem. internat. Edit. *6*, 892 (1967).

[2] Cf. Angew. Chem. *79*, 386 (1967); Angew. Chem. internat. Edit. *6*, 892 (1967).

A 45-page report on "Value and Valuation of Drugs" has been written by *J. Büchli*. A short introduction on the development of drugs and the role played therein by the pharmaceutical industry precedes a discussion of methods used in their evaluation: analytical-chemical methods, pharmacological problems regarding mechanism of action, toxicity and side effects, and the carrying out and evaluation of clinical tests. The chapter (64 references) closes with a section dealing with state controls in a number of countries. – The article by *C. A. Winter* "Nonsteroid Antiinflammatory Agents" covers 50 pages. A short introduction on the nature and mechanism of the formation of inflammation and chemical intermediate carriers that could play a role is followed by a description of methods for the production of inflammation in animal experiments, a special section being devoted to arthritis, which is regarded as a symptom but not as a primary cause. Finally, the groups of antiinflammatory compounds are discussed. The relatively sparse and uncertain results regarding theory and therapy of diseases of connective tissue invite further research into this important topic (64 pages, 500 references). – There follows a detailed 156-page treatment of "The Effect of Form on the Action of a Drug" by *K. Münzel* (472 references). "The therapeutic action of a medicament undoubtedly depends mainly on its chemical structure..... The action can, however, be influenced decisively and changed by the form in which the pharmaceutical is administered", as is shown with the aid of many examples.

A review of "New Drugs" is given by *W. Kunz*. The many new introductions are arranged in groups according to their applications, and subdivided further according to parent substance. The structural formula, trade name, and international name are given for each substance (69 pages, 419 references). The theme "Molecular Pharmacology, a Basis for Drug Design" is dealt with in 101 pages by *E. J. Ariens*. A discussion of the mode of action, based mainly on the receptor theory, represents a starting point for positive planning (numerous structural formulas, 384 references).

The volume closes with an article by *F. Labhardt* dealing with "The Application of Psychopharmaceuticals in Psychosomatic Medicine". A short introduction on the term psychosomatic medicine and a statement of the problems involved precede a discussion of the most important psychosomatic disturbances and their symptoms, and of relevant methods of investigation. There follows a consideration of modern psychopharmaceuticals and their applications, dosages, and side effects. Finally the author points out that, in spite of the proportions that psychopharmacotherapy has assumed in recent years, a certain degree of uncertainty still surrounds its effects, a fact that invites further scientific research and clinical observation (84 references). – A detailed subject index for the present volume and indexes of the authors and articles in the ten volumes that have so far been published increases the value of the series. The production of the book, with its many figures, tables, and structural formulas, is once again exemplary.

O. Schaumann [NB 744 IE]

Fortschritte der Arzneimittelforschung (Progress in Drug Research) Vol. 11. Edited by *E. Jucker*. Birkhäuser-Verlag, Basel-Stuttgart 1968 1st Edit., 572 pp., numerous figs. and tables, bound DM 116.–.

In a 37-page paper entitled "Mescaline and Related Compounds" *A. R. Patel* reports on their natural occurrence, their biogenesis, the various syntheses, their physical constants, and the analytical methods. The behavior of mescaline in the body and its biochemical and neurophysical action on animals and men are then discussed, as well as the theory of the mechanism of this effect. Finally, there is a brief section on the derivatives of mescaline (370 references).

"The Photochemistry of Drugs and Related Substances" is discussed by *S. T. Reid* with the aid of more than 300 structural formulas and 500 references. After a brief theoretical introduction concerning the mechanism of photochemical transformation, each class of compounds is discussed separately (alkenes, dienes, trienes, aldehydes, ketones, aromatics, and finally nitrogen-containing compounds) (72 pp.).

An extensive report on "Investigations on the Biochemistry and Pharmacology of Thymoleptics" is given by *M. H. Bickel*. With the introduction of the iminodibenzyl derivative imipramine (Tofranil ®) in 1958 as a prototype thymoleptic, a new and successful era began in the drug treatment of endogenous depressions. The next sections give a detailed description of the testing methods, metabolism, the relationship between constitution and action, as well as the manner of action of compounds in this class (102 pp., 475 references).

A very extensive report on "Oral Anticoagulants" is given by *E. Renk* and *W. G. Stoll*. The chemistry of coumarin and 1,3-indanedione is discussed first, with reference to their constitution and methods of synthesis and to the relationships between constitution and action. This is followed by a section on the physiology of coagulation and its inhibition by substances contained in the body, as well as the influence of synthetic compounds on this process. After a discussion of the general pharmacology and the metabolism of anticoagulants, the report finishes with a detailed section on their therapeutic application (129 pp., 899 references).

A. Kreutzberger reports on "The Amidine Structure in Pharmaceutical Research" (87 pp.). Following an historical introduction the syntheses are described and the naturally occurring amidines listed. This is followed by a discussion of their therapeutic applications, as antidiabetics, as antiprotozoan and antibacterial agents, as well as cytostatics, local anesthetics, and virostatics. The reading of this very full report is simplified by the inclusion of 400 structural formulas.

The present volume is made particularly valuable by the inclusion of a general subject index of all 11 published volumes, which lists about 14,000 entries in 115 pages and thus makes the whole work into an invaluable source of information. Once again the book ends with an author index and a list of contents of the volumes already published. The production is again exemplary.

O. Schaumann [NB 753 IE]

The Mass Spectra of Organic Molecules. By *J. H. Beynon, R. A. Saunders*, and *A. E. Williams*. Elsevier Publishing Company, Amsterdam-London-New York, 1968. 1st Edit., ix, 510 pp., 181 figs., 20 tables, bound, Dfl. 97.50.

One of the first books in which mass-spectrometric methods were collected for the chemist was *J. H. Beynon*'s "Mass Spectrometry and its Application to Organic Chemistry", published in 1960[1]. *J. H. Beynon, R. A. Saunders*, and *A. E. Williams* have now again attempted to collect and compare the often widely scattered information given in the literature. Comparison of equivalent chapters in the two books dealing with fundamental apparatus and methods of mass spectrometry shows that the new book does not replace the earlier monograph but rather supplements it. While in the former the mass spectrometers and measuring techniques were fully discussed in more than 300 pages, the authors summarize this subject in the present work in 37 pages. Because of this cramped presentation, a newcomer to the field receives only an inadequate impression of the problems connected with the recording and evaluation of mass spectra.

The book is mainly intended to give instruction and assistance in mass-spectrometric structural analysis of organic compounds. To avoid errors, it is necessary to know the properties of the ionic types formed in the mass spectrometer. These are discussed in the second chapter, which contains a full and very good section on metastable ions. The formation of rearranged ions, which often gives rise to great difficulties in structural analysis, is explained. At this point one would

[1] Cf. Angew. Chem. *73*, 634 (1961).

have liked to see a reference to the work of *Brown* and *Djerassi*[2], which forms a good supplement to this section of the book.

The work presented to date on the mass-spectrometric behavior of organic substances has shown that mass spectra are determined by the heteroatoms and the functional groups. In discussing mass spectra, the authors have therefore classified the organic compounds according to their heteroatoms, as hydrocarbons and compounds of oxygen, nitrogen, sulfur, halogens, boron, phosphorus, and silicon. It is understandable that this classification is somewhat arbitrary if several different heteroatoms are present in the molecule. However, the index at the end of the book simplifies the search for a particular class of compounds.

The important characteristics necessary for identification and structural analysis are here presented more forcibly than in similar works, without necessarily a full discussion of the mechanism by which the fragments are formed. The treatment covers not only the mass spectra of monofunctional compounds, which gave a particularly clear picture of fragmentation, but also the mass spectra of polyfunctional compounds and natural products with complicated structures, such as steroids. The methods of mass-spectrometric structure analysis are illustrated by numerous well-chosen examples. The possibilities and limits of the method are discussed in the concluding chapter, with reference to 17 examples.

Random checks have shown that the literature up to 1967 has not, after all, been covered completely. This limits to some extent the use of the book as a reference work, as is suggested by the text of the dust-cover. The book can be recommended as an extensive introduction to organic mass spectrometry and as a good introduction to mass-spectrometric structure analysis. *H. F. Grützmacher* [NB 749 IE]

Chemie der Eiweisskörper (The Chemistry of Proteins). By *E. Waldschmidt-Leitz* and *O. Kirchmeier*. Ferdinand Enke-Verlag, Stuttgart 1968. 3rd Edit., xi, 258 pp., 8 illustrations, 37 tables. Cloth-bound DM 57.00.

The long established work under review has been extended by a few chapters to indicate the new developments that have taken place since the publication of the 2nd edition. The description of the synthesis and degradation of amino acids in living organisms deserves especial mention. The reader is given a good and concise review with ample literature references.

The book deals primarily with the classical chemistry of amino acids (coherent treatments of this subject are hard to find), with the synthesis, preparation, and structure analyses of peptides, the properties of proteins, and elucidation of their amino-acid sequences, and finally describes, in brief, a considerable number of proteins. In only a few instances would it have been desirable to discuss new developments in greater detail, *e.g.* the denaturation of proteins or the determination of the tertiary and quaternary structures of proteins as they are known today. All chapters are carefully supported by literature citations, which enables the student to deepen his understanding by contact with the original work. The book is well produced and, as usual, the presentation is very clear; in all, it is a very suitable reference work. *H. Fasold* [NB 760 IE]

Atlas of Electron Spin Resonance Spectra. By *B. H. J. Bielski* and *J. M. Gębicki*. Academic Press Inc., London-New York 1967. 1st Edit., xiii, 664 pp., numerous figures and tables, bound, $ 27.00.

A collection of ESR spectra has long been awaited by research workers in this field. The two authors must be commended for undertaking this laborious task of collecting spectra from the widely scattered data in the published literature. The atlas contains well over a thousand reproductions of ESR spectra derived from paramagnetic species in solution, in gases, in glasses, and in powders – but not, however, in single crystals. The reproductions are neatly executed and well arranged. Most of the spectra were published before the end of 1964; only a few are taken from more recent or from unpublished work. A certain selectivity limits the completeness of the work, but increases its reliability. No attempt has been made to verify the correctness of the data. Apart from the ESR spectra, ancillary information – such as the paramagnetic species, their preparation, the recording conditions, and coupling constants – is listed.

While the atlas largely comes up to our expectations, indeed its usefulness has already been proved several times in the reviewer's laboratory, certain shortcomings should not be overlooked. In the first place, the spectra have not been selected carefully enough. This is particularly true of the spectra of radicals that have been recorded under similar conditions, without essentially differing from each other. Such spectra could have been omitted, together with the line diagrams showing the schematic hyperfine structure, which are largely superfluous. The spin densities calculated from the measured coupling constants using a somewhat arbitrary proportionality factor are also unnecessary.

Frequent errors are found in the formulas of the paramagnetic species and in the coupling constants indicated. For instance three different formulas are used for the three spectra given for the allyl radicals (pp. 29 and 30):

$CH_2{=}CH{-}\dot{C}H_2$; $CH_2{=}CH{-}\dot{C}H_2 + \dot{C}H_2{-}CH{=}CH_2$; and $H_2C{=}CH{=}CH_2$. They appear as different species; moreover, in the mesomeric notation the + sign should be replaced by the usual double-headed arrow (↔).

The radical cation whose spectrum is reproduced on p. 538 was obtained from 1,3,6,8-tetraazapyrene and not from the 4,5,9,10-tetradeuterio derivative as quoted.

For the radical anion of pyrene the coupling constant of the two equivalent protons in positions 2 and 7 is erroneously given twice on p. 533 ($a_2^H = -1.09$ G and $a_{2,7}^H = 1.05$ G). The first value is correct, apart from the incorrect negative sign which cannot be determined from the spectrum given.

The numerical indices of the coupling constants of the *p*-nitrotoluene radical anion (p. 628, top) are meaningless, since the numbering is missing on the corresponding formula. If the numbers are taken to be those normally used in chemical nomenclature for *p*-nitrotoluene they are actually misleading.

When all is said and done, however, this atlas is a very useful and commendable aid which every ESR laboratory should posses. Nevertheless, a critical approach is indicated, and it would be wise to consult the original literature at the same time. *F. Gerson* [NB 757 IE]

Nuclear Magnetic Resonance Spectra and Chemical Structure. Vol. 1: The Spectral NMR Parameters of Compounds with Analyzed Spectra. By *W. Brügel*. Academic Press, New York-London / Dr. Dietrich Steinkopff-Verlag, Darmstadt 1967. 1st Edit., xviii, 235 pp., loose-leaf, $ 35.00.

In comparison to the familiar "infra-red Brügel" the present volume offers not just another spectroscopic method but an entirely different selection. Whereas the older book was – and is – an introduction, this work is almost exclusively a summary, an ambitious atlas of spectra which no longer merely lists the spectra themselves, as produced by the spectrograph, but lists them in an extracted form.

To pass on to the form and content, it might be said that this is not really a book at all, but rather a file of medium thickness in the A 4 format. The work is divided into an introduction in German and English (7 pp.) tables (212 pp., English text), a bibliography (520 citations), and an alphabetical subject index (English, about 2500 entries).

[2] Cf. *P. Brown* and *C. Djerassi*, Angew. Chem. 79, 481 (1967); Angew. Chem. internat. Edit. 6, 477 (1967).

The part containing the tables is divided into two major groups. The first deals mainly with substances in which only the protons are capable of nuclear resonance, or in which only proton resonance was measured, and the second, relatively small, group contains data relating to nuclei other than H. Inorganic substances and polymers are not considered except for isotactic polystyrene. The tables contain the nuclear resonance parameters (chemical shift and coupling constants) of the particular substance, with the solvent used, its concentration, and the literature reference. Only those substances are listed whose spectra had been accurately evaluated. The literature has been included up to 1966.

The alphabetical division into 88 basic substances and their derivatives is very easy to refer to but in some cases a little confusing. The tables under the heading 'anthracene' or 'naphthalene' do not contain all the data on these compounds; the reader still has to refer to the voluminous chapter on benzene, under the subheading of 'condensed aromatics'. Numerous benzo compounds are listed under 'benzene', while others – like benzimidazole, benzofurazan, *etc.* – are listed under their own names. However, all the substances are easily found in the subject index.

This work has been printed on good, strong paper – a necessary precaution if frequent use is envisaged. It will be very useful to anyone engaged in the practice of nuclear resonance spectroscopy, not least because he can rely on the author's critical treatment of the literature.

This work should be brought up to date from time to time. Perhaps the recently published data on polymers could then also be taken into account. *D. Hummel* [NB 758 IE]

The Chemistry of Non-Aqueous Solvents. Vol. 1: Principles and Techniques. Edited by *J. J. Lagowski*. Academic Press, New York-London 1966. 1st Edit., xi, 403 pp., 18 figures, 6 tables, $ 16.50.

This book covers the more important aspects of reactions and physical measurements in non-aqueous media – including theoretical fundamentals – as well as the methods generally used in investigations in low-boiling media and molten salts. The following topics are treated: 1. Lewis acid-base exchange in polar non-aqueous media (*D. W. Meek*); 2. Solvation of electrolytes and solvent equilibria (*E. Price*); 3. Acid functions in amphiprotic media (*R. G. Bates*); Electrode potentials in non-aqueous solvents (*H. Strehlow*); 5. Solvent extraction of inorganic substances (*L. J. Katzin*); 6. Experimental techniques for low-boiling media (*J. Nassler*); 7. Experimental techniques for the investigation of molten salts (*R. A. Bailey* and *G. J. Janz*).

The first chapter is written in a fluent and easily understandable style. All essential aspects and modern points of view are discussed. The reader is first familiarized with the out-of-date concepts (*e.g.* $SOCl_2$ as electrolyte in liquid SO_2), which are appropiately corrected in another part of the book. This consideration of the historical course of the topic under review is an attractive and interesting feature of the work. The reviewer would, however, have preferred the text to have been based on more modern and up-to-date knowledge and the historical development to have been brought more into the margin.

Section 2 contains a precise and clearly arranged treatment of the influence of solvation on ionization equilibria. Modern techniques of investigation are taken into consideration, *e.g.* NMR measurements for the evaluation of interactions between cations and solvent molecules.

Section 3 is somewhat exacting and demands a great deal of the reader. For example, the reviewer is of the opinion that *Izmailov*'s ideas for the derivation of the solvation energy of the proton is treated far too briefly. However, it must be emphasized that the section as a whole is very clearly written. Section 4 is written with remarkable didactic skill. Those who are acquainted with the fundamentals of electrochemistry and thermodynamics will have very little difficulty in understanding this contribution. The reader is given such an excellent and impressive survey of the measurement and evaluation of electrode potentials in non-aqueous media that he has no need to refer to the original literature.

The author of Section 5 has been confronted with the difficult task of working through the extensive amount of original literature concerning the separation of substances by distribution between two solvents. He has, however, succeeded in compiling a representative review of the principles of the many methods presently being used.

Section 6 is of immense value to all chemists who are concerned with, or are likely to concern themselves with non-aqueous solutions. The techniques used for preparation of solutions are described mainly for lower-boiling media. Particular interest attaches to solutions of solids on which physical measurements or chemical reactions are to be carried out. All the physical methods that have become of importance in the chemistry of non-aqueous solvents, *e.g.* polarography, Raman spectroscopy, *etc.*, are so treated that one can perform experiments as a rule without further ado, mainly because of numerous and well illustrated figures of apparatus and experimental set-ups that have been included.

The experimental side is also to the fore in Section 7; however, for a complete understanding of the fundamentals of processes the necessary theoretical explanations are also included. Methods for the determination of magnetic susceptibility, electrochemical and spectroscopic methods, and methods for the investigation of transport phenomena are treated, as are also and techniques such as calorimetry cryoscopy. Adsorption chromatography and chemical reactions in molten salts are also dealt with.

All sections are supplemented with a fully comprehensive bibliography. This work, which will appear in several volumes, has closed a gap in the "secondary literature". For this reason, our thanks goes out to the editor, who has made a name for himself particularly through his investigations on solutions in liquid ammonia. All chemists with an interest, or potential interest, in the field of non-aqueous solutions will welcome the appearance of this work.

O. Schmitz-Du Mont [NB 745 IE]

Halogen Chemistry. Edited by *V. Gutmann*. Academic Press, London-New York 1967. Volume 2: 1st Edit., xii, 481 pp., many figures and tables, 115 s; Volume 3: 1st Edit., xiv, 471 pp., many figures and tables, 115 s.

In this three-volume work on halogen chemistry the editor gives a review of the present-day position of the subject. Unfortunately, the date of publication chosen is somewhat late, for a number of the topics dealt with have recently been treated in standard text books of fluorine chemistry and of inorganic chemistry.

Volume 2 is concerned primarily with preparative chemistry and with covalent halogen compounds; halogen oxides and halogen acids have, however, been rather neglected. Compounds of halogens with elements of the 3rd and 6th main groups are likewise unconsidered.

This volume contains the following chapters: 1. Sulfur-Nitrogen-Halogen Compounds (*O. Glemser* and *M. Fild*); 2. Fluorophosphoranes (*R. Schmutzler*); 3. Halides of Arsenic and Antimony (*L. Kolditz*): 4. Inorganic Silicon Halides (*E. Hengge*); 5. Organoelement Halides of Germanium, Tin, and Lead (*J. Ruidich, H. Schmidbauer,* and *H. Schumann*); 6. Equilibria Involving Halide Complexes in Aqueous Solution (*G. P. Haight jr.*); 7. Halogenation and Halogen Exchange in Fused Salt Media (*N. R. Thompson* and *B. Tittle*); and 8. Covalent Oxychlorides as Solvents (*V. Gutmann*).

The authors of the individual articles, who are undoubtedly experts in their fields, have all contributed to the development of halogen chemistry by their own work.

In the first five chapters, structures, fluorine magnetic resonance data, and a number of reaction mechanisms are given, in addition to chemical properties and reactions. The

articles are clearly arranged, make for easy reading, and are readily comprehensible. Chapter 6 describes the properties of halogen ions as ligands; chapter 8 deals with solvent properties of oxychlorides on the basis of a "solvent definition of acids and bases" and of a "coordination model of nonaqueous solutions". Chapter 7 provides a review of the application of salt melts in the preparation of fluorine-carbon compounds. The formation of complex ions in the melt is also discussed and examples of the manufacture of metals are given.

Volume 3 likewise contains eight chapters, the first three being devoted mainly to theoretical aspects of halogen chemistry. The others deal with the preparation and properties of metal-halogen compounds. 1. Halides containing Multicentered Metal-Metal Bonds (*D. L. Kepert* and *K. Vrieze*); 2. The Nature of the Metal-Halogen Bonds (*R. G. Pearson* and *R. J. Mawby*); 3. Review of Metal-Halogen Vibrational Frequencies (*R. J. H. Clark*); 4. The Halides of Niobium and Tantalum (*F. Fairbrother*); 5. Pentahalides of the Transition Metals (*A. D. Beveridge* and *H. C. Clark*); 6. Halide Chemistry of Chromium, Molybdenum, and Tungsten (*J. E. Fergusson*); 7. Halogen Chemistry of the Actinides (*K. W. Bagnall*); and 8. Halogeno-Metal Carbonyls and Related Compounds (*F. Calderazzo*).

Apart from the somewhat arbitrary choice of subject matter and a certain amount of duplication in the individual articles, these two volumes certainly represent a welcome addition for the chemist interested in these topics. With their help he can rapidly gain a comprehensive picture of the latest results in halogen research. Furthermore, since the volumes also contain various stimuli for further work they should on no account be absent from any chemical library.

A. Haas [NB 740 IE]

Porous Carbon Solids. Edited by *R. L. Bond.* Academic Press London-New York 1967, 1st Edit., xi, 311 pp., numerous illustrations and tables, bound $ 14.50 / 80 s.

This book deals with the possible methods for determining the pore structure of solids. The title is misleading insofar as nearly all the methods are generally applicable. Only in the results quoted as examples do synthetic graphites, activated carbons, and natural coals receive special treatment.

The theoretical and experimental aspects of the methods are described in eight sections in which, however, some procedures are treated too briefly. This is particularly true of the description of the evaluation of the gas adsorption isotherm which is the most important procedure in the determination of pores having a radius of less than 100 Å. Better and more detailed information on this subject can be found elsewhere. The recently developed t-plot method of *de Boer* and *Lippens* is not mentioned at all. The next section describes the possible methods of determining the pore size distribution by adsorption of molecules of various sizes from solutions and also by the use of gaseous molecular 'probes' which give a good measure of the molecular sieve properties of coals and narrow pore carbons. Density measurements by displacement of helium or liquids are also described. The characterization of pore structure by permeability measurements of gases and liquids is described very thoroughly and critically; the limits of validity of the theoretical assumptions are particularly discussed. The same is true of mercury porosimetry, the standard method for the determination of pore sizes with radii between 10 μ and 100 Å. The last chapters describe direct representation of relatively large pores, using radiographic methods. In this, the pores are filled with a liquid that absorbs X-rays more strongly than carbon, for instance liquid bismuth or silver

This book certainly enriches the literature, particularly in the treatment of the less well-known procedures. The reviewer especially liked the criticism of the various methods. The standard procedures are, however, described more clearly and thoroughly in other works. *H. P. Boehm* [NB 754 IE]

The Solid-Gas Interface. Vol. 2. Edited by *F. A. Flood.* Marcel Dekker Inc., New York 1967. 1st Edit., xiii, 660 pp., numerous illustrations, $ 27.50.

Shortly after the appearance of the first volume[1], which dealt essentially with the foundations and theory of physical adsorption, a second volume has now appeared. Acknowledged experts report on modern methods of measurement and their application to the problem of physical adsorption.

R. L. McIntosh deals with dielectric measurements on adsorption systems and discusses the results obtained. *P. W. Selwood* discusses the application of the investigation of magnetic properties of suitable systems for the study of adsorbent-adsorbate interactions and adsorption bonding.

In an extensive article *R. M. Barrer* treats the problems of material transport in porous media and in adsorption phases. *H. W. Habgood* deals with the theoretical foundations of gas chromatography and shows how this method can be applied to investigations on adsorption, in particular to the determination of adsorption isotherms and heats of adsorption. *S. Ross* and *E. D. Tolles* deal with the sorption of gases by solids covered with liquids. Finally, *W. Prins* discusses the take-up of adsorbate by the adsorbent and the resulting volume changes of the adsorbent.

The thermodynamic and kinetic aspects important in the study of adsorption are discussed by *B. E. Conway. P. J. Sereda* and *R. F. Feldman* show how the mechanical properties of the adsorbent are influenced by the presence of an adsorbate.

Measurements of surface potentials provide valuable information on bonding of the adsorbate. *F. C. Tompkins* deals with the most important methods of determination, discusses the results obtained in several systems, and comments on the conclusions to be drawn. By means of a band model *A. C. Zettlemoyer* and *R. D. Iyengar* discuss the interaction between adsorbates and semi-conductor surfaces.

The relationships during the impingment of a molecule on the surface of a solid and particularly its accommodation, is dealt with in two articles: *F. M. Devienne* deals mainly with the experimental results, and *E. A. Flood* and *J. P. Hobson* discuss the possibilities of a theoretical treatment of the problem.

J. N. Hodgons reports on the optical properties of the solid-gas interface; *C. H. Amberg* explains the methods and applications of IR spectroscopy.

The measurements of electron spin resonance and nuclear magnetic resonance, first applied to the study of adsorption only a few years ago, are described by *J. G. Aston*, and *M. J. D. Low* describes the application of the Mössbauer effect. *E. D. Eanes* and *A. S. Posner* put forward small-angle X-ray scattering as a valuable method of studying the adsorbing surfaces.

J. R. Dacey describes the adsorptive properties of activated carbon in comparison with other adsorbents. *B. G. Linsen* and *A. van den Heuvel* draw the reader's attention to the significance of pore structure in adsorption. The problem of hysteresis in the field of adsorption is discussed by *D. H. Everett.*

As in the first volume, *G. D. Halsey* ends by reviewing critically each chapter of the book.

This two-volume work is not a textbook on physical adsorption – the structure is too heterogeneous and the chapters are too little attuned to one another for this purpose. The book is rather directed to those already occupied with problems of adsorption, acquainting them with the most recent theoretical and experimental developments. The 1050 references in the first volume and those numbering over 2000, in the second volume include work from 1966. It should be particularly emphasized that not only are the commonly used methods dealt with, but also the more special procedures, often with very illuminating results. *G. Wedler* [NB 751 IE]

Zwierzak, A. 292 [G.E. 285]

SUBJECT INDEX

FP = Full paper (review article) CR = Conference report
SC = Short communication LA = Literature abstract
G.E. = Reference to the German Edition of Angewandte Chemie. References are given for Review Articles, Short Communications, and Conference Reports only.

ABSOLUTE configuration, of chlorophyll (SC) 221 [G.E. *80*, 233 (1968)]

~ of bacteriochlorophyll (SC) 222 [G.E. *80*, 234 (1968)]

~ of [2.2]paracyclophanecarboxylic acid (SC) 383 [G.E. *80*, 405 (1968)]

~ of (−)-threo-2-ethyl-3-methylsuccinic acid (SC) 543 [G.E. *80*, 562 (1968)]

Absorption spectra of liquids in the millimeter range (LA) 240

Adsorbed molecules, Optical excitation and ionization (CR) 401 [G.E. *80*, 368 (1968)]

Aceheptylene, Crystal structure and molecular structure of 3,5,8,10-tetramethyl-~ (SC) 543 [G.E. *80*, 564 (1968)]

Acenaphthylene, Structure and hydrolysis of the ate-complex from tritylsodium, ~ and triphenylborane (SC) 139 [G.E. *80*, 149 (1968)]

Acetonitrile, Mono-Na ~ and homologous compounds (LA) 238

Acetophenone, New photochemical reaction of ~ (LA) 237

Acetylacetone, Bis(chloromercuri)-2,4-pentanedione, an unusual ~ derivative (SC) 629 [G.E. *80*, 664 (1968)]

Acetylene, High-temperature synthesis of amino acids in the system ~/ammonia/carbon dioxide (SC) 392 [G.E. *80*, 396 (1968)]

Electrical properties of linear poly-~ (LA) 555

Acetylene compounds, Conversion into small-ring compounds (CR) 288 [G.E. *80*, 200 (1968)]

The trimethylsilyl group can be used as a protective group for terminal alkynes (LA) 311

N-Acetylphenylalanyl-tRNA (LA) 152

Acid-base catalysis, Elementary steps in ~. Proton transfer reactions in aqueous solutions (SC) 818 [G.E. *80*, 857 (1968)]

Acid-base titrations on powdered quartz (LA) 235

Acrolein, Some properties of 3-phenoxy-~ (CR) 227 [G.E. *80*, 200 (1968)]

Acrylic compounds, Acryl- und Methacrylverbindungen (Acrylic and Methacrylic Compounds) (Book Review) 484

Acrylonitrile as a hard and soft base in di-μ-acrylonitrilebis(tricarbonyliron) (SC) 222 [G.E. *80*, 239 (1968)]

β-Acylacrylates, New synthesis of esters of γ-keto acids and of ~ (LA) 482

Adamantane, New possibilities of direct substitution of ~ (SC) 894 [G.E. *80*, 970 (1968)]

$As_4(NCH_3)_6$ has an ~ structure (LA) 235

Unusually stable α-lactam derived from ~ (LA) 239

Spirohomo-~ (LA) 832

1-Adamantanecarbaldehydes, Synthesis (SC) 894 [G.E. *80*, 970 (1968)]

Adenosine triphosphate, Formation from adenosine diphosphate (ADP) and phosphate during oxidation of durohydroquinone monoacetate (SC) 213 [G.E. *80*, 190 (1968)]

Formation from adenosine diphosphate (ADP) and phosphate during oxidation of mercaptoacetate by bromine (SC) 893 [G.E. *80*, 915 (1968)]

Adhesion, Wetting and ~ behavior of liquid indium on solid aluminum (LA) 654

Treatise on ~ and Adhesives (Book Review) 319

Adhesives, Recent developments in the ~ field (FP) 598 [G.E. *80*, 641 (1968)]

Treatise on Adhesion and ~ (Book Review) 319

Adsorbents, New ~ suitable for thin layer chromatography (LA) 900

Adsorption, Studies on the ~ of gases on clean metal surfaces with the aid of field-emission and field-ion microscope techniques (FP) 668 [G.E. *80*, 673 (1968)]

Formation of electron-donor-acceptor complexes as a basis for specific ~ (SC) 948 [G.E. *80*, 1035 (1968)]

~ of alkali salts onto silica gel (LA) 483

~ of trace elements from sea water (LA) 959

Infrared Spectra of Adsorbed Species (Book Review) 486

~ from Solutions of Non-Electrolytes (Book Review) 746

Adsorption calorimetry (CR) 310 [G.E. *80*, 290 (1968)]

Aflatoxin B_1, Analysis of foodstuffs with particular reference to quality control (CR) 956 [G.E. *80*, 1003 (1968)]

Agglomeration, Investigations on the ~ of polymer latices (CR) 399 [G.E. *80*, 414 (1968)]

DL-Akuammigine, Synthesis and configuration of heterocyclic indole derivatives. Stereoselective total synthesis of ~ and DL-tetrahydroalstonine (CR) 552 [G.E. *80*, 536 (1968)]

Alcohol dehydrogenase, Benzyl ~ (LA) 312

Methanol is oxidized in *Pseudomonas* by an unusual ~ (LA) 314

Alcohols, Dehydration on aluminum oxide (FP) 791 [G.E. *80*, 778 (1968)]

Photochemical addition to purines (LA) 742

Aldehydes, Synthesis of (R)- and (S)-~ and -ketones from chiral sec-alkyl halides (SC) 620 [G.E. *80*, 618 (1968)]

Conversion of olefins into ~ (LA) 481

Aldol condensations, Directed ~ (FP) 7 [G.E. *80*, 8 (1968)]

Alicyclic chemistry, Advances in ~ (Book Review) 244

Alkaloids, Model reaction for the biosynthesis of the crinin ~ (SC) 223 [G.E. *80*, 238 (1968)]

Indole ~ (Book Review) 245

Introduction to the ~ (Book Review) 656

Alkanefluorodithiophosphonates, Volatile transition metal ~ (SC) 815 [G.E. *80*, 844 (1968)]

Alkenylamines, Formation of 3,4-diaza-1,3,5-hexatrienes from ~ and diazoalkanes (SC) 138 [G.E. *80*, 153 (1968)]

Cyclobutanones from ~ and ketenes by two-stage addition (SC) 737 [G.E. *80*, 759 (1968)]

New process for the synthesis of aminals and ~ (LA) 82

Alkenynylamine, New synthesis (SC) 209 [G.E. *80*, 193 (1968)]

Alkoxyalkylcarbene, Hydrogen-deuterium exchange in ~-transition metal complexes (SC) 390 [G.E. *80*, 402 (1968)]

Alkylation, Olefin ~ in biosynthesis (FP) 903 [G.E. *80*, 977 (1968)]

Abnormal reactions in ~ of silicon and germanium tetrahalides (CR) 310 [G.E. *80*, 321 (1968)]

para-Substitution in the Ziegler-Zeiser ~ (LA) 151

Alkyl halides, Reduction of organic compounds with chromium(II) salts (FP) 247 [G.E. *80*, 271 (1968)]

Alkylidenephosphoranes, Syntheses of cyclopropanes and azirines by means of ~ (CR) 640 [G.E. *80*, 628 (1968)]

Alkyl iodides, Synthesis (LA) 653

N-Alkylthioformamides, Separation and properties of the cis-trans-isomers (SC) 467 [G.E. *80*, 448 (1968)]

Alkynes, see Acetylene compounds

Allenes, Addition of 4,4,6-trimethyl-1,3,2-dioxaborinane (LA) 832

Allosterism, Properties of the allosteric forms of yeast glyceraldehyde-3-phosphate-dehydrogenase (CR) 401 [G.E. *80*, 369 (1968)]

Allyl alcohol, Molecular geometry (LA) 312

π-Allyl complexes, Bimetallic ~ of nickel and palladium (SC) 879 [G.E. *80*, 968 (1968)]

π-Allylpalladium chloride complexes, New method of preparation (LA) 238

Allylmalonic ester, Preparation of 1,4-dienes by reduction of sodio-~ with lithium aluminum hydride (SC) 61 [G.E. *80*, 44 (1968)]

Aluminum, Wetting and adhesion behavior of liquid indium on solid ~ (LA) 654

Aluminum compounds, Formation of polymethyl(methylene)aluminum (SC) 217 [G.E. *80*, 235 (1968)]

Polymerization reaction of trimethylaluminum (CR) 399 [G.E. *80*, 413 (1968)]

Dimer-monomer equilibrium of triethylaluminum in n-hexadecane solution (LA) 152

Aluminum oxide, Dehydration of alcohols on ~ (FP) 791 [G.E. *80*, 778 (1968)]

Aluminumphosphorus compounds, Formation and properties of medium and high molecular weight compounds of elements of groups 3, 4, and 5 (FP) 1 [G.E. *80*, 2 (1968)]

Amide ions NH_2^- as color centers in crystalline KCl, KBr, and KI (LA) 957

Amides, Sulfonyl hydrazones of cyclic ~ and quaternary azo sulfones of heterocycles as reagents in azo chemistry (FP) 335 [G.E. *80*, 343 (1968)]

Ethynylogous ~ and urethanes (SC) 459 [G.E. *80*, 443 (1968)]

Amidines, Cycloaddition of isocyanates and isothiocyanates to ~ and guanidines (SC) 291 [G.E. *80*, 281 (1968)]

Aminals, New process for the synthesis of ~ and enamines (LA) 82

Amines, Preparation, properties, and reactions of polychloroamine derivatives (FP) 856 [G.E. *80*, 942 (1968)]

The Gabriel synthesis of primary ~ (FP) 919 [G.E. *80*, 986 (1968)]

Synthesis of O,O-diethyl N,N-dichlorophosphoramidate and its use for the preparation of β-chloro ~ from olefins (SC) 292 [G.E. *80*, 285 (1968)]

Stereospecific synthesis of vicinal di-~ (LA) 81

Amine oxides, Aromatic ~ (Book Review) 833

Amino acids, Biosynthesis of aromatic ~ and its regulation (FP) 350 [G.E. *80*, 384 (1968)]

Synthesis of N-tert-butyloxycarbonyl- and N-tert-amyloxycarbonyl-~ (SC) 379 [G.E. *80*, 364 (1968)]

High-temperature synthesis of ~ in the system acetylene/ammonia/carbon dioxide (SC) 392 [G.E. *80*, 396 (1968)]

Degradation of fructose ~ to N-2-furoylmethyl-~ Intermediates in browning reactions (SC) 628 [G.E. *80*, 627 (1968)]

Synthesis of ~ from N,N-bis(trimethylsilyl)glycine esters (SC) 809 [G.E. *80*, 797 (1968)]

Synthesis of N-(*t*-butyloxycarbonyl)-~ (LA) 150

Three new α-~ (LA) 313

Photolysis of N-(2,4-dinitrophenyl)-α-~ (LA) 482

Amino acid complexes, Polarimetric study of simple and mixed metal-~ (CR) 228 [G.E. *80*, 201 (1968)]

N-Aminoaziridines, Preparation and rearrangements to hexulose hydrazones (SC) 134 [G.E. *80*, 120 (1968)]

4-Amino-4-deoxy-D-galactose, Synthesis of derivatives (SC) 458 [G.E. *80*, 441 (1968)]

Aminolysis, Structure of the products of ~ of aminopentachlorocyclotriphosphazenes (SC) 212 [G.E. *80*, 192 (1968)]

Kinetics of the ~ of methoxyphenylcarbenepentacarbonylchromium(0) (SC) 817 [G.E. *80*, 847 (1968)]

Aminopentachlorocyclotriphosphazenes Structure of the products of aminolysis (SC) 212 [G.E. *80*, 192 (1968)]

Aminphenols, Diazotizability in concentrated tetrafluoroboric acid (LA) 150

Aminophosphine imines, Diamino-tert-butylphosphine. – Synthesis and conversion into N-silylated ~ with nonequivalent replaceability of the hydrogen atoms (SC) 541 [G.E. *80*, 560 (1968)]

3-Aminopropenals, New rearrangement of substituted ~ (SC) 460 [G.E. *80*, 444 (1968)]

2-Amino-1,3-selenazol-2-inium bromide, Crystal structure (SC) 811 [G.E. *80*, 793 (1968)]

Aminotransferase activity (LA) 554

Ammonia, Mass-spectrometric study of the synthesis of ~ on iron tips (SC) 139 [G.E. *80*, 151 (1968)]

High-temperature synthesis of amino acids in the system acetylene/~/carbon dioxide (SC) 392 [G.E. *80*, 396 (1968)]

Ammonium salts, The reaction cross-section of ~ for scattering of subthermal neutrons (LA) 958

Ammonolysis, Preparation of tetraaminophosphonium salts by ~ of the triamino(methylthio)phosphonium ion (SC) 210 [G.E. *80*, 234 (1968)]

N-tert-Amyloxycarbonylamino acids, Synthesis of N-tert-butyloxycarbonyl- and ~ (SC) 379 [G.E. *80*, 364 (1968)]

Analysis, Problems and possibilities of modern trace ~ (FP) 252 [G.E. *80*, 297 (1968)]

Analysis, Hoppe-Seyler/Thierfelder, Handbuch der physiologisch- und pathologisch-chemischen Analyse, für Ärzte, Biologen und Chemiker. (Hoppe-Seyler/Thierfelder, Handbook of physiological and pathological chemical ~ for physicians, biologists and chemists) (Book Review) 555

Praktikum der qualitativen Analyse (Practical handbook of qualitative ~) (Book Review) 556

Treatise on Analytical Chemistry (Book Review) 245

Anhydrides, Simplified process for preparation of ~ of aromatic acids (SC) 465 [G.E. *80*, 487 (1968)]

Annulenes, Synthesis of 9,10,19,20-tetradehydrotetrabenzo[acgi]cyclododecene (SC) 225 [G.E. *80*, 240 (1968)]

Attempted preparation of 7,8,15,16-tetradehydrodinaphtho[1,8-ab;1,8-fg]cyclodecene (SC) 226 [G.E. *80*, 241 (1968)]

11,11-Dihalogeno-1,6-methano-[10]-~ as dihalogenocarbene transfer agents (SC) 288 [G.E. *80*, 278 (1968)]

Annulene polyoxides, Synthesis (LA) 555

Antamanide, Discovery, isolation, elucidation of structure, and synthesis (FP) 204 [G.E. *80*, 209 (1968)]

Anthracene derivatives, Formation (LA) 554

Antiaromatic rings, Small ~ (FP) 565 [G.E. *80*, 573 (1968)]

Antibiotics as inhibitors of nucleic acid and protein synthesis (FP) 693 [G.E. 710 (1968)]

Antimony, Electrical conductivity and formation of chalcogenide glasses in Ge–As–Se and Ge–Sb–Se melts (SC) 947 [G.E. *80*, 999 (1968)]

Structure of molten ~ (SC) 947 [G.E. *80*, 999 (1968)]

Antimony ylide, Crystalline ~ (LA) 148

Antioxidants, Analysis of foodstuffs with particular reference to quality control (CR) 956 [G.E. *80*, 1003 (1968)]

Aromatic compounds, High-melting ~ as stationary phases in gas chromatography (SC) 724 [G.E. *80*, 754 (1968)]

Preparation of tri- and tetra-substituted ~ (SC) 727 [G.E. *80*, 704 (1968)]

Condensation of D-glucose with ~ in liquid hydrogen fluoride (CR) 146 [G.E. *80*, 156 (1968)]

The decomposition of ~ in the focus of a laser beam (LA) 899

Carbocyclic non-benzenoid ~ (Book Review) 156

Aromatic substitution, Third mechanism (AE_a) of nucleophilic ~ (SC) 617 [G.E. *80*, 614 (1968)]

Arsenic, Electrical conductivity and formation of chalcogenide glasses in Ge–As–Se and Ge–Sb–Se melts (SC) 947 [G.E. *80*, 999 (1968)]

Arsenic compounds, Spirocyclic 1:2 adduct of tetrakis(diphenylarsorylmethyl)-methane and hydrogen peroxide (SC) 738 [G.E. *80*, 755 (1968)]

$As_4(NCH_3)_6$ has an adamantane structure (LA) 235

Arsenic sesquioxide, Behavior of modifications (CR) 480 [G.E. *80*, 495 (1968)]

Arsenides, Ternary nitrides, phosphides, and ~ of lithium (FP) 360 [G.E. *80*, 373 (1968)]

Arsinecyclopentadienyldicarbonylmanganese(I) (SC) 634 [G.E. *80*, 625 (1968)]

Arsines, Simple synthesis of oligomeric phenyl-phosphines and -~ (SC) 218 [G.E. *80*, 240 (1968)]

Arylcarbenes, New precursors (SC) 462 [G.E. *80*, 442 (1968)]

Ascorbic acid, Constitution and synthesis of an aci-reductone formed on non-oxidative degradation of dehydro-~ (SC) 732 [G.E. *80*, 755 (1968)]

L-Asparaginase, Two ~-s (LA) 81

Asterane, Carbosilane $Si_6Cl_8C_6H_8$ with an ~ structure (SC) 383 [G.E. *80*, 397 (1968)]

~-s (CR) 306 [G.E. *80*, 290 (1968)]

Asymmetric catalytic hydrogenation with an optically active phosphine-rhodium complex in homogeneous solution (SC) 942 [G.E. *80*, 1034 (1968)]

Asymmetric induction in intramolecular reactions of carbenoids (SC) 539 [G.E. *80*, 534 (1968)]

Asymmetric reduction of polyvinylacetophenone (SC) 216 [G.E. *80*, 236 (1968)]

Asymmetric synthesis of geminal chloronitroso compounds (SC) 388 [G.E. *80*, 395 (1968)]

Atomic absorption spectroscopy and analysis by atomic absorption (Book Review) 902

Automerization, ^{13}C-Experiments on carbon skeleton rearrangements: ~ of naphthalene (SC) 548 [G.E. *80*, 567 (1968)]

Autoxidation of dimedone derivatives (SC) 299 [G.E. *80*, 319 (1968)]

Axon membrane, Electrical excitation of the ~ as co-operative exchange (CR) 829 [G.E. *80*, 806 (1968)]

Azaallyl groups, Dimerization of ~, diazaallyl, and oxaazaallyl groups by way of copper-containing intermediates (SC) 131 [G.E. *80*, 117 (1968)]

Dimerization of oxaallyl, ~, oxaphosphaallyl, and oxathiaallyl groups by way of organocopper compounds (SC) 540 [G.E. *80*, 565 (1968)]

7-Azabicyclo[4.1.0]heptane, Slow inversion at pyramidal nitrogen: Isolation of diastereomeric 7-chloro-~ at room temperature (SC) 224 [G.E. *80*, 197 (1968)]

Azabicyclopentane, Formation of an ~ derivative on photolysis of α-azidostyrene (SC) 130 [G.E. *80*, 119 (1968)]

Azafulvenes, Heterofulvalenes and ~ (SC) 296 [G.E. *80*, 277 (1968)]

2-Azapyrene (SC) 376 [G.E. *80*, 367 (1968)]

3-Azaquadricyclane, Synthesis and pyrolysis of ~ derivatives. – New azepine synthesis (SC) 67 [G.E. *80*, 78 (1968)]

Cycloadditions to derivatives of ~ (Bishomopyrrole) (SC) 727 [G.E. *80*, 699 (1968)]

Azepine, Synthesis and pyrolysis of 3-azaquadricyclane derivatives. – New ~ synthesis (SC) 67 [G.E. *80*, 78 (1968)]

Azides, Proof of $N_\gamma N_\beta$-elimination from Staudinger adducts $R_3P{=}N_\gamma{-}N_\beta{=}N_\alpha{-}X$ by ^{15}N-isotopic labeling (SC) 636 [G.E. *80*, 667 (1968)]

α-Azidostyrene, Formation of an azabicyclopentane derivative on photolysis of ~ (SC) 130 [G.E. *80*, 119 (1968)]

Aziridines, Preparation of N-amino-~ and rearrangements to hexulose hydrazones (SC) 134 [G.E. *80*, 120 (1968)]

Generator system for 1-(2-chloroethyl)-~ (SC) 627 [G.E. *80*, 621 (1968)]

Preparation by reduction of α-chloronitriles (LA) 149

2-Monosubstituted ~ (LA) 236

Aziridinones, α-Lactams (~) (FP) 25 [G.E. *80*, 27 (1968)]

Azirines, Syntheses of cyclopropanes and ~ by means of alkylidenephosphoranes (CR) 640 [G.E. *80*, 628 (1968)]

Synthesis and chemistry of 1-~ (CR) 643 [G.E. *80*, 631 (1968)]

Azo chemistry, Sulfonyl hydrazones of cyclic amides and quaternary azo sulfones of heterocycles as reagents in ~ (FP) 335 [G.E. *80*, 343 (1968)]

Azo compounds, d-Orbital effects in PN and SiC π-electron systems (CR) 400 [G.E. *80*, 368 (1968)]

1,1-Bis(benzeneazo)-2,2-dimethylpropane (LA) 402

Azo coupling, Unusual reaction (LA) 402

Azo dyes, Heterocyclic ~ in complex chemistry and in analytical chemistry (CR) 307 [G.E. *80*, 291 (1968)]

Azoisobutyrodinitrile, Preparation and use of derivatives that can be determined colorimetrically (CR) 395 [G.E. *80*, 409 (1968)]

Azomethine imine, Synthesis by means of 1-alkylidene- and 1-(arylalkylidene)-3-pyrazolidene N,N-betaines, a new type of stable ~ (SC) 214 [G.E. *80*, 196 (1968)]

1-Alkylidene- and 1-arylalkylidene-3-iminopyrazolidine N,N-betaine salts, a new type of ~ stabilized by mesomerism (SC) 888 [G.E. *80*, 911 (1968)]

Azymethines, Detection of open-chain intermediates in the formation of β-lactams from ketenes and ~ (SC) 826 [G.E. *80*, 802 (1968)]

Azo sulfones, Sulfonyl hydrazones of cyclic amides and quaternary ~ of heterocycles as reagents in azo chemistry (FP) 335 [G.E. *80*, 343 (1968)]

Azulenium salt, Synthesis of a cyclopropenylidene-~ (LA) 402

Azuleno[8,8a,1,2-def]heptalene (SC) 808 [G.E. *80*, 801 (1968)]

BACTERIAL cells, Growth, Function, and Regulation in ~ (Book Review) 156

Bacteriochlorophyll, Absolute configuration (SC) 222 [G.E. *80*, 234 (1968)]

Barium, Organic compounds of magnesium, beryllium, calcium, strontium, and ~ (Book review) 744

Barrelene, Photoisomerization of mono- and dibenzo-~ (LA) 832

Base, Acrylonitrile as a hard and soft ~ in di-μ-acrylonitrilebis(tricarbonyliron) (SC) 222 [G.E. *80*, 239 (1968)]

Beckmann rearrangement, Preparation of ketene imines by ~ (SC) 304 [G.E. *80*, 314 (1968)]

1H-2-Benzazepin-1-one, Synthesis of derivatives of isoquinoline, of 1,3-benzoselenazin-4-one, and of ~ (SC) 464 [G.E. *80*, 484 (1968)]

Benzene, "Bicarburet of hydrogen". Reappraisal of the discovery of ~ in 1825 with the analytical methods of 1968 (FP) 345 [G.E. *80*, 337 (1968)]

1,1-Bis(benzeneazo)-2,2-dimethylpropane (LA) 402

Benzenediazonium-2-carboxylate, Mechanism of formation of dehydrobenzene from ~ (SC) 389 [G.E. *80*, 404 (1968)]

Benzene radical anion, Ion pair formation in ~ solutions (SC) 953 [G.E. *80*, 996 (1968)]

A reinterpretation of the ESR spectrum attributed to a non-degenerate state of the ~ (SC) 954 [G.E. *80*, 997 (1968)]

Influence of solvent pretreatment and electrolyte addition on the ESR spectra of aromatic radical anions (SC) 954 [G.E. *80*, 998 (1968)]

Benzimidazole, 2,4,5,6-Tetrahydro-5,5,7-trimethyl-~-2-thiones, a new group of ~ derivatives (SC) 68 [G.E. *80*, 46 (1968)]

Benzobarrelene, Photoisomerization of mono- and di-~ (LA) 832

Benzocycloalkenes, New synthesis (SC) 637 [G.E. *80*, 668 (1968)]

Benzocycloheptenes, Photochemical synthesis of substituted 5H- and 7H-~ (SC) 371 [G.E. *80*, 359 (1968)]

Simple synthesis of ~ (SC) 379 [G.E. *80*, 366 (1968)]

Benzo[a]-1,2-dicarba-closo-dodecarborane Synthesis (LA) 831

Benzofulvenes, Iso-~ (SC) 297 [G.E. *80*, 312 (1968)]

Benzoic acid, Frequency-, temperature-, and concentration-dependent absorption of ultrasonic radiation by ~ solutions (LA) 313

1,3-Benzoselenazin-4-one, Synthesis of derivatives of isoquinoline, of ~, and of 1H-2-benzazepin-1-one (SC) 464 [G.E. *80*, 484 (1968)]

Benzoxazole, Ring expansion to quinoline 1-oxides (LA) 149

Benzoylium cation, Identification by IR spectroscopy (SC) 70 [G.E. *80*, 40 (1968)]

Benzyl alcohol dehydrogenase (LA) 312

Beryllium, Organic compounds of magnesium, ~, calcium, strontium, and barium (Book Review) 744

Bicyclo[6.2.0]decapentaene (SC) 635 [G.E. *80*, 665 (1968)]

Bicyclo[4.2.2]deca-2,4,7,9-tetraene, Degenerate thermal valence isomerization of the ~ skeleton (SC) 823 [G.E. *80*, 803 (1968)]

Bicyclo[6.2.0]deca-2,4,6,9-tetraene (CR) 645 [G.E. *80*, 632 (1968)]

Bicyclo[3.2.0]hepta-2,6-diene, Polymerization of unsaturated highly strained ring systems with Ziegler-Natta catalysts and with group VIII metal halides (CR) 394 [G.E. *80*, 408 (1968)]

trans-Bicyclo[5.1.0]octane (SC) 891 [G.E. *80*, 914 (1968)]

Bicyclo[4.2.0]oct-7-ene, Polymerization of unsaturated highly strained ring systems with Ziegler-Natta catalysts and with group VIII metal halides (CR) 394 [G.E. *80*, 408 (1968)]

Bicyclo[2.1.0]pentane, The mechanism and stereochemistry of the addition of olefins to ~ (LA) 958

Bicyclo[*x*.2.0] systems, Synthesis and chemistry (CR) 645 [G.E. *80*, 632 (1968)]

Bile salts (Book Review) 318

Biochemistry, Comprehensive ~ (Book Review) 901, 901

Dynamische Biochemie (Dynamic ~) (Book Review) 404

Bioenergetics, Comprehensive Biochemistry (Book Review) 316

Biological Chemistry (Book Review) 84

Bioluminescence, Luciferins, bioluminescent substances (FP) 407 [G.E. *80*, 417 (1968)]

Biophysics, Molecular ~ (Book Review) 656

Biphenylene, Induced paramagnetic ring-current in the four-membered ring of ~ and related hydrocarbons (CR) 642 [G.E. *80*, 629 (1968)]

1-(*p*-Biphenylyl)-1-methylethoxycarbonyl groups (LA) 742

Bipyramid, Ligand reorganization in the trigonal ~ (SC) 725 [G.E. *80*, 700 (1968)]

Bis(as-indacenyliron), Synthesis (LA) 652

Bis(2,2'-biphenylylene)tellurium, Synthesis (LA) 653

Bis-carbene with a quintet ground state (LA) 312

Bis(chloromercuri)-2,4-pentanedione, an unusual acetylacetone derivative (SC) 629 [G.E. *80*, 664 (1968)]

Bis(diethoxyphosphinyl) (trimethylammonio)methylide, a stable N-ylide (SC) 463 [G.E. *80*, 445 (1968)]

Bis-(1-ethyl-2-quinolyl)phosphamethine cyanine perchlorate, Crystal structure (SC) 69 [G.E. *80*, 40 (1968)]

Bishomopyrrole, Cycloadditions to derivatives of 3-azaquadricyclane (~) (SC) 727 [G.E. *80*, 699 (1068)]

Bis(phosphonylmethyl)alkylphosphine oxides, Preparation and properties of ~ and the corresponding acids (SC) 385 [G.E. *80*, 401 (1968)]

Bis(phosphonylmethyl)phosphinates, Preparation and properties of ~ and bis-(dihydroxyphosphonylmethyl)phosphinic acid (SC) 384 [G.E. *80*, 400 (1968)]

Bis(tricarbonylcyclopentadienylchromium), a catalyst for selective hydrogenation (SC) 631 [G.E. *80*, 663 (1968)]

Bis(trimethylsilyl)diimine and tetrakis-(trimethylsilyl)hydrazine (SC) 640 [G.E. *80*, 661 (1968)]

N,N-Bis(trimethylsilyl)glycine esters, Synthesis of amino acids from ~ (SC) 809 [G.E. *80*, 797 (1968)]

Bis(triphenylstannyl)mercury (LA) 959

Blood, Replacement of plasma by high molecular weight substances (FP) 702 [G.E. *80*, 719 (1968)]

Boranes, Tris(dimethylamino)boranetricarbonyltungsten (SC) 293 [G.E. *80*, 282 (1968)]

Addition of substituted vinyloxy-~ to nitriles (SC) 735 [G.E. *80*, 756 (1968)]

Synthesis of benzo[a]-1,2-dicarba-*closo*-dodeca-~ (LA) 831

Boranocarbonates, Preparation and properties (LA) 149

Boron complex, ESR-Investigation of a new titanium-~ (SC) 821 [G.E. *80*, 796 (1968)]

Boron heterocycles, Formation from vicinally diborylated cis-alkenes at high temperature (SC) 286 [G.E. *80*, 288 (1968)]

Boron nitride, Formation and properties of medium and high molecular weight compounds of elements of groups 3, 4, and 5 (FP) 1 [G.E. *80*, 2 (1968)]

1-Bromocyclotrideca-1,2-diene-4,8,10-triyne (LA) 653

Browning reactions, Degradation of fructose amino acids to N-(2-furoylmethyl)-amino acids. Intermediates in ~ (SC) 628 [G.E. *80*, 627 (1968)]

Bullvalene, Octamethylsemi-~ (SC) 537 [G.E. *80*, 531 (1968)]

Rearrangements in the ~ system induced by heavy-metal salts (SC) 736 [G.E. *80*, 758 (1968)]

Butadiene, cis,trans- and trans,trans-1,3,6-Octatriene from ~ (SC) 882 [G.E. *80*, 967 (1968)]

Butanol, Dehydration of gaseous [2-D]-2-~ over $CaSO_4$ (SC) 140 [G.E. *80*, 150 (1968)]

2-Butanone, Identification of the $n-\sigma^*$ transition in the electron excitation spectrum of ~ (SC) *626* [G.E. *80*, 613 (1968)]

tert-Butyl fluoroformate, a new reagent for peptide synthesis (SC) 380 [G.E. *80*, 396 (1968)]

Butyl ketones, Preparation of (S)-2-methyl-~ and (S)sec-~ from optically active 2-methyl-1-butanol by the dithiane method (SC) 619 [G.E. *80*, 617 (1968)]

N-tert-Butyloxycarbonyl-amino acids, Synthesis of ~ and N-tert-amyloxycarbonylamino acids (SC) 379 [G.E. *80*, 364 (1968)]

Synthesis of ~ (LA) 150

CALCIUM, Organic compounds of magnesium, beryllium, ~, strontium, and barium (Book Review) 744

Calcium carbide, Vapor pressure above the ~ phase (LA) 81

Calcium sulfate, Dehydration of gaseous [2-D]-2-Butanol over ~ (SC) 140 [G.E. *80*, 150 (1968)]

Calorimetry, Adsorption ~ (CR) 310 [G.E. *80*, 290 (1968)]

Carbanions, Formation from esters of orthothiocarbonic acid (LA) 151

Oxidative dimerization of ~ (LA) 237

Carbaphosphollide ion, New transition metal complexes with the ~ (LA) 833

Carbenes, 11,11-Dihalogeno-1,6-methano-[10]annulene as dihalogeno-~ transfer agents (SC) 288 [G.E. *80*, 278 (1968)]

Hydrogen-deuterium exchange in alkoxyalkyl-~-transition metal complexes (SC) 390 [G.E. *80*, 402 (1968)]

New precursors for aryl-~ (SC) 462 [G.E. *80*, 442 (1968)]

Monofluoro-~ and its syn/anti selectivity (SC) 820 [G.E. *80*, 849 (1968)]

Rearrangements of highly unsaturated cyclopropyl ~ (CR) 644 [G.E. *80*, 631 (1968)]

Reactions of cyclopropyl-~ (CR) 646 [G.E. *80*, 634 (1968)]

Insertion of dihalogeno-~ into Si–Hg and Ge–Hg bonds (LA) 81

Bis-~ with a quintet ground state (LA) 312

~ undergo addition to hexafluorobenzene (LA) 831

Carbene complex, Direct synthesis of a mercury salt-~ (SC) 141 [G.E. *80*, 154 (1968)]

Carbenepentacarbonylchromium(0), Kinetics of the aminolysis of methoxyphenyl-~ (SC) 817 [G.E. *80*, 847 (1968)]

Carbene transfer, Synthesis of cyclopropyl ethers and cyclopropanols by ~. – Acetolysis of cyclopropyl *p*-toluenesulfonates (FP) 588 [G.E. *80*, 603 (1968)]

Carbenoids, Asymmetric induction in intramolecular reactions of ~ (SC) 539 [G.E. *80*, 534 (1968)]

Carbodiimides, Dimerization (SC) 72 [G.E. *80*, 83 (1968)]

Carbohydrates, Structure and the function of gangliosides (FP) 87 [G.E. *80*, 89 (1968)]

Synthesis of methyl 4,6-O-benzylidene-2,3-(2-hydroxyethylidene)-2,3-dideoxy-α-D-mannopyranoside, a cyclopropane sugar (SC) 142 [G.E. *80*, 152 (1968)]

New route to branched sugars (LA) 80

Zuckerchemie. Eine Einführung (Sugar chemistry. An Introduction) (Book Review) 241

Carbon, Hexagonal diamond, a new modification of ~ (LA) 151

Some reactions of the species C_4 (LA) 899

Porous ~ solids (Book Review) 963

Carbon dioxide, High-temperature synthesis of amino acids in the system acetylene/ammonia/~ (SC) 392 [G.E. *80*, 396 (1968)]

Carbonic acids, Chalcogeno-~ and their anions (FP) 868 [G.E. *80*, 954 (1968)]

Carbonium ion, Memory effects and stereochemistry in multiple ~ rearrangements (FP) 799 [G.E. *80*, 765 (1968)]

Formation of dialkoxy-~s from ketals by removal of alkyl groups by means of ~s (SC) 64 [G.E. *80*, 81 (1968)]

Studies with stable ~s (CR) 234 [G.E. *80*, 246 (1968)]

Phosphorylation involving ~s, phosphonium, and sulfonium ions (LA) 311

Carbon monoxide, Photolysis and radiolysis of ~ in the gaseous, liquid, and solid state at 298 °K, 77 °K, and 20.4 °K (CR) 553 [G.E. *80*, 538 (1968)]

Carbonylation of olefins under mild temperature conditions in the presence of palladium complexes (FP) 329 [G.E. *80*, 352 (1968)]

Carbonyliridium chloride, Crystal structure (SC) 812 [G.E. *80*, 844 (1968)]

Carbonylmetalate, Nucleophilic reactions of metal carbonyl anions with fluorocarbons (FP) 747 [G.E. *80*, 835 (1968)]

Carbonylmetal complexes, Kinetic studies on substitution reactions of ~ (FP) 930 [G.E. *80*, 1017 (1968)]

Carbonyl olefination with α-metalated isocyanides (SC) 805 [G.E. *80*, 842 (1968)]

N-Carbonylsulfamoyl chloride, Reactions with ~ (FP) 172 [G.E. *80*, 179 (1968)]

Carbosilane $Si_6Cl_8C_6H_8$ with an asterane structure (SC) 383 [G.E. *80*, 397 (1968)]

Carboxamides, cis-trans Isomerism of N-monosubstituted amides (CR) 228 [G.E. *80*, 201 (1968)]

Carboxonium salts, Stable cyclic ~ (SC) 461 [G.E. *80*, 490 (1968)]

Carboxylic acids, Synthesis of ~ *via* PO-activated olefination of tetraethyl dimethylaminomethylenediphosphonate (SC) 391 [G.E. *80*, 364 (1968)]

New reaction of thionyl chloride with ~ (LA) 403

Phosphorus nitride chloride as an activator of ~ (LA) 830

Cardenolide, New synthesis (SC) 300 [G.E. *80*, 317 (1968)]

Catalase from human erythrocytes crystallizes in the form of tubes (LA) 153

Catalysis, Elementary steps in acid-base ~. Proton transfer reactions in aqueous solutions (SC) 818 [G.E. *80*, 857 (1968)]

Fourth international ~ congress (CR) 896 [G.E. *80*, 917 (1968)]

Introduction to the Principles of Heterogeneous ~ (Book Review) 486

Catalyst, Dehydration of gaseous [2-D]-2-butanol over $CaSO_4$ (SC) 140 [G.E. 150 (1968)]

Bis(tricarbonylcyclopentadienylchromium), a ~ for selective hydrogenation (SC) 631 [G.E. *80*, 663 (1968)]

Mechanism of elimination over solid ~-s (CR) 232 [G.E. *80*, 242 (1968)]

Surface layer of Ag_2O_3 on silver ~-s (LA) 313

Catalytic reactions, Microcalorimetric investigation of heterogeneous ~ (CR) 228 [G.E. *80*, 200 (1968)]

Cellulose, New gels from ~ and their uses in chromatography (CR) 400 [G.E. *80*, 414 (1968)]

Central nervous system, Stoffwechsel im Zentralnervensystem (Metabolism in the ~) (Book Review) 242

Chalcogenides, Preparative chemistry (CR) 308 [G.E. *80*, 292 (1968)]

Chalcogenocarbonic acids, ~ and their anions (FP) 868 [G.E. *80*, 954 (1968)]

Chemiluminescence, Oxygen radicals and ~ (CR) 477 [G.E. *80*, 449 (1968)]

~of cyclic diacylhydrazides and diazaquinones (CR) 480 [G.E. *80*, 494 (1968)]

Chemisorption, Individual steps in the ~ of gases on metals (CR) 146 [G.E. *80*, 155 (1968)]

~ on metal films (CR) 307 [G.E. *80*, 289 (1968)]

Chemotaxonomy, Chemotaxonomie der Pflanzen (~ of Plants) (Book Review) 154

Chestnut, Structure of the principal aglycon of horse ~ saponin (SC) 547 [G.E. *80*, 563 (1968)]

Chlorine, The reaction of mercury atoms with ~ atoms (LA) 957

Chlorination, Preparation, properties, and reactions of polychloroamine derivatives (FP) 856 [G.E. *80*, 942 (1968)]

Chlorine dioxide, Mechanism for the ~ explosion (LA) 831

Chloro amine, Preparation, properties, and reactions of poly-~ derivatives (FP) 856 [G.E. *80*, 942 (1968)]

β-Chloro amines, Synthesis of O,O-diethyl N,N-dichlorophosphoramidate and its use for the preparation of ~ from olefins (SC) 292 [G.E. *80*, 285 (1968)]

7-Chloro-7-azabicyclo[4.1.0]heptanes, Slow inversion at pyramidal nitrogen: Isolation of diastereomeric ~ at room temperature (SC) 224 [G.E. *80*, 197 (1968)]

1-(2-Chloroethyl)aziridine,Generator system for (SC) 627 [G.E. *80*, 621 (1968)]

O-Chloroformyloximes (LA) 311

α-Chloronitriles, Preparation of aziridines by reduction of ~ (LA) 149

Chloronitroso compounds, Preparation of geminal ~ (SC) 387 [G.E. *80*, 395 (1968)]

Asymmetric synthesis of geminal ~ (SC) 388 [G.E. *80*, 395 (1968)]

Chlorophyll, Absolute configuration (SC) 221 [G.E. *80*, 233 (1968)]

Absolute configuration of bacterio-~ (SC) 222 [G.E. *80*, 234 (1968)]

~-water interaction (SC) 286 [G.E. *80*, 283 (1968)]

N-Chloro-N-(trifluoromethyl)-fluorosulfonamide (SC) 218 [G.E. *80*, 236 (1968)]

Cholesteric liquids, Recent results in the field of liquid crystals (FP) 97 [G.E. *80*, 99 (1968)]

Chromatography, New adsorbents suitable for thin layer ~ (LA) 900

Chromatographisches Praktikum (Practical ~) (Book Review) 959

Chromium complexes, Binuclear ~ with dioxane as bridging ligand (SC) 544 [G.E. *80*, 564 (1968)]

Chromium compounds, Tris(organometalo)phosphine-pentacarbonylchromium and -dicarbonylnitrosylcobalt (SC) 300 [G.E. *80*, 318 (1968)]

Bis(tricarbonylcyclopentadienylchromium), a catalyst for selective hydrogenation (SC) 631 [G.E. *80*, 663 (1968)]

Kinetics of the aminolysis of methoxyphenylcarbenepentacarbonylchromium-(0) (SC) 817 [G.E. *80*, 847 (1968)]

Pentacarbonyl-(2,3-diphenylcyclopropenylidene)chromium(0) (SC) 950 [G.E. *80*, 1032 (1968)]

Fragmentation of specifically deuterated tri-*n*-alkylchromium compounds (SC) 951 [G.E. *80*, 1029 (1968)]

The transfer of electronic excitation energy from a complex cation (hexaureachromium(III)) to an anion (hexacyanochromate(III)) (LA) 899

Chromium(II) salts, Reduction of organic compounds with ~ (FP) 247 [G.E. *80*, 271 (1968)]

Chromium thiospinels, Preparation of single crystals of ~ by means of transport reactions (SC) 542 [G.E. *80*, 562 (1968)]

Chromosomes, Cytogenetics of human tumors (FP) 709 [G.E. *80*, 747 (1968)]

Structure of ~ (CR) 397 [G.E. *80*, 412 (1968)]

Chymotrypsin, Analysis of foodstuffs with particular reference to quality control (CR) 956 [G.E. *80*, 1033 (1968)]

Circular dichroism and optical dispersion – Principles and application to the investigation of the stereochemistry of natural products (FP) 14 [G.E. *80*, 15 (1968)]

Clathrate compounds (Book Review) 902

Clay, Chemistry (FP) 681 [G.E. *80*, 736 (1968)]

Cleavage surfaces of silicon single crystals (LA) 830

Coat protein, Monomer of the fd phage ~ (LA) 151

Cobalt compounds, Preparation and properties of a bicyclic hydridodiethylcobalt complex (SC) 129 [G.E. *80*, 115 (1968)]

Tris(organometalo)phosphine-pentacarbonylchromium and -dicarbonylnitrosylcobalt (SC) 300 [G.E. *80*, 318 (1968)]

Tris(triphenylphosphine)cobalt dihydride (LA) 80

Use of dipotassium tetraisothiocyanatocobaltate(II) for the detection of oxygen-containing organic molecules (LA) 149

Cobalt squarate, Unit cells and absorption spectra of the cubic squarates of cobalt and nickel (SC) 638 [G.E. *80*, 664 (1968)]

Coenzymes, Tetrahydropterins as ~ of enzymatic hydroxylation (CR) 477 [G.E. *80*, 492 (1968)]

Mode of action of the B_{12} ~ in the reduction of ribonucleotides (LA) 314

Collagen, Kollagen (~) (Book Review) 316

Collagen-proline hydroxylase, Cofactor requirement (LA) 150

Color centers, Amide ions NH_2^- as ~ in crystalline KCl, KBr, and KI (LA) 957

Colorimetry, Handbuch der Kolorimetrie (Handbook of ~) (Book Review) 485

Combustion, Cool flames of hydrocarbons (FP) 45 [G.E. *80*, 53 (1968)]

Complexes, Observations on the crystal structure of electron-donor-acceptor ~ (FP) 659 [G.E. *80*, 688 (1968)]

Kinetic studies on substitution reactions of carbonylmetal ~ (FP) 930 [G.E. *80*, 1017 (1968)]

Structure and hydrolysis of the ate-~ from tritylsodium, acenaphthylene, and triphenylborane (SC) 139 [G.E. *80*, 149 (1968)]

New metal ~ of tetracyanoethylene (SC) 305 [G.E. *80*, 314 (1968)]

Hydrogen-deuterium exchange in alkoxyalkylcarbene - transition metal ~ (SC) 390 [G.E. *80*, 402 (1968)]

Formation of electron-donor-acceptor ~ as a basis for specific adsorption (SC) 948 [G.E. *80*, 1035 (1968)]

1,5,9-Cyclododecatriene ~ of nickel(0) (SC) 949 [G.E. *80*, 1033 (1968)]

Formation and properties of molecular ~ in the excited state (CR) 147 [G.E. *80*, 156 (1968)]

Polarimetric study of simple and mixed metal-amino acid ~ (CR) 228 [G.E. *80*, 201 (1968)]

New results in the chemistry of complex compounds of metals in lower oxidation states (CR) 231 [G.E. *80*, 244 (1968)]

Phenyllithium ~ of transition metals (CR) 898 [G.E. *80*, 972 (1968)]

New transition metal ~ with the carbaphosphollide ion (LA) 833

Conductance of electrolyte solutions (FP) 260 [G.E. *80*, 253 (1968)]

Configuration, see absolute configuration.

Conformation, Cooperative conformational changes of the helix structures of biopolymers and analogous model substances in solution (CR) 478 [G.E. *80*, 450 (1968)]

~ equilibrium in cis-3,5-dimethylpiperidine (LA) 831

Poly-α-amino acids. Protein models for conformational studies (Book Review) 745

Cool flames of hydrocarbons (FP) 45 [G.E. *80*, 53 (1968)]

Copolymers, Nuclear magnetic resonance spectroscopy of tactic ~ (CR) 393 [G.E. *80*, 407 (1968)]

Chemical heterogeneity of ~ – experimental studies on compatibility (CR) 397 [G.E. *80*, 411 (1968)]

Copper, Catalytically active component of cytochrome c oxidase (LA) 153

Analysis of ~ and its Alloys (Book Review) 318

Copper compounds, Deprotonation of glycine amide in a ternary copper(II) complex (SC) 137 [G.E. *80*, 124 (1968)]

Structure of dimethylnitrosaminecopper(II) chloride (SC) 470 [G.E. *80*, 444 (1968)]

Dimerization of oxaallyl, azaallyl, oxaphosphaallyl, and oxathiaallyl groups by way of organo-~ (SC) 540 [G.E. *80*, 565 (1968)]

Dehydrodimerization of heteroarylated alkanes by way of organo-~ (SC) 541 [G.E. *80*, 566 (1968)]

Investigation of the ionic mobility of some copper(I) compounds by nuclear magnetic resonance (CR) 476 [G.E. *80*, 449 (1968)]

Reactions of organo-~ with halogenoolefins (LA) 310

Corphin, a corrinoid-porphinoid ligand system (SC) 623 [G.E. *80*, 622 (1968)]

Corrinoid, Corphin, a ~-porphinoid ligand system (SC) 623 [G.E. *80*, 622 (1968)]

Crinin alkaloids, Model reaction for the biosynthesis (SC) 223 [G.E. *80*, 238 (1968)]

Crop protection, Die wissenschaftlichen Grundlagen des Pflanzenschutzes (The Scientific Principles of ~) (Book Review) 154

Crustacyanin, a chromoprotein from lobster shell (LA) 313

Crystals, Recent results in the field of liquid ~ (FP) 97 [G.E. *80*, 99 (1968)]

Crystal chemistry, New developments in the ~ of multicomponent oxides (CR) 231 [G.E. *80*, 243 (1968)]

Kristallchemie (~) (Book Review) 404

Crystallization during polymerization (FP) 912 [G.E. *80*, 1009 (1968)]

Crystal nuclei, Submicroscopic ~ in the solution crystallization of polyethylene (CR) 396 [G.E. *80*, 410 (1968)]

Crystal structure, Observations on the ~ ~ of electron donor-acceptor complexes (FP) 659 [G.E. *80*, 688 (1968)]

~ of bis-(1-ethyl-2-quinolyl)phosphamethinecyanine perchlorate (SC) 69 [G.E. *80*, 40 (1968)]

~ of triisopropylidenecyclopropane (SC) 465 [G.E. *80*, 487 (1968)]

~ and molecular structure of 3,5,8,10-tetramethylaceheptylene (SC) 543 [G.E. *80*, 564 (1968)]

~ of 2-amino-1,3-selenazol-2-inium bromide (SC) 811 [G.E. *80*, 793 (1968)]

~ of 2,6-dimethyl-4-phenylphosphabenzene (SC) 811 [G.E. *80*, 843 (1968)]

~ of "$Ir(CO)_3Cl$" = $Ir(CO)_{2,93}Cl_{1,07}$ (SC) 812 [G.E. *80*, 844 (1968)]

~ and molecular structure of 4-methylpentaleno[6,6a,1,2-def]heptalene (SC) 816 [G.E. *80*, 795 (1968)]

~ of 1,2,8,9-tetraaza-1,8-cyclotetradecadiene-3,10-ylene diacetate (SC) 944 [G.E. *80*, 1001 (1968)]

Cubane structure, closo-Tetrakis(phenylstannylphosphine), an organostannylphosphine with a ~ (SC) 813 [G.E. *80*, 846 (1968)]

Cumulenes, New investigations of hetero-~ and their derivatives (CR) 479 [G.E. *80*, 496 (1968)]

Cyanic esters from thiocyanates (SC) 67 [G.E. *80*, 42 (1968)]

Cyanogen chloride, Fluorination (LA) 82

Cybister, Protective materials in the secretion from the prothoracic protective gland of a Mexican ~ species (SC) 62 [G.E. *80*, 45 (1968)]

Cybisterol, Protective materials in the secretion from the prothoracic protective gland of a Mexican *cybister* species (SC) 62 [G.E. *80*, 45 (1968)]

Cyclization, Sterically induced intramolecular ~ of an α,β-unsaturated nitro compound (SC) 637 [G.E. *80*, 666 (1968)]

Cycloadditions, — definition, classification, and characterization (FP) 321 [G.E. *80*, 329 (1968)]

~ of isocyanates and isothiocyanates to amidines and guanidines (SC) 291 [G.E. *80*, 281 (1968)]

Cycloadducts from trichloroallenyllithium (SC) 470 [G.E. *80*, 481 (1968)]

~ to derivatives of 3-azaquadricyclane (*bishomopyrrole*) (SC) 727 [G.E. *80*, 699 (1968)]

~ of dichloroketene (CR) 643 [G.E. *80*, 630 (1968)]

Preparation of small rings by ~ of polar compounds (CR) 646 [G.E. *80*, 633 (1968)]

1,4-~ (Book Review) 654

Cyclobutadiene, Photolysis of tetramethylcyclobutenedicarboxylic anhydride, a possible route to tetramethyl-~ (SC) 537 [G.E. *80*, 532 (1968)]

Stable ~ (SC) 824 [G.E. *80*, 804 (1968)]

Dimers of 1,2-dimethyl-~ (LA) 239

~ and related compounds (Book Review) 655

Cyclobutanones from enamines and ketenes by two-stage addition (SC) 737 [G.E. *80*, 759 (1968)]

Cyclobuta[b]quinoxalines, Synthesis (SC) 135 [G.E. *80*, 121 (1968)]

Cyclobutenes, Isomerizations in ~ (FP) 559 [G.E. *80*, 585 (1968)]

Polymerization of unsaturated highly strained ring systems with Ziegler-Natta catalysts and with group VIII metal halides (CR) 394 [G.E. *80*, 408 (1968)]

Cyclobutenediylium dyes (FP) 530 [G.E. *80*, 541 (1968)]

Cyclobutenide ion, 1-Methyl-2,3,4-trimethylene-~ (SC) 538 [G.E. *80*, 532 (1968)]

1,4,7-Cyclodecatrienes, Preparation of tri- and tetra-substituted aromatic compounds (SC) 727 [G.E. *80*, 704 (1968)]

Cyclodecasulfur, Cycloheptasulfur, S_7, and ~, S_{10} — Two new sulfur rings (SC) 632 [G.E. *80*, 660 (1968)]

Mass-spectrometric study of cycloheptasulfur, S_7 and ~, S_{10} (SC) 633 [G.E. *80*, 661 (1968)]

cis-2-Cyclodecenone, Photochemical rearrangement (LA) 403

Cyclodehydrogenations, Photochemical ~ in the indole series (SC) 466 [G.E. *80*, 486 (1968)]

1,5,9-Cyclododecatriene complexes of nickel(0) (SC) 949 [G.E. *80*, 1033 (1968)]

6H-Cyclohepta[c]furan-6-one (LA) 742

Cycloheptasulfur, S_7, and cyclodecasulfur, S_{10} — Two new sulfur rings (SC) 632 [G.E. *80*, 660 (1968)]

Mass-spectrometric study of ~, S_7, and cyclodecasulfur, S_{10} (SC) 633 [G.E. *80*, 661 (1968)]

1,2-Cyclohexadiene (LA) 742

Cyclohexadienones, Specific fragmentation (CR) 229 [G.E. *80*, 201 (1968)]

1,2-Cyclohexanediol, 1,6-C—C linkage on pressure-hydrogenation of α-hydroxyadipaldehyde (SC) 66 [G.E. *80*, 42 (1968)]

Cyclooctasulfur, Kinetics of the ring-opening in liquid ~ (LA) 830

Cyclooctatetraene, σ,π-$C_8H_8Os(CO)_3$, an unusual cyclooctatetraene transition metal complex (SC) 639 [G.E. *80*, 662 (1968)]

The course of synthesis of ~ (LA) 957

Cyclooctenes, Stereospecific cis additions of dichloroketene to cis- and trans-~ (SC) 221 [G.E. *80*, 221 (1968)]

Cyclopentadienecarbonitrile, Thermal rearrangement of phenylnitrene into ~ (LA) 741

Cyclopentadienone, Synthesis of 2,2'-diethynylbiphenyl and its reaction with ~ derivatives (SC) 378 [G.E. *80*, 366 (1968)]

Cyclopropane, Recent developments in the stereochemistry of ~ ring opening (FP) 577 [G.E. *80*, 592 (1968)]

Synthesis of gem-dimethyl-~-s by means of 2-diazopropane (SC) 65 [G.E. *80*, 42 (1968)]

New route to 1,1-disubstituted ~-s (SC) 456 [G.E. *80*, 439 (1968)]

Crystal structure of triisopropylidene-~ (SC) 465 [G.E. *80*, 487 (1968)]

Syntheses of ~-s and azirines by means of alkylidenephosphoranes (CR) 640 [G.E. *80*, 628 (1968)]

Cyclopropanol, Synthesis of cyclopropyl ethers and ~-s by carbene transfer — Acetolysis of cyclopropyl *p*-toluenesulfonates (FP) 588 [G.E. *80*, 603 (1968)]

Electrophilic cleavage of ~-s by halogenating agents (CR) 642 [G.E. *80*, 629 (1968)]

Cyclopropanone, Reactivity of ~ and some of its adducts (CR) 641 [G.E. *80*, 628 (1968)]

Cyclopropenes, Diels-Alder reactions of tetrahalo-~ (CR) 649 [G.E. *80*, 636 (1968)]

Reaction of halogenated ~ with 1,3-dienes (LA) 402

Cyclopropenyl anion, Small antiaromatic rings (FP) 565 [G.E. *80*, 573 (1968)]

Cyclopropenylideneazulenium salt, Synthesis (LA) 402

Cyclopropenylium ions, Quinodimethanes from 1,2-diaryl-3-ethoxy-~ (SC) 809 [G.E. *80*, 798 (1968)]

Derivatives of trichloro-~ (CR) 649 [G.E. *80*, 636 (1968)]

Cyclopropyl bromides, Direct conversion into cyclopropyloxy derivatives (CR) 645 [G.E. *80*, 632 (1968)]

Cyclopropyl carbenes, Rearrangements of highly unsaturated ~ (CR) 644 [G.E. *80*, 631 (1968)]

Reactions of ~ (CR) 646 [G.E. *80*, 634 (1968)]

Cyclopropylcarbonyl compounds, Syntheses (FP) 570 [G.E. *80*, 578 (1968)]

Cyclopropyl ethers, Synthesis of ~ and cyclopropanols by carbene transfer — Acetolysis of cyclopropyl *p*-toluenesulfonates (FP) 588 [G.E. *80*, 603 (1968)]

Cyclopropyl ketones, Conversion of acetylene compounds into small-ring compounds (CR) 228 [G.E. *80*, 200 (1968)]

Aminomethyl ~ from 3-amino-2-oxoalkylphosphonates (CR) 647 [G.E. *80*, 635 (1968)]

Cyclopropyloxy derivatives, Direct conversion of cyclopropyl bromides into ~ (CR) 645 [G.E. *80*, 632 (1968)]

Cyclotetraveratrylene (LA) 482

Cyclothiodepsipeptides, Thiacyclols and ~ (SC) 884 [G.E. *80*, 909 (1968)]

Cyclotrideca-1,2-diene-4,8,10-triyne, 1-Bromo-~ (LA) 653

Cyclotriphosphazenes, Hydrogen-substituted ~ formed by NH→PH tautomerization (SC) 209 [G.E. *80*, 197 (1968)]

Structure of the products of aminolysis of aminopentachloro-~ (SC) 212 [G.E. *80*, 192 (1968)]

Cytochrome c oxidase, Copper as a catalytically active component of ~ (LA) 153

Cytogenetics of human tumors (FP) 709 [G.E. *80*, 747 (1968)]

DECARBOXYLASE, Binding of the substrate in yeast pyruvate ~ (SC) 68 [G.E. *80*, 41 (1968)]

A new test for the determination of pyruvate ~ activity (SC) 886 [G.E. *80*, 907 (1968)]

Degenerate thermal valence isomerization of the bicyclo[4.2.2]deca-2,4,7,9-tetraene skeleton (SC) 823 [G.E. *80*, 803 (1968)]

Degradation of poly(ethylene terephthalate) (FP) 182 [G.E. *80*, 225 (1968)]

Dehydration, of alcohols on aluminum oxide (FP) 791 [G.E. *80*, 778 (1968)]

~ of gaseous [2-D]-2-butanol over $CaSO_4$ (SC) 140 [G.E. *80*, 150 (1968)]

Dehydroascorbic acid, Constitution and synthesis of an aci-reductone formed on non-oxidative degradation of ~ (SC) 732 [G.E. *80*, 755 (1968)]

Dehydrobenzene, Photolysis of iodoaromatic compounds (FP) 36 [G.E. *80*, 69 (1968)]

Mechanism of formation of ~ from benzenediazonium-2-carboxylate (SC) 389 [G.E. *80*, 404 (1968)]

Dehydrochlorination, Dimethylaminotrimethylstannane as a dehydrochlorinating agent (LA) 482

Dehydrodimerization of heteroarylated alkanes by way of organocopper compounds (SC) 541 [G.E. *80*, 566 (1968)]

Dehydrogenase reactions, Study of the mechanism of ~ by measurement of the isotope effects (CR) 740 [G.E. *80*, 706 (1968)]

Deoxyhemoglobin, Three-dimensional Fourier synthesis of human ~ (LA) 314

Depsipeptides, Thiacyclols and cyclothio-~ (SC) 884 [G.E. *80*, 909 (1968)]

Desulfurization, Electrolytic ~ of 2-mercapto carboxylic acids and the corresponding disulfides (SC) 638 [G.E. *80*, 664 (1968)]

Tris(diethylamino)phosphine (LA) 832

Detonation, Formulas for the calculation of the ~ properties of explosives (LA) 652

Deuterated compounds, Versatile method for preparation of C-~ (SC) 455 [G.E. *80*, 438 (1968)]

Deuterioethanol, Synthesis, on a preparative scale, of ethanol stereospecifically labeled on hydrogen (SC) 892 [G.E. *80*, 915 (1968)]

Deuterium, H/D isotope effect of saltlike hydrides (LA) 148

Dewar-benzene, Acid-catalyzed rearrangement of hexamethylprismane and hexamethyl-~ (SC) 467 [G.E. *80*, 447 (1968)]

Kinetics and thermochemistry of the thermal rearrangements of hexamethyl-(~) and of hexamethylprismane (CR) 646 [G.E. *80*, 633 (1968)]

Dextran, Replacement of plasma by high molecular weight substances (FP) 702 [G.E. *80*, 719 (1968)]

Di-μ-acrylonitrilebis(tricarbonyliron), Acrylonitrile as a hard and soft base in ~ (SC) 222 [G.E. *80*, 239 (1968)]

Diacylhydrazides, Chemiluminescence of cyclic ~ and diazaquinones (CR) 480 [G.E. *80*, 494 (1968)]

Diagonal electrophoresis techniques (LA) 153

Dialkoxycarbonium ions, Formation from ketals by removal of alkyl groups by means of carbonium ions (SC) 64 [G.E. *80*, 81 (1968)]

Diamines, Method for the stereospecific synthesis of vicinal ~ (LA) 81

Diaminosulfur diimide, the aza analog of sulfuric acid (SC) 546 [G.E. *80*, 561 (1968)]

Diamino-tert-butylphosphine, Synthesis and conversion into N-silylated aminophosphine imines with non-equivalent replaceability of the hydrogen atoms (SC) 541 [G.E. *80*, 560 (1968)]

2,5-Diamino-6-hydroxy-4-ribityl-aminopyrimidine, Accumulation in a riboflavin-deficient mutant (SC) 219 [G.E. *80*, 237 (1968)]

Diamond, Hexagonal ~ a new modification of carbon (LA) 151

1,2-Diaryl-2-arylthiovinyl-2,4,6-trinitrobenzenesulfonate (LA) 833

Diazaallyl groups, Dimerization of azaallyl, ~, and oxaazaallyl groups by way of copper-containing intermediates (SC) 131 [G.E. *80*, 117 (1968)]

3,4-Diaza-1,3,5-hexatrienes, Formation from alkenylamines and diazoalkanes (SC) 138 [G.E. *80*, 153 (1968)]

2,7-Diazapyrene and its bis(N-methyl) quaternary salt (SC) 814 [G.E. *80*, 799 (1968)]

Diazaquinones, Chemiluminescence of cyclic diacylhydrazides and ~ (CR) 480 [G.E. *80*, 494 (1968)]

1H-Diazepine-1-carboxylate, Photochemical synthesis of ethyl ~ (SC) 129 [G.E. *80*, 117 (1968)]

1,3-Diazetidine, Dimerization of carbodiimides (SC) 72 [G.E. *80*, 83 (1968)]

Diazoalkanes, Formation of 3,4-diaza-1,3,5-hexatrienes from alkenylamines and ~ (SC) 138 [G.E. *80*, 153 (1968)]

Diazoketones, Photosensitized decomposition (CR) 644 [G.E. *80*, 631 (1968)]

2-Diazopropane, Synthesis of gem-dimethylcyclopropanes by means of ~ (SC) 65 [G.E. *80*, 42 (1968)]

Diazotization of aminophenols in concentrated tetrafluoroboric acid (LA) 150

Dibenz[e,h]azulene-2,8-dione, Synthesis of 1,3-diphenyl-2,8-dihydro-~ (SC) 377 [G.E. *80*, 365 (1968)]

Dibenzo[b,d]phosphorin (SC) 465 [G.E. *80*, 486 (1968)]

Dibenzo[b,e]phosphorin, 10-Phenyl-~ (SC) 889 [G.E. *80*, 912 (1968)]

Dibenzothiepin-10,11-dione, Acid-catalyzed ring contraction (SC) 128 [G.E. *80*, 115 (1968)]

6,6'-Dibromoindigotin, Precursor of antique purple (LA) 311

Di-tert-butyloxadiaziridine (LA) 403

Dichloroketene, Stereospecific cis additions of ~ to cis- and trans-cyclooctenes (SC) 221 [G.E. *80*, 221 (1968)]

Cycloadditions of ~ (CR) 643 [G.E. *80*, 630 (1968)]

N-(Dichloromethylene)fluoroformamide, N-Fluorosulfamidoyl fluoride, pentafluorosulfur N-fluoro-N-(fluorosulfonyl)amide, and ~ (SC) 630 [G.E. *80*, 626 (1968)]

N,N-Dichlorophosphoramidate, Synthesis of O,O-diethyl ~ and its use for the preparation of β-chloro amines from olefins (SC) 292 [G.E. *80*, 285 (1968)]

2,5-Dichlorothiophene, New type of polymerization (LA) 743

Dichlorovinylene carbonate, Synthesis by means of ~ (4,5-dichloro-1,3-dioxol-2-one) as dienophile and photocyclophile (SC) 215 [G.E. *80*, 194 (1968)]

Dicyclohept[cd-ij]azulene, Azuleno[8,8a,1,2-def]heptalene (SC) 808 [G.E. *80*, 801 (1968)]

Di-π-cyclopentadienyltitanium(IV) pentaselenide (LA) 239

2,3-Didehydropyridine, Adduct with furan (LA) 651

4,5-Didehydropyrimidine, Existence of the heteroaryne 6-tert-butyl-~ (LA) 238

Diels-Alder reactions of tetrahalocyclopropenes (CR) 649 [G.E. *80*, 636 (1968)]

Dienes, Preparation of 1,4-~ by reduction of sodioallylmalonic ester with lithium aluminum hydride (SC) 61 [G.E. *80*, 44 (1968)]

Reaction of halogenated cyclopropenes with 1,3-~ (LA) 402

Tetrasulfur tetranitride reacts as an inorganic ~ (LA) 652

2,2'-Diethynylbiphenyl, Synthesis of ~ and its reaction with cyclopentadienone derivatives (SC) 378 [G.E. *80*, 366 (1968)]

Diffusion, anomalies of ~ and relaxation in high molecular weight systems with miscibility gaps (CR) 394 [G.E. *80*, 408 (1968)]

~-controlled reaction steps in free-radical polymerization (CR) 399 [G.E. *80*, 413 (1968)]

1,1-Difluorobenzocyclopropene (SC) 289 [G.E. *80*, 279 (1968)]

Difluorodiphosphate, Synthesis of dipotassium ~ by thermal reaction of tetraphosphorus decaoxide with potassium fluoride (SC) 622 [G.E. *80*, 616 (1968)]

Dihalogenocarbene, 11,11-Dihalogeno-1,6-methano-[10]annulenes as ~ transfer agents (SC) 288 [G.E. *80*, 278 (1968)]

11,11-Dihalogeno-1,6-methano-[10]annulenes as dihalogenocarbene transfer agents (SC) 288 [G.E. *80*, 278 (1968)]

9,10-Dihydroanthracene, Trans-annular rearrangement (LA) 743

2,5-Dihydrofurans, General synthesis (LA) 554

Dihydroxyuranyl-urea complex, Structure (LA) 150

Diimine, Bis(trimethylsilyl)-~ and tetrakis(trimethylsilyl)hydrazine (SC) 640 [G.E. *80*, 661 (1968)]

Dimedone, Autoxidation of ~ derivatives (SC) 299 [G.E. *80*, 319 (1968)]

Dimerization of oxaallyl, azaallyl, oxaphosphaallyl, and oxathiaallyl groups by way of organocopper compounds (SC) 540 [G.E. *80*, 565 (1968)]

o-Dimethoxybenzene, Dipole moment (LA) 654

Dimethylaminotrimethylstannane, Dehydrochlorinating agent (LA) 482

1,2-Dimethylcyclobutadiene, Dimers (LA) 239

Dimethylcyclopropanes, Synthesis of gem-~ by means of 2-diazopropane (SC) 65 [G.E. *80*, 42 (1968)]

Dimethylnitrosaminecopper(II) chloride, Structure (SC) 470 [G.E. *80*, 444 (1968)]

2,6-Dimethyl-4-phenylphosphabenzene, Structure (SC) 811 [G.E. *80*, 843 (1968)]

cis-3,5-Dimethylpiperidine, Conformation equilibrium (LA) 831

Dimethyl sulfoxide, Explosive mixtures of periodic acid and ~ (LA) 653

N-(2,4-Dinitrophenyl)-α-amino acids, Photolysis (LA) 482

4,6-Dioxa-1-azabicyclo[3.3.0]octanes, Synthesis of 1,3-dioxa-6-azacyclooctanes from ~ (SC) 731 [G.E. *80*, 703 (1968)]

1,3-Dioxa-6-azacyclooctanes, Synthesis from 4,6-dioxa-1-azabicyclo[3.3.0]octanes (SC) 731 [G.E. *80*, 703 (1968)]

1,3,2-Dioxaborinane, Addition of 4,4,6-trimethyl-~ to allenes (LA) 832

Dioxane, Binuclear chromium complex with ~ as bridging ligand (SC) 544 [G.E. *80*, 564 (1968)]

1,8-Dioxa-4,5,11,12-tetraaza-4,11-cyclotetradecadiene-3,10-diol, Unusual formation of the unusual 1,2,8,9-tetraaza-1,8-cyclotetradecadiene-3,10-diol system and its 5,12-dioxa analog (SC) 943 [G.E. *80*, 1000 (1968)]

4,6-Dioxo-2-arylperhydro-1,3,5,2-triazaphosphorine 2-oxide (LA) 742

1,3-Dioxol-2-one, Synthesis by means of dichlorovinylene carbonate (4,5-dichloro-~) as dienophile and photocyclophile (SC) 215 [G.E. *80*, 194 (1968)]

P,P-Diphenyl-N,N-bis(trimethylsilyl)-phosphinamide, New synthesis (SC) 382 [G.E. *80*, 399 (1968)]

1,3-Diphenyl-2,8-dihydrodibenz[e,h]azulene-2,8-dione, Synthesis (SC) 377 [G.E. *80*, 365 (1968)]

2,4-Diphenylthietane S,S-dioxides, cis- and trans-~ (LA) 654

Diphthalocyaninato-thorium(IV) and -uranium(IV) (SC) 819 [G.E. *80*, 792 (1968)]

Diphthalocyaninato-uranium(IV), Diphthalocyaninato-thorium(IV) and ~ (SC) 819 [G.E. *80*, 792 (1968)]

Dipole moment of *o*-dimethoxybenzene (LA) 654

Dirhenium dihydratoheptoxide $Re_2O_7(OH_2)_2$ – New type of water bonding in an aquoxide (SC) 295 [G.E. *80*, 286 (1968)]

Discharge, Organic synthesis in the plasma of high voltage ~ (CR) 230 [G.E. *80*, 202 (1968)]

Dispiro[2.0.2.2]oct-7-ene (LA) 743

Disulfane, Molecular structure of gaseous ~ (LA) 239

Disulfides, Electrolytic desulfurization of 2-mercapto carboxylic acids and the corresponding ~ (SC) 638 [G.E. *80*, 664 (1968)]

Diterpene, Lumiphorbol triacetate, a cage-like derivative of the ~, 4α-phorbol (SC) 890 [G.E. *80*, 913 (1968)]

Dithiane method, Preparation of (S)-2-methylbutyl and (S)-sec-butyl ketones from optically active 2-methyl-1-butanol by the ~ (SC) 619 [G.E. *80*, 617 (1968)]

Dithiophosphonates, Volatile transition metal alkanefluoro-~ (SC) 815 [G.E. 80, 844 (1968)]

Dodecacarbonyltriruthenium (FP) 427 [G.E. *80*, 460 (1968)]

Drugs, Fortschritte der Arzneimittelforschung (Progress in ~ research) (Book Review) 959, 960

~ affecting the peripheral nervous system (Book Review) 656

Durohydroquinone monoacetate, Formation of adenosine triphosphate (ATP) from adenosine diphosphate (ADP) and phosphate during oxidation of ~ (SC) 213 [G.E. *80*, 190 (1968)]

Dyes, Cyclobutenediylium ~ (FP) 530 [G.E. *80*, 541 (1968)]

Grundlagen der Synthese von Zwischenprodukten und Farbstoffen (Principles of the Synthesis of Intermediates and Dyestuffs) (Book Review) 241

ELECTRICAL conductivity and formation of chalcogenide glasses in Ge-As-Se and Ge-Sb-Se melts (SC) 947 [G.E. *80*, 999 (1968)]

Electric fields, Behavior of molecules in high ~ and at surfaces (CR) 231 [G.E. *80*, 243 (1968)]

Electroanalytical chemistry (Book Review) 160

Electrochemistry, Electrochemical oxidation of diphenyldiazomethane (SC) 290 [G.E. *80*, 280 (1968)]

The growth of anodic mercuric sulfide films (LA) 957

Lehrbuch der Elektrochemie (Textbook of ~) (Book Review) 315

Electrolytes, Kinetic investigations with solid ~ (CR) 307 [G.E. *80*, 292 (1968)]

Electrolyte solutions, Conductance (FP) 260 [G.E. *80*, 253 (1968)]

Electrolytic desulfurization of 2-mercapto carboxylic acids and the corresponding disulfides (SC) 638 [G.E. *80*, 664 (1968)]

Electrolytic reduction, Stereochemistry of the ~ of the C–Cl bond (LA) 312

Electrons, Formation and properties of solvated ~ (FP) 190 [G.E. *80*, 165 (1968)]

Solvated ~ (Book Review) 557

Electron-balance bonds, Trimethylsilyl derivatives of germanium and tin. – ~ of silicon (SC) 212 [G.E. *80*, 192 (1968)]

Electron configuration, Structures of compounds of elements in valence states with $4s^2$ and $5s^2$ ~ (CR) 651 [G.E. *80*, 669 (1968)]

Electron donor-acceptor complexes, Crystal structure (FP) 659 [G.E. *80*, 688 (1968)]

Formation of ~ as a basis for specific adsorption (SC) 948 [G.E. *80*, 1035 (1968)]

Electron donors, Tetraaminoethylenes as strong ~ (FP) 766 [G.E. *80*, 809 (1968)]

Electron-rich olefins, Reactions (FP) 754 [G.E. *80*, 823 (1968)]

Electron states, Energies of bonding ~ in simple molecules (LA) 555

π-Electron systems, Kurze Anleitung zur Berechnung von π-Elektronensystemen (A Short Introduction to the Calculation of ~) (Book Reviews) 155

Electrophilic additions to Unsaturated Systems (Book Review) 244

Electrophilic cleavage of cyclopropanols by halogenating agents (CR) 642 [G.E. *80*, 629 (1968)]

Electrophilic substitution at phosphorus (FP) 606 [G.E. *80*, 649 (1968)]

Electrophoresis, Diagonal ~ techniques (LA) 153

Cross ~, its Principles and Applications (Book Review) 317

Elimination, Catalytic ~ and isomerization reactions of O-heterocycles (CR) 227 [G.E. *80*, 200 (1968)]

Mechanism of ~-s over solid catalysts (CR) 232 [G.E. *80*, 242 (1968)]

Ellipsometry, Methods and results of optical investigations on semiconductor interfaces (FP) 161 [G.E. *80*, 213 (1968)]

Enamines see Alkenylamines

Encyclopedia, The ~ of Chemistry (Book Review) 85

Ullmanns Encyklopädie der technischen Chemie (Ullman's ~ of industrial chemistry) (Book Review) 834

Energy differences in the inner molecular orbitals of tert-butyl and trimethylsilyl phenyl ketones (SC) 885 [G.E. *80*, 906 (1968)]

Epiminoalkanes, Synthesis of long-chain cis- and trans-~ and the corresponding epiminoalkan-1-ols (LA) 651

Epiminoalkan-1-ols, Synthesis of long-chain cis- and trans-epiminoalkanes and the corresponding ~ (LA) 651

Episulfones, Decomposition of the thiirane 1,1-dioxides (~) (LA) 554

Epoxides, An abnormal ring cleavage of 1α,2α-epoxy-3-keto steroids by hydrogen fluoride (SC) 893 [G.E. *80*, 916 (1968)]

Epoxyamines, New class of organic compounds (LA) 237

Erythrocytes, Catalase from human ~ crystallizes in the form of tubes (LA) 153

ESR spectroscopy, ESR measurements on nitrogen-fixing titanium-alkali metal systems (SC) 386 [G.E. *80*, 398 (1968)]

ESR-Investigation of a new titanium-boron complex (SC) 821 [G.E. *80*, 796 (1968)]

ESR-Investigation on the stability of the titanium-carbon bond in soluble Ziegler-Natta catalysts (SC) 822 [G.E. *80*, 796 (1968)]

A reinterpretation of the ESR spectrum attributed to a non-degenerate state of the benzene radical anion (SC) 954 [G.E. *80*, 997 (1968)]

Influence of solvent pretreatment and electrolyte addition on the ESR spectra of aromatic radical anions (SC) 954 [G.E. *80*, 998 (1968)]

Atlas of electron spin resonance spectra (Book Review) 961

Esters, Ultrasonic absorption of alkyl ~ (LA) 830

Ethanol, Synthesis, on a preparative scale, of ~ stereospecifically labeled on hydrogen (SC) 892 [G.E. *80*, 915 (1968)]

Reactions with methyl radicals (LA) 830

N-Ethylbenzoisoazolium cations, Reaction with nucleophiles (LA) 312

Ethylene oxide, Wittig reactions with the aid of ~ (SC) 536 [G.E. *80*, 535 (1968)]

2-Ethyl-3-methylsuccinic acid, Absolute configuration of (–)-threo-~ (SC) 543 [G.E. *80*, 562 (1968)]

Ethyl trichloroallenecarboxylate, Preparation and dimerization (SC) 472 [G.E. *80*, 483 (1968)]

Evolution, Darwinian ~ experiment (LA) 313

Excitable systems, Kinetic principles (CR) 146 [G.E. *80*, 156 (1968)]

Excitation, Optical ~ and ionization of adsorbed molecules (CR) 401 [G.E. *80*, 368 (1968)]

Excitation energy, The transfer of electronic ~ from a complex cation (hexaureachromium(III)) to an anion (hexacyanochromate(III)) (LA) 899

Excited state, Formation and properties of molecular complexes in the ~ (CR) 147 [G.E. *80*, 156 (1968)]

Explosion, Explosive mixtures of periodic acid and dimethyl sulfoxide (LA) 653

Mechanism for the chlorine dioxide ~ (LA) 831

Explosives, Formulas for the calculation of the detonation properties of ~ (LA) 652

FERROCENE, Bonding in the ~-tetracyanoethylene (TCNE) adduct (1:1) (LA) 82

~-labeled proteins (LA) 236

Fiber keratins, Transformation processes (CR) 234 [G.E. *80*, 246 (1968)]

Field-emission, Studies on the adsorption of gases on clean metal surfaces with the aid of ~ and field-ion microscopy techniques (FP) 668 [G.E. *80*, 673 (1968)]

Field-ion microscopy, Studies on the adsorption of gases on clean metal surfaces with the aid of field-emission and ~ techniques (FP) 668 [G.E. *80*, 673 (1968)]

Flames, Cool ~ of hydrocarbons (FP) 45 [G.E. *80*, 53 (1968)]

Soot formation in premixed hydrocarbon ~ (FP) 414 [G.E. *80*, 425 (1968)]

Flavoprotein, Free-radical ~ (LA) 312

Fluorenones, Ring expansion to phenanthryl ethers (LA) 153

Fluorescence, ~ of peri-condensed non-alternant polycyclic hydrocarbons (LA) 958

Shifts in the ~ bands at different wavelengths of excitation (LA) 958

Fluorides, Structure of some ~, oxides, and oxide ~: the $RbNiCrF_6$ type (CR) 227 [G.E. *80*, 199 (1968)]

Fluorimetry, Analysis of foodstuffs with particular reference to quality control (CR) 956 [G.E. *80*, 1003 (1968)]

Fluorination of cyanogen chloride (LA) 82

Fluorocarbene, Mono-~ and its syn/anti selectivity (SC) 820 [G.E. *80*, 849 (1968)]

Fluorocarbons, Nucleophilic reactions with metal carbonyl anions (FP) 747 [G.E. *80*, 835 (1968)]

Fluorocarbon peroxides (LA) 741

Fluorodithiophosphonates, Volatile transition metal alkane-~ (SC) 815 [G.E. *80*, 844 (1968)]

Fluoroformate, tert-Butyl ~, a new reagent for peptide synthesis (SC) 380 [G.E. *80*, 396 (1968)]

N-(Fluoroformyl)iminosulfur dichloride and N-(chloroformyl)iminosulfur dichloride (SC) 217 [G.E. *80*, 235 (1968)]

N-Fluorosulfamidoyl fluoride, pentafluorosulfur N-fluoro-N-(fluorosulfonyl)-amide, and N-(dichloromethylene)fluoroformamide (SC) 630 [G.E. *80*, 626 (1968)]

Fluorotelluric acids (LA) 82

Food chemistry, Handbuch der Lebensmittelchemie (Manual of ~) (Book Review) 743

Foodstuffs, Analysis of ~ with particular reference to quality control (CR) 956 [G.E. *80*, 1003 (1968)]

Formazanes, Triaryl-~ (LA) 482

Fossil plants, Organic compounds in ~ (*Voltzia brongniarti*, *Coniferales*) (SC) 631 [G.E. *80*, 666 (1968)]

Fragmentation, ~ of specifically deuterated tri-*n*-alkylchromium compounds (SC) 951 [G.E. *80*, 1029 (1968)]

Specific ~ of cyclohexadienones (CR) 229 [G.E. *80*, 201 (1968)]

Porphin derivatives as experimental models for mass-spectroscopic ~ reactions (CR) 479 [G.E. *80*, 495 (1968)]

Friedel-Crafts reactions of octachlorocyclotetra(phosphazene) (SC) 887 [G.E. *80*, 910 (1968)]

Fructose amino acids, Degradation to N-(2-furoylmethyl)amino acids. Intermediates in browning reactions (SC) 628 [G.E. *80*, 627 (1968)]

Fructose metabolism, Biochemistry (CR) 650 [G.E. *80*, 669 (1968)]

Fuel cells, Second international meeting (CR) 76 [G.E. *80*, 46 (1968)]

Fulvalenes, Hetero-~ and azafulvenes (SC) 296 [G.E. *80*, 277 (1968)]

Fulvenes, Heterofulvalenes and aza-~ (SC) 296 [G.E. *80*, 277 (1968)]

Isobenzo-~ (SC) 297 [G.E. *80*, 312 (1968)]

Simple synthesis of substituted ~ from 6-fulvenyl *p*-toluenesulfonates (SC) 806 [G.E. *80*, 800 (1968)]

Furan, Modification of the orientation of substitution reactions on thiophene and ~ derivatives (FP) 519 [G.E. *80*, 547 (1968)]

Adduct of a 2,3-didehydropyridine with ~ (LA) 651

Photolytic isomerization of poly-tert-butyl-~-s (LA) 832

Furo[3,4-d]tropone, 6H-Cyclohepta[c]-furan-6-one (LA) 742

N-(2-Furoylmethyl)amino acids, Degradation of fructose amino acids to ~. Intermediates in browning reactions (SC) 628 [G.E. *80*, 627 (1968)]

GABRIEL synthesis of primary amines (FP) 919 [G.E. *80*, 986 (1968)]

Galvanic elements, Metal–non-metal (CR) 230 [G.E. *80*, 202 (1968)]

Gangliosides, Structure and function (FP) 87 [G.E. *80*, 89 (1968)]

Gas chromatography, High-melting aromatic compounds as stationary phases in ~ (SC) 724 [G.E. *80*, 754 (1968)]

Gases, Studies on the adsorption of ~ on clean metal surfaces with the aid of field-emission and field-ion microscope techniques (FP) 668 [G.E. *80*, 673 (1968)]

Gas phase reactions, rate theory (Book Review) 319

Gelatin, Replacement of plasma by high molecular weight substances (FP) 702 [G.E. *80*, 719 (1968)]

Gel chromatography, Separation efficiency (CR) 395 [G.E. *80*, 409 (1968)]

Gelchromatographie (~) (Book Review) 484

Gels, Synthesis of organic polymer ~ with very uniform mesh sizes (CR) 394 [G.E. *80*, 408 (1968)]

New ~ from cellulose and their uses in chromatography (CR) 400 [G.E. *80*, 414 (1968)]

Germanium, Electrical conductivity and formation of chalcogenide glasses in Ge–As–Se and Ge–Sb–Se melts (SC) 947 [G.E. *80*, 999 (1968)]

Germanium complexes, Tris(imidodiphosphinato) cationic complexes of silicon, germanium, and tin (SC) 549 [G.E. *80*, 558 (1968)]

Germanium compounds, Trimethylsilyl derivatives of germanium and tin. – Electron-balance bonds of silicon (SC) 212 [G.E. *80*, 192 (1968)]

Insertion of dihalogenocarbenes into Si–Hg and Ge–Hg bonds (LA) 81

Germanium tetrahalides, Abnormal reactions in alkylation of silicon and ~ (CR) 310 [G.E. *80*, 321 (1968)]

Glasses, Electrical conductivity and formation of chalcogenide ~ in Ge–As–Se and Ge–Sb–Se melts (SC) 947 [G.E. *80*, 999 (1968)]

D-Glucose, Condensation of ~ with aromatic systems in liquid hydrogen fluoride (CR) 146 [G.E. *80*, 156 (1968)]

Glucosides, Conversion of phenylalanine into lignin-forming ~ (LA) 80

Glutamate dehydrogenase, Structure of ~ from ox liver (CR) 649 [G.E. *80*, 669 (1968)]

Glyceraldehyde - 3 - phosphate - dehydrogenase, Properties of the allosteric forms of yeast ~ (CR) 401 [G.E. *80*, 369 (1968)]

Glycine amide, Deprotonation in a ternary copper(II)-complex (SC) 137 [G.E. *80*, 124 (1968)]

Gold complexes, Eight-membered gold-oxygen ring (LA) 483

Grafting of polymers on active fillers; polymerization of styrene in the presence of carbon black (CR) 399 [G.E. *80*, 413 (1968)]

Gramicidin S, Synthesis of all-L-~ (SC) 883 [G.E. *80*, 907 (1968)]

Grignard syntheses, Trimethylsilyl group as protective group for terminal alkynes (LA) 311

Guaianolides and Germacranolides (Book Review) 160

Guanidines, Cycloaddition of isocyanates and isothiocyanates to amidines and ~ (SC) 291 [G.E. *80*, 281 (1968)]

HALIDES, New method for estimating thermodynamic properties of crystalline substances: alkali ~ and hydrides (NaCl system) (CR) 227 [G.E. *80*, 200 (1968)]

Halogenating agents, Electrophilic cleavage of cyclopropanols by ~ (CR) 642 [G.E. *80*, 629 (1968)]

Halogen chemistry (Book Review) 746, 962

1-Halogenoalkyl isocyanates (SC) 621 [G.E. *80*, 620 (1968)]

Halogenoolefins, Reactions with organocopper compounds (LA) 310

Halogenosilanes, Direct synthesis of organo-~ (FP) [G.E. *80*, 133 (1968)]

Volatile silanes can be halogenated in stages with silver chloride or bromide (LA) 152

o-Halogenostyrenes, Kinetics of the free-radical polymerization of styrene and ~ at low initiator concentrations (CR) 397 [G.E. *80*, 411 (1968)]

Hammett constants, of phosphorus-containing groups determined from nuclear magnetic resonance spectra of *para*-phosphorus-substituted toluenes (SC) 544 [G.E. *80*, 559 (1968)]

~ of phosphorus-containing groups determined from nuclear magnetic resonance spectra of *meta*- and *ortho*-phosphorus-substituted toluenes (SC) 545 [G.E. *80*, 559 (1968)]

Heat of solution, Strongly exothermic ~ of palladium in molten tin (LA) 899

Helix structures, Cooperative conformational changes of the ~ of biopolymers and analogous model substances in solution (CR) 478 [G.E. *80*, 450 (1968)]

Hemoglobin, Three-dimensional Fourier synthesis of human deoxy-~ (LA) 314

Heteroarylated alkanes, Dehydrodimerization by way of organocopper compounds (SC) 541 [G.E. *80*, 566 (1968)]

Heterocumulenes, New investigations of ~ and their derivatives (CR) 479 [G.E. *80*, 496 (1968)]

Heterocycles, Sulfonyl hydrazones of cyclic amides and quaternary azo sulfones of ~ as reagents in azo chemistry (FP) 335 [G.E. *80*, 343 (1968)]

Catalytic elimination and isomerization reactions of O-~ (CR) 227 [G.E. *80*, 200 (1968)]

Reactive aromatic ~ containing tetravalent sulfur (LA) 237

Heterofulvalenes and azafulvenes (SC) 296 [G.E. *80*, 277 (1968)]

Heterogeneity, Chemical ~ of copolymers -- experimental studies on compatibility (CR) 397 [G.E. *80*, 411 (1968)]

Hexaamidoplumbate, Dipotassium ~-(IV) (SC) 950 [G.E. *80*, 1029 (1968)]

Hexafluorides, Oxidizing properties of the third transition series ~ and related compounds (FP) 433 [G.E. *80*, 453 (1968)]

Hexafluorobenzene, Addition of carbenes (LA) 831

Hexahydrofuro[2,3-b]pyrrol-2-ones, Synthesis (SC) 303 [G.E. *80*, 317 (1968)]

Hexamethyl-Dewar-benzene, Acid-catalyzed rearrangement of hexamethylprismane and ~ (SC) 467 [G.E. *80*, 447 (1968)]

Kinetics and thermochemistry of the thermal rearrangements of ~ and of hexamethylprismane (CR) 646 [G.E. *80*, 633 (1968)]

Hexamethylprismane, Acid-catalyzed rearrangement of ~ and hexamethyl-Dewar-benzene (SC) 467 [G.E. *80*, 447 (1968)]

Kinetics and thermochemistry of the thermal rearrangement of hexamethyl-Dewar-benzene) and of ~ (CR) 646 [G.E. *80*, 633 (1968)]

Hexobarbital, Synthesis of both ~ enantiomers and of (+)-thiohexobarbital from (-+)-methyl 2-cyano-2-(1-cyclohexenyl)propionate (SC) 463 [G.E. *80*, 483 (1968)]

Hexulose hydrazones, Preparation of N-aminoaziridines and rearrangements to ~ (SC) 134 [G.E. *80*, 120 (1968)]

High-pressure, properties and structure of liquids (CR) 829 [G.E. *80*, 806 (1968)]

Chemical reactions at ~-s (Book Review) 833

History of chemistry, Histoire Brève de la Chimie (Short ~) (Book Review) 157

Entwicklung der Chemie in der neueren Zeit (Development of Chemistry in Modern Times) (Book Review) 243

Homoserine, Three new α-amino acids (LA) 313

Hydrazine, Bis(trimethylsilyl)diimine and tetrakis(trimethylsilyl)-~ (SC) 640 [G.E. *80*, 661 (1968)]

N,N'-Hydrazodisulfonyl difluoride, Sulfur dichloride (chlorosulfonyl)imide and ~ (SC) 63 [G.E. *80*, 43 (1968)]

Hydrazones, Mechanism of the Wolff-Kishner reduction, elimination, and isomerization reactions (FP) 120 [G.E. *80*, 141 (1968)]

Hydrazyls, New ~ of low molecular weight and polymeric ~ (SC) 945 [G.E. *80*, 1002 (1968)]

Hydrides, New method for estimating thermodynamic properties of crystalline substances: alkali halides and ~ (NaCl sytem) (CR) 227 [G.E. *80*, 200(1968)]

H/D isotope effect of saltlike ~ (LA) 148

Hydridodiethylcobalt complex, Preparation and properties of a bicyclic ~ (SC) 129 [G.E. *80*, 115 (1968)]

Hydrocarbons, Valence isomerizations of C_9H_{10} ~ (SC) 468 [G.E. *80*, 446(1968)]

The fluorescence of peri-condensed non-alternate polycyclic ~ (LA) *958*

Hydrocarbon flames, Cool ~ (FP) 45 [G.E. *80*, 53 (1968)]

Soot formation in premixed ~ (FP) 414 [G.E. *80*, 425 (1968)]

Hydrogenation, 1,6-C–C linkage on pressure-~ of α-hydroxyadipaldehyde (SC) 66 [G.E. *80*, 42 (1968)]

Passivation of Raney nickel by nitriles. -- ~ in acid solution (SC) 141 [G.E. *80*, 152 (1968)]

Catalytic ~ of indole (SC) 208 [G.E. *80*, 189 (1968)]

Bis(tricarbonylcyclopentadienylchromium), a catalyst for selective ~ (SC) 631 [G.E. *80*, 663 (1968)]

~ of polyenes by tricarbonylcyclopentadienylhydridomolybdenum and -tungsten (SC) 880 [G.E. *80*, 968 (1968)]

Asymmetric catalytic ~ with an optically active phosphine rhodium complex in homogeneous solution (SC) 942 [G.E. *80*, 1034 (1968)]

Hydrogen fluoride, Condensation of D-glucose with aromatic systems in liquid ~ (CR) 146 [G.E. *80*, 156 (1968)]

Hydrogen peroxide, Spirocyclic 1:2 adduct of tetrakis(diphenylarsorylmethyl)-methane and ~ (SC) 738 [G.E. *80*, 755 (1968)]

α-Hydroxyadipaldehyde, 1,6-C–C linkage on pressure-hydrogenation of ~ (SC) 66 [G.E. *80*, 42 (1968)]

Ring closure of ~ (SC) 952 [G.E. *80*, 1033 (1968)]

Hydroxylammonium fluoride (LA) 311

Hydroxylase, Cofactor requirement of collagen-proline ~ (LA) 150

Hydroxylation, Tetrahydropterins as coenzymes of enzymatic ~ (CR) 477 [G.E. *80*, 492 (1968)]

2-Hydroxy-6-oxo-trans-2-trans-4-heptadienoic acid, Microbiological conversion of 3-methylpyrocatechol into ~ (LA) 481

12β-Hydroxy-4,6-pregnadiene-3,20-dione, Protective materials in the secretion from the prothoracic protective gland of a Mexican cybister species (SC) 62 [G.E. *80*, 45 (1968)]

4-Hydroxythienopyrimidines (SC) 136 [G.E. *80*, 122 (1968)]

Hyperfine interactions (Book Review) 486

IMIDAZOLE, Iron derivatives of five-membered carbon-nitrogen heterocycles (SC) 70 [G.E. *80*, 38 (1968)]

Unusual azo coupling reaction (LA) 402

Iminosulfur dichloride,N-(Fluoroformyl)-~ and N-(chloroformyl)-~ (SC) 217 [G.E. *80*, 235 (1968)]

Incompatibility, of polymer mixtures (CR) 393 [G.E. *80*, 407 (1968)]

Effect of structure on the ~ of polymer mixtures in solution (CR) 394 [G.E. *80*, 408 (1968)]

Indirect nuclear spin coupling, Mechanism (CR) 309 [G.E. *80*, 320 (1968)]

Indigo, Tetramethylpyrrole-~ (SC) 734 [G.E. *80*, 758 (1968)]

Indium, Wetting and adhesion behavior of liquid ~ on solid aluminum (LA) 654

Indole, Catalytic hydrogenation (SC) 208 [G.E. *80*, 189 (1968)]

Photochemical cyclodehydrogenations in the ~ series (SC) 466 [G.E. *80*, 486 (1968)]

New synthesis of ~ derivatives (CR) 230 [G.E. *80*, 203 (1968)]

Synthesis and configuration of heterocyclic ~ derivatives. Stereoselective total synthesis of DL-akuammigine and DL-tetrahydroalstonine (CR) 552 [G.E. *80*, 536 (1968)]

Indole alkaloids (Book Review) 245

Indomycinones, Indomycins and ~ (CR) 481 [G.E. *80*, 493 (1968)]

Indomycins and indomycinones (CR) 481 [G.E. *80*, 493 (1968)]

INDOR technique, Use in the solution of structural problems in organophosphorus chemistry (SC) 814 [G.E. *80*, 794 (1968)]

Infrared spectroscopy, Distortions of IR bands as a result of finite spectral slit width (LA) 151

Infrared Spectra of Adsorbed Species (Book Review) 486

~ in Surface Chemistry (Book Review) 486

Insulin, Precursor of the biosynthesis (LA) 81

Interfaces, Methods and results of optical investigations on semiconductor ~ (FP) 161 [G.E. *80*, 213 (1968)]

Intermetallic compounds, The superconducting properties of ternary ~ having a β-tungsten structure (LA) 957

Inventor, Der Arbeitnehmer als Erfinder (The employee as ~) (Book Review) 83

Inversion, Slow ~ at pyramidal nitrogen: Isolation of diastereomeric 7-chloro-7-azabicyclo[4.1.0]heptanes at room temperature (SC) 224 [G.E. *80*, 197 (1968)]

Iodine, Proof of the existence of I_4 in ~ vapor (LA) 958

Iodine compounds, Fluorides and perfluoroorgano-substituted compounds of I^{1+} and I^{3+} (CR) 309 [G.E. *80*, 321 (1968)]

Iodoaromatic compounds, Photolysis of ~ (FP) 36 [G.E. *80*, 69 (1968)]

Ion exchange, Electrical excitation of the axon membrane as co-operative ~ (CR) 829 [G.E. *80*, 806 (1968)]

~ properties of a titanium hexacyanoferrate(II) complex (LA) 82

Ionic mobility, Investigation of the ~ of some copper(I) compounds by nuclear magnetic resonance (CR) 476 [G.E. *80*, 449 (1968)]

Ionization, Optical excitation and ~ of adsorbed molecules (CR) 401 [G.E. 368 (1968)]

Ion pair formation in benzene radical anion solutions (SC) 953 [G.E. *80*, 996 (1968)]

Iridium compounds, Crystal structure of "$Ir(CO)_3Cl$" = $Ir(CO)_{2.93}Cl_{1.07}$ (SC) 812 [G.E. *80*, 844 (1968)]

Structure of β-$RuCl_3$, RuI_3, $IrBr_3$, and IrI_3 (CR) 148 [G.E. *80*, 155 (1968)]

Iron, Mass-spectrometric study of the synthesis of NH_3 on ~ tips (SC) 139 [G.E. *80*, 151 (1968)]

Iron compounds, Iron derivatives of five-membered carbon-nitrogen heterocycles (SC) 70 [G.E. *80*, 38 (1968)]

Acrylonitrile as a hard and soft base in di-μ-acrylonitrilebis(tricarbonyliron) (SC) 222 [G.E. *80*, 239 (1968)]

Pentacoordinated metal(0)-trifluorophosphine derivatives (LA) 652

Synthesis of bis(as-indacenyliron) (LA) 652

Irradiation damage, Investigations of the chemical causes of biological ~ (CR) 551 [G.E. *80*, 536 (1968)]

Isobenzofulvenes (SC) 297 [G.E. *80*, 312 (1968)]

Isocyanates, Cycloaddition of ~ and isothiocyanates to amidines and guanidines (SC) 291 [G.E. *80*, 281 (1968)]

Formation of phenylazomethyl ~ on oxidation of 2-phenylsemicarbazones (SC) 293 [G.E. *80*, 287 (1968)]

Anellated 1,3,5-triazine-2,4-diones as dimers of heterocyclic ~ (SC) 381 [G.E. *80*, 363 (1968)]

Synthesis of substituted oxetane-2,3-diimines from ~ (SC) 389 [G.E. *80*, 406 (1968)]

Phosphorus(V) ~ (SC) 618 [G.E. *80*, 620 (1968)]

1-Halogenoalkyl ~ (SC) 621 [G.E. *80*, 620 (1968)]

A new synthesis of ~ and isothiocyanates (SC) 941 [G.E. *80*, 1028 (1968)]

Isocyanato carboxylic acids, Preparation of silyl esters of ~ (SC) 942 [G.E. *80*, 1029 (1968)]

Isocyanides, Phosphinylmethyl ~ (SC) 372 [G.E. *80*, 394 (1968)]

Carbonyl olefination with α-metalated ~ (SC) 805 [G.E. *80*, 842 (1968)]

Isoindoline 1,1,2-Trimethyl-3-methylene-~ (SC) 373 [G.E. *80*, 361 (1968)]

Isomerism, cis-trans ~ of N-monosubstituted amides (CR) 228 [G.E. *80*, 201 (1968)]

Isomerizations, in cyclobutenes (FP) 559 [G.E. *80*, 585 (1968)]

Catalytic eliminations and ~ of O-heterocycles (CR) 227 [G.E. *80*, 200 (1968)]

Isoquinoline, Synthesis of derivatives of ~, of 1,3-benzoselenazin-4-one, and of 1H-2-benzazepin-1-one (SC) 464 [G.E. *80*, 484 (1968)]

Isothiocyanates, Cycloaddition of isocyanates and ~ to amidines and guanidines (SC) 291 [G.E. *80*, 281 (1968)]

A new synthesis of isocyanates and ~ (SC) 941 [G.E. *80*, 1028 (1968)]

Raman spectra of the tetra-~ complexes of the IIB metals (LA) 312

Isotopes, Rapid chemical separations for the study of short-lived atomic nuclei (CR) 78 [G.E. *80*, 85 (1968)]

Isotope effect, Study of the mechanism of dehydrogenase reactions by measurement of the ~ (CR) 740 [G.E. *80*, 706 (1968)]

H/D ~ of salt-like hydrides (LA) 148

Isotope-exchange experiments to determine the mechanism of the enzymatic phosphoenolpyruvate (PEP) synthesis (LA) 152

KAOLIN, Chemistry of clay (FP) 681 [G.E. *80*, 736 (1968)]

Keratins, Transformation processes in fiber ~ (CR) 234 [G.E. *80*, 246 (1968)]

Ketals, Formation of dialkoxycarbonium ions from ~ by removal of alkyl groups by means of carbonium ions (SC) 64 [G.E. *80*, 81 (1968)]

Ketanils and ketimines (LA) 239

Ketene, Cyclobutanones from enamines and ~s by two-stage addition (SC) 737 [G.E. *80*, 759 (1968)]

Detection of open-chain intermediates in the formation of β-lactams from ~s and azomethines (SC) 826 [G.E. *80*, 802 (1968)]

Di-tert-butylthio-~ and di-tert-butylthio-~ S-oxide (LA) 900

Keteneimines, Preparation of ~ by Beckmann rearrangement (SC) 304 [G.E. *80*, 314 (1968)]

Ketimines, N-Nitroso-~ (LA) 900

γ-Keto acids, New synthesis of esters of ~ and of β-acylacrylates (LA) 482

Ketones, Synthesis of (R)- and (S)-aldehydes and -~s from chiral sec-alkyl halides (SC) 620 [G.E. *80*, 618 (1968)]

Energy differences in the inner molecular orbitals of tert-butyl and trimethylsilyl phenyl ~ (SC) 885 [G.E. *80*, 906 (1968)]

Aminomethyl cyclopropyl ~ from 3-amino-2-oxoalkylphosphonates (CR) 647 [G.E. *80*, 635 (1968)]

Preparation of α,β-unsaturated ~ (LA) 741

Kinetics, of the aminolysis of methoxyphenylcarbenepentacarbonylchromium(0) (SC) 817 [G.E. *80*, 847 (1968)]

Kinetic investigations with solid electrolytes (CR) 307 [G.E. *80*, 292 (1968)]

~ and thermochemistry of the thermal rearrangements of hexamethyl-Dewarbenzene and of hexamethylprismane (CR) 646 [G.E. *80*, 633 (1968)]

~ of the ring-opening in liquid cyclooctasulfur (LA) 830

Progress in Reaction ~ (Book Review) 157

Gas Phase Reaction Rate Theory (Book Review) 319

~ of Inorganic Reactions (Book Review) 405

L'analyse cinétique de la transformation chimique (Kinetic analysis of chemical reactions) (Book Review) 656

Kuhn, Richard ~ in memoriam (FP) 489 [G.E. *80*, 501 (1968)]

LACTAMS, α-~ (Aziridinones) (FP) 25 [G.E. *80*, 27 (1968)]

Detection of open-chain intermediates in the formation of β-~ from ketenes and azomethines (SC) 826 [G.E. *80*, 802 (1968)]

Cationic polymerization of ~ (CR) 233 [G.E. *80*, 245 (1968)]

Unusually stable α-~ (LA) 239

Lanthanons, Industrial chemistry of the ~, yttrium, thorium, and uranium (Book Review) 556

Laser, The decomposition of aromatic compounds in the focus of a ~ beam (LA) 899

Latent image, Redox behavior of the ~ in silver halide films (CR) 550 [G.E. *80*, 537 (1968)]

Latices, Investigations on the agglomeration of polymer ~ (CR) 399 [G.E. *80*, 414 (1968)]

Lead compounds, Dipotassium hexaamidoplumbate(IV) (SC) 950 [G.E. 1029 (1968)]

$Pb(H_2PO_4)_4 \cdot (C_6H_5)_3PO$, lead(IV) tetrakis(dihydrogen phosphate) stabilized by triphenylphosphine oxide (SC) 946 [G.E. *80*, 1031 (1968)]

Recent findings in the organic chemistry of tin and lead (CR) 78 [G.E. *80*, 48 (1968)]

Ligand field theory, Einführung in die Liganden-Feldtheorie (Introduction to ~) (Book Review) 316

Ligand reorganization in the trigonal bipyramid (SC) 725 [G.E. *80*, 700 (1968)]

Lignin, Conversion of phenylalanine into ~-forming glucosides (LA) 80

Chemistry of ~ (Book Review) 320

Lipids, Simple ultramicro method for the quantitative determination of nitrogen in ~ (LA) 313

Liquid crystals, Recent results in the field of ~ (FP) 97 [G.E. *80*, 99 (1968)]

Liquids, High-pressure properties and structure of ~ (CR) 829 [G.E. *80*, 806 (1968)]

Absorption spectra of ~ in the millimeter range (LA) 240

Surface tension of ~ (LA) 652

Lithium, Ternary nitrides, phosphides, and arsenides of ~ (FP) 360 [G.E. *80*, 373 (1968)]

Lobster shell, Crustacyanin, a chromoprotein from ~ (LA) 313

Luciferase, Luciferins, bioluminescent substances (FP) 407 [G.E. *80*, 417 (1968)]

Luciferins, bioluminescent substances (FP) 407 [G.E. *80*, 417 (1968)]

Luminescence, Luciferins, bioluminescent substances (FP) 407 [G.E. *80*, 417 (1968)]

Oxygen radicals and chemi-~ (CR) 447 [G.E. *80*, 449 (1968)]

Chemi-~ of cyclic diacylhydrazides and diazaquinolines (CR) 480 [G.E. *80*, 494 (1968)]

Lumiphorbol triacetate, a cage-like derivative of the diterpene 4α-phorbol (SC) 890 [G.E. *80*, 913 (1968)]

MACROCYCLIC compounds, New general synthesis (LA) 653

Macromolecular colloquium (CR) 393 [G.E. *80*, 407 (1968)]

Macromolecules, Hindered rotation in macromolecular solids, investigated by nuclear magnetic resonance (CR) 828 [G.E. *80*, 851 (1968)]

Magnesium, Organic compounds of ~ beryllium, calcium, strontium, and barium (Book Review) 744

Magnetic properties, Landolt-Börnstein, Zahlenwerte und Funktionen aus Naturwissenschaften und Technik (Landolt-Börnstein, Numerical Values and Functions from Science and Technology) (Book Review) 315

Malonic ester, Preparation of 1,4-dienes by reduction of sodioallyl-~ with lithium aluminum hydride (SC) 61 [G.E. *80*, 44 (1968)]

Manganese compounds, Arsinecyclopentadienyldicarbonylmanganese(I) (SC) 634 [G.E. *80*, 625 (1968)]

Complexes of trivalent manganese (LA) 150

Novel manganese(II) complexes with the coordination number 8 (LA) 237

Mannose, Synthesis of methyl 4,6-O-benzylidene-2,3-(2-hydroxyethylidene)-2,3-dideoxy-α-D-mannopyranoside, a cyclopropane sugar (SC) 142 [G.E. *80*, 152 (1968)]

Mass spectra, The ~ of organic molecules (Book Review) 960

Mass spectrometry, Study of the synthesis of NH_3 on iron tips (SC) 139 [G.E. *80*, 151 (1968)]

Study of cycloheptasulfur, S_7, and cyclodecasulfur, S_{10} (SC) 633 [G.E. *80*, 661 (1968)]

Porphin derivatives as experimental models for mass-spectroscopic fragmentation reactions (CR) 479 [G.E. *80*, 495 (1968)]

Interpretation of Mass Spectra (Book Review) 85

Massenspektrometrische Strukturanalyse organischer Verbindungen. Eine *Einführung*. (*Mass Spectrometric Structural* Analysis of Organic Compounds. An Introduction) (Book Review) 240

Introduction to ~ (Book Review) 318

Mass Spectrometric Analysis of Solids (Book Review) 405

Mathematics, Physikalisch-chemisches Rechnen in Wissenschaft und Technik (Physicochemical Calculation in Science and Industry) (Book Review) 315

Memory effects and stereochemistry in multiple carbonium ion rearrangements (FP) 779 [G.E. *80*, 765 (1968)]

2-Mercapto carboxylic acids, Electrolytic desulfurization of ~ and the corresponding disulfides (SC) 638 [G.E. *80*, 664 (1968)]

Mercury, The reaction of ~ atoms with chlorine atoms (LA) 957

Mercury compounds, Direct synthesis of a mercury salt-carbene complex (SC) 141 [G.E. *80*, 154 (1968)]

Bis(chloromercuri)-2,4-pentanedione an unusual acetylacetone derivative (SC) 629 [G.E. *80*, 664 (1968)]

Bis(triphenylstannyl)mercury (LA) 959

Insertion of dihalogenocarbenes into Si–Hg and Ge–Hg bonds (LA) 81

The growth of anodic mercuric sulfide films (LA) 957

Merrifield synthesis, Synthesis of oligonucleotides on a polymeric carrier (SC) 473 [G.E. *80*, 488 (1968)]

Importance of the ~ in macromolecular chemistry (CR) 399 [G.E. *80*, 413 (1968)]

Mesoporphyrin IX, Preparation of titanyl and vanadyl ~ dimethyl esters (SC) 891 [G.E. *80*, 914 (1968)]

Metabolism, Stoffwechsel im Zentralnervensystem (~ in the Central Nervous System) (Book Review) 242

Metal carbonyl anions, Nucleophilic reactions of ~ with fluorocarbons (FP) 747 [G.E. *80*, 835 (1968)]

Metal films, Chemisorption on ~ (CR) 307 [G.E. *80*, 289 (1968)]

Metals, Individual steps in the chemisorption of gases on ~ (CR) 146 [G.E. *80*, 155 (1968)]

Methacrylic compounds, Acryl- und Methacrylverbindungen (Acrylic and ~) (Book Review) 484

Methanol is oxidized in *Pseudomonas* by an unusual alcohol dehydrogenase (LA) 314

3,8-Methanopentahendecafulvalene, 11,12,13,14-Tetraphenyl-~ (SC) 729 [G.E. *80*, 698 (1968)]

Methods of elemento-organic chemistry (Book Review) 156

Methods of organic chemistry, Methoden der organischen Chemie (~) (Book Review) 154

Methoxyphenylcarbenepentacarbonylchromium(0), Kinetics of the aminolysis of ~ (SC) 817 [G.E. *80*, 847 (1968)]

(S)-2-Methylbutyl ketone, Preparation of ~ and (S)-sec-butyl ketones from optically active 2-methyl-1-butanol by the dithiane method (SC) 619 [G.E. *80*, 617 (1968)]

4-Methylpentaleno[6,6a,1,2-def]heptalene, Crystal and molecular structure (SC) 816 [G.E. *80*, 795 (1968)]

Methylpotassium, Preparation and structure (SC) 133 [G.E. *80*, 123 (1968)]

3-Methylpyrocatechol, Microbiological conversion of ~ into 2-hydroxy-6-oxo-trans-2-trans-4-heptadienoic acid (LA) 481

Methyl radicals, Reactions with ethanol (LA) 830

1-Methyl-2,3,4-trimethylenecyclobutenide ion (SC) 538 [G.E. *80*, 532 (1968)]

Microchemical methods, Handbuch der mikrochemischen Methoden (Handbook of ~) (Book Review) 241

Micrococcus nuclease (LA) 151

Micromethods, Mikromethoden für das klinisch-chemische und biochemische Laboratorium (~ for the clinical and biological laboratory) (Book Review) 83

Molds, *New siderамins from* ~ (CR) 551 [G.E. *80*, 569 (1968)]

Molecular movements, Nuclear resonance studies of ~ and phase changes in solid organic substances (CR) 79 [G.E. *80*, 85 (1968)]

Molybdates, Trithio-~ (SC) 817 [G.E. *80*, 846 (1968)]

Molybdenum compounds, Hydrogenation of polyenes by tricarbonylcyclopentadienylhydridomolybdenum and -tungsten (SC) 880 [G.E. *80*, 968 (1968)]

Ternary oxides of rutile structure: Systems containing WO_2, MoO_2, VO_2 or TiO_2 (CR) 229 [G.E. *80*, 202 (1968)]

Montmorillonite, *Chemistry of clay* (FP) 681 [G.E. *80*, 736 (1968)]

Morphogenesis, Comprehensive biochemistry (Book Review) 317

NAPHTHALENE, ^{13}C-Experiments on carbon skeleton rearrangements: Automerization of ~ (SC) 548 [G.E. *80*, 567 (1968)]

1,2-Naphthalene oxide (SC) 374 [G.E. *80*, 402 (1968)]

Neptunium complex, Tetrakis(cyclopentadienyl)neptunium(IV) (SC) 634 [G.E. *80*, 661 (1968)]

Nerve stimulation, Electrical excitation of the axon membrane as co-operative ion exchange (CR) 829 [G.E. *80*, 806 (1968)]

Neutrons, The reaction cross-section of ammonium salts for scattering of subthermal ~ (LA) 958

Nickel, 1,5,9-Cyclododecatriene complexes of ~-(0) (SC) 949 [G.E. *80*, 1033 (1968)]

Passivation of Raney ~ by nitriles. – Hydrogenation in acid solution (SC) 141 [G.E. *80*, 152 (1968)]

Fixation of molecular nitrogen on ~ (SC) 731 [G.E. *80*, 705 (1968)]

Nickel *compounds*, Bimetallic π-allyl complexes of nickel and palladium (SC) 879 [G.E. *80*, 968 (1968)]

Nickel squarate, Unit cells and absorption spectra of the cubic squarates of cobalt and nickel (SC) 638 [G.E. *80*, 664 (1968)]

Nicotinamide adenine dinucleotide, New reaction (LA) 312

Niobium, Chemistry of ~ and tantalum (Book Review) 744

Nitrene, Thermal rearrangement of phenyl-~ into cyclopentadienecarbonitrile (LA) 741

Nitrides, Ternary ~, phosphides, and arsenides of lithium (FP) 360 [G.E. *80*, 373 (1968)]

Nitrile groups, New method for the introduction of ~ (SC) 377 [G.E. *80*, 397 (1968)]

Nitriles, Addition of substituted vinyloxyboranes to ~ (SC) 735 [G.E. *80*, 756 (1968)]

One-stage synthesis of aliphatic ~ (LA) 149

Nitro compound, Sterically induced intramolecular cyclization of an α,β-unsaturated ~ (SC) 637 [G.E. *80*, 666 (1968)]

Nitro-dimethylamine, Structure of nitroso- and ~ (SC) 806 [G.E. *80*, 842 (1968)]

Nitro groups, A new possibility of removing ~ (LA) 958

Nitrogen, Slow inversion at pyramidal ~: *Isolation of diastereomeric 7-chloro-7-azabicyclo*[4.1.0]heptanes at room temperature (SC) 224 [G.E. *80*, 197 (1968)]

Fixation of molecular ~ on nickel (SC) 731 [G.E. *80*, 705 (1968)]

Simple ultramicro method for the quantitative determination of ~ in lipids (LA) 313

Organic Compounds with ~-~ Bonds (Book Review) 85

Organic Chemistry of ~ (Book Review) 485

Nitrogen elimination, Proof of $N_\gamma N_\beta$-*elimination from Staudinger adducts* $R_3P{=}N_\gamma{-}N_\beta{=}N_\alpha{-}X$ by ^{15}N-isotopic labeling (SC) 636 [G.E. *80*, 667 (1968)]

Nitrogen fixation, ESR measurements on nitrogen-fixing titanium-alkali metal systems (SC) 386 [G.E. *80*, 398 (1968)]

Nitrogen oxide fluorides (FP) 440 [G.E. *80*, 466 (1968)]

Nitrosodimethylamine, Structure of ~ and nitro-dimethylamine (SC) 806 [G.E. *80*, 842 (1968)]

N-Nitrosoketimines (LA) 900

o-Nitrotoluene, Exchange of oxygen and hydrogen atoms (LA) 481

NMR spectroscopy, Hammett constants of phosphorus-containing groups determined by ~ of *para*-phosphorus-substituted toluenes (SC) 544 [G.E. *80*, 559 (1968)]

Hammett constants of phosphorus-containing groups determined by ~ of *meta*- and *ortho*-phosphorus-substituted toluenes (SC) 545 [G.E. *80*, 559 (1968)]

Use of the INDOR technique in the solution of structural problems in organophosphorus chemistry (SC) 814 [G.E. *80*, 794 (1968)]

Use of ~ to detect intramolecular rotations (CR) 898 [G.E. *80*, 971 (1968)]

~ of molecular movements and phase changes in solid organic substances (CR) 79 [G.E. *80*, 85 (1968)]

Mechanism of indirect nuclear spin coupling (CR) 309 [G.E. *80*, 320 (1968)]

~ of tactic copolymers (CR) 393 [G.E. *80*, 407 (1968)]

Investigation of the ionic mobility of some copper(I) compounds by ~ (CR) 476 [G.E. *80*, 449 (1968)]

Induced paramagnetic ring-current in the four-membered ring of biphenylene and related hydrocarbons (CR) 642 [G.E. *80*, 629 (1968)]

Hindered rotation in macromolecular solids, investigated by ~ (CR) 828 [G.E. *80*, 851 (1968)]

Tetramethylsilane (LA) 742

Kernmagnetische Resonanz (Nuclear Magnetic Resonance) (Book Review) 242

Introduction to practical High Resolution ~ (Book Review) 244

High Resolution ~ (Book Review) 245

Nuclear Magnetic Resonance (Book Review) 318

Nuclear magnetic resonance spectra and chemical structure (Book Review) 961

Structure of high-resolution NMR spectra (Book Review) 557

Noble gases, Transport processes of ~ in solids, especially nuclear fuels (CR) 739 [G.E. *80*, 706 (1968)]

Nobel Lectures Chemistry 1901–1921 and 1922–1941 (Book Review) 84

Nuclear chemistry, Introduction (Book Review) 84

Nuclear fission, Rapid chemical separations for the study of short-lived atomic nuclei (CR) 78 [G.E. *80*, 85 (1968)]

Nuclear fuels, Transport processes of noble gases in solids, especially ~ (CR) 739 [G.E. *80*, 706 (1968)]

Nuclease, Micrococcus ~ (LA) 151

Nucleic acids, Antibiotics as inhibitors of ~ and protein synthesis (FP) 693 [G.E. *80*, 710 (1968)]

Single crystals of phenylalanine-specific transfer ribonucleic acid (SC) 895 [G.E. *80*, 969 (1968)]

N-Acetyl-phenylalanyl-tRNA (LA) 152

Mechanism of tRNA degradation by polynucleotide phosphorylases (LA) 237

Self assembly of the fr-phage from the subunits of the coat protein and the phage RNA (LA) 310

Biologically active DNA (LA) 314

RNA synthesis in the direction 3′→5′ (LA) 314

Nucleophilic reactions of metal carbonyl anions with fluorocarbons (FP) 747 [G.E. *80*, 835 (1968)]

Nucleophilic substitution, Third mechanism (AE_a) of nucleophilic aromatic substitution (SC) 617 [G.E. *80*, 614 (1968)]

Formation of small rings by intramolecular ~ (CR) 648 [G.E. *80*, 634 (1968)]

Nucleotides, Synthesis of oligo-~ on a polymeric carrier (SC) 473 [G.E. *80*, 488 (1968)]

Preparation of eleven labeled tri-~ (LA) 236

The mode of action of the B_{12} coenzyme in the reduction of ribonucleotides (LA) 314

OCTACHLOROCYCLOTETRA-(PHOSPHAZENE), Friedel-Crafts reactions of ~ (SC) 887 [G.E. *80*, 910 (1968)]

Octametaphosphates, Preparation (SC) 71 [G.E. *80*, 80 (1968)]

Octamethylsemibullvalene (SC) 537 [G.E. *80*, 531 (1968)]

1,3,6-Octatriene, cis,trans- and trans,trans- ~ from butadiene (SC) 882 [G.E. *80*, 967 (1968)]

Olefin alkylation in biosynthesis (FP) 903 [G.E. *80*, 977 (1968)]

Olefination, Synthesis of carboxylic acids *via* PO-activated ~ of tetraethyl dimethylaminomethylenediphosphonate (SC) 391 [G.E. *80*, 364 (1968)]

Carbonyl ~ with α-metalated isocyanides (SC) 805 [G.E. *80*, 842 (1968)]

Olefins, Reduction of organic compounds with chromium(II) salts (FP) 247 [G.E. *80*, 271 (1968)]

Carbonylation of ~ under mild temperature conditions in the presence of palladium complexes (FP) 329 [G.E. *80*, 352 (1968)]

Reactions of electron-rich ~ (FP) 754 [G.E. *80*, 823 (1968)]

Hydrogenation of polyenes by tricarbonylcyclopentadienylhydridomolybdenum and -tungsten (SC) 880 [G.E. *80*, 968 (1968)]

The mechanism and stereochemistry of the addition of ~ to bicyclo[2.10]pentane (LA) 958

Oligophenyls, oligophenylenes, and polyphenyls, a class of thermally very stable compounds (FP) 835 [G.E. *80*, 932 (1968)]

Oxidative addition of dimethyl sodiomalonate and sodioacetylacetone to ~ (SC) 474 [G.E. *80*, 485 (1968)]

Conversion of ~ into aldehydes (LA) 481

Reaction of SCl_2 with cyclic poly-~ (LA) 830

Optical excitation and ionization of adsorbed molecules (CR) 401 [G.E. *80*, 368 (1968)]

Optical rotatory dispersion, Circular dichroism and ~ – Principles and application to the investigation of the stereochemistry of natural products (FP) 14 [G.E. *80*, 15 (1968)]

Orbitals, Energy differences in the inner molecular ~ of tert-butyl and trimethylsilyl phenyl ketones (SC) 885 [G.E. *80*, 906 (1968)]

d-Orbital effects, in PN and SiC π-electron systems (CR) 400 [G.E. *80*, 368 (1968)]

Valence and reactivity: International symposium on ~ (CR) 475 [G.E. *80*, 491 (1968)]

Organometallic compounds, Methods of synthesis, physical constants and chemical reactions (Book Review) 900

Organohalogenosilanes, Direct synthesis (FP) [G.E. *80*, 133 (1968)]

Organophosphorus chemistry, Use of the INDOR technique in the solution of structural problems in ~ (SC) 814 [G.E. *80*, 794 (1968)]

Organostannylphosphine, Cyclic ~-s (SC) 812 [G.E. *80*, 845 (1968)]

closo-Tetrakis(phenylstannylphosphine), an ~ with a cubane structure (SC) 813 [G.E. *80*, 846 (1968)]

Orotic acid, Preparation from 4-chloromethyluracil (SC) 383 [G.E. *80*, 405 (1968)]

Orthothiocarbonic acid, Carbanion formation from esters of ~ (LA) 151

Osmium complex, σ,π-$C_8H_8Os(CO)_3$, an unusual cyclooctatetraene transition metal complex (SC) 639 [G.E. *80*, 662 (1968)]

Pentacoordinated metal(0)-trifluorophosphine derivatives (LA) 652

Osmium oxide pentafluoride, first compound with heptavalent Os (LA) 554

Oxaallyl groups, Dimerization of ~, azaallyl, oxaphosphaallyl, and oxathiaallyl groups by way of organocopper compounds (SC) 540 [G.E. *80*, 565 (1968)]

Oxaazaallyl groups, Dimerization of azaallyl, diazaallyl, and ~ by way of copper-containing intermediates (SC) 131 [G.E. *80*, 117 (1968)]

Oxadiaziridine, Di-tert-butyl-~ (LA) 403

Oxaphosphaallyl groups, Dimerization of oxaallyl, azaallyl, ~, and oxathiaallyl groups by way of organocopper compounds (SC) 540 [G.E. *80*, 565 (1968)]

Oxathiaallyl groups, Dimerization of oxaallyl, azaallyl, oxaphosphaallyl, and ~ by way of organocopper compounds (SC) 540 [G.E. *80*, 565 (1968)]

Oxazoles, 5-Acyloxy-~ and their rearrangement to 4-acyloxazol-5-ones (SC) 61 [G.E. *80*, 78 (1968)]

Oxazol-5-ones, 5-Acyloxyoxazoles and their rearrangement to 4-acyl-~ (SC) 61 [G.E. *80*, 78 (1968)]

Course of acid hydrolysis of 4-alkylidene- and 4-arylalkylidene-~ (SC) 726 [G.E. *80*, 701 (1968)]

Oxetane-2,3-diimines, Synthesis of substituted ~ from isocyanates (SC) 389 [G.E. *80*, 406 (1968)]

Oxidation, Oxidizing properties of the third transition series hexafluorides and related compounds (FP) 433 [G.E. *80*, 453 (1968)]

Electrochemical ~ of diphenyldiazomethane (SC) 290 [G.E. *80*, 280 (1968)]

Formation of adenosine triphosphate (ATP) from adenosine diphosphate (ADP) and phosphate during ~ of mercaptoacetate by bromine (SC) 893 [G.E. *80*, 915 (1968)]

Formation of adenosine triphosphate (ATP) from adenosine diphosphate (ADP) and phosphate during ~ of durohydroquinone monoacetate (SC) 213 [G.E. *80*, 190 (1968)]

Oxidative dimerization of carbanions (LA) 237

Oxide fluorides, Structure of some fluorides, oxides, and ~: the $RbNiCrF_6$ type (CR) 227 [G.E. *80*, 199 (1968)]

Oxides, Structure of some fluorides, ~, and oxide fluorides: the $RbNiCrF_6$ type (CR) 227 [G.E. *80*, 199 (1968)]

Ternary ~ of rutile structure: Systems containing WO_2, MoO_2, VO_2 or TiO_2 (CR) 229 [G.E. *80*, 202 (1968)]

New developments in the crystal chemistry of multicomponent ~ (CR) 231 [G.E. *80*, 243 (1968)]

Oxo synthesis, Mechanism (CR) 552 [G.E. *80*, 568 (1968)]

Oxygen, Use of dipotassium tetraisothiocyanatocobaltate(II) for the detection of ~-containing organic molecules (LA) 149

Oxygen radicals and chemiluminescence (CR) 477 [G.E. *80*, 449 (1968)]

Oxyphosphoranes, Stereoisomerism at the P atom of cyclic ~ (LA) 483

PAINTINGS, Investigations of Roman wall ~ (CR) 478 [G.E. *80*, 494 (1968)]

Palladium, Strongly exothermic heats of solution of ~ in molten tin (LA) 899

The ~-Hydrogen System (Book Review) 487

Palladium complexes, Carbonylation of olefins under mild temperature conditions in the presence of ~ (FP) 329 [G.E. *80*, 352 (1968)]

Palladium compounds, Bimetallic π-allyl complexes of nickel and palladium (SC) 879 [G.E. *80*, 968 (1968)]

[2.2]Paracyclophanes, Electrophilic substitution of monosubstituted ~ (LA) 483

[2.2]Paracyclophanecarboxylic acid, Absolute configuration (SC) 383 [G.E. *80*, 405 (1968)]

Paramagnetic electron resonance, Die Anwendung der paramagnetischen Elektronenresonanz in der Chemie (Use of ~ in Chemistry) (Book Review) 404

Paramagnetic ring current, Induced ~ in the four-membered ring of biphenylene and related hydrocarbons (CR) 642 [G.E. *80*, 629 (1968)]

Passivation of Raney nickel by nitriles. — Hydrogenation in acid solution (SC) 141 [G.E. *80*, 152 (1968)]

Pentacarbonyl(2,3-diphenylcyclopropenylidene)chromium(0) (SC) 950 [G.E. *80*, 1032 (1968)]

9-Pentacyclo[4.3.0.$0^{2,4}$.$0^{3,8}$.$0^{5,7}$]nonyl *p*-nitrobenzoate (LA) 899

Pentacyclo[5.2.0.$0^{2,9}$.$0^{3,5}$.$0^{6,8}$]nonane-1,7-dicarboxylate (SC) 887 [G.E. *80*, 910 (1968)]

Pentafluorosulfur N-fluoro-N-(fluorosulfonyl)amide, N-Fluorosulfamidoyl fluoride, ~, and N-(dichloromethylene)fluoroformamide (SC) 630 [G.E. *80*, 626 (1968)]

Pentaleno[6,6a,1,2-def]heptalene, Crystal and molecular structure of 4-methyl-~ (SC) 816 [G.E. *80*, 795 (1968)]

Pentathiane, Synthesis (SC) 301 [G.E. *80*, 320 (1968)]

Peptides, Discovery, isolation, elucidation of structure, and synthesis of antamanide (FP) 204 [G.E. *80*, 209 (1968)]

Thiacyclols and cyclothiodepsi-~ (SC) 884 [G.E. *80*, 909 (1968)]

Peptide synthesis, tert-Butyl fluoroformate, a new reagent for ~ (SC) 380 [G.E. *80*, 396 (1968)]

Use of 1-(*p*-biphenylyl)-1-methylethoxycarbonyl groups (LA) 742

Perbromate ion (LA) 653

Perchlorobutatriene and perchloro[4]radialene (SC) 375 [G.E. *80*, 367 (1968)]

Perchloro-[4]radialene, Perchlorobutatriene and ~ (SC) 375 [G.E. *80*, 367 (1968)]

Periodic acid, Explosive mixtures of ~ and dimethyl sulfoxide (LA) 653

Peroxides, Chemistry of organic ~ (CR) 143 [G.E. *80*, 125 (1968)]

Perrhenic acid, Rhenium(VII) oxide and ~ (CR) 308 [G.E. *80*, 291 (1968)]

Phage, Monomer of the fd ~ coat protein (LA) 151

Self assembly of the fr-~ from the subunits of the coat protein and the phage RNA (LA) 310

Phase changes, Nuclear resonance studies of molecular movements and ~ in solid organic substances (CR) 79 [G.E. *80*, 85 (1968)]

Phenanthryl ethers, Ring expansion of fluorenones to ~ (LA) 153

3-Phenoxyacrolein, Properties (CR) 227 [G.E. *80*, 200 (1968)]

Phenylalanine, Single crystals of ~-specific transfer ribonucleic acid (SC) 895 [G.E. *80*, 969 (1968)]

Conversion into ligninforming glucosides (LA) 80

Phenylalanyl-tRNA, N-Acetyl-~ (LA) 152

Phenylazomethyl isocyanates, Formation on oxidation of 2-phenylsemicarbazones (SC) 293 [G.E. *80*, 287 (1968)]

10-Phenyldibenzo[b,e]phosphorin (SC) 889 [G.E. *80*, 912 (1968)]

Phenylhydroxylamine, Oxidation by OH radicals (LA) 240

Phenyllithium complexes of transition metals (CR) 898 [G.E. *80*, 972 (1968)]

N-Phenylnaphtho[2,3-b]azetinone (SC) 303 [G.E. *80*, 316 (1968)]

2-Phenylsemicarbazones, Formation of phenylazomethyl isocyanates on oxidation of ~ (SC) 293 [G.E. *80*, 287 (1968)]

Phenylnitrene, Thermal rearrangement into cyclopentadienecarbonitrile (LA) 741

4α-Phorbol, Lumiphorbol triacetate, a cage-like derivative of the diterpene ~ (SC) 890 [G.E. *80*, 913 (1968)]

1-Phosphabarrelenes, Substituted ~ (1-phospha[2.2.0]octa-2,5,7-trienes) (SC) 733 [G.E. *80*, 702 (1968)]

Phosphabenzene, see Phosphorin

Phosphamethinecyanine perchlorate, Crystal structure of bis-(1-ethyl-2-quinolyl)-~ (SC) 69 [G.E. *80*, 40 (1968)]

1-Phospha[2.2.2]octa-2,5,7-trienes, Substituted 1-phosphabarrelenes (~) (SC) 733 [G.E. *80*, 702 (1968)]

Phosphates, Structure of the anion $[O_3P{-}P(O_2){-}PO_3]^{5-}$ in pentasodium triphosphate(IV,III,IV)-14-water (SC) 622 [G.E. *80*, 616 (1968)]

$Pb(H_2PO_4)_4{\cdot}(C_6H_5)_3PO$, lead(IV) tetrakis(dihydrogen ~) stabilized by triphenylphosphine oxide (SC) 946 [G.E. *80*, 1031 (1968)]

Synthesis of dipotassium difluorodiphosphate by thermal reaction of tetraphosphorus decaoxide with potassium fluoride (SC) 622 [G.E. *80*, 616 (1968)]

Phosphatides, Biochemistry of ~ containing vinyl ethers (plasmalogens) (CR) 309 [G.E. *80*, 321 (1968)]

Phosphazene, Friedel-Crafts reactions of octachlorocyclotetra(~) (SC) 887 [G.E. *80*, 910 (1968)]

~s, Hydrogen-substituted cyclotri-~ formed by NH→PH tautomerization (SC) 209 [G.E. *80*, 197 (1968)]

Structure of the products of aminolysis of aminopentachlorocyclotri-~ (SC) 212 [G.E. *80*, 192 (1968)]

Phosphides, Ternary nitrides, ~, and arsenides of lithium (FP) 360 [G.E. *80*, 373 (1968)]

Phosphinamide, New synthesis of P,P-diphenyl-N,N-bis(trimethylsily)-~ (SC) 382 [G.E. *80*, 399 (1968)]

Phosphinates, Preparation and properties of bis(phosphonylmethyl)-~ and bis(dihydroxyphosphonylmethyl)phosphinic acid (SC) 384 [G.E. *80*, 400 (1968)]

Phosphine, Preparation and properties of a bicyclic hydridodiethylcobalt complex (SC) 129 [G.E. *80*, 115 (1968)]

$PbH_2PO_4)_4 \cdot (C_6H_5)_3PO$, lead(IV) tetrakis(dihydrogen phosphate) stabilized by triphenyl-~ oxide (SC) 946 [G.E. *80*, 1031 (1968)]

X-Ray structure analysis of tri-μ-chlorobis[bis(tri-n-butylphosphine)ruthenium chloride] (SC) 131 [G.E. *80*, 116 (1968)]

PH_3 – new ligand in a transition metal complex (SC) 136 [G.E. *80*, 122 (1968)]

Simple synthesis of oligomeric phenyl-~-s and -arsines (SC) 218 [G.E. *80*, 240 (1968)]

Diamino-tert-butyl-~. – Synthesis and conversion into N-silylated amino-~ imines with non-equivalent replaceability of the hydrogen atoms (SC) 541 [G.E. *80*, 560 (1968)]

Cyclic organostannyl-~-s (SC) 812 [G.E. *80*, 845 (1968)]

closo-Tetrakis(phenylstannyl-~), an organostannyl-~ with a cubane structure (SC) 846 [G.E. *80*, 846 (1968)]

Tris(triphenyl-~)cobalt dihydride (LA) 80

Tungsten hexahydride 3(dimethylphenyl-~) (LA) 654

Tris(diethylamino)-~ (LA) 832

Phosphine imines, N,P-Organometalated ~ from aminophosphines (SC) 75 [G.E. *80*, 83 (1968)]

Phosphine oxides, Preparation and properties of bis(phosphonylmethyl)alkyl-~ and the corresponding acids (SC) 385 [G.E. *80*, 401 (1968)]

Preparation and properties of tris(phosphonylmethyl)-~ and the corresponding acid (SC) 385 [G.E. *80*, 401 (1968)]

Phosphinerhodium complex, Asymmetric catalytic hydrogenation with an optically active ~ in homogeneous solution (SC) 942 [G.E. *80*, 1034 (1968)]

Phosphinic acid, Preparation and properties of bis(phosphonylmethyl)phosphinates and bis(dihydroxyphosphonylmethyl)-~ (SC) 384 [G.E. *80*, 400 (1968)]

Phosphinylmethyl isocyanides (SC) 372 [G.E. *80*, 394 (1968)]

Phosphonate, Synthesis of carboxylic acids *via* PO-activated olefination of tetraethyl dimethylaminomethylenedi-~(SC) 391 [G.E. *80*, 364 (1968)]

Phosphonium ions, Phosphorylation involving carbonium, ~, and sulfonium ions (LA) 311

Phosphonium salts, Preparation of tetraamino-~ by ammonolysis of the triamino(methylthio)phosphonium ion (SC) 210 [G.E. *80*, 234 (1968)]

Phosphoranes, Syntheses of cyclopropanes and azirines by means of alkylidene-~ (CR) 640 [G.E. *80*, 628 (1968)]

Phosphoranylidenepyruvic acid esters, Triphenyl-~ (LA) 236

Phosphorin, Oxidation products of ~ (SC) 371 [G.E. *80*, 359 (1968)]

10-Phenyldibenzo[b,e]-~ (SC) 889 [G.E. *80*, 912 (1968)]

Preparation of 2,4,6-tri-tert-butylpyrylium tetrafluoroborate, 2,4,6-tri-tert-butylpyridine, and 2,4,6-tri-tert-butyl-~ (SC) 460 [G.E. *80*, 489 (1968)]

1,1-Dialkoxy- and 1,1-diaryloxy-~-s, a new class of organophosphorus compounds (SC) 881 [G.E. *80*, 966 (1968)]

Dibenzo[b,d]-~ (SC) 465 [G.E. *80*, 486 (1968)]

Structure of 2,6-dimethyl-4-phenyl-~ (SC) 811 [G.E. *80*, 843 (1968)]

Phosphorus, $S_E(P)$: Electrophilic substitution at ~ (FP) 606 [G.E. *80*, 649 (1968)]

Hammett constants of ~-containing groups determined from nuclear magnetic resonance spectra of *para*-~-substituted toluenes (SC) 544 [G.E. *80*, 559 (1968)]

Hammett constants of ~-containing groups determined from nuclear magnetic resonance spectra of *meta*- und *ortho*-~-substituted toluenes (SC) 545 [G.E. *80*, 559 (1968)]

Organic chemistry of ~ (Book Review) 745

Phosphorus compounds, Formation and properties of medium and high molecular weight compounds of elements of groups 3, 4, and 5 (FP) 1 [G.E. *80*, 2 (1968)]

Four-membered ring system containing hexacoordinated phosphorus (SC) 299 [G.E. *80*, 281 (1968)]

Use of the INDOR technique in the solution of structural problems in organophosphorus chemistry (SC) 814 [G.E. *80*, 794 (1968)]

Valence force constants of various ~ (CR) 232 [G.E. *80*, 246 (1968)]

d-Orbital effects in PN and SiC π-electron systems (CR) 400 [G.E. *80*, 368 (1968)]

Phosphorus(V) isocyanates (SC) 618 [G.E. *80*, 620 (1968)]

Phosphorus nitride-chloride as an activator of carboxylic acids (LA) 830

Phosphorus ylides, Silyl shift in ~ (SC) 220 [G.E. *80*, 239 (1968)]

Phosphorylation, Formation of adenosine triphosphate (ATP) from adenosine diphosphate (ADP) and phosphate during oxidation of durohydroquinone monoacetate (SC) 213 [G.E. *80*, 190 (1968)]

Formation of adenosine triphosphate (ATP) from adenosine diphosphate (ADP) and phosphate during oxidation of mercaptoacetate by bromine (SC) 893 [G.E. *80*, 915 (1968)]

~-s involving carbonium, phosphonium, and sulfonium ions (LA) 311

Photobiology, Comprehensive Biochemistry (Book Review) 901

Photochemistry, Photochemical synthesis of ethyl 1H-diazepine-1-carboxylate (SC) 129 [G.E. *80*, 117 (1968)]

Photochemical cyclodehydrogenations in the indole series (SC) 466 [G.E. *80*, 486 (1968)]

New photochemical reaction of acetophenone (LA) 237

Photochemical addition of alcohols to purines (LA) 742

Photolytic isomerization of poly-tert-butylfurans (LA) 832

Organic ~ (Book Review) 246

Photocyclophile, Synthesis by means of dichlorovinylene carbonate (4,5-dichloro-1,3-dioxol-2-one) as dienophile and ~ (SC) 215 [G.E. *80*, 194 (1968)]

Photography, Redox behavior of the latent image in silver halide films (CR) 550 [G.E. *80*, 537 (1968)]

Photolysis, Photolysis of iodoaromatic compounds (FP) 36 [G.E. *80*, 69 (1968)]

Formation of an azabicyclopentane derivative on~ of α-azidostyrene (SC) 130 [G.E. *80*, 119 (1968)]

~ of tetramethylcyclobutenedicarboxylic anhydride, a possible route to tetramethylcyclobutadiene (SC) 537 [G.E. *80*, 532 (1968)]

~ of N-(2,4-dinitrophenyl)-α-amino acids (LA) 482

Photosynthesis, Structure of the ~ apparatus (CR) 396 [G.E. *80*, 410 (1968)]

o-Phthalates, Synthesis of macrocyclic ~ (LA) 830

Phthalocyanin complex, Diphthalocyaninato-thorium(IV) and -uranium(IV) (SC) 819 [G.E. *80*, 792 (1968)]

Plants, Chemotaxonomie der Pflanzen (Chemotaxonomy of ~) (Book Review) 154

Plasma, Replacement of ~ by high molecular weight substances (FP) 702 [G.E. *80*, 719 (1968)]

Organic synthesis in the ~ of high voltage discharge (CR) 230 [G.E. *80*, 202 (1968)]

Plasmalogens, Biochemistry of phosphatides containing vinyl ethers (~) (CR) 309 [G.E. *80*, 321 (1968)]

Plastics dictionary, Kunststofftechnisches Wörterbuch (~) (Book Review) 241

Platinum complexes, Use of tetrakis(triphenylphosphine)platinum(0) as initiator for radical polymerizations (LA) 240

Plumbate, Dipotassium hexaamido-~-(IV) (SC) 950 [G.E. *80*, 1029 (1968)]

Preparation of halogeno- and acetatoorgano-~-s (SC) 72 [G.E. *80*, 79 (1968)]

Polarimetry of simple and mixed metal-amino acid complexes (CR) 228 [G.E. *80*, 201 (1968)]

Polyacetylene, Electrical properties of linear ~ (LA) 555

Polyamides, Poly-β-amides (FP) 278 [G.E. *80*, 304 (1968)]

Oxidation of pyrrolic impurities in ~ (CR) 740 [G.E. *80*, 761 (1968)]

Poly-α-amino acids, Protein models for conformational studies (Book Review) 745

Polychloroamine derivatives, Preparation, properties, and reactions of ~ (FP) 856 [G.E. *80*, 942 (1968)]

Polyenes, Hydrogenation of ~ by tricarbonylcyclopentadienylhydridomolybdenum and -tungsten (SC) 880 [G.E. *80*, 968 (1968)]

Polyester fibers, Degradation of poly(ethylene terephthalate) (FP) 182 [G.E. *80*, 225 (1968)]

Polyether, Twelve-membered ~ rings (LA) 554

Polyethylene, Submicroscopic crystal nuclei in the solution crystallization of ~ (CR) 396 [G.E. *80*, 410 (1968)]

Poly(ethylene terephthalate), Degradation (FP) 182 [G.E. *80*, 225 (1968)]

Polyisoprenoid synthesis, Olefin alkylation in biosynthesis (FP) 903 [G.E. *80*, 977 (1968)]

Polymers, Formation and properties of medium and high molecular weight compounds of elements of groups 3, 4, and 5 (FP) 1 [G.E. *80*, 2 (1968)]

Resolution of racemates on optically active ~ (LA) 148

Organic Chemistry of Synthetic High ~ (Book Review) 405

Heteroatom ring systems and ~ (Book Review) 557

Encyclopedia of Polymer Science and Technology (Book Review) 158, 159

~, see also Copolymers

Polymer gels, Synthesis of organic ~ with very uniform mesh sizes (CR) 394 [G.E. *80*, 408 (1968)]

Polymer mixtures, Incompatibility (CR) 393 [G.E. *80*, 407 (1968)]

Effect of structure on the incompatibility of ~ in solution (CR) 394 [G.E. *80*, 408 (1968)]

Polymerization, Trends in radiation ~ (FP) 845 [G.E. *80*, 921 (1968)]

Crystallization during ~ (FP) 912 [G.E. *80*, 1009 (1968)]

Cationic ~ of lactams 233 [G.E. *80*, 245 (1968)]

~ of unsaturated highly strained ring systems with Ziegler-Natta catalysts and with group VIII metal halides (CR) 394 [G.E. *80*, 408 (1968)]

Kinetics of the free-radical ~ of styrene and *o*-halogenostyrenes at low initiator concentrations (CR) 397 [G.E. *80*, 411 (1968)]

Effect of the solvent on anionic ~ (CR) 398 [G.E. *80*, 412 (1968)]

~ reaction of trimethylaluminum (CR) 399 [G.E. *80*, 413 (1968)]

Diffusion-controlled reaction steps in free-radical ~ (CR) 399 [G.E. *80*, 413 (1968)]

New type of ~ (LA) 743

Use of tetrakis(triphenylphosphine)-platinum(0) as initiator for radical ~ (LA) 240

Polymethyl(methylene)aluminum, Formation (SC) 217 [G.E. *80*, 235 (1968)]

Polynucleotide phosphorylases, Mechanism of tRNA degradation by ~ (LA) 237

Polyolefins, Reaction of SCl_2 with cyclic ~ (LA) 830

~, Structure and Properties (Book Review) 243

Polyphenyls, Oligophenyls, oligophenylenes, and ~, a class of thermally very stable compounds (FP) 835 [G.E. *80*, 932 (1968)]

Polyradicals, Recent studies on the preparation of stable ~ (CR) 393 [G.E. *80*, 407 (1968)]

Polysaccharides, Formation of ordered structures from ~ solutions (CR) 395 [G.E. *80*, 409 (1968)]

Chemistry and enzymology of marine algal ~ (Book Review) 746

Poly-tert-butylfuran, Photolytic isomerization (LA) 832

Polyvinylacetophenone, Asymmetric reduction (SC) 216 [G.E. *80*, 236 (1968)]

Poly-S-vinyl monothioacetals, Synthesis and depolymerization (CR) 397 [G.E. *80*, 411 (1968)]

Polyvinylpyrrolidone, Replacement of plasma by high molecular weight substances (FP) 702 [G.E. *80*, 719 (1968)]

Porphin derivatives as experimental models for mass-spectroscopic fragmentation reactions (CR) 479 [G.E. *80*, 495 (1968)]

Porphinoid, Corphin, a corrinoid-~ ligand system (SC) 623 [G.E. *80*, 622 (1968)]

Porphyrin, Preparation of titanyl and vanadyl mesoporphyrin IX dimethyl esters (SC) 891 [G.E. *80*, 914 (1968)]

Potassium bromide, Amide ions NH_2^- as color centers in crystalline KCl, KBr, and KI (LA) 957

Potassium chloride, Amide ions NH_2^- as color centers in crystalline KCl, KBr, and KI (LA) 957

Potassium iodide, Amide ions NH_2^- as color centers in crystalline KCl, KBr, and KI (LA) 957

Prismane, Acid-catalyzed rearrangement of hexamethyl-~ and hexamethyl-Dewar-benzene (SC) 467 [G.E. *80*, 447 (1968)]

Kinetics and thermochemistry of the thermal rearrangement of hexamethyl-Dewar-benzene and of hexamethyl-~ (CR) 646 [G.E. *80*, 633 (1968)]

Proline hydroxylase, Cofactor requirement of collagen-~ (LA) 150

Protein, Monomer of the fd phage coat ~ (LA) 151

Ferrocene-labeled ~-s (LA) 236

Self assembly of the fr-phage from the subunits of the coat ~ and the phage RNA (LA) 310

Crustacyanin, a chromo-~ from lobster shell (LA) 313

Techniques in ~ Chemistry (Book Review) 155

Protein models, Poly-α-amino acids. ~ for conformational studies (Book Review) 745

Protein synthesis, Antibiotics as inhibitors of nucleic acid and ~ (FP) 693 [G.E. *80*, 710 (1968)]

Proteins, Chemie der Eiweißkörper (The chemistry of ~) (Book Review) 961

Proton transfer, Elementary steps in acid-base catalysis. ~ reactions in aqueous solutions (SC) 818 [G.E. *80*, 857 (1968)]

Investigation of ~ processes by electrochemical relaxation techniques (CR) 79 [G.E. *80*, 84 (1968)]

Pteridine, New synthesis (SC) 535 [G.E. *80*, 534 (1968)]

Purines, Photochemical addition of alcohols (LA) 742

Puromycin, Synthesis of an analog (SC) 457 [G.E. *80*, 440 (1968)]

Pyrazole, Iron derivatives of five-membered carbon-nitrogen heterocycles (SC) 70 [G.E. *80*, 38 (1968)]

Pyrazolidine, 1-Alkylidene- and 1-arylalkylidene-3-imino-~ N,N-betaine salts, a new type of azomethine imine stabilized by mesomerism (SC) 888 [G.E. *80*, 911 (1968)]

3-Pyrazolidone N,N-betaines, Syntheses by means of 1-alkylidene- and 1-(arylalkylidene)-~ a new type of stable azomethine imine (SC) 214 [G.E. *80*, 196 (1968)]

Pyrazoloquinones, Vinyl-~ (CR) 398 [G.E. *80*, 412 (1968)]

Pyridine, Macrocyclic compounds with 2,6-bridging ~ rings (LA) 830

Pyridinophane, Macrocyclic compounds with 2,6-bridging pyridine rings (LA) 830

Pyrimidine, New 4-hydroxythieno-~-s (SC) 136 [G.E. *80*, 122 (1968)]

Accumulation of 2,5-diamino-6-hydroxy-4-ribitylamino-~ in a riboflavin-deficient mutant (SC) 219 [G.E. *80*, 237 (1968)]

Investigations of the chemical causes of biological irradiation damage (CR) 551 [G.E. *80*, 536 (1968)]

Existence of 6-tert-butyl-4,5-didehydro-~ (LA) 238

Pyrrole, Synthesis of ~ derivatives (SC) 733 [G.E. *80*, 702 (1968)]

Simple synthesis of substituted 1,2,3-triphenyl-~-s (SC) 946 [G.E. *80*, 1002 (1968)]

Tetramethyl-~-indigo (SC) 734 [G.E. *80*, 758 (1968)]

Syntheses in the pyrrolone and ~ series (CR) 235 [G.E. *80*, 242 (1968)]

Oxidation of pyrrolic impurities in polyamides (CR) 740 [G.E. *80*, 761 (1968)]

Pyrrolone, Syntheses in the ~ and pyrrole series (CR) 235 [G.E. *80*, 242 (1968)]

Pyruvate decarboxylase, A new test for the determination of ~ activity (SC) 886 [G.E. *80*, 907 (1968)]

Binding of the substrate in yeast ~ (SC) 68 [G.E. *80*, 41 (1968)]

QUANTUM-mechanical prediction of the existence and properties of the unknown molecule BeH_2 (CR) 230 [G.E. *80*, 245 (1968)]

Quartz, Acid-base titrations on powdered ~ (LA) 235

Quinodimethanes from 1,2-diaryl-3-ethoxycyclopropenylium ions (SC) 809 [G.E. *80*, 798 (1968)]

Quinoline 1-oxides, Ring expansion of benzoxazole to form ~ (LA) 149

Quinones, Chemiluminescence of cyclic diacylhydrazides and diaza-~ (CR) 480 [G.E. *80*, 494 (1968)]

Quinone methide imines (SC) 74 [G.E. *80*, 38 (1968)]

Quinoxalines, Synthesis of cyclobuta[b]-~ (SC) 135 [G.E. *80*, 121 (1968)]

RACEMATES, Resolution on optically active polymers (LA) 148

Radiation, Trends in ~ polymerization (FP) 845 [G.E. *80*, 921 (1968)]

Actions Chimiques et Biologiques des Radiations (Chemical and Biological Action of ~) (Book Review) 243

Radiation Chemistry, Strahlenchemie. Grundlagen – Technik – Anwendung (~. Principles – Techniques – Applications) (Book Review) 901

Radical, A reinterpretation of the ESR spectrum attributed to a non-degenerate state of the benzene ~ anion (SC) 954 [G.E. *80*, 997 (1968)]

Influence of solvent pretreatment and electrolyte addition on the ESR spectra of aromatic ~ anions (SC) 954 [G.E. *80*, 998 (1968)]

Ion pair formation in benzene ~ anion solutions (SC) 953 [G.E. *80*, 996 (1968)]

Radicals, Photolysis of iodoaromatic compounds (FP) 36 [G.E. *80*, 69 (1968)]

Free radical studies at low temperatures (FP) 507 [G.E. *80*, 519 (1968)]

New hydrazyls of lower molecular weight and polymeric hydrazyls (SC) 945 [G.E. *80*, 1002 (1968)]

Recent studies on the preparation of stable poly-~ (CR) 393 [G.E. *80*, 407 (1968)]

Kinetics of the free-radical polymerization of styrene and *o*-halogenostyrenes at low initiator concentrations (CR) 397 [G.E. *80*, 411 (1968)]

Diffusion-controlled reaction steps in free-radical polymerization (CR) 399 [G.E. *80*, 413 (1968)]

Oxygen ~ and chemiluminescence (CR) 477 [G.E. *80*, 449 (1968)]

Formation of methylenecyclohexadiene derivatives on dimerization of di- and triarylmethyl ~ (LA) 238

Oxidation of phenylhydroxylamine by OH ~ (LA) 240

Reactions of methyl ~ with ethanol (LA) 830

Structure of Inorganic ~ (Book Review) 317

Radical polymerizations, Use of tetrakis-(triphenylphosphine)platinum(0) as initiator for ~ (LA) 240

Radiospirometry of the oxidation *in vivo* of [17α-^{3}H]testosterone and its esters at C-17 (SC) 211 [G.E. *80*, 191 (1968)]

Raman spectra of the tetraisothiocyanate complexes of the IIB metals (LA) 312

Raney nickel, Passivation by nitriles. – Hydrogenation in acid solution (SC) 141 [G.E. *80*, 152 (1968)]

Reactivity, Valence and ~: International symposium on d-orbital effects (CR) 475 [G.E. *80*, 491 (1968)]

Reaction cross-section of ammonium salts for scattering of subthermal neutrons (LA) 958

Rearrangement, Isomerizations in cyclobutenes (FP) 559 [G.E. *80*, 585 (1968)]

Memory effects and stereochemistry in multiple carbonium ion ~-s (FP) 779 [G.E. *80*, 765 (1968)]

5-Acyloxyoxazoles and their ~-s to 4-acyloxazol-5-ones (SC) 61 [G.E. *80*, 78 (1968)]

New ~ of the Smiles reaction type (SC) 291 [I.E. *80*, 284 (1968)]

New ~ of substituted 3-aminopropenals (SC) 460 [G.E. *80*, 444 (1968)]

Acid-catalyzed ~ of hexamethylprismane and hexamethyl-Dewar-benzene (SC) 467 [G.E. *80*, 447 (1968)]

^{13}C-Experiments on carbon skeleton ~-s: Automerization of naphthalene (SC) 548 [G.E. *80*, 567 (1968)]

~-s in the bullvalene system induced by heavy-metal salts (SC) 736 [G.E. *80*, (1968)]

~-s of highly unsaturated cyclopropyl carbenes (CR) 644 [G.E. *80*, 631 (1968)]

Kinetics and thermochemistry of the thermal ~ of hexamethyl-Dewar-benzene and of hexamethylprismane (CR) 646 [G.E. *80*, 633 (1968)]

Aromatic sigmatropic ~-s (CR) 740 [G.E. *80*, 760 (1968)]

Photochemical ~ of cis-2-cyclodecenone (LA) 403

Thermal ~ of phenylnitrene into cyclopentadienecarbonitrile (LA) 741

Trans-annular ~ of 9,10-dihydroanthracene (LA) 743

Aromatic ~-s (Book Review) 744

Reduction, of organic compounds with chromium(II) salts (FP) 247 [G.E. *80*, 271 (1968)]

Asymmetric ~ of polyvinylacetophenone (SC) 216 [G.E. *80*, 236 (1968)]

Stereochemistry of the electrolytic ~ of the C–Cl bond (LA) 312

Reductone, Constitution and synthesis of an aci-~ formed on non-oxidative degradation of dehydroascorbic acid (SC) 732 [G.E. *80*, 755 (1968)]

Relaxation, Diffusion anomalies and ~ in high molecular weight systems with miscibility gaps (CR) 394 [G.E. *80*, 408 (1968)]

Rhenium compounds, Dirhenium dihydratoheptoxide $Re_2O_7(OH_2)_2$ – New type of water bonding in an aquoxide (SC) 295 [G.E. *80*, 286 (1968)]

Novel tricarbonylchlororhenium(I) and reactions of substituted carbonylchlororheniums(I) with water and other oxygen-containing ligands (SC) 627 [G.E. *80*, 621 (1968)]

Chemistry of Technetium and Rhenium (Book Review) 84

Rhenium(VII) oxide and perrhenic acid (CR) 308 [G.E. *80*, 291 (1968)]

Riboflavin, Accumulation of 2,5-diamino-6-hydroxy-4-ribitylaminopyrimidine in a ~-deficient mutant (SC) 219 [G.E. *80*, 237 (1968)]

Ribonucleic acid, Single crystals of phenylalanine-specific transfer ~ (SC) 895 [G.E. *80*, 969 (1968)]

Ribosome crystals (LA) 153

Ring cleavage, An abnormal ~ of 1α,2α-epoxy-3-keto steroids by hydrogen fluoride (SC) 893 [G.E. *80*, 916 (1968)]

Ring closure, 1,6-C–C linkage on pressure-hydrogenation of α-hydroxyadipaldehyde (SC) 66 [G.E. *80*, 42 (1968)]

~ of 2-hydroxyadipaldehyde (SC) 952 [G.E. *80*, 1033 (1968)]

Ring contraction, Acid-catalyzed ~ of dibenzothiepin-10,11-dione (SC) 128 [G.E. *80*, 115 (1968)]

New type of ~ (LA) 831

Ring-current, Induced paramagnetic ~ in the four-membered ring of biphenylene and related hydrocarbons (CR) 642 [G.E. *80*, 629 (1968)]

Ring expansion, of benzoxazole to form quinoline 1-oxides (LA) 149

~ of fluorenones to phenanthryl ethers (LA) 153

Ring opening, Recent developments in the stereochemistry of cyclopropane ~ (FP) 577 [G.E. *80*, 592 (1968)]

Kinetics of the ~ in liquid cyclooctasulfur (LA) 830

Rings, The fluorescence of peri-condensed non-alternant polycyclic hydrocarbons (LA) 958

Rotation, Hindered ~ in macromolecular solids, investigated by nuclear magnetic resonance (CR) 828 [G.E. *80*, 851 (1968)]

Use of nuclear magnetic resonance to detect intramolecular ~-s (CR) 898 [G.E. *80*, 971 (1968)]

Ruthenium compounds, Dodecacarbonyltriruthenium (FP) 427 [G.E. *80*, 460 (1968)]

X-Ray structure analysis of tri-μ-chlorobis[bis(tri-n-butylphosphine)ruthenium chloride] (SC) 131 [G.E. *80*, 116 (1968)]

Fine structure of ruthenium(III) bromide (CR) 147 [G.E. *80*, 155 (1968)]

Structure of β-$RuCl_3$, RuI_3, $IrBr_3$, and IrI_3 (CR) 148 [G.E. *80*, 155 (1968)]

Carbon atom at the center of a Ru_6-octahedron (LA) 554

Pentacoordinated metal(0)-trifluorophosphine derivatives (LA) 652

Rutile, Ternary oxides of ~ structure: Systems containing WO_2, MoO_2, VO_2 or TiO_2 (CR) 229 [G.E. *80*, 202 (1968)]

SANTOLINATRIENE, Synthesis (SC) 629 [G.E. *80*, 626 (1968)]

Saponin, Structure of the principal aglycon of horse chestnut ~ (SC) 547 [G.E. *80*, 563 (1968)]

Sea water, The adsorption of trace elements from ~ (LA) 959

Selenazol-2-inium bromide, Crystal structure of 2-amino-~ (SC) 811 [G.E. *80*, 793 (1968)]

Selenium, Electrical conductivity and formation of chalcogenide glasses in Ge–As–Se and Ge–Sb–Se melts (SC) 947 [G.E. *80*, 999 (1968)]

Arrangement of the atoms in vitreous ~ (LA) 654

Selenium ylide, Synthesis (LA) 151

Semibullvalene, Octamethyl-~ (SC) 537 [G.E. *80*, 531 (1968)]

Semicarbazones, Formation of phenylazomethyl isocyanates on oxidation of 2-phenyl-~ (SC) 293 [G.E. *80*, 287 (1968)]

Semiconductors, Ternary compounds as ~ (CR) 400 [G.E. *80*, 369 (1968)]

Semiconductor interfaces, Methods and results of optical investigations on ~ (FP) 161 [G.E. *80*, 213 (1968)]

Shikimic acid, Biosynthesis of aromatic amino acids and its regulation (FP) 350 [G.E. *80*, 384 (1968)]

Sideramins, New ~ from molds (CR) 551 [G.E. *80*, 569 (1968)]

Sigmatropic rearrangements, Aromatic ~ (CR) 740 [G.E. *80*, 760 (1968)]

Silanes, Direct synthesis of organohalogeno-~ (FP) 112 [G.E. *80*, 133 (1968)]

Volatile ~ can be halogenated in stages with silver chloride or bromide (LA) 152

Silanide, Coordination behavior of triphenyl-~ (SC) 374 [G.E. *80*, 360 (1968)]

Silica gel, Adsorption of alkali salts onto ~ (LA) 483

Silicic acid, Formation and properties of medium and high molecular weight compounds of elements of groups 3, 4, and 5 (FP) 1 [G.E. *80*, 2 (1968)]

Tris(*o*-arylenedioxo)- and bis(*o*-arylenedioxo)-organo-~-s containing hexacoordinated and pentacoordinated silicon (SC) 826 [G.E. *80*, 849 (1968)]

Silicon, Trimethylsilyl derivatives of germanium and tin. – Electron-balance bonds of ~ (SC) 212 [G.E. *80*, 192 (1968)]

Cleavage surfaces of ~ single crystals (LA) 830

Silicon compounds, Formation and properties of medium and high molecular weight compounds of elements of groups 3, 4, and 5 (FP) 1 [G.E. *80*, 2 (1968)]

Compounds with Si–Ti linkages (SC) 142 [G.E. *80*, 153 (1968)]

Tris(imidodiphosphinato) cationic complexes of silicon, germanium, and tin (SC) 549 [G.E. *80*, 558 (1968)]

d-Orbital effects in PN and SiC π-electron systems (CR) 400 [G.E. *80*, 368 (1968)]

7-, 8-, and 9-membered silacyclic hydroxy and oxo compounds (LA) 80

Insertion of dihalogenocarbenes into Si–Hg and Ge–Hg bonds (LA) 81

Silicones, Formation and properties of medium and high molecular weight compounds of elements of groups 3, 4, and 5 (FP) 1 [G.E. *80*, 2 (1968)]

Silicon tetrahalides, Abnormal reactions in alkylation of ~ and germanium tetrahalides (CR) 310 [G.E. *80*, 321 (1968)]

Silver catalysts, Surface layer of Ag_2O_3 on ~ (LA) 313

Silver halide films, Redox behavior of the latent image in ~ (CR) 550 [G.E. *80*, 537 (1968)]

Silylamines, Synthesis of amino acids from N,N-bis(trimethylsilyl)glycine esters (SC) 809 [G.E. *80*, 797 (1968)]

Silyl compounds, Trimethylsilyl derivatives of germanium and tin. – Electron-balance bonds of silicon (SC) 212 [G.E. *80*, 192 (1968)]

Silyldiimines, Bis(trimethylsilyl)diimine and tetrakis(trimethylsilyl)hydrazine (SC) 640 [G.E. *80*, 661 (1968)]

Silyl esters, Preparation of ~ of isocyanato carboxylic acids (SC) 942 [G.E. *80*, 1029 (1968)]

Silylhydrazine, Bis(trimethylsilyl)diimine and tetrakis(trimethylsilyl)hydrazine (SC) 640 [G.E. *80*, 661 (1968)]

Silyl shift, Silyl shift in phosphorus ylides (SC) 220 [G.E. *80*, 239 (1968)]

Single crystals, Cleavage surfaces of silicon ~ (LA) 830

Small rings, International symposium on the chemistry of ~ (CR) 640 [G.E. *80*, 628 (1968)]

Smectic liquids, Recent results in the field of liquid crystals (FP) 97 [G.E. *80*, 99 (1968)]

Smiles reaction, New rearrangement of the ~ type (SC) 291 [G.E. *80*, 284 (1968)]

Sodioacetylacetone. Oxidative addition of dimethyl sodiomalonate and ~ to olefins (SC) 474 [G.E. *80*, 485 (1968)]

Sodiomalonate, Oxidative addition of dimethyl ~ and sodioacetylacetone to olefins (SC) 474 [G.E. *80*, 485 (1968)]

Sodium hexathiohypophosphate (LA) 554

Soil biochemistry (Book Review) 487

Solid-gas interface (Book Review) 319, 963

Solid substances, Reaktionen an und in Festen Stoffen (Reactions on and in ~) (Book Review) 242

Solidification, Fractional ~ (Book Review) 487

Solvated electrons, Formation and properties (FP) 190 [G.E. *80*, 165 (1968)]

Solvent, Effect on anionic polymerizations (CR) 398 [G.E. *80*, 412 (1968)]

~ Effects on Reaction Rates and Mechanisms (Book Review) 158

Chemistry of non-aqueous ~-s (Book Review) 557, 962

Soot formation in premixed hydrocarbon flames (FP) 414 [G.E. *80*, 425 (1968)]

Spectroscopy, Methods and results of optical investigations on semiconductor interfaces (FP) 161 [G.E. *80*, 213 (1968)]

Spectrometric Identification of Organic Compounds (Book Review) 405

Spin coupling, Mechanism of indirect nuclear ~ (CR) 309 [G.E. *80*, 320 (1968)]

Spirohomoadamantane (LA) 832

Squalene epoxide, Olefin alkylation in biosynthesis (FP) 903 [G.E. *80*, 977 (1968)]

Squarates, Unit cells and absorption spectra of the cubic ~ of cobalt and nickel (SC) 638 [G.E. *80*, 664 (1968)]

Squaric acid, Cyclobutenediylium dyes (FP) 530 [G.E. *80*, 541 (1968)]

Stannane, Dimethylaminotrimethyl-~ is an efficient dehydrochlorinating agent (LA) 482

Stannylphosphine, Cyclic organo-~-s (SC) 812 [G.E. *80*, 845 (1968)]

closo-Tetrakis(phenylstannylphosphine), an organo-~ with a cubane structure (SC) 846 [G.E. *80*, 846 (1968)]

Starch, Replacement of plasma by high molecular weight substances (FP) 702 [G.E. *80*, 719 (1968)]

Stationary phases, High-melting aromatic compounds as ~ in gas chromatography (SC) 724 [G.E. *80*, 754 (1968)]

Staudinger adducts, Proof of $N_\gamma N_\beta$-elimination from ~ $R_3P{=}N_\beta{-}N_\gamma{=}N{-}X$ by ^{15}N-isotopic labeling (SC) 636 [G.E. *80*, 667 (1968)]

Stereochemistry, Circular dichroism and optical dispersion – Principles and application to the investigation of the ~ of natural products (FP) 14 [G.E. *80*, 15 (1968)]

Recent developments in the ~ of cyclopropane ring opening (FP) 577 [G.E. *80*, 592 (1968)]

Memory effects and ~ in multiple carbonium ion rearrangements (FP) 779 [G.E. *80*, 765 (1968)]

Mechanism and ~ of Wittig-olefin syntheses (CR) 650 [G.E. *80*, 637 (1968)]

The mechanism and ~ of the addition of olefins to bicyclo[2.10]pentane (LA) 958

~ of the electrolytic reduction of the C–Cl bond (LA) 312

Einführung in die Stereochemie (Introduction to ~) (Book Review) 403

Stereoisomerism at the P atom of cyclic oxyphosphoranes (LA) 483

Stereoselectivity, Monofluorocarbene and its syn/anti selectivity (SC) 820 [G.E. *80*, 849 (1968)]

Steroids, An abnormal ring cleavage of 1α,2α-epoxy-3-keto ~ by hydrogen fluoride (SC) 893 [G.E. *80*, 916 (1968)]

Microbial transformations of ~ (Book Review) 156

Strontium, Organic compounds of magnesium, beryllium, calcium, ~, and barium (Book Review) 744

Structure analysis, Structure of molten antimony (SC) 947 [G.E. *80*, 999 (1968)]

Structural chemistry, Perspectives in ~ (Book Review) 745

Styrene, Kinetics of the free-radical polymerization of ~ and *o*-halogeno-~-s at low initiator concentrations (CR) 397 [G.E. *80*, 411 (1968)]

Grafting of polymers on active fillers; polymerization of ~ in the presence of carbon black (CR) 399 [G.E. *80*, 413 (1968)]

Substitution, Modification of the orientation of ~ reactions on thiophene and furan derivatives (FP) 519 [G.E. *80*, 547 (1968)]

Electrophilic ~ at phosphorus (FP) 606 [G.E. *80*, 649 (1968)]

Kinetic studies on ~ reactions of carbonylmetal complexes (FP) 930 [G.E. *80*, 1017 (1968)]

Third mechanism of nucleophilic aromatic ~ (SC) 617 [G.E. *80*, 614 (1968)]

Formation of small rings by intramolecular nucleophilic ~ (CR) 648 [G.E. *80*, 634 (1968)]

Succinic acid, Absolute configuration of (–)-threo-2-ethyl-3-methyl-~ (SC) 543 [G.E. *80*, 562 (1968)]

Sulfamoyl chloride, Reactions with *N*-carbonyl-~ (FP) 172 [G.E. *80*, 179 (1968)]

Sulfenes, Formation from aliphatic sulfonyl chlorides and trialkylamines (CR) 229 [G.E. *80*, 202 (1968)]

Sulfinate, S-Thioacylation of the ~ anion: Preparation and properties of some sulfonylformamides, -thioformamides, and -formamidines (SC) 734 [G.E. *80*, 704 (1968)]

Sulfine, Sulfinyl-~ and a sulfonyl-~ (LA) 653

Sulfones, Sulfonyl hydrazones of cyclic amides and quaternary azo ~ of heterocycles as reagents in azo chemistry (FP) 335 [G.E. *80*, 343 (1968)]

Sulfonium ions, Phosphorylations involving carbonium, phosphonium, and ~ (LA) 311

Sulfonylformamides, S-Thioacylation of the sulfinate anion; Preparation and properties of some ~, -thioformamides, and -formamidines (SC) 734 [G.E. *80*, 704 (1968)]

Sulfonylformamidines, S-Thioacylation of the sulfinate anion: Preparation and properties of some sulfonylformamides, -thioformamides, and ~ (SC) 734 [G.E. *80*, 704 (1968)]

Sulfonyl hydrazones of cyclic amides and quaternary azo sulfones of heterocycles as reagents in azo chemistry (FP) 335 [G.E. *80*, 343 (1968)]

Sulfonylsulfine, Sulfinylsulfine and a ~ (LA) 653

Sulfonylthioformamides, S-Thioacylation of the sulfinate anion: Preparation and properties of some sulfonylformamides, ~, and -formamidines (SC) 734 [G.E. *80*, 704 (1968)]

Sulfur, Cyclohepta-~ and cyclodeca-~ – Two new ~ rings (SC) 632 [G.E. *80*, 660 (1968)]

Kinetics of the ring-opening in liquid cycloocta-~ (LA) 830

Sulfur compounds, Reactive aromatic heterocycles containing tetravalent sulfur (LA) 237

Sulfur dichloride, (chlorosulfonyl)imide and N,N'-hydrazodisulfonyl difluoride (SC) 63 [G.E. *80*, 43 (1968)]

Reaction of ~ with cyclic polyolefins (LA) 830

Sulfurous acid, Analysis of foodstuffs with particular reference to quality control (CR) 956 [G.E. *80*, 1003 (1968)]

Sulfuryl diamide, New type of compound of ~ (LA) 149

Superconducting properties of ternary intermetallic compounds having a β-tungsten structure (LA) 957

Superconductivity, Cause (LA) 483

Surfaces, Behavior of molecules in high electric fields and at ~ (CR) 231 [G.E. *80*, 243 (1968)]

Surface chemistry, Infrared Spectroscopy in ~ (Book Review) 486

Surface layer of Ag_2O_3 on silver catalysts (LA) 313

Surface reactions, Study by diffraction of low-energy electrons (CR) 234 [G.E. *80*, 244 (1968)]

Surface tension of liquids (LA) 652

Synthetic Methods of Organic Chemistry (Book Review) 485

TANTALUM, Chemistry of Niobium and ~ (Book Review) 744

Tautomerization, Hydrogen-substituted cyclotriphosphazenes formed by NH → PH ~ (SC) 209 [G.E. *80*, 197 (1968)]

Technetium, Chemistry of ~ and Rhenium (Book Review) 84

Technetium compounds, New ~ (LA) 482

Tellurium compounds, Synthesis of bis-(2,2'-biphenylylene)tellurium (LA) 653

Testosterone, Radiospirometric determination of the oxidation *in vivo* of [17α-^{3}H]-~ and its esters at C-17 (SC) 211 [G.E. *80*, 191 (1968)]

Tetraaminoethylene, Reactions of electron-rich olefins (FP) 754 [G.E. *80*, 823 (1968)]

~-s as strong electron donors (FP) 766 [G.E. *80*, 809 (1968)]

Tetraaminophosphonium salts, Preparation by ammonolysis of the triamino-(methylthio)phosphonium ion (SC) 210 [G.E. *80*, 234 (1968)]

Tetraazasulfate, Diaminosulfur diimide, the aza analog of sulfuric acid (SC) 546 [G.E. *80*, 561 (1968)]

1,2,8,9-Tetraaza-1,8-cyclotetradecadiene-3,10-diol, Unusual formation of the unusual ~ system and its 5,12-dioxa analog (SC) 943 [G.E. *80*, 1000 (1968)]

1,2,8,9-Tetraaza-1,8-cyclotetradecadiene-3,10-ylene diacetate, Crystal structure of ~ (SC) 944 [G.E. *80*, 1001 (1968)]

Tetracyanoethylene, New metal complexes (SC) 305 [G.E. *80*, 314 (1968)]

Bonding in the ferrocene-~ adduct (1:1) (LA) 82

Tetracyclo[4.3.0.$0^{2,4}$.$0^{3,7}$]non-8-en-5-yl cation (LA) 899

Tetrafluoroammonium cation, Existence (LA) 152

Tetrahalocyclopropenes, Diels-Alder reactions (CR) 649 [G.E. *80*, 636 (1968)]

DL-Tetrahydroalstonine, Synthesis and configuration of heterocyclic indole derivatives. Stereoselective total synthesis of DL-akuammigine and ~ (CR) 552 [G.E. *80*, 536 (1968)]

Tetrahydropterins as coenzymes of enzymatic hydroxylation (CR) 477 [G.E. *80*, 492 (1968)]

2,4,5,6-Tetrahydro-5,5,7-trimethylbenzimidazole-2-thiones, new group of benzimidazole derivatives (SC) 68 [G.E. *80*, 46 (1968)]

Tetraisothiocyanatocobaltate(II), Use of dipotassium ~ for the detection of oxygen-containing organic molecules (LA) 149

Tetrakis(cyclopentadienyl)neptunium(IV) (SC) 634 [G.E. *80*, 661 (1968)]

Tetrakis(diphenylarsorylmethyl)methane, Spirocyclic 1:2 adduct of ~ and hydrogen peroxide (SC) 738 [G.E. *80*, 755 (1968)]

closo-Tetrakis(phenylstannylphosphine), an organostannylphosphine with a cubane structure (SC) 813 [G.E. *80*, 846 (1968)]

Tetrakis(trimethylsilyl)hydrazine, Bis(trimethylsilyl)diimine and ~ (SC) 640 [G.E. *80*, 661 (1968)]

Tetrakis(triphenylphosphine)platinum(0) Use as initiator for radical polymerizations (LA) 240

Tetramethoxyethylene, Reactions of electron-rich olefins (FP) 754 [G.E. *80*, 823 (1968)]

3,5,8,10-Tetramethylaceheptylene, Crystal structure and molecular structure (SC) 543 [G.E. *80*, 564 (1968)]

Tetramethylcyclobutadiene, Photolysis of tetramethylcyclobutenedicarboxylic anhydride, a possible route to ~ (SC) 537 [G.E. *80*, 532 (1968)]

Tetramethylpyrrole-indigo (SC) 734 [G.E. *80*, 758 (1968)]

Tetramethylsilane (LA) 742

1,4,7,10-Tetraoxacyclododecanes, Twelve-membered polyether rings (LA) 554

Tetrasulfur tetranitride, Inorganic diene (LA) 652

Textbooks, Praktische Chemie für Mediziner (Practical Chemistry for Doctors and Medical Students) (Book Review) 484

Theoretical chemistry, Handbuch der theoretischen Chemie (Handbook of ~) (Book Review) 484

Thermodynamic properties, New method for estimating ~ of crystalline substances: alkali halides and hydrides (NaCl system) (CR) 227 [G.E. *80*, 200 (1968)]

Thermokinetic measurements (CR) 233 [G.E. *80*, 242 (1968)]

Thiacyclols and cyclothiodepsipeptides (SC) 884 [G.E. *80*, 909 (1968)]

Thiadiazaphosphorine, Synthesis of 2H-1,3,5,2-PV-~ derivatives (SC) 943 [G.E. *80*, 1030 (1968)]

Thienopyrimidines, New 4-hydroxy-~ (SC) 136 [G.E. *80*, 122 (1968)]

Thietane S,S-dioxides, cis- and trans-2,4-diphenyl-~ (LA) 654

Thiirane 1,1-dioxides, Decomposition (LA) 554

Thin layer chromatography, New adsorbents suitable for ~ (LA) 900

S-Thioacylation of the sulfinate anion: Preparation and properties of some sulfonylformamides, -thioformamides, and -formamidines (SC) 734 [G.E. *80*, 704 (1968)]

Thioacylium cation, First synthesis (SC) 548 [G.E. *80*, 567 (1968)]

Thiocarboxamides, Synthesis by the azolide method (SC) 302 [G.E. *80*, 315 (1968)]

Thiocyanates, Cyanic ester from ~ (SC) 67 [G.E. *80*, 42 (1968)]

Thioformamides, Separation and properties of the cis-trans-isomers of N-alkyl-~ (SC) 467 [G.E. *80*, 448 (1968)]

Thiohexobarbital, Synthesis of both hexobarbital enantiomers and of (+)-methyl 2-cyano-2-(1-cyclohexenyl)propionate (SC) 463 [G.E. *80*, 483 (1968)]

Thioketene, Di-tert-butyl-~ and di-tert-butyl-~ S-oxide (LA) 900

N-Thionylacetamide (LA) 236

Thionyl chloride, New reaction with a carboxylic acid (SA) 403

Thiophene, Modification of the orientation of substitution reactions on ~ and furan derivatives (FP) 519 [G.E. *80*, 547 (1968)]

Thiospinels, Preparation of single crystals of chromium ~ by means of transport reactions (SC) 542 [G.E. *80*, 562 (1968)]

Thorium compounds, Diphthalocyaninato-thorium(IV) and -uranium(IV) (SC) 819 [G.E. *80*, 792 (1968)]

Tin, Strongly exothermic heats of solution of palladium in molten ~ (LA) 899

Tin compounds, Trimethylsilyl derivatives of germanium and tin. – Electron-balance bonds of silicon (SC) 212 [G.E. *80*, 192 (1968)]

Tris(imidodiphosphinato) cationic complexes of silicon, germanium, and tin (SC) 549 [G.E. *80*, 558 (1968)]

Recent findings in the organic chemistry of tin and lead (CR) 78 [G.E. *80*, 48 (1968)]

Bis(triphenylstannyl)mercury (LA) 959

New red modification of tin(II) oxide and the known red and black modifications (LA) 311

Organische Chemie des Zinns (Organic Chemistry of Tin) (Book Review) 316

Titanium-boron complex, ESR-Investigation of a new ~ (SC) 821 [G.E. *80*, 796 (1968)]

Titanium-carbon bond, ESR-Investigation on the stability of the ~ in soluble Ziegler-Natta-catalysts (SC) 822 [G.E. *80*, 796 (1968)]

Titanium compounds, Compounds with Si–Ti linkages (SC) 142 [G.E. *80*, 153 (1968)]

ESR measurements on nitrogen-fixing titanium-alkali metal systems (SC) 386 [G.E. *80*, 398 (1968)]

Preparation of titanyl and vanadyl mesoporphyrin IX dimethyl esters (SC) 891 [G.E. *80*, 914 (1968)]

Titanium dioxide, Ternary oxides of rutile structure: Systems containing WO_2, MoO_2, VO_2 or ~ (CR) 229 [G.E. *80*, 202 (1968)]

Titanium hexacyanoferrate(II) complex, Ion-exchange properties of a ~ (LA) 82

Titanium(IV) pentaselenide, Di-π-cyclopentadienyl-~ (LA) 239

Titrations, Acid-base ~ on powdered quartz (LA) 235

Toluenes, Hammett constants of phosphorus-containing groups determined from nuclear magnetic resonance spectra of *para*-phosphorus-substituted ~ (SC) 544 [G.E. *80*, 559 (1968)]

Hammett constants of phosphorus-containing groups determined from nuclear magnetic resonance spectra of *meta*- and *ortho*-phosphorus-substituted ~ (SC) 545 [G.E. *80*, 559 (1968)]

Toxicology, Handbook of Industrial ~ (Book Review) 558

Toxikologie-Fibel für Ärzte, Apotheker, Naturwissenschaftler, Juristen und Studierende (~ primer for physicians, pharmacists, scientists, lawyers, and students) (Book Review) 655

Toxins, Discovery, isolation, elucidation of structure, and synthesis of antamanide (FP) 204 [G.E. *80*, 209 (1968)]

Trace analysis, Problems and possibilities of modern ~ (FP) 252 [G.E. *80*, 297 (1968)]

Trace elements, The adsorption of ~ from sea water (LA) 959

Transitions, Identification of the n–σ* ~ in the electron excitation spectrum of 2-butanone (SC) 626 [G.E. *80*, 613 (1968)]

Transport processes of noble gases in solids, especially nuclear fuels (CR) 739 [G.E. *80*, 706 (1968)]

Transport reactions, Preparation of single crystals of chromium thiospinels by means of ~ (SC) 542 [G.E. *80*, 562 (1968)]

Tri-n-alkylchromium compounds, Fragmentation of specifically deuterated ~ (SC) 951 [G.E. *80*, 1029 (1968)]

Triarylformazanes (LA) 482

Triazane derivatives, New synthesis (SA) 403

1,3,5,2-Triazaphosphorine 2-oxide, 4,6-Dioxo-2-arylperhydro-~ (LA) 742

1,3,5-Triazine-2,4-diones, Synthesis of anellated ~ (SC) 380 [G.E. *80*, 362 (1968)]

Anellated ~ as dimers of heterocyclic isocyanates (SC) 381 [G.E. *80*, 363 (1968)]

s-Triazinetriones, Preparation and properties of the diastereoisomeric 1,3,5-triglycidyl-~ (CR) 827 [G.E. *80*, 851 (1968)]

1,2,4-Triazole, Iron derivatives of five-membered carbon-nitrogen heterocycles (SC) 70 [G.E. *80*, 38 (1968)]

Tribochemistry, Grundlagen der Tribochemie (Fundamentals of ~) (Book Review) 556

Tricarbonylchlororhenium(I), Novel ~ and reactions of substituted carbonylchlororheniums(I) with water and other oxygen-containing ligands (SC) 627 [G.E. *80*, 621 (1968)]

Trichloroallene, Cycloadducts from trichloroallenyllithium (SC) 470 [G.E. *80*, 481 (1968)]

~, Preparation and dimerization (SC) 471 [G.E. *80*, 482 (1968)]

Preparation and dimerization of ethyl ~-carboxylate (SC) 472 [G.E. *80*, 483 (1968)]

Trichlorocyclopropenylium ion, Derivatives (CR) 649 [G.E. *80*, 636 (1968)]

Tricyanovinylation of aromatic compounds without electropositive substituents (LA) 81

exo-Tricyclo[3.2.1.$0^{2,4}$]octane (CR) 644 [G.E. *80*, 631 (1968)]

Triethylaluminum, Dimer-monomer equilibrium of ~ in n-hexadecane solution (LA) 152

Trifluorodithioacetic acid, Preparation and properties (SC) 301 [G.E. *80*, 319 (1968)]

Trifluorophosphine, Pentacoordinated metal(0)-~ derivatives (LA) 652

1,3,5-Triglycidyl-s-triazinetriones, Preparation and properties of the diastereoisomeric ~ (CR) 827 [G.E. *80*, 851 (1968)]

Trigonal bipyramid, Ligand reorganization in the ~ (SC) 725 [G.E. *80*, 700 (1968)]

Triisopropylidenecyclopropane, Crystal structure (SC) 465 [G.E. *80*, 487 (1968)]

Trimethylaluminum, Polymerization reaction (CR) 399 [G.E. *80*, 413 (1968)]

Trimethylene, Triplet ~ species (CR) 641 [G.E. *80*, 629 (1968)]

1,1,2-Trimethyl-3-methyleneisoindoline (SC) 373 [G.E. *80*, 361 (1968)]

Trimethylsilyl group as protective group for terminal alkynes (LA) 311

Trinucleotides, Preparation of eleven labeled ~ (LA) 236

1,2,3-Triphenylaziridine, Photochemistry (LA) 555

Triphenylborane, Structure and hydrolysis of the ate-complex from tritylsodium, acenaphthylene, and ~ (SC) 139 [G.E. *80*, 149 (1968)]

1,2,3-Triphenylpyrroles, Simple synthesis of substituted ~ (SC) 946 [G.E. *80*, 1002 (1968)]

Triphenylsilanide, Coordination behavior (SC) 374 [G.E. *80*, 360 (1968)]

Triplet trimethylene species (CR) 641 [G.E. *80*, 629 (1968)]

Tris(diethylamino)phosphine (LA) 832

Tris(dimethylamino)boranetricarbonyltungsten (SC) 293 [G.E. *80*, 282 (1968)]

Tris(imidophosphinato) complexes of silicon, germanium, and tin (SC) 549 [G.E. *80*, 558 (1968)]

Tris(phosphonylmethyl)phosphine oxides, Preparation and properties of ~ oxides and the corresponding acid (SC) 385 [G.E. *80*, 401 (1968)]

Tris(triphenylphosphine)cobalt dihydride (LA) 80

2,4,6-Tri-tert-butylphosphorin, Preparation of 2,4,6-tri-tert-butylpyrylium tetrafluoroborate, 2,4,6-tri-tert-butylpyridine, and ~ (SC) 460 [G.E. *80*, 489 (1968)]

2,4,6-Tri-tert-butylpyridine, Preparation of 2,4,6-tri-tert-butylpyrylium tetrafluoroborate, ~, and 2,4,6-tri-tert-butylphosphorin (SC) 460 [G.E. *80*, 489 (1968)]

2,4,6-Tri-tert-butylpyrylium tetrafluoroborate, Preparation of ~, 2,4,6-tri-tert-butylpyridine, and 2,4,6-tri-tert-butylphosphorin (SC) 460 [G.E. *80*, 489 (1968)]

Trithiomolybdates (SC) 817 [G.E. *80*, 846 (1968)]

Tritioethanol, Synthesis, on a preparative scale, of ethanol stereospecifically labeled on hydrogen (SC) 892 [G.E. *80*, 915 (1968)]

Tritylsodium, Structure and hydrolysis of the ate-complex from ~, acenaphthylene, and triphenylborane (SC) 139 [G.E. *80*, 149 (1968)]

Trypsin, Analysis of foodstuffs with particular reference to quality control (CR) 956 [G.E. *80*, 1003 (1968)]

Tumors, Cytogenetics of human ~ (FP) 709 [G.E. *80*, 747 (1968)]

Tungsten, Studies on the adsorption of gases on clean metal surfaces with the aid of field-emission and field-ion microscopy techniques (FP) 668 [G.E. *80*, 673 (1968)]

The superconducting properties of ternary intermetallic compounds having a β-~ structure (LA) 957

Tungsten compounds, Hydrogenation of polyenes by tricarbonylcyclopentadienylhydridomolybdenum and -tungsten (SC) 880 [G.E. *80*, 968 (1968)]

Preparation of tungsten pentafluoride (SC) 132 [G.E. *80*, 118 (1968)]

Tris(dimethylamino)boranetricarbonyltungsten (SC) 293 [G.E. *80*, 282 (1968)]

Preparation and properties of tungsten oxide bromide (SC) 294 [G.E. *80*, 286 (1968)]

Ternary oxides of rutile structure: Systems containing WO_2, MoO_2, VO_2 or TiO_2 (CR) 229 [G.E. *80*, 202 (1968)]

Tungsten hexahydride 3 (dimethylphenylphosphine) (LA) 654

Twisting vibration, Direct observation of the ~ of C_2H_6, CH_3CD_3, and C_2D_6 (LA) 651

ULTRASONIC absorption of alkyl esters (LA) 830

Ultrasonic radiation, Frequency-, temperature, and concentration-dependent absorption of ~ by benzoic acid solution (LA) 313

Ultraviolet spectrum, Identification of the n–σ* transition in the electron excitation spectrum of 2-butanone (SC) 626 [G.E. *80*, 613 (1968)]

Uranium compounds, Diphthalocyaninato-thorium(IV) and -uranium(IV) (SC) 819 [G.E. *80*, 792 (1968)]

Urea, Structure of the dihydroxyuranyl-~ complex (LA) 150

Urethanes, Ethynylogous amides and ~ (SC) 459 [G.E. *80*, 443 (1968)]

VALENCE and reactivity: International symposium on d-orbital effects (CR) 475 [G.E. *80*, 491 (1968)]

Valence force constants of various phosphorus compounds (CR) 232 [G.E. *80*, 246 (1968)]

Valence isomerization, of C_9H_{10} hydrocarbons (SC) 468 [G.E. *80*, 446 (1968)]

Degenerate thermal ~ of the bicyclo-[4.2.2]deca-2,4,7,9-tetraene skeleton (SC) 823 [G.E. *80*, 803 (1968)]

Valence states, Structures of compounds of elements in ~ with $4s^2$ and $5s^2$ electron configurations (CR) 651 [G.E. *80*, 669 (1968)]

Vanadium compounds, Preparation of titanyl and vanadyl mesoporphyrin IX dimethyl esters (SC) 891 [G.E. *80*, 914 (1968)]

Vanadium complex, PH_3 – A new ligand in a transition metal complex (SC) 136 [G.E. *80*, 122 (1968)]

Vanadium dioxide, Ternary oxides of rutile structure: Systems containing WO_2, MoO_2, ~ or TiO_2 (CR) 229 [G.E. *80*, 202 (1968)]

Vapor pressure above the calcium carbide phase (LA) 81

Vermiculite, Chemistry of clay (FP) 681 [G.E. *80*, 736 (1968)]

Vinylene carbonate, Syntheses by means of *dichloro-*~ (*4,5-dichloro-1,3-dioxol-2-one*) as dienophile and photocyclophile (SC) 215 [G.E. *80*, 194 (1968)]

Vinyloxyboranes, Addition of substituted ~ to nitriles (SC) 735 [G.E. *80*, 756 (1968)]

Vinylpyrazoloquinones (CR) 398 [G.E. *80*, 412 (1968)]

Viscometry, Viskosimetrie (~) (Book Review) 241

Vitamins, Mode of action of the B_{12} coenzyme in the reduction of ribonucleotides (LA) 314

Biochemie der Vitamine (Biochemistry of the ~) (Book Review) 155

WALL paintings, Investigations of Roman ~ (CR) 478 [G.E. *80*, 494 (1968)]

Wetting and adhesion behavior of liquid indium on solid aluminum (LA) 654

Wittig reactions, with the aid of ethylene oxide (SC) 536 [G.E. *80*, 535 (1968)]

Mechanism and stereochemistry of Wittig olefin syntheses (CR) 650 [G.E. *80*, 637 (1968)]

Wolff-Kishner reactions, Mechanism of the Wolff-Kishner reduction, elimination, and isomerization reactions (FP) 120 [G.E. *80*, 141 (1968)]

XANTHINE oxidase from milk (LA) 80

Xenon fluorides, Vapor pressures and melting points of XeF_2 and XeF_4 (LA) 742

X-Ray analysis, of tri-μ-chlorobis[bis-(tri-n-butylphosphine)ruthenium chloride] (SC) 131 [G.E. *80*, 116 (1968)]

Preparation and structure of methylpotassium (SC) 133 [G.E. *80*, 123 (1968)]

Structure of dimethylnitrosaminecopper(II) chloride (SC) 470 [G.E. *80*, 444 (1968)]

Structure of the principal aglycon of horse chestnut saponin (SC) 547 [G.E. *80*, 563 (1968)]

~ of non-stabilized ylids (SC) 730 [G.E. *80*, 697 (1968)]

~, see also Crystal structure

YEAST, Binding of the substrate in ~ pyruvate decarboxylase (SC) 68 [G.E. *80*, 41 (1968)]

Accumulation of 2,5-diamino-6-hydroxy-4-ribitylaminopyrimidine in a riboflavin-deficient mutant (SC) 219 [G.E. *80*, 237 (1968)]

Ylide, Silyl shift in phosphorus ~-s (SC) 220 [G.E. *80*, 239 (1968)]

Bis(diethoxyphosphinyl)(trimethylammonio)methylide, a stable N-~ (SC) 463 [G.E. *80*, 445 (1968)]

X-ray study of non-stabilized ~-s (SC) 730 [G.E. *80*, 697 (1968)]

Crystalline antimony ~ (LA) 148

Synthesis of a selenium ~ (LA) 151

ZIEGLER-Natta catalysts, ESR-Investigation on the stability of the titanium-carbon bond in soluble ~ (SC) 822 [G.E. *80*, 796 (1968)]

Ziegler-Zeiser alkylation, *para*-Substitution in the ~ (LA) 150
