In a branched biosynthetic chain, it is necessary to regulate the main pathway as well as each individual chain. This is possible *e.g.* if the first step of the main pathway is catalyzed by isozymes, each of which is specifically inhibited by an end product situated beyond the branching point (see Scheme 1). However, this control may also be exerted through a single enzyme, which is inhibited only when all the end products are present at the same time (multivalent negative feedback). A third possibility for regulation in the main pathway is that biosynthesis of the enzyme is suppressed only by the simultaneous presence of end products of several chains (multivalent repression). It would be useful if the end product of one chain in a branched biosynthetic chain not only inhibited the first enzyme of its own chain, but also simultaneously activated the first enzyme of another chain. Multivalent induction, in which an enzyme of one chain is induced by end products of several chains, has also been observed.

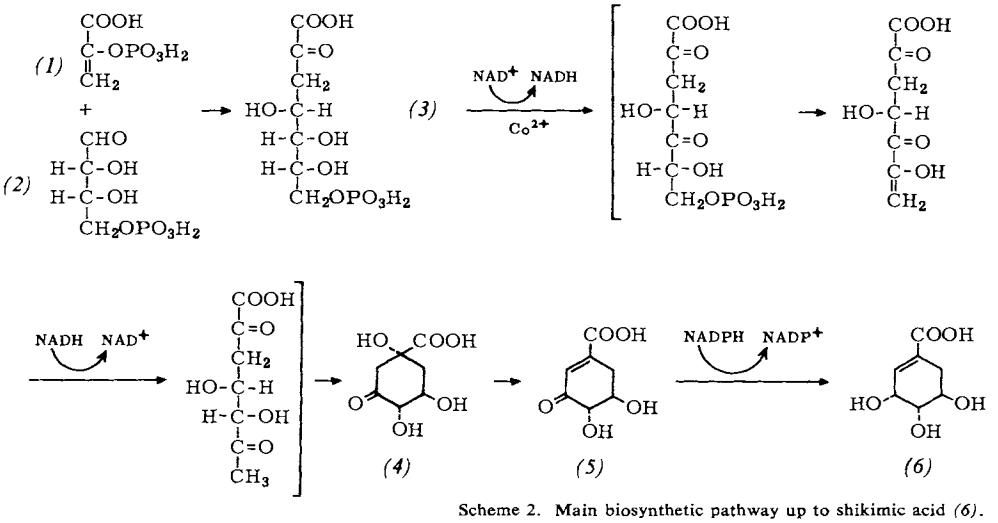
Biochemical deficiency mutants having a suitable genetic block have frequently been introduced into the synthetic chain in order to study biosynthetic processes. (For descriptions of methods, see [1].)

1.1. Definitions

An organism that can grow with CO_2 as its source of carbon is said to be autotrophic; if an organic carbon source is necessary, the organism is heterotrophic. Many microorganisms in nature ("wild strains" = prototrophic forms) synthesize all the compounds that they need to live from a simple organic carbon source and inorganic salts. In a prototrophic organism, the DNA can be changed in such a way by the action of a mutagen that one enzyme disappears (genetic blockage by mutation). The resulting "auxotrophic" forms (biochemical deficiency mutants) also require the end product or one of the compounds of the pathway beyond the genetic block for their growth. A single mutation can also lead to a polyauxotrophic organism, which requires several end products for its growth, owing to mutation in the main stem of a branched biosynthetic chain. Biochemical deficiency mutants cannot grow in media that lack the end product of the broken synthetic path. However, the synthetic chain remains capable of functioning as far as the genetic block; the intermediate product formed in this way is often released into the medium (accumulation).

2. The Main Pathway of the Biosynthesis of Aromatic Amino Acids

The first step in the main pathway is the condensation of phosphoenolpyruvic acid *(1)* with erythrose 4-phosphate *(2)* to form 2-keto-3-deoxyarabinoheptonic acid 7-phosphate *(3)* [2] (see Scheme 2).



Scheme 2. Main biosynthetic pathway up to shikimic acid *(6)*.

[1] *H. Hellmann* and *F. Lingens*, Angew. Chem. *73*, 107 (1961).

[2] *P. R. Srinivasan*, *M. Katagiri*, and *D. B. Sprinson*, J. Amer. chem. Soc. *77*, 4943 (1955).

The enzyme that catalyzes this reaction (DAHP synthetase = PODH lyase: E.C. 4.1.2.15) requires neither a metal ion nor another cofactor [3]. Later investigations showed that in *E. coli* and many other microorganisms this step is catalyzed by isozymes, which all initiate the same reaction and are all characteristically inhibited by the end products of the branched biosynthetic chain.

The second step in the biosynthesis is the conversion of *(3)* into 5,5-didehydroquinic acid *(4)* [4].

This ring closure probably proceeds *via* three intermediates with seven carbon atoms in each. The oxidation at C-5 of *(3)* facilitates the elimination of phosphate in the next step. This is followed by reduction of this carbonyl group to a hydroxyl group, with restoration of the original configuration of *(3)*. The resulting 2,6-diketone cyclizes to give *(4)* [5].

In the third step, *(4)* is dehydrated to form 5,5-didehydroshikimic acid *(5)*. The enzyme involved in this dehydration is highly specific, and does not dehydrate quinic acid to shikimic acid [6]. *(5)* is then reduced to shikimic acid *(6)* (the reductase requires NADPH as the cofactor [7]).

A polyauxotrophic mutant of *E. coli* whose phenylalanine, tyrosine, tryptophan, *p*-aminobenzoic acid, and *p*-hydroxybenzoic acid requirements can be satisfied by shikimic acid alone releases *(5)* into the medium under starvation [8]; this mutant lacks the reductase for the conversion of *(5)* into *(6)*. In polyauxotrophic mutants of *E. coli* [9,10] and *S. cerevisiae* [11] that cannot utilize shikimic acid for growth, shikimic acid has been detected as an accumulated product.

Shikimic acid is phosphorylated with ATP to the 5-phosphate *(7)* [12,13] (see Scheme 3), which then reacts with phosphoenolpyruvic acid to give the 3-enolpyruvyl ether *(8)* of shikimic acid 5-phosphate [14].

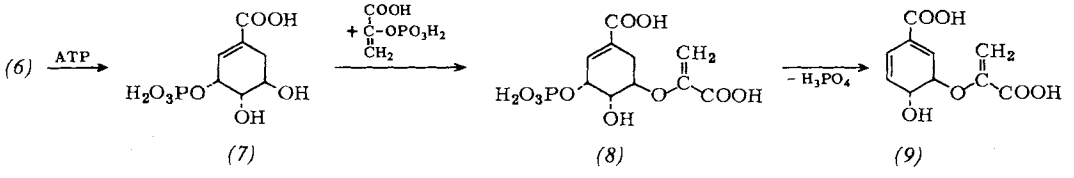
Phosphates frequently cannot be detected as accumulation products, since they are ionized compounds and so do not pass through the cell wall [15]. Moreover, phosphates are readily attacked by "nonspecific" phosphatases, and then cannot be found.

The compound *(8)* was for a long time erroneously regarded as the product at the branching point in the biosynthesis, from which the syntheses of phenylalanine, tyrosine, tryptophan, *etc.*, begin. It was noticeable, however, that *(8)* occurred as an accumulated product (in the dephosphorylated form) only in polyauxotrophic mutants. A product of the branching point, on the other hand, should occur as an accumulated product in mutants that are blocked in the first step after the branch in one of the possible biosynthetic chains. Thus different mutants should give the same accumulated product. This has in fact been found for various *S. cerevisiae* mutants, which accumulated the same branching product [16]. This secondary product of *(8)* was first detected with an *A. aerogenes* mutant, which was dependent on the simultaneous supply of phenylalanine, tyrosine, and tryptophan as a result of several mutations [17,18].

Finally, *(8)* loses phosphoric acid to give the 3-enolpyruvyl ether of *trans*-3,4-dihydroprotocatechuic acid *(9)* (chorismic acid, χωρισμος = separation) [19].

Chorismic acid closes the main stem of the biosynthesis of aromatic amino acids. The five synthetic chains that branch out from this point will now be discussed.

It should be noted that quinic acid has also been postulated as a link in the main chain. This assumption is based on the observation of the activity of this compound as a growth factor for *Aerobacter aerogenes*. This organism can synthesize 5,5-didehydroquinic acid from quinic acid [20,21]. No other microorganism examined so far has this ability. However, quinic acid is not a link in the biosynthetic chain, but serves *A. aerogenes* as an additional source of 5,5-didehydroquinic acid.



(7) (8) (9)

Scheme 3. Main biosynthetic pathway up to chorismic acid *(9)*.

It was particularly difficult to establish the structure of this intermediate, since it is unstable and is released in the dephosphorylated form by suitably blocked mutants.

3. Biosynthesis of Phenylalanine and Tyrosine

The common starting material for the biosynthesis of phenylalanine and tyrosine is prephenic acid *(10)* which is formed enzymatically from chorismic acid *(9)* [22]. The conversion of *(9)* into *(10)*, which is catalyzed by chorismate mutase, may be regarded as a Claisen rearrangement. It can also be effected in the

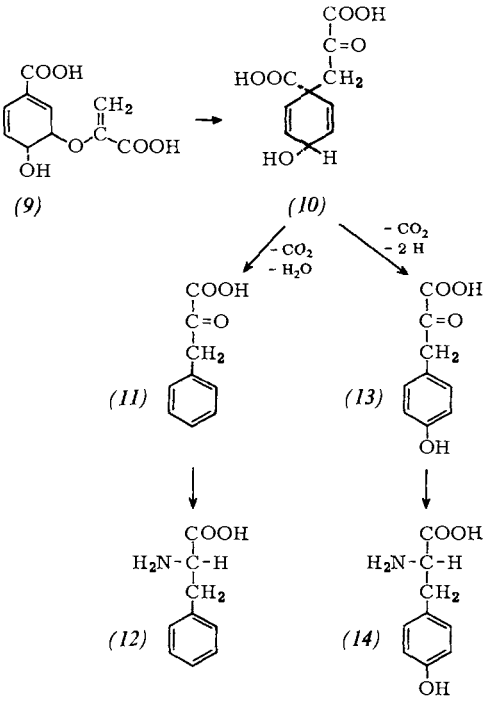
absence of enzyme by careful heating of *(9)* in buffer solutions at pH = 7.0.

Prephenic acid *(10)* is enzymatically aromatized at pH = 7 to phenylpyruvic *(11)* and *p*-hydroxyphenylpyruvic acid *(13)*. The formation of *(11)* is catalyzed by prephenate dehydratase [23].

This reaction proceeds readily in weakly acidic media in the absence of enzyme. This explains why a mutant that lacks prephenate dehydratase, and which accumulates *(10)* under deficiency conditions, can grow readily with the accumulated product after decomposition to form *(11)* if the acidification of the medium is not prevented by continuous addition of alkali [24, 25].

Reductive transamination of phenylpyruvic acid *(11)* leads to phenylalanine *(12)* (see Scheme 4).

p-Hydroxyphenylpyruvic acid *(13)* is formed from prephenic acid *(10)* with catalysis by prephenate dehydrogenase. This reaction requires NAD as a cofactor [26]. The reductive transamination of *(13)* yields tyrosine *(14)*.



Scheme 4. Biosynthetic pathways to phenylalanine *(12)* and tyrosine *(14)*.

4. Biosynthesis of Tryptophan

The first link in the biosynthetic chain leading to tryptophan is anthranilic acid *(15)* (see Scheme 5). Though the transformation of chorismic acid *(9)* into anthranilic acid is a complex process, this reaction is catalyzed [27,28], at least in *N. crassa* and *S. cerevisiae*, by a single enzyme. The amide nitrogen of glutamine gives the amino group in *(15)* [29]. It might be assumed that this biosynthesis proceeds *via* the 3-enolpyruvyl ether of *trans*-2,3-dihydro-3-hydroxyanthranilic acid *(15a)*;

however, this compound has not yet been detected [16, 30, 31].

In the investigation of the conversion of *(9)* into *(15)*, the formation of phenolcarboxylic acids and phenols has been observed with some microorganisms [34]. The occurrence of large quantities of *p*-hydroxybenzoic acid *(24)* is understandable, since this compound is readily formed, both enzymatically and spontaneously, from *(9)*. The formation of protocatechuic acid *(9c)* could be imagined as resulting from the initial cleavage of the ether linkage in *(9)* to form *trans*-3,4-dihydroprotocatechuic acid *(9a)*, which is then dehydrogenated. Decarboxylation of *(9c)* yields pyrocatechol. If starved of nitrogen, a 3-enolpyruvyl ether of *trans*-2,3-dihydro-2,3-dihydroxybenzoic acid *(9b)* could occur as an analog of the nitrogen compound. The occurrence of this compound would readily explain the formation of salicylic acid (removal of pyruvic acid), as well as the formation of 2,3-dihydroxybenzoic acid (cleavage of the ether linkage and dehydrogenation). *trans*-2,3-Dihydro-3-hydroxyanthranilic acid *(15b)* has been isolated from a *Streptomyces aureofaciens* mutant having a reduced ability to synthesize tetracycline [35]. It may be assumed that this compound is formed by cleavage of the ether linkage in the postulated intermediate *(15a)*.

Cox and *Gibson* [36] very recently showed that 2,3-dihydroxybenzoic acid has an additional growth effect on polyauxotrophic mutants of *E. coli*, but is not a precursor of ubiquinone or vitamin K. However, this compound is evidently also formed in excess of actual requirements, since the accumulation of the serine compound of 2,3-dihydroxybenzoic acid has been observed with *E. coli* [37].

2,3-Dihydro-2,3-dihydroxybenzoic acid was recently detected as an intermediate in the biosynthesis of 2,3-dihydroxybenzoic acid [37a].

N-Pyruvoylanthranilic acid, which is reported to occur as an accumulation product of *A. aerogenes* [38], has been postulated as an intermediate in the conversion of chorismic acid *(9)* into anthranilic acid. *N*-Pyruvoylanthranilic acid has been synthesized [39], but could not be converted into anthranilic acid in enzymatic tests with *S. cerevisiae* extracts [28].

The conversion of *(9)* into *(15)* can be inhibited by glutamine-like substances. No intermediates of the transformation could be detected in inhibition experiments with 6-diazo-5-oxonorleucine. A mutant that normally accumulates anthranilic acid as a result of genetic blocking of the tryptophan biosynthesis chain gives chorismic acid *(9)* and products of the other biosynthetic branches in the presence of 6-diazo-5-oxonorleucine [40]. *(9)* is accumulated in good yield by a series of phe$^-$ and/or tyr$^-$ mutants [*] of *S. cerevisiae* and *E. coli*. The yield can be increased by the addition of diazooxonorleucine if suitably precultured and accumulated [41].

It is interesting to note that chorismic acid can be detected as an accumulation product when diazooxonorleucine is allowed to act on the wild strains of *E. coli* and *S. cerevisiae* [41].

The next step in the biosynthesis of tryptophan is the reaction of anthranilic acid *(15)* with 1-pyrophosphoryl-D-ribose 5-phosphate to give 1-*o*-carboxyphenyl-D-ribosylamine 5-phosphate *(16)* (see Scheme 6). This compound, which had for a long time been formulated as an intermediate [42], was recently also detected enzymatically [43].

The corresponding phosphate-free compound should be expected as an accumulation product with suitably blocked tryptophan-deficient mutants. However, only anthranilic acid is in fact found.

The assumption that 1-*o*-carboxyphenyl-D-ribosylamine could not be detected because of its instability was incorrect; the compound [42] could be recovered unchanged from the culture medium by microorganism in a model experiment [44]. It must therefore be assumed that the unstable primary accumulation product *(16)* breaks down into anthranilic acid and ribose 5-phosphate, which is transferred to the carbohydrate metabolism.

As the biosynthesis proceeds, 1-*N*-(*o*-carboxyphenylamino)-1-deoxy-D-ribulose 5-phosphate *(17)* is formed by an Amadori rearrangement of *(16)*.

Tryptophan-requiring mutants of *A. aerogenes* [45] and *S. cerevisiae* [46] having a genetic block in the next stage of the biosynthetic chain accumulate 1-*N*-(*o*-carboxyphenylamino)-1-deoxy-D-ribulose if starved of tryptophan. This compound and its phosphate *(17)* can also be obtained by synthesis [47].

(17) is cyclized in the next step to form an indole compound *(18)* by dehydration and decarboxylation on the C atom that carried the carboxyl group, as could be shown by the conversion of 4-methylanthranilic acid into 6-methylindole [48]. The C atoms 1 and 2 of the ribulose supply the missing C atoms of the pyrrole ring [49].

The formation of 3-(indol-3-yl)glycerine-1-phosphate *(18)* was detected with enzyme extracts [50]. Tryptophan-requiring mutants of *E. coli* and *Salmonella typhimurium* release 1-indol-3-ylglycerine into the medium [42]; correspondingly blocked mutants of *S. cerevisiae* surprisingly accumulate not

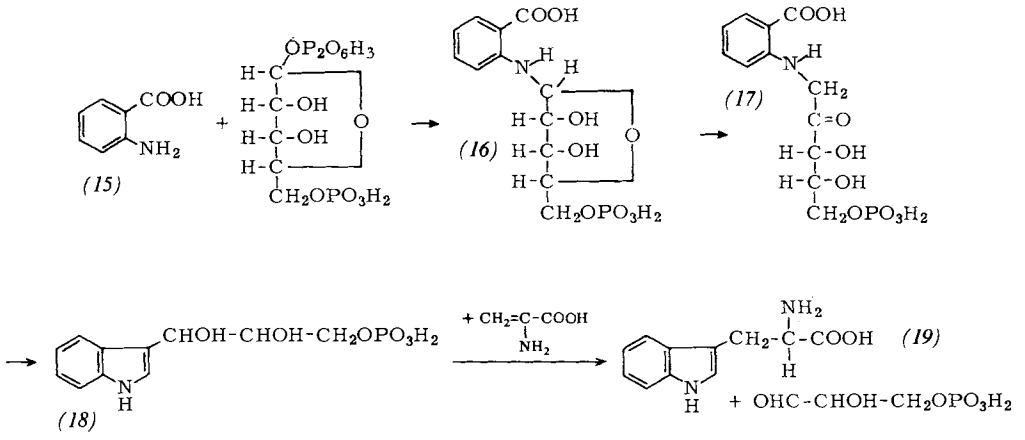


Scheme 6. Biosynthetic pathway to tryptophan *(19)*.

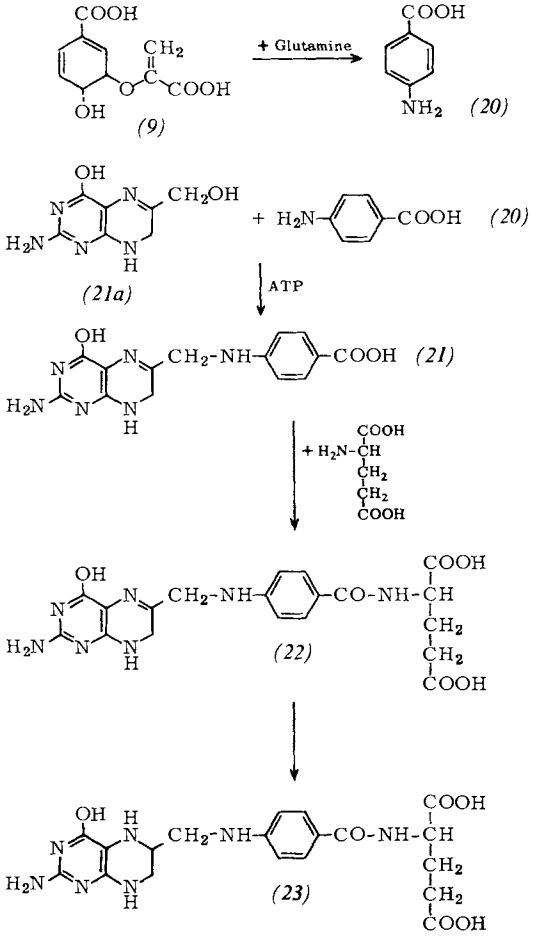
this compound, but 3,3-di(indol-3-yl)-1,2-propanediol[51]. A crude enzyme extract of *S. cerevisiae* converts *(18)* into the 1-phosphate of 3,3-di(indol-3-yl)-1,2-propanediol[51].

3-Hydroxy-3-(indol-3-yl)-2-oxopropyl phosphate was also detected[51]. One might have thought that a biosynthesis of tryptophan could take place *via* this compound with retention of the side chain, as in the biosynthesis of histidine. However, the intermediates tryptophanol phosphate, tryptophanol, and tryptophanal that would be required in this case could not replace tryptophan for a number of microorganisms[52].

The last step of the tryptophan synthesis is the condensation of *(18)* with α-aminoacrylic acid (formed from serine by intramolecular elimination of water), with elimination of glyceraldehyde phosphate to form tryptophan *(19)*. The tryptophan synthetase that catalyzes this reaction consists of two components A and B[53–55], and may be regarded as a multienzyme complex[56]. If part B is absent (owing to mutation), the second part of the reaction does not take place. Tryptophan-requiring mutants of this type accumulate indole if starved of tryptophan.

5. Biosynthesis of *p*-Aminobenzoic Acid and Folic Acid

It has been shown with enzyme extracts from yeast that *p*-aminobenzoic acid *(20)* is formed from shikimic acid 5-phosphate *(7)* with glutamine as the nitrogen donor and NAD[57] (see Scheme 7). Later investigations showed that this biosynthesis also proceeds *via* chorismic acid *(9)*[58]. No intermediates have yet been found in the conversion of *(9)* into *(20)*. Genetic studies[58a] and cross-feeding tests on mutants of *Neurospora*[58b] and of *E. coli*[58c] indicate that an intermediate is formed.



Scheme 7. Biosynthetic pathway to tetrahydrofolic acid *(23)*.

p-Aminobenzoic acid is the starting material for the biosynthesis of folic acid. According to studies by *Brown et al.*, the biosynthesis in *E. coli* proceeds as follows: *p*-Aminobenzoic acid is first condensed with 2-amino-4-hydroxy-6-hydroxymethyl-7,8-dihydropteridine *(21a)* in the presence of ATP to give dihydropteroic

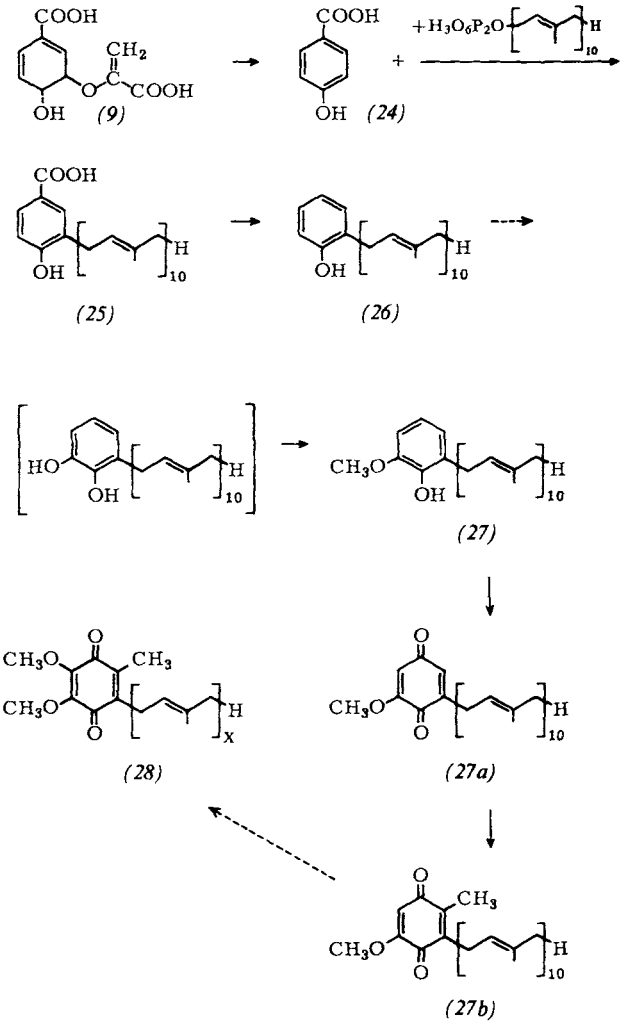
acid *(21)*; *(21)* then reacts with glutamic acid to form dihydrofolic acid *(22)*, which is finally reduced to the biologically active tetrahydrofolic acid *(23)* [59].

6. Biosynthesis of *p*-Hydroxybenzoic Acid and of Ubiquinone

p-Hydroxybenzoic acid *(24)* is formed both enzymatically and spontaneously from chorismic acid *(9)* (see Scheme 8).



Scheme 8. Biosynthetic pathway to ubiquinone *(28)*. In yeast ubiquinone x = 6.

It has been shown in enzyme experiments that for *E. coli*, ^{14}C-shikimic acid is incorporated into ubiquinone. The degree of incorporation is decreased by the addition of *(24)* [60]. This shows that the biosynthesis of ubiquinone can proceed *via* *p*-hydroxybenzoic acid. It has been found with enzyme extracts from *Rhodospirillum rubrum* that *(24)* reacts first with decaprenyl pyrophosphate to form 3-decaprenyl-4-hydroxybenzoic acid *(25)*, which is then decarboxylated to give 2-decaprenylphenol *(26)* [61].

2-Decaprenyl-6-methoxyphenol *(27)* has been isolated as another intermediate in the synthesis of ubiquinone in *Rhodospirillum rubrum* [62,63]. The 3-decaprenylpyrocatechol postulated as an intermediate in the transition from *(26)* to *(27)* has not yet been detected. Other intermediates [*(27a)* and *(27b)*] of the biosynthesis of ubiquinone have recently been detected [63a].

In the discussion of the formation of ubiquinone, it must be borne in mind that *p*-hydroxybenzoic acid *(24)* can be formed, not only from chorismic acid *(9)*, but also from tyrosine. It has been assumed that *(24)* is converted into *p*-hydroxybenzaldehyde, which can also be formed from *p*-hydroxyphenylpyruvic acid by a nonenzymatic reaction. *p*-Hydroxybenzaldehyde is thought to be the starting material both for the quinone ring of ubiquinone and for *p*-hydroxybenzyl alcohol. It should be mentioned that mammals can also synthesize tetrahydrofolic acid *(23)*. The necessary *p*-hydroxybenzoic acid is presumably produced *e.g.* by rats from tyrosine, since there is no chorismic acid available [64]. It is interesting to observe that the protozoon *Tetrahymena pyriformis* can form the benzoquinone ring of ubiquinone from shikimic acid, whereas this organism lacks the enzymes for the synthesis of tryptophan and phenylalanine [65].

7. Biosynthesis of Vitamin K [*]

Davis observed that polyauxotrophic mutants of *E. coli* that depend on the simultaneous supply of phenylalanine, tyrosine, tryptophan, *p*-aminobenzoic acid, and *p*-hydroxybenzoic acid grow better when an unknown sixth factor, which is present in the usual whole medium for bacteria, is also added [66]. This factor is probably a compound that can be converted into vitamin K. It is known from investigations by *Cox* and *Gibson* that vitamin K is formed by the sixth biosynthetic pathway. ^{14}C-Shikimic acid is converted into ^{14}C-vitamin K; the radioactivity in vitamin K could not be reduced by the addition of *p*-hydroxybenzoic acid. In experiments with other substances, 3,4-dihydroxybenzaldehyde and adrenaline were found to be effective [67]. However, it cannot be concluded from this that the two compounds are true intermediates of the biosynthetic chain. *Leistner*, *Schmitt*, and *Zenk* [67a] detected α-naphthol *(29)* as a precursor of vitamin

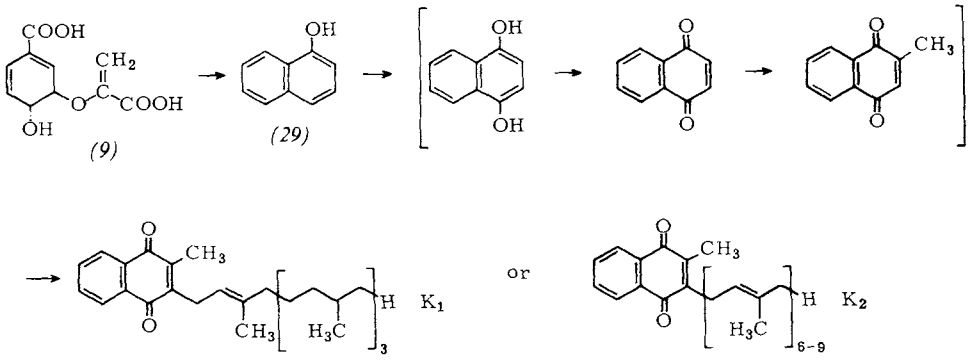


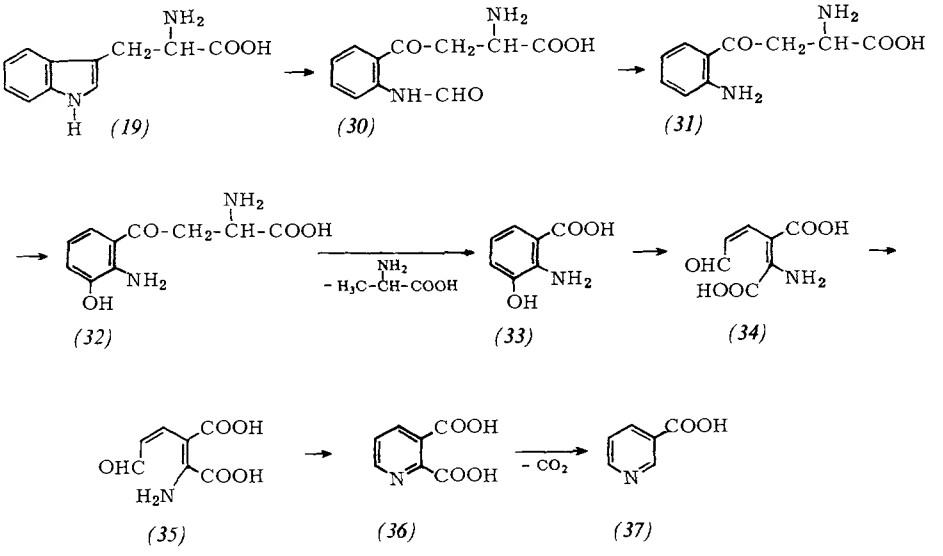
Scheme 9. Biosynthetic pathway to vitamin K.

K_2; these authors postulated other intermediates of the biosynthetic pathway (see Scheme 9).

Davis showed earlier that the sixth factor of the medium could be replaced by pyrocatechol derivatives [68]. *Martius* and *Leuzinger* found that the vitamin K-heterotrophic anaerobic bacterium *Fusiformis nigrescens* converts 1,4-naphthoquinone into 2-methylnaphthoquinone and thence into vitamin $K_{2(45)}$, *i.e.* a vitamin K_2 with 45 C atoms in the side chain. Methionine acts as a methyl donor, but active formate and the β-carbon atom of serine do not [69].

8. Biosynthesis of Nicotinic Acid

The biosynthesis of nicotinic acid is related to the biosynthesis of aromatic amino acids, since the starting material for this synthesis in many organisms is tryptophan [70]. There is also at least one other route, which does not start with aromatic compounds. Some mammals, including man, can synthesize nicotinic acid from tryptophan, so that the definition of a vitamin is not strictly satisfied in this case. The same biosynthetic pathway is followed by fungi, yeasts, and certain phycomycetes [71–73]. In the first step, tryptophan *(19)* is converted into formylkynurenine *(30)*, from which kynurenine *(31)* is formed by cleavage with a formylkynurenine amidase [74]; *(31)* is finally hydroxylated to give 3-hydroxykynurenine *(32)* (see Scheme 10). This is cleaved by kynureninase into 3-hydroxyanthranilic acid *(33)* and alanine [75]. Ring cleavage in 3-hydroxyanthranilic acid *(33)* by a 3-hydroxyanthranilate oxygenase gives 2-amino-3-formylvinylfumaric acid



Scheme 10. Biosynthetic pathway to nicotinic acid *(37)*.

(34) [76, 77]. This compound must be isomerized into 2-amino-3-formylvinylmaleic acid *(35)* before ring closure can take place to give the pyridine system. Quinolinic acid *(36)* is formed, and decarboxylation of *(36)* yields nicotinic acid *(37)*.

[79] *R. A. Mitchell*, *H. H. Kaug*, and *L. M. Henderson*, J. biol. Chemistry *238*, 1151 (1963).

The 3-hydroxyanthranilate oxygenase was first detected in the liver [78,79]. This enzyme has recently also been detected in *Saccharomyces cerevisiae* [80].

Some authors think it possible that the ring closure is preceded by the decarboxylation, so that the synthesis does not proceed *via* quinolinic acid. However, quinolinic acid exhibits good growth activity for nicotinic acid-deficient mutants of *S. cerevisiae* [71].

Another route for the biosynthesis of nicotinic acid requires aspartic acid and a C_3 compound such as glycerol or glyceraldehyde phosphate as starting materials [81–83]. This route is used with few exceptions by bacteria, as well as by cyanophyceae, green algae, some phycomycetes, and higher plants. It is interesting in this connection to note that the biosynthesis of lysine can also proceed by two routes, *i.e. via* α-aminoadipic acid or *via* α,ε-diaminopimelic acid. A comparison of the results showed that microorganisms that form lysine *via* α-aminoadipic acid synthesize nicotinic acid from tryptophan. When the biosynthesis of lysine proceeds by the α,ε-diaminopimelic acid route, nicotinic acid is generally not formed from tryptophan [73].

9. Regulation of the Biosynthesis of Aromatic Amino Acids

The aromatic amino acids regulate their own biosynthetic pathways by allosteric inhibition, and sometimes also activation, of the following enzymes: 2-keto-3-deoxyarabinoheptonic acid 7-phosphate (DAHP synthetase) [*(1)* + *(2)* → *(3)*], chorismate mutase [*(9)* → *(10)*], prephenate dehydrogenase [*(10)* → *(13)*], prephenate dehydratase [*(10)* → *(11)*], anthranilate synthetase [*(9)* → *(15)*], and *p*-aminobenzoate synthetase [*(9)* → *(20)*] (See Scheme 11).

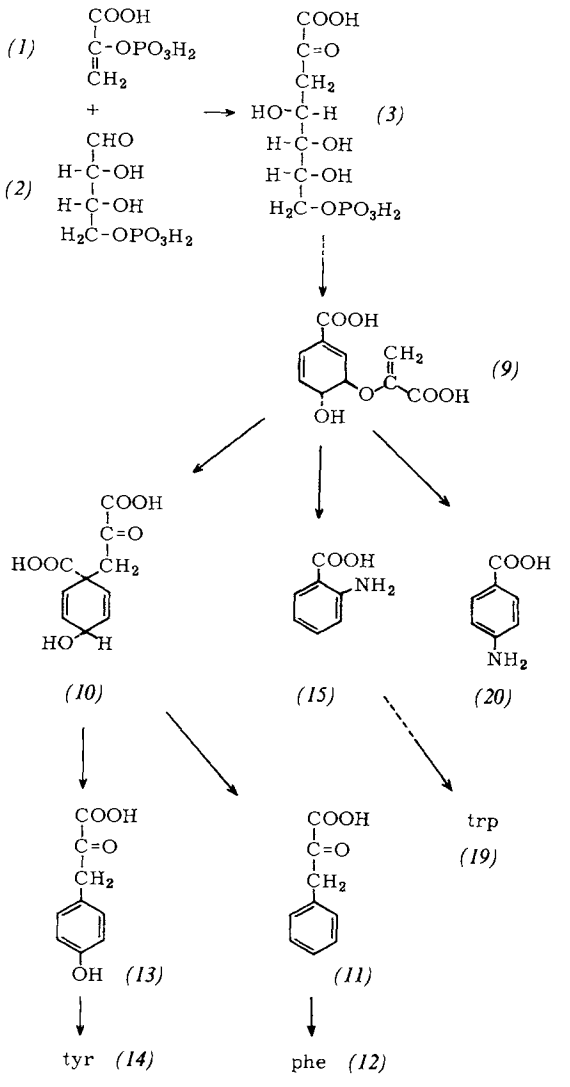
It has not yet been established how the biosynthesis of the vitamins derived from this branched synthetic chain is regulated.

Enzymes whose activities are subject to regulation are allosteric proteins. According to *Monod, Wyman*, and *Changeux* [84], these are oligomers of identical subunits, which are linked by noncovalent bonds. Each subunit has stereospecific sites for the substrate and other ligands (effectors). The oligomer (allosteric protein) occurs in the energetically different states R and T, which are in equilibrium with each other and which differ in the quaternary structure of the protein. The ligands have different affinities for the R and T states, the equilibrium between the two states depending on the concentration of the ligands. This model occurs in two forms:

1. The K system: The effectors and the substrate have different affinities for the R and T states. The effector thus influences the affinity of the enzyme protein for the substrate, and the substrate influences the affinity of the protein for the effector.

2. The V system: In this case the substrate has the same affinity for both states. Consequently the addition of the substrate is not influenced by the effector and *vice versa*. However, the two states differ in their catalytic activity, so that an effector that displaces the equilibrium in favor of the state with the lower catalytic activity inhibits the enzyme.

The investigation of the enzymes for the biosynthesis of aromatic amino acids in microorganisms has not yet progressed to the point where an assignment to these systems can be made in every case. In addition to the allosteric control of the enzymes present, regulation can also be achieved by repression and induction of the biosynthesis of all the enzymes.



Scheme 11. Regulation of the biosynthesis of aromatic amino acids.

Table 1. Inhibiting action of L-phenylalanine and L-tyrosine on enzymes from *A. aerogenes*.

Amino acid added	Inhibition of

[84] *J. Monod, J. Wyman*, and *J. P. Changeux*, J. molecular Biol. *12*, 88 (1965).

In *Escherichia coli*, the first enzyme in the main chain, DAHP synthetase, consists of three isozymes, one of which is allosterically inhibited and repressed by L-phenylalanine and the other by L-tyrosine. The third enzyme is not subject to allosteric inhibition, but is repressed by L-tryptophan [85–91].

The conversion of chorismic acid *(9)* into prephenic acid *(10)* in *E. coli* and *Aerobacter aerogenes* is catalyzed by two isozymes. Each of these chorismate mutases is combined in a complex with the enzymes prephenate dehydrogenase and prephenate dehydratase, both of which are also inhibited by the end products [92]. Table 1 shows the values of the allosteric inhibition in *A. aerogenes*. The chorismate mutase P and the prephenate dehydratase are incompletely repressed by L-phenylalanine. L-Tyrosine represses one of the two isozymes and the prephenate dehydrogenase.

The enzymes of the tryptophan biosynthesis in *E. coli* and *A. aerogenes* are coordinately repressed by L-tryptophan, and the anthranilate synthetase is completely inhibited [93–95].

Jensen and *Nester* [96–99] have found that in *Bacillus subtilis*, the first step in the main branch is allosterically inhibited by prephenic acid and by chorismic acid, but not by the final amino acids. There is only one DAHP synthetase. The chorismate mutase is not inhibited either by L-tyrosine or by L-phenylalanine; however, these amino acids inhibit the prephenate dehydrogenase and dehydratase. The prephenic acid that accumulates as a result of this inhibition can inhibit the DAHP synthetase. L-Tryptophan acts as a negative effector on the anthranilate synthetase; this can lead to an accumulation of chorismic acid, which also inhibits the DAHP synthetase, though to a smaller extent. L-Phenylalanine, L-tyrosine, and L-tryptophan cause repression of the DAHP synthetase.

A peculiarity is found in the regulation of the biosynthesis of tryptophan in *Pseudomonas putida* [100]. The last enzyme in the chain, the tryptophan synthetase, is induced by its substrate 3-(indol-3-yl)-glycerol-1-phosphate. This enzyme is not affected by L-tryptophan, whereas the other enzymes of the pathway are repressed by this amino acid.

Investigations on *Saccharomyces cerevisiae* have shown [101,102] that L-tyrosine causes allosteric inhibition of the tyrosine-sensitive isozyme of the DAHP synthetase, the chorismate mutase, and the prephenate dehydrogenase. An excess of L-tyrosine in *S. cerevisiae* can be eliminated by induction of degradation to tyrosol. L-Phenylalanine at high concentrations causes inhibition of the phenylalanine-sensitive isozyme of the DAHP synthetase and of the prephenate dehydratase. The biosynthesis of the prephenate dehydratase is also repressed by L-phenylalanine. It is reasonable that an excess of L-phenylalanine should at the same time cause both induction and activation of the prephenate dehydrogenase. The degradation of L-phenylalanine in *S. cerevisiae*, which can serve to eliminate an excess of this amino acid, leads to β-phenylethanol.

It can be shown that L-tryptophan inhibits the first enzyme in its biosynthetic chain, *i.e.* the anthranilate synthetase; the synthesis of this enzyme is repressed by L-tryptophan, which, at the same time causes an increase in the rate of synthesis in another branch of the biosynthetic chain by induction and activation of chorismate mutase. L-Tryptophan is also degraded in *S. cerevisiae*, the product being tryptophol. Simultaneous addition of excesses of L-tryptosine, L-phenylalanine, and L-tryptophan leads not only to the phenomena described, but also to multivalent induction of the *p*-aminobenzoate synthetase, with a consequent release of *p*-aminobenzoic acid into the medium.

Further investigation of the enzymes affected by regulation show that these are allosteric proteins. The two DAHP synthetases, which are inhibited by L-tyrosine and by L-phenylalanine respectively, belong to the V system, while chorismate mutase and prephenate dehydrogenase belong to the K system [102].

The chorismate mutase of *Neurospora crassa* also belongs to the K system of allosteric enzymes, and is activated by L-tryptophan and inhibited by L-tyrosine and by L-phenylalanine. The anthranilate synthetase of *Neurospora* can also be inhibited by L-tryptophan [103]. In a study of the regulation of the biosynthesis of aromatic compounds in *Claviceps paspali*, it was found that an alkaloid-producing strain has an anthranilate synthetase that is not allosterically inhibited by L-tryptophan [104,105]. This evidently ensures that L-tryptophan is produced in sufficient quantities for the syn-

thesis of the alkaloid. *Claviceps paspali* contains three DAHP synthetases, which are inhibited by L-phenylalanine, L-tyrosine, and L-tryptophan respectively. (The tryptophan-sensitive isozyme accounts for most (60 %) of the total activity.) The chorismate mutase, which again belongs to the K system, is inhibited both by L-tyrosine and by L-phenylalanine. This inhibition is eliminated by L-tryptophan, which thus acts as a positive effector. Some tryptophan-like compounds can also activate the chorismate mutase; the latter can be resolved into two isozymes, but only after substantial concentration [106]. The prephenate dehydratase is allosterically inhibited by L-phenylalanine and the prephenate dehydrogenase by L-tyrosine.

Ternary Nitrides, Phosphides, and Arsenides of Lithium

BY R. JUZA, K. LANGER, AND K. VON BENDA[*]

Ternary phases have been prepared from lithium, another metal, and nitrogen, phosphorus, or arsenic. The ternary compounds, in particular the nitrides, are thermally more stable than the binary compounds. The lithium gives rise to a relatively high polar bonding component. At high temperatures, lithium and the second metal are often randomly distributed among the interstices of the metalloid lattice. The ordering processes that take place with decreasing temperature are investigated by X-ray and magnetic methods and by differential thermal analysis. The phases are classified on a structural basis into seven groups.

1. Introduction

Ternary compounds of lithium with a metal (M) (usually of the first long period) and with nitrogen, phosphorus, or arsenic (X) in various combinations have been prepared and studied. Though work in this field is by no means closed, it has already been found that these compounds can be classified on a crystallochemical basis into a few groups of widely differing natures.

The choice of lithium as the invariable component was decided at the beginning of the experiments by the following considerations:

The strongly electropositive lithium has a low ionization potential, and its compounds are relatively strongly polar. The polar bonding component in Li_3N or Li_3P is greater than in *e.g.* AlN or AlP, or in fact than in any transition metal nitride or phosphide. Thus as we pass from a binary compound of a metal with an element of the nitrogen group to a ternary compound of the same metal containing lithium, the polar bonding component should increase.

The incorporation of lithium was also expected to have special structural consequences. It was known from investigations on $LiFeO_2$ [1] and Li_2TiO_3 [2] that even relatively highly charged ions can be randomly distributed together with lithium ions over the same special position – in this case of the NaCl lattice. This interchangeability despite the large difference in charge is due to the fact that the sizes of the Li ion and of the M^{n+} ions are approximately the same. However, the random distribution of the metals is stable only at high temperatures, and is retained in a metastable state on quenching of the ternary oxides; in the structures that are stable at low temperatures, Li^+ and Fe^{3+} or Ti^{4+} are distributed in a regular manner [3–5].

The single reported observation of a ternary nitride containing lithium – Li_3FeN_2 [6] – was important for

our present investigation of the chemistry of the metal nitrides. We expected to be able to extend our knowledge of the chemistry of metal nitrogen compounds to the ternary nitrides containing lithium.

Three methods have been used for the *preparation* of ternary *nitrides* of lithium and a second metal (M):

1) nitriding of a mixture of Li_3N + M with N_2 or NH_3;

2) nitriding of an alloy Li_mM;

3) reaction of the binary nitrides Li_3N + M_nN in an atmosphere of N_2.

The reactions were carried out either in a stream of the gas or in a closed vessel, which generally allowed volumetric measurement of the nitrogen absorption. The last method proved particularly useful when the formation of the ternary nitride gave a higher oxidation state of M than that in the binary metal nitride. It was also found useful in some cases to increase the pressure (*e.g.* to 200 atm).

The ternary *phosphides* were prepared from Li_3P with metal and phosphorus or with the metal phosphide (sometimes with addition of phosphorus), and the ternary *arsenides* from Li_3As, metal, and arsenic.

It was often difficult to find a suitable container material for the preparative work. The binary Li compounds are extremely reactive; for example, Li_3N reacts with quartz glass or ceramic materials. On the other hand, phosphorus and arsenic react with metal vessels at high temperatures. Copper or molybdenum vessels were found to be suitable for the preparation of ternary nitrides, and sintered alumina crucibles for the preparation of phosphides or arsenides.

Nearly all the Li compounds investigated are very sensitive to hydrolysis. A technique was developed, therefore, which made possible the preparation and investigation of samples in total absence of moisture and oxygen; all work was carried out under carefully dried protective gas (N_2, Ar).

2. Phases that Can Be Derived from a Binary Lithium Compound

2.1. Phases $(Li,M)_2X$ Derived from the CaF_2 Type

The lithium chalcogenides crystallize in the antifluorite lattice (C1 type). This same lattice or a superstructure of the antifluorite type also occurs in the ternary lithium compounds discussed below, in which the chalcogen is replaced by elements of group V (X = N, P, As). The change in the charge on the nonmetal from −2 to −3 is compensated for by cations of higher charge (M^{n+}) in the cation lattice, assuming that the substance has an electrovalent structure. Compounds of this type have the general formula $Li_{2n-3}M^nX_{n-1}$ (Table 1).

Table 1. Compounds $(Li,M)_2X$ derived from the CaF_2 type. Z = number of formula units in the unit cell, V_M = molar volume.

2.1.1. Random Distribution of Metal Atoms

Figure 1 shows the face-centered cubic arrangement of the X atoms in the unit cell of the antifluorite structure, with the tetrahedral and octahedral lattice sites. (The tetrahedral and octahedral coordination are each indicated for one point.) The ternary compounds have a pure antifluorite structure when both metals randomly occupy the "tetrahedral positions" 1–8, while the "octahedral positions" remain unoccupied.

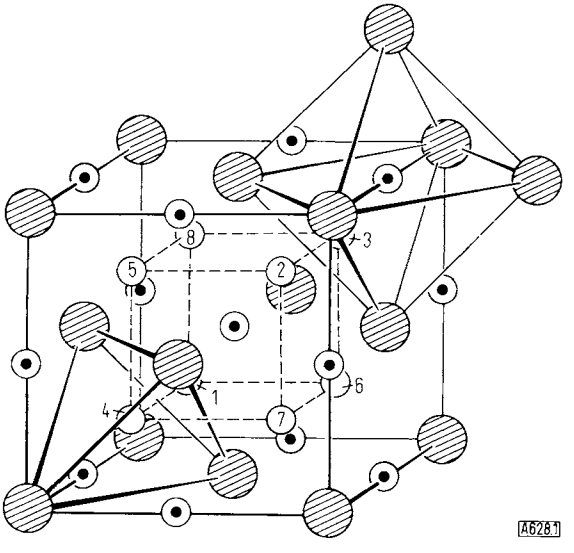

Fig. 1. Unit cell of a face-centered cubic X lattice with the following sites ● = X atoms, ①—⑧ = tetrahedral sites, ⊙ = octahedral sites.

This is the case in LiMgN [7]. This compound is bright red-brown, and when heated to 1100 °C, it decomposes without melting and with volatilization of Li and N_2. Both the color and the decomposition without melting indicate a high ionic bonding component. Estimation by *Pauling*'s method [8] gives 63 % ionic character for an LiN single bond and 55 % for an MgN single bond, *i.e.* the values are roughly the same. The polar component is only slightly lower than in an MgO single bond (73 %). Since the ionic radii of Li^+ and Mg^{2+} are also approximately equal (0.68 Å and 0.66 Å, according to *Ahrens*), the conditions are particularly favorable for a random distribution of the metals. LiMgP [9] and LiMgAs [10] also belong to the pure antifluorite type. However, it is not known in any of these three cases whether the random distribution of the metals is the arrangement that is stable at room temperature.

This series also includes the high-temperature form of the phase LiMnAs [11]. However, the random distribution of lithium and manganese is stable only at temperatures above 500 °C and does not persist on quenching even as a metastable state (cf. Section 2.2.). No other ternary compounds having the composition LiMX and having the pure antifluorite structure are known as yet.

2.1.2. Ordered Distribution of Metal Atoms

In the analogous zinc compound LiZnN [7], the metals are distributed in a regular arrangement. Zinc occupies the tetrahedral positions 1, 3, 5, and 7, and lithium the positions 2, 4, 6, and 8 (Fig. 1). The space symmetry O_h^5 of the lattice with random occupation of the tetrahedral sites is decreased to T_d^2. The zinc and the nitrogen form a zinc blende lattice, and lithium is inserted into the interstices to neutralize the charge. The same is true of LiZnP and LiZnAs [9]. These substances are much more closely packed than the magnesium compounds containing the same element X, though for equal ionic bonding components less dense structures are to be expected because of the greater radius of Zn^{2+}. This closer packing and the deeper color (LiZnN is black) reflect a lower polarity in the zinc compounds.

The structures of the compounds listed in the third section of Table 1 are also closely related to the antifluorite type. The tetrahedral sites in the metalloid lattice which is in principle always cubic close packed, are also occupied in a regular manner. However, since there is less than one M atom per X atom, a highly symmetrical M distribution is possible only on multiplication of the unit cell. Figure 2a shows the distribution of Al in the unit cell of the Li_3AlN_2 structure (space group T_h^7) [12]. The face-centering N atoms of the eight unit cells and the Al atoms are displaced from the ideal positions in such a way that the Al–N distances are about 12 % smaller than the distances from the N atoms to the other tetrahedral sites, in which the lithium is situated. Li_3GaN_2 [12] and Li_3GaP_2 [13] have isotypic crystal structures. In Li_3GaAs_2 [13] there is slight tetragonal distortion, and in Li_3AlP_2 and Li_3AlAs_2 [14] slight orthorhombic distortion of this structure (Table 1).

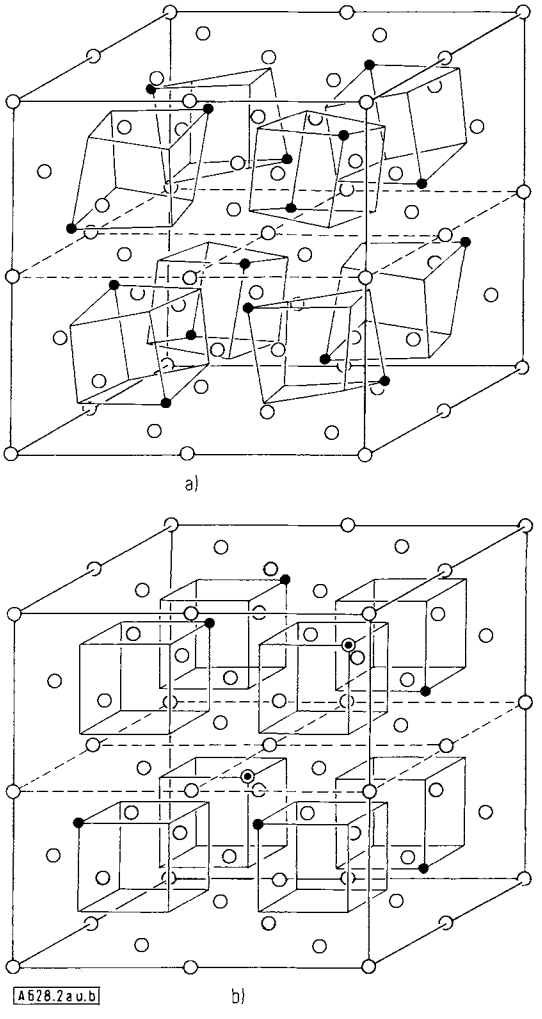

Fig. 2. Distribution of aluminum and vanadium in the structures of Li_3AlN_2 and Li_7VN_4 (lithium occupies the free corners of the "cubes" situated in the octants). a) Li_3AlN_2; O = nitrogen, ● = aluminum. b) Li_7VN_4; O = nitrogen (in the ideal position), ◎ = vanadium in sixfold position, ⊙ = vanadium in twofold position.

Volume considerations as used by *W. Biltz* were frequently found to be useful in the present investigations. For example, Figure 3 shows a plot of the molar volumes of some nitrides, phosphides, and arsenides against the molar volumes of a series of isotypic aluminum compounds (the change from the wurtzite to the zinc blende structure between AlN and AlP has no volume-chemical effect). A deviation from

linearity points to a change in structure. Li_3AlN_2, Li_3AlP_2, and Li_3AlAs_2 are found to be isotypic. Among the binary lithium compounds, Li_3P, Li_3As, and the high-temperature modification of Li_3Sb are isotypic and crystallize hexagonally in the Na_3As structure (Section 2.4.). Li_3N is much less dense, but its looser packing is lost on formation of the ternary compound Li_3AlN_2.

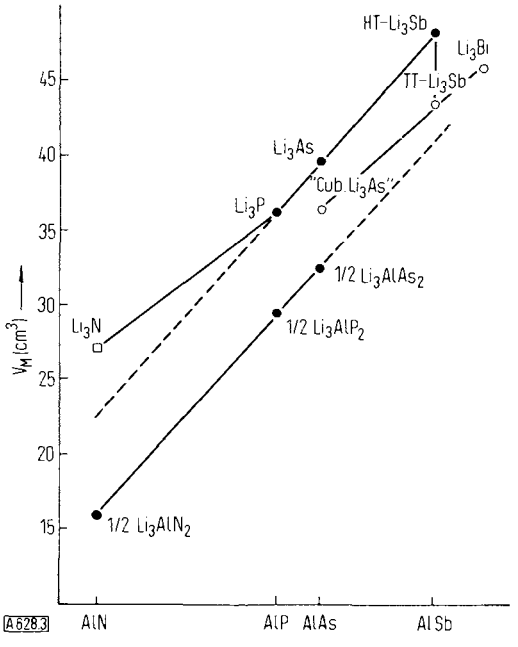

Fig. 3. Molar volumes of Li_3AlX_2 and Li_3X compounds.

The superstructures of the cubic Li_5TiN_3 and Li_5GeN_3 [15] can also be assigned to the Li_3AlN_2 structural type on the basis of intensity calculations if a random distribution of 0.67 M and 0.33 Li over the Al positions shown in Fig. 2a is assumed [15].

Figure 2b shows the distribution of the metals in the structure of the isotypic compounds Li_7VN_4 and Li_7MnN_4, which have cubic structures of space group T_d^4 [16]. For better comparison with the Al compound, the origin was placed in $\frac{111}{888}$ of the actual unit cell in the space group T_d^4. Vanadium occupies one twofold position and one sixfold position; the vanadium ions of the sixfold position form chains with lithium parallel to the three crystallographic axes.

In this connection mention should also be made of Li_9CrN_5 [17] which has been prepared by various methods (preferably from Li_3N and CrN under nitrogen at 240 atm and 600–800 °C). The structure has not yet been established but this compound again appears to have a superstructure of the antifluorite type, since it forms an unbroken series of solid solutions with Li_2O, in which the lattice constant decreases and the superstructure lines disappear as the Li_2O content increases.

The heavier metals of the group V (niobium and tantalum) and group VI (molybdenum and tungsten) triads also give ternary nitrides in which the metals have oxidation states of +5 and +6 respectively [17, 18]. The thermal stability increases with increasing atomic number, while the depth of color decreases, as in the oxygen compounds. The compounds are probably isotypic with one another, but not with Li_7VN_4 and Li_9CrN_5.

It is interesting to note that in the ternary nitrides of the transition metals of groups IV to VII, the metals have a very much *higher oxidation state* in relation to nitrogen than in the binary compounds having highest nitrogen contents, *i.e.* TiN, VN, CrN, and Mn_3N_2 (the high oxidation states were verified by measurement of the nitrogen absorption during the reaction, by redox titration, and by total analysis). In the Li–Cr–N system, CrN actually reacts with Li_3N under argon to form Cr_2N and Li_9CrN_5 [17]; thus the partial pressure of nitrogen over the ternary compound of chromium in the oxidation state +6 is lower than over CrN.

One might have expected that highly charged M ions (V^{5+}, Mn^{5+}) would give distinctly *anionic structural groups* comparable to the VO_4^{3-} groups of the orthovanadates. This is not so, since the resulting structures would then have been much more complicated and not so closely related to the antifluorite type. On the other hand MN_4 tetrahedra in the superstructures of the compound with M = Al, Ga, Ti, V, and Mn already differ appreciably from LiN_4 tetrahedra. This can be seen even in the Al compounds in which the AlN_4 tetrahedra are much more closely packed than the LiN_4 tetrahedra. In the case of the vanadium compounds, the parameters are not yet known with sufficient accuracy to yield any detailed information. These compounds probably occupy an intermediate position between pronouncedly complex compounds and pure atom-ion lattices. Moreover, the high negative charge of the supposed complex and the large number of cations would scarcely be paralleled anywhere else.

Some information about the nature of the bonds between the transition metal and the nitrogen would be desirable in this connection. The transition metal and the lithium are practically equivalent in the structure; the percentage of transition metal ions *e.g.* in Li_7VN_4 is low. On the basis of the electronegativities the predominating LiN bonds are strongly polarized. The polarity of the VN bond, or of the transition metal-nitrogen bond in general, cannot be estimated at present.

2.2. Phases (Li, M, □)$_3$X Derived from the Li_3Bi Type

Li_3Bi has a cubic structure of the filled antifluorite type, in which the octahedral sites of the face-centered cubic Bi lattice are occupied as well as the tetrahedral sites 1–8 (Fig. 1). This type also occurs as the low-

[15] *R. Juza, H. H. Weber,* and *E. Meyer-Simon,* Z. anorg. allg. Chem. *273*, 48 (1953).

[16] *R. Juza, E. Anschütz,* and *H. Puff,* Angew. Chem. *71*, 161 (1959).

[17] *R. Juza* and *J. Haug,* Z. anorg. allg. Chem. *309*, 276 (1961).

[18] *R. Juza, W. Gieren,* and *J. Haug,* Z. anorg. allg. Chem. *300*, 61 (1959).

temperature form of Li_3Sb, but has not been observed in Li_3As and Li_3P. However, ternary phases of this cubic type have been found in the systems Li–Mn–As[11], Li–V–As, Li–V–P, Li–Ti–As, and Li–Ti–P[19]; thus this lattice can be stabilized by the replacement of lithium by transition metals. Fig. 4 shows the arsenide phases in a section of the ternary diagram of the Li–M–As system (the thick portions of the lines and the shaded areas indicate the regions of homogeneity).

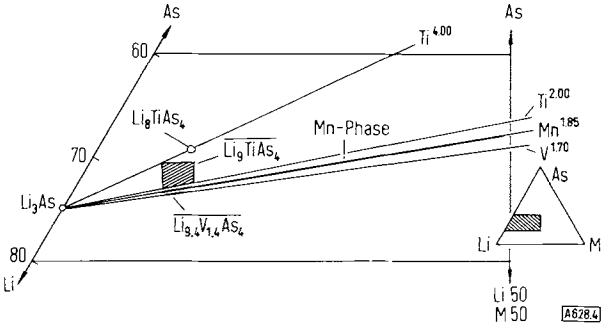

Fig. 4. Ternary cubic phases in the systems Li–Ti–As, Li–V–As, and Li–Mn–As (atom-%).

Since the transition metals M are incorporated in oxidation states higher than +1, vacancies appear in the structure as the M content increases. The phases will therefore be denoted by the formula $(Li,M,\square)_{12}X_4$, taking into account the fact that the unit cells contain four X, or eight times this. As in the compounds discussed in Section 2.1. a random or a regular distribution of Li and M is also possible in the ternary phases of the Li_3Bi type; both have been observed. According to all the investigations carried out so far, the M-atoms always occupy the tetrahedral sites, and disordered distribution between tetrahedral and octahedral sites has never been observed. Another characteristic feature is that at room temperature, the random distribution is stable or metastable only in phases having low M contents and in which the oxidation state of the transition metal is low.

In the ternary system containing *manganese* high-temperature X-ray patterns have established a single-phase range at 530 °C from $(Li_{9.8}\ Mn_{1.2}\square_1)As_4$ to $(Li_{4.6}Mn_4\square_{3.4})As_4$ (Fig. 4). This single-phase range may be regarded as corresponding to a solid solution between LiMnAs, which crystallizes in the antifluorite structure (Section 2.1.), and the hypothetical cubic Li_3As, with the Li_3Bi lattice. The cubic form of the normally hexagonal Li_3As (Section 2.4.) is stabilized by the incorporation of manganese, with simultaneous appearance of vacancies in the cation lattice. The lattice constant of the cubic form of Li_3As (about 6.22 Å) can be extrapolated from Figure 5; Figure 3 shows that this Li_3As modification would be too close-packed, but fits in with the trend of the cubic form of Li_3Sb and Li_3Bi.

In the cubic high-temperature phase $(Li, Mn,\square)_{12}As_4$ the initially randomly distributed Li and M atoms

[19] *K. Langer* and *R. Juza*, Z. anorg. allg. Chem., in press.

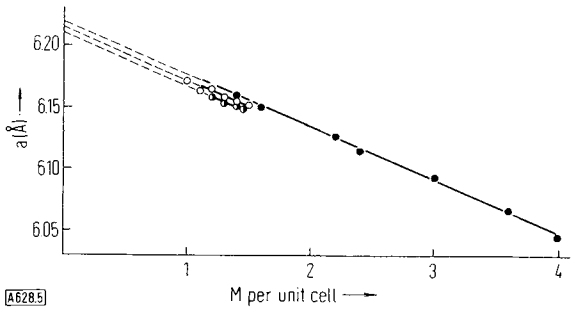

Fig. 5. Lattice constants of the cubic phases (Li, M, $\square)_{12}As_4$.
O M = $Ti^{2.00}$ (800 °C; quenched), ◑ M = $V^{1.70}$ (750 °C; quenched), ● M = $Mn^{1.85}$ (525 °C; high temperature diffraction patterns, recalculated for 20 °C by thermal expansion coefficient).

assume regular arrangements at low temperatures to give four other phases, whose homogeneity ranges are shown in Figure 6 (the diagram was obtained from the results of high-temperature X-ray analysis as well as by investigation of samples that had been tempered to equilibrium at 60 °C; the ordering processes in rapidly cooled samples are too slow at room temperature to reach the equilibrium state).

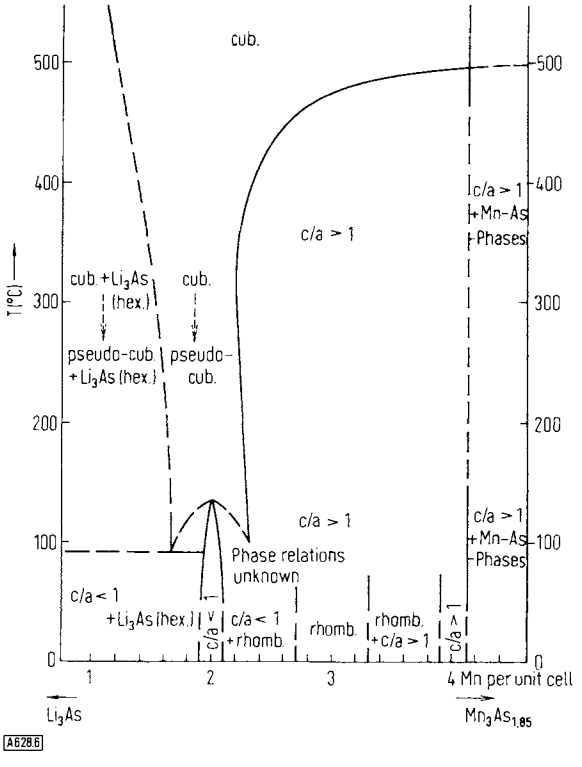

Fig. 6. Subsolidus diagram of the section Li_3As–$Mn_3As_{1.85}$.

This diagram is valid for the pseudobinary section Li_3As–$Mn_3As_{1.85}$. Samples in which the oxidation state of the manganese differs from +1.85 were not obtained in a homogeneous state at 60 °C. This is interesting, since Mn^{2+}, with its half-filled 3d shell, has a relatively stable electron configuration. However, a maximum oxidation number of +1.88 is also found for manganese in the Mg–Mn–As system[20].

The first step in the *ordering process* that occurs with falling temperature, at all Mn contents between 1.6 and 4 Mn per

[20] *R. Juza* and *R. Kroebel*, Z. anorg. allg. Chem. *331*, 187 (1964).

cell, is an accumulation of the Mn in every second layer of tetrahedral sites perpendicular to one of the crystallographic axes *e.g.* in sites 1, 4, 6, and 7 (Fig. 1). The tetrahedral sites 2, 3, 5, and 8 then contain only lithium. Further Li occupy some of the four octahedral sites. The space symmetry O_h^5 for a random distribution decreases to D_{4h}^7.

At *low Mn contents* in the cell (less than 2.2 Mn per 4 As), the lattice dimensions remain the same. The unit cell is still cubic, though the symmetry of the Mn arrangement becomes tetragonal, *i.e.* a "pseudocubic phase" occurs (Fig. 6). For a composition $(Li_{8.3}Mn_2\square_{1.7})As_4$, the state of order of the manganese distribution in the "pseudocubic phase" is not yet optimal. The "pseudocubic phase" changes rapidly at 136 to 140 °C into a "tetragonal phase $c/a < 1$" ($c/a = 0.978$), in which the Mn, according to the intensity calculation, are very probably arranged in chains along the *c* axis, *e.g.* in positions 1 and 4 (Fig. 1). It is found in general that the strongest contraction always takes place in the direction of densest occupation by Mn.

At *higher Mn contents* (more than 2.2 Mn per cell), the lattice contracts in the first step of the rearrangement process to form the "tetragonal phase $c/a > 1$", as a result of the accumulation of Mn in every second layer of tetrahedral sites in the a_1a_2 plane. At the composition $(Li_{4.6}Mn_4\square_{3.4})As_4$, the Mn distribution has achieved its maximum order in the "tetragonal phase $c/a > 1$", since with 4 Mn per cell, every second layer of tetrahedral sites normal to the *c* axis (positions 1, 4, 6, and 7) is fully occupied by Mn.

This is not so for $(Li_{6.45}Mn_3\square_{2.55})As_4$, since in this case 3 Mn and 1 Li are randomly distributed among the positions 1,4,6, and 7 in the "tetragonal phase $c/a > 1$". At low temperatures, therefore, another ordered phase having an orthorhombic unit cell is formed ($a = 5.92_8$ $b = 6.12_9$, $c = 6.20_0$ Å). It has not been fully established how the Mn are arranged in this phase, particularly since a superstructure of the cell mentioned probably occurs.

The three low-temperature phases centered around 4, 3, and 2 Mn per cell are separated at 60 °C by two-phase regions. At less than about 1.9 Mn per cell, hexagonal Li_3As and the ordered phase with 2 Mn per cell occur as phase separation products of the "pseudocubic phase".

Manganese(II) compounds generally have a high *paramagnetic susceptibility* owing to the presence of five unpaired electrons in the half-filled 3d shell. On the other hand, interaction between the spin moments of the Mn ions can lead to antiferromagnetism. MnO is the classic example of the occurrence of antiferromagnetism[21]; below the Néel temperature (127 °K) the paramagnetic susceptibility shows a marked decrease, and the compound passes into the antiferromagnetic state. Neutron diffraction measurements showed that MnO, which crystallizes in the NaCl lattice, then has a magnetic superstructure: it contains two cation sublattices. The spin moments of the Mn^{2+} ions are parallel to one another in one of the cation sublattices, but antiparallel to the spin moments in the second cation sublattice[22].

The ternary Li–Mn–As phases should be paramagnetic, and this paramagnetism should depend on the "*dilution*" of Mn^{2+} ions by diamagnetic ions (Li^+, As^{3-}); an increase in susceptibility was in fact found with increasing dilution[23]. Moreover, the increasing order and the decrease in the Mn–Mn distances with fall in temperature should affect the susceptibility at a given dilution.

The *temperature-dependence* of the susceptibility, and at the same time its dependence on the degree of order of the lattice and on the MnMn distances, will be discussed with the aid of two series of experiments (cf. Fig. 7):

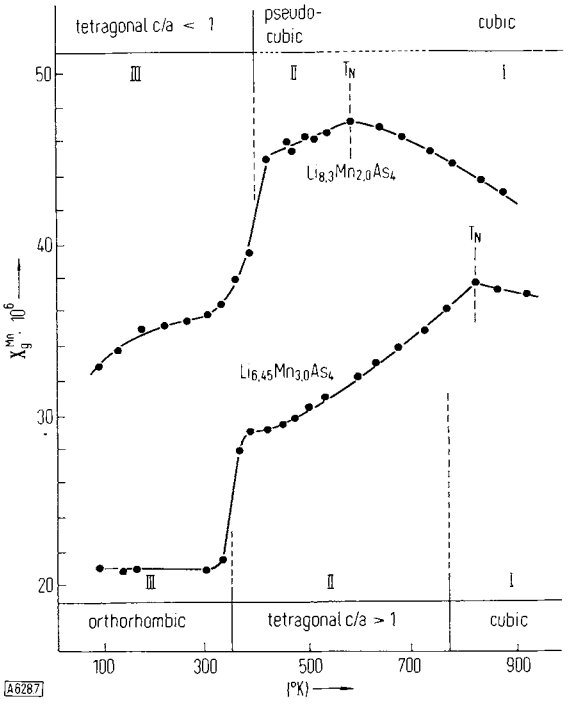

Fig. 7. Gram susceptibility of manganese as a function of temperature for the compositions $(Li_{8.3}Mn_2\square_{1.7})As_4$ and $(Li_{6.45}Mn_3\bullet_{2.55})As_4$.

The cubic high-temperature phase with *low Mn content* $(Li_{8.3}Mn_2\square_{1.7})As_4$ shows the expected increase in magnetic susceptibility with falling temperature at high temperatures in the range of random distribution of Li and Mn; this increase in susceptibility obeys the Curie-Weiss law. The susceptibility found is only about 50 % of the value calculated for free Mn^{2+} ions. The paramagnetic Curie temperature is strongly negative; there is thus spin coupling between the Mn ions. The shortest possible MnMn distance (3.06_5 Å) is only relatively rarely realized, owing to the random distribution of 2 Mn over eight possible positions. When the temperature falls below T_N, the susceptibility decreases. This is the range in which the "pseudocubic phase" with preferential arrangement of the Mn in layers normal to the *c* axis occurs. The shortest possible MnMn distance remains 3.06_5 Å. The point at which the susceptibility begins to decrease has to be regarded as the Néel temperature. A second strong decrease in susceptibility corresponds to the transition into the "tetragonal phase $c/a < 1$" (MnMn distance = 3.02 Å within the Mn chains).

In the phase having a *higher Mn content*, $(Li_{6.45}Mn_3\square_{2.55})As_4$ the region in which the paramagnetism obeys the Curie-Weiss law ends at a higher temperature; the shortest possible MnMn distance, which is 3.04 Å, is somewhat smaller than in the compound having a lower manganese content. An antiferromagnetic phase evidently occurs in the region of the "tetragonal phase $c/a > 1$" (Mn in planes normal to the *c* axis; shortest MnMn distance = 3.01_0 Å). The Néel temperature is about 50 °C higher than the temperature at which the cubic → "tetragonal $c/a > 1$" transition was detected by X-ray methods. This is probably because the change in the lattice dimensions is preceded by a pseudocubic preordering of the Mn (as above at 2 Mn per cell), which was not detected in the X-ray studies. As was mentioned earlier, the antiferro-

[21] *H. Bizette, C. F. Squire,* and *B. Tsai,* C. R. hebd. Séances Acad. Sci. *207,* 449 (1938).

[22] *W. L. Roth,* Physic. Rev. *110,* 1333 (1958).

[23] *R. Juza, H. D. Trapp,* and *H. Seidel,* Z. anorg. allg. Chem., *356,* 273 (1968).

magnetic compound must have two cation sublattices with antiparallel spin directions. However, these can be detected and described only by neutron diffraction studies. A second decrease in susceptibility corresponds to the transition to the orthorhombic phase. The MnMn distance in this phase (2.96 Å) is smaller than in any other phase. The magnetic susceptibility is only about 10 % of the value expected for free Mn^{2+} ions, and is independent of the temperature. The orthorhombic phase probably exhibits a Pauli paramagnetism, which is associated with the occurrence of collective electrons resulting from the small metal-metal distances.

The cubic high-temperature phase discussed at the beginning of this section, with random distribution of lithium and manganese over the tetrahedral sites and more or less complete occupation of the octahedral sites by other lithium atoms, corresponds to a ternary *vanadium phase* [19] (Fig. 4), which is homogeneous for compositions between $(Li_{10}V_{1.2}\square_{0.8})As_4$ and $(Li_{9.6}V_{1.4}\square_1)As_4$ on quenching from 750 °C. This range may be regarded as corresponding to solid solutions of the sample having the highest vanadium content with Li_3As (up to 0.67 mole). The oxidation state of the vanadium is again found to be slightly lower than +2. The increase in the number of lattice vacancies in the $(Li, V, \square)_{12}As_4$ phase, as in the cubic Mn phase, leads to contraction of the lattice. The lattice constants (Fig. 5) exhibit parallelism with those of the cubic manganese phase, and so suggest derivation from the hypothetic cubic Li_3As phase. The ternary $(Li,V,\square)_{12}As_4$ phase corresponds to the ternary phosphide $(Li_{9.8}V_{1.2}\square_1)P_4$, though no variation of composition has been found for the latter. In contrast to the samples having low manganese contents, *e.g.* $(Li_{9.4}Mn_{1.4}\square_{1.2})As_4$, there is no evidence of any slow decomposition of the vanadium phases at room temperature into hexagonal Li_3As or Li_3P and ordered phases having higher vanadium contents. The analogs of the manganese-rich phases are not formed in the systems Li–V–As and Li–V–P, or in the systems Li–Ti–As and Li–Ti–P, which will be discussed subsequently.

The ternary arsenides and phosphides of *titanium* differ from the corresponding phases of manganese and vanadium in that the titanium occurs in these substances in variable oxidation states.

In the Li–Ti–As system, the phase having the cubic unit cell and a random distribution of Li and Ti was found in the shaded region in Figure 4. The tie-line Li_3As–"Ti_3As_2" (Ti has an oxidation number of +2), for which the lattice constants are plotted in Figure 5, in this case forms only the lower limit of the phase range, which widens toward the As corner. This is due to the observed increase in the As content of the phase, which corresponds to an increase in the number of metal vacancies in relation to the unit cell of the structure. The resulting contraction of the cell indicates a continuous increase in the oxidation number from +2 to about +3.5. $(Li_9Ti_1\square_2)As_4$ may be regarded as the characteristic composition of this phase. Moreover, when the oxidation number of Ti is +4, a compound $(Li_8Ti_1\square_3)As_4$ having a superstructure with the eightfold unit cell of the basic structure occurs.

Similar phases have been found in the system Li–Ti–P. The phase having the small unit cell is again centered on the composition $(Li_9Ti_1\square_2)P_4$ with Ti^{III}; the oxidation number of the titanium can vary between +2.5 and +3.5. Solid solutions are not formed with Li_3P. The phase corresponds in this respect to the ternary vanadium phosphide. The phase with Ti^{IV} and the superstructure again has the composition $(Li_8Ti_1\square_3)P_4$.

The ternary titanium arsenides and phosphides occupy a position intermediate between the corresponding phases of vanadium and manganese in the Li_3Bi-type on the one hand and the ternary arsenides and phosphides of the main group metals (*e.g.* Al and Ga) in the antifluorite-type on the other. The maximum oxidation number is reached in the ternary phases of titanium, as in the compounds derived from the antifluorite type; on the other hand, these phases correspond to the phases derived from the Li_3Bi type, owing to the presence of lithium in some of the octahedral sites and owing to the phases with low oxidation numbers.

2.3. Solid Solutions $(Li,M)_3N$ Derived from Li_3N

Cu_3N is endothermic (ΔH = 17.8 kcal) and decomposes rapidly even at 450 °C [24]. The nitrides of nickel and of cobalt are only slightly more stable [25]. However, all three metals absorb nitrogen in a fast reaction in mixtures with Li_3N at 600–700 °C and at a nitrogen pressure of only 1 atm [26]. The nitride formed is stabilized as a solid solution in Li_3N. In the structure of Li_3N [27] (Fig. 8), the nitrogen ions, which predominantly determine the cell dimensions, have a primitive hexagonal arrangement. The compound thus has a relatively bulky structure, as can be seen from its high molar volume (Fig. 3). Lithium occupies a twofold and a onefold position; the latter is characterized by the shortest metal-nitrogen distance.

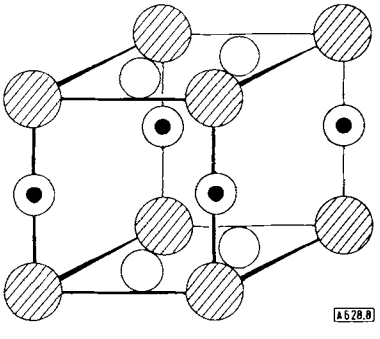

Fig. 8. Unit cell of Li_3N. ● = nitrogen, ○ = lithium in twofold position, □ = lithium in onefold position.

The replacement of lithium by heavy metals (the heavy metals mentioned are randomly substituted for lithium in the onefold position) leads in all three cases to a marked shortening (up to 9 %) of the *c* axis, a slight increase in the *a* axis, and a large decrease in the volume of the unit cell. Solid solutions having maximum heavy metal content are: $(Li_{2.4}Co_{0.5})N$, $(Li_{2.4}Ni_{0.6})N$, and $(Li_{2.7}Cu_{0.3})N$.

[24] *R. Juza* and *H. Hahn*, Z. anorg. allg. Chem. *241*, 172 (1939).

[25] *P. H. Emmet*, *S. B. Hendriks*, and *S. Brunauer*, J. chem. Soc. (London) *52*, 1456 (1930).

[26] *W. Sachse* and *R. Juza*, Z. anorg. allg. Chem. *259*, 278 (1949).

[27] *E. Zintl* and *G. Brauer*, Z. Elektrochem. angew. physik. Chem. *41*, 102 (1935).

Li_3N is the most strongly salt-like of all metal nitrides. Co_3N and Ni_3N are interstitial compounds having predominantly metallic properties. Cu_3N has a coordination lattice with a strongly ionic component. The incorporation of the heavy metals into the host lattice of Li_3N evidently levels the large differences in the character of transition metal-nitrogen bonding in the binary compounds.

2.4. Phases $(Li,M)_3As$ Derived from the Hexagonal Li_3As

It was of interest to know whether the lithium in the hexagonal Li_3As could be replaced by copper in the same way as in Li_3N. In the ternary system Li–Cu–As (Fig. 9), there is a single-phase region above 560 °C, which extends from Li_3As to Li_2CuAs; at room temperature, on the other hand, one finds only Li_3As and Li_2CuAs, with no miscibility of the two phases.

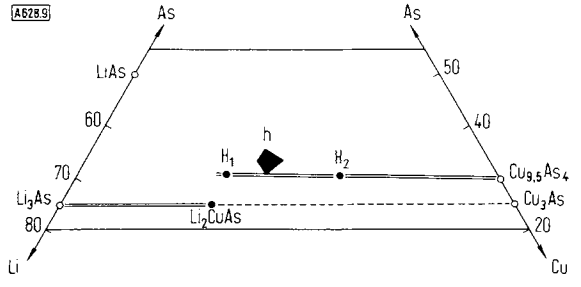

Fig. 9. Ternary phases in the system Li–Cu–As (atom-%). Double line: single phase at 650 °C; shaded points and area: ternary phases at room temperature.

Li_3As crystallizes in the hexagonal Na_3As structure [28] (DO_{18} type, D^4_{6h}; Fig. 10: the triple elementary cell is shown). The arsenic is approximately hexagonal close packed. The lithium occupies fourfold and twofold positions. At 560 °C, the lithium in the twofold position can be progressively replaced by copper. This position is completely occupied by copper at the composition Li_2CuAs. It is interesting to note that the twofold position is situated in the center of an equilateral triangle of arsenic *i.e.* in a triangular site; copper also occurs in triangular sites in other compounds. Moreover, this position has the smallest metal arsenic distance in the lattice. No similar solid solutions or compounds Li_2MAs (M = transition metal) have been found in the systems examined by us.

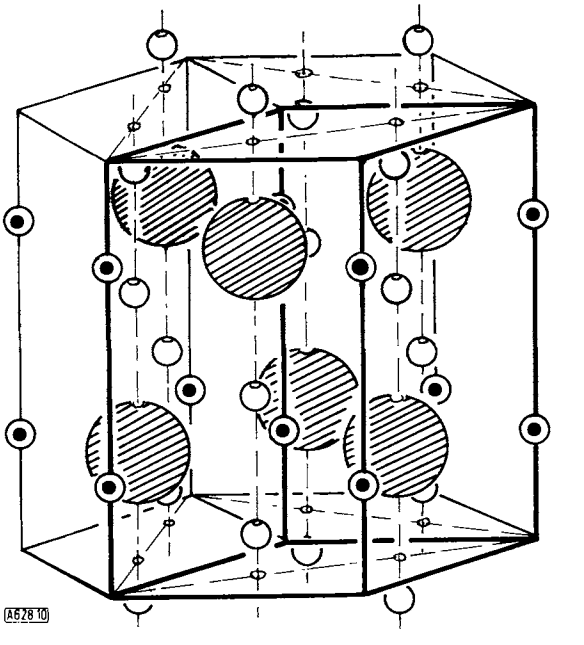

Fig. 10. Structure of Li_3As (Na_3As type according to *Brauer* and *Zintl*). ⊚ = arsenic, ⊙ = lithium in twofold position, O = lithium in fourfold position.

[28] *G. Brauer* and *E. Zintl*, Z. physik. Chem., Abt. B *37*, 323 (1937).

Mansmann[29] showed that a twofold Cu position in the structure given by *Steenberg*[30] for β-Cu_3As (cf. Section 3.3.) must be corrected. The structure thus becomes anti-isostructural with LaF_3 as corrected by *Mansmann*[31]. *Mansmann* also showed that in Na_3P, which, according to *Brauer* and *Zintl*[28], crystallizes in the Na_3As structure given by these authors, the lattice constant *a* must be increased by a factor of $\sqrt{3}$. Thus Na_3P also has a corrected anti-LaF_3 unit cell, and is isotypic with β-Cu_3As.

According to *Brauer* and *Zintl*, Li_3As is isotypic with Na_3P. The larger cell found for Na_3P cannot be detected for Li_3As by X-ray methods, owing to the unfavorable ratio of the atomic numbers. Thus it is not certain whether Li_3As crystallizes in the structure shown in Figure 10 or in the structure found by *Mansmann* for Na_3P, Cu_3As, and LaF_3. Li_2CuAs does not crystallize with the larger cell, but as shown in Figure 10; this can be stated with certainty because of the high scattering power of Cu.

Mention should now be made of the *changes* in the *molar volume* and in the lattice dimensions that are

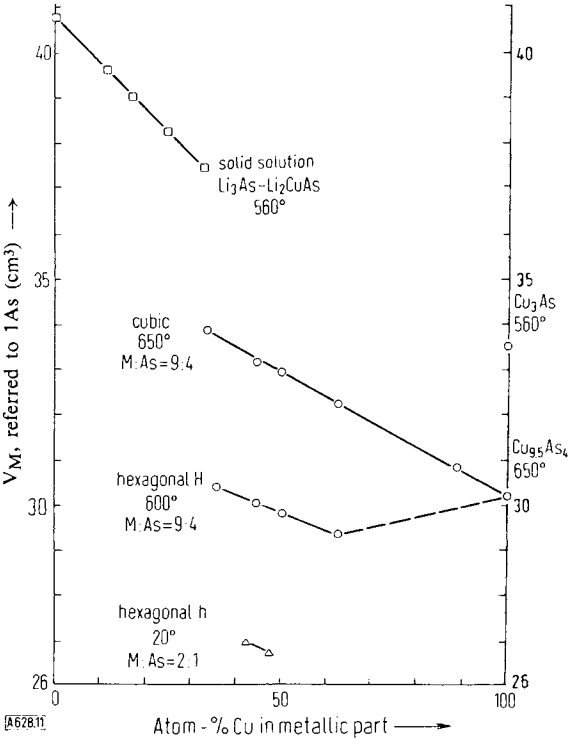

Fig. 11. Molar volume of lithium copper arsenides (calculated from the X-ray densities).

[29] *M. Mansmann*, Z. Kristallogr., Kristallgeometr., Kristallphysik, Kristallchem. *122*, 399 (1965).

[30] *B. Steenberg*, Ark. Kem., Mineralog. Geol., Ser. A *12*, No. 26 (1936–1938).

[31] *M. Mansmann*, Z. Kristallogr., Kristallgeometr., Kristallphysik, Kristallchem. *122*, 375 (1965).

characteristic of all the substitutions of lithium by heavy metal discussed here. As is shown in Figure 11, the molar volume (based on one As atom) decreases on incorporation of copper; the lattice constants along the Cu–As layer (*a* axis) are considerably shortened and the lattice dilates slightly along the *c* axis.

Comparison of these and similar contractions with the bonding radii for metallic and for ionic bonds respectively leads to agreement with a predominantly metallic bonding state, but not with predominantly ion bonding. From the point of view of polar bonding it is necessary to take into account a strong polarization of electrons in the layers occupied by copper and arsenic which shortens the interatomic distances as well as weaker bonding perpendicular to the layers due to the lithium situated between the layers.

3. Phases that Can Be Derived from a Transition Metal Compound

3.1. Solid Solutions $(Fe,Li)_2As$ Derived from the Cu_2Sb Type

The binary phases Fe_2As [32], Mn_2As [33], and Cr_2As [34] crystallize in the tetragonal system, and are isotypic with Cu_2Sb [32] (C 38 type) in the space group D_{4h}^7. The metalloid atoms in this lattice have in principle a face-centered cubic arrangement, with the metal atoms situated in the interstices (Fig. 12). This structure is related to the antifluorite type, but has a lower symmetry; the bonding in phases having this structure is predominantly intermetallic.

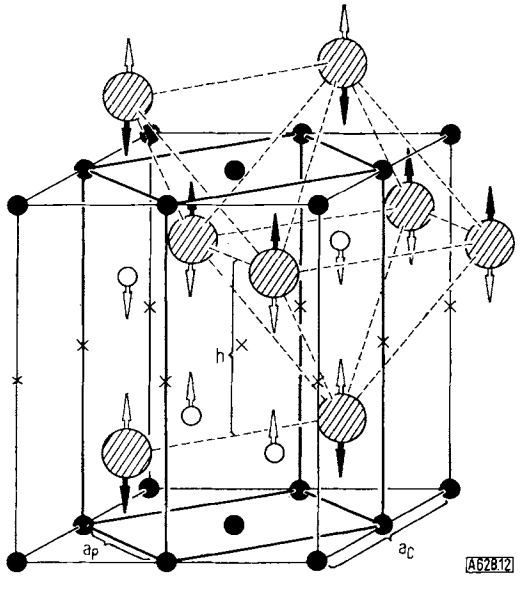

Fig. 12. Cu_2Sb type (unit cell shown in thick lines) and its relationship to the antifluorite type. ● = metalloid (X), ● = metal in distorted tetrahedral coordination (z = 0), ○ = metal in distorted octahedral coordination.

The actual translation unit of this lattice is the P cell indicated by thick lines. The axial relationships between this and the large C cell are $c_P = c_C$, $a_P\sqrt{2} = a_C$. The C cell has the same number of formula units and fundamentally the same structure as the unit cell shown in Figure 1; the origin of its coordinates are situated at $^1/_4$, $^1/_4$, $^1/_4$, *i.e.* at the point 1 in Figure 1. (The face centered X-arrangement in Figure 1 appears here as the "X-tetrahedra" situated in the C-cell.) However, the X lattice in the Cu_2Sb type is tetragonally distorted by about 15 % along the *c* axis in relation to the true face-centered cubic arrangement (axial ratio $c/a > \sqrt{2}$); the X-atoms (ideal position $z_X = 0.75$) are displaced slightly in the direction of the white arrows. As in the low-temperature form of the LiMnAs phase, there are close packed $(MX_{4/4})_\infty$ polyhedral layers in the a_1a_2 plane. The coordination of X around the transition metal in these layers at the level $z = 0$ is not truly tetrahedral (symmetry T_d), but tetragonal bisphenoidal (symmetry S_4); the coordination polyhedron is a tetrahedron that is stretched parallel to the *c* axis. The bisphenoidal sites (crosses in Fig. 12) at the level $z = 0.5$ are unoccupied. The second metal atom enters the position that would be the octahedral site in a true cubic close packed X lattice. Since this position in D_{4h}^7 has a free *z* parameter, the coordination in this case is 1+4+1. The lattice on the whole has a layer character, which results in increased cleavage of the crystals perpendicular to the *c* axis.

A ternary solid solution $(Fe, Li)_2As$[35] is derived from the binary Fe_2As phase of this structure (Fig.13).

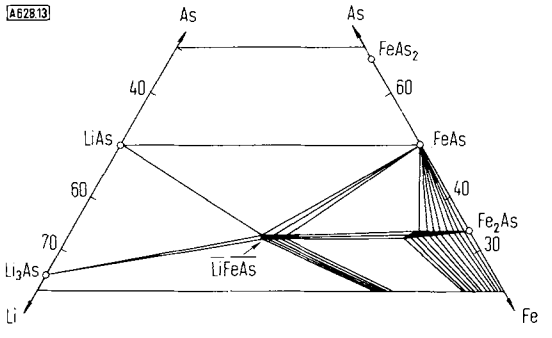

Fig. 13. Phases in the system Li—Fe—As (atom-%; samples quenched from 800 °C).

On the join (Fe + Li):As = 2:1, on which the solid solution has the composition $(Fe_{2-x}Li_x)As$, x can be equal to 0.25. This gives a substitution solid solution, in which up to 25 % of the Fe in the "octahedral position" is replaced by Li; the random incorporation of Li leads to an expansion of the lattice by about 1.7 % without alteration of the c/a ratio. The As parameter ($z_{As} = 0.735$ in Fe_2As) changes only very slightly or not at all, while the As atoms are still displaced (in accordance with the white arrows in Fig. 8) from the ideal positions (at $z_{As} = 0.75$).

In addition to the substituting lithium, a certain further quantity of lithium can be incorporated into this solid solution in the bisphenoidally distorted "tetrahedral sites" (at $z = 0.5$). Solid solutions of the composition $(Fe_{2-x}Li_{3/2x})As$ (Fe_2As–Li_3As section) are homogeneous up to the composition $(Fe_{1.75}Li_{0.38})As$, and have distinctly larger lattice constants than $(Fe_{2-x}Li_x)As$ for equal substitution x. Similar solid solutions may be formed by Mn_2As.

3.2. Compounds LiMX Derived from the Cu_2Sb Type

When the degree of substitution of Li for Fe in the Fe_2As structure is greater than 25 %, the ternary phase LiFeAs (cf. Fig. 13) occurs in the Li–Fe–As system in addition to the Fe_2As solid solution [35]. In this phase the "octahedral position" is completely occupied by lithium. The transition from the Fe_2As solid solution to the ternary compound is accompanied by a change in the arsenic parameter from $z < 0.75$ to $z > 0.75$ ($z_{As} = 0.76$ in $Li_{1.1}FeAs$). The As atoms are now displaced in the direction of the black arrows (Fig. 12). LiCoAs and LiFeP [35] have similar structures, in which the arsenic or phosphorus parameter is again 0.76. The three compounds are stable down to room temperature and have been obtained in homogeneous form only with a small excess of metal. (*e.g.* (Li + Fe):As = 2.1:1); thus the experimental result shows that the oxidation number of the transition metal is again slightly less than +2.

LiFeAs is involved in reactions with the binary substances $FeAs_2$, FeAs, LiAs, and Li_3As between 800 and 500 °C, which have not yet been studied in detail. Another characteristic of this compound is that to a small extent it can form solid solutions with the Fe_2As solid solution described above (limiting compositions on quenching from 800 °C: $Li_{1.1}FeAs$–$Li_{0.1}Fe_{1.2}As$).

No corresponding solid solution LiFeP–Fe_2P has been found, probably because Fe_2P crystallizes in a special hexagonal lattice [36]. The situation is more complicated in the system Li–Co–As, since the ternary phase $LiCo_3As_2$ [35], which has not yet been extensively studied, occurs between LiCoAs and the binary boundary phase Co_2As, which is not isotypic with Fe_2As [37].

Cr does not give a phase analogous to LiFeAs, LiFeP, and LiCoAs. However, it was possible to obtain a series of solid solutions $Li_{1.1}Fe_{1-x}Cr_xAs$ with $0 < x < 0.5$ [35], from which the cell dimensions of the pure Cr phase could be extrapolated.

It is interesting to *compare* the binary and ternary substances having the common feature of layers of transition metal at $z = 0$ surrounded by arsenic in a tetrahedral or distorted tetrahedral arrangement.

Figure 14 shows plots of the dimensions of the P cells and two quantities that characterize the properties of the $(MAs_{4/4})_\infty$ layers against the atomic number of the transition metal. h (cf. Fig. 12) is the distance between the $(MAs_{4/4})_\infty$ layers, and s is the tetragonal bisphenoidal stretching of the coordination tetrahedra [*]. The extrapolated data are plotted for the hypothetical LiMX phase in the case of chromium. The transition from the binary to the ternary compound is indicated in each case by an arrow. The change on formation of the $(Fe, Li)_2As$ solid solution (which is not shown) is very small, but is in the same sense.

It can be seen from Figure 14 that very close packing of the layers in the a_1a_2 plane of the ternary Cr phase would give a relatively large distance between the layers. This is probably why the structure becomes unstable when the layer contains only chromium.

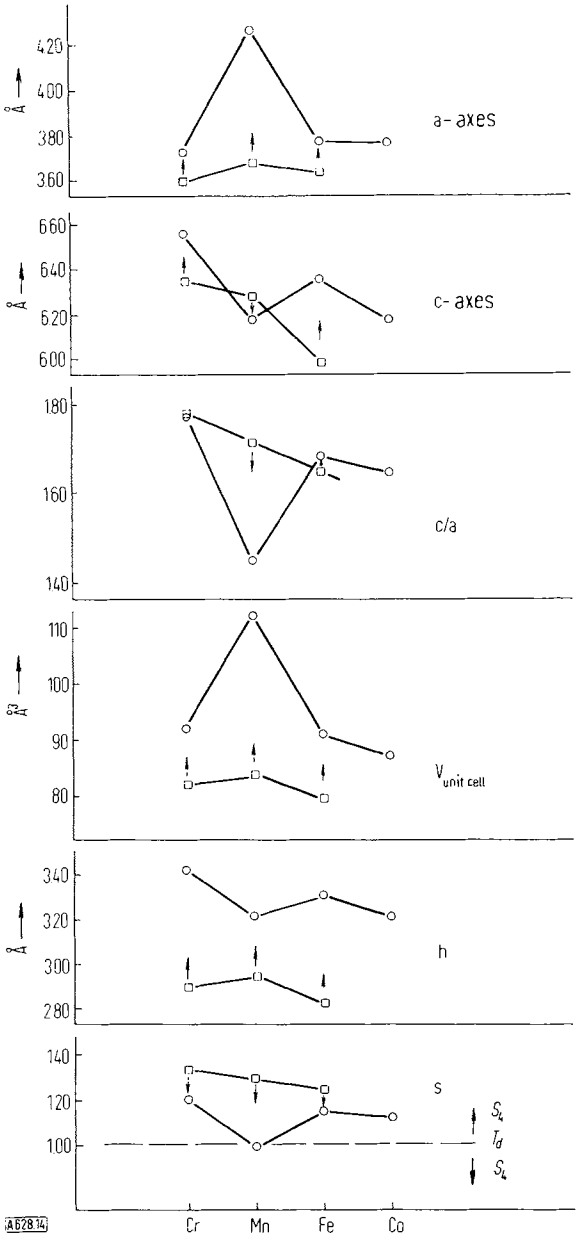

Fig. 14. Relationship between the crystallographic properties of M_2As phases in the Cu_2Sb type and of LiMAs phases (cf. text). □ = M_2As, O = LiMAs.

The cell dimensions of the ternary compounds of chromium, iron, and cobalt decrease continuously. The manganese compound does not comply with this continuity; while the cell dimensions of the binary compound Mn_2As are only slightly greater than those of its neighbors, the ternary compound LiMnAs occupies a special position. This difference in behavior can be correlated with the difference in the positions occupied by lithium; the intensity calculation for the compound LiMnAs (c/a = 1.024 for the C-lattice) shows that lithium is situated in the tetrahedral sites (z = 0.5). In the phases LiFeAs and LiCoAs, on the other hand, the lithium is situated in the o tahedral sites. Since the X-ray determination of the positions is subject to some uncertainty owing to the low scattering power of lithium, a consideration of distances is also

[36] *S. Rundqvist* and *F. Jellinek*, Acta chem. scand. *13*, 425 (1959).

[37] *R. D. Heyding* and *L. D. Calvert*, Canad. J. Chem. *35*, 449 (1957).

[*] The quantity s is the c/a ratio of the prism that can be circumscribed about the tetragonally distorted coordination "tetrahedra" around the transition metal. It is found from the lattice constants of the P cell and the arsenic parameter: $s = 2\bar{z}_{As} \cdot \frac{c}{a}\sqrt{2}$.

useful as a further indication of the difference in the behavior of lithium. The arrangement of Li (in tetrahedral sites in the manganese compound and in octahedral sites in the other compounds) leads in every case to Li–As distances of 2.67 Å. If the lithium were situated in the octahedral sites of the manganese compound, the Li–As distance would be 3.01 Å *i.e.* it would be much too large [35].

A valuable aspect for bond-theory treatment of the phases is apparent from Fig. 14: the distortion of the tetrahedral field around the transition metal in the $(MAs_{4/4})_\infty$ layer is reduced on removal of the transition metal from the "octahedral position" of the M_2As phases. This leads, in the case of manganese with its half-filled 3d shell, to a true tetrahedral coordination. The distance *h* between the tetrahedral layers always increases.

3.3. Phases $(Cu,Li)_{9.5}As_4$ Derived from $Cu_{9.5}As_4$

Whereas the behavior of Li_3As toward Cu_3As (Section 2.4.) is relatively simple, the behavior of the copper arsenides toward Li_3As is very complex. One might expect Cu_3As to form a complete range of solid solutions with Li_3As, since β-Cu_3As changes at 450 to 460 °C into a high-temperature modification of Na_3As type. However, no such complete series of solid solutions occurs. The curve of the molar volume of the Li_3As–Li_2CuAs solid solutions (Fig. 11) cannot be extrapolated to the molar volume of Cu_3As. The variation of the lattice constants makes it even clearer that a series of solid solutions cannot exist.

In addition to Cu_3As, there is another copper arsenide having a higher arsenic content. This is "Cu_5As_2", which according to our investigations has the composition $Cu_{9.5}As_4$. A high-temperature modification of this phase crystallizes in the cubic system with one formula unit $Cu_{9.5}As_4$ in the unit cell [38]. On rapid cooling, it changes into an orthorhombic low-temperature modification at 315 °C. This modification has two formula units in the unit cell, and its structure is closely related to that of the high-temperature modification [38].

$Cu_{9.5}As_4$ leads to several ternary phases, whose structures, though related, differ according to composition and temperature (640 °C, 600 °C, 20 °C). Copper in the cubic $Cu_{9.5}As_4$ phase can be replaced by lithium at 640 °C (cf. Fig. 9); this replacement can be continued up to a composition $Li_6Cu_3As_4$, with simultaneous expansion of the cubic unit cell. Since the structure of the cubic $Cu_{9.5}As_4$ is not yet accurately known, nothing can be said about the nature of the replacement of copper by lithium. Another single-phase range extending approximately from $Li_3Cu_6As_4$ to $Li_6Cu_3As_4$ is formed at 600 °C; this phase (H) crystallizes in the hexagonal system with a large unit cell. The solid solution H breaks down at room temperature into the boundary phases $Li_{5.8}Cu_{3.2}As_4$ (H_1) and $Li_{3.4}Cu_{5.7}As_4$ (H_2). The phase H also gives the phase LiCuAs (h) at room temperature. This phase is also hexagonal, but has a small unit cell. Samples having compositions in the LiCuAs phase range (Fig. 9) thus have three modifications, *i.e.* a cubic modification at high temperatures, a hexagonal modification with a large unit cell (H) at medium temperatures, and a hexagonal modification with a small unit cell (h) at room temperature. It can be seen from Figure 11 that the packing in these phases becomes increasingly close in the order mentioned. Geometrical relationships between the lattice constants and similar X-ray intensities point to the existence of a structural relationship, which has not yet been elucidated. There is no simple structural relationship between these phases and the LiMX phases derived from the Cu_2Sb-type (Section 3.2.).

4. Concluding Remarks

Ternary compounds of lithium with elements of the nitrogen group have not yet been very extensively studied. Many articles on ternary oxides of lithium have been published, but none of them contains information that enables parallels to be drawn with the nitrogen compounds. It is more likely that such parallels exist for the ternary compounds of lithium with the heavier chalcogens, about which much less is known [39–42]. The only analogy known is the close relation between magnetic properties of the Li–Mn–As phases and of the solid solutions resulting from the substitution of manganese by lithium in MnSe [43,44]. However, it was important to us that it was possible to follow consistently the points mentioned in the introduction regarding the new nitrogen, phosphorus, and arsenic compounds. We expect that exhaustive investigation of a number of phases will provide interesting disclosures concerning bonding in these phases.

We are grateful to the Deutsche Forschungsgemeinschaft and to the Fonds der Chemischen Industrie for their support of these investigations.

Photochemical Synthesis of Substituted 5*H*- and 7*H*-Benzocycloheptenes[1]

By *H. Dürr* and *G. Scheppers*[*]

Dedicated to Prof. A. Steinhofer on the occasion of his 60th birthday

Photolysis of 5-diazocyclopentadienes in olefins leads, *via* the intermediate cyclopentadienylidenes, to the formation of spiroheptadienes by addition, or to the formation of alkenylcyclopentadienes by insertion[2].

We have found that the spironorcaradienes *(2)* that are expected to be formed by the pyrolysis of 5-diazocyclopentadienes *(1a)–(1d)* in benzene are not stable but rearrange[3] under the reaction conditions. Alongside the phenylcyclopentadienes *(3)*, 5*H*- and/or 7*H*-benzocycloheptenes *(4)* and *(5)* are formed by a reaction, which, to the best of our knowledge, is a new type of rearrangement reaction. The product isolated depends upon the substituents R^1–R^4 (see Table).

The compounds were identified IR- and NMR-spectroscopically; *(5a)* was also identified chemically by hydrogenation to 1,2,3,4 - tetraphenyl - 6,7,8,9 - tetrahydro - 5*H* - benzocycloheptene[4a], which proved to be identical in all respects[5] with a compound formed by reaction of cycloheptyne[4b] and tetraphenylcyclopentadienone.

(b)	C_6H_5	H	H	C_6H_5	0	0	18–21	—	—	117–119
(c)	Cl	Cl	Cl	Cl	16–17	16–17	0	39–40	78–80	—
(d)	*o*-Phenylene		*o*-Phenylene		0	45–50		—	90–100	

Procedure:

A solution of 1.00 g (2.60 mmole) of *(1a)* in 200 ml of distilled benzene was irradiated in an N_2 atmosphere for one hour with a Philips high-pressure mercury vapor lamp (HPK 125, λ = 280 nm, Pyrex filter). After removal of solvent by distillation, the residue was chromatographed twice on silica gel with benzene/petroleum ether (b.p. 60–90 °C) (1:9). The first fraction to leave the column contains *(5)*. The presence of compounds *(3a)* and *(5a)* in the eluate is confirmed by thin layer chromatography, as well as IR and NMR spectroscopy.

Oxidation Products of Phosphorin

By *K. Dimroth, K. Vogel, W. Mach*, and *U. Schoeler*[*]

Dedicated to Prof. A. Steinhofer on the occasion of his 60th birthday

Solutions of 2,4,6-triphenylphosphorin and other arylated phosphorins in benzene become deep blue when shaken with conc. $HClO_4$ or H_2SO_4. They are decolorized by addition of water or aqueous sodium acetate solution. When the colorless solutions thus obtained are treated with strong acids, also with nonoxidizing acids such as trifluoroacetic acid, they become blue again.

Since the first blue coloration occurs only with oxidizing acids it must be concerned with an oxidation reaction and not merely with protonation of the phosphorus. Once oxidation has occurred, the oxidation product is converted by nonoxidizing acids into the blue salt which yields the colorless, non-protonated product on treatment with bases. Several products, which could not yet be separated, are formed in the oxidation.

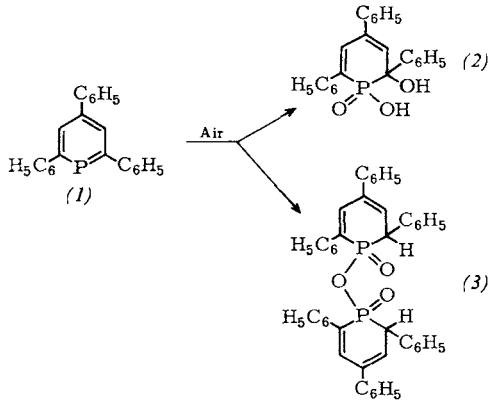
Pure products are obtained if a solution of 2,4,6-triphenylphosphorin in benzene is left exposed to the air for a considerable time. After *ca.* ten days colorless crystals separate. A further product is obtained on evaporation of the mother liquor. The first compound has m.p. 162–165 °C and composition $C_{23}H_{19}O_3P$, and its structure is probably *(2)*. Osmometric molecular-weight determination gives values indicating association. With trifluoroacetic *(2)* at once gives a blue color.

(2), UV: λ_{max} = 250 nm, $\varepsilon = 1.3\times10^4$ (in acetonitrile);
IR: 2600 to 2800 cm^{-1} and 940 to 970 cm^{-1} (P–OH), 1174 cm^{-1} (P=O) in KBr, 3612 cm^{-1} (C–OH) in CCl_4;
NMR: singlet at –6.6 ppm (1 H, COH); –10 to –11 ppm (broad, 1 H, P–OH); band complex at –7.8 to –7 ppm (17 H, aromatic and olefinic).

The second compound is soluble in benzene, has the composition $C_{46}H_{36}O_3P_2$, melts at 225 °C, and reacts with trifluoroacetic acid only slowly and with blue coloration. It may have structure *(3)*.

(3), UV: λ_{max} = 264 nm, $\varepsilon = 2.9\times10^4$ (in acetonitrile);
NMR: quartet at –3.4 ppm (2 benzyl-H); $J_{P\text{-}CH}$ = 27 Hz, $J_{Ha/Hb}$ = 5 Hz; band complex at –7.8 to –6.8 ppm (34 H, aromatic and olefinic);
Molecular weight (mass spectrometric) = 698.

Compound *(3)* quickly exchanges deuterium with deuterated solvents, the NMR signal at −10.5 ppm disappearing.

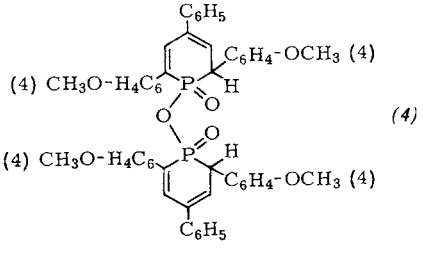


(1) *(2)* *(3)*

A compound of m.p. 195 °C analogous to *(3)*, and to which we ascribe structure *(4)*, was obtained from 2,6-bis-(4-methoxyphenyl)-4-phenylphosphorin.

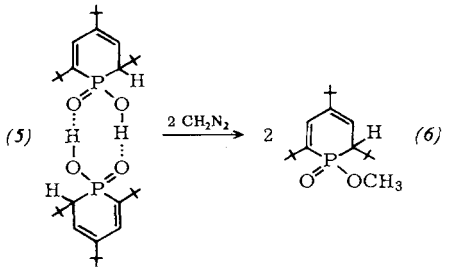
(4), UV: $\lambda_{max} = 240$ nm, $\varepsilon = 8.3 \times 10^4$ (in methanol);

NMR: quartet at −3.3 ppm (2 benzyl-H), $J_{P-CH} = 28$ Hz, $J_{Ha/Hb} = 5$ Hz; singlet at −3.70 ppm (6 H,O−CH_3), singlet at −3.72 (6 H, O−CH_3); band complex at −7.5 to −6.5 (30 H (aromatic and olefinic);
Molecular weight (mass spectrometric) = 820 (± 5); further fragments at *m/e* = 400 and 384, of which the second peak is to be ascribed to 2,6-bis-(4-methoxyphenyl)-4-phenylphosphorin.



(4)

If 2,4,6-tri-*tert*-butylphosphorin is oxidized under similar conditions, a colorless crystalline product $C_{17}H_{31}O_2P$, m.p. 203 °C, is formed. Osmometric and mass-spectrometric studies show that it is dimeric, and on the basis of the NMR data we assign to it the structure *(5)*.



(5) *(6)*

(5), UV (in *n*-hexane): $\lambda_1 = 237$ nm, $\varepsilon = 2925$, $\lambda_{max} = 275$ nm, $\varepsilon = 4075$;

IR (in CCl_4): P−OH: 2600–2900 cm^{-1}, 2200–2400 cm^{-1}, P−OH: 940 cm^{-1}, P−O: 1170 cm^{-1};

NMR (in $CDCl_3$): singlet $\delta = -12.2$ ppm (1 H); quartet $\delta = -6.63$ ppm, J_1 (P−CH) = 36.5 Hz, $J_2 = 2.0$ Hz (1 H); octet $\delta = -5.92$ ppm, J_3 (P−CH) = 22 Hz, $J_4 = 6$ Hz, $J_2 = 2$ Hz (1 H); quartet $\delta = -2.15$ ppm, J_5 (P−CH) = 24 Hz, $J_4 = 6$ Hz (1 H); singlet $\delta = -1.34$ ppm (9 H); singlet $\delta = -1.15$ ppm (9 H); singlet $\delta = -1.10$ ppm (9 H).
Molecular weight (mass spectrometric): 298 (monomer), 595 ± 1 (dimer).

The same product is obtained on treating 2,4,6-tri-*tert*-butylphosphorin with bromine water, hydrogen peroxide in acetone, or nitric/sulfuric acid at 0 °C. With diazomethane in ether/methanol, colorless crystals (m.p. 51 °C, composition $C_{18}H_{33}O_2P$) are obtained, whose structure is assigned by NMR.

(6), UV (in cyclohexane): $\lambda_1 = 247$ nm, $\varepsilon = 3300$; $\lambda_2 = 278$ nm, $\varepsilon = 3460$;

IR (in CCl_4): P−O−C: 1040 cm^{-1}; P=O: 1220 cm^{-1};

NMR: Quartet $\delta = -6.52$ ppm (1 H); J_1 (P−CH) = 36 Hz, J_2 (H−H) = 2 Hz; octet $\delta = -5.75$ ppm (1 H); J_3 (P−CH) = 23 Hz, J_4 (H−H) = 7 Hz; J_2 (H−H) = 2 Hz; doublet $\delta = -3.54$ ppm (3 H); J_5 (P−CH) = 11 Hz; quartet $\delta = -2.00$ ppm (1 H); J_6 (P−CH) = 23 Hz; $J_4 = 7$ Hz; singlet $\delta = -1.29$ ppm (9 H); singlet $\delta = -1.10$ ppm (9 H); singlet $\delta = -1.08$ ppm (9 H).
Molecular weight (mass spectrometric) = 312.

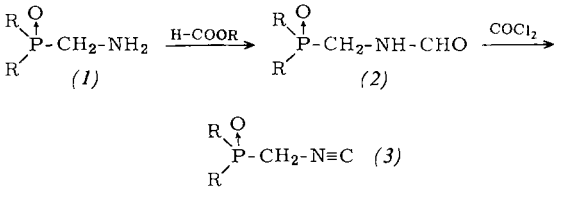
Phosphinylmethyl Isocyanides

By *N. Kreutzkamp* and *K. Lämmerhirt* [*]

Dedicated to Prof. H. Böhme on the occasion of his 60th birthday

The *P,P*-diphenyl- (R = C_6H_5) and *P,P*-dibenzyl- derivatives (R = $CH_2-C_6H_5$) of the previously unknown phosphinylmethyl isocyanides *(3)* have been prepared. These represent the first examples of such derivatives and were obtained from the corresponding *N*-phosphinylmethylformamides *(2)* by means of the Ugi reaction [1]. The formamides *(2)*

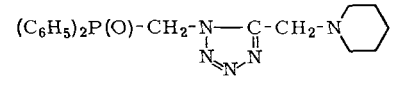


(1) *(2)* *(3)*

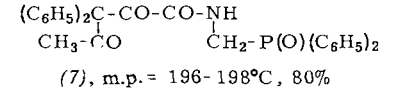
are obtainable in quantitative yields from the amines *(1)* and ethyl formate.

(4), m.p. = 115-116°C, 60%

(5), m.p. = 209-210°C, 41%



(6), m.p. = 163°C, 67%



(7), m.p. = 196-198°C, 80%

The phosphinylmethyl isocyanides *(3)* are relatively stable, colorless, odorless, solid substances, which afford the otherwise unobtainable tertiary phosphine oxides when subjected to either the Passerini or Ugi reactions. Compounds *(4)–(7)* represent examples of the oxides thus obtainable.

Procedure:

Phosphinylmethyl isocyanides: 10.8 ml of a 20 % solution of phosgene in toluene is added dropwise at 15–20 °C, with stirring, to a solution of 5.2 g of *N*-diphenylphosphinylmethylformamide and 6.6 ml triethylamine in 30 ml methylene chloride. The reaction mixture is concentrated by evaporation under vacuum and the residue thus obtained is boiled several times with fresh portions of benzene. The combined benzene solutions are then concentrated and *P,P*-diphenylphosphinylmethyl isocyanide precipitates out (m.p. 146–148 °C on recrystallization from benzene; yield 80 %).

P,P-Dibenzylphosphinylmethyl isocyanide (m.p. 143–144 °C) can be obtained from *N*-dibenzylphosphinylmethylformamide in 72 % yield by using the same procedure.

N-(*P,P*-Diphenylphosphinylmethyl)piperidinoacetamide *(4)*: A mixture of 10 ml methanol, 1.7 g piperidine, 2 ml 10 N HCl, and 2 ml 40 % formaldehyde solution is prepared under ice-cold conditions. 4.8 g *P,P*-diphenylphosphinylmethyl isocyanide is added in small portions. The resulting mixture is allowed to stand for 72 hours at 20 °C and finally evaporated under vacuum. The oily residue is taken up in hydrochloric acid, extracted twice with methylene chloride, and the aqueous phase rendered alkaline. Extraction with methylene chloride then affords the required compound as an oil, which solidifies on rubbing with ether and which can be recrystallized from benzene.

1 - Diphenylphosphinylmethyl - 5 - piperidinomethyltetrazole *(6)*: An ice cold solution of 1.7 g piperidine in 20 ml of acetone is prepared and treated successively with 2 ml 40 % formaldehyde solution, 5 ml 12.5 % hydrochloric acid, 1.3 g sodium azide in 10 ml H_2O, and 4.8 g *P,P*-diphenylphosphinylmethyl isocyanide. The mixture is stirred for an hour at 20 °C, saturated with potassium carbonate, and then extracted with acetone. On evaporation of the acetone extract there remains an oil which solidifies on rubbing with ether. The crystals thus obtained can be recrystallized from ethanol.

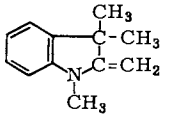
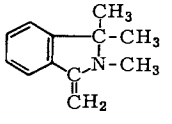
By *A. Fabrycy* and *A. Kosmider* [*]

1,3,3-Trimethyl-2-methyleneindoline *(1)*, normally referred to as Fischer's base, has long been known.



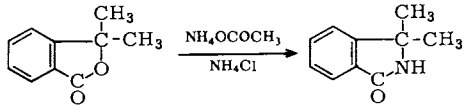
(1)



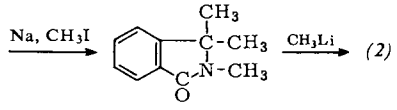
(2)

We have now synthesized 1,1,2-trimethyl-3-methyleneisoindoline *(2)* that is isomeric with *(1)*.

We have obtained 3,3-dimethyl-1-isoindolinone *(4)* [1] by the action of a mixture of ammonium acetate and ammonium chloride on dimethylphthalide *(3)* in an autoclave for 24 h at 400 °C/130 atm, the yield being 65 %. In contrast to other phthalides [2] the compound *(3)* does not exchange its O for N under milder conditions.



(3) *(4)*



(5)

1,1,2-Trimethyl-3-methyleneisoindoline *(2)* is a basic liquid that darkens in air; its structure was confirmed by elemental analysis and IR and NMR spectra.

With *p*-dialkylaminobenzaldehyde compound *(2)* forms red dyes that have good light- and wash-fastness on polyacrylonitrile fibers.

Experimental:

Dimethylphthalide *(3)* (200 g), ammonium acetate (300 g), and ammonium chloride (150 g) are heated in a 1-liter autoclave for 24 h at 380 °C; the pressure rises to 120–130 atm. After cooling, the semisolid brownish-black mass is rubbed three times with warm ethyl methyl ketone (total 800 ml), and the extract is filtered. The filtrate is washed with water (200 ml), treated with active charcoal, dried over Na_2SO_4, and concentrated to 250 ml. After cooling to −20 °C, the 3,3-dimethyl-1-isoindolinone *(4)* that crystallizes out is filtered off and washed with a little ethyl methyl ketone. Further amounts of the product can be obtained from the filtrate by evaporation to half its volume. Recrystallized from benzene the substance has m.p. 161 °C; the yield is 98 g (65 %).

The isoindolinone *(4)* (80.5 g, 0.5 mole), finely cut sodium (12.5 g), and anhydrous benzene (1.3 liter) are heated under reflux with stirring for 3–7 h (the time depends on the state of division of the sodium). After cooling the solid material is filtered off [no unchanged *(4)* can be recovered from the filtrate] and suspended in anhydrous benzene (500 ml). Methyl iodide (150 g) in benzene (200 ml) is added dropwise with stirring and warming (reflux condenser) during 8 h. The resulting mixture is heated for a further 2 h, cooled, and filtered, and the unreacted methyl iodide and the solvent are distilled off (water-bath). The residual yellow viscous liquid is distilled in a vacuum. 2,3,3-Trimethyl-1-isoindolinone *(5)* distils at 135–136 °C/3 torr; m.p. 35–36 °C; yield 61 g (70 %).

The isoindolinone *(5)* (17.5 g, 0.1 mole) in ether (100 ml) is added dropwise to a solution of methyllithium (from 2.5 g = 0.5 mole of Li) in ether (100 ml) at 15 °C and the whole is boiled for 1 h, then after cooling treated with water (100 ml). The ethereal layer is washed with water, dried over Na_2SO_4, and freed from solvent. On subsequent vacuum distillation the base *(2)* distils at 84–86 °C/3 torr; $n_D^{20} = 1.5719$; yield 14.7 g (85 %). Its perchlorate forms colorless crystals that melt at 197–198 °C.

The Coordination Behavior of Triphenylsilanide[1]

By *Th. Kruck, E. Job,* and *U. Klose*[*]

π-Cyclopentadienyl- and CO-stabilized neutral complexes containing a covalent metal-silicon bond have been prepared in recent years for various transition metals. These are non-polar compounds of the types $Y_3Si-M(CO)_n$ (M = Mn or Co), $(\pi\text{-}C_5H_5)(CO)_3M-SiY_3$ (M = Cr or Mo), and $(\pi\text{-}C_5H_5)_2Zr(Cl)SiY_3$ (Y = alkyl, aryl, and halogen)[2], synthesized by replacement of an H or halogen atom attached to the complexed metal by the SiY_3 group by means of Y_3Si-X [X = H or $N(CH_3)_2$] or $LiSi(C_6H_5)_3$. We now report on the first metal complexes in which a silanide donor ligand, $:SiY_3^{\ominus}$, is attached to a transition metal atom by a coordinate bond.

Triphenylsilanide was the first of many possible combinations to be examined for ability to act as a σ donor. The $Si(C_6H_5)_3^{\ominus}$ ion is not only isoelectronic with the commonly used complexing ligand triphenylphosphine, but it also contains free 3d orbitals in the central atom, which allow metal → silicon back-bonding. Owing to its negative charge it should be a stronger donor than the phosphine ligand, and it therefore seemed to us that π acceptors would also have to be attached to the metal to stabilize the M–Si bond.

We therefore allowed $LiSi(C_6H_5)_3$ (which is readily obtainable by reduction of hexaphenyldisilane with lithium) to react with tetracarbonylnickel[3] (molar ratio 1:3) in tetrahydrofuran (THF). Above about −20 °C, the reaction led initially to a deep green, soluble intermediate, which has not yet been examined in any detail. Above about 0 °C vigorous evolution of CO takes place and the intermediate is converted within a few minutes into the monosubstituted carbonyl anion, triphenylsilanidotricarbonylnickelate(0)[4]:

$$Ni(CO)_4 + Si(C_6H_5)_3^{\ominus} \rightarrow [(C_6H_5)_3SiNi(CO)_3]^{\ominus} + CO$$

The lithium salt $Li[(C_6H_5)_3SiNi(CO)_3]\cdot 2\,THF$ can be precipitated from the orange solution with hexane. It crystallizes as light yellow needles, which are unstable in air, melt at 99 to 101 °C, and decompose with darkening of their color above about 110 °C. It dissolves very readily in water and in polar organic solvents, less readily in benzene, and not at all in aliphatic hydrocarbons. The anion is surprisingly stable in water, so that precipitation reactions are possible with bulky univalent cations. The light yellow $[N(CH_3)_4][(C_6H_5)_3SiNi(CO)_3]$ is obtained as shining leaflets, which sinter with decomposition at 200 °C.

The ionic constitution of these substances is confirmed by such precipitation reactions, by conductivity measurements, and by their diamagnetic behavior. The IR spectrum [ν_{CO} = 2003 (A_1) and 1936 cm^{-1} (E), solid in KBr] indicates that the anion has the expected distorted-tetrahedral structure (C_{3v} symmetry).

The much greater reactivity of triphenylsilanide as compared with triphenylphosphine is rather surprising. This high reactivity is also seen in the substitution of pentacarbonyliron at only 25–30 °C when this compound is treated in a similar manner with $LiSi(C_6H_5)_3$ (molar ratio 3:1) in THF. The reaction again leads smoothly to the light yellow lithium salt of the monosubstituted anion $[(C_6H_5)_3SiFe(CO)_4]^{\ominus}$ whose IR spectrum [ν_{CO} = 2007 (A_1), 1906 (A_1), and 1880 cm^{-1} (E), solution in THF, or 2002, 1925, 1891, and 1825 cm^{-1}, solid in KBr] clearly points to a trigonal-bipyramidal structure having symmetry C_{3v}. The triphenylsilanidotetracarbonylferrate(0) is unstable in the presence of an excess of $LiSi(C_6H_5)_3$, at least at room temperature; it decomposes with loss of an $Si(C_6H_5)_3^{\ominus}$ ion:

$$[(C_6H_5)_3SiFe(CO)_4]^{\ominus} + Si(C_6H_5)_3^{\ominus} \rightarrow [Fe(CO_4)]^{2\ominus} + (C_6H_5)_3Si-Si(C_6H_5)_3$$

The strong long-wave shift of the C–O stretching frequencies of the silanide complexes in relation to those of the isosteric compounds $Ni(CO)_3P(C_6H_5)_3$ (ν_{CO} = 2070 and 2000 cm^{-1} [5]) and $Fe(CO)_4P(C_6H_5)_3$ (ν_{CO} = 2051, 1978, and 1945 cm^{-1} [6]) is in agreement with the anionic character of the new ligand, which leads to a high negative charge on the metal, and hence to considerable M → CO back-bonding.

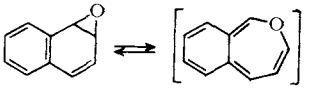
1,2-Naphthalene Oxide

By *E. Vogel* and *F.-G. Klärner*[*]

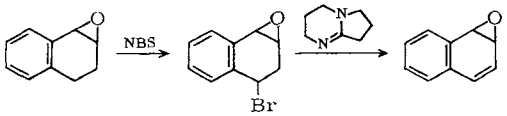
In order to gain a better understanding of arene oxide-oxepin equilibrium systems, it was desirable to have "frozen-in" arene oxides available for purposes of comparison. 8,9-Indan oxide and 9,10-tetralin oxide[1] have recently been prepared and it is found that the tri- and tetramethylene chains that function as brackets in these molecules restrict arene oxide-oxepin isomerization to such a degree that the oxepin form is no longer detectable by spectroscopic methods.



(1) *(2)*

We suspected that the previously unknown 1,2-naphthalene oxide *(1)* would prove to be another fixed arene oxide. Judging by the results obtained with benzonorcaradiene[2,3], it was to be expected that the rearrangement of *(1)* to the isomeric oxepin *(2)* would be relatively strongly endothermic, owing to the loss of benzene resonance, and that *(2)* would be formed at most as a short-lived intermediate in an inversion process[3].

The synthetic route to 1,2-naphthalene oxide that we envisaged involved the introduction of a double bond into 1,2-dihydronaphthalene oxide *(3)*[4]. On reaction with *N*-bromosuccinimide, compound *(3)* yields a bromide *(4)*, m.p. 94–95 °C, the NMR spectrum of which shows the bromine substituent to be in the benzylic position. However, the configurative relationship of the substituent to the epoxide ring remains unsettled. Whereas earlier attempts to dehydrohalogenate *(4)* to 1,2-naphthalene oxide with various bases had been unsuccessful[5], the use of 1,5-diazabicyclo[4.3.0]-non-5-ene[6] (0 °C, tetrahydrofuran) led to the desired product.



(3) *(4)* *(1)*

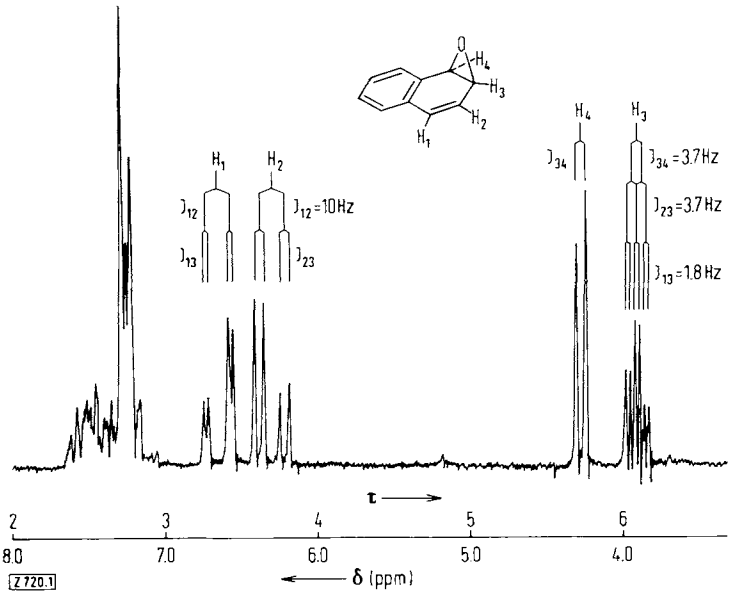


Figure 1. ^{1}H—NMR spectrum of 1,2-naphthalene oxide (in CCl_4; 60 MHz; tetramethylsilane as internal standard). No absorption beyond $\tau = 6.2$.

1,2 Naphthalene oxide is obtained as a colorless crystalline compound that in the solid state rapidly rearranges – sometimes with explosive violence – to α-naphthol.

The presence of 1,2-naphthalene oxide follows unequivocally from the NMR spectrum reproduced in Figure 1. If the isomeric oxepin derivative *(2)* were present, then the signals corresponding to the protons H^3 and H^4 would appear at lower field strengths and, furthermore, the absorption due to H^4 would be a singlet. The electronic spectrum of the oxide [maxima at 220 (ε = 17600), 268 (8850), and 304 nm (1570) in dioxane] is remarkably similar to that of benzonorcaradiene[2]. This finding rules out the possibility that 1,2-naphthalene oxide is in equilibrium with a significant concentration of the isomeric oxepin *(2)*, which is doubtless colored.

Compound *(1)* is relatively stable in solution (ether). In the presence of catalytic amounts of a protic or a Lewis acid it spontaneously isomerizes to α-naphthol. Attempts to convert *(1)* into the known *trans*-1,2-dihydronaphthalene-1,2-diol[7] have been unsuccessful.

The fact that a number of authors have recently invoked 1,2-naphthalene oxide and other arene oxides as intermediates in enzymatic oxygenations of aromatic compounds[7,8] seems a further justification for the publication of these results.

Synthesis of 1,2-Naphthalene Oxide

a) *4-Bromo-1,2-epoxy-1,2,3,4-tetrahydronaphthalene (4)*

N-Bromosuccinimide (7.12 g, 40 mmole) and α,α'-azoisobutyrodinitrile (0.1 g) are added to a solution of 1,2-epoxy-1,2,3,4-tetrahydronaphthalene *(3)* (5.84 g, 40 mmole) in CCl_4 (75 ml). Once the reaction has been started by quickly heating the mixture to boiling, no more heat has to be supplied. Succinimide and unreacted *N*-bromosuccinimide are filtered off and the filtrate is concentrated under vacuum until the bromide *(4)* begins to precipitate. On cooling to −10 °C, the main part of *(4)* crystallizes out in almost pure form; a further crop of *(4)* is obtained by working up the mother liquor. Recrystallization from ether/ethyl acetate (5:1) affords 2.1 g of *(4)* (23 % yield) having m.p. 94–95 °C (decomp.).

b) *1,2-Naphthalene Oxide (1)*

1,5-Diazabicyclo[4.3.0]non-5-ene (400 mg, 3.2 mmole) is added dropwise, with stirring at 0 °C under an N_2 atmosphere, to 4-bromo-1,2-epoxy-1,2,3,4-tetrahydronaphthalene *(4)* (450 mg, 2 mmole) in tetrahydrofuran (5 ml). The reaction mixture is stirred for 12 h at 0 °C and then allowed to stand for a further 12 h at this temperature. The tetrahydrofuran is evaporated off at 0 °C under vacuum and the residue is treated first with 15 ml of pentane and then with 2 ml of water. The aqueous phase is extracted once again with 15 ml of pentane and the combined pentane solutions are washed three times with dilute KOH and dried over K_2CO_3. On cooling to −80 °C, *(1)* crystallizes out as colorless needles, yield 240 mg (83 %). It is not possible to determine the exact melting point of *(1)* because it rearranges rapidly to α-naphthol.

In order to prevent the occurrence of acid catalysis during the preparation, all glass apparatus is washed with concentrated ammonia.

Perchlorobutatriene and Perchloro-[4]radialene

By *B. Heinrich* and *A. Roedig* [*]

The remarkable thermal instability of perchloroallene[1] in conjunction with observations carried out on the dimerization of perchlorobutenyne[2] prompted us to synthesize perchlorobutatriene *(4)*. The synthesis was accomplished by

reaction of β,β-dichloroacrolein with trichloromethyllithium[3] in tetrahydrofuran at −120 °C, treatment of the carbinol *(1)* (m.p. 78 °C) with PCl_5 at 60 °C, and dehydrochlorination of the *sym*-hexachlorobutene *(3)* with potassium *tert*-butoxide in light petroleum (fraction 50–70 °C) at room temperature.

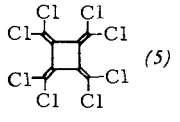
$$Cl_2C{=}CH{-}CHO \xrightarrow{CCl_3Li} \underset{(1)}{Cl_2C{=}CH{-}CHOH{-}CCl_3} \xrightarrow{PCl_5}$$

$$\underset{(2)}{Cl_2C{=}CH{-}CHCl{-}CCl_3} + \underset{(3)}{CCl_3{-}CH{=}CH{-}CCl_3} \rightarrow \underset{(4)}{Cl_2C{=}C{=}C{=}CCl_2}$$

The first reaction step proceeds almost quantitatively. On replacement of OH by Cl in compound *(1)*, the main product is compound *(2)* (b.p. 58–60 °C/0.1 torr), which, however, may be separated easily from *(3)* (m.p. 83.5 °C, yield of pure product 25 %). A subsequent allyl rearrangement *(2)* → *(3)* does not take place. The colorless crystalline compound *(4)* (m.p. 59–60 °C) that is obtained from *(3)* in 43 % yield can be sublimed without losses at 12 torr (bath temperature 55 °C) and is surprisingly stable compared to perchloroallene and to perfluorobutatriene[4], which in the liquid state explodes at temperatures above −5 °C. In CCl_4, it adds chlorine quantitatively to form perchlorobutadiene.

Apart from the strong C=C absorption at 1601 cm^{-1}, the extremely simple IR spectrum (KBr) of compound *(4)* shows only a split band at 855–880 cm^{-1} and a further weak band at 748 cm^{-1}. Its UV spectrum is characteristic of butatrienes[5,6]; the maxima (256 nm, log ε = 4.25, and 292 nm, log ε = 4.99) are merely displaced toward longer wavelengths as a result of chlorine substitution.

When heated for several hours at 100 °C in aprotic solvents, compound *(4)* yields, alongside small amounts of an explosive polymeric product, a colorless dimer (m.p. 164 °C, yield 50 %) that is not identical with any of the known



(5)

compounds C_8Cl_8[2,7] derived from perchlorobutenyne. The structure *(5)* is indicated by *inter alia* the following criteria:

a) the analogous behavior of other butatrienes[8] and cumulenes[9], which dimerize photochemically or thermally to [4]radialenes,

b) the UV spectrum, whose general form and maxima (232 nm, log ε = 4.30, 298 nm, log ε = 4.32, 312 nm, log ε = 4.27, 342 nm, log ε = 3.91) are very similar to those seen in the spectrum of tetramethylenecyclobutane[10], apart from the red shift caused by chlorine substitution, and

c) the dipole moment of 0.2 D, which within the range of application of the Debye theorem is to be regarded, to a first approximation, as zero.

Compound *(5)* is thermally stable at temperatures above 200 °C and does not rearrange to any of the perchlorobutenyne dimers. Our results thus refute the otherwise reasonable assumption that the formation of these C_8Cl_8 isomers could proceed *via* the intermediates *(4)* and *(5)*.

Perchlorobutatriene (4)

Compound *(3)* (20 g) is stirred for 70 h with potassium *tert*-butoxide (30 g) in anhydrous petroleum ether with exclusion of air. The mixture is centrifuged and the separated supernatant liquid is treated with a further 5 g-portion of potassium *tert*-butoxide and stirred for another 50 h. The solution remaining on removal of the solids is concentrated under vacuum and the crude product thus obtained is taken up in methanol (60 ml), filtered, and frozen out by cooling to −70 °C. Recrystallization is from a little ethanol, with gentle warming. All the mother liquors are evaporated to dryness under vacuum, the residue is sublimed and recrystallized, and then united with the preliminary charge. After drying over P_2O_5 under vacuum and sublimation at 11 torr (bath temperature 55 °C), 6.0 g (41.5 %) of colorless coarse crystals (m.p. 59–60 °C) is obtained.

Perchloro-[4]radialene (5)

Compound *(4)* (500 mg) is dissolved in anhydrous carbon tetrachloride (0.5 ml) and, after addition of a trace of hydroquinone, heated in a tube to 100 °C for 65 h. Carbon tetrachloride (2 ml) is added to the solution, which is then separated from insolubles by centrifugation. The solvent is removed under vacuum and the resulting residue is recrystallized twice from light petroleum (b.p. 50–70 °C). After sublimation at 0.01 torr (bath temperature 120–130 °C), 242 mg (48.5 %) of colorless crystals (m.p. 164 °C) is obtained.

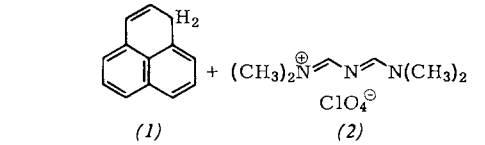
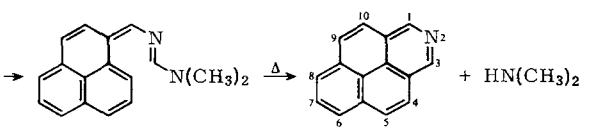
2-Azapyrene

By *R. Kirchlechner* and *Ch. Jutz* [*]

The reaction of phenalene *(1)*[1] with 3-dimethylamino-2-azapropenylideneammonium perchlorate *(2)*[2] and sodium methoxide in pyridine leads to the orange colored amine *(3)*, which on heating undergoes ring closure to 2-azapyrene *(4)*. Only one other monoazapyrene, thebenidine (4-azapyrene)[3], has previously been reported.



(1) *(2)*



(3) *(4)*

2-Azapyrene *(4)*, pale yellow crystals, m.p. 162–165 °C, partly decomposes both on melting and on sublimation in vacuum. (Methyl iodide derivative, m.p. 281–284 °C; picrate, m.p. 280 °C.) Its UV spectrum (in ethanol) resembles that of pyrene: λ_{max} = 375 nm (log ε = 4.01); 370 (3.48); 356 (3.83); 332 (4.83); 316.5 (4.61); 304 (4.25); 294 (sh) (3.89); 270.5 (4.53); 260 (4.52); 240 (4.99).

Solutions of *(4)* in organic solvents display an intensive blue fluorescence and in aqueous mineral acids a blue-green fluorescence. In the NMR spectrum ($CDCl_3$) a singlet occurs at $\tau = 0.87$, which is ascribed to the protons H-1 and H-3 (the neighboring protons to the ring nitrogen); the remaining protons show a characteristic split multiplet with main signals at $\tau = 2.05$, 2.18, 2.38, and 2.50. In trifluoroacetic acid *(4)* is protonated and H-1 and H-3 give rise to a doublet, $J = 6$ Hz, at $\tau = 0.53$. The multiplet of the remaining ring protons occurs well downfield at $\tau = 1.43$, 1.53, 1.60, 1.67, and 1.80. IR spectrum (KBr disk): 1618, 1582, 1534, 1449, 1412, 1377, 1351, 1250, 1238, 1208, 1180, 1134, 1071, 1052, 1013, 971, 884, 840, 820, 808, 804, 750, 709, 683 cm^{-1}.

Procedure:

A mixture of 332 mg (2 mmole) phenalene *(1)* and 475 mg (2.1 mmole) 3-dimethylamino-2-azapropenylideneammonium perchlorate *(2)* in 25 ml of water-free pyridine is treated, under purified nitrogen, with 2.2 mmole of sodium methoxide. The resulting mixture is stirred for 6h and then boiled under reflux for a further 10h. The pyridine is distilled off under vacuum and the residue taken up in a little methylene chloride and passed through a short Al_2O_3 column (activity grade III), The residue obtained on evaporating the eluate is dissolved in 20 ml 4 N HCl (with warming if necessary), filtered, and neutralized whilst hot with aqueous ammonia. 2-Azapyrene separates out as fine needles, yield 250 mg (61 %). On recrystallization from a methanol/water mixture the 4-azapyrene recovered has m.p. 162–165 °C.

A New Method for the Introduction of Nitrile Groups

By *D. vor der Brück*, *A. Tapia*, *R. Riechel*, and *H. Plieninger* [*]

Reaction of nucleophilic heterocycles (XH) with ethoxycarbonyliminotriphenylphosphorane *(1)* [1] and BF_3-ether leads to the formation of nitriles, as well as triphenylphosphine oxide, sometimes in very good yield.

$$XH + (C_6H_5)_3P{=}N{-}CO_2C_2H_5 + BF_3{\cdot}(C_2H_5)_2O \xrightarrow{THF} X{-}C{\equiv}N + (C_6H_5)_3P{=}O + C_2H_5OH$$

(1)

The following compounds have been obtained in this way:
Pyrrole-2-carbonitrile, yield 45 %.

Ethyl-3-cyano-2,4-dimethylpyrrole-5-carboxylate, m.p. 177 °C, yield 46 %.

3-Ethyl-2,4-dimethylpyrrole-5-carbonitrile, m.p. 134 °C, yield 57 %.

2,3,4-Trimethylpyrrole-5-carbonitrile, m.p. 139 °C, yield 50 %.

Indole-3-carbonitrile, m.p. 181 °C, yield 65 %.

2-Ethoxy-1-methylindole-3-carbonitrile, m.p. 126 °C, yield 96 %.

Reaction of 3,4-dimethyl-2,5-dihydropyrrol-2-one yields 2-ethoxy-3,4-dimethylpyrrole-5-carbonitrile in 15 % yield (m.p. 90 °C).

In the case of acid-sensitive compounds this synthesis appears to be more favorable than nitrile synthesis by way of cyanates [2].

Procedure:

Ethoxycarbonyliminophosphorane (1.5 mmole) and BF_3-ether (1.5 mmole) are dissolved in *ca.* 50 ml of tetrahydrofuran, 1 mmole of the heterocyclic compound is added, and the mixture boiled under reflux for about 4 hours. The solvent is then evaporated off under vacuum and the resulting residue chromatographed on silica gel, or aluminum oxide, with ether/petroleum ether. The triphenylphosphine oxide remains on the column.

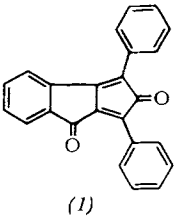
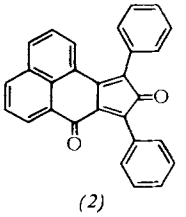
Synthesis of 1,3-Diphenyl-2,8-dihydrodibenz[*e*,*h*]-azulene-2,8-dione

By *W. Ried* and *J. Ehret* [*]

Condensations of diketones with dibenzyl ketone are well known [1,2]. The corresponding reactions with triketones lead to the formation of the "ketocyclones" *(1)* [3] and *(2)* [4], which possess a further carbonyl group vinylogous to the carbonyl function of the cyclopentadienone. These compounds are of value for the synthesis of substituted fluorenones [3], pentalenes [5], benzanthrones [4], and other ring systems [6].

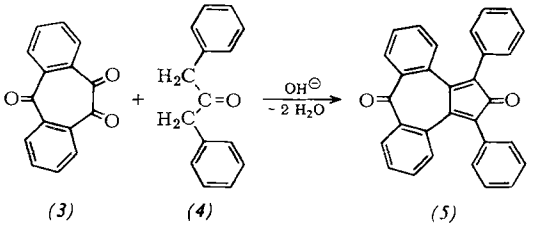


(1)



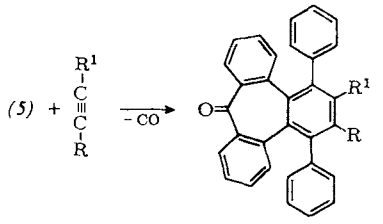
(2)

The "ketocyclones" *(1)* and *(2)*, in which the cyclopentadienone system is condensed with a five- or six-membered ring, finds its continuation in the 1,3-diphenyl-2,8-dihydrodibenz[*e*,*h*]azulene-2,8-dione *(5)* with a condensed seven membered ring. Compound *(5)* can be formed from 10,11-dihydro-5*H*-dibenzo[*a*,*d*]cycloheptene-5,10,11-trione *(3)* and dibenzyl ketone *(4)* in 50–60 % yield, the otherwise observed benzilic acid type rearrangement to anthraquinone [7] taking place only to a small extent.



(3) *(4)* *(5)*

When crystallized from ethanol, *(5)* forms shining violet crystals m.p. 248–249 °C. Diels-Alder reactions of *(5)* with dienophilic agents afford the tribenzocycloheptenes *(6a)* to

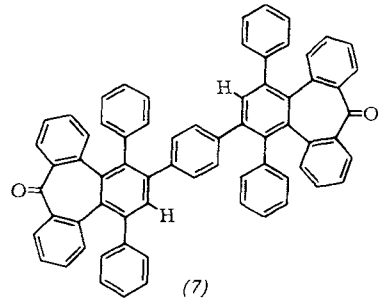


(6)

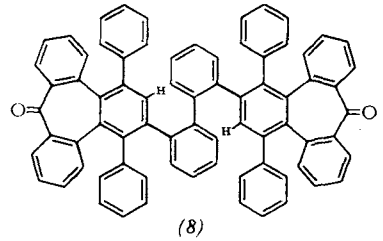
	R	R^1	M.p. (°C)	Yield (%)	Recrystallized from
(6a)	$-CO_2CH_3$	$-CO_2CH_3$	251	45	dry ethanol
(6b)	$-CO-C_6H_5$	$-CO-C_6H_5$	302–303	65	benzene
(6c)	$-C_6H_5$	$-CH_3$	260–261	50	dry ethanol
(6d)	$-C_6H_5$	$-C_6H_5$	379–380	45	benzene

(6d), of which *(6d)* has already been synthesized by another method [8].

Compound *(5)* reacts with 1,4-diethynylbenzene to form *(7)* [m.p. 429–430 °C, from xylene] and with 2,2′-diethynylbiphenyl [9] to form *(8)* [m.p. 388–389 °C, from xylene].



(7)



(8)

Procedure:

a) Synthesis of *(5)*: 2.36 g (0.01 mole) of *(3)* and 2.10 g (0.01 mole) of *(4)* are dissolved in 200 ml water-free ethanol at room temperature. 1.75 ml 10 % methanolic KOH is added dropwise, and with vigorous stirring, to the ice-cold solution. The resulting mixture is allowed to stand for 48 hours at a temperature of 6–8 °C. The crystals of *(5)* that separate out are filtered off under suction and recrystallized from water-free ethanol or acetonitrile (Yield 50–60 %).

b) Synthesis of *(6a)–(6d)*, *(7)*, and of *(8)*: Molar quantities of *(5)* and an acetylenic compound are heated, in β-decalol if the latter is not liquid, for several hours until evolution of gas ceases, extensive decoloration taking place.

The reaction mixture is then cooled, diluted with ethanol, and the precipitate filtered off by suction. The crude product is then recrystallized (using the respective solvents given above for the compounds *(6a)–(6d)*, *(7)*, and *(8)*).

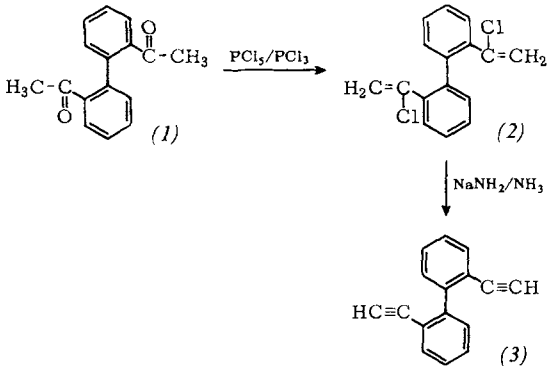
Synthesis of 2,2′-Diethynylbiphenyl and its Reaction with Cyclopentadienone Derivatives

By *W. Ried* and *V. B. Saxena* [*]

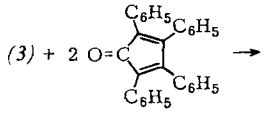
The hitherto unknown 2,2′-diethynylbiphenyl *(3)* is of interest as a starting material for photoreactions and thermochemical reactions. It can be synthesized as follows:



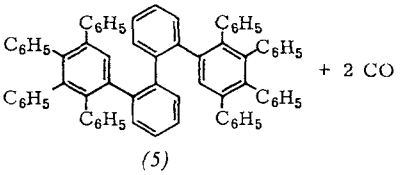
(1) (2) (3)

2,2′-Diacetylbiphenyl *(1)* [1] reacts with PCl_5/PCl_3 at 40 °C, giving 2,2′-bis(1-chlorovinyl)biphenyl *(2)*, from which 2 moles of HCl are removed on reaction with $NaNH_2$ [2] in liquid NH_3. The product *(3)* crystallizes as colorless leaflets and melts at 49 °C.

Both ethynyl groups of *(3)* react with cyclopentadienone derivatives, *e.g.* *(4)*, at elevated temperature, with evolution of CO and formation of polyphenylenes, *e.g.* *(5)* (colorless crystals, m.p. 235 °C).



(4)



(5)

Synthesis of 2,2′-Diethynylbiphenyl (3)

2,2′-Diacetylbiphenyl (6 g, 0.025 mole) and PCl_5 (20 g, 0.1 mole) are heated in PCl_3 (50 ml) at 40 °C for 48 h with stirring, then the mixture is evaporated in a vacuum and the

residue is treated with ice. The aqueous suspension is extracted with benzene (about 300 ml), and the organic phase is at once chromatographed on acid Al_2O_3. Benzene (1000 ml) is used for elution. After evaporation of the solvent the residue is taken up in ether, and the solution is decanted at once into a suspension of $NaNH_2$ prepared from sodium (6 g) and iron(III) nitrate (0.3 g) in liquid ammonia (400 ml) at −40 °C. The mixture is stirred for 2 h at −40 °C. Ammonium chloride (15 g) is added to decompose the excess of sodium amide, and the ammonia is allowed to evaporate overnight. The mixture is then hydrolyzed with dilute sulfuric acid, and the organic component is extracted into ether. After evaporation of the ether the residue is chromatographed in benzene on acid Al_2O_3. The eluate is evaporated and the residue is kept at −30 °C for 2 days. Yield: 1.2 g (*ca.* 25 %) of colorless leaflets, m.p. 49 °C.

Reactions of Cyclopentadienone Derivatives with 2,2'-Diethynylbiphenyl

1 mole of *(3)* and 2 moles of the cyclopentadienone derivative are heated in a small volume of 2-decalol under nitrogen until gas evolution ceases and decoloration is almost complete (several hours). After cooling, the product is filtered off and recrystallized from ethyl acetate or *o*-dichlorobenzene.

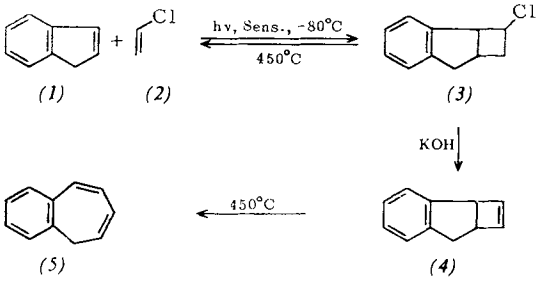
A Simple Synthesis of Benzocycloheptene

By *W. Metzner* and *K. Morgenstern* [*]

In the presence of photosensitizers, indene *(1)* adds on 1,2-dichloroethylene with formation of 1,2-dichloro-1,2,2a,7b-tetrahydrocyclobuta[*b*]indene [1]. Extension of this reaction to vinyl chloride *(2)* suggested itself as a simple means of synthesizing the hitherto difficultly accessible [2] benzocycloheptene *(5)*.

Irradiation (Philips HPK 125 W, pyrex filter glass) of *(1)* and benzophenone in liquid *(2)* at −80 °C resulted in the formation of the adduct *(3)* (yield 69 %) as a mixture of two stereoisomers (molar ratio 10:1; b.p. 82–86 °C/0.8 torr). Attempts to convert *(3)* into *(5)* [4] by thermal elimination of HCl [3] led to fission into the starting materials of the photoreaction.



However, compound *(3)* is dehydrohalogenated to the hitherto unknown 2a,7b-dihydrocyclobuta[*b*]indene *(4)* (yield 60 %; b.p. 43–45 °C/0.3–0.5 torr; $n_D^{20} = 1.5642$) when treated with KOH/triethylene glycol at 230 °C. Thermal valence isomerization [5] of *(4)* leads to the formation of *(5)* in 83 % yield [4].

Synthesis of *N-tert*-Butyloxycarbonyl- and *N-tert*-Amyloxycarbonylamino Acids

By *B. Rzeszotarska* and *S. Wiejak* [*]

N-tert-Butyloxycarbonylamino acids (BOC-amino acids) and the less frequently used *N-tert*-amyloxycarbonylamino acids (AOC-amino acids) are particularly suitable for the synthesis of peptides. However, their syntheses involve preparative difficulties that are connected with the instability of *tert*-alkyl chloroformates, the well-known disadvantage of the azide method and of the several-step synthetic route.

Recently we described a method [1] for the introduction of the benzyloxycarbonyl amino-protecting group by means of benzyl 8-quinolyl carbonate. By an analogous procedure we have now prepared the *tert*-butyl and *tert*-amyl 8-quinolyl carbonates and obtained BOC- and AOC-amino acids by their reaction with amino acids.

Procedure:

A solution of *tert*-butyl or *tert*-amyl chloroformate (prepared according to reference [2]) is added dropwise at −60 °C to a solution of 8-hydroxyquinoline and triethylamine (molar ratio 1:1) in tetrahydrofuran, which is also cooled to −60 °C. The mixture is allowed to stand for 24 h at −25 °C and for 24 h at 20 °C and the solvent is then evaporated off under vacuum. The residue is dissolved in ethyl acetate and the resulting solution is washed first with water, then with ice-cold 0.1 N HCl, and once more with water. It is finally dried over $MgSO_4$ and the solvent is evaporated off. The mixed carbonates, which are obtained in *ca.* 70 % yield, crystallize out of an alcohol/water solution. *tert*-Butyl 8-quinolyl carbonate melts 69.5–72 °C (softening temperature 67 °C) and *tert*-amyl 8-quinolyl carbonate melts at 46–46.5 °C. Both substances can be stored almost indefinitely at room temperature.

A solution of the amino acid (0.5 mmole in 0.55 ml of 1 N NaOH) is mixed with a solution of the *tert*-alkyl 8-quinolyl carbonate (0.75 mmole) in dimethylformamide (0.9 ml) and the mixture is heated to 70 °C (water-bath temperature) for 1.5 h. The solvents are evaporated off under vacuum, the residue is dissolved in water, and 8-hydroxyquinoline and unreacted carbonate are removed by extraction into ethyl acetate. The aqueous solution is acidified with 4 N HCl and

Derivative	Yield (%)	M.p. of crude product
BOC-L-Ala	96	80.5–82
BOC-Gly	98	84.5–86.5
BOC-L-Pro	92	131–133.5
BOC-L-Val	91	72–75
AOC-Gly	98	80–83
AOC-L-Try	86	121–123
AOC-L-Ser	95	oil

extracted into ethyl acetate. On evaporation of the solvent, the BOC- or AOC-amino acid crystallizes out in almost pure form.

tert-Butyl Fluoroformate, a New Reagent for Peptide Syntheses

By *E. Schnabel, H. Herzog, P. Hoffmann, E. Klauke,* and *I. Ugi*[*]

The *tert*-butoxycarbonyl group (BOC) is nowadays frequently used in peptide chemistry for the protection of amino groups. Synthesis of BOC-amino acids[1] is, however, rather laborious. We therefore sought a convenient and generally applicable reagent for introduction of the BOC group – a reagent that could also be stored. *tert*-Butyl fluoroformate *(1)*[3] is obtained from carbonyl chloride fluoride[2] and *tert*-butyl alcohol at *ca.* −25 °C:

$$(CH_3)_3COH + ClCOF \xrightarrow{-HCl} (CH_3)_3COCOF$$
(1)

The ester *(1)* distills unchanged in a vacuum (b.p. −8 to −7 °C/1.9 torr; + 4 °C/15 torr; $n_D^{10} = 1.3591$; $\nu_{CO} = 1830$ cm^{-1}) and may be stored for months at 0 °C to room temperature, depending on its purity. It reacts rapidly (within 1 to 4 h) with α-amino acids at low temperatures (*e.g.*, below 0 °C) at pH 8 to 10, with formation of BOC-α-amino acids. Yields are usually 85–95 %, even when crude ester *(1)* is used.

tert-Butyl Fluoroformate

370 g of *tert*-butyl alcohol is placed in a 2-liter three-necked flask fitted with a stirrer, a thermometer, and a reflux condenser (−60 °C). 595 g of carbonyl chloride fluoride is condensed in at a bath temperature of approximately −70 °C. Part of the *tert*-butyl alcohol dissolves. The contents of the flask are then warmed. When the temperature of the mixture reaches −40 °C distinct refluxing sets in (condenser temperature below −45 °C) and weak evolution of hydrogen chloride starts. After 1½ h the temperature is allowed to rise slowly (over a period of 3 h) to −10 °C, the excess of carbonyl chloride fluoride being removed by allowing the temperature of the reflux condenser to increase and condensing the vapor in a downward low-temperature condenser. Above *ca.* −30 °C evolution of hydrogen chloride becomes distinctly faster and at −20 °C is rapid. At this temperature a clear colorless solution is formed. The solution is stirred at −10 °C until evolution of hydrogen chloride ceases (5–6 h). After short degassing (at *ca.* 200 torr) the crude solution can be used as reagent. Its content of *tert*-butyl fluoroformate amounts to about 60 %, the remainder being mainly *tert*-butyl alcohol. The pure ester can be obtained by distillation. Very similar results are obtained if the reaction is carried out in trichlorofluoromethane as solvent or in presence of isobutene as hydrogen chloride acceptor.

Synthesis of BOC-serine

5.3 g of serine is slurried in a mixture of 10 ml of dioxane and 10 ml of 4 N NaOH and, after cooling to −15 °C, 5 ml of the crude solution of *tert*-butyl fluoroformate is added. The mixture is stirred for 2 h at room temperature, its pH being continuously adjusted to 8.5, then it is filtered and the filtrate is extracted with 30 ml of ether. After acidification with citric acid and addition of sodium chloride to saturation, the solution is extracted four times with 30 ml portions of ethyl acetate. The ethyl acetate extracts are combined, washed five times with 10 ml of saturated sodium chloride solution and twice with water. The solvent is then distilled off, leaving a syrupy residue (9.3 g, 90 %) that crystallizes on standing.

(7a)	C_6H_5	53	259–263 (decomp.)
(7b)	*p*-ClC_6H_4	84.5	257–263 (decomp.)
(7c)	*m,p*-$Cl_2C_6H_3$	63	238–241 (decomp.)
(8a)	C_6H_5	63	above 210 (decomp.) [a]
(8b)	*p*-ClC_6H_4	74	234 (decomp.)

[a] Measured in a sealed tube.

It is possible to use the free 2-amino heterocycles in place of the 2-acetylamino compounds; however, at least 3 moles of aryl isocyanate are then required and diarylureas are formed as by-products instead of arylacetamides.

Because of the great variability of the starting materials, the above synthesis of 3-aryl-*s*-triazine-2,5-diones will probably find a wide range of application.

Procedure for the synthesis of (2):

A mixture of 2-acetylaminobenzothiazole *(1)* (1 mole), aryl isocyanate (2.5 mole), and anhydrous pyridine (2.5 mole) is heated to 135 °C for 3–4 h, and then taken up in anhydrous ether (500 ml if experiment is conducted on a 0.1 molar scale). After 30 min, the mixture is filtered under suction. The crude crystals, which are usually pale yellow, are washed thoroughly with ether and alcohol; if necessary, they can be recrystallized from glycol monomethyl ether acetate with addition of activated charcoal. The same general procedure can be used for the synthesis of *(6)–(8)*.

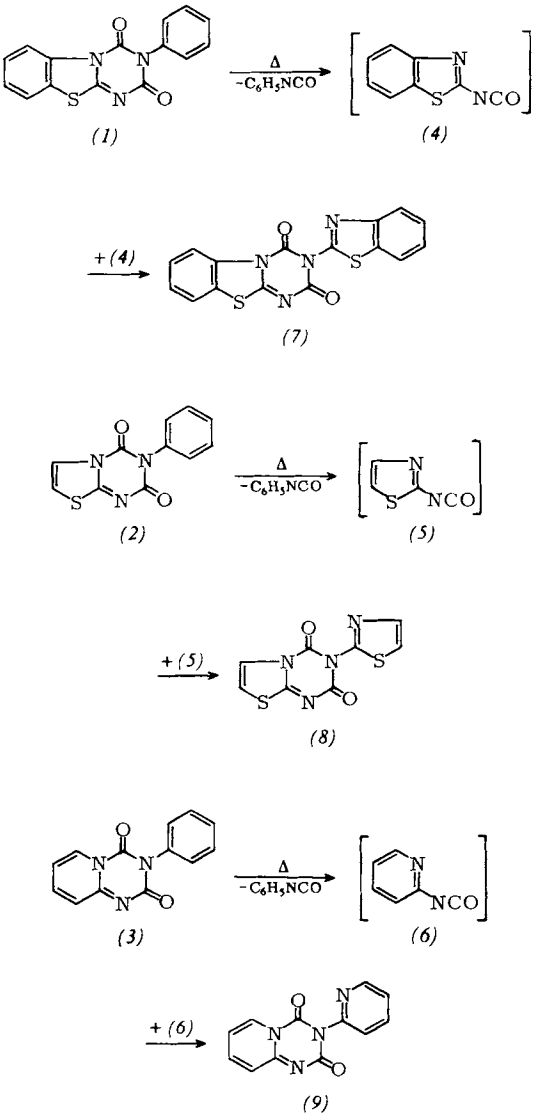
Anellated 1,3,5-Triazine-2,4-diones as Dimers of Heterocyclic Isocyanates

By *U. v. Gizycki* and *G. Oertel* [*]

When the anellated 3-phenyl-1,3,5-triazine-2,4-diones *(1)–(3)* [1] are heated, they lose phenyl isocyanate quantitatively. The heterocyclic isocyanates *(4)*, *(5)*, and *(6)* that are formed in this reaction cyclodimerize to give the crystalline compounds 2-(2-benzothiazolyl)benzothiazolo[3,2-*a*]-[1,3,5]triazine-1,3-dione *(7)*, m.p. above 305 °C (decomp.), 2-(2-thiazolyl)thiazolo[3,2-*a*][1,3,5]triazine-1,3-dione *(8)*, m.p. above 230 °C, or 2-(2-pyridyl)pyrido[1,2-*a*][1,3,5]triazine-1,3-dione *(9)*, m.p. 243–245 °C.



(1) *(4)* *(7)* *(2)* *(5)* *(8)* *(3)* *(6)* *(9)*

The tendency of isocyanates of types *(4)* to *(6)* to undergo cyclodimerization is known in the case of 2-isothiocyanatopyridine, which is also isolable only as a dimer of type *(9)* (S instead of O) [2]. On the other hand, the iminoalkyl isocyanates that are formed when dialkyl amidines are treated with phosgene are isolated only as the monomers [3].

The dimers *(7)* to *(9)* are well crystalline, colorless to pale yellow compounds whose IR spectra show characteristic double bands in the carbonyl region between 1680 and 1705 and 1730 and 1750 cm^{-1}. The NMR spectrum of compound *(8)* contains two four-line systems at δ = 7.15; 7.25; 7.7; 7.8 ppm and δ = 7.82; 7.85; 7.89; 7.92 ppm.

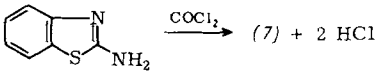
Thermolysis of compounds *(1)* to *(3)* follows the general pattern for anellated 3-aryl-1,3,5-triazine-2,4-diones of this type.

Procedure for the thermolysis and isolation of the products:

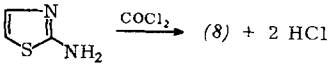
The starting materials *(1)–(3)* are heated to 300 °C at 0.2 torr for 1 h in a suitable distillation apparatus (*e.g.* round bottom flask, column, condenser, receiver); phenyl isocyanate collects in the receiver, which is cooled to −78 °C. The reaction products *(7)–(9)*, which are deposited in the apparatus, may be recrystallized from benzene/acetonitrile. Compound *(9)* can be separated from starting material that has also sublimed over by fractional crystallization from benzene/acetonitrile, *(9)* being more readily soluble than the impurities in this solvent system.

Since compounds *(7)* to *(9)* are to be regarded as dimeric isocyanates their preparation may be carried out according to one of the usual methods of preparing isocyanates, *e.g.*:

1) Reaction of 2-aminobenzothiazole *(10)* or 2-aminothiazole *(11)* with phosgene at −10 °C followed by heating the reaction mixture to 110 °C in chlorobenzene. Compound *(7)* or *(8)* is formed in 71 or 21 % yield respectively.

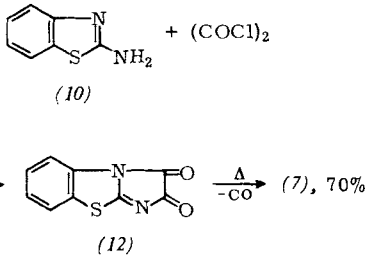


(10)



(11)

2) Reaction of *(10)* with oxalyl chloride (5 h, 70 °C, in benzene) and thermolysis of the crude product *(12)*.



3) Thermolysis of phenylurethanes. Compound *(9)* can be obtained particularly easily by this method.

New Synthesis of *P,P*-Diphenyl-*N,N*-bis(trimethylsilyl)phosphinamide

By *O. Schmitz-DuMont* and *W. Jansen*[*]

A suspension of the potassium salt of diphenylphosphinamide[1] in anhydrous ether reacts with trimethylsilicon chloride to form *P,P*-diphenyl-*N*-trimethylsilylphosphinamide *(1)*.

$$(C_6H_5)_2PNHK + ClSi(CH_3)_3 \rightarrow KCl + (C_6H_5)_2PNH{-}Si(CH_3)_3 \quad (1)$$

The resulting ethereal solution is filtered to remove KCl and evaporated to dryness. The residue is recrystallized from liquid NH_3. Compound *(1)* is obtained, in 60 % yield, as strongly doubly refracting, colorless needles, m.p. 41–42 °C, that are readily soluble is ether, dioxane, and benzene, but difficultly soluble in liquid NH_3 at −70 °C. IR spectrum in KBr: $\bar{\nu}$ (N–H) = 3230 cm^{-1} and $\bar{\nu}_{as}$ (Si–N–P) = 908 cm^{-1}. The structure

$$(C_6H_5)_2P[Si(CH_3)_3]{=}NH$$

is ruled out by the absence of the P=N band, which would appear at about 1300 cm^{-1}, and by the reaction of *(1)* with sulfur to form

$$(C_6H_5)_2P(S)NH{-}Si(CH_3)_3$$

[IR spectrum in $CHCl_3$: $\bar{\nu}$ (N–H) = 3355 cm^{-1}, $\bar{\nu}_{as}$(Si-P-N) = 908 cm^{-1}].

In liquid ammonia, compound *(1)* reacts with potassium amide to give the ether-soluble potassium salt *(2)*.

$$(C_6H_5)_2PN[Si(CH_3)_3]K \quad (2)$$

When an ethereal solution of this salt is treated with trimethylsilicon chloride it yields the bis(trimethylsilyl) compound *(3)*.

$$(C_6H_5)_3PN[Si(CH_3)_3]_2 \quad (3)$$

In compound *(3)*, both trimethylsilyl groups are bonded to the nitrogen atom. The structure

$$(C_6H_5)_3P[Si(CH_3)_3]{=}BN{-}Si(CH_3)_3$$

can be discounted since the P=N bands are not present in the IR spectrum and compound *(3)* reacts with sulfur to give

$$(C_6H_5)_3P(S)N[Si(CH_3)_3]_2$$

Compound *(3)*, which has also been obtained by another method[2], can be crystallized by dissolution in a small amount of benzene and subsequent passage of NH_3 at −20 °C. It forms colorless doubly refracting platelets, m.p. 49–50 °C, is readily soluble in ether, benzene, and chloroform but less so in liquid NH_3. Instead of one Si–N–P vibration at 908 cm^{-1}, the IR spectrum (in KBr) shows two very strong bands at 864 and 918 cm^{-1}, which can be assigned to the asymmetric vibrations of Si–N–P and Si–N–Si.

The recently reported[3] lithium salt

$$(tert\text{-}C_4H_9)_2PN[Si(CH_3)_3]Li$$

reacts differently from *(2)* to yield.

$$(tert\text{-}C_4H_9)_2P[Si(CH_3)_3]{=}N{-}Si(CH_3)_3.$$

Clearly the lone pair of electrons that is present on the phosphorus atom in the potassium salt *(2)* is involved to such an extent in the resonance system of the two phenyl groups that it is no longer available for the bonding of $(CH_3)_3Si^+$ to the phosphorus atom.

Preparation of Orotic Acid from 4-Chloromethyluracil

By *P. Rambacher* and *N. Kaniss*[*]

The attempted oxidation of readily accessible 4-methyluracil to orotic acid[1] by means of potassium hexacyanoferrate(III) gave the desired product only in poor yield. Oxidation of uracil-4-aldehyde[2] is also of little practical importance because the aldehyde itself is not readily available. However, if hydrogen peroxide is allowed to react, in alkaline solution, with 4-chloromethyluracil *(2)*, which can be easily prepared from urea and γ-chloroacetoacetyl chloride *(1)*, orotic acid is obtained in good yield.

4-Chloromethyluracil (2): A solution of *(1)*, which is prepared by passing chlorine (35.5 g) into a solution of diketene (38.5 ml) in trichloroethylene (125 ml) at 20 °C[3], is added over a period of 45 min to a solution of urea (30 g) in acetic anhydride (200 ml) that contains pyridine (41 ml) at 20 °C. The reaction mixture is stirred for 12 h, and on subsequent cooling with ice 29 g of a coarse crystalline product is precipitated. After recrystallization from 225 ml of glacial acetic acid 23.5 g of 4-chloromethyluracil is obtained. Contrary to values given by other workers for the melting point of 4-chloromethyluracil[4,5], the product we obtained melts at 240 °C with decomposition.

Orotic Acid: Compound *(2)* (8 g) is added over a period of 3 min to a solution of NaOH (12 g) in water (100 ml) and 35 % hydrogen peroxide (20 ml), the temperature being kept below 50 °C. The reaction mixture is stirred for 30 min and then allowed to run into a mixture of conc. hydrochloric acid (74 ml) and water (200 ml), whereupon orotic acid is precipitated (yield 6.5 g). The orotic acid obtained is practically pure and crystallizes with one mole of water. The product of the above synthesis is identical with that prepared from oxaloacetic ester and urea[6] or thiourea[7].

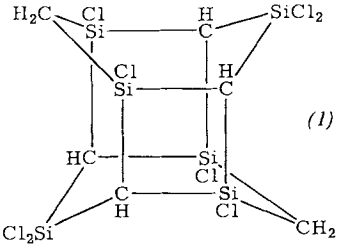
A Carbosilane $Si_6Cl_8C_6H_8$ with an Asterane Structure

By *G. Fritz*, *R. Haase*, and *H. Scheer*[*]

The compound $Si_6Cl_8C_6H_8$ *(1)* was isolated from the products of pyrolysis of CH_3SiCl_3. It is formed alongside 2,2,4,4,6,6,8,8-octachloro-2,4,6,8-tetrasilabicyclo[3.3.0]oct-1(5)-ene *(2)*[1].

The mass spectrum of *(1)* shows the molecular ion having the lowest isotopic masses at m/e = 527.67428 (the formula $Si_6Cl_8C_6H_8$ gives a molecular weight of 532 calculated for the lowest isotopic masses). The ^1H–NMR spectrum of *(1)* contains a resonance line at 94 Hz and a second one at 115 Hz in an intensity ratio of 1:1; these are ascribed to CH protons. Si–CH_3 can be ruled out on the basis of the positions of these signals. The number of protons in *(1)* could be determined ^1H–NMR spectroscopically by carrying out measurements on a mixture of known proportions of *(1)* and octamethylcyclotetrasiloxane and integrating the area of the signals arising from the protons in this mixture. Compound *(1)* contains two sets of four equivalent protons which are present in two CH_2 groups and four CH groups. According to their chemical properties, the eight chlorine atoms in compound *(1)* are all bonded directly to silicon atoms. The structure 1,3,3,5,7,9,9,11-octachloro-1,3,5,7,9,11-hexasilapentacyclo[6.4.0.0^{2,7}.0^{4,11}.0^{5,10}]dodecane *(1)* is in agreement with all experimental results.



(1)

Procedure:

Vaporized CH_3SiCl_3 is pumped by means of a circulating pump through a quartz tube heated to 700 °C, unreacted CH_3SiCl_3 being recirculated to the reaction zone. After 30 days, 2 to 3 liters of a mixture containing numerous silicon compounds is present[2]. On removal of Cl_3Si-CH_2-$SiCl_3$ and $(Cl_2Si–CH_2)_3$ by distillation, a mixture of colorless crystals is precipitated, which consists mainly of *(2)* and *(1)*. Compound *(2)* can be removed from the crystalline product by dissolution in diethyl ether, in which *(1)* is only difficultly soluble. When a saturated solution of *(1)* in CCl_4 at *ca.* 70 °C is allowed to cool slowly to room temperature, *(1)* crystallizes out as highly refractive white crystals, which sublime at 210 °C ($p_{atmospheric}$, N_2 atmosphere).

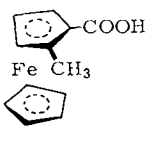
The Absolute Configuration of [2.2]Paracyclophanecarboxylic Acid

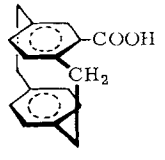
By *H. Falk* and *K. Schlögl*[*]

[2.2]Paracyclophanecarboxylic acid *(2)*[1] as well as metallocenecarboxylic acids, such as methylferrocene-α-carboxylic acid *(1)*[2], can be obtained in optically active form because of their special molecular geometry.

The closely related topology of the environment of the carboxyl group in the acids *(1)* and *(2)* enabled us to determine the absolute configuration of *(2)*, this being the first example of a planar chiral compound[3] with known absolute configuration.



(+)-*(1S)*-*(1)*



(+)-*(S)*-*(2)*

Kinetic resolution of the anhydride of racemic *(1)* with (−)-α-phenethylamine (in dry pyridine at 0 °C) affords the dextrorotatory acid in 6.5 % optical yield[4,5]; the absolute configuration of (+)-*(1)* has been established as (1*S*)[2] by two independent methods[6]. Analogous results were also obtained for other methylmetallocene-α-carboxylic acids[5]. Reaction of the anhydride of racemic [2.2]paracyclophanecarboxylic acid with (−)-phenethylamine yielded also the dextrorotatory carboxylic acid: $[\alpha]_D^{20} = +6.2°$ (*c* = 1 in $CHCl_3$). Optical yield: 3.9 %. The very similar topology of the reaction areas both in *(1)* and in *(2)* ought to determine the result of the kinetic resolution. Hence, the arrangements $COOH/CH_3$ and $COOH/CH_2$ in (+)-*(1)* and (+)-*(2)*, respectively, have the same chiralities, and (+)-*(2)* and its subsequent products[1] should consequently have the absolute configuration (*S*)[3].

In the case of *(2)*, as with the methylmetallocene-α-carboxylic acids[2,5], the salt formed from the (+)-acid and (−)-phenethylamine is the lesser soluble in ethanol. Two consecutive crystallizations afforded a salt ($[\alpha]_D^{20} = +97°$; *c* = 0.5 in $CHCl_3$), from which optically pure acid (+)-*(2)* could be isolated: $[\alpha]_D^{20} = +164°$ (*c* = 0.5 in $CHCl_3$); ref.[1] gives +160° (*via* the brucine salt).

Optically active acetyl[2.2]paracyclophane *(3)* ($[\alpha]_D^{20} = +65°$, *c* = 0.5 in $CHCl_3$) was obtained from (+)-*(2)* by reaction of the acid chloride with $Cd(CH_3)_2$.

Additional information as to the absolute configuration of *(2)* may be gained from ORD and CD studies on the ketone *(3)* and the acid *(2)*, but mainly from chemical correlations. These problems are now under investigation.

Preparation and Properties of Bis(phosphonylmethyl)phosphinates and Bis(dihydroxyphosphonylmethyl)phosphinic Acid[1]

By *Ludwig Maier*[*]

Bis(hydroxymethyl)phosphinic acid *(1)* can be chlorinated with $SOCl_2$[2] or PCl_5[3] to give bis(chloromethyl)phosphinyl chloride *(2)* in excellent yield.

$$(HOCH_2)_2P(O)OH + 3\ SOCl_2 \rightarrow (ClCH_2)_2P(O)Cl + 3\ HCl + 3\ SO_2$$
(1) *(2)*

Esterification of *(2)* with alcohols in the presence of a tertiary amine leads to good yields of bis(chloromethyl)phosphinates *(3)*, which undergo a Michaelis-Arbusov reaction when heated for several hours with trivalent phosphorus esters (phosphites, phosphonites, or phosphinites) at 170–180 °C. The reaction affords bis(phosphonylmethyl)-, bis(phosphinylmethyl)-, and bis(oxophosphinomethyl)phosphinates *(4)* in very good yields.

(4f)	H	C_6H_5	C_6H_5	m.p. 246–250 °C		83.0			

[a] With 85% H_3PO_4 as external standard. — [b] Decomposes on distillation.

Compound *(4f)* is formed by loss of ethylene at the reaction temperature of 170 °C. The same cleavage has been observed with other phosphinates[6].

The structures of compounds *(4a)*–*(4f)* were proved by ^{31}P- and ^1H–NMR spectroscopy. The ^1H–NMR spectrum of *(4a)* contains signals for CH_3 at δ = 1.30 (triplet, J_{HH} = 7 Hz, 15 H), PCH_2P at δ = 2.80 (quartet, $J_{P_\alpha H}$ = 18.5 Hz, $J_{P_\beta H}$ = 20.3 Hz, 3.94 H), $P_\alpha OCH_2$ at δ = 4.18, $P_\beta OCH_2$ at δ = 4.21 (J_{HH} = 7 Hz, J_{PH} = 7.8 Hz in both cases, total number of protons 10.13 H).

Hydrolysis of *(4a)* by refluxing with conc. HCl gives the free acid $HO(O)P_\alpha[CH_2P_\beta(O)(OH)_2]_2 \cdot 2\ H_2O$ as a viscous oil which does not crystallize but which gives a crystalline cyclohexylamine salt, m.p. 205.2 °C. On titration this acid behaves as a tetrabasic acid with breaks at pH = 5.2 (three equivalents) and at pH = 8.8 (one equivalent). The fifth proton can be titrated only after addition of NaCl. The ^{31}P–NMR spectrum of the acid shows signals at −37.3 ppm (P_α) and −17.5 ppm (P_β) in an intensity ratio of 1:2; its ^1H–NMR shows signals for PCH_2P at δ = 3.15 (quartet, $J_{P_\alpha H}$ = 18.2 Hz, $J_{P_\beta H}$ = 20.3 Hz, 4 H) and for OH + H_2O at δ =

The structure of compounds *(4)* was proved by ^{31}P- and ^{1}H–NMR spectroscopy. The ^{31}P–NMR spectrum of compound *(4a)* contains signals for P_α at –34.5 ppm and P_β at –21.3 ppm in an intensity ratio of 1:2. The ^{1}H–NMR spectrum also confirms the given structure: CH_3CH_2 at δ = 1.35 (J_{HH} = 7 Hz, 12 H), PCH_2P at δ = 2.71 and 2.76 ($J_{P\alpha H}$ = 15.6 Hz, $J_{P\beta H}$ = 20.5 Hz, 4.4 H), CH_2OP at δ = 4.15 and 4.18 (J_{HH} = 7 Hz, J_{PH} = 8.5 Hz, 8.05 H), and PCH_3 at δ = 1.81 (J_{PH} = 13.7 Hz, 3.3 H).

Hydrolysis of *(4c)* by refluxing with conc. HCl yields bis(dihydroxyphosphonylmethyl)dodecylphosphine oxide, $C_{12}H_{25}(O)P(CH_2PO_3H_2)_2$, which behaves as a tetrabasic acid on titration, with breaks at pH = 4 (two equivalents), pH = 6.9 (one equivalent), and pH = 9.6 (one equivalent). The acid, the disodium salt (m.p. 405–410 °C), and the tetrasodium salt (m.p. > 460 °C) are highly surface active and are excellent chelating agents.

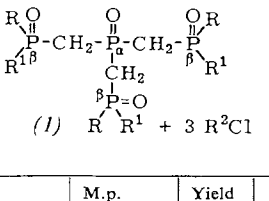
Preparation and Properties of Tris(phosphonylmethyl)phosphine Oxides and the Corresponding Acid[1]

By *Ludwig Maier*[*]

Tris(chloromethyl)phosphine oxide was first prepared by oxidation of tris(chloromethyl)phosphine with nitric acid[2] and it was later obtained in about 30% yield by chlorination of tris(hydroxymethyl)phosphine oxide with PCl_5[3]. We have found that the yield of $(ClCH_2)_3P{=}O$ can be increased to 60% if pure $(HOCH_2)_3P{=}O$ is used as starting material. A yield of 60% of $(ClCH_2)_3P{=}O$ is also obtained when $(ClCH_2)_3P$ is oxidized with bromine, whereas oxidation with H_2O_2 affords a mixture of $(ClCH_2)_3P{=}O$ and $CH_3(ClCH_2)_2PO$, the latter apparently being formed *via* a pseudoallyl rearrangement[4]. When recrystallized from water, tris(chloromethyl)-phosphine oxide forms lustrous crystals having m.p. 100 to 101.5 °C, ^{31}P–NMR (in $CHCl_3$) –39.2 ppm, ^{1}H–NMR (in $CDCl_3$) δ = 3.92 (J_{PH} = 6.5 Hz).

Like the bis(chloromethyl)phosphine oxides[1], tris(chloromethyl)phosphine oxide undergoes a Michaelis-Arbusov reaction when heated for several hours at 170 °C with trivalent phosphorus esters (phosphites, phosphonites, or phosphinites) to give tris(phosphonylmethyl)-, tris(phosphinylmethyl)-, and tris(oxophosphinomethyl)phosphine oxides *(1)* in good yields.



(1)

	R	R^1	M.p. (°C)	Yield (%)	^{31}P–NMR (ppm) [a] P_α	P_β	P_α:P_β
(1a)	CH_3O	CH_3O	169–171	5.7	−31.0	−22.8	1:3
(1b)	C_2H_5O	C_2H_5O	168–170	76.7	−34.0	−21.0	1:3
(1c)	iso-C_3H_7O	iso-C_3H_7O	85–87	85.0	−28.9	−18.6	1:3
(1d)	*n*-C_4H_9O	*n*-C_4H_9O	109–111	61.8	−29.7	−19.6	1:3
(1e)	2-Ethyl-hexyl-O-	2-Ethyl-hexyl-O-	oil	82.0	−29.3	−21.0	1:3
(1f)	C_4H_9O	C_6H_5	oil	83.7	−29.0	−34.7	1:3
(1g)	C_6H_5	C_6H_5	223–234	97.5	−31.0	−24.4	1:3

[a] In $CDCl_3$ with 85% H_3PO_4 as external standard.

Compounds *(1a)–(1e)* possess an extraordinarily high adsorption capacity. For example, a warm 2% solution of *(1b)* in benzene solidifies completely on cooling so that no benzene can be poured off.

The structure of compounds *(1a)–(1g)* was proved by ^{31}P- and ^{1}H–NMR spectroscopy. The ^{31}P–NMR spectrum of *(1b)* contains signals for P_α at −34.0 and P_β at −21.0 ppm (intensity ratio 1:3). The ^{1}H–NMR spectrum also agrees with the structure proposed: $\underline{CH_3CH_2}$ at $\delta = 1.30$ (J_{HH} = 7.0 Hz, 18 H), PCH_2P at $\delta = \overline{2.93}$ ($J_{P\alpha H}$ = 15.6 Hz, $J_{P\beta H}$ = 20.0 Hz, 6 H), and $POCH_2$ at $\delta = 4.15$ (J_{HH} = 7 Hz, J_{PH} = 7.9 Hz, 12.1 H).

Hydrolysis of *(1b)* by refluxing with conc. HCl as well as thermal decomposition of *(1c)* at 190 °C give tris(dihydroxyphosphonylmethyl)phosphine oxide $O{=}P_\alpha[CH_2P_\beta O_3H_2]_3$ in quantitative yield. The ^{31}P–NMR spectrum of the acid shows signals for P_α at −37.8 ppm and P_β at −15.3 ppm. On titration, two breaks are recorded at pH = 4.4 (three equivalents) and pH = 10.7 (three equivalents). The acid forms a crystalline cyclohexylamine salt (m.p. 190 °C) as well as trisodium and hexasodium salts. It is an excellent chelating agent.

ESR Measurements on Nitrogen-Fixing Titanium-Alkali Metal Systems[1]

By *G. Henrici-Olivé* and *S. Olivé*[*]

In recent communications[2,3] we suggested that negatively charged transition metal complexes with alkali metal counterions are formed during the reduction of transition metal salts with alkali naphthalide in tetrahydrofuran. We now present convincing ESR evidence for the existence of such transition metal-alkali metal interaction, in the particular case of dicyclopentadienyltitanium dichloride (Cp_2TiCl_2), after reduction with alkali naphthalide.

Several of the reduced transition metal complexes are able to fix and to reduce nitrogen under mild conditions[4]. A time-dependent nitrogen fixation has also been observed in the case of the titanium compound described here, and particularly after reduction with lithium naphthalide (LiNp), NH_3:Ti in molar ratios of 0.5, 0.7, and 0.96 being obtained after 2, 4, and 16 hours respectively (at $[Cp_2TiCl_2]_0 = 3\times10^{-2}$ mole/l; LiNp: Ti = 6 (mole/mole), and 1 atm of N_2).

If the reduction is carried out under argon, the reaction solution gives the ESR spectrum shown in Fig. 1a. At molar ratios Li:Ti between 3 and 4 this is the only signal observed. Its intensity has a maximum at Li/Ti = 3.5, and is nearly zero at Li/Ti = 4.0. At higher ratios the signal of LiNp appears. The ESR spectrum shown in Fig. 1a disappears if the argon is subsequently replaced by nitrogen. If the reduction is carried out from the very beginning under nitrogen, conditions under which the system fixes N_2, the spectrum does not appear at all.

The predominant hyperfine splitting (HFS) in the spectrum of Fig. 1a has the intensity distribution 1:2:1, indicating the interaction of the unpaired electron(s) of the titanium with two equivalent hydrogen nuclei within the complex. The relatively high coupling constant (see Table 1) points to Ti–H bonds. Each of the three lines is further split into four equidistant lines of equal intensity. In the present system this can be due only to interaction with one Li nucleus (nuclear spin I = 3/2).

Furthermore, a relatively weak interaction with aromatic hydrogen atoms is to be observed which splits each of the twelve lines mentioned into an odd number of very narrow lines, although well resolved only at $T \leqslant 0$ °C. These protons are situated on the Cp-rings, which are not eliminated during the reduction with LiNp. The spectrum also shows pronounced line width effects in the hydrogen as well as in the lithium HFS that are probably due to anisotropy of the g-value and the hyperfine tensors. However, these effects have not yet been quantitatively interpreted.

A very similar spectrum is obtained if the reduction is carried out with NaNp (Fig. 1b; only the high field part of the spectrum is shown). Whereas the 1:2:1 hydrogen splitting is identical for both complexes, the 1:1:1:1 sodium splitting (I_{Na} = 3/2) is considerably greater than that of the lithium

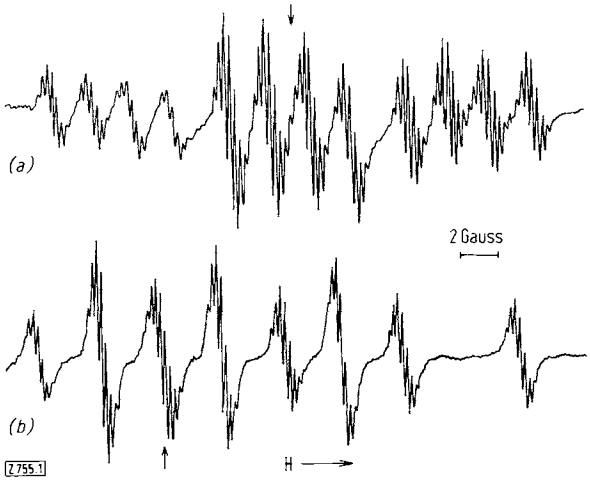

Fig. 1. ESR spectra of the reaction solutions (a) Cp_2TiCl_2 + LiNp and (b) Cp_2TiCl_2 + NaNp at −40 °C in tetrahydrofuran under argon. Arrows indicate center of spectra.

(Table 1); as a consequence, the three quadruplets, which are clearly separated in the upper spectrum, become superimposed in the lower one, the last line of the first and the first line of the last quadruplet coinciding in the center of spectrum 1b.

Table 1. ESR parameters of the complexes formed from Cp_2TiCl_2 and alkali naphthalides.

Alkali naphthalide	g-value	T (°C)	a_H (1:2:1) (gauss)	a_H (aromatic) (gauss)	$a_{alkali\ metal}$ (gauss)
LiNp	1.9938	20	9.5	–	2.5
		0	9.8	0.27	2.4
		−40	9.6	0.27	2.3
		−80	9.5	0.25	2.1
NaNp	1.9938	20	9.5	0.23	6.3
		−40	9.8	0.23	6.7

Second derivative representation of one of the line groups (Fig. 2) shows that the aromatic HFS consists of an odd number of lines. Nine lines can be detected, the intensity distribution of which makes it probable that ten hydrogen atoms, *i.e.* two Cp-rings, are the cause of this HFS. (The extreme lines, the intensities of which are only 0.4/100 of that of the center line, cannot be seen [11]).

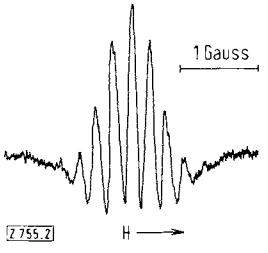

Fig. 2. Second derivative representation of the last high field group of lines of the spectrum of Fig. 1b.

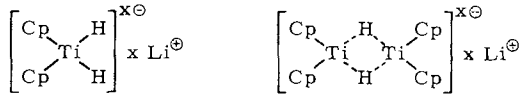
It should be noted that the reaction solution is only weakly paramagnetic at molar ratios $3 < Li:Ti < 4$, and a rough double integration [5] of the ESR spectra intensities accounts only for 10–20 % of the Ti possessing one unpaired electron.

The ESR data suggest either of the two structures:



(1) *(2)*

where x is the number of negative charges, as in the complexes described previously [2, 3]. Presumably several complexes, with varying x, are in equilibrium, but only one is ESR active.

A complex $Cp_2Ti(III)H_2Ti(III)Cp_2$ (*i.e.* a species analogous to *(2)*, but with $x = 0$) has been suggested by *Brintzinger* for the reaction product of Cp_2TiCl_2 and ethylmagnesium chloride in tetrahydrofuran [6]; however, this suggestion was recently rejected in favor of a complex analogous to *(1)* [7]. Also in the present case a dimeric structure containing two Ti(III) species is highly improbable, since no evidence could be detected for the existence of a triplet state (no "half field line" [8], no dipole-dipole interaction in rigid media at low temperatures [9]). The observation, on the other hand, that under nitrogen a molar ratio of NH_3: Ti = 1 (*i.e.* N_2: Ti = 0.5) could not be exceeded, points strongly to a complex containing two Ti atoms. Thus, most probably, structure *(2)* has to be considered, the ESR active species being that with $x = 1$, *i.e.* with only one unpaired electron per complex unit.

The extraordinarily high coupling constants of the alkali metals (Table 1), which indicate about 2.4 % and 2.0 % of unpaired spin density at the Li and Na nucleus respectively, show that these metals must be relatively tightly bound to the Ti, presumably within the inner coordination sphere. This is consistent with the observed low temperature-dependence of the alkali metal splitting, suggesting little or no ionic dissociation.

Concerning the fixation of nitrogen it is assumed at the present stage of the investigation that a similar mechanism is at work as that suggested recently for other reduced metal complexes [4]: the negative charges of the complexes are used up for the reduction of the nitrogen molecule.

A Productive Method for the Preparation of Geminal Chloronitroso Compounds

By *H. Diekmann* and *W. Lüttke* [*]

Several methods are known for the preparation of geminal chloronitroso compounds $R^1R^2C(NO)Cl$ [1–7], all except one [2] being based on the reaction of oximes with chlorinating agents containing positively polarized chlorine. We have found that treatment of the oximes with alkyl hypochlorites in trichlorofluoromethane represents a method possessing considerable advantages over previous processes: In all cases investigated the yields are almost quantitative; the products are obtained in a high state of purity; and the mild reaction conditions even permit smooth preparation of the very unstable chloronitroso compounds that are derived from aldoximes.

The alkyl hypochlorites used as chlorinating agents are either isolated as such or are prepared in solution [8] by shaking the corresponding alcohol in trichlorofluoromethane with aqueous hypochlorous acid. The solution, whose hypochlorite content can be checked iodometrically, can be used directly for the reaction with the oxime. With most oximes the reaction proceeds smoothly and is complete within a few minutes, even at temperatures as low as −70 °C. It is only in the case of highly substituted reactants, such as *tert*-butyl methyl ketoxime and *tert*-butyl hypochlorite, that the reaction mixture has to stand at room temperature for about half an hour. As a rule, the pre-cooled hypochlorite solution was added dropwise and rapidly to a solution of the oxime kept at −40 °C in a cryostat, the operation being carried out in a darkened room. The reaction mixture was gradually warmed to room temperature while being stirred. If the oxime is insufficiently soluble in trichlorofluoromethane, chloroform is added to the mixture. Product recovery can be executed mildly and simply by virtue of the low boiling point of tri-

chlorofluoromethane (23 °C/760 torr). After the solvent has been evaporated off, if necessary under reduced pressure, the highly volatile, monomeric chloronitroso compounds are fractionally distilled. (Note: to facilitate separation the hypochlorite should be prepared from an alcohol having a sufficiently different boiling point.) The less volatile chloronitroso compounds are either recrystallized from a suitable solvent (*e.g.* methanol) or may be distilled or sublimed under vacuum. Products obtained from aldoximes are precipitated from the reaction solution as colorless nitroso dimers.

No appreciable interference occurs when the reaction is carried out in the presence of compounds having olefinic double bonds. In a competition experiment, a 1:1 mixture of 1-pentene and acetone oxime was treated with 1.05 equivalents of *tert*-butyl hypochlorite; the yield of chloronitroso compound was not affected.

R^1	R^2	$R^1R^2C(NO)Cl$ B.p. (°C/torr)	M.p. (°C)	Yield (%) [b]
H	CH_3		65 (dimer)	> 90
H	C_6H_5		35 (dimer) [a]	> 90
CH_3	CH_3	8/20		> 95
CH_3	$C(CH_3)_3$		122	> 95
CH_3	n-C_4H_9	45/20		> 95
CH_3	$CH_2-C_6H_5$		12	> 95
$-(CH_2)_5-$		52/12		> 95

[a] When heated rapidly the compound melts at about 35 °C with development of a deep blue color, which gives way within a few seconds to the pale yellow color of the rearrangement product α-chlorobenzaldoxime.

[b] The yields were determined spectrophotometrically, measurement being conducted on the n-π* transition of the chloronitroso compound, which lies at about 650 nm. The homogeneity of the product was examined on the basis of this absorption, the NMR spectra, and the melting point or boiling point.

Asymmetric Synthesis of Geminal Chloronitroso Compounds

By *H. Diekmann* and *W. Lüttke* [*]

Optically active chloronitroso compounds, which are of interest for mechanistic investigations and, on account of the isolated absorption band of their n-π* transition ($\lambda_{max} \approx$ 650 nm), for ORD measurements, were first obtained by *Mitchell et al.* [1–3]. A reaction reported by us [4] opened up the possibility of an asymmetric synthesis of α-chloronitroso compounds by treatment of a suitable oxime with hypochlorites of optically active alcohols. Asymmetric synthesis has advantages over chemical separation for the preparation of rather unstable chloronitroso compounds; moreover, the reaction is less time-consuming but generally it proceeds only stereoselectively. The results obtained on reaction of phenylacetone oxime with a number of different alkyl hypochlorites are given in Table 1. According to the results, the hypochlorite of the readily accessible (−)-isoborneol [5] is, up to the present, the most effective asymmetric reaction partner. The dextrorotatory form of 2-chloro-2-nitroso-1-phenylpropane was obtained only with (−)-neoisopinocampheol; all other alcohols led to the formation of the levorotatory antipodes.

Table 1. Results of the reaction of alkyl hypochlorites of various alcohols with phenylacetone oxime.

Alcohol	$[\alpha]_D^{20}$	React.temp. (°C)	Products $[\alpha]_D^{20}$ [a]
(−)-Isoborneol (1 *R*:2 *R*)	−27.5 ° (c = 0.9; ethanol)	−78	−58 °
(−)-2-Methyl-isoborneol (1 *R*:2 *R*)	−26.2 (c = 2.6; ethanol)	−74	−15.8 °
(−)-Neoiso-pinocampheol (1 *S*:2 *S*:3 *R*)	−35.4 ° (c = 2; benzene)	−76	+18.2 °
(−)-Menthol (1 *R*:3 *R*:4 *S*)	−48 ° (c = 2; ethanol)	−76	−16.4 °
(−)-1-Phenyl-ethanol (*S*)	−47.5 ° (c = 3.6; methanol)	−78	−13.2 °

[a] 2-Chloro-2-nitroso-1-phenylpropane.

Table 2 contains the results obtained on reaction of isobornyl hypochlorite with several different methyl ketoximes.

Table 2.

Oxime	React.temp. (°C)	Product $[\alpha]_D^{20}$
tert-Butyl methyl ketoxime	−70	− 9.8 °
Cyclopropyl methyl ketoxime	−78	−106 °
n-Butyl methyl ketoxime	−78	− 8.4 °
Methyl-i-propyl ketoxime	−78	− 28 °
2,2-Dimethylcyclohexanone oxime	−86	− 8.6 °

The preparations are carried out in the same manner as described in a previous report [4]; however, in order to achieve high stereoselectivity the reactions should be carried out as slowly as possible by reducing the temperature. The reaction products can be worked up by chromatography on silica gel (particle size less than 0.08 mm, deactivated with 10 % water) using petroleum ether (b.p. 35–40 °C) as solvent.

We thank Dr. *F. Woldbye* of the Tekniske Høgskole, Lyngbye (Denmark) for the measurement of an ORD curve of 2-chloro-2-nitroso-1-phenylpropane. It shows the expected Cotton Effect for the absorption maximum of the n-π* transition at 650 nm.

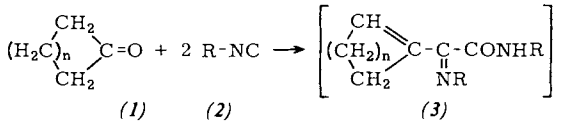
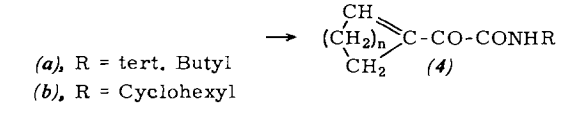
Synthesis of Substituted Oxetane-2,3-diimines from Isocyanides

By *H.-J. Kabbe* [*]

Reaction of alicyclic ketones *(1)* (n = 2–5, 9) with the isocyanides *(2a)* and *(2b)* in the presence of approximately equimolar amounts of boron trifluoride ether affords up to 40 % yields of the unsaturated oxo acid amides *(4)* if the ketimines *(3)* assumed to be formed as intermediates are hydrolyzed by acid at the end of the condensation [1].



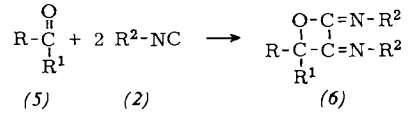
(1) *(2)* *(3)*



(a), R = tert. Butyl
(b), R = Cyclohexyl

(4)

If, however, the reaction is effected in the presence of only catalytic amounts (2–3 mole-%, calculated on the ketone) of boron trifluoride ether and the mixtures are worked up under neutral or weakly basic instead of acid conditions, then the substituted oxetane-2,3-diimines *(6)* are obtained, some of them in very good yield.



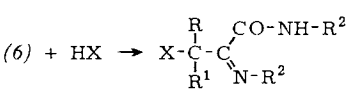
(5) *(2)* *(6)*

R	R^1	R^2	*(6)*, yield (%)	*(6)*, m.p. (°C) [b.p. (°C/torr)]
CH_3	H	*tert*-Butyl	91	[78/12]
CH_3	CH_2Cl	*tert*-Butyl	92	48–50 [65/0.05]
C_6H_5	H	*tert*-Butyl	74	75–76
$-(CH_2)_5-$		*tert*-Butyl	93	55–57
CH_3	CH_3	Cyclohexyl	60	57–59 [120/0.05]
$(CH_3)_2CH$	H	Isobutyl	75	[95/0.01]
CH_3	H	Allyl	53.5	[80/0.06]

Not merely ketones but also aldehydes can be used as the carbonyl components *(5)*; they may contain halogen, ester, ether, nitro, or alkylthio groups.

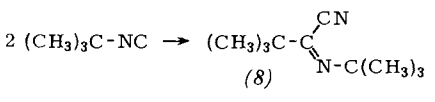
All the oxetanes *(6)* studied so far are characterized by a double band in the IR spectrum between 1720 and 1730 cm^{-1}.

The oxetanes *(6)* may be opened with different reagents H–X (acids, amines, or water) to give amides *(7)*.



(7)

During the course of these investigations it was found that *tert*-butyl isocyanide is dimerized to the nitrile *(8)* in 70 % yield by catalytic amounts of boron trifluoride.



(8)

Synthesis of (6), $R = CH_3$, $R^1 = H$, R^2 = tert-butyl:

Acetaldehyde (88 g, 2 moles), *tert*-butyl isocyanide (460 ml, 4 moles), and light petroleum (400 ml) are stirred together and treated over a period of 15 min with a solution of BF_3-ether (5 ml, 0.04 mole) in ether (200 ml) while being cooled in a CO_2 bath at −15 °C. The temperature of the mixture in a melting ice bath rises from 0 to 20 °C during 20 h. Then the mixture is stirred with saturated sodium hydrogen carbonate solution (400 ml) and extracted with ether. The extract is dried over Na_2SO_4 and distilled, giving *N,N'*-di-*tert*-butyl-4-methyloxetane-2,3-diimine (yield 381 g, 91 %).

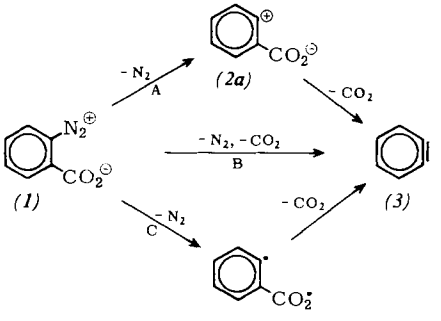
Mechanism of Formation of Dehydrobenzene from Benzenediazonium-2-carboxylate

By *R. Gompper*, *G. Seybold*, and *B. Schmolke* [*]

In recent years benzenediazonium-2-carboxylate *(1)* has been frequently used as starting material for the synthesis of dehydrobenzene *(3)* [1] since it is easy to prepare [2] and reacts at low temperatures to form secondary products of dehydrobenzene in relatively high yields [3].

The decomposition of *(1)* into *(3)* could proceed either synchronously (mechanism B) or asynchronously (mechanisms A and C).

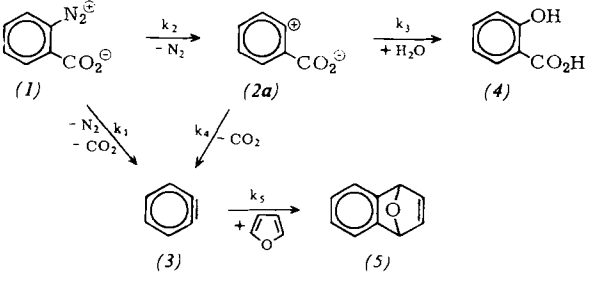


(1) *(2a)* *(3)*

Reaction of *(1)* with water leads to the formation of salicylic acid *(4)* [4] in good yield. This can be assumed to be an S_N1-reaction in which the intermediate *(2a)*, or a similar intermediate is formed (preliminary measurements of the rate of decomposition of *(1)* in acetonitrile/water mixtures support this assumption).

If *(1)* is allowed to decompose in acetonitrile/water/furan mixtures, salicylic acid *(4)* and 1,4-epoxy-1,4-dihydronaphthalene *(5)* can be isolated in overall yields of *ca.* 85 %.

If *(3)* were liberated from *(1)* *via* mechanism B the formation of *(5)* and of *(4)* would be two independent reactions, in which the water concentration does not have any influence on the yield ratio $Q_1 = (5)/(4)$ (which has the constant value $K_B = k_1/k_2$).



(1) *(2a)* *(4)* *(3)* *(5)*

In the case of mechanism A, however, Q_1 does depend on the water concentration. If concentration values are chosen such that $[H_2O] \gg [(1)]$ and it is assumed that $k_5 \gg k_4$[5] then by the method of the quasistationary state

$$Q_1 = k_4/k_3\,[H_2O] \text{ or } Q_1\,[H_2O] = k_4/k_3 = K_A$$

Results obtained in nine experiments are shown in Table 1 [the yields of *(5)* and *(4)* were determined gravimetrically:

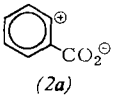
Table 1. Formation of *(4)* and *(5)* from *(1)* [results from nine experiments].

Expt.	[(1)] (mmole/liter)	$[H_2O]$ (mole/liter)	[Furan] (mole/liter)	Total Yield [a] (%)	Q_1 mmole *(5)* / mmole *(4)*	K_A (mole/liter)
a	61.1	1.88	1.48	90.4	2.50	4.70
b	78.0	3.70	1.48	89.7	1.21	4.48
c	69.3	5.56	1.48	86.3	0.71	3.95
d	46.9	1.30	1.13	82.4	2.94	3.93
e	57.6	2.59	1.13	81.8	1.83	4.74
f	43.6	3.86	1.11	94.8	1.28	4.94
g	32.2	2.23	0.56	84.0	1.74	3.88
h	18.7	2.30	0.88	83.4	1.61	3.71
i	21.2	2.24	1.14	84.4	1.97	4.42
					Mean =	4.30

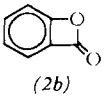
[a] Determined as α-naphthol + dibromosalicylic acid.

(5) as α-naphthol[6], *(4)* as dibromosalicylic acid[7]; the reactions solutions – 150 ml to 250 ml – were homogeneous throughout the duration of the experiment (36 h at 25 °C)]. The ratio Q_1 is inversely proportional to the water concentration; the constancy of K_A appears, in view of the complicated working up, to be quite satisfactory. The experiments (g) to (i) in which the water concentration was kept constant and the furan concentration was varied, show that not only is Q_1 independent of the furan concentration but also indicate that the whole of *(3)* is trapped by furan with formation of *(5)* [phenol, which could be formed from *(3)* and water, could not be detected gas chromatographically].

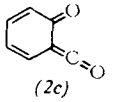
The reactions leading to the formation of *(3)*, *(5)*, and *(4)* from *(1)* are not independent of one another, but involve a common step and thus a common intermediate. Concerning the nature of this common intermediate, one must take into consideration the fact that the valence isomers *(2c)* and



(2a)



(2b)



(2c)

(2b) could in fact exist in a rapidly established thermodynamic equilibrium with the intermediate *(2a)*. One would expect that the intermediate *(2a)* would react with the excess of acetonitrile available (cf. ref.[8]). However, the formation of *N*-acetylanthranilic acid could not be detected. Further, the fact that the formation of *(3)* is possible in such a nucleophilic solvent as dimethyl sulfoxide[9] indicates (cf. also ref. [10]) that *(2a)* plays but a secondary role. The decomposition of *(1)* in acetonitrile/methanol/furan mixtures affords further information about the nature of the intermediate (reaction conditions analogous with those given above). The reaction mixture contains mainly *(5)*, some methyl salicylate, and a little anisole. The yield ratio Q_2 = [*(5)* + anisole]/[methyl salicylate] is inversely proportional to the methanol concentration (Table 2).

Table 2. Formation of *(5)*, anisole, and the methyl ester of *(4)* from *(1)* [results from six experiments].

Expt.	[(1)] (mmole/liter)	$[CH_3OH]$ (mole/liter)	[Furan] (mole/liter)	Q_2 mmole ((5) + anisole) / mmole (4)-methyl ester	$Q_2\,[CH_3OH]$ (mmole/liter)
a	12.7	5.00	1.06	19.25	96.3
b	19.3	6.24	1.18	16.50	102.9
c	18.0	7.50	1.10	14.35	107.6
d	19.4	8.77	1.19	12.15	106.7
e	12.8	10.14	0.99	10.18	103.2
f	16.9	11.32	1.04	9.19	104.0
				Mean =	103.4

The results indicate that *(5)* and methyl salicylate are also formed *via* a common intermediate.

Methyl salicylate can be formed from *(2b)* as well as from *(2c)*. However, the only route to *(3)* *via* elimination of CO_2 is from *(2b)*. If *(2b)* were in equilibrium with *(2c)* the equilibrium would be accessible also from *(2c)* or from suitable precursors; investigation of this is in progress. There are several indications that suggest the occurrence of *(2b)* (cf. ref.[3]); however, no conclusive evidence is as yet available.

Hydrogen-Deuterium Exchange in Alkoxyalkylcarbene-Transition Metal Complexes

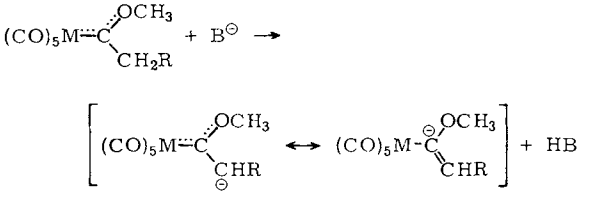
By *C. G. Kreiter*[*]

Replacement of a hydrogen atom in methane by substituents of the type $-NO_2$, $-CHO$, $-COCH_3$, or $-COOR$ leads to enhanced reactivity of the remaining methyl hydrogen atoms. A measure of this reactivity is afforded, for example, by the comparison of coupling reactions of active methylene compounds[1] or by exchange of the protons on the C-atom for deuterium[2]. The bonding of the carbene residue in pentacarbonylphenylmethoxycarbenechromium(0), as determined by X-ray analysis[3], resembles closely that of methyl benzoate. The reactions of various carbene complexes with ammonia or amines also show a certain similarity between the complexes and esters [5]. We have investigated whether the protons of a methyl group attached to the RO–C(M)– residue are as activated as those of a methyl group attached to a RO–C(O)– residue.

$(CO)_5MC(CH_3)OCH_3$ [M = Cr, Mo, W] and π-$CH_3C_5H_4(CO)_2MnC(CH_3)OCH_3$[4] were dissolved in [*O*–D]-methanol at room temperature (99 % D). When catalytic amounts of sodium methoxide[6] are added to the mixture its ^1H–NMR spectrum reveals an immediate exchange of the protons of the $C-CH_3$ group in the carbene residue of the complex. However, the exchange proceeds so rapidly that it cannot be followed ^1H–NMR spectroscopically. Nitromethane is the only substituted methane that exhibits such a rapid H/D exchange under similar conditions.

In the case of acetone and of acetonitrile the rate of exchange of methyl protons for deuterium is orders of magnitude slower[2]. No H/D exchange has been observed in the case of methoxymethylcarbene complexes in [*O*–D]-methanol without sodium methoxide, or in presence of some [D_2]-sulfuric acid.

Ethylmethoxycarbenepentacarbonylchromium(0) possesses activated methylene protons which are similarly replaced very rapidly by deuterium. One can observe the disappearance of the signal of the methylene protons and the collapse of the three components of the triplet of the methyl protons to a somewhat broadened singlet. We assume that the H/D exchange is made possible by virtue of the ready formation of an anion. Stabilization would be possible by the donation of the negative charge in the "vacant" p_z orbital of the carbene C-atom. Methanolic solutions of equivalent amounts of



$(CO_5)MC(CH_2R)OCH_3$ and sodium methoxide become deep red-brown at room temperature and the corresponding hexacarbonylmetals very soon separate out. The compounds deuterated on the $C-CH_2R$ group can be isolated from the solutions in [*O*–D]-methanol with small concentrations of methoxide.

Similarly, the alkoxy group is slowly exchanged in the presence of base catalysts. Ethoxymethylcarbenepentacarbonylchromium(0) reacts with an excess of methanol in the presence of sodium methoxide within a few days at room temperature to give almost quantitative yields of pentacarbonylmethoxymethylcarbenechromium(0).

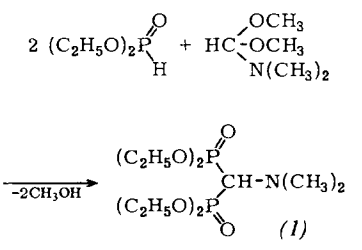
Synthesis of Carboxylic Acids *via* PO-Activated Olefination of Tetraethyl Dimethylaminomethylenediphosphonate

By *H. Gross* and *B. Costisella*[*]

We have succeeded in preparing the hitherto unknown compound tetraethyl dimethylaminomethylenediphosphonate *(1)* (yield 60–62 %, b.p. 114–115 °C/0.03 torr) by warming a mixture of dimethylformamide acetal and 2 moles of diethyl phosphite to 60–80 °C for a short period and then distilling the product under high vacuum. The NMR spectrum of *(1)* (in CCl_4, 60 MHz) contains the following signals: $\tau_{CH_3-CH_2}$ = 8.68 triplet (J = 7 Hz), 5.88 multiplet (J = 4 Hz); $\tau_{N(CH_3)_2}$ = 7.41 triplet (J = 1.5 Hz); $\tau_{=CH-}$ = 6.80 triplet (J = 25 Hz); proton ratio = 12:8:6:1.

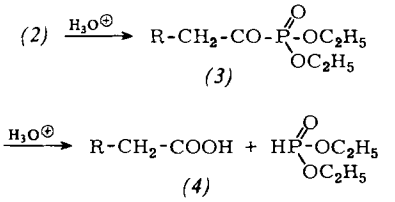


If compound *(1)*, which contains a highly acidic proton, is allowed to react first with sodium hydride and then with aldehydes (equimolar quantities) in dioxane solution according to the Horner olefination method[1], the likewise hitherto unknown compound diethyl 1-dimethylaminoalkenylphosphonate *(2)* is obtained by pouring the reaction mixture into water, extracting into ether, and then distilling the organic phase.

	R	B.p. (°C/torr)	Yield (%)
(2a)	C_6H_5	105–106/0.01	66
(2b)	4-NO_2–C_6H_4		64
(2c)	3,4-(–OCH_2O–)C_6H_3	150–153/0.02	75
(2d)	C_6H_5–CH=CH–	135–139/0.01	60

NMR spectrum of *(2a)*: $\tau_{CH_3-CH_2}$ = 8.67 triplet (J = 7Hz), 5.9 multiplet (J = 8 Hz); $\tau_{N(CH_3)_2}$ = 7.4 doublet (J = 2 Hz); $\tau_{=CH-}$ = 3.36 doublet (J = 15 Hz); $\tau_{C_6H_5}$ = 2.48 to 2.82 multiplet; proton ratio = 6:6:4:1:5.

If the phosphonates *(2)* are dissolved in 2 N hydrochloric acid, the acylphosphonates *(3)* are precipitated as oils that can be purified by distillation.



NMR spectrum of *(3)* [R = C_6H_5, b.p. 100 °C/0.04 torr, yield 66 %]: $\tau_{CH_3-CH_2}$ = 8.72 triplet (J = 7 Hz), 5.96 multiplet (J = 4 Hz); τ_{CH_2} = 6.5 singlet; $\tau_{C_6H_5}$ = 2.81.

	R	M.p. (°C)	Yield (%) [a]
(4a)	C_6H_5	72–74	75 (44)
(4b)	4-NO_2–C_6H_5	143–145	80 (46)
(4c)	3,4-(–OCH_2O–)C_6H_3	126–128	90 (68)

[a] The yields are calculated with respect to pure or crude *(2)*; those in parentheses are calculated on the amount of aldehyde.

Acylphosphonates of type *(3)* are hydrolyzed smoothly in strongly acid media to carboxylic acids *(4)* and dialkyl phosphites[2]. It is not necessary to isolate *(3)* in order to prepare the carboxylic acids *(4)*; if the crude product *(2)* is dissolved in concentrated hydrochloric acid, rapidly heated to boiling, and then cooled the required carboxylic acid is precipitated in some cases in pure form (according to its melting point).

This process permits the ready synthesis of carboxylic acids from the aldehydes containing one less carbon atom. Ketones do not react under the conditions described.

Diethyl 1-dimethylaminostyrylphosphonate (2a)

A solution of *(1)* (3.31 g, 0.01 mole) in dry dioxane (5 ml) is added dropwise at room temperature to a suspension of NaH (0.24 g, 0.01 mole) in dry dioxane (5 ml) (liberation of H_2, temperature of reactants increases to 38 °C). When the reaction has subsided, benzaldehyde (1.06 g, 0.01 mole) is added and the reaction mixture is heated to 60 °C for 1 h. The mixture is finally poured into water, extracted three times with ether, and dried over Na_2SO_4. 1.70 g (66.5 %) of *(2a)* is obtained on distillation.

Phenylacetic acid (4a)

A sample of *(2a)* (2.83 g) is boiled briefly with conc. HCl (5 ml), the mixture is allowed to cool and diluted with water; the acid that is precipitated is filtered off under suction. 1.0 g (74 %) of *(4a)* is obtained after drying over P_4O_{10}.

High-temperature Synthesis of Amino Acids in the System Acetylene/Ammonia/Carbon Dioxide

By *K. Samochocka, A. L. Kawczynski*, and *M. Taube* [*]

The abiogenetic synthesis of amino acids under conditions such as those prevailing in a primeval atmosphere[1] is usually assumed[2] to proceed according to the scheme of the Strecker reaction:

$$\text{Substrate} \xrightarrow{\text{Pyrolysis}} \text{Radicals} + H_2$$

$$\text{Radicals} + {}^*CO_2 \rightarrow {}^*R\text{–}C(=O)H$$

$${}^*CO_2 + H_2 \rightarrow {}^*CO + H_2O$$

$${}^*CO + NH_3 \rightarrow H{}^*CN + H_2O$$

$$C_2H_2 + NH_3 \xrightarrow{\text{Pyrolysis}} \text{HCN} + \text{other products}$$

$${}^*R\text{–}C(=O)H + HCN \rightarrow {}^*R\text{–}HC(OH)\text{–}CN$$

$${}^*R\text{–}HC(OH)\text{–}CN + NH_3 \rightarrow {}^*R\text{–}HC(NH_2)\text{–}CN$$

$${}^*R\text{–}HC(NH_2)\text{–}CN \xrightarrow{\text{Hydrolysis}} {}^*R\text{–}CH(NH_2)\text{–}CO_2H$$

If $^{14}CO_2$ is used in the synthesis, and if the reaction does in fact proceed according to the Strecker reaction scheme, the amino acids which are formed ought to be labeled in the side chain and in the carboxyl groups.

We used the following gas mixtures:

(i) $C_2H_2 + NH_3$ (1:1 mole/mole)

(ii) $C_2H_2 + NH_3 + {}^{14}CO_2$ (1:1:1)

The gas mixtures were fed through a quartz tube heated at 600 °C (diameter of tube 0.8 cm; rate of flow of gas 500 to 520 cm^3/min) and then collected in water. The resulting solution was heated at 70 °C for 35 hours and then evaporated under vacuum. The residue thus obtained was taken up in 5 N HCl and heated at 70 °C for 5 hours. Subsequent evaporation in vacuum afforded the amino acids, which were analyzed by high-voltage paper electrophoresis (50 V/cm). The results of analysis are given in the Table. In both systems the total yield of amino acids amounted to about 1 % (referred to the amount of ammonia used).

$C_2H_2 + NH_3$		$C_2H_2 + NH_3 + {}^{14}CO_2$	
Gly	β-Ala	Gly	β-Ala
Ala	β-Phe	Ala	β-Phe
Phe	Try	Phe	Leu
Ser	Asp	Ser	Val
Thr		Thr	Lys
			Arg

Remarkably, not one of the amino acids obtained proved to be radioactively labeled. Further, we did not obtain any radioactively labeled carboxylic acids[3], and in the system $C_2H_2 + NH_3 + CO_2$ no carbohydrates. It follows then that the CO_2 does not take part in the reaction; nor does the reaction proceed according to the Strecker reaction scheme. The latter statement is further supported by the fact that we obtained β-amino acids that cannot occur in a Strecker type synthesis.

This work was supported in part by the International Atomic Energy Agency (Research Contract No. 562/RB).

Macromolecular Colloquium

The Macromolecular Colloquium was held in Freiburg/Br. from February 29 to March 2, 1968.

From the lectures:

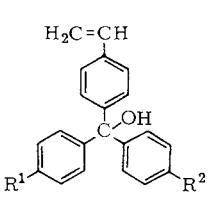
Recent Studies on the Preparation of Stable Polyradicals

By *D. Braun, R. J. Faust,* and *B. Meier*[*]

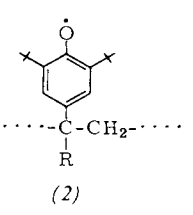
Whereas neutral macromolecular substances and polyions have been extensively studied, very little is known about macromolecules having stable free-radical monomer units. Polymers having an unpaired electron in many or, in the ideal case, in all of their monomer units are known as polyradicals[1].

Polymeric triarylhydrazyls and polyradical-ions have already been described[2]. Polycarbon radicals and polyoxygen radicals have now been synthesized.

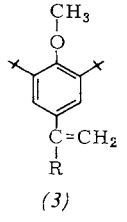
Polymers or copolymers of 4-vinyltriarylmethanols *(1)* can be converted into polymeric triarylmethyl chlorides, which react with zinc or alkali metals in the complete absence of water and oxygen to form polymeric triarylmethyl radicals. The polyradicals react with an excess of alkali metal to form polyanions; reaction with oxygen leads first to polymeric peroxy radicals, which then crosslink with formation of peroxides. The poly-4-vinyltriarylmethyl radicals disproportionate slowly in light to give diamagnetic products containing triarylmethane and quinodimethane groups.



(1a), $R^1 = R^2 = H$
(1b), $R^1 = H$; $R^2 = C_6H_5$
(1c), $R^1 = R^2 = C_6H_5$



(2)



(3)

R = H, CH_3
—+ = $C(CH_3)_3$

Polyphenoxyls of the type *(2)* can be prepared by dehydrogenation of sterically hindered polyphenols with lead dioxide in an inert atmosphere. The starting materials are obtained *e.g.* by cationic homopolymerization or copolymerization of 4-vinyl- or 4-isopropenyl-2,6-di-*tert*-butylphenol, or by polymerization of *(3)* followed by cleavage of the ether linkages with alkali metal. When R = CH_3, a polyradical analogous to 2,4,6-tri-*tert*-butylphenoxyl is obtained; this polyradical is very stable in an inert atmosphere. The polyphenoxyls obtained with R = H are much more stable than the low molecular weight model.

Nuclear Magnetic Resonance Spectroscopy of Tactic Copolymers

By *E. Klesper, H.-J. Cantow,* and *W. Gronski*[*]

If we consider the formation of binary copolymers from two monosubstituted α-olefins, there are many possible arrangements since each of the monomer units being built into the chain has a pseudoasymmetric carbon atom. Thus, for example, the position of the ^1H–NMR signals of the α-methyl groups in copolymers of methyl methacrylate and methacrylic acid is influenced by the nature and the d or l position of the substituents on the monomer units in the immediate vicinity. There are 20 possible magnetically distinct triads of monomer sequences, six being isotactic, six syndyotactic, and eight heterotactic. In view of the relatively broad line width resulting from the limited mobility of polymer chains, the separation of 20 signals hardly seems possible.

We therefore used Ziegler-Natta catalysts to prepare highly syndyotactic poly(methyl methacrylate), from which cosyndyotactic methyl methacrylate (a) – methacrylic acid (b) copolymer was prepared by partial hydrolysis.

The number of triads then decreased to six; these are the two "chemically pure" (aaa and bbb) and the four composite triads, *i.e.* two resulting from "chemical nodes" between two blocks (aab and abb) and two being due to chemically alternating groups (aba and bab).

The corresponding resonance positions were found by measurements in pyridine at 100 MHz. The signals were assigned on the basis of model substances, chemical shift, results of changing solvents, and statistical considerations. Comparison of the experimentally determined population of the various triads with the calculated values indicates that the hydrolyzing agent attacks randomly along the syndyotactic polymer chain.

On partial hydrolysis of highly isotactic poly(methyl methacrylate), only four strong resonances were found, and these have been tentatively assigned. Improved resolution of proton magnetic resonance signals became possible when we carried out our measurements with the Varian super-conducting nuclear magnetic resonance spectrometer at 220 MHz.

Incompatibility of Polymer Mixtures

By *R. Kuhn, H.-J. Cantow,* and *W. Burchard*[*]

Light-scattering measurements on a polystyrene (PS) having $\bar{M}_w \approx 10^5$ in the isorefractive polymer/solvent system polymethyl methacrylate (PMMA)/benzene[1] showed that the second osmotic virial coefficient A_2 of PS is strongly dependent on the average viscometric molecular weight M_v and on the concentration of the PMMA, whereas between 20 and 60 °C it is practically independent of the temperature. If c_Θ is the PMMA concentration at the Θ point, at which A_2 of the PS is zero, and if the measured PMMA concentration c is normalized to c/c_Θ, one obtains an unambiguous relationship between A_2 and c/c_Θ, which is independent of the molecular weight and the molecular weight distribution of the PMMA used.

The influence of the monomer, dimer, and trimer and of the hydrogenated monomer of methyl methacrylate on A_2 of the PS is also discussed as a function of the volume ratio of benzene to oligomer. The PS studied forms a Θ system in PMMA at a degree of polymerization of $\bar{P}_w \approx 17$ without the addition of benzene.

The dependence of the phase separation in PMMA/PS/benzene on the variables of the system is assessed from the first cloud point. Predictions concerning compatibility limits have been satisfactorily confirmed with solvent-free films of PMMA/PS [1].

Measurement of the angular dependence of the scattered light for a PS having $\bar{M}_w \approx 10^6$ showed that the c_Θ concentrations are practically independent of the molecular weight of the PS, and that the radii of inertia r of the PS decrease only very slightly with increasing PMMA concentration, and are about 50 % higher at the Θ point than the r_Θ values found in binary solutions. The measured radii of inertia are practically independent of temperature so long as there is no visible clouding. The radii of inertia increase very rapidly at the visual cloud point.

Polymerization of Unsaturated Highly Strained Ring Systems with Ziegler-Natta Catalysts and with Group VIII Metal Halides

By *G. Dall'Asta* [*]

Monomers such as cyclobutene, 1-methylcyclobutene, 3-methylcyclobutene, bicyclo[4.2.0]oct-7-ene, and bicyclo-[3.2.0]hepta-2,6-diene owe their remarkable ease of polymerization to the highly strained cyclobutene ring. These monomers can therefore be polymerized both with Ziegler-Natta catalysts and with the less active halides of metals of the group VIII triad in polar solvents. The polymerization proceeds either with opening of the double bond or with ring opening. When the monomer contains more than one ring, polymerization always proceeds *via* the more energetic four-membered ring.

The chemical structure of the polymer is determined mainly by the transition element in the catalyst system, though the metal of the organometallic compound also influences the polymerization with respect to both the reaction rate and the structure of the polymer. Conclusions can be drawn from this behavior regarding the nature and mode of action of Ziegler-Natta catalysts.

Effect of Structure on the Incompatibility of Polymer Mixtures in Solution

By *O. Fuchs* [*]

According to the literature, polyvinyl acetate and polymethyl acrylate are incompatible in the solid state. Though a clear film is obtained on evaporation of a solution of the two polymers, *e.g.* in ethyl acetate, the inhomogeneity of the film becomes evident when it is held for a short time in the vapor of a liquid that solvates only one of the polymers well. As expected, the polymers are also incompatible in solution, and two separate layers are formed. When equal weights of the two polymers are used, IR examination shows that one layer contains twice as much of one polymer as of the other, and *vice versa.*

To determine the effects of small differences in constitution on the incompatibility of polymer mixtures in solution, 15 polyacrylates and polymethacrylates were examined. The polymers differ in the length and branching of the alkyl groups and in their molecular weights. The polymers were examined in pairs in benzene as the common solvent at 20 °C (a total of 98 pairs). The limiting concentration c_g at which the two polymers of a pair just become compatible on dilution of the mixture was taken as the degree of incompatibility. Thus a high c_g value indicates good compatibility. The results show that even slight differences in the constitution of the polymers lead to incompatibility. The variation of the c_g values on variation of the size of the alkyl groups in the polymers can be qualitatively understood from the point of view of molecular physics. The c_g value decreases with increasing molecular weight of one of the two components.

Diffusion Anomalies and Relaxation in High Molecular Weight Systems with Miscibility Gaps

By *J. Fuhrmann* and *G. Rehage* [*]

The diffusion coefficient and its concentration-dependence can be calculated by the Boltzmann-Matano method if the concentration profile is known. The concentration profiles found by us in interferometric measurements on vitreously solidifying systems with miscibility gaps exhibit a characteristic course, the evaluation of which yields diffusion coefficients that depend in a complicated manner on time. The time-dependence in these systems is due to a second irreversible process induced by diffusion. The superposition of the two processes leads to the anomalous diffusion.

The diffusion anomalies measured by interferometry can be used for the analysis of the second process. The diffusion anomalies occurring in the mixed phase between vitreous polystyrene and pure cyclohexane are discussed with the aid of the measured concentration profile. In the case of this diffusion anomaly, the analysis of the diffusion-induced relaxation from the vitreous state into the state of internal thermodynamic equilibrium can be used to characterize the inhibited non-equilibrium state of the vitreous polymer. Biaxially drawn polystyrene samples with different molecular orientations were used for the experiments.

Synthesis of Organic Polymer Gels with Very Uniform Mesh Sizes

By *G. Greber* and *P. Haussmann* [*]

In connection with the fractionation of polymers by gel chromatography, we were interested in hitherto unknown organic polymer gels having very uniform but widely variable mesh sizes. One conceivable route to gel systems of this type starts with "living" polystyrene (PST) or poly-α-methylstyrene (PMST) molecules having very narrow molecular weight distributions. These molecules can be crosslinked at their chain ends by direct termination with reactive halogen compounds having three or more active functional groups (*e.g.* $SiCl_4$). This one-step process can also be carried out in

two stages. The first stage is the synthesis of macromolecules having two bifunctional or polyfunctional end groups from "living" polymers; these macromolecules are then crosslinked in the second stage. In both cases the mesh size of the resulting gels is determined by the molecular weight of the "living" polymer molecules used.

Direct termination of "living" PST and PMST with equimolar quantities of $SiCl_4$ at −60 °C, surprisingly, does not result in appreciable crosslinking, but results only in a linear growth reaction. The incorporated Cl−Si−Cl groups are then so strongly sterically hindered by the adjacent macromolecule residues that they cannot react with further organosodium end groups. It is only when the reaction temperature is raised to +20 °C that about 50 % crosslinking of "living" PST takes place. No corresponding reaction occurs with "living" PMST, owing to the low ceiling temperature of this system. On the other hand, this low ceiling temperature is the reason that PMST molecules having a very narrow molecular weight distribution can be prepared much more readily than corresponding PST molecules.

In an attempt to find crosslinking reactions that take place even at low temperatures with PMST molecules, we treated "living" PMST with an excess of *p*-vinylphenyldimethylchlorosilane. When naphthalenesodium is added to a solution of the resulting PMST molecules with two $p\text{-}CH_2{=}CH{-}C_6H_4{-}Si(CH_3)_2{-}$ end groups in tetrahydrofuran at −70 °C, practically quantitative crosslinking takes place *via* the *p*-vinylphenylsilicon end groups. This two-step crosslinking process can be carried out more simply by a one-step procedure. "Living" PMST is terminated with a small deficit of *p*-vinylphenyldimethylchlorosilane, and crosslinked gels are formed directly.

Separation Efficiency in Gel Chromatography

By *W. Heitz* [*]

The separation efficiency describes the spreading of a chromatographic zone during migration through the column. To investigate the effects of experimental factors on the separation efficiency, polystyrene gels and polyvinyl acetate gels with crosslinking agent concentrations of between 1 and 30 mole-% were prepared by bead polymerization. Sharp bead-size fractions having average particle diameters of 0.015–1 mm were used for the experiments. Methyl-substituted *p*-oligophenylenes were used as the test substances.

With the aid of reduced quantities (reduced plate height $h = H/d_p$, reduced velocity $\nu = vd_p/D$; H = height of the theoretical plate, d_p = particle diameter of the gel, v = linear elution rate of the mobile phase, D = diffusion coefficient of the solute), the separation efficiency found by experiment can be represented, according to *Giddings*, by

$$h = b/\nu + c_s\nu + \sum_i \frac{1}{1/a_i + 1/c_{mi}\nu}$$

The b term is due to the spreading of the zone by diffusion; its effect decreases with increasing flow rate. This term is negligible in the usual gel-chromatographic separations.

The c_s term is due to the nonequilibrium in the stationary phase. The transport of matter in the stationary phase is controlled by the permeation coefficient. c_s is therefore a substance-dependent quantity when the diffusion coefficient in the mobile phase and the permeation coefficient in the gel differ appreciably. In agreement with this, the reduced separation efficiency in gels having low crosslink densities and in macroporous gels can be described by a single curve for the compounds investigated (c_s = 0.1). This curve is independent of the particle size of the gel. In gels whose pore size is determined by the content of crosslinking agent, the substance-dependence increases with increasing crosslink density. These substance-dependent curves are also independent of the particle size of the gel. For substances that cannot penetrate into the gel, c_s is found to be zero, *i.e.* h is independent of ν.

The summation term describes the regularity of the packing (a_i) and the nonequilibrium states in the mobile phase (c_{mi}). Any irregularity in the packing leads to nonequilibrium. Owing to the coupling of the two quantities, the summation term disappears for low reduced velocities, and has a constant value a for higher velocities. This is confirmed by experiment. The magnitude of the summation term is strongly influenced by the nature of the packing.

At extremely high flow rates, the elution volume is not constant, but decreases with increasing flow rate until it is ultimately equal to the external volume v_0. In this case the exchange process is kinetically controlled, and the curves are highly asymmetric.

Formation of Ordered Structures from Polysaccharide Solutions

By *H. Bittiger, E. Husemann,* and *B. Pfannemüller* [*]

To obtain a better understanding of the formation of ordered structures in plant and animal organisms, the effects of conditions during the crystallization of macromolecules from dilute solution on the nature of the molecular and supermolecular structures were studied.

It is shown that for cellulose and amylose derivatives, the folded individual molecules can change into extended fibrils on alteration of the concentration, and that depending on the solvent, globular particles, folded individual molecules, or single crystals can be formed. The effects of complexing agents are demonstrated for amylose solutions. Single crystals of varying morphology are formed with alcohols, whereas iodine leads to the formation of fibrils, the length of which increases in proportion to the degree of polymerization, while the diameter remains constant. The structure of these amylose-iodine fibrils is discussed in relation to that of natural cellulose fibrils.

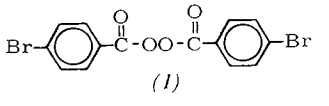
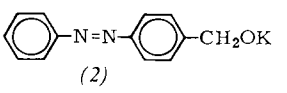
Preparation and Use of Derivatives of Azoisobutyrodinitrile that can be Determined Colorimetrically

By *H. Kämmerer* and *G. Sextro* [*]

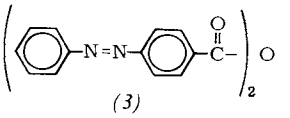
The analysis of the end groups of macromolecular substances is of great importance in the determination of the formation or of the structure of macromolecular products. Thus with bis(*p*-bromobenzoyl) peroxide *(1)*, the covalent incorporation



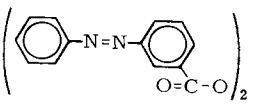
(1)



(2)



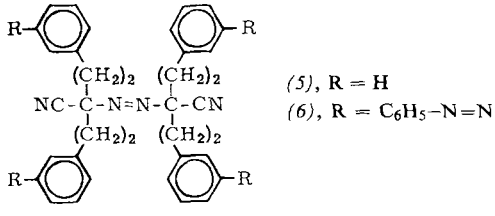
(3)



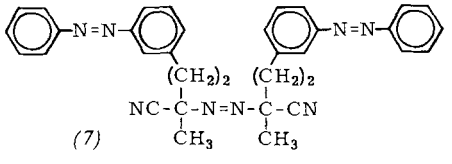
(4)

of initiator fragments in the macromolecules in free-radical chain polymerization was determined by elemental analysis [1]. A transfer reaction with traces of water has been quantitatively determined in the anionic polymerization of ethylene oxide with potassium 4-benzeneazobenzyloxide *(2)* by subsequent reaction of the polyethylene oxides with the anhydride of 4-benzeneazobenzoic acid *(3)* [2]. When styrene is polymerized with bis(3-benzeneazobenzoyl) peroxide *(4)* or with the 4-isomer of *(4)*, the polymer contains end groups that can be determined colorimetrically. This permits the determination of the number average molecular weight or of the degree of branching resulting from a graft reaction [3]. The peroxide *(4)* has the disadvantage that it forms carbon radicals as well as oxygen radicals on decomposition.

To contribute to the discussion of whether monomers can be polymerized by initiators containing azobenzene groups without the occurrence of interfering side reactions [4], the initiators *(5)–(7)* were prepared. These are derivatives of α,α'-azoisobutyrodinitrile. They are expected to decompose by a first-order process, the decomposition not being induced and being practically independent of the solvent.



(5), R = H
(6), R = C_6H_5–N=N–



(7)

Methyl methacrylate was polymerized in bulk at 50 °C with *(5)* and *(7)*, and styrene at 70 °C with *(6)* and *(7)*. It can be shown that initiator fragments are covalently bound in the polymers. The quantitative evaluation is not yet complete.

Submicroscopic Crystal Nuclei in the Solution Crystallization of Polyethylene

By *D. J. Blundell* and *A. Keller* [*]

It was shown in an earlier investigation on single crystals of polyethylene [1] that submicroscopic units can be obtained above the clearing point of suspensions of single crystals (determined from optical clearing and measured dilatometrically). Though these units represent only an extremely small fraction of the original crystals, they act as nuclei for new crystals on cooling, and so have a considerable influence on the course of crystallization. The factors that influence these nuclei and the structure of the nuclei were studied in the present work.

The number of nuclei, which could be estimated from the number of uniform crystals formed from them, depends on the following variables: the highest temperature to which the suspension was heated (T_s), the heating rate, the morphology of the original suspension, and the molecular weight distribution. The number of nuclei per unit mass of polymer was not affected by the time for which the suspension was kept at T_s or by the concentration of the original suspension, and was only slightly influenced by the subsequent crystallization conditions.

The nuclei, which could be identified by electron microscopy from the slight thickening in the center of the crystals which they induced, were also detected by light scattering in solutions that had been kept above the clearing temperature of the original suspensions. These investigations led to the conclusion that the nuclei are formed from a high molecular weight fraction of the polymer (molecular weight $\approx 10^7$), which changes its conformation during the heating process in such a way that it is stable at T_s.

Correlation of the dimensions and number of nuclei with the molecular weight distribution of the starting material indicates that each nucleus is formed from a single molecule. Moreover, the temperature-dependence of the scattering power between T_s and the clearing point indicates that such a monomolecular nucleus is in equilibrium with its own amorphous environment. On the other hand, difficulties arise in the interpretation of the angular dependence of the scattering. It is most readily explained by a nucleus structure having several parts, which also explains the novel twinning observed in the crystals formed from the nuclei.

Structure of the Photosynthetic Apparatus

By *W. Kreutz* [*]

The primary photosynthetic processes take place in the green plant cells on a sterically definite structure, the lamellar system of the chloroplasts. The lamellae of this system have a special sublayer and plane structure. The lamellae are also combined in pairs to form morphological and functional units, the thylacoids.

The layer structure of the lamellae was determined by X-ray measurements from the electron density distribution along the axis of the lamella (normal to the plane). Each lamella is found to consist of three sublayers a, b, and c. In the thylacoids two lamellae are combined in such a way as to give a layer sequence abccba (a is a protein layer (36–38 Å), b a layer of porphyrin rings (11–13 Å), and c a lipid layer (21–23 Å)). The two c layers are separated by a water layer 10–20 Å thick. The thylacoids are stacked in a periodic manner. The period is about 250 Å in the living cell, while in the dry state the thylacoids are in contact. Their period is then reduced to 160–170 Å.

The plane structure is determined mainly by the structure of the protein layer. It is possible to distinguish essentially two types of protein in the protein layer, *i.e.* structural protein and enzyme proteins. The structural protein (41.4 Å×41.4 Å) forms two-dimensional microcrystals of only 16 lattice cells in a square arrangement, both *in vivo* and *in vitro*. These microcrystals (size 165.6 Å×165.6 Å) in turn form two-dimensional aggregates to give the basic skeleton of the protein layer. Experimental results indicate that the enzymatic proteins of the primary processes are built into this superstructure in a definite manner.

On the basis of the layer and plane structure, it can be shown, with the aid of the spectroscopic data for chlorophyll

in vivo and the exciton theory, that the porphyrin rings of chlorophyll in layer b must be inclined at an angle of 55° to the plane. It is also possible to provide an explanation of the absorption maxima and a scheme for the two-dimensional distribution of the porphyrin rings.

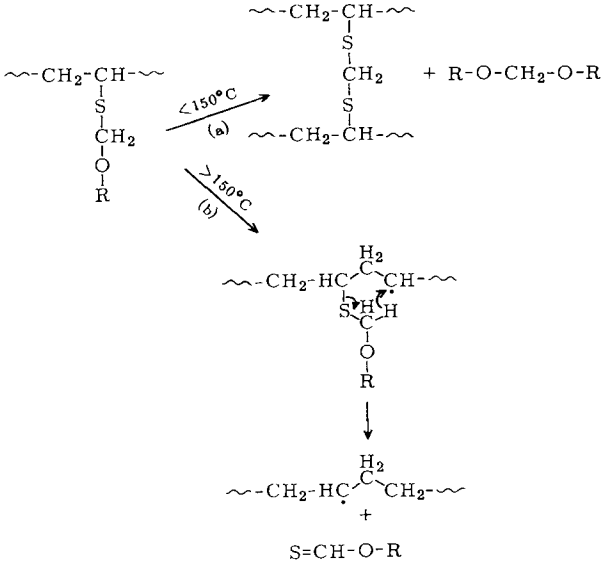
Synthesis and Depolymerization of Poly-*S*-vinyl Monothioacetals

By *K. D. Gollmer, R. Kroker, H. Ringsdorf,* and *U. Zahorsky*[*]

S-Vinyl monothioacetals ($CH_2=CH-S-CH_2-O-R$) were prepared from β-hydroxyethyl compounds by dehydration and the free-radical and cationic polymerization behavior of the monomers was studied. The overall polymerization rates, which are strongly dependent on the substituent (R), are correlated with structure parameters found by spectroscopy (UV, IR, NMR). The influence of the substituent on the polymerization behavior of the vinyl monothioacetals can be traced to inductive and steric effects, and can be correlated with the Taft parameters.

The degradation reactions of the poly-*S*-vinyl monothioacetals and their monomers were investigated by mass spectrometry. Up to 150 °C, practically the only reaction is transacetalization of the polymer (path (a)), while above 150 °C, thioesters and hydrocarbon fragments are formed *via* free radicals (path (b)).



The conclusions concerning the degradation were confirmed with the aid of deuterated model compounds.

The Chemical Heterogeneity of Copolymers — Experimental Studies on Compatibility

By *F. Kollinsky* and *G. Markert*[*]

Two chemically homogeneous methyl methacrylate/butyl acrylate copolymers form optically homogeneous (*i.e.* clear) mixtures in bulk only if the difference in their methyl methacrylate contents does not exceed 10–20 mole-%.

As torsional vibration experiments show, the mechanical homogeneity limit occurs at the same difference in the methyl methacrylate contents. In inhomogeneous systems, the positions of the damping maxima correspond to the compositions of the two components.

Electron micrographs show the presence of structures of the order of magnitude of 30 Å even in some optically or mechanically homogeneous systems. The phase size increases suddenly near the turbidity limit. In mixtures of three components, the intermediate composition does not aid compatibility.

In copolymers with broad continuous chemical distributions, microphases are formed from mutually compatible macromolecules. Optical and mechanical homogeneity or inhomogeneity is then a question of the size of the individual microphases. Suppression of transfer reactions in the polymer leads to an increase in the size of the microphases, while the size decreases when these reactions are encouraged. In agreement with this, graft copolymerization has a homogenizing effect.

Preliminary experiments on copolymers of other monomers indicate that these observations are generally valid.

Kinetics of the Free-Radical Polymerization of Styrene and *o*-Halogenostyrenes at Low Initiator Concentrations

By *O. F. Olaj*[*]

The kinetics of the free-radical polymerization of styrene and of some halogenostyrenes at low initiator concentrations have been studied with particular reference to the question of whether the rates of initiation due to spontaneous thermal radical formation in the monomer and due to the decomposition of the added initiator are additive. The analysis of both polymerization rates and degrees of polymerization shows that deviations from additivity occur with all the monomers studied, and particularly with *o*-bromo- and *o*-chlorostyrene. These deviations result in suppression of the contribution due to spontaneous initiation at higher polymerization rates, and frequently in a maximum degree of polymerization at finite initiator concentrations.

These effects generally become more pronounced with decreasing polymerization temperature. The results can be explained on the basis of a chain transfer reaction to the intermediate that leads to spontaneous radical formation; moreover, the termination of the radical chains by the primary radicals formed in the spontaneous initiation process probably also has to be taken into account (particularly in the cases of *o*-bromostyrene and 2,5-dichlorostyrene).

The Structure of Chromosomes

By *C. Pelling*[*]

In spite of the importance of chromosomes as carriers of genetic information for the cell, their molecular structure is practically unknown. The morphologically relatively simple filament structures have been extensively studied under the microscope, but our chemical knowledge is limited to a simple assignment of the chromosomal components to the three classes of substances deoxyribonucleic acid (DNA), ribonucleic acid (RNA), and proteins. Since RNA is not always present, and since the role of the proteins is unknown, discussions at present are confined to the molecular arrange-

ment of the DNA in the chromosome: Has the chromosomal filament a continuous polynucleotide chain, or does it consist of DNA fragments having different molecular weights, and possibly different functions? The following facts are known so far.

1. The DNA filaments do not occur in bundles in the chromosome, *i.e.* there is only one (double) DNA filament per chromosome element (chromatid). This is shown by the semi-conservatively named replication behavior of the chromosomes of plant and animal cells (*Taylor*).

2. Autoradiographic experiments show that at least in the DNA replication phase, one chromatid breaks down into many independently replicating DNA segments (replicons) arranged in succession (*Lima de Faria, Keyl* and *Pelling, Plaut*). However, it cannot be concluded from this that the DNA is permanently in the fragmented state.

3. If DNA is extracted under particularly mild conditions from isolated cell nuclei, filaments of different lengths are found on examination with the electron microscope. In one case analyzed so far, the length distribution found agrees with that expected on cytological grounds for the DNA growth units (replicons).

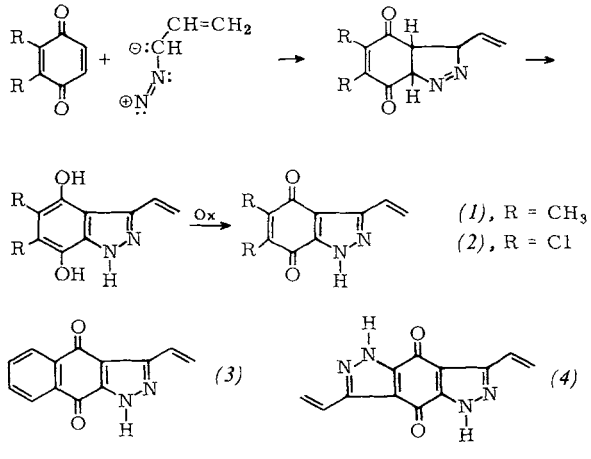
Vinylpyrazoloquinones

By *G. Manecke, G. Ramlow, W. Storck,* and *W. Hübner*[*]

Quinone-based redox polymers have until now been prepared only from carbocyclic quinones. In the present work, several (heterocyclic) vinylpyrazoloquinones were prepared and examined.

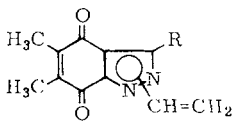
The 3-vinylpyrazoloquinones *(1)–(4)* are formed on addition of vinyldiazomethane to quinones.

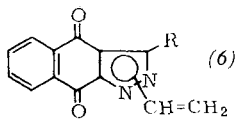


The chemically very stable pyrazoloquinones [with the exception of *(2)*] can undergo free-radical polymerization. Attempts to polymerize the hydroquinone diacetate of *(2)* were also successful. *(4)* acts as a crosslinking agent.

Sulfalkylation on the secondary N atom yielded satisfactorily crystallizing, water-soluble monomers. When the reaction was carried out on crosslinked copolymers, *e.g.* of *(3)* and *(4)*, redox resins that swell in water were formed.

Vinylation with vinyl acetate in the presence of mercury acetate gave *N*-vinylpyrazoloquinones. Both possible isomers, *e.g. (5c)* and *(5d)* from *(1)*, were formed in every case. The *N*-vinyl groups of the anthraquinone-like compounds *(6)* were polymerizable, whereas the naphthoquinone analogs *(5)* did not polymerize.





(a), 1-Vinyl, R = H
(b), 2-Vinyl, R = H
(c), 1-Vinyl, R = Vinyl
(d), 2-Vinyl, R = Vinyl

Readily polymerizable derivatives *(7)* of the pyrazolobenzoquinones could be prepared by epoxidation in the 5,6-position. The epoxide groups could be removed from the polymers by reduction.

Vinylpyrazoloquinones such as *(5c)* or *(6d)* with two vinyl groups gave crosslinked redox copolymers consisting exclusively of quinones. The redox copolymers had a high redox capacity and a high resistance to undesirable degradation reactions.

Effect of the Solvent on Anionic Polymerizations

By *D. J. Worsfold, E. Franta,* and *P. Rempp*[*]

In the polymerization of styrene and of dienes or other monomers with an organometallic initiator in aprotic solvents the active chain ends are always ion pairs, which can associate or dissociate, depending on the solvent.

In polymerizations in hydrocarbons, the ion pairs can associate to form aggregates if the cation is Li^+ or Na^+. With Rb^+ and Cs^+ ions, this association is suppressed because of the primary charge distribution, and the ion pairs remain independent. This can be seen from the change in the growth rate constants, the order of the reaction increasing from $1/n$ to 1 along the series of alkali metals.

Solvents such as ether, dioxane, or THF solvate the organometallic end groups better, and the ion pairs are stable. In solvents containing ether, the growth reaction always retains its first order kinetics if the dielectric constant is small enough. However, when the dielectric constant of the solvent is increased, the ion pairs can exhibit electrolytic dissociation. Since the free anions take part in the polymerization with much higher rate constants, the order of the growth reaction with respect to the concentration of active end groups is again lower than 1.

However, the reactivity of the ion pair depends on the polarity of the solvent. The polymerization rate can be considerably increased by addition of a polar solvent. This can only be partly explained by the increasing degree of dissociation; it must be assumed that the ion pairs are selectively solvated, so that their reactivity increases. It cannot be decided whether this is due to changes in the solvation of the transition state or to an ion pair separated by the solvent. The addition of highly polar solvents such as hexamethylphosphoramide, even in small quantities, leads to large changes in the kinetics. The effect of the cations in this case can be attributed to differences in solvation.

In some cases the reactivity of the free ions is completely independent of the solvent, *e.g.* in mixtures of benzene and THF or of dioxane and THF.

Grafting of Polymers on Active Fillers; Polymerization of Styrene in the Presence of Carbon Black

By *J. B. Donnet, L. Geldreich, G. Peter,* and *G. Riess*[*]

The possibilities of grafting polymers on surface active fillers such as carbon black were studied in an effort to increase the compatibility and the adhesion at the polymer-filler interface. Thermal polymerization of styrene in the presence of various carbon blacks results first in retardation, followed by an accelerated reaction, which is usually accompanied by grafting. The retardation could be attributed to quinoid groups on the surface of the carbon black ,which also play an important part in the grafting. The acceleration of the polymerization is due to the growing polystyrene chains, which are adsorbed or grafted onto the surface. This observation could be interpreted by means of the Langmuir-Hinshelwood theory.

The results obtained also show that the degree of grafting depends on the type of carbon black.

Importance of the Merrifield Synthesis in Macromolecular Chemistry

By *M. Rothe, W. Dunkel, K.-D. Steffen,* and *Hj. Schneider*[*]

The stepwise amide linkage of ε-aminocaproates on the Merrifield insoluble polymeric support was investigated with the object of obtaining rigorously molecularly uniform macromolecules. By the use of dimeric and tetrameric units for the chain growth and by linkage with the aid of diester chlorides of phosphorous acid instead of the carbodiimide used in the original process, it was possible to obtain low polymers $H[NH(CH_2)_5CO]_nOH$ containing up to 25 monomer units (molecular weight 2847) that were uniform on thin layer electrophoresis.

Sequence oligomers of the structure H(prolyl-glycyl-glycyl)$_n$OH and oligopeptides of L-proline containing up to seven monomer units were also synthesized in view of their possible suitability as collagen models. Spectroscopic and optical rotation measurements indicate the existence of stable conformations of the polyproline helix type, even at these low degrees of polymerization. For example, mutarotation occurs between a strongly and a weakly levorotatory form (rotation difference of $\approx 300°$ in the case of hepta-L-proline), which can be distinguished by IR spectroscopy, and which are thought to exist in a left-handed helix with *trans*-amide linkages and a right-handed helix with *cis*-amide linkages.

Diffusion-Controlled Reaction Steps in Free-radical Polymerization

By *J. P. Fischer, G. Mücke,* and *G. V. Schulz*[*]

Stationary measurements and measurements with intermittent chain initiation (sector method) were used to determine the absolute rates of all the reaction steps of the polymerization of polymethyl methacrylate initiated by the photochemical decomposition of azobis(cyclohexanonitrile): decomposition (quantum yield), chain initiation (efficiency), propagation, transfer, and termination. The viscosity of the solvent, including monomer, was varied by a factor of 170; the termination rate constant decreases to the same degree, showing that this reaction step is entirely diffusion-controlled. The efficiency decreases by a factor of 5, which leads to certain conclusions regarding the cage effect. The propagation rate is independent of the viscosity.

A model proposed for the diffusion-controlled chain termination provides an explanation both for the fact that the termination constant is independent of the molecular weight and for the increase in the termination constant during the early stages of the polymerization.

A Polymerization Reaction of Trimethylaluminum

By *H. Sinn, F. Bandermann,* and *H. Hinck*[*]

The band at 460 nm in the spectrum of the reaction product of bis(cyclopentadienyl)titanium(IV) compounds with $Al(CH_3)_3$ corresponds to the formation of $\geq Ti-CH_2-Al\leq$ groupings by the reaction

$$\geq Ti\text{-}CH_3 + CH_3\text{-}Al\leq \longrightarrow CH_4 + \geq Ti\text{-}CH_2\text{-}Al\leq$$

The $-CH_2-Al\leq$ residue on the titanium can be exchanged in the same way as a normal alkyl group:

$$\geq Ti\text{-}CH_2\text{-}Al\begin{matrix}CH_3\\CH_3\end{matrix} + Al(CH_3)_3 \longrightarrow$$

$$\geq Ti\text{-}CH_3 + (CH_3)_2Al\text{-}CH_2\text{-}Al(CH_3)_2 \quad (1)$$

The organoaluminum products *(1)* react further, with elimination of methane:

$$\geq Ti\text{-}CH_3 + \underset{(1)}{(CH_3)_2Al\text{-}CH_2\text{-}Al\begin{matrix}CH_3\\CH_3\end{matrix}} \xrightarrow{-CH_4}$$

$$\geq Ti\text{-}CH_2\text{-}\underset{CH_3}{Al}\text{-}CH_2\text{-}\underset{CH_3}{Al}\text{-}CH_3$$

The reaction sequence continues indefinitely, and leads to polymers of the type *(2)*.

$$CH_3\text{-}\underset{CH_3}{Al}\text{-}CH_2(Al(CH_3)\text{-}CH_2)_n\text{-}\underset{CH_3}{Al}\text{-}CH_3 \quad (2)$$

These polymers are practically insoluble in aliphatic hydrocarbons, are swollen by aromatic compounds, and dissolve in tetrahydrofuran. They react *e.g.* with titanium tetrachloride to form products having an atomic ratio Ti:Al ≤ 1. These reaction products polymerize olefins and diolefins, sometimes stereospecifically.

Investigations on the Agglomeration of Polymer Latices

By *H.-G. Keppler, H. Wesslau,* and *J. Stabenow*[*]

Polymer dispersions are not always compatible with one another, even when prepared with the same emulsifier. If the polymer of one dispersion contains hydrophilic groups, *e.g.* as a result of the use of small quantities of water-solubel

monomers in the emulsion polymerization (type A), while the other contains no hydrophilic groups (type S), a mixture of the two dispersions often coagulates within a few seconds after preparation. However, addition of a small percentage of type A can lead to agglomeration of the particles of an S-type dispersion. For example, when a polybutyl acrylate dispersion having an average particle size of 800 Å is mixed with 1 wt-% of a dispersion of a copolymer of 95 % of ethyl acrylate and 5 % of acrylic acid, followed by adjustment of the pH to 8–9, a latex having $\overline{D}_n$ = 6300 Å and $\overline{D}_w$ = 7300 Å is obtained. The particles continue to grow on further addition of any S-type dispersion.

Schemes for the agglomeration were developed on the basis of particle size distribution functions and with the aid of latices labeled with polymerizable dyes, as well as by the use of electron micrographs with special preparation techniques. The emulsifier sheath is thought to afford the latex particles only limited protection against association (coagulation). When latex particles of type S meet only other particles of the same type, the electrical double layer formed by the emulsifier provides adequate protection against coagulation. When type-S particles collide with type-A particles, on the other hand, irreversible association takes place. Any S particle coming into contact with the surface of an A particle is held fast and fused with other particles to form a secondary particle, with the hydrophilic A particle "floating" on its surface. The A particle remains active practically indefinitely, and takes up further S-type particles that may be added.

New Gels from Cellulose and their Uses in Chromatography

By *H. Determann* and *Th. Wieland*[*]

Spherical cellulose particles are prepared by emulsification of aqueous solutions of cellulose (in tetramminecopper(II) hydroxide or solutions of complex Cd^{2+} or Fe^{2+} salts) or of sodium cellulose xanthate in benzene followed by regeneration with organic acids. The density of the network can be varied by variation of the cellulose concentration in the complex salt solutions. The beads obtained are substantially amorphous, whereas those formed on slower precipitation from xanthate solution contain large crystalline regions. The efficiency of the new cellulose gels in chromatographic separations could be seen in the perfect separation of *E. coli* bacteria, dextran blue, and benzyl alcohol. The elution position of the polydisperse high molecular weight dextran dye depends on the crosslink density.

The new gels can also be used for the separation of macromolecular substances up to the range of microscopically visible particles (mitochondria, microsomes). [VB 118 IE]

Ternary Compounds as Semiconductors

By *H.-U. Schuster*[*]

Not only binary compounds with the crystal structure of zinc blende and of wurtzite but also a large number of ternary compounds with tetrahedral structures (*e.g.*, chalcopyrite type) are now known to be semiconductors.

Semiconductor properties are, however, not confined to compounds with tetrahedral structures. The semiconductors Mg_2Si, Mg_2Ge, and Mg_2Sn crystallize in the antifluorite-type lattice. In these compounds only the Mg atoms are in tetrahedral environments, and the Si, Ge, and Sn have coordination number 8. Finally a filled antifluorite-type lattice can be ascribed to the semiconductor Li_3Bi[1], the cubic face-centered bismuth lattice having Li atoms occupying not only the tetrahedral vacancies but also the octahedral vacancies that are still free in Mg_2Si. Ternary compounds with a modified Li_3Bi structure are the Li_2MgSn prepared by *Laves*[2], which according to *Mooser* and *Pearson*[1] has semiconductor properties, and a series of compounds prepared during the present investigations:

$LiCu_2Si$ pale violet		
$LiCu_2Ge$ pale violet	Li_2CuGe medium brown	$Li_2Zn\,Ge$ gray
	Li_2CuSn dark violet	Li_2CdGe gray
$LiAg_2Sn$ pale blue	Li_2AgSn deep violet	Li_2HgGe gray
	Li_2AuSn orange	

These compounds are sensitive to hydrolysis, are prepared by reaction of the elements in tantalum crucibles under argon, have a metallic sheen, and, when they contain elements of the copper group, are colored. Their structure is composed of a cubic face-centered unit cell of atoms X (X = Si, Ge, or Sn), whose octahedral vacancies are all occupied by Li and whose tetrahedral vacancies of the composition LiM_2X are occupied only by IB atoms, and of the composition Li_2MX are occupied statistically by IB or II B atoms (M) and Li.

On measurement of the electrical resistance in relation to temperature for polycrystalline samples, the weakly diamagnetic compounds of IB elements show metallic behavior and compounds of the II B elements show semiconductor properties. Excitation energies were calculated from the absorption spectra of the germanides of the zinc group (maxima between 1080 and 1300 nm): ΔE = 1.10 (Li_2ZnGe), 0.99 (Li_2CdGe), 0.93 (Li_2HgGe) eV.

d-Orbital Effects in PN and SiC π-Electron Systems

By *H. Bock*[*]

Phosphorus-azo compounds $X_2OP{-}N{=}N{-}POX_2$ are violet; the n → π* excitation energy of the four-center chromophore P–N=N–P is unexpectedly low. Investigations by electron spectroscopy as well as MO calculations on numerous carbon-azo compounds have led to the assumption that the long wavelength shift in the absorption maximum is, in the main, caused by additional d–π* interaction between unoccupied phosphorus 3d orbitals and the N=N π* state[1].

To obtain information on d-orbital effects of this type, by means of which many differences in properties between compounds of elements with principal quantum numbers n = 2 and those with $n \geqslant 3$ are explained under the general heading of "$p_\pi d_\pi$-contributions", we have used R_3Si- and R_3C-substituted compounds as simple models. More than two hundred derivatives of linear and cyclic, alternant and

nonalternant, isoconjugated and heteroatomic π-electron systems (polyenes, polyines, aromatic compounds, aryl ethers, ketones, ketimines) have been synthesized and the relative energy differences between them have been measured[2]: ground-state changes by means of vertical ionization potentials as well as charge-transfer transitions in suitable donor-acceptor complexes, and variations in antibonding orbitals by means of half-wave reduction potentials as well as ESR coupling constants of radical anions. The total differences are obtained from the electronic spectra.

The experimental results can be interpreted by different inductive polarization $+ I_{SiR_3} > + I_{CR_3}$ and an additional electron back-donation $Si_{(d)} \leftarrow C_\pi$, which also explain other characteristic properties of the molecules, such as stretching and deformation vibrational frequencies, ^1H-NMR signals, and dipole moments. Calculations by HMO and PPP procedures permit correlation and numerical reproduction of the experimental values. Whether the acceptor function of the R_3Si groups simulated in the Si parameters used are to be ascribed solely to silicon 3d-orbitals and what degree of importance attaches to the σ-states that have so far been neglected, will be subject of further investigations on this central problem of inorganic non-metal chemistry.

Optical Excitation and Ionization of Adsorbed Molecules

By *H. Moesta*[*]

The lack of spectroscopic information is felt in our still unsatisfactory ideas about the nature of the bonding in adsorption. New methods have now been developed for UV-spectroscopic investigation of chemisorptive bonding. Technical requirements are the use of ultrahigh vacuum processes (UHV) and of an extremely powerful light source that operates also in the short-wave ultraviolet region (~800 Å) under UHV conditions. Further, methods of detecting changes in the bonding state are needed that permit measurement with very small samples (some 10^{10} molecules). We have studied:

1. Adsorbed alkali atoms on W and Pt as models for the investigation of the principal processes.

2. Polyatomic gases such as CO, N_2, H_2, NH_3, HCN, *etc.*, on metals such as Fe, Pt, and Ni.

3. NaCl molecules on NaCl cleavage planes as model for non-metallic systems.

Experiments in project (1) were carried out with a UHV mass spectrometer and a surface-ionization ion source. Differences in ionization were observed on irradiation with visible or near-ultraviolet radiation; this dependence on wave length can be correlated with adsorption in shifted or broadened atomic terms of the adsorbate.

Experiments for project (2) have only just begun. An exploding-wire light source has been developed that delivers monochromatic light with 10^{16} quanta per flash behind a monochromator at 1500 Å. Changes in the contact potential were measured for detecting photoreactions of adsorbed molecules.

Experiments for project (3) concern the rate of evaporation of NaCl crystals, which was measured in a UHV microbalance, (i) with illumination and (ii) without illumination. The evaporation corresponds to desorption of NaCl molecules. The enthalpy of evaporation decreases on irradiation by light in the region of the ground lattice absorption.

Findings in the three lines of research were discussed in relation to catalysis and to modern problems of extra-terrestrial chemistry.

Properties of the Allosteric Forms of Yeast Glyceraldehyde-3-phosphate-dehydrogenase

By *K. Kirschner*[*]

At pH 8.5 and 40 °C nicotinamide-adenine dinucleotide (NAD) is bound to glyceraldehyde-3-phosphate-dehydrogenase (GAPDH) from bakers' yeast by a cooperative process; the saturation curve of the tetrameric enzyme has a sigmoid shape. Temperature-jump relaxation measurements have shown that this behavior can be described by *Monod*'s allosteric mechanism[1]. The isomerization of one allosteric form of the enzyme into the other is so slow ($t_{1/2}$ = 0.1–5 sec) that various properties of the less affine T form can be studied with the aid of the "stopped-flow" method. After rapid mixing of apo-GAPDH with NAD the kinetics of the formation of the enzyme-coenzyme complex can be followed by its absorption spectrum. The time course is clearly biphasic. The first, very rapid phase can be interpreted as the binding of coenzyme to the preferred form of the pre-equilibrium ($4\ NAD + T_0 \rightarrow T_4$). In the second, slow phase the transient species T_4 changes into the stable form R_4.

The number of binding sites ($n' = 4$) and the dissociation constant K' of the T form can both be determined by rapid titration with NAD; the results agree satisfactorily with those obtained from relaxation measurements. Further, the difference spectrum of the two forms T_4 and R_4 was measured by the same procedure: T_4 has a weaker absorption band at 360 nm. The spectrophotometric titration curve was calculated by means of the extinction coefficients of T_4 and R_4 obtained in this way; agreement with experiment was good.

Similar experiments show that, even when all the substrates are bound (3-phosphoglyceraldehyde, NAD, and arsenate), the T form is enzymatically inactive. The kinetic results are supported by the results of rapid spectrophotometric titration of the SH groups of the enzyme with *Ellman*'s reagent [5,5'-dithiobis(nitrobenzoic acid), DTNB] in the presence and then in the absence of NAD. The two allosteric forms T and R behave differently: the four identical SH groups of the enzymatically inactive T form react with DTNB eighty times faster than those of the R form. To a first approximation the rate constants do not depend on the presence or absence of NAD. Quantitative evaluation of the SH titration permits an independent determination of the characteristic equilibrium constants L_0 and L_4 and calculation of the theoretical $\bar{R}$ function[2]; agreement between experiment and theory is satisfactory.

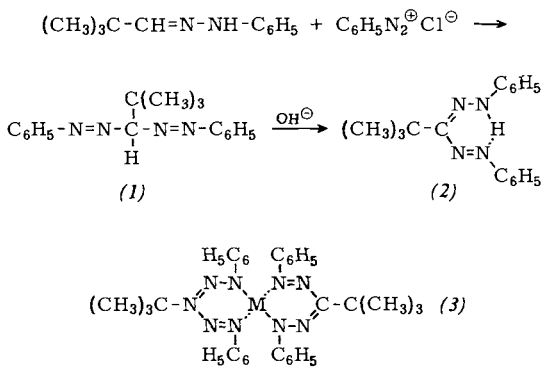
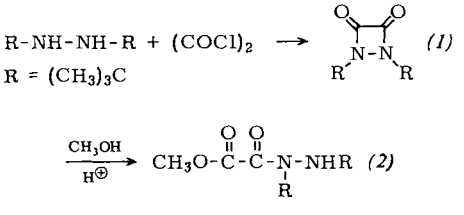
1,1-Bis(benzeneazo)-2,2-dimethylpropane *(1)* is formed on coupling of benzenediazonium chloride with dimethylpropionaldehyde phenylhydrazone in pyridine/DMF. During an attempt to prepare 3-*tert*-butyl-1,5-diphenylformazane *(2)* *F. A. Neugebauer* and *H. Trischmann* obtained *(1)* instead of the expected product.



Whereas the known bis(arylazo)methanes immediately rearrange above pH = 8 to give formazanes, and are unstable in bulk, *(1)* can be stored for months in the dark and can be recrystallized from pyridine/water. This compound is converted into the formazane *(2)*, *via* the anion, only by strong bases (NaOH, NaOR) in aprotic solvents. *(1)* and *(2)* give the metal complex *(3)* with nickel or cobalt acetate in methanol. / Liebigs Ann. Chem. *706*, 107 (1967) / –DK.

[Rd 794 IE]

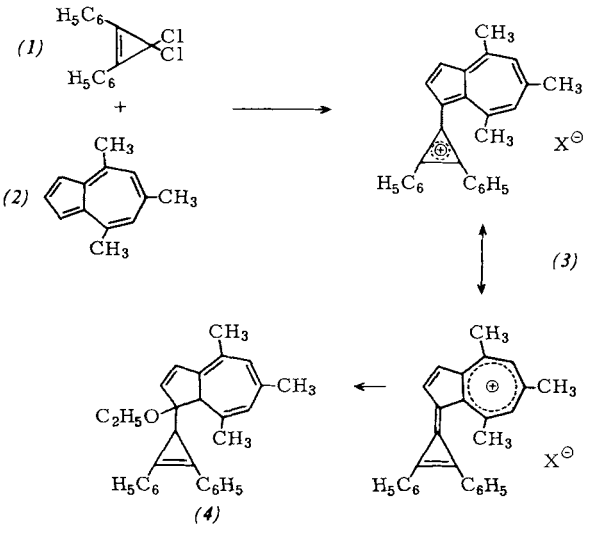
1,2-Diazetidinedione has been prepared for the first time in the form of its di-*tert*-butyl derivative *(1)* by *J. C. Stowell*. The reaction of *N,N'*-di-*tert*-butylhydrazine with oxalyl chloride gave *(1)* as yellow crystals, m.p. 56–57 °C, b.p. 64 °C/0.2 torr. *(1)* can be stored indefinitely at room temperature under nitrogen, but is rapidly decomposed by air. The IR absorption of *(1)* occurs at about 1813 cm^{-1} (amide carbonyl).



On addition of a trace of HCl to a methanolic solution of *(1)*, methyl oxalate *N,N'*-di-*tert*-butylhydrazide *(2)* is rapidly formed. *N,N'*-Di-*tert*-butylhydrazine was prepared by hydrogenation (Pd/C) of 2,2'-azoisobutane, which was obtained by the reaction of *N,N'*-di-*tert*-butylsulfamide with aqueous alkaline hypochlorite solution. / J. org. Chemistry *32*, 2360 (1967) / –DK.

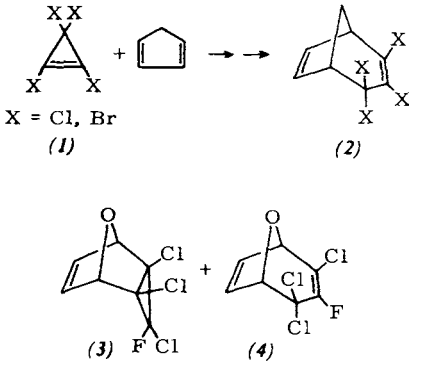
[Rd 799 IE]

The synthesis of a cyclopropenylideneazulenium salt *(3)* has been described by *B. Föhlisch* and *P. Bürgle*. 4,6,8-Trimethylazulene *(2)* reacts with an equimolar quantity of 3,3-dichloro-1,2-diphenylcyclopropene *(1)* (which can be readily prepared from diphenylcyclopropenone and phosgene) when heated in benzene, to give the red-brown chloride *(3)*. This can be readily converted into the more stable perchlorate (X = ClO_4; yield 67%. dec. p. 199–200 °C). Nucleophilic addition of ethanol to *(3)* leads to the blue-violet azulene derivative *(4)* (yield 81%, dec. p. 160 °C). No formation of calicene derivatives has been observed in the nucleophilic reaction. /



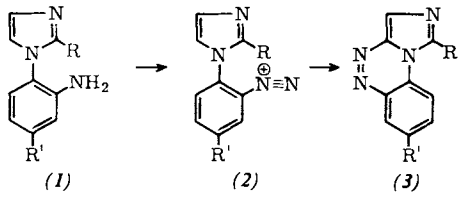
Liebigs Ann. Chem. *705*, 164 (1967) / –DK. [Rd 796 IE]

The reaction of halogenated cyclopropenes with 1,3-dienes has been studied by *S. W. Tobey* and *D. C. F. Law*. Tetrachloro- and tetrabromocyclopropene *(1)* react with an excess of cyclopentadiene at room temperature, probably *via* a tricyclic intermediate, to give very good yields of *(2)*. Furan reacts similarly. 1,2,3-Trichloro-3-fluorocyclopropene gives two products with furan, *i.e.* the tricyclic compound *(3)* (Diels-Alder adduct) and the rearranged bicyclic compound *(4)*.



Stable Diels-Alder adducts are also formed from 1,3-butadiene and tetrahalogenocyclopropenone at 100 °C. The reactivity of *(1)* decreases in the order Br > Cl > F. / Chem. Engng. News *45*, No. 42, p. 45 (1967) / –Ma. [Rd 814 IE]

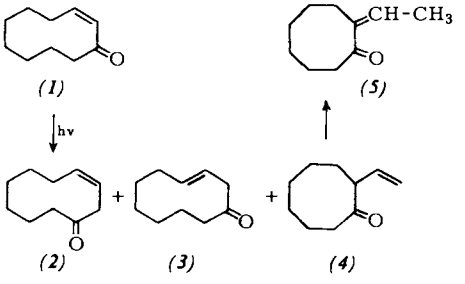
An unusual azo coupling reaction in the imidazole series has been described by *A. M. Simonov, L. M. Sitkina*, and *A. F. Pozharskii*. Salts of the *o*-(imidazol-1-yl)phenyldiazonium ion *(2)*, which are prepared by diazotization of *N*-(*o*-aminophenyl)imidazoles *(1)*, undergo intramolecular coupling in position 5 of the imidazole ring to form the new aromatic imidazo[5,1-*c*][1,2,4]benzotriazine system *(3)*. When position 5 is already occupied, the coupling takes place in position 2, though less readily. The reaction probably involves the unprotonated imidazole ring.



(1) *(2)* *(3)*

(3): R = R′ = H, m.p. 210–211 °C; R = CH_3, R′ = H, m.p. 229–230 °C; R = H, R′ = OCH_3, m.p. 251–252 °C; R = H, R′ = Br, m.p. 242–243 °C; R = H, R′ = NO_2, m.p. 194 to 195 °C. / Chem. and Ind. *1967*, 1454 / –Ma. [Rd 817 IE]

The photochemical rearrangement of *cis*-2-cyclodecenone *(1)* has been studied by *R. G. Carlson* and *J. H. Bateman*. Irradiation of a 1% solution of *(1)* in benzene or *tert*-butanol led to rapid isomerization into *cis*- and *trans*-3-cyclodecenones [*(2)* and *(3)*] and this was followed by the slower formation of 2-vinylcyclooctanone *(4)* (approx. 35%). Compound *(4)*



(1) *(5)* *(2)* *(3)* *(4)*

isomerizes readily into 2-ethylidenecyclooctanone *(5)*. The photolytic ring contraction to give *(4)* is reversible. / Tetrahedron Letters *1967*, 4151 / –Ma. [Rd 818 IE]

A new synthesis of triazane derivatives has been described by *D. J. Blackstock* and *D. A. R. Happer*. Acetone 2-phenylsemicarbazone *(1)* reacts quantitatively with 1 mole of I_2 to form the isocyanate *(2)*, which results from a Hofmann rearrangement:

$$(CH_3)_2C{=}N{-}N(C_6H_5){-}CO{-}NH_2 \xrightarrow{I_2} (CH_3)_2C{=}N{-}N(C_6H_5){-}N{=}C{=}O + HI$$

(1) *(2)*

(2) (b.p. 91–93 °C/0.5 torr) reacts with amines and alcohols to give ureas and urethanes *(3)*:

$$(CH_3)_2C{=}N{-}N(C_6H_5){-}N{=}C{=}O \xrightarrow{H-R} (CH_3)_2C{=}N{-}N(C_6H_5){-}NH{-}CO{-}R$$

(2) *(3)*

R = OCH_3, OC_2H_5, $OC(CH_3)_3$, NH_2, NC_5H_{10}

The triazaneurethanes *(3)* can also be obtained directly from the semicarbazone *(1)* with 1 mole of I_2 and 3 mole of sodium alkoxide, and the urea derivatives with 1 mole of I_2, 2 mole of sodium alkoxide, and 1 mole of NH_3 or amine. Acetone 2-phenylthiosemicarbazone gave a 65% yield of an isothiocyanate, which afforded analogous triazane derivatives. / Chem. Commun. *1968*, 63 / –Ma. [Rd 820 IE]

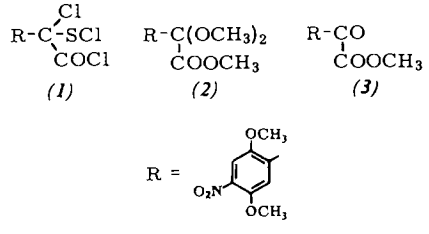
Di-*tert*-butyloxadiaziridine *(1)*, the first known compound with an azoxy group in the cyclic form, has been synthesized by *S. S. Hecht* and *F. D. Greene* by irradiation of the open-chain compound *(2)* in pentane at 10 °C with a quartz lamp. Chromatography of the product gave an oil that does not exhibit the UV absorption shown by *(2)*, and which evidently

$$(CH_3)_3C{-}\overset{\ominus}{O}{-}\overset{\oplus}{N}{=}N{-}C(CH_3)_3 \longrightarrow (CH_3)_3C{-}\underset{O}{N}{-}N{-}C(CH_3)_3$$

(2) *(1)*

has the constitution *(1)*. The compound is thermally unstable and changes quantitatively back into *(2)* ($t_{1/2}$ at 20 °C approx. 8 h in CCl_4, 3 h in CH_3NO_2). *(1)* does not react with water and is moderately stable in acidic media. / J. Amer. chem. Soc. *89*, 6761 (1967) / –Ma. [Rd 821 IE]

A new reaction of thionyl chloride with a carboxylic acid in the presence of a tertiary amine has been described by *M. S. Simon*, *J. B. Rogers*, *W. Saenger*, and *J. Z. Gougoutas*. 2,5-Bis(methoxy)-4-nitrophenylacetic acid gave about 80% of a compound containing sulfur, which was identified by X-ray analysis as α-chloro-α-chlorosulfenyl-2,5-bis(methoxy)-4-nitrophenylacetyl chloride *(1)*. Phenylacetic acid gave a similar compound, so that the reaction is probably generally applicable. Compound *(1)* is converted back into the substituted



(1) *(2)* *(3)*

phenylacetic acid on reaction with water. Reaction with boiling CH_3OH yields the ketal ester *(2)*, while boiling water/CH_3OH gives both *(2)* and the keto ester *(3)*. *(1)* reacts vigorously with DMSO at 100 °C to form 2,5-bis(methoxy)-4-nitrobenzoic acid. / J. Amer. chem. Soc. *89*, 5838 (1967) / –Ma. [Rd 822 IE]

BOOK REVIEWS

Einführung in die Stereochemie (Introduction to Stereochemistry). By *K. Mislow*. Translation of the American Original by *H. Grünewald*. Verlag Chemie GmbH., Weinheim1967. 1st Edit.,vii,172 pp., 84 figures, paper, DM 19.-.

After the absence of a German textbook on stereochemistry for some decades, a translation of 'Eliel' and now of the 'Introduction to Stereochemistry' by *Mislow* have become available. The 'Introduction' treads new paths both in classification of the material and in terminology. It contains three chapters: Structure and Symmetry, Stereoisomerism, and Separation and Configuration of Stereoisomers.

Chapter 1 begins by explaining, with the aid of numerous diagrams, the relationship between the bond geometry of carbon compounds and the coordination number and then extends the results to hybridized states. Symmetry elements are utilized from the start and point groups are soon introduced, particular emphasis being placed on mirror-image symmetry. A section on molecular distortion and strain

energy follows, which treats the relationships between the change in molecular geometry and the energy content. The chapter closes with a critical discussion of conventional molecular models.

Chapter 2, Stereoisomerism, opens with the sentence that is fundamental to further understanding of the book: "Isomers or structural isomers are defined as chemical species which have the same molecular formula but differ in structure and are separated by energy barriers". Constitutional isomers and stereoisomers are next distinguished ("Stereoisomerism arises because molecules which have the same constitution may still differ in the spatial arrangements of their atoms") and this is followed by the important definition: "Stereoisomers which are related as object and nonsuperimposable mirror image are called enantiomers or antipodes, whereas those which are not so related are called diastereomers". If this widely based definition is accepted, the *cis-trans* olefins designated as geometrical isomers in the past must now be regarded as diastereomers. The chapter goes on to discuss optical activity, including optical rotatory dispersion and circular dichroism. A section that deserves special mention is that describing rotational isomerism of single bonds (conformational isomerism) in which two very useful terms are coined. The terms enantiomeric and diastereomeric are replaced in those cases where they refer to the stereochemistry of the surroundings of an atom or group by enantiotopic and diastereotopic. After a useful introduction to the stereochemistry of macromolecules, the chapter concludes with a discussion of topological isomerism (*e.g.* catenanes).

In Chapter 3 the main emphasis is placed on the development and interpretation of the fundamentals of kinetic resolution of racemates and asymmetric synthesis, and on the determination of absolute configurations by both chemical and physical methods.

A set of exercises is given at the end of each chapter, answers following at the end of the book.

In its few pages the book provides an outline of modern stereochemistry, and as a result the high information density does not make for easy reading. True understanding and appreciation of the material is possible only if the reader works his way through the exercises, which are described by the author as an integral part of the book, since they are designed to advance the student, through the inclusion of new subject matter, beyond the descriptive material.

The broad definitions of stereoisomerism and diastereomerism are very useful for the advanced reader, but are difficult to understand for the beginner because the subordinate terms geometrical isomerism, conformational isomerism, and "conventional" diastereomerism are used without sufficient discrimination.

Viewed as a whole, *Mislow*'s "Introduction" is too difficult for the true beginner. For students preparing for their first degree, however, the book is not only a valuable supplement but a good textbook which offers fundamentals and results of stereochemical research in concentrated and modern form. In this sense the book can be recommended to all advanced students and postgraduates. *H. J. Bestmann* [NB 689 IE]

Kristallchemie (Crystal chemistry). By *J. Zemann*, Sammlung Göschen, Vol. 1200/1220a, Walter de Gruyter & Co., Berlin 1966, 144 pp., 90 figures, paper covers, DM 5.80.

To fit a rapidly growing field of research such as crystal chemistry into the framework of the Sammlung Göschen necessitates the practice of the art of omission. The author has deleted material in those realms in which even long monographs and collective works prove unsatisfactory, owing to the obvious impossibility of comprehensive treatment, *e.g.* in the compiling of special structural data. This small book is intended mainly for chemists, for whom it represents a well conceived introduction by virtue of its lucid general chapters on structural units and their bonding, and the fundamental treatment and description of chemical structures in the crystalline state. A desirable feature in future editions would be the provision of space for discussing additional material, *e.g.* the structure of molecules and complexes or possibly crystallographic and chemical comparisons of transition metal compounds, for the benefit of chemists taking an increasing interest in these problems.

H. G. v. Schnering [NB 693 IE]

Die Anwendung der paramagnetischen Elektronenresonanz in der Chemie (The Use of Paramagnetic Electron Resonance in Chemistry). By *L. A. Bljumenfeld, V. V. Vojevodski* and *A. G. Semjonow*. Translated from the Russian by *K. Heuer* and *Hannelore Heuer*. Akademische Verlagsgesellschaft, Frankfurt/Main 1966, 308 pages, 120 figures, and 20 tables, DM 55.–.

This book is addressed to the reader who wishes to use electron resonance to solve his chemical problems. The monograph, completed in 1961–1962 (with a few more recent additions by the translators) consists of a predominantly theoretical part (experimental technique, theory, evaluation of results) and of a part dealing with the application of the method.

A relatively large amount of space is devoted to a description of the design principles of the spectrometer. The chemist will generally skip this chapter because a commercial instrument is normally available. The theory of spectra (fine structure, *g*-factor and its anisotropy) in crystals is discussed in detail, whereas the anisotropic hyperfine structure and also the isotropic hyperfine structure are dealt with rather briefly. The treatment of the evaluation of the spectra is biased toward the study of crystalline samples.

Few publications, and these mostly the authors' own, are discussed to illustrate applications (chemical reactions, delocalization phenomena, radiolysis of solids, kinetics, *etc.*). This method prevents the inquiring chemist from becoming confused by a mass of individual results and directs him to fundamentals, but it does mean that he can seek solutions to his own particular problems only in the literature, especially in view of the year of publication of the original edition. The reproduction of the spectra leaves something to be desired, and the collection of the literature references at the end of the book makes reading more difficult. In view of the quantity of theoretical and experimental work published in the field during recent years the book only partially satisfies the needs of research workers in this field. For the chemist who wishes merely to familiarize himself with the method and its possibilities, the book will prove to be a useful acquisition.

K. Scheffler [NB 692 IE]

Dynamische Biochemie, Teil II. (Dynamic Biochemistry, Part II). By *E. Hofmann*. Wissenschaftliche Taschenbücher, Vol. 37. Akademie-Verlag, Berlin 1966. 1st Edit. 270 pages, 38 figures, 9 tables, paper covers, DM 12.50.

Among the pocket books published in recent years those of the Akademie-Verlag, Berlin, are distinguished by thorough, didactic editing and scientific accuracy. The volume "Dynamic Biochemistry, Part II" describes the fundamentals of protein and nucleic acid metabolism and the modern discoveries about cell make-up, regulation mechanisms, and molecular biology in a concise, pregnant, and scientifically impeccable manner. This well written book contains an amazing wealth of detail and interesting biochemical comparison material for such a small volume. Complicated relationships are illustrated by means of clear, if necessarily somewhat abridged diagrams. Even where the scope permits only indications, they are never given merely as keywords. Objections to modern interpretations are also discussed, though it has of course not been possible to take into account the results of the last two years, which have destroyed many

hypotheses. The one real feature whose absence will be felt is a reference to the chemo-osmotic theory of oxidative phosphorylations. Actual mistakes are neither frequent nor significant. Particular mention is due to the exceptionally neat and faultless presentation, combined with the very acceptable price. Every student interested in this (alas all too often neglected) subject will be able to afford the sound information contained in this excellent volume.

L. Jaenicke [NB 720 IE]

Mass Spectrometric Analysis of Solids. Edited by *J. Ahearn*. Elsevier Publishing Company, Amsterdam-London-New York 1966. 1st Edit., viii, 175 pp., 46 figures, 13 tables, Dfl. 30.–.

As a result of its high sensitivity, the simplicity of handling samples, and the relative ease of interpreting spectra, mass spectrometric analysis of solids is finding ever-increasing fields of application. The present book, which comprises five chapters written by experts, provides a review of the present state of this field.

Chapter 1, by *A. J. Ahearn*, gives a general introduction to the subject. In Chapter 2, *R. E. Honig* treats the methods of ion production used in analysis of solids. Methods of evaluation and analytical errors are also dealt with insofar as they are affected by the type of ion source. The use of photographic plates in quantitative mass spectroscopic analysis is decribed by *E. B. Owens* in Chapter 3, in which the blackening process, properties of photoemulsions for ion detection, density measurements, and methods for quantitative evaluation of spectra receive a critical treatment. Chapter 4, by *J. W. Guthrie*, deals with special analytical processes and mentions investigations of liquids, organic substances, metals of low melting point, as well as insulators and powders of varying conductivity. Further, the application of standards and measurements on very small samples are treated thoroughly. In the last Chapter, *W. M. Hickam* and *G. G. Sweeney* describe the application of the mass spectrograph as a microprobe. In such work the surface of the sample is examined by means of a tungsten tip, which serves as a spark electrode. There is also a short section dealing with the use of negative ions for analysis – a subject that is all too often neglected.

The text is written clearly and concisely, and apart from providing a general introduction it contains a wealth of data, in the form of tables and diagrams, that will also be of value to the expert. The bibliography at the end of each section is also useful. The book can be recommended to all who are concerned with analysis of solids, and particularly with trace analysis, as well as to all libraries frequented by chemists and physicists.

H. Hintenberger [NB 696 IE]

Spectrometric Identification of Organic Compounds. By *R. M. Silverstein* and *G. C. Bassler*, John Wiley and Sons, New York-London-Sydney 1967, 2nd Edit., ix, 256 pages, numerous illustrations, 75 s.

The publication of the 2nd edition of Silverstein-Bassler in 1967 follows four years after that of the 1st[1]. The aim and presentation remain unaltered, but the text has been completely rewritten, the exercises revised and supplemented, and numerous new figures, tables, and literature references inserted. Thus, practically all the shortcomings of the 1st edition have been eliminated. It is only difficult to understand why the UV bands are still denoted by the out-of-date system of *Burawoy* and why in the compilation of the notations for the aromatic bands it is precisely those of *Clar* and *Platt* that are missing.

In view of the increasing importance attached to physical methods in organic chemistry today, the trouble taken by the authors in preparing the 2nd edition is extremely welcome. Chapter 2 (Mass Spectroscopy) has been considerably expanded. All mass spectra are now shown graphically (instead of in tabular form as previously), so that typical spectra are much easier to recognize. Chapter 3 (IR Spectroscopy) clarifies the discussion of characteristic group frequencies of individual classes of compounds by reproducing more than 40 typical spectra. Chapter 4 (NMR spectroscopy) contains new sections dealing with protons on heteroatoms, coupling of protons with other nuclei, more complex spin-spin coupling, chemically but not magnetically equivalent protons, effects of an asymmetric center, virtual coupling, vicinal and geminal coupling in rigid systems, long-range coupling, and spin-spin decoupling.

In all chapters the data has been expanded and supplemented to such an extent that this excellent guide to identification of spectra will serve not merely as a text-book and exercise book but also as a quick reference source for the organic chemist in his laboratory. The book can be recommended without reservation to all who wish to learn about the application of spectroscopic methods to structural problems in organic chemistry, and to those who use spectroscopic methods in their research.

M. Klessinger [NB 713 IE]

Organic Chemistry of Synthetic High Polymers. By *R. W. Lenz*. Interscience Publishers, a Division of John Wiley & Sons, New York-London-Sydney, 1967. 1st Edit., xvi, 837 pages, 120 s.

This book attempts for the first time to present the entire field, including up-to-date results, in very concise and clear form. In principle the attempt has succeeded. Having regard to the vast amount of material covering such a wide range of topics, it would have succeeded even better if more than three of the chapters had been written by specialists. Some of the chapters are very short and assume considerable knowledge. To compensate, the most important literature references have been included – though only a few Russian ones – enabling the original works to be studied.

A number of detailed objections may be raised, of which the most important are the following: The gain recorded by the new systematic classification of polyreactions (1.1–1.3) over older concepts is outweighed by the future confusion that will arise, particularly for the non-specialist. The chapter dealing with inorganic polymers (6.6) leads to a wrong emphasis by omitting the most important classes. The degradation of a cationic chain end with an anion (9–15, p. 245) is much more like the degradation of an anionic chain end with an electrophilic group than a radical recombination (9–13, p. 245).

A β-elimination (9–16, p. 245) does not represent a disproportionation. By contrast to anionic end groups, the degradation reaction on free radical end groups is governed by the probability of the collision of two chain ends, *i.e.* purely thermodynamically; the comparison between "living polymers" and relatively stable radicals (cf. p. 247) is therefore not justified.

A great advantage of the book is the strict classification of the material and the generally concise and clear style. The references to model reactions involving species of low molecular weight that are given for many polyreactions are extremely useful and the frequent numerical examples given with the formulas contribute much to the clarity of the book. This welcome new publication undoubtedly enriches the literature in this field and will find a wide readership.

G. Greber [NB 711 IE]

Kinetics of Inorganic Reactions. By *A. G. Sykes*, Pergamon Press. Oxford 1966, 1st Edit., viii, 310 pages, 35 figures, 42 tables, paper covers, 30 s.

The fields of chemistry which have recently emerged out of the shadows into the limelight of general interest undoubtedly include that of inorganic reaction mechanisms. The retail book trade provides as good a confirmation as any of

this statement: within 12 months the new edition of the standard work by *Basolo-Pearson*, and the admirable monograph by *Langford-Gray* on ligand exchange reactions, are now being followed by the present book by *A. G. Sykes* which would be better entitled "Kinetics and Mechanisms of Inorganic Reactions".

The detailed classification seems a little confusing at first sight, but becomes sensible after a more detailed study of the material. The introduction is followed by a discussion of the experimental methods underlying kinetic investigations; one notes with satisfaction that the very topical technique of the study of fast chemical reactions has not been neglected. This chapter is likely to be very instructive, especially to the uninitiated. By contrast, the subsequent guide to the evaluation of experimental results is very brief indeed. The main part of the book (Chapters 4–15) is divided into two large sections: Gas-phase reactions and reactions in solution. The latter include isotope exchange reactions, redox reactions, acid-base reactions, substitution reactions of octahedral, square-planar, and tetrahedral complexes, and reactions of the hydrated electron. Unfortunately, no mention is made of catalytically controlled reactions in solution.

The book must be regarded as an introduction – and no more – into the field of kinetics and mechanisms of inorganic reactions. As revealed in the preface, it is intended primarily for senior undergraduate students, to whom it can be thoroughly recommended. The reasonable price offers no obstacle in this respect. *H. Werner* [NB 704 IE]

Luciferins, Bioluminescent Substances

BY T. GOTO AND Y. KISHI[*]

The bioluminescence of the American firefly Photinus is due to the reaction of 2-(6-hydroxybenzothiazol-2-yl)-Δ^2-1,3-thiazoline-4-carboxylic acid ("firefly luciferin") with the enzyme luciferase in the presence of ATP and magnesium ion. In the crustacean Cypridina, on the other hand, the bioluminescence is due to the reaction of a luciferase with 8-(3-guanidinopropyl)-6-indol-3-yl-2-(1-methylpropyl)-3,7-dihydroimidazo[1,2-a]-pyrazin-3-one ("Cypridina luciferin"). The luciferin in Latia is 1,3,3-trimethyl-2-(4-formyloxy-3-methyl-3-butenyl)-1-cyclohexene and that in Renilla is a tryptamine derivative that has not yet been accurately identified; the luciferins of other luminescent organisms are not yet known. A review is given of the investigations which have been carried out on the above luciferins and the course of the luciferin-luciferase reaction is examined. Numerous spectral data obtained during the examination of these compounds are included in the text.

1. The Luciferin-Luciferase Reaction[1]

Some eighty years ago, *Dubois* found that the bioluminescence of the luminescent beetle *Pyrophorus* is due to the luciferin-luciferase reaction. Bioluminescence was observed when a hot aqueous extract ("luciferin") of the insect was mixed with a cold aqueous extract ("luciferase") after the initial luminescence had disappeared. This observation led to numerous studies on the luciferin-luciferase reaction in many bioluminescent organisms (see Table 1). It is now known that hot water extracts luciferin and destroys luciferase; the cold-water extract contains luciferase, and also luciferin at first, but the latter changes into an inactive oxidation product on standing in air.

The luciferin-luciferase reaction is the emission of light as a result of the enzyme (a luciferase)-catalyzed oxidation (generally with oxygen) of a substrate (a luciferin). Thus "luciferin" is the name given to a substance having special properties, and is not the name of one compound or of a class of compounds. For example, luciferin from the American firefly *Photinus*

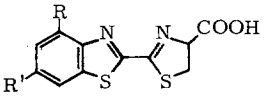
is completely different from luciferin from the marine crustacean *Cypridina*. The luciferases of these organisms are also different.

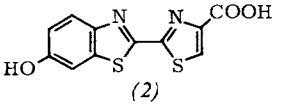
2. Isolation and Structure of Firefly Luciferin

The luciferin-luciferase reaction in firefly was discovered by *Harvey* [5] in 1916. This author first prepared "luciferin" and "luciferase" solutions from the lanterns of luminous insects as well as from non-luminous insects. Luciferin and luciferase from luminous insects emitted light when mixed, as did luciferin from non-luminous insects and luciferase from luminous insects. Luciferin and luciferase from non-luminous insects or luciferin from luminous insects and luciferase from non-luminous insects did not exhibit luminescence when mixed. The emission of light thus evidently depended on the source of the luciferase.

In 1947, *McElroy* showed that the "luciferin" obtained by *Harvey* was in fact adenosine triphosphate (ATP) [5]. The firefly luciferin was first isolated in 1957 from *Photinus pyralis* [6]. This substance is stable in oxygen-free alkaline media, but is readily oxidized by oxygen to dehydroluciferin, a compound that can also be isolated from the firefly. The UV spectrum of the luciferin indicates a benzothiazole chromophore, and acid hydrolysis affords 6-hydroxybenzothiazole and cysteine. Consideration of these facts led to the assignment of structure *(1)* to the luciferin [7] and of structure *(2)* to the dehydroluciferin.



(1) R = H, R' = OH
(3) R = H, R' = NH_2
(4) R = R' = OH



(2)

The structures of the compounds were also verified by total synthesis from ethyl *N*-(*p*-methoxyphenyl)oxamate. Only D-(−)-luciferin produced light, and was therefore identical with the natural compound; L-(+)-luciferin was inactive. The UV, fluorescence, and emission spectra of firefly luciferin *(1)* and dehydroluciferin *(2)* are shown in Figures 1 and 2 [8].

Of several analogs of luciferin [9] that have been synthesized and tested for bioluminescence, only "aminoluciferin" *(3)* and "4-hydroxyluciferin" *(4)* gave a positive reaction, aminoluciferin giving red luminescence.

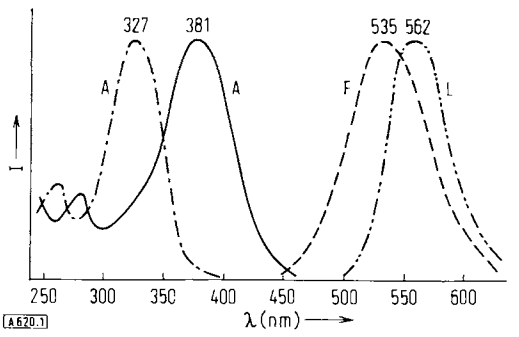


Fig. 1. Spectrum of the luciferin *(1)* of the American firefly *Photinus*. (—·—·) acid, (—) base, (— — —) base. A, absorption; F, fluorescence; L, luminescence.

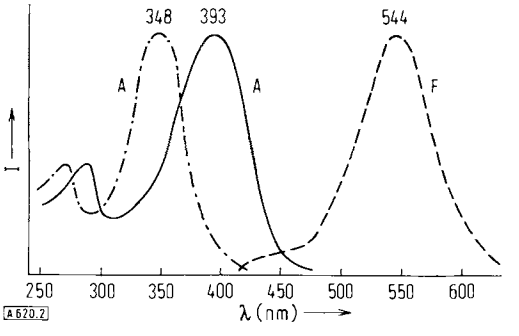

Fig. 2. Spectrum of dehydroluciferin *(2)* of the American firefly *Photinus*. (—·—·) acid, (—) base, (— — —) base. A, absorption; F, fluorescence.

Though the various species of fireflies differ in the color of the light emitted (from green to yellow), all the species examined, including *Photinus*, *Photuris*, *Pyrophorus*, *Diphotus*, and *Lecontea*, contain the luciferin *(1)* [10]. The luciferin of *Luciola cruciata* was also identical with that of *Photinus* [11].

3. The Luminescence of the Firefly [12]

The luminescence of the firefly requires the presence of luciferin (LH_2), luciferase (E), magnesium ions, ATP, and oxygen. The first step is a dark reaction leading to the formation of enzyme-bound luciferyl adenylate (LH_2–AMP) [13].

$$LH_2 + ATP + E \underset{}{\overset{Mg^{2+}}{\rightleftharpoons}} E\text{-}(LH_2\text{–}AMP) + P\text{–}P$$

As can be seen from Figure 3a, this reaction depends on the concentrations of luciferin and of ATP. In the next step the enzyme complex E–(LH_2–AMP) reacts with oxygen and light is emitted; the reaction product remains bound to the enzyme. Because of this product inhibition, the reaction leading to the emission of light also depends on the quantity of luciferase (cf. Fig. 3b).

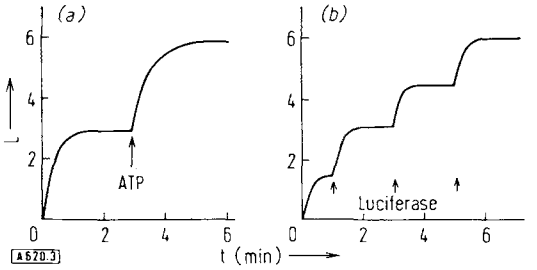

Fig. 3. Luminescence of the American firefly *Photinus*.
(a) on introduction of ATP and (b) on successive introduction of luciferase. L = integrated light units (arbitrary units).

Dehydroluciferin (L) was formerly regarded as a direct product of the reaction leading to light emission. However, more recent results indicate that dehydroluciferin does not correspond to the ground state of the excited intermediate, but is instead an alternative oxidation product, which is not involved in the emission of light, and cannot be regarded as a product formed from the excited intermediate.

Since one mole of luciferin consumes one mole of oxygen [8], equation (a) cannot be correct. The alternative equation (b) is also wrong, since it would not provide the required energy of more than 60 kcal/mole, and

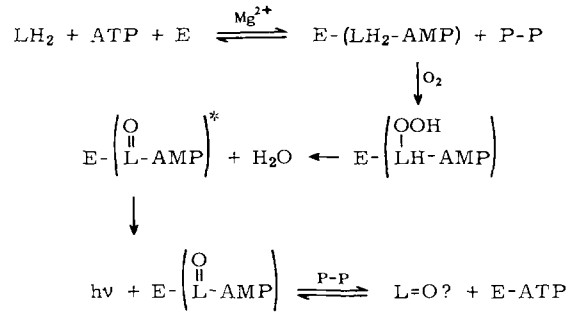
$$E\text{–}(LH_2\text{–}AMP) + {}^1/_2\,O_2 \rightarrow E\text{–}(L\text{–}AMP) + H_2O + h\nu \quad (a)$$

$$E\text{–}(LH_2\text{–}AMP) + O_2 \rightarrow E\text{–}(L\text{–}AMP) + H_2O_2 + h\nu \quad (b)$$

no H_2O_2 has been detected in the reaction mixture. Moreover, the fluorescence spectra of dehydroluciferin and its derivatives do not agree with the bioluminescence spectra. UV spectroscopic studies point to a possible intermediate having an absorption maximum at 400–410 nm [14]. Since the bioluminescence quantum yield is close to one [15], the fluorescence yield of the intermediate must be almost 100 %.

Synthetic L-luciferin does not exhibit bioluminescence and does not consume oxygen, but like D-luciferin, it reacts with ATP to liberate pyrophosphate (P–P) when treated with ATP, luciferase, and magnesium ions [12]. On the basis of all the known results, it is possible to formulate Scheme 1.

The reaction would provide more than 100 kcal/mole; the product L=O has not yet been detected. L and possibly L=O inhibit the production of light, and can be removed from the enzyme by the addition of pyrophosphate or of coenzyme A.

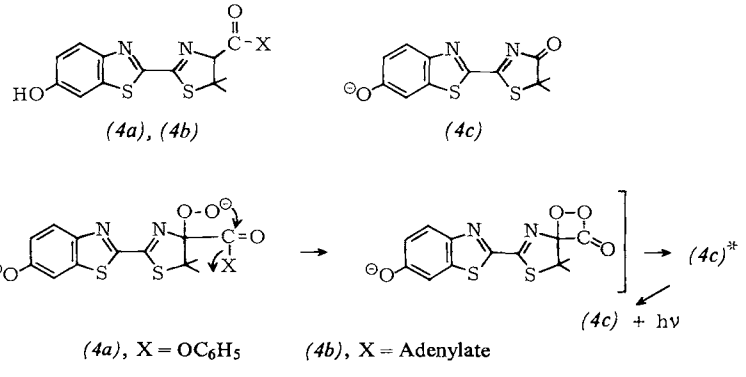


Scheme 1. Suggested scheme for the luciferin (LH_2)-luciferase(E) reaction.

The active center of firefly (Photinus) luciferase was thought to consist of two thiol groups. However, contrary to the belief that the energy source for the bioluminescence would be the energy-rich phosphate bond, there is no indication of any rupture of the anhydride bond in luciferyl adenylate and formation of an LH_2–S–E bond during bioluminescence [12].

Synthetic firefly luciferyl adenylate exhibits chemiluminescence in the absence of the enzyme when treated with KOH or potassium *tert*-butoxide in dimethyl sulfoxide [16].

Recently, *McCapra et al.* [16a] and *Seliger et al.* [16b] reported the chemiluminescence of 5,5-dimethylluciferin derivatives, *i.e.* the phenyl ester *(4a)* and the adenylate *(4b)*, respectively, and identified the ketone *(4c)* as the reaction product. The fluorescence spectrum of *(4c)* is superimposable on the chemiluminescence spectrum. The proposed mechanism involves a peroxide intermediate having a four-membered ring; similar intermediates occur in the chemiluminescence of lophine derivatives and of derivatives of acridinecarboxylic acids.



The chemiluminescence of luciferyl adenylate in DMSO and the fluorescence of the spent chemiluminescence reaction mixtures are identical with the fluorescence of the anion *(4c)*. The product of this chemiluminescence, however, proved to be too unstable to be isolated. *In-vitro* bioluminescence of luciferin at pH 7.5 is yellow-green (565 nm), but in acidic media (pH 6.0) it becomes red (620 nm). The chemiluminescence of luciferyl adenylate (red emission) corresponds

to the bioluminescence, and little information is available concerning the yellow-green emitting species in bioluminescence. *Seliger et al.* suggested the possibility of the dianion of *(4c)* acting as the emitter.

4. Isolation and Structure of Cypridina Luciferin

The crustacean *Cypridina hilgendorfii* is abundant along the coast of Japan. The organism is about 3 mm long, and emits a strongly luminescent secretion into sea water. The luciferin-luciferase reaction of *Cypridina* was discovered by *Harvey* in 1917 [5]. The luminescent activity is preserved almost indefinitely in completely dry *Cypridina*, and the luminescence is restored by moisture. Attempts to isolate the luciferin from dry *Cypridina* led at first to a "purified", but not to a crystalline luciferin [17].

The reason for the difficulty encountered in the extraction and purification of the luciferin is that the substance is present in dry *Cypridina* only in very small quantities, and is extremely unstable to oxygen and water. The most successful of the methods developed was the benzoylation method described by *Anderson* [18], in which the luciferin is benzoylated in butanol extract with a large excess of benzoyl chloride and without a basic catalyst.

Crystalline luciferin was obtained in 1957 [19] from *Anderson*'s benzoyl luciferin, which was first purified by chromatography on cellulose powder. The luciferin crystallized out from an aqueous-methanolic solution as the hydrochloride on acidification with concentrated hydrochloric acid.

Since 1917, several workers have proposed partial structures for luciferin on the basis of the "purified" product. For example, the luciferin is claimed to be a peptone, a phospholipid, a polyhydroxybenzene derivative, a hydroquinone-like compound having a ketohydroxy side chain, a flavoprotein, a pyridine nucleotide, and a chromopolypeptide [20].

Though the UV spectra indicate that "purified" luciferin is practically identical with the crystalline product, acid hydrolysis of the "purified" luciferin gives about 20 amino acids [20], whereas that of crystalline luciferin gives only a few [19]. Catalytic hydrogenation gives a compound (hydroluciferin) whose UV spectrum is typical of an indole [19]. It has been difficult to carry out a structural analysis of the luciferin because of the small quantity of material available, and a structure that seemed plausible at first [21] was later found to be wrong. Quantitative determination of the amino acid compositions of luciferin and of hydroluciferin with the aid of the amino acid analyzer [22, 24] gave the results shown in Table 2.

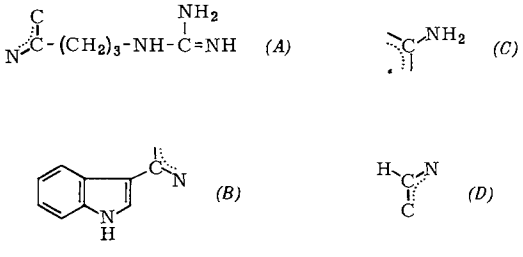
Table 2. Amino acids obtained from Cypridina luciferin and hydroluciferin by acid hydrolysis *in vacuo* or under oxygen.

	From luciferin *(11)*		From hydroluciferin	
	Vacuum	O_2	Vacuum	O_2
Glycine	0.96	0.93	0.03	0.12
Arginine [a]	0.62	0.38	0.03	0.41
Isoleucine [b]	0.16	0.16	0.98	0.96
Ammonia	0.27	0.33	0.40	0.41

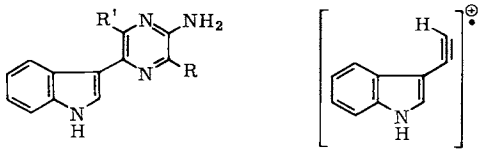
[a] Combined amounts of arginine, γ-guanidinobutyric acid, and proline.
[b] Combined amounts of isoleucine and alloisoleucine; both acids being produced in nearly the same amounts.

In 1961, *Johnson et al.* extracted luciferin directly from living *Cypridina* [23]. Apart from saving a great deal of time, this permits an increase in the yield by a factor of more than ten (about 20 mg of crystalline luciferin per kg of moist *Cypridina*).

The complete structure of *Cypridina* luciferin *(11)* was determined chemically in 1966 [24]. Enzymatic (luminescence) or non-enzymatic air oxidation of *(11)* yields two fluorescent substances, *i.e.* oxyluciferin *(9)* and etioluciferin *(5a)*; *(9)* can be converted into *(5a)* by acid hydrolysis. The structure of etioluciferin *(5a)* was established as follows: On hydrolysis with $Ba(OH)_2$ in the absence of oxygen it gave etioluciferamine, the composition of which was found by high-resolution mass spectrometry to be $C_{15}H_{17}N_5$. The etioluciferin itself has a guanidino group in place of an amino group, and has the composition $C_{16}H_{19}N_7$. On catalytic hydrogenation it gave a compound (hydroetioluciferin) having a UV spectrum typical of the indole nucleus; the pH-dependence of the UV spectrum pointed to a β-aminomethylindole structure (*B*). The NMR spectrum of *(5a)* in conjunction with the amino acid composition led to the partial structures (*A*) and (*D*). The partial structure (*C*) was deduced from the p*K* values and the diazo coupling reaction of *(5a)*.



There are only two possible complete structures *(5a)* and *(5b)* that can be formed from these four partial structures. *(5b)* is ruled out by the mass spectrum of etioluciferamine, since the peak at $m/e = 141$ must be assigned to the radical ion *(6)*.



(5a) R = $(CH_2)_3$-NH-C(=NH)-NH$_2$, R' = H

(5b) R = H, R' = $(CH_2)_3$-NH-C(=NH)-NH$_2$

(6) m/e = 141

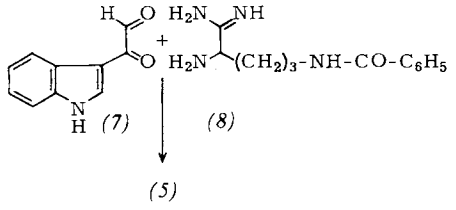
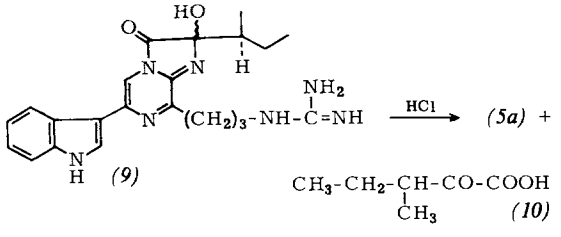
[24] *Y. Kishi, T. Goto, Y. Hirata, O. Shimomura,* and *F. H. Johnson*, Tetrahedron Letters *1966*, 3427; in [3], p. 89.

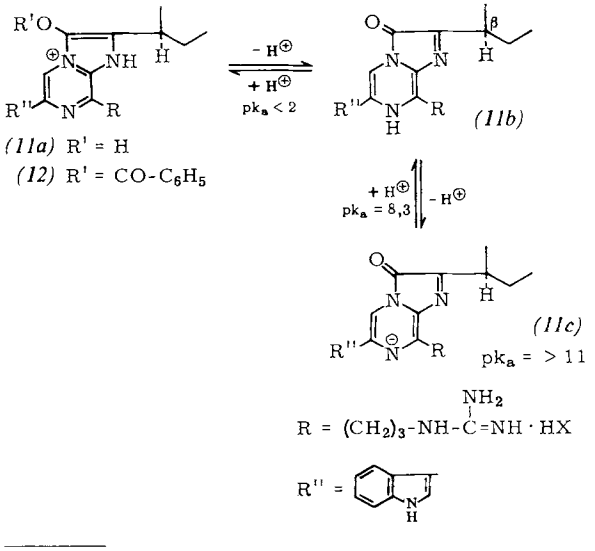
The structure *(5a)* was finally confirmed by total synthesis from *(7)* and *(8)* [25], which were treated successively with sodium hydroxide solution, methanolic KOH, and $H_2N-C(=NH)-SCH_3$. The assumptions concerning the relative positions of the amino and indole groups on the pyrazine nucleus were confirmed by the UV and NMR spectra [26].



On treatment with hydrochloric acid, oxyluciferin *(9)* gives α-oxo-β-methylvaleric acid *(10)* as well as *(5a)*. The NMR spectrum of *(9)* contains a sharp OH singlet signal. It can be seen from Table 2 that the nitrogen atom that appears as isoleucine does not also form arginine or glycine. Since the keto acid *(10)* must be derived from the isoleucine part, C-2 of *(10)* must have been attached to the primary amino group of *(5a)*. This leads to the structure *(9)* for the oxyluciferin.



The NMR spectrum of Cypridina luciferin contains no OH signal. The orange-red solution of luciferin hydrobromide in methanol is decolorized by anhydrous HBr, and the UV spectrum of the solution is then very similar to that of *(5a)*. Luciferin has three pK_a values, *i.e.* <2, 8.3, and >11; it is yellow in basic media. The three forms of the luciferin are best formulated as *(11a)*, *(11b)*, and *(11c)*.



The UV, fluorescence, and emission spectra of Cypridina luciferin and oxyluciferin are shown in Figures 4 and 5.

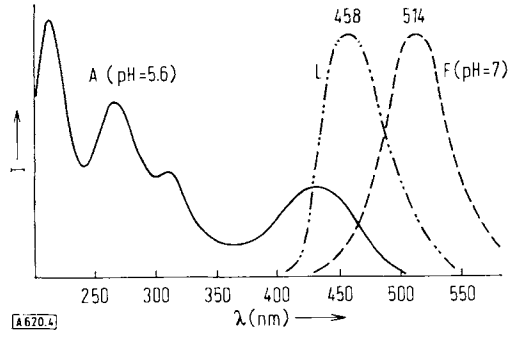


Fig. 4. Spectrum of Cypridina luciferin *(11)*. (—) acid, (— — —) base. A, absorption; F, fluorescence; L, luminescence.

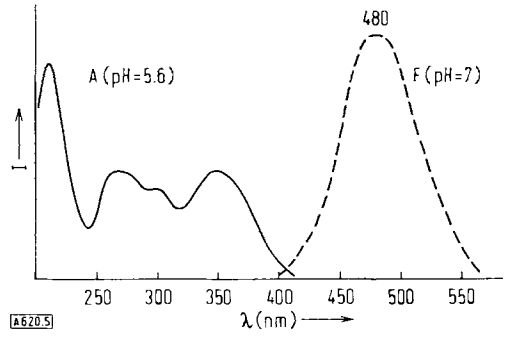

Fig. 5. Spectrum of Cypridina oxyluciferin *(9)*. (—) acid, (— — —) base. A, absorption; F fluorescence.

The benzoylated Cypridina luciferin obtained by *Anderson*'s method has a UV spectrum similar to that of *(5a)* or *(11a)*, and probably has the structure *(12)*.

The absolute configuration at the β carbon atom of the isoleucine portion was determined enzymatically as follows: Hydrolysis of hydroluciferin gave a mixture of isoleucine and alloisoleucine; this mixture was treated with L- and D-amino-acid oxidases and the products were examined with an amino acid analyzer. It was found that Cypridina luciferin is built up from tryptamine, arginine, and L-isoleucine portions. This structure explains the unusual result of the amino acid analysis (Table 2) [27].

Cypridina luciferin has been obtained by total synthesis from *(10)* and *(5a)* (reaction with Pt/H_2 or Al/Hg followed by reaction with dicyclohexylcarbodiimide).

The luciferins of the luminous fish *Apogon* and *Parapriacanthus* are identical with Cypridina luciferin [28].

5. The Luminescence of *Cypridina*

As early as 1919, *Harvey* observed that the *in-vitro* luminescence of *Cypridina* is a first-order reaction (Fig. 6) [5]. Further kinetic studies by *Chase* and *Lorenz* showed that two first-order reactions take place, one of which produces light while the other is a dark re-

action [29]. According to *Johnson et al.* [30], one molecule of luciferin consumes one atom of oxygen during luminescence; the quantum yield is at least 0.28. Since the light-producing reaction and the dark reaction gave the same products, *i.e.* oxyluciferin *(9)* and etioluciferin *(5a)*, the luminescence reaction can be represented by

$$LH_2 + {}^1/_2\,O_2 \xrightarrow{\text{Enzyme}} (9) + (5a) + h\nu$$

In air, an orange-red aqueous luciferin solution turns red, and then colorless, owing to autoxidation (Fig. 7) [19].

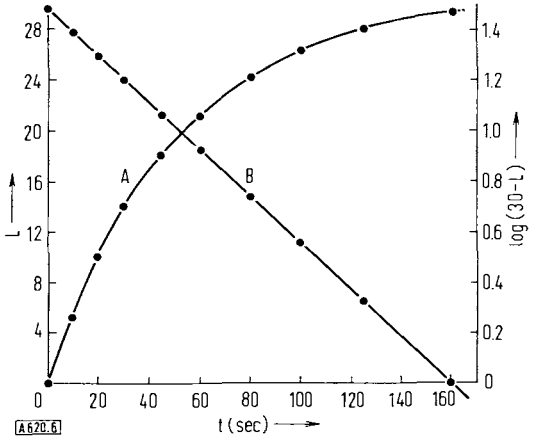

Fig. 6. Bioluminescence in the system Cypridina luciferin/luciferase. The left-hand ordinate refers to curve A (L = integrated light units) and the right-hand ordinate to curve B.

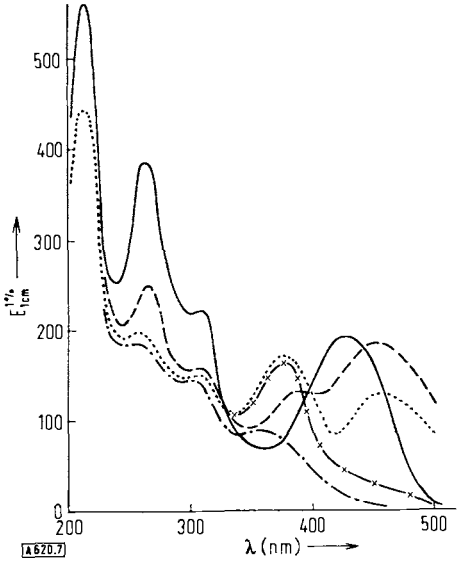

Fig. 7. Non-enzymatic oxidation of Cypridina luciferin with air in phosphate-buffered aqueous solution at pH = 5.6.
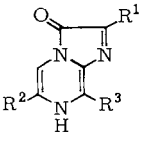
(—) freshly prepared solution, (— — —) after 1 day, (. . . .) after 3 days, (—×—) after 7 days, (—·—·) after 52 days.

A similar change is observed in the spectrum of the bioluminescence in the presence of the enzyme [31], but the enzyme-catalyzed reaction is extremely fast. The initial red shift points to the formation of a red substance, which can be isolated from the reaction mixture. This red substance emits very little light in the presence of the enzyme, but the luminous activity can be restored by chemical reduction; addition of a reducing agent such as ascorbic acid to the reaction mixture prevents the formation of the red substance [32]. This phenomenon was observed by *Harvey*, *Anderson*, and others, who regarded it as a reversible oxidation of the luciferin [5]. However, the structure of this substance and its role in the reaction leading to the emission of light are not yet known.

Cypridina luciferin exhibits spontaneous chemiluminescence [33] when dissolved in dimethyl sulfoxide, with or without a base, in the presence of oxygen, though the quantum yield of this chemiluminescence is low (*ca.* 0.15% of bioluminescence). When diglyme containing acetate buffer is used as the solvent, the quantum yield of the chemiluminescence of luciferin increases to more than 10% of that of bioluminescence and is then about twice as great as that of luminol chemiluminescence in DMSO with potassium *tert*-butoxide [33a]. The simplest analog *(13)* of luciferin is also chemiluminescent in DMSO with acetate buffer and consumes one mole of oxygen during the reaction [33a]. *McCapra* and *Chang* [33b] studied the chemiluminescence of the 6-phenyl-2,8-dimethyl derivative *(14)* in



(13), $R^1 = R^2 = R^3 = H$
(14), $R^1 = R^3 = CH_3$, $R^2 = C_6H_5$
(15), $R^1 = CH(CH_3)\text{-}CH_2\text{-}CH_3$, $R^2 = C_6H_5$, $R^3 = (CH_2)_3\text{-}NH\text{-}C(=NH)\text{-}NH_2$
(16), $R^1 = CH(CH_3)\text{-}CH_2\text{-}CH_3$, $R^2 =$ Indolyl, $R^3 = CH_2\text{-}CH_2\text{-}NH\text{-}C(=NH)\text{-}NH_2$

DMSO in the presence of potassium *tert*-butoxide. They isolated as the reaction product 2-acetamino-3-methyl-5-phenylpyrazine (shown as the anion *(17)*), whose fluorescence spectrum in the alkaline medium corresponds to the chemiluminescence spectrum, and suggested a mechanism involving a four-membered ring peroxide intermediate (see Section 3). Kinetic investigations indicate a participation of radical intermediates [33a].

Bioluminescence of *Cypridina* is more dependent on the structure of the substrate than the above chemiluminescence. Thus, phenyldesindolylluciferin *(15)* is very weakly bioluminescent, whereas the bioluminescence activity of norluciferin *(16)* is comparable with that of luciferin [33c]. Replacement of the alkyl side

(17)

chain (R^1) of luciferin by other alkyl groups diminishes the bioluminescence activity moderately, but hydrolysis of the guanidino group of luciferin to the corresponding amino group lowers the activity [25, 33d] considerably.

6. Bacterial Luciferin

In bacterial luminescence, reduced flavin mononucleotide, an enzyme, oxygen, and a long-chain aliphatic aldehyde are essential factors for the production of light. The quantum yield is very low and the reactions involved are complicated. The aldehyde was initially regarded as the bacterial luciferin [34], but its role in the reaction has not yet been definitely established [8, 35]. Despite extensive efforts to explain the luminescence, it is not certain which substance is to be regarded as the bacterial luciferin.

7. Renilla Luciferin

Renilla luciferin was isolated in a purified form from *Renilla reniformis* by *Cormier et al.* [36]. It is stable in neutral or basic solution, and in acidic solution it is converted into "activated luciferin", which emits light (λ_{max} = 485 nm) in the presence of luciferase or on autoxidation (without enzyme), with formation of an oxidized luciferin. Activated luciferin is also formed on incubation of luciferin with luciferase, calcium ions, and adenosine 3′,5′-diphosphate under anaerobic conditions.

Renilla luciferin is a tryptamine derivative with an anionic group. Alkaline hydrolysis of the dehydroluciferin yields tryptamine. Activation of the luciferin is accompanied by removal of the anionic group, which may be sulfate.

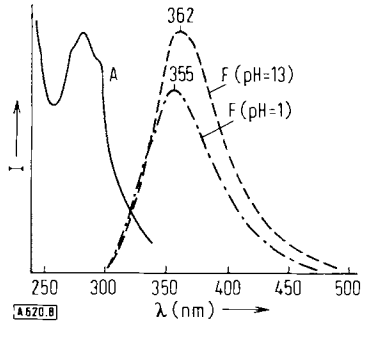

Fig. 8. Spectrum of Renilla luciferin. (—) neutral, (— — —) base, (—·—·) acid. A, absorption; F, fluorescence.

Thus the reaction leading to the emission of light again proceeds in at least two steps. In the first step, which is a dark reaction, sulfate is probably transferred from the luciferin to the adenosine 3′,5′-diphosphate, with formation of active luciferin. This is enzymatically oxidized in the second step, and light is emitted. The absorption and fluorescence spectrum of Renilla luciferin are shown in Figure 8.

8. Odontosyllis Luciferin

The luminescence of *Odontosyllis* involves a luciferin, luciferase, and oxygen. *McElroy* [8] found a fluorescence emission maximum at about 510 nm for partly purified luciferin; this maximum agrees with that observed during luminescence. Autoxidized luciferin can be reduced to the active form.

Shimomura et al. [37] recently obtained a purified luciferin from *Odontosyllis enopla* as a colorless, nonfluorescent substance. After light emission (λ_{max} = 507 nm), a fluorescent product having a fluorescence maximum at 507 nm was obtained. Attempts to convert this product into an active luciferin with reducing agents have been unsuccessful. The absorption and luminescence spectra of Odontosyllis luciferin and of the luminescent product are shown in Figure 9.

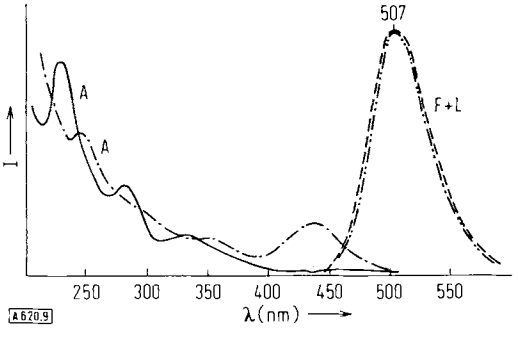

Fig. 9. Spectrum of Odontosyllis luciferin (neutral) (——) and of the luminescent product(s) (neutral) (—·—·), neutral (— — —), (—··—··) neutral. A, absorption; F, fluorescence; L, luminescence.

In the absence of enzyme, Odontosyllis luciferin can be readily oxidized to a pink substance having absorption maxima at 260, 330, and 520 nm. This change can be brought about by the addition of iodine. The pink substance remains unchanged in the presence of oxygen and luciferase.

Luciferin has been isolated in an almost pure state from the fresh-water snail *Latia* [38]. The substance gives an absorption maximum at 212 nm and two IR bands at 1745 cm^{-1} (strong) and 1685 cm^{-1} (weak). Latia luciferin is fairly volatile, and has a molecular weight of 236 (determined by mass spectrometry). When the luciferin is mixed with luciferase solution, a luminescence with an emission maximum at 520 nm can be observed.

Recently, *Shimoura* and *Johnson* deduced the structure of Latia luciferin *(18)* and its luminescent product

Soot Formation in Premixed Hydrocarbon Flames

BY K. H. HOMANN [*]

The critical fuel-oxygen ratio for soot formation and its dependence on temperature and pressure are discussed for various hydrocarbons. It is shown in the case of the Bunsen flame that the shape and structure of the flame front also have a decisive effect on soot formation. In the reaction zone of fuel-rich hydrocarbon flames, unsaturated compounds are formed, and the concentration profiles of these products can provide quantitative information about their importance in soot formation. The "mechanism" of soot formation is discussed on the basis of the concentrations of higher hydrocarbons and the variation of the number and size of the soot particles. The effects of electric fields and foreign additives on soot formation have been given consideration.

1. Introduction

The familiar yellow light of a candle flame is due to the continuous thermal radiation of solid particles of soot, whereas the bluish light of an oxygen-rich hydrocarbon flame is mainly due to the emission from molecules. Interest in soot particles as a source of light has been rather pushed into the background by the importance of soot formation in other fields. Large quantities of soot are used as a filler in the rubber industry. Fine carbon blacks with high blackening powers are finding growing use in paints and lacquers. On the other hand, soot formation is very undesirable in many combustion processes, such as in diesel engines or in gas turbines, since soot particles are difficult to burn, and are partly deposited as a hard coating or leave the motor together with the exhaust gases to pollute the atmosphere. In industrial firing systems, soot is desirable in the flame because of the radiation of heat, but not in the cool exhaust gases.

Thermal processes yield various types of carbon-like deposits, ranging from very hard, brittle, and sometimes vitreous substances to the loose, oily gas blacks.

[*] Dr. K. H. Homann
Institut für Physikalische Chemie der Universität
34 Göttingen, Bürgerstrasse 50 (Germany)

They differ in their chemical composition, as well as in their color, which can be from brown to deep black. The properties of a carbon black, though well known, give little information about its formation. In order to establish how and through what intermediates solid particles of soot are formed in the gas phase, it is necessary to measure both the concentrations of the gaseous reactants and the course of the growth of the particle in the flame. The chemistry of soot formation depends, not only on the nature of the fuel, but also on the structure of the flame, its temperature distribution, and the pressure at which it burns. In the following we shall deal with premixed flames burning without secondary air and examine the conditions necessary for the generation of solid carbon particles from gaseous reactants.

2. Experimental Facts

2.1. Limits of Soot Formation

The critical fuel/oxygen (air) ratio in the unburnt gas at which soot formation can just be observed will be called the limiting ratio for soot formation, or simply the soot limit.

If thermodynamic equilibrium were completely established between the gaseous components and solid carbon (graphite) in the burnt gas of fuel-rich flames the overall flame reaction would be represented by the equation

$$C_mH_n + y\,O_2 \rightarrow 2\,y\,CO + \frac{n}{2}\,H_2 + (m-2\,y)\,C_{solid.}$$

Solid carbon would separate out when $m \geq 2y$, *i.e.* when the C/O ratio rises above ~ 1. This is valid in good approximation for a temperature range between 1500 and 2500 °K. At higher temperatures the concentrations of acetylenic hydrocarbons and also of atoms (mainly H), carbon species C_n, and hydrocarbon radicals have to be taken into consideration.

The above temperature range includes rich hydrocarbon-air and hydrocarbon-oxygen flames, with the exception of an acetylene-oxygen flame at atmospheric pressure. (The adiabatic temperature for this flame having a C/O ratio ≈ 1 is around 3300 °K, so that the burnt gas contains 17% of H atoms and 2% of unburnt acetylene in equilibrium; the theoretical soot limit in this case lies between C/O ratios of 1.03 and 1.07 [1].)

In practice, not all the reactions are in equilibrium, and the burnt gas of soot forming flames contains considerable quantities of water vapor and carbon dioxide, together with various hydrocarbons [2]. Neither the Boudouard equilibrium nor the equilibrium between hydrocarbons and solid carbon is established.

If an equilibrium is assumed between acetylene and soot in the burnt gas of rich acetylene flames (Fig. 11), the Gibbs free energy of the soot should be more than 10 kcal/mole higher than that of graphite. However, this is not confirmed by measurements of its heat of combustion [3]. Moreover, even a Gibbs free energy of this order would not explain a corresponding soot–CO_2–CO equilibrium.

The soot limit depends not only on the nature of the fuel, but also on flame properties such as the structure of the flame front, the temperature, quenching effects of the burner, and dilution by inert gas. In many investigations the appearance or disappearance of soot when changing the fuel/oxygen ratio was determined by visual observation of the radiation due to the soot. This method is simple and gives, within certain limits, reproducible results. However, the question of whether the emission from a given soot concentration is visible depends on the temperature of the flame and on the optical properties of the soot particles. Thus, the soot limits determined in this way correspond to a very low, but not always equal, concentration of soot. Moreover, the limiting ratio of the starting mixture in most cases is not the same as the true C/O ratio at the point of formation of the soot (cf. Section 2.4). However, this does not detract from the significance of these soot limits for practical purposes.

Street and *Thomas* [4] used the visual method to determine the soot limits of many hydrocarbons and oxygenated organic compounds; all the results differ appreciably from the theoretical limits. The results obtained by these authors are listed in Table 1 as critical C/O atomic ratios and (cf. *Daniels* [5]) as the number of oxygen atoms per molecule of fuel (N_O) at the soot limit.

These soot limits were determined for Bunsen flames, which sometimes exhibited disturbances of the flame front (see

Table 1.

Hydrocarbon	$(C/O)_{crit.}$	Number of oxygen atoms per molecule of hydrocarbon at the soot limit (N_O)	$\frac{\Delta N_O}{\Delta CH_2}$

[5] *P. H. Daniels,* Combust. and Flame *4*, 45 (1960).

Section 2.4) and did not have the same temperature at the region of soot formation; thus, for reasons mentioned earlier, their absolute values are of no great theoretical significance. The difference in the N_0 value per additional CH_2 unit is strikingly constant[5]. However, these patterns will have to be checked by measurements on flat flames at approximately the same temperature, where the uniform occurrence of soot can be more readily correlated with the initial composition of the mixture.

The dependence of the soot limit on the shape of the flame can be seen from Figure 1; extensive measurements on flat flames of various fuels have not yet been

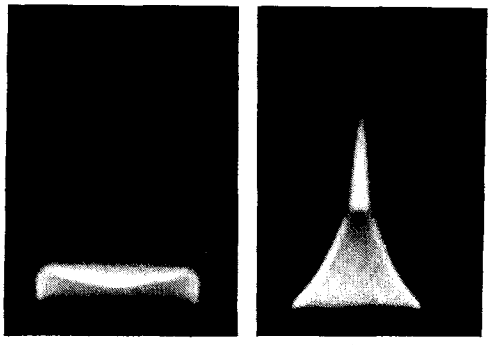

Fig. 1. (a) Approximately flat, non soot forming benzene-air flame on a nozzle burner.
(b) Conical flame of the same composition and with equal throughput; soot formed at tip (type 2).

completed. Despite these reservations, it is safe to say that the critical C/O ratio for the three C_2-hydrocarbons in stationary flames at atmospheric pressure decreases in the order acetylene > ethylene > ethane. Thus acetylene, which forms copious amounts of soot in rich mixtures, requires less oxygen to prevent the appearance of soot than ethylene, which in turn requires less than ethane. This has sometimes led to the erroneous belief that acetylene cannot play a very important part as an intermediate in soot formation. One reason for the higher oxygen consumption of ethane and ethylene is the increased formation of water as compared to the acetylene flame. *Jost*[6] discussed the possibility that OH radicals attack acetylene less at the C–H bond than at the C≡C bond; the result is preferential formation of CO and H_2. This is supported by recent estimations, according to which the C–H bond energy is more than 15 kcal/mole higher in acetylene than in ethane[7]. Another reason for the difference in the soot limits of these three hydrocarbons is the difference in the maximum flame temperatures of the corresponding mixtures. Whereas *Bone et al.*[8] found no soot in explosion flames of mixtures $C_2H_4 + O_2$ and $C_2H_2 + O_2$ (*i.e.* C/O = 1) in closed vessels, soot is formed in stationary burner flames of corresponding fuel-air mixtures.

A more appropriate criterion for the comparison of the soot limits of various fuels is provided by the composition of the burnt gas. *Fenimore et al.*[9] found an empirical relationship between the concentrations of some burnt gas components at the soot limits for flat flames at reduced pressure on cooled burners:

$$\frac{(p_{CH_4} + 2\,p_{C_2H_2})\,(p_{H_2})^{1/2}}{p_{H_2O}} \approx \text{const.}$$

The validity of this relationship is satisfactory for short-chain paraffins (methane to butane, isobutane, neopentane), ethylene, and acetylene with pure oxygen; the maximum temperature of the flames was kept at 1600 °K.

The formula can be interpreted as showing that soot formation is promoted by hydrocarbons and inhibited by hydroxyl radicals, since the OH concentration is proportional to $p_{H_2O}/(p_{H_2})^{1/2}$ when the components H, H_2, OH, and H_2O are in equilibrium. When investigating the soot limits in flat ethylene-air flames, *Millikan*[10] found that soot formation takes place only in a flame zone in which the OH concentration has reached its equilibrium concentration in the burnt gas; the OH concentration may be significantly higher in the main reaction zone than at equilibrium[11–13].

2.2. Dependence of the Soot Limits and Soot Yield on Temperature

Street and *Thomas*[4] studied the dependence of the soot limits of fuel-air mixtures on the maximum flame temperature by preheating of the unburnt gas. *Millikan*[10] as well as *Flossdorf* and *Wagner*[14], varied the temperature of flat ethylene-air flames on cooled burners by variation of the flow velocity. In both methods, higher temperatures allow the burning of richer mixtures without soot formation. Fig. 2 shows how both the absolute soot concentration and the visually determined soot limit vary with the temperature.

The C/O ratios corresponding to the soot limit are given by the intersections of the curves with the broken lines. It can be seen from this diagram that even for the same fuel-air mixture, the soot limits found visually are to some extent arbitrary.

Under certain conditions, however, the quantity of soot in the burnt gas may increase with rising temperature. This is particularly so when the flame burns at a higher pressure and the burnt gas is protected against loss of heat. Most of the soot in this case is produced by pyrolysis of unburnt hydrocarbons in the exhaust gas. Apart from the heating of the gas, this soot formation is unconnected with the processes in and a short way behind the oxidation zone (cf. Section 3.3).

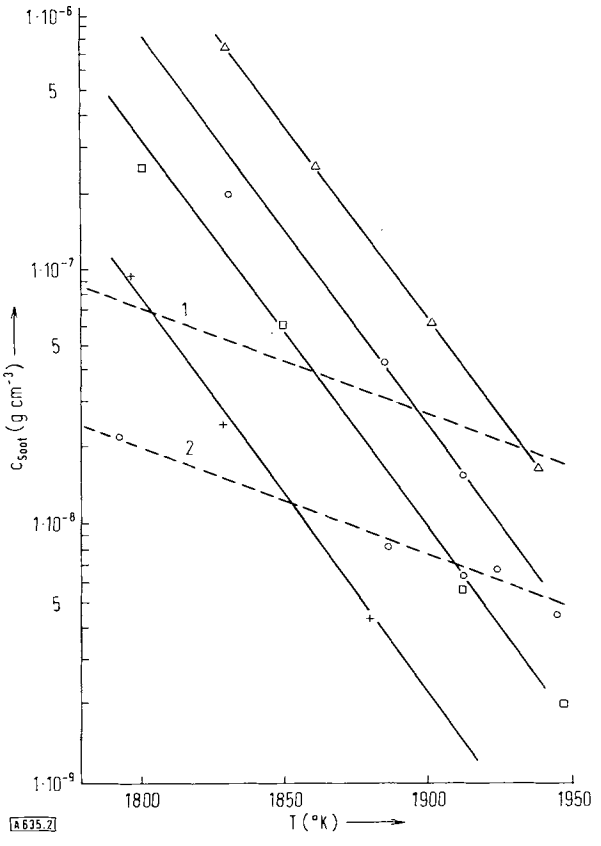

Fig. 2. Soot concentration and soot limits (1 after *Millikan* [10], 2 after *Flossdorf* [14]) in the burnt gas of flat ethylene-air flames as a function of the maximum flame temperature, C/O = 0.620 (+), 0.646 (□), 0.660 (○), and 0.678 (Δ). The soot concentration is normalized to a burnt gas density at 2000 °K and 1 atm.

The temperature-dependence of the yield of soot under these conditions was studied by *Macfarlane et al.* [15] for *n*-hexane flames by diluting their mixtures with inert gases of different molar heat capacities (Fig. 3). At pressures > 1 atm, a rise in temperature still moves the soot limit to higher C/O ratios. On further enrichment with fuel, however, the yield of soot in the hotter flame B increases much more rapidly, and then

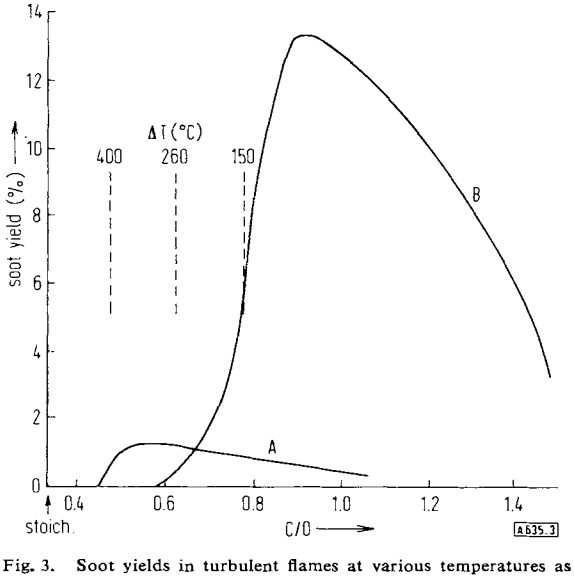

Fig. 3. Soot yields in turbulent flames at various temperatures as a function of the C/O ratio in the unburnt gas. Combustion mixture: *n*-hexane/oxygen + nitrogen (A), + argon (B). $p = 15$ atm [15].

[15] *J. J. Macfarlane, F. H. Holderness,* and *F. S. E. Whitcher,* Combust. and Flame *8*, 215 (1964).

decreases again. The temperature rise in relation to A is not the same for all mixtures. The calculated difference in the maximum temperatures is given for three compositions. The decrease in soot formation in very rich mixtures as a result of the fall in the maximum flame temperature can be observed for most fuels only at increased pressures. At atmospheric pressure mixtures as rich as this in many instances lie outside the ignition limits.

2.3. Dependence of the Soot Limits and Yield of Soot on Pressure

The question of whether the critical C/O ratio for soot formation depends on the total pressure has been studied both for stationary flames between pressures of 10 torr and 20 atm and for explosion flames at pressures up to 100 atm. For acetylene flames on Bunsen burners, *Gaydon et al.* [16] found only a very small change in the soot limit over a pressure range extending from a few torr to atmospheric pressure. *Bonne* and *Wagner* [12] used absorption measurements to determine the quantity of soot formed in flat flames of acetylene-oxygen between 15 and 100 torr; when the flow rate of the unburnt gases was kept constant, the soot limit showed no dependence on pressure. Figure 4 gives the dependence on pressure of some properties of acetylene-oxygen flames at subatmospheric pressure.

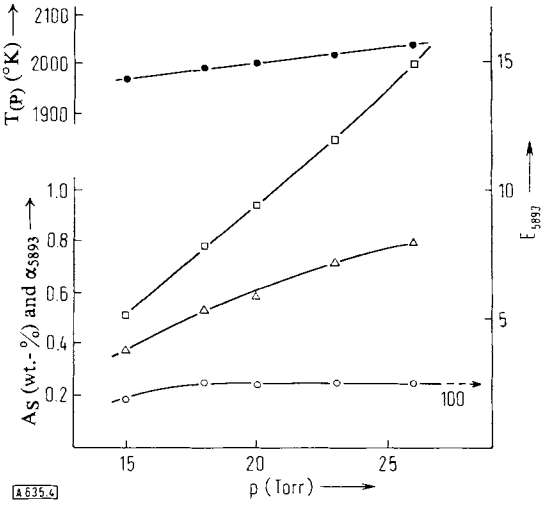

Fig. 4. Continuous emission (E; □) and absorption (α,Δ) at 5893 Å, quantity of soot (A_S; ○), and particle temperature ($T_{(P)}$; ●) at various pressures in the burnt gas of an acetylene-oxygen flame (C/O = 1.3) [12].

Though the soot limits are only slightly influenced by pressure, the yield of soot in rich flames changes considerably at high pressures. This is important to the operation of jet motors. At a working pressure of 10 to 15 atm, combustion is often accompanied by considerable soot formation, as may be observed *e.g.* when a jet aircraft takes off. However, it is again necessary to distinguish between the soot formation that is directly associated with the reactions in the oxidation zone and the formation of soot by pyrolysis

[16] *A. G. Gaydon* and *H. G. Wolfhard*: Flames. Chapman and Hall, London 1960, p. 182.

in the burnt gas. Experiments on low-pressure flames [12] show that the soot formation immediately behind the flame front is practically unaffected by variation of the pressure, whereas pyrolysis in the burnt gas is strongly dependent on pressure.

This is shown by experiments carried out by *Macfarlane et al.* [15] on the combustion of C_3- and C_6-hydrocarbons with air at pressures up to 20 atm. Some of their results are illustrated in Fig. 5. Benzene gives large quantities of soot even in

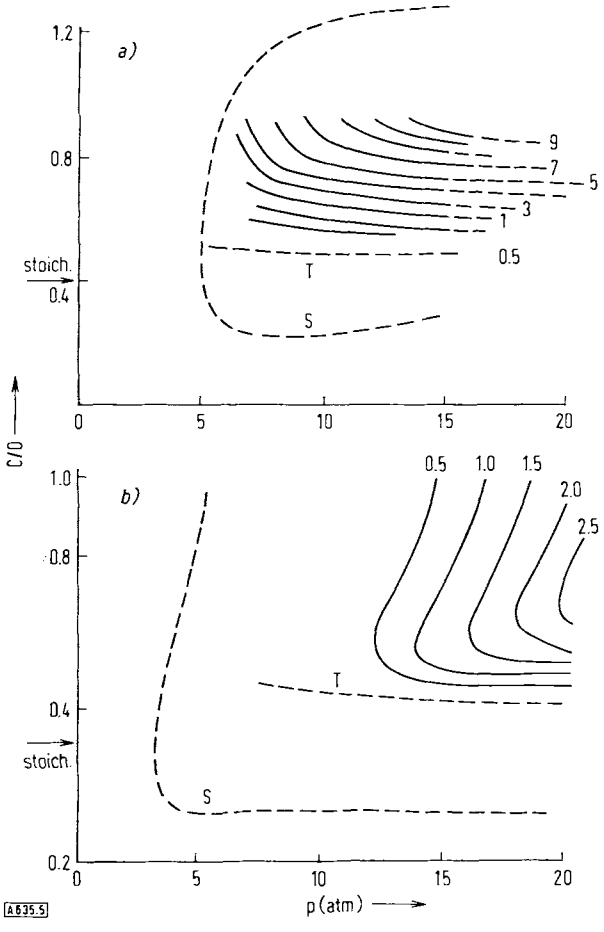

Fig. 5. Soot yield (as parameter in % of C in the fuel) as a function of the pressure and C/O ratio in turbulent flames of (a) benzene, (b) *n*-hexane. T = soot limit, S = stability limit of the flame [15].

relatively lean mixtures; between C/O = 0.5 and 0.8, the yield of soot increases only slightly with pressure, but rapidly with the C/O ratio. The situation is substantially reversed in the case of *n*-hexane; the yield of soot for relatively rich mixtures increases faster with the pressure, whereas at C/O > 0.6 and at constant pressure, it decreases with increasing C/O. These measurements again show the insensitivity of the soot limits to changes in pressure.

Soot formation in explosion flames has been studied at even higher pressures. The only results available are those for methane and ethane obtained in earlier work by *Bone* and *Townend* [17], who found a complicated relationship between soot formation and pressure. For mixtures $2\,CH_4 + O_2$ and $C_2H_6 + O_2$, 20–30% of the hydrocarbon used reacted to form soot between 1 and 10 atm, only 1–3% of soot was obtained at 100 atm. No attempt will be made here to explain these results, since the "temperature history" of the non-isentropically compressed gas before combustion probably influences the soot formation.

2.4. Appearance of Soot-Forming Burner Flames

The simplest case of a stationary burner flame is a flat "one-dimensional" flame having a planar flame front. Such flames can be approximately realized by the use of flat porous plates as flame holders. If a flame of this type forms soot, the planes of equal soot concentration and of equal soot emission are situated downstream from and parallel to the flame front (Fig. 6). Thus the luminous soot zone is linearly related to the flame front at all points [*]. In practice, there are deviations from this behavior at the burner rim (cf. [12]). The extent to which the soot zone overlaps with the oxidation zone depends *inter alia* on the fuel, the maximum flame temperature, and the combustion pressure [2, 10].

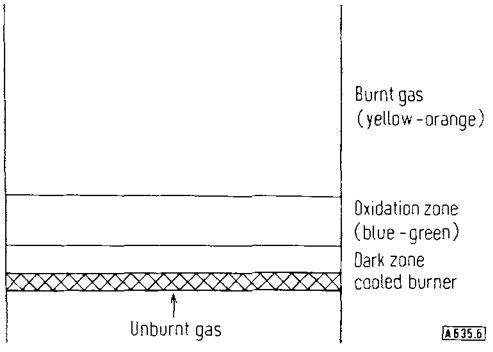

Fig. 6. Oxidation and soot zones in a flat flame (schematic).

The complexity of the mutual effects of chemical reactions, transport processes, and hydrodynamics is externally scarcely visible from a one-dimensional flame; however, they become obvious if the conditions for one-dimensional behavior are no longer satisfied.

An example of this is the formation of soot in an approximately conical flame, which is familiar in the form of the Bunsen flame or the nozzle burner flame. The soot formation in this case depends on the concentration ratios of many substances, the temperature at the site of soot formation, and the thermal history of the mixture present at this point. Thus luminosity due to soot that is nonuniform with respect to the flame front can be a sensitive indication of a nonuniform distribution of concentrations and temperatures along the flame front.

Bunsen flames can be classified into four types, according to the spatial distribution of the luminosity due to soot; many flames encountered in practice are mixtures of two or more of these basic types [4, 14, 18].

Type 1: The yellow luminosity extends with approximately uniform brightness over the entire cone, corresponding roughly to the uniform distribution of soot over a flat flame; *Behrens* [18] calls this the "acetylene type", since it occurs in a particularly pure form with this fuel (Fig. 7).

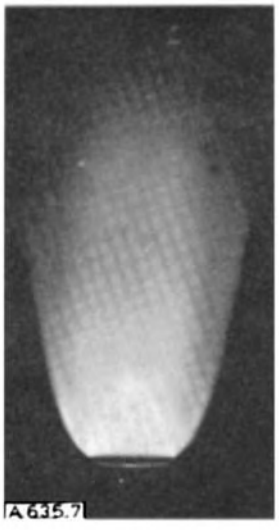
Type 2: The soot is formed only above the tip of the cone, and extends into the burnt gas as a more or less narrow strip [19]. The soot formation begins either closely above the

[*] The same is true of ideally spherical flames, which may also be regarded as one-dimensional in this sense.

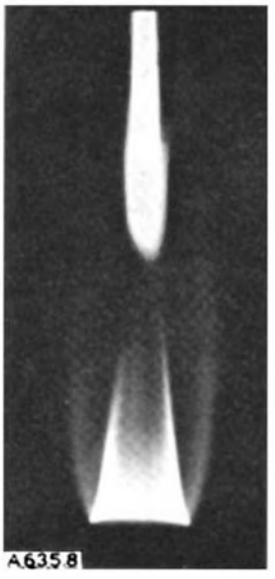
[18] *H. Behrens*, Naturwissenschaften *32*, 299 (1944); Z. physik. Chem. *196*, 78 (1950); *ibid. 199*, 1 (1952).

[19] *W. Jost*, Naturwissenschaften *39*, 418 (1952).

tip (Fig. 1b) or some distance away from it (Fig. 8). This ("benzene type" according to *Behrens*) is how soot formation takes place in flames of benzene and other aromatic compounds, paraffins ($n > 3$), cycloparaffins, and some fuels containing oxygen, such as alcohols (except methanol), ketones, and ethers, *i.e.* generally in fuels having high molecular weights.



flame (type 1 + 3).



air flame; the thread of soot is separated from the cone (type 2).

Type 3: The luminosity due to soot occurs only at the base of the cone, and surrounds the flame like a bowl [18]. This type of soot formation occurs only in flames that are in close contact with the rim of the burner, *i.e.* for mixtures with high burning velocities (Fig. 7).

Type 4: The soot distribution in this type is associated with the occurrence of a disturbance of the flame front. In rich mixtures, many fuels give an undulating flame front, which partially breaks up when the fuel content is further increased. With Bunsen flames this disturbance appears as wave crests and troughs extending from the base of the cone to below the tip [20]; in plan view, flames of this type resemble a polyhedron with spokes (polyhedral flames). When the mixture is sufficiently rich, the soot forms above the wave crests, so that several bands of soot extend from the disturbed cone into the burnt gas (Fig. 9). If the flame front is sufficiently well developed at the apex of the cone, soot formation of type 2 also takes place here. A corresponding disturbance with luminous streaks above the crests in the flame front can also occur in flames that are flat when burning in lean mixtures (Fig. 10) [14].

Fig. 9. Disturbed benzene-air flame with several threads of soot (type 4 + 2).

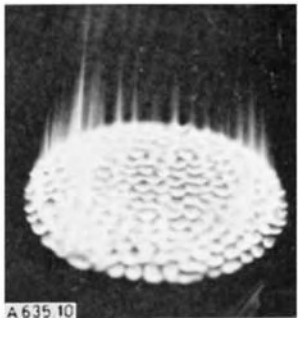


Fig. 10. Cellular benzene-air flame with threads of soot over the crests of the flame front.

What is the explanation for these various appearances of soot? In view of the complexity of the relationships and the lack of adequate quantitative measurements, we must confine this discussion to qualitative considerations. It is useful, not only to compare the properties of the fuels, but also to examine the external factors that particularly favor or suppress a given type, or that cause a transition from one type to another.

The uniform distribution of the luminous soot over the cone (type 1) shows that the surfaces of equal concentration of the substances that are important to soot formation and those of equal temperature, have a form very similar to that of the flame front, at least in the neighborhood of the latter.

Deviations from a uniform distribution in relation to the flame front can be caused by various factors. The most important of these include partial pyrolysis of the fuel before combustion and variation of the concentration ratios along the flame front as a result of selective diffusion of various particles. This occurs when concentration and temperature gradients exist transverse to the local flow direction, as is the case *e.g.* in Bunsen flames, when the flame front is disturbed, and also in turbulent flames [21, 22]. Other factors are temperature changes due both to pyrolysis and to variations in the heat of reaction and thermal conductivity, which depend on the composition of the mixture.

Measurements of the composition of the burnt gas above the apex of the cone in benzene flames (type 2) by *Jost et al.* [23] gave a higher C/O ratio than lower down over the cone. The temperature in the tip of the flame is lower than in the flame front under the tip; this is shown by a darker spot in the flame front at the tip, where soot formation begins when further fuel is supplied to the unburnt gas.

The hydrogen content inside the cone increases with increasing height; for example, in the case of *n*-heptane-air mixtures [24], the mole fraction of hydrogen slightly below the tip of the flame is about three times that of the original fuel mole fraction. The reason for this accumulation is that of all the combustion products hydrogen diffuses back farthest into the fresh gas; as a result of the superimposed flow and the narrowing of the cone, its concentration increases from the base upward. Hydrogen atoms contribute to this diffusion. The diffusion of the hydrogen into the unburnt gas leads to opposing fuel and oxygen concentration gradients. Though diffusion into a multicomponent mixture cannot be quantitatively described without detailed calculations, it may be assumed that

[24] *J. Flossdorf*, Dissertation, Universität Göttingen, 1968.

the oxygen diffuses more rapidly towards the flame front than the heavier fuel molecules, so that the fuel accumulates along the axis of the cone [22, 23].

We determined fuel build-ups inside the cone by injection of a fuel-air mixture into the apex of the cone of a very slightly sooting benzene-air flame from underneath by means of a quartz capillary. The composition and flow of the mixture were adjusted so that the natural soot formation was not perceptibly disturbed; the injected mixture then just corresponded to the natural mixture in the tip of the flame. The increase in benzene concentration found in this way was about 5%, which agrees with the results obtained for the C/O ratio in the burnt gas above the tip.

However, this fuel build-up only partly explains the soot formation at the tip. This can be seen from the fact that a corresponding addition of fuel to the original unburnt mixture leads to a reinforced soot formation at the top, but there is still no soot formation over large parts of the flame front. The build-up of combustible substances can increase with advancing pyrolysis of the unburnt fuel to form higher hydrocarbons inside the cone; the accumulation of pyrolysis products along the axis of the cone is another reason for the preferential soot formation at the tip of the flame.

Pyrolysis, accumulation of fuel along the axis of the cone, and lowering of the temperature at the apex of the cone (because of the richer mixture at this point) together result in the formation of soot at the tip. Which of these factors has the greatest effect on the soot formation varies from one case to another. The extent to which pyrolysis and selective transport processes take place depends on the time for which the fuel mixture is exposed to these effects. Thus, long cones and low flow rates (corresponding to low burning velocities) favor soot formation at the apex; conversely, flames with flat cones and high flow rates (*i.e.* with relatively high burning velocities) exhibit more uniform soot formation distributed over the entire cone (acetylene, ethylene). Thus, fuels that tend to pyrolyze and those having high molecular weights mainly form soot as in flame type 2, whereas fuels that are thermally relatively stable and have a molecular weight comparable with that of oxygen favor flame type 1.

The effect of the back-diffusion of hydrogen can be substantially eliminated if, instead of nitrogen, sufficient hydrogen is added to a fuel-oxygen mixture to make its mole fraction in the unburnt gas equal to that in the burnt gas, so that there is no diffusion of molecular hydrogen. The soot formation in a flame of this nature corresponds almost perfectly to type 1. However, the preferential soot formation at the apex cannot be entirely avoided, since the pyrolysis of the fuel is not completely prevented by the addition of hydrogen.

Substantially the same observations apply to the formation of soot above the wave crests of disturbed flames (type 4) as for the apex of the cone [14, 22]. However, if the disturbance becomes so strong that the front breaks up over the wave crests, the combustion mixture, which is also enriched in fuel, flows straight into the hot burnt gas of the environment, and the soot formation is even more strongly promoted by pyrolysis than in a closed flame front. The flame disturbance and the resulting irregular soot distribution can also be prevented by the addition of hydrogen to the original mixture.

The soot formation at the bottom edge of the cone (type 3) is only due to the quenching effect of the burner rim; it disappears if the flame can be raised slightly from the rim of the burner by an increase in the flow rate. In addition to the removal of heat by the burner, the elimination of active particles (which promote combustion) by recombination at the surface undoubtedly also plays some part. The nature of this effect is not yet known in detail.

2.5. Formation of Higher Hydrocarbons

The first phase of the formation of soot in flames with a continuous front is strongly influenced by the processes in the oxidation zone. To obtain an understanding of these relationships, therefore, it is necessary to carry out concentration measurements in the flame front itself. Methods for the analysis of more or less stable intermediates in the reaction zone of flames have been greatly refined during the past ten years [2, 25–27]. Since spatial resolution of the principal reaction zone of premixed flames is difficult at atmospheric pressure, most of the concentration profiles were measured at low pressures, at which the reaction zone is correspondingly extended.

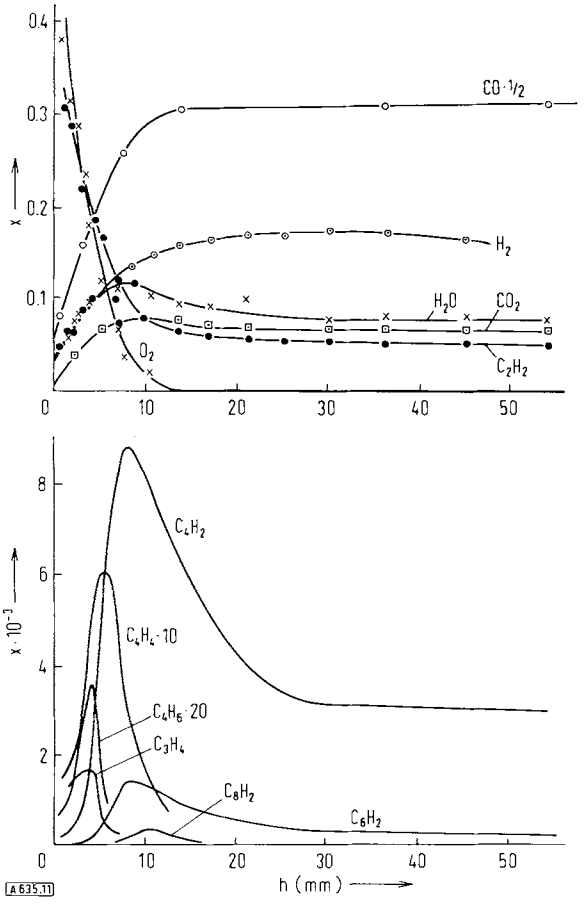

Fig. 11. Concentration profiles (h = height over burner) of a slightly soot forming acetylene-oxygen flame. C/O = 0.95, p = 20 torr.

[25] *R. M. Fristrom* and *A. A. Westenberg*: Flame Structure. McGraw-Hill, New York 1965.

[27] *K. H. Homann* in *C. F. H. Tipper*: Oxidation and Combustion Reviews. Elsevier, Amsterdam 1967, Vol. 2, p. 230.

Even in the oxidation zone of oxygen-rich flames, small concentrations of other, generally less saturated hydrocarbons are formed, the number of carbon atoms being either equal to or smaller than the number in the original fuel [28]. The higher the fuel content of the mixture, the greater is the concentration of these intermediates formed, and hydrocarbons containing more carbon atoms than the original fuel are also formed [29]. We have determined concentration profiles in soot forming flat methane, ethylene, acetylene, propane, and benzene flames by mass spectroscopy (the samples passed directly from the flame into the ion source *via* a molecular beam) [2, 3, 30, 31]. It is possible in this way to analyze, not only stable reaction products, but also free-radical intermediates.

Fig. 11 shows concentration profiles of some hydrocarbon intermediates in an acetylene-oxygen flame. The C_3-intermediates such as propylene and methylacetylene (C_3H_4) reach their maximum concentration in the oxidation zone; they disappear again before the oxygen is consumed, and soot is formed. The same is true of butadiene, dimethylacetylene (C_4H_6), and vinylacetylene (C_4H_4), the concentration maxima of which occur before those of diacetylene (C_4H_2) and the higher polyacetylenes. C_5-hydrocarbons can be detected in traces in rich mixtures of the light aliphatic fuels, but no aliphatic hydrocarbons with a higher odd number of C atoms have been found. Benzene is formed in the oxidation zone of acetylene, ethylene, and propane flames in concentrations of the order of 10^{-2} mole-%, and largely disappears before the soot formation [2].

In contrast to these relatively hydrogen-rich intermediates, the polyacetylenes C_4H_2, C_6H_2, *etc.*, which have been found up to $C_{12}H_2$ in rich acetylene flames, reach their maximum concentration only at the end of the oxidation zone; these form the greater part of the unsaturated hydrocarbons. Lower polyacetylenes are formed even in non-sooty acetylene flames, but are completely oxidized again in the case of burning mixtures having a C/O ratio of up to 0.75 [3]. In richer flames their concentration at first decreases behind the oxidation zone, but subsequently shows practically no further change in the burnt gas. At $C/O > 0.9$, the soot formation begins at the zone where the polyacetylene concentration falls off again (see Section 2.6). With richer mixtures, the concentrations of all the polyacetylenes steadily increase, and "equilibria" of the type

$$C_4H_2 + H_2 \rightleftharpoons 2\,C_2H_2$$
$$C_6H_2 + H_2 \rightleftharpoons C_4H_2 + C_2H_2$$
$$C_8H_2 + H_2 \rightleftharpoons C_6H_2 + C_2H_2$$
etc.

exist between acetylene, polyacetylenes, and hydrogen.

Polyacetylenes are not the only higher hydrocarbons in the burnt gas of rich flames. A large number of high molecular weight polycyclic compounds can be detected [32, 33]. It has long been known [34–37] that polycyclic aromatic hydrocarbons can be extracted from many types of soots. Concentration profiles of these

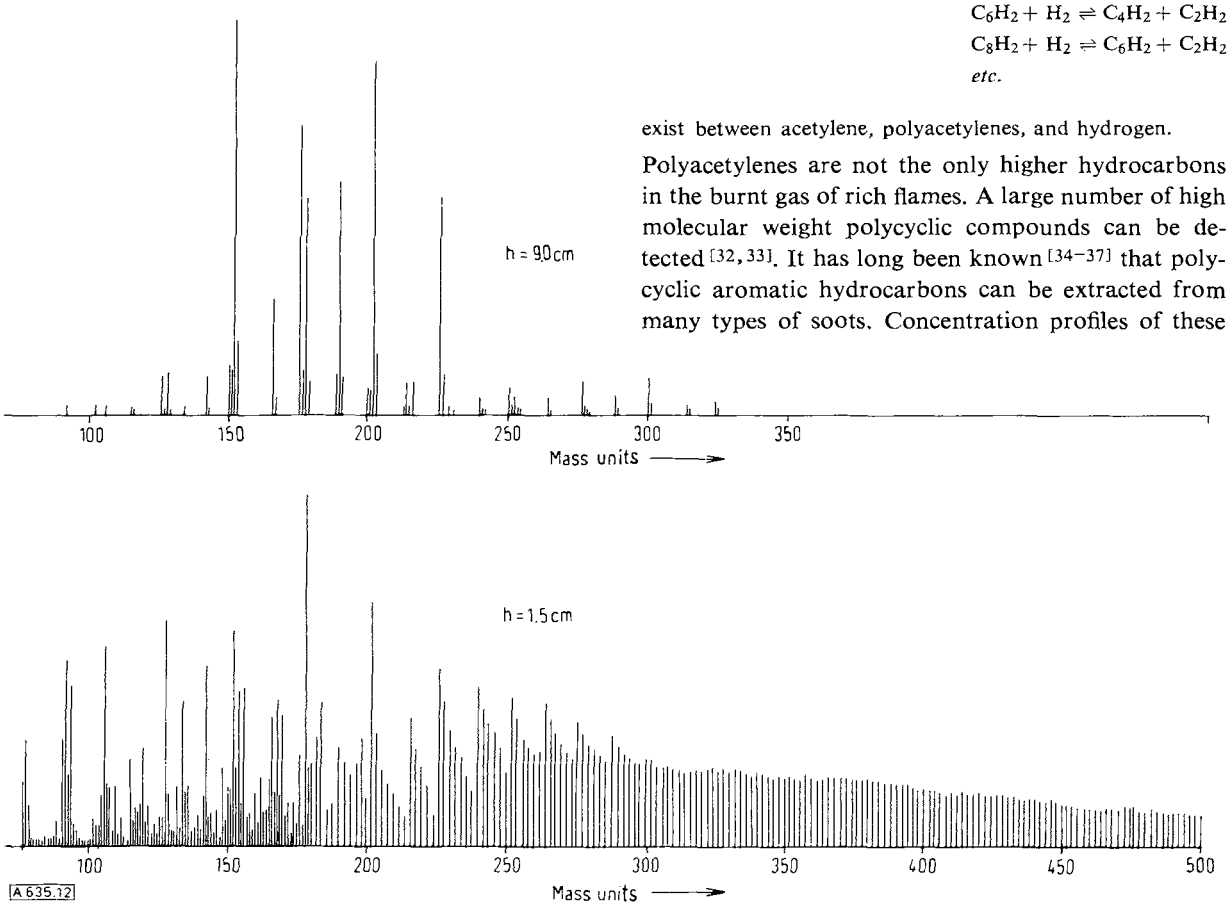

Fig. 12. Mass spectra of the volatile components in soot from various heights (h = height over burner) in a flat acetylene-oxygen flame. C/O = 1.37, p = 20 torr. The odd numbered mass peaks due to the ^{13}C isotopes above 180 mass units are not shown.

components have recently [33] been determined directly in the flame by mass-spectrometric analysis. The nature of the hydrocarbons is strongly dependent on the flame zone from which the soot sample is obtained (Fig. 12). The most abundant at 9 cm above the burner are pyrene (202 mass units), acenaphthylene (152), and anthracene or phenanthrene (178). The electron energy in the ionization was 10 eV, so that there was no fragmentation of the molecule-ions. The concentrations of these aromatic compounds steadily increase with increasing height in the flame.

Very many more compounds are present close behind the oxidation zone 1.5 cm above the burner. The mass gaps between the pure aromatic compounds are filled with substances that contain more hydrogen and have side chains. Their masses extend over a range of from $\approx$ 90 to over 500 mass units; almost every even mass number in this range is occupied by a molecule peak. Most of these substances do not remain unchanged, but are converted into soot. Not only can they be evaporated from quenched soot samples in a high vacuum, but they can also be determined directly in the flame by mass spectrometry [33]. At 20 torr burning pressure, these intermediates reach their maximum concentration 4–5 mm after the end of the oxidation zone (the maximum being earlier for the lighter products and somewhat later for the heavier), and have completely disappeared after a further 15 mm. Their individual mole fractions are of the order of 10^{-7}. The hydrocarbon intermediates in the flames of the other lower aliphatic compounds are qualitatively very similar [2].

The formation of hydrocarbons from aromatic compounds at high temperatures has been studied mainly in thermal decompositions [38–40]. Acetylene and polyacetylenes are also formed in the oxidation zone of benzene flames [2], and partly react further in the burnt gas as in aliphatic fuels. However, whereas aromatic compounds (apart from benzene) are formed only behind the oxidation zone and in relatively low concentrations (mole fraction $\approx 10^{-5}$) in the flames of lower aliphatic fuels, they are formed in relatively large numbers and quantities together with the oxidation products in the principal reaction zone of the benzene flame. The concentrations of *e.g.* phenylacetylene, indene, methylnaphthalene, and biphenyl pass through a maximum at the end of the oxidation zone and fall off again in the burnt gas; the concentrations of other compounds such as naphthalene, acenaphthylene, anthracene, and pyrene continue to increase in the burnt gas. In addition to the pure aromatic compounds a large number of very reactive polycyclic compounds having higher hydrogen contents are also formed as intermediates similar to those from aliphatic fuels, though still inside the oxidation zone [33].

2.6. Growth and Properties of Soot Particles

Two phases can be recognized in the growth of the soot particles in premixed flames. The first phase is strongly coupled with the reactions in the oxidation zone, and finishes relatively quickly. The second phase, which lasts very much longer, is based on a thermal decomposition, and extends for some distance into the burnt gas (depending on the temperature distribution and the hydrocarbon concentrations). These phases are often referred to in the literature as nucleation and growth, but this is not an entirely adequate description (see Section 3).

The characteristic appearance of various types of soot in electron micrographs, which show the formation of bulky aggregates of clusters or chains of more or less spherical particles is due to the second phase (Fig. 13b). During the first phase of growth, the particles grow without forming clusters of distinguishable individuals (Fig. 13a). To gain an insight into the kinetics of the formation and growth of individual particles, it is necessary to follow the variation of the number and size of the particles and the total quantity of soot; a chemical analysis of the growing particles can also provide information about the substances involved in their formation.

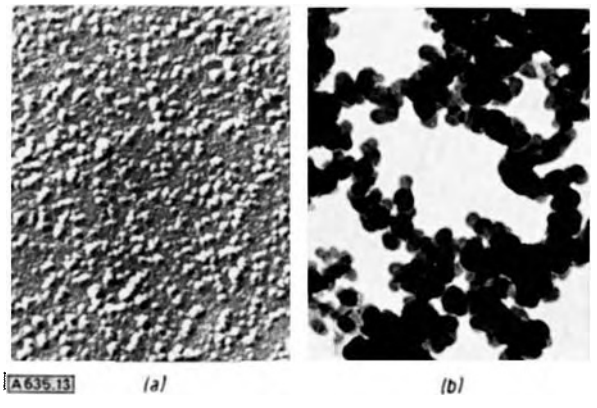

Fig. 13. Electron micrographs of soot from an acetylene-oxygen flame (magnification 51 000 ×).
(a) Close behind the oxidation zone (20 torr; oblique shadowing at 30 °).
(b) In the exhaust gas (1 atm).

The particle size may be determined by optical methods as well as by electron microscopy [41,42]. Electron microscopy has the advantage that the diameters of individual particles down to $\approx$ 40 Å can be measured directly with ordinary instruments, and the size distributions can be determined. In optical measurements, the flame is not affected by sampling, but these methods have the disadvantage that they give only an average particle size. Moreover, the calculation of the particle size involves the optical properties and the shape of the soot particles; these are not very well known, particularly in the case of the very small particles close to the oxidation zone.

Thus the particle size determination described by *Becker* [43], which is based on the dispersion of the absorption coefficients of the particles, cannot be used for the soot near the oxidation zone, since the soot in this region has anomalous optical properties. These are possibly associated with its high initial hydrogen content [12,44,45]. *Bonne* [12,46] found average par-

ticle sizes from the emissivity of the soot, which is a function of the particle size for small particles. Finally, light scattered by the soot particles has also been used to determine particle sizes [47]. However, the accuracy of the optical methods cannot compare with that of the electron microscope.

The soot concentration at a given point in the flame can be measured by aspiration of a given volume of gas from the flame at this point, the soot then being removed from this gas and weighed [3] or burnt to form carbon dioxide [48]; absorption measurements *in situ* [12,46] provide a suitable direct method, particularly for flat flames and for exhaust gas. (This method has the disadvantage that the absorption coefficients of very small soot particles under the conditions prevailing in the flame are not very accurately known.) The average number of particles can be calculated from the quantity of soot and the average particle size.

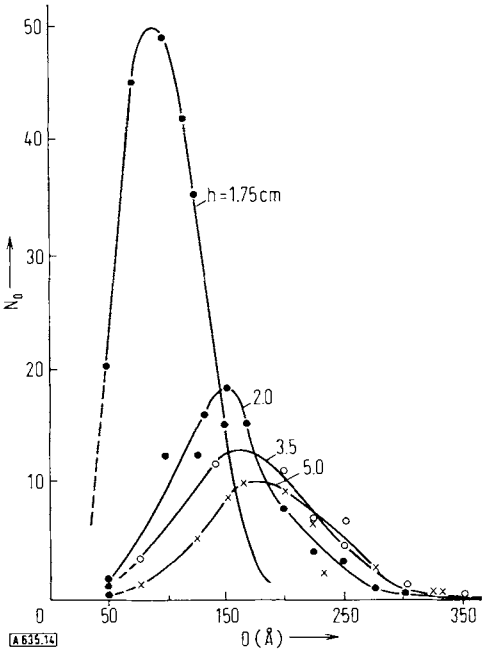

Fig. 14. Size distribution of soot particles at various heights (h = height over burner) in an acetylene-oxygen flame. C/O = 1.6, p = 20 torr.

Fig. 14 shows the size distribution of the soot particles (individual particles, no aggregation) at various heights in an acetylene-oxygen flame. The total number of particles falls off from the end of the oxidation zone (which is about 1.1 cm above the burner in this flame) rapidly at first and then more slowly, while the diameter of the particles increases up to a height of 6 cm, after which there is practically no further change in size. The curves correspond to approximately normal distributions. In this process the total quantity of soot at first increases steadily, until the first phase of the soot formation is complete at a height of $\approx$ 5 cm above the burner, and the concentration in low-pressure flames remains practically constant (Fig. 15); at higher pressures, this first phase takes place in a correspondingly narrower zone [48].

It can also be seen in Figure 15 that the acetylene and polyacetylene concentrations remain constant after the end of the first phase. The increase in the quantity of soot with richer fuel mixtures is almost exclusively due to an increase in the number of particles, the size of the particles remaining approximately the same up to the end of the first growth phase. The first phase of growth ends earlier in richer flames. In benzene-oxygen flames of the same C/O ratio, which form much more soot than acetylene flames, the particles have increased both in size and in number after the first phase.

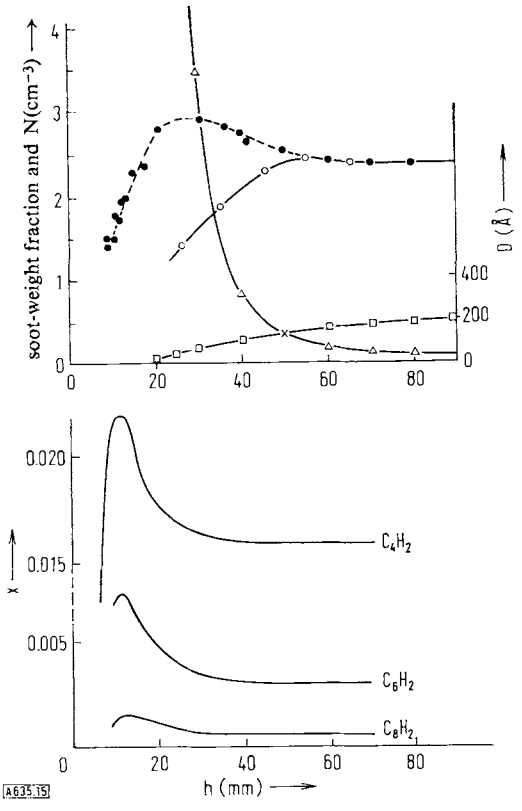

Fig. 15. Profiles of the soot concentration, number of particles, and particle size, as well as the polyacetylene concentrations, in an acetylene-oxygen flame (h = height over burner) C/O = 1.37, p = 20 torr. ● weight fraction of soot (10^{-3}; absorption), ○ weight fraction of soot (10^{-3}, electron microscope), Δ $N(10^{10}$ cm$^{-3})$, □ D(Å).

The soot concentration found by absorption is higher in the vicinity of the oxidation zone than the value found by removal of a sample (Fig. 15). The additional absorption is due to large hydrocarbon molecules and radicals, which absorb almost continuously at these temperatures, and which are probably identical with those found by mass spectrometry (Fig. 12).

An important indication of the source of soot particles is provided by the variation of their H/C ratio in the flame (Fig. 16). The first measurable soot has a high hydrogen content that corresponds approximately to the composition C_8H_2. The hydrogen content decreases rapidly at first, and then more slowly. The maximum rate of soot formation in the first phase agrees well

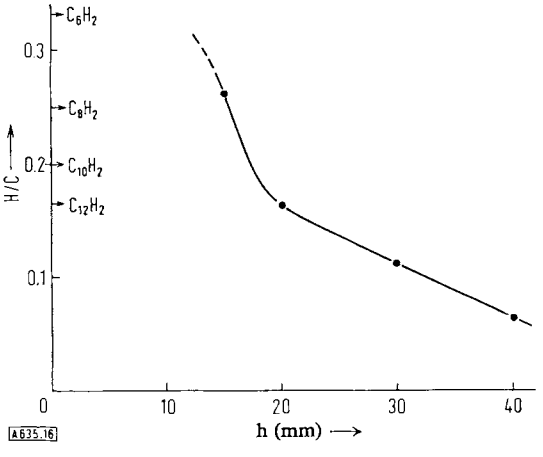

Fig. 16. Atomic ratio H/C in soot at various heights (h = height over burner) in an acetylene-oxygen flame. C/O = 1.7, p = 20 torr.

with that expected if the total concentration of soot grows through addition of higher polyacetylenes (C_8H_2 to $C_{10}H_2$) to soot particles by collisions with no activation energy [33]. The good agreement with the H/C ratio at this point is striking.

New, rapidly growing soot particles have a pronounced free-radical character as can be seen from the ESR signals of soot samples taken from close behind the oxidation zone. This free-radical character decreases rapidly with increasing age and growth of the particles. The subsequent slow growth of the particles in the second growth phase is due to heterogeneous decomposition of unsaturated hydrocarbons, *e.g.* of acetylene [49] and lower polyacetylenes, and probably partly of aromatic compounds, on their surface. This process requires an appreciable activation energy, and is slow in comparison with the first growth phase.

Very little is known about the forces that hold the larger soot particles together in chain networks. Electric forces may be involved. When sampled, these aggregates can be broken down again into the individual particles by ultrasonic radiation [50].

3. Discussion of the Soot Formation

3.1. General

There are numerous theories, or rather chemical models, for the mechanism of soot formation [*]. Individual points of many theories are also valid for the situation in premixed flames; however, the different hypotheses are mostly based on the observation of single phenomena, which could not always be seen in their true relation to the process as a whole, owing to lack of comprehensive information.

3.2. Differences from Condensation

In the theory of the condensation of a vapor, the concept of a nucleus leading to a particle of the new phase [53] is rigidly defined. This is not so in the formation of soot in the gas phase, though the word "nucleus" is often used in this connection. This concept is not very helpful in the consideration of soot formation, and really means nothing more than a small particle that is capable of further growth. There is no critical particle size above which the rate of growth (as in condensation) is greater than the rate of vaporization, and which could be correlated with a certain degree of supersaturation of "soot vapor". The growth of soot particles takes place under conditions that are far removed from an equilibrium state. At the temperatures in hydrocarbon flames, there is no evidence that existing soot particles, no matter how small, vaporize again; all that can happen to them is oxidation.

Johnson and *Anderson* [54] have shown that in the pyrolysis of acetylene, soot particles are not formed by condensation of high-boiling reaction products followed by "graphitization" [55]; such droplets are formed only when the reacting gases have cooled by several hundred degrees. Direct condensation of carbon vapor at very high temperatures, such as prevail *e.g.* in cyanogen-oxygen flames would be conceivable; however, the soot formation in these flames is slight in comparison with corresponding hydrocarbon flames [56–58].

3.3. Path of Soot Formation

The process as a whole is far from well enough known to allow a description of the "mechanism of soot formation" in the usual manner by a series of reactions. However, an attempt will be made to interpret the course of soot formation in premixed flames of lower hydrocarbons as far as is permitted by the essentially quantitative results obtained so far.

In the first, cooler portion of the oxidation zone, free-radical reactions lead to hydrocarbons containing more carbon atoms than the original fuel (*e.g.* $C_2H_2 + CH_2 \rightarrow C_3H_4$; $C_2H_2 + C_2H \rightarrow$ polyacetylenes). Those with relatively high hydrogen contents, such as propylene, methylacetylene, butadiene, or vinylacetylene, have no great direct importance in the formation of soot, since they disappear again before solid particles are formed.

Acetylene and the polyacetylenes predominate in the hotter part. The latter reach their maximum concentration at the end of the oxidation zone, where the oxygen supplied has been consumed; they are very probably formed by free-radical reactions

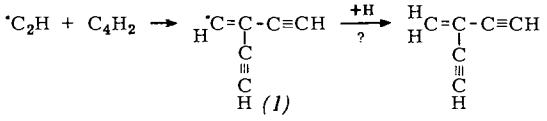
C_2H and C_4H_3 have been detected by mass spectroscopy [30]. C_2H can naturally also react directly with C_4H_2 to form C_6H_3 *etc.*

This mechanism for the formation of polyacetylenes and polyacetylene radicals is sufficiently fast only in the radical-rich oxidation zone, but no longer plays any great part in the burnt gas, despite the appreciable acetylene concentration in this region. Continuation of the growth of polyacetylenes cannot lead directly to soot particles, which are not giant chain molecules. However, there are other possible reactions besides chain growth. When C_2H or any other hydrocarbon radical reacts with a polyacetylene, the probability of attack on a terminal carbon atom decreases with increasing chain length; reaction on any other C-atom, if it does not result in cleavage of the chain, cannot lead again to a polyacetylene, since polyacetylenes cannot be branched, *e.g.* [33]:



(1)

The radical *(1)* can attain stability at low temperatures by formation of a methylene group, but such a substance, like vinylacetylene, is very unstable at the maximum temperature of the flame. It is therefore reasonable to assume that a radical such as *(1)* can add on further acetylene and polyacetylenes without loss of its free-radical character; the products are radicals with several branches, which can readily undergo ring closure to form five- or six-membered rings [*]. This leads to the formation of the relatively hydrogen-rich hydrocarbons with side chains found in the region of from about 100 to more than 500 mass units; at flame temperature many of these heavy cyclic hydrocarbons, which probably possess free-radical character [59], remain reactive and they add on further polyacetylenes and also combine with one another. Fast growth is caused in particular by the combination of larger particles.

There is practically no criterion of the size beyond which these particles are to be regarded as soot. As they grow, their free-radical character and their hydrogen content decrease. The decrease in the hydrogen content can be partly explained by the fact that the more reactive higher polyacetylenes add more readily if the free-radical character of the particles decreases.

The numerous heavy polycyclic hydrocarbons include the relatively inert pure aromatic compounds such as pyrene and phenanthrene. It must be concluded from their concentration profiles that these may be regarded as by-products rather than as reactive intermediates in the formation of soot [33, 38, 60]. Unlike the majority of the reactive polycyclic compounds, they continue to be formed in the burnt gases; it is therefore possible that they are also formed by heterogeneous reactions on the surface of soot particles, and evaporate off because of their relatively high vapor pressure.

Sharkey et al. [61] found a similar situation in investigations on the thermal stability of polycyclic aromatic compounds and their derivatives. Pure aromatic compounds such as naphthalene, phenanthrene, chrysene, pyrene, and anthracene were found to be relatively stable. However, compounds with side chains, such as methyl- and dimethylnaphthalene, methylphenanthrene, and substances having higher hydrogen contents, such as dihydroanthracene, indene, and indane reacted much more rapidly and gave products having four times the molecular weight of the starting material. Many of these aromatic compounds have free-radical character at higher temperatures [59].

The rapid decrease in the number of particles can be quantitatively explained if at each collision two particles remain together to form a larger particle. The shape of the particles is rounded off again by the simultaneous addition of hydrocarbons, so that they remain roughly spherical during the first growth phase. When this addition lags behind the association of the particles in the second phase, aggregates in the form of clusters or chains result (Fig. 13b). The heterogeneous decomposition of hydrocarbons, which now leads to a further increase in the quantity of soot, is slow in relation to the growth in the first phase. Since the concentration of hydrocarbon radicals in the burnt gas is low, the formation of new small particles in this zone is also very slow.

The soot formation in benzene flames differs from that in the flames of aliphatic fuels in that more benzene rings are involved from the outset in the formation of the reactive cyclic hydrocarbons in the region between about 100 to 600 mass units. Owing to the supply of larger "structural units", heavy hydrocarbons are formed even in the oxidation zone, and the soot formation zone partly overlaps with the radical-rich principal reaction zone of the flame [2]. Very many more hydrocarbon radicals can thus grow into larger particles, and the number of particles formed is much greater than *e.g.* in acetylene flames with the same C/O ratio. Thus benzene gives higher yields both of soot and of polycyclic aromatic compounds than lower aliphatic hydrocarbons [62].

3.4. Effect of Temperature

The decrease in the quantity of soot with rising flame temperature except for very rich flames is related to the reactions of the OH radical and the formation of water and carbon dioxide [63]. During the temperature rise in the first part of the oxidation zone, water and carbon dioxide are formed, mainly by the reactions

$$H_2 + OH \rightarrow H_2O + H \quad (1)$$

$$C_xH_y + OH \rightarrow H_2O + C_xH_{(y-1)} \quad (2)$$

$$CO + OH \rightarrow CO_2 + H \quad (3)$$

[*] However, the benzene found in flames of lower aliphatic compounds is formed earlier, together with C_4H_6 and C_3H_6. Its formation must be assumed to result from direct ring closure of a C_6-chain having a relatively high hydrogen content.

[62] *W. Morgeneyer*, Dissertation, Universität Göttingen, to be presented 1968.

[63] *K. H. Homann*, Combust. and Flame *11*, 265 (1967).

Sufficient oxygen is bound in this way to make the formation of higher hydrocarbons initially faster than their oxidation. With rising temperature in the flame front and in the burnt gas, the reverse reactions (1) and (3) become significant; water and carbon dioxide are consumed (Fig. 11) with regeneration of OH, which can now oxidize the higher hydrocarbons. The higher the temperature in the burnt gas, the lower is the concentration of water and carbon dioxide[2], and the soot limit is displaced toward its theoretical value.

3.5. Effect of Electric Fields

The electric conductivity of a hydrocarbon flame is mainly due to chemi-ionization[*] in the oxidation zone. Ions are formed in concentrations of about 10^9–10^{10} ions/cm^3 at atmospheric pressure[64]. A considerable proportion of these ions consists of positive and of negative hydrocarbon ions with molecular weights of up to ≈ 100. In rich flames, the heavier negative ions in particular have masses similar to those of the uncharged higher unsaturated hydrocarbons (polyacetylenes). However, their concentrations are several orders of magnitude lower[65].

There is no doubt that a certain percentage of the soot particles in the flame is positively charged. The soot formation both in diffusion flames and in premixed flames is strongly influenced by electric fields in certain circumstances[66].

To determine the effect of ions on the soot formation we studied the action of electric fields on flat premixed flames at pressures of up to 100 torr. The burner surface was used as the cathode, and the anode was a wire gauze placed 15 cm above the burner[67,68]. The phenomena observed can be best explained with the aid of a current-voltage curve (Fig. 17).

In a non soot forming flame, the curve has the expected shape. After a steep increase in current, a saturation current (determined by the chemi-ion concentration) is reached, and when a discharge occurs, the current assumes very high values.

In a soot forming flame, on the other hand, the current increases much more slowly, since there is less chemi-ionization. When the voltage is raised above 500 V, there is a slight decrease, and with the rapid increase in current at 800 V the soot luminosity disappears almost instantaneously. On ignition of the regular gaseous discharge, which takes place at a much lower voltage in this flame, a band of soot luminosity extends with the discharge through the burnt gas to the anode.

These phenomena can be interpreted as follows. Below 800 V the current is transported by positive and negative ions and

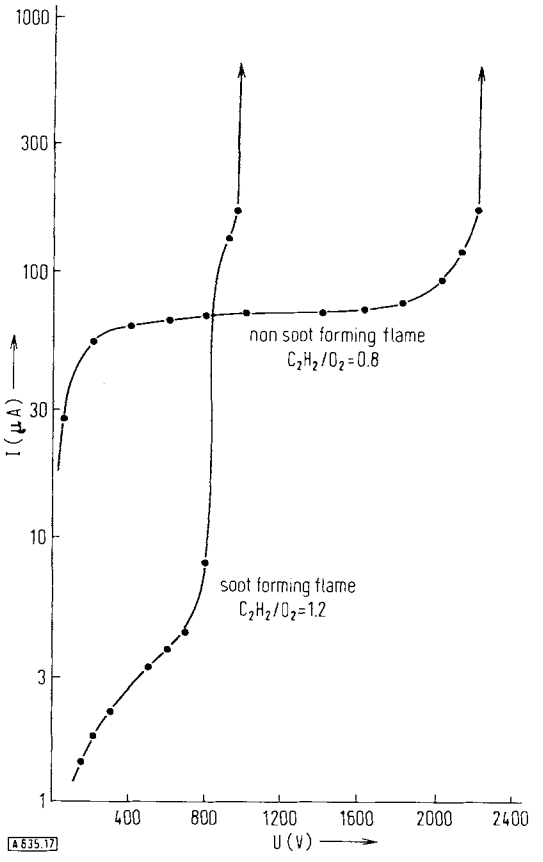

Fig. 17. Current-voltage curves of a soot forming and of a non soot forming flat acetylene-oxygen flame. $p = 30$ torr.

by electrons. At sufficiently high field strengths the few positively charged soot particles migrate back through the oxidation zone; a small portion is burnt, and the remainder is deposited on the negatively charged burner surface. This results in a slight decrease in the luminosity due to the soot between 500 and 800 V.

Above 800 V the soot particles, the ionization potential of which is very much lower than that of any other components of the flame, can be ionized by collisions with electrons. The new charge carriers formed by this "pre-discharge" cause the rapid increase in current. They can also ionize further soot particles until practically all the soot is positively charged and migrates to the negatively charged burner; the luminosity of the soot in the burnt gas is then almost completely extinguished. This also shows that soot particles are charged while still near to the oxidation zone and that practically no new small particles are formed within some distance from it. If such particles were formed they would continue to grow as they migrated, and would also emit light. New soot formation begins in the burnt gas only on establishment of a regular gaseous discharge. This leads to the formation of large quantities of free hydrocarbon radicals that promote soot formation.

The details of the process are difficult to understand, particularly since the variation of potential in the soot forming flame is unknown. However, it seems rather unlikely that ions play a decisive part as starting particles for soot formation so long as no suitable field is applied to the flame. The concentration of the ions in the absence of a field is several orders of magnitude lower than the concentration of hydrocarbon radicals. Moreover, if ions were important, the number of particles in the flames of rich mixtures should decrease as well as the ion concentration, but this is contrary to the observed facts. The ion concentration is increased

[*] Chemi-ionization is the formation of ions in non-equilibrium concentration as direct products of the reaction between uncharged species.

by many orders of magnitude by the addition of salts of alkali metals to the flame, but the soot formation is unaffected.

However, it is interesting to note that soot containing very small quantities of finely divided alkali metal salts burns much more readily than ordinary soot on subsequent introduction of air. This is also true of the combustion of soot deposits on surfaces [69].

4. Conclusion

This review has been confined to pure hydrocarbon fuels, since these are the systems that have been most thoroughly studied. Soot formation in the flames of fuels containing oxygen, *e.g.* ethanol, is also largely due to acetylene and polyacetylenes, and not to compounds such as higher alcohols or aldehydes [30]. The question of the effect of hetero atoms (nitrogen, sulfur, halogens, *etc*) on the mechanism of soot formation [70] has been deliberately avoided, since the existing results in this connection are not yet sufficient to allow any interpretation.

The same is true of the action of foreign additives in the flame [4, 36]. The effects of many substances on soot formation have already been studied. For practical reasons, the question of primary interest was whether the additive promoted or inhibited soot formation or had no influence. Thus barium salts of organic acids have recently been used to reduce soot formation in diesel motors; however, ideas on the mechanism of this inhibition are still only conjecture [71, 73]. The intensification of soot formation by *e.g.* sulfur trioxide and halogens is also still only incompletely understood.

For lack of information, the question of the process of soot formation in hydrocarbon-fluorine and hydrocarbon-chlorine flames has also been avoided, as has the interesting fact that perchlorinated hydrocarbons burn with fluorine but do not form soot, provided that no hydrogen is supplied to the flame in any form [72].

I am very grateful to Professor Dr. W. Jost for his kind and continuous support of my work and for the interest he has shown in it. Special thanks are due to Professor Dr. H. Gg. Wagner for many valuable suggestions and discussions. I thank the Deutsche Forschungsgemeinschaft and the Fraunhofer-Gesellschaft for their generous support of the investigations on combustion processes.

Dodecacarbonyltriruthenium

BY M. I. BRUCE AND F. G. A. STONE[*]

Dedicated to Prof. H. J. Emeléus on the occasion of his 65th birthday

Since the pioneering work of Mond and his coworkers the metal carbonyls and their derivatives have been under active study, and, as in other areas of inorganic chemistry, research activity has greatly increased in the last twenty years. Whereas hitherto our knowledge of the carbonyls of the heavier transition metals has been seriously hampered by a lack of good methods of synthesis, new preparative methods have recently been developed for $Ru_3(CO)_{12}$, and many new ruthenium carbonyl complexes are being discovered as its chemistry is explored.

1. Introduction

Dodecacarbonyltriruthenium was discovered in 1910, but was not characterized as such. *Mond et al.* [1] observed the formation of volatile rose to orange crystals by the action of carbon monoxide on ruthenium metal at 300 °C and 350 to 450 atmospheres. Subsequently, a chocolate brown nonvolatile amorphous compound, insoluble in benzene but soluble in water, was claimed as a product of the same reaction and assigned the formula $Ru(CO)_2$ [2].

A more thorough investigation [3] of the ruthenium black-carbon monoxide system showed that $Ru(CO)_5$ was formed

at 180 °C and 200 atmospheres, as a colorless volatile liquid, which, in the presence of sunlight or on warming to 50 °C in benzene, readily formed the orange crystalline complex referred to above. The orange compound was incorrectly assigned the formula $Ru_2(CO)_9$, mainly by analogy with $Fe_2(CO)_9$. A dichroic green-red product, insoluble in most solvents, but giving intensely green solutions with pyridine was also obtained, and was thought to be $Ru(CO)_4$. The synthesis of a ruthenium carbonyl by the action of carbon monoxide on ruthenium disulfide at 200 °C and 200–300 atmospheres in the presence of copper, zinc, or lead was also reported [4]. Much of this early work on ruthenium and other metal carbonyls was reviewed by *Emeléus* and *Anderson* [5] in a text which helped to stimulate the growth of modern inorganic chemistry by presenting the subject as offering unlimited opportunities for developing new experimental methods of a physicochemical nature, and the exploration, at that time, of little known fields.

2. Physical Properties of $Ru_3(CO)_{12}$

The reddish-orange colored crystalline ruthenium carbonyl was shown to be incorrectly formulated as $Ru_2(CO)_9$ as a result of an X-ray crystallographic study [6] on the presumed $Os_2(CO)_9$. The latter proved to be a trimeric tetracarbonyl $[Os(CO)_4]_3$ with a molecular structure involving a triangle of osmium atoms and no bridging carbonyl groups [7]. The ruthenium analog was shown to be isostructural, and the formulation was therefore revised to $[Ru(CO)_4]_3$ [6]. A detailed report of the molecular structure of dodecacarbonyltriruthenium has only recently been given [8]. As shown in Figure 1, $Ru_3(CO)_{12}$ has D_{3h} symmetry; its structure differs from that established for $Fe_3(CO)_{12}$ [9] in that none of the three metal-metal bonds is supported by bridging carbonyl groups.

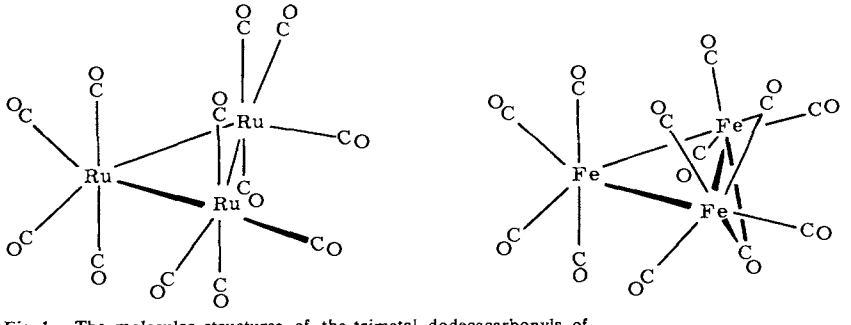

Fig. 1. The molecular structures of the trimetal dodecacarbonyls of ruthenium and iron in the crystalline state.

$Ru_3(CO)_{12}$ is soluble in benzene, toluene, chloroform, and carbon tetrachloride, but is insoluble in methanol or water. It is stable to air and to light, both as a solid and in solution. Some physical properties are given in Table 1.

Table 1. Physical properties of $Ru_3(CO)_{12}$.

The color of the carbonyl has been discussed [12], and the absorption at 391 nm has been ascribed to the metal-metal interactions [13]. The high resolution mass spectrum shows successive loss of twelve carbonyl groups to give a stable Ru_3^+ cluster, and no migration of carbonyl groups to form $Ru(CO)_n^+$ ions ($n>4$) occurs, as is observed in the spectrum of $Fe_3(CO)_{12}$ [14, 15].

3. Synthesis

In the last few years a series of syntheses of $Ru_3(CO)_{12}$ have been reported which are of increasing simplicity and efficiency. Reduction of tris(acetylacetonato)ruthenium(III) with equimolar mixtures of carbon monoxide and hydrogen at 140–160 °C and 200–300 atmospheres in methanol affords $Ru_3(CO)_{12}$ in 76% yield [16]; the method was later modified to give $Ru(CO)_5$ [17]. Treatment of ruthenium stearate in hydrocarbon solutions with carbon monoxide and

hydrogen at 200 °C and 240 atmospheres [18] leads to the formation of $Ru(CO)_5$, which on decomposition affords $Ru_3(CO)_{12}$ in 60% yield.

The simplest and most efficient preparation of the carbonyl is by low-pressure (< 10 atm) carbonylation of methanol solutions of ruthenium trichloride at about 65 °C in the presence of zinc as a halogen acceptor [19]; the $Ru_3(CO)_{12}$ obtained is essentially pure, large orange crystals forming on the surface of the zinc. Yields are around 70%, and can exceed 80% if the solutions are recycled. In the absence of zinc, the dimeric metal carbonyl chloride, $[Ru(CO)_3Cl_2]_2$ is formed in high yield, along with a small amount of $Ru_3(CO)_{12}$. Stirring a suspension of this carbonyl chloride in aqueous potassium carbonate solution also gives $Ru_3(CO)_{12}$, in a slow reaction which must involve disproportionation of $[Ru(CO)_3Cl_2]_2$ to give $Ru_3(CO)_{12}$ and perhaps $K_2[Ru(CO)_2Cl_4]$ [20].

Passage of carbon monoxide at ambient pressures into alcoholic solutions of $RuCl_3$ does not afford $Ru_3(CO)_{12}$, but addition of donor ligands yields carbonyl chloride complexes, *e.g.* $[C_6H_5(C_2H_5)_2P]_3RuCl_2(CO)$ or *cis*-$[(C_2H_5)_3P]_2RuCl_2(CO)_2$ [21]. In this way, complexes containing amines [22,23], phosphines [21,22], arsines [21,22], stibines [22], a variety of sulfur-containing ligands [23,24], and $SnCl_3$ [22–24] groups as ligands to ruthenium have been prepared, as well as some diene [25] complexes.

4. Chemical Reactions of $Ru_3(CO)_{12}$

Following the ready availability of $Ru_3(CO)_{12}$ many aspects of its chemistry and that of its derivatives have been explored. A summary of results is given in this section, with some comparison with analogous reactions of $Fe_3(CO)_{12}$ where appropriate.

Chlorine, bromine, or iodine react with $Ru_3(CO)_{12}$ affording four types of complex: mononuclear $Ru(CO)_4X_2$; binuclear $[Ru(CO)_3X_2]_2$; trinuclear $[Ru(CO)_4X_2]_3$; and polymeric $[Ru(CO)_2X_2]_n$ [26]. Iron appears to form only the mononuclear and the polymeric species, although the complex $Fe(CO)_3Br_2$ [27] may be dimeric and related to $[Ru(CO)_3Cl_2]_2$ [26].

$[Ru(CO)_2I_2]_n$ was first obtained by *Manchot* and *Manchot* [3]. The dimeric carbonyl halide $[Ru(CO)_3Br_2]_2$ [26a] has a molecular structure which is based on octahedral coordination for the ruthenium atoms with two octahedra sharing a common edge formed by bridging halogen atoms. Isomers are possible, and both white and yellow forms of $[Ru(CO)_3Cl_2]_2$ are known [19]. The trimeric complexes $[Ru(CO)_4X_2]_3$ probably have molecular structures in which the Ru_3 cluster is retained.

Reactions of $Ru_3(CO)_{12}$ with thiols also give several products, *viz.*, $[Ru(CO)_3SR]_2$, polymeric $[Ru(CO)_2(SR)_2]_n$ (R = CH_3, C_2H_5, *n*-C_4H_9, or C_6H_5), and $Ru(SC_6H_5)_3$ [26]. The iron complex $[Fe(CO)_3SC_2H_5]_2$ is known to have a structure with bridging SC_2H_5 groups, and in which the S and Fe atoms adopt a "butterfly"-like arrangement, as a consequence of metal-metal bonding [28]. The ruthenium analogs probably have similar structures. The polymeric derivatives $[Ru(CO)_2(SR)_2]_n$ are thought [26] to have a chain structure similar to that proposed for $[Ru(CO)_2X_2]_n$ [29].

Several studies have been made of the reaction between triphenylphosphine and $Ru_3(CO)_{12}$. Trinuclear complexes $Ru_3(CO)_9[P(C_6H_5)_3]_3$ are obtained [26, 30–32] but different accounts report different carbonyl stretching frequencies in the infrared spectra of the products. The metal atom cluster is preserved, but apparently mixtures of different isomers are formed, the composition of which depends on the solvent employed for the reaction [32]. Similar reactions with $Fe_3(CO)_{12}$ give only the mononuclear complexes $Fe(CO)_4P(C_6H_5)_3$ and $Fe(CO)_3[P(C_6H_5)_3]_2$ [33], except under the mildest conditions, when a complex $Fe_3(CO)_{11}P(C_6H_5)_3$ can be isolated in 2% yield [34]. Interestingly, crystals of this complex contain a 1:1 mixture of two isomers [35]. Prolonged refluxing of chloroform solutions of triphenylphosphine and $Ru_3(CO)_{12}$ gives an orange-yellow complex, $Ru(CO)_3[P(C_6H_5)_3]Cl_2$, which also appears to be a mixture of isomers [32].

Reactions between $Ru_3(CO)_{12}$ and tri-*n*-butylphosphine or triphenyl phosphite also afford trinuclear complexes $Ru_3(CO)_9(PR_3)_3$, but if the carbonyl is heated in solution with excess of the phosphine under CO pressure, mononuclear complexes $Ru(CO)_3(PR_3)_2$, of the type first reported by *Collman* and *Roper* [36], are produced [31]. The triphenylarsine complex, $Ru_3(CO)_{10}[As(C_6H_5)_3]_2$, has also been made. This compound reacts more readily than the triphenylphos-

phine complex with carbon tetrachloride or chloroform [32]. Reaction of $Ru_3(CO)_{12}$ with the bidentate ligand, tetramethyldiphosphine, leads to the formation of $[(CH_3)_2PRu(CO)_3]_2$ [30] which appears to be similar in nature to $[(CH_3)_2PFe(CO)_3]_2$ [37]. Reaction of the ruthenium compound with iodine affords $[(CH_3)_2PRu(CO)_3I]_2$, presumably by cleavage of the ruthenium-ruthenium bond. Reactions between $Ru_3(CO)_{12}$ and the tetradentate ligands $[o\text{-}(C_6H_5)_2PC_6H_4]_3P$ (QP) and $[o\text{-}(C_6H_5)_2AsC_6H_4]_3As$ (QAS) have also been studied [38]. At 100 °C in chlorobenzene the complexes Ru(CO) (QP) and Ru(CO) (QAS) are produced; the Ru_3 cluster in $Ru_3(CO)_{12}$ does not survive reactions with these ligands.

The action of moist nitric oxide in dichloromethane on $Ru_3(CO)_{12}$ affords polymeric $[Ru(CO)_2(NO)_2]_n$ [30]. Earlier, an unstable red crystalline nitrosyl with the unlikely formulation $Ru(NO)_5$ had been claimed as the product of treating $Ru_3(CO)_{12}$ with nitric oxide at 120 °C [3].

Under appropriate conditions the metal-metal bonds in $Ru_3(CO)_{12}$ can be cleaved to give the $[Ru(CO)_4]^{2-}$ anion; this is best obtained by the action of sodium in liquid ammonia on the carbonyl, evaporation of the ammonia leaving a buff-colored residue, presumably $Na_2Ru(CO)_4$ [39]. Treatment of this solid with phosphoric acid yields $H_2Ru(CO)_4$ [40], a hitherto uncharacterized hydride analogous to the long known $H_2Fe(CO)_4$. $H_2Ru(CO)_4$ is a very unstable colorless liquid which rapidly decomposes to a red-brown solid, probably $H_2Ru_3(CO)_{12}$, at temperatures above −40 °C. In contrast $H_2Os(CO)_4$ is stable above 100 °C [41]. It is interesting to speculate that such a polynuclear hydride could have a molecular structure in which the three ruthenium atoms form a bent metal-metal sequence as in $HRe_2Mn(CO)_{14}$ [42]. Mononuclear $H_2Ru(CO)_4$ exhibits a high field proton resonance at $\tau = 17.6$ in its NMR spectrum, and a ruthenium-hydrogen stretching frequency $\nu(Ru-H) = 1980\ cm^{-1}$ in its IR spectrum. In $D_2Ru(CO)_4$, $\nu(Ru-D)$ occurs at 1380 cm^{-1}. $H_2Ru(CO)_4$ reacts with phosphines to give the complexes $H_2Ru(CO)_2(PR_3)_2$, which are more conveniently prepared by reduction of the readily available $(R_3P)_2Ru(CO)_2Cl_2$ (R = C_2H_5 or C_6H_5) with $LiAlH_4$ [40] (*e.g.* $H_2Ru(CO)_2[P(C_2H_5)_3]_2$; ^1H-NMR: $\tau = 18.48$, $J(P-H) = 24$ Hz (triplet)). These hydrides undergo the expected reactions, such as with chlorinated solvents ($CHCl_3$ or CCl_4) to give $(R_3P)_2Ru(CO)_2Cl_2$, and with Me_3SiCl or Me_3SnCl to give the corresponding $(R_3P)_2Ru(CO)_2[M(CH_3)_3]_2$ (M = Si or Sn) complexes.

Several polynuclear ruthenium carbonyl hydrides have been characterized. The action of carbon monoxide and hydrogen on carbonylated ruthenium trichloride solutions in the presence of silver powder gives $H_4Ru_4(CO)_{12}$ [43,44]. Another hydride characterized by mass spectrometry is $H_2Ru_4(CO)_{13}$ [44]. A mixed hydride $HRuCo_3(CO)_{12}$ has been prepared [45], in a similar manner to $HFeCo_3(CO)_{12}$ [46], by refluxing ruthenium and cobalt carbonyls in acetone, and acidifying the product.

The anion $[Ru(CO)_4]^{2-}$ has been used to prepare $[(C_6H_5)_3PAu]_2Ru(CO)_4$ [decomp. 170 °C; νCO: 2026, 1952, and 1935 cm^{-1} (CS_2)] by treatment with $(C_6H_5)_3PAuCl$ [47].

There is currently considerable interest in complexes wherein silicon, germanium, or tin atoms are σ-bonded to transition metals. Recently the chemistry of organotin-iron carbonyl compounds has been reviewed, and a number of new complexes described [48]. It was, therefore, of interest to extend this field by studying ruthenium carbonyl derivatives of the Group IV elements.

Treatment of the $[Ru(CO)_4]^{2-}$ anion with R_3SnCl (R = C_6H_5 or $C_6H_5CH_2$) affords air-stable *trans*-$(R_3Sn)_2Ru(CO)_4$ [49]. The stereochemistry is assigned on the basis of the single carbonyl stretching band observed in the infrared spectra of these complexes (*e.g.* *trans*-$[(C_6H_5CH_2)_3Sn]_2Ru(CO)_4$; m.p. 99 °C, νCO: 2021 cm^{-1}). In contrast Me_3SnCl and the anion afford *cis*-$[(CH_3)_3Sn]_2Ru(CO)_4$ (a yellow liquid, b.p. 80 °C/10^{-2} torr, νCO: 2084 (s), 2024 (s), 2012 (w), and 2003 (s) cm^{-1}). With R_3SnCl (R = C_2H_5, *n*-C_3H_7, or *n*-C_4H_9) mixtures of *cis* and *trans* compounds, $(R_3Sn)_2Ru(CO)_4$, are obtained. Similar complexes are formed from $Ru(CO)_4H_2$ and trimethyltin hydride or triphenyltin chloride [40].

The complexes $(R_3Sn)_2Ru(CO)_4$ are best obtained by reacting triorganotin hydrides with $Ru_3(CO)_{12}$ [49]. It had been shown earlier that the iron analogs can be prepared similarly from iron carbonyls [48]. However, with the ruthenium carbonyl a novel type of diamagnetic complex $R_{10}Sn_4Ru_2(CO)_6$ is also produced, albeit in low yield. These polynuclear tin-ruthenium compounds are probably formed in the reactions by thermal decomposition of the mononuclear ruthenium species, since pyrolysis of $[(CH_3)_3Sn]_2Ru(CO)_4$ produces some $(CH_3)_{10}Sn_4Ru_2(CO)_6$ *(I)* (νCO: 2036 (w), 2000 (s), and 1982 (m) cm^{-1}), which has the novel molecular structure shown, as established by an X-ray crystallographic study [50].

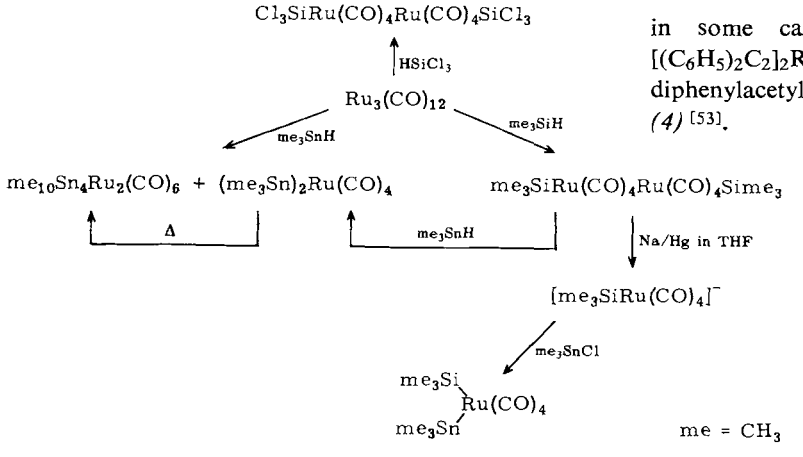
(2)

Reactions between $Ru_3(CO)_{12}$ and triorganosilanes follow a different course, complexes such as *(2)* (m.p. 129 °C; sublimes at 50 °C/10^{-3} torr) being produced in high yield. In contrast, under comparable conditions trimethylsilane and $Fe_3(CO)_{12}$ do not afford a stable silicon-iron complex. Moreover, with trichlorosilane $Ru_3(CO)_{12}$ gives $[Cl_3SiRu(CO)_4]_2$ *(3)* [51], whereas $Fe_3(CO)_{12}$ yields *cis*-$(Cl_3Si)_2Fe(CO)_4$ and $[Cl_2SiFe(CO)_4]_2$ [52]. Dimeric complexes $[R_2SnFe(CO)_4]_2$ analogous to $[Cl_2SiFe(CO)_4]_2$ are well known but iron complexes similar to *(1)* and *(2)* or *(3)* have not been prepared. Reaction of *(2)* with trimethylstannane gives $[(CH_3)_3Sn]_2Ru(CO)_4$ and $(CH_3)_3SiH$, but apparently the presence of the chlorine atoms in *(3)* enhances the stability of the silicon-ruthenium and ruthenium-ruthenium bonds since *(3)* does not react with trimethylstannane.



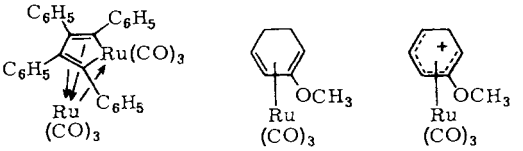
Scheme 1. Organosilicon and organotin complexes from $Ru_3(CO)_{12}$.

The discovery that an anion $[(CH_3)_3SiRu(CO)_4]^-$ can be obtained from *(2)* has led to the synthesis of a complex $(CH_3)_3Sn[(CH_3)_3Si]Ru(CO)_4$ in which two different group IV elements are bonded to ruthenium. Formation of $[(CH_3)_3SiRu(CO)_4]^-$ from *(2)* is reminiscent of the well known formation of $[(C_6H_5)_3PMn(CO)_4]^-$ from $[(C_6H_5)_3PMn(CO)_4]_2$. The infrared spectrum of *(2)* in the carbonyl region (νCO: 2040 (w), 2015 (vs), and 2010 (w, sh) cm^{-1}) is in accord with the structure proposed, being very similar to those of complexes of type $[R_3PMn(CO)_4]_2$. The high resolution mass spectrum of *(2)*, besides showing a molecular ion has a strong peak corresponding to $(CH_3)_3SiRu(CO)_4^+$.

Complex *(2)* undergoes a novel reaction with triphenylphosphine affording $[(C_6H_5)_3P]_2Ru(CO)_3$ and $[(CH_3)_3Si]_2Ru(CO)_2[P(C_6H_5)_3]_2$; under comparable conditions *(3)* does not react with the phosphine.

Reactions between $Ru_3(CO)_{12}$ and several hydrocarbons have been investigated. Unlike in the corresponding reactions involving $Fe_3(CO)_{12}$, several of the ruthenium complexes retain the metal atom cluster, for example, one product from cycloocta-1,3-diene is formulated as $C_8H_{12}Ru_3(CO)_{10}$ [30] and another from diphenylacetylene as $[(C_6H_5)_2C_2]_3Ru_3(CO)_9$ [53].

Diphenylacetylene affords several complexes, depending on the reaction conditions. In one study [54], in which the products were separated by thin-layer chromatography, complexes of formula $(C_6H_5)_2C_2Ru_3(CO)_9$, $[(C_6H_5)_2C_2]_2Ru_2(CO)_6$, $(C_6H_5)_2C_2Ru_2(CO)_6$, $[(C_6H_5)_2C_2]_2Ru_3(CO)_8$, $[(C_6H_5)_2C_2]_2Ru_2(CO)_7$, and $[(C_6H_5)_2C_2]_2Ru(CO)_4$ were obtained. The formulas of several of these complexes are similar to those of compounds obtained from acetylene and $Fe_3(CO)_{12}$ [55]. Structures may



(4) *(5)* *(6)*

in some cases be assigned by analogy, thus $[(C_6H_5)_2C_2]_2Ru_2(CO)_6$ formed from the carbonyl and diphenylacetylene in decalin at 200 °C is probably *(4)* [53].

The products obtained from similar reactions with other acetylenes depend on the substituents present [53]. 4,4'-Dichlorodiphenylacetylene gives dark red $[(ClC_6H_4)_2C_2]_3Ru_3(CO)_9$, analogous to $[(C_6H_5)_2C_2]_3Ru_3(CO)_9$ mentioned above, and orange $[(ClC_6H_4)_2C_2]_2Ru_3(CO)_8$ which probably has a structure similar to that of the black isomer of

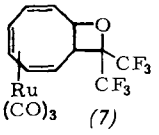
$[(C_6H_5)_2C_2]_2Fe_3(CO)_8$ [56]. 3-Hexyne [53] and hexafluoro-2-butyne [57] afford tetra-substituted cyclopentadienone-ruthenium tricarbonyl complexes, $(R_4C_4CO)Ru(CO)_3$ ($R = C_2H_5$ or CF_3) as the major products, along with trace amounts of what are probably polynuclear complexes. Dimethyl acetylenedicarboxylate is quantitatively trimerized to $C_6(CO_2CH_3)_6$ on heating with $Ru_3(CO)_{12}$ [53].

1,3-Cyclohexadienes react with $Ru_3(CO)_{12}$ to give the corresponding tricarbonylcyclohexadieneruthenium compounds [26]. The product from 2,5-dihydroanisole is a single isomer *(5)*, in contrast to the mixture of isomers formed from iron carbonyl. Proton abstraction with trityl tetrafluoroborate gives the cation *(6)*.

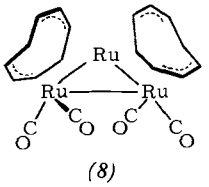
Tetracyclone and $Ru_3(CO)_{12}$ yield tricarbonyltetracycloneruthenium [57]. A ligand-exchange reaction occurs with tetraphenylcyclobutadienepalladium(II) bromide to give π-$(C_6H_5)_4C_4Ru(CO)_3$ [53]. Tricarbonylcyclobutadieneruthenium has been prepared [58] by treating 3,4-dichlorocyclobutene with the anion $[Ru(CO)_4]^{2-}$.

By refluxing cyclooctatetraene and $Ru_3(CO)_{12}$ in a hydrocarbon solvent at least four complexes are obtained. The compound π-$C_8H_8Ru(CO)_3$ [59,60] is the analog of π-$C_8H_8Fe(CO)_3$ [61], a complex which has been studied extensively on account of its being a stereochemically non-rigid molecule [62–65]. The ruthenium complex also exhibits a temperature-dependent ^1H–NMR spectrum but one capable of greater resolution at low temperatures. These studies [59,60] have established that the molecular structure of the ruthenium compound, and almost certainly that of the iron complex, in solution involves 1,3-diene to metal bonding [63,65] rather than 1,5-coordination of the C_8H_8 ring [64].

The compound $C_8H_8Ru(CO)_3$ undergoes 1,2-addition reactions [66] with suitably active molecules such as hexafluoroacetone or $(CF_3)_2C{=}C(CN)_2$ to give products such as *(7)*. These reactions are probably similar to the supposed Diels-Alder adduct of the corresponding iron complex and tetracyanoethylene [67,68].



(7)



(8)

Cyclooctatetraene is displaced from $C_8H_8Ru(CO)_3$ by iodine or phosphines to give the complexes $[Ru(CO)_3I_2]_2$ and *trans*-$(R_3P)_2Ru(CO)_3$, respectively. Mercuric halides or thiocyanate react with $C_8H_8Ru(CO)_3$ to afford the binuclear complexes $[Ru(CO)_3(HgX)X]_2$ (X = Cl, Br, or SCN), which further react with pyridine to give the complexes $Ru(CO)_3py(HgX)X$, which retain the Ru–Hg bond [69].

Other cyclooctatetraene-ruthenium complexes characterized so far include π-$C_8H_8Ru_2(CO)_6$ [69,70], π-$C_8H_8Ru_2(CO)_5$ [69,70], and $(\pi$-$C_8H_8)_2Ru_3(CO)_4$ [70]. The last named complex is particularly novel since it is both a metal atom cluster compound and a stereochemically non-rigid molecule. The molecular structure *(8)* has been established for this compound by an X-ray crystallographic study [71].

Prolonged heating of $Ru_3(CO)_{12}$ in benzene or cyclohexane at 150 °C gives a new cluster carbonyl formulated as $Ru_6(CO)_{18}$ [72]. Refluxing the carbonyl in toluene, xylene, or mesitylene gives other clusters such as red $Ru_6(CO)_{17}C$ and purple $Ru_6(CO)_{14}C$(arene) [73]. The hydrocarbons in these reactions may not be the source of the unique carbon atom but rather a CO group may have been degraded.

Ultraviolet irradiation of mixtures of $Ru_3(CO)_{12}$ and $Os_3(CO)_{12}$ has led to redistribution reactions affording $Ru_2Os(CO)_{12}$ and $RuOs_2(CO)_{12}$ [74].

Summary

A comparison of the chemistry of $Fe_3(CO)_{12}$ and $Ru_3(CO)_{12}$ indicates that in the former compound, the metal-metal bonds are easily broken, and it is only under the mildest conditions that compounds retaining the Fe_3 cluster are obtained. In contrast, the ruthenium cluster is much more robust, and many structurally new types of complexes with ruthenium-ruthenium bonds can be obtained, as is evident from the above review. For this reason further studies on $Ru_3(CO)_{12}$ and on the osmium analog are likely to be very worthwhile.

The Oxidizing Properties of the Third Transition Series Hexafluorides and Related Compounds

BY NEIL BARTLETT[*]

Dedicated to Prof. H. J. Emeléus on the occasion of his 65th birthday

Some of the transition metal hexafluorides demonstrate an astonishing oxidizing power. In particular may be mentioned PtF_6, which is capable of oxidizing molecular oxygen or xenon, a process requiring an electron affinity, $E(PtF_6)$, > -156 kcal·mole^{-1}. From a comparative study of all of the hexafluorides of the third transition series the electron affinity is seen to increase regularly in the sequence $WF_6 < ReF_6 < OsF_6 < IrF_6 < PtF_6$. The increase in E with unit increase in atomic number of M appears to be ≈ -20 kcal·mole^{-1}. On the other hand the ability of the hexafluorides to accept F^- decreases along this series. This effect enables IrF_6 to be more effective than PtF_6 in the generation of nitrogen oxide trifluoride, ONF_3, by the oxidative fluorination of nitrosyl fluoride, ONF. Both PtF_6 and IrF_6 interact spontaneously with ONF or O_2NF to generate fluorine, at or below room temperature. The decrease in F^--acceptor ability along the series, which stands in sharp contrast to the increase in electron affinity, suggests that ligand crowding increases sharply across the series from WF_6 to PtF_6. This accords with the observed decrease in molecular volume along the series, both in the hexafluorides and in the MF_6^- salts. It is clear from this comparison that the species IrF_6 and PtF_6 are close to a minimum volume for this series. The oxide pentafluorides $ReOF_5$ and $OsOF_5$ are similar in oxidizing ability to their respective hexafluorides but are poorer F^- acceptors. Evidently the ligand crowding in MOF_5 molecules is greater than in MF_6.

1. Introduction

The discovery of dioxygenyl hexafluoroplatinate(v), O_2PtF_6[1,2], revealed the remarkable oxidizing properties of platinum hexafluoride. The crystal structure and magnetic, spectroscopic[**], and chemical properties of O_2PtF_6 all point to the ionic formulation $O_2^+[PtF_6]^-$.

The lattice energy was estimated from *Kapustinskii*'s equation[3],

$$U = 287.2\ \Sigma n\ \frac{z_1 z_2}{r_c + r_a}\left(1 - \frac{0.345}{r_c + r_a}\right)$$

where Σn is the number of ions in the molecule ($= y + x$ in $A_y(MF_6)_x$), z_1 and z_2 the ionic charges, and $r_c + r_a$ the sum of the ionic radii referred to coordination number six. In the case of $O_2^+[PtF_6]^{-1}$, $U = -125$ kcal·mole^{-1}. From the Born-Haber cycle, given in Figure 1, the electron affinity of the hexafluoride $E_{(PtF_6)}$ is required to be > -156 kcal·mole^{-1} in order that the oxidation of molecular oxygen (ionization potential $I_{(O_2)} = 281$ kcal·mole^{-1} [4]), by the hexafluoride, should occur spontaneously. Of course there is a considerable decrease in entropy for the process and for processes like it,

$$O_{2(g)} + PtF_{6(g)} \rightarrow O_2^+[PtF_6]_{(s)} \qquad (1)$$

hence $E_{(PtF_6)}$ needs to be considerably in excess of -156 kcal·mole^{-1} for spontaneous reaction.

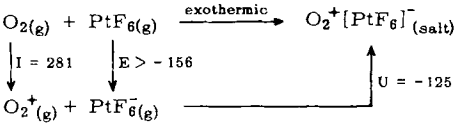

Fig. 1. A Born-Haber Cycle for $O_2^+(PtF_6)^-$. (Enthalpies in kcal·mole^{-1}.)

It may be argued that London dispersion forces and multipole forces[5] would add energy to that computed from *Kapustinskii*'s equation. This may be so, but this additional term is unlikely to exceed the enthalpy of formation of orthorhombic PtF_6 crystals from the vapor (*i.e.*, -11 kcal·mole^{-1})[6]. Furthermore it is probable that reaction (1) is more exothermic than -25 kcal·mole^{-1}, since the solid is not sublimable *in vacuo* below 90 °C[2]. Even allowing for additional lattice energy terms, it is probable that $E_{(PtF_6)}$ well exceeds -156 kcal·mole^{-1}.

Not only was it evident that PtF_6 should be capable of bringing about further spectacular oxidations but it seemed that other hexafluorides and related compounds could at least approach, or perhaps exceed it in oxidizing ability. A survey of the oxidizing properties of

hexafluorides of the third transition series and a comparison of these fluorides with the oxide pentafluorides ($OsOF_5$ and $ReOF_5$), with ReF_7, and with hexafluorides of the second transition series was therefore undertaken.

2. Oxidation of Noble Gases

After having solved the O_2PtF_6 problem our attention was immediately focused on the possible oxidation of xenon, the ionization potential of which ($I_{(Xe)}$ = 280 kcal·mole^{-1}) [4] is almost identical to that of molecular oxygen. Further, in the case of an $[MF_6]^-$ salt the lattice energy is not greatly dependent on the cation size; it appeared probable, therefore, that PtF_6 would oxidize this noble gas. Indeed the lattice energy for $Xe^+[PtF_6]^-_{(c)}$ is unlikely to be less exothermic than -120 kcal·mole^{-1}, which is the appropriate value for an estimated Xe^+ radius of 1.5 Å. The predicted oxidation of xenon by PtF_6 did occur spontaneously at room temperature [7]. The product, however, is not as simple as first formulated [8].

This reaction has been repeated many times and followed tensimetrically as well as gravimetrically [9]. The combining ratio Xe: PtF_6 always lies between 1:1 and 1:2, with the former favored when the xenon is in excess and the concentration of the reactants is low. *Mahieux* [10] may well have produced similar material by exploding a platinum wire in Xe/F_2 gas, products of composition $XePtF_6$ and $Xe(PtF_6)_2$ being indicated. The product from $PtF_6 + Xe$ reactions is always plastic and, but for minor crystalline components, amorphous to X-rays. The product, irrespective of composition, is paramagnetic, and shows infrared absorption at 650 cm^{-1} (vs) and at 550 cm^{-1} (s), which spectra are similar to the spectra of $O_2^+[PtF_6]^-$ [2] and $NO^+[PtF_6]^-$ [11,12] and certainly characteristic of Pt(v) in a fluorine ligand environment.

If an excess of PtF_6 is used and the product, of composition $Xe(PtF_6)_2$, is warmed to ~ 60 °C a red solid is obtained which gives a characteristic X-ray diffraction pattern [9]. This product is structurally almost identical to the adduct XeF_2, 2 IrF_5 that was prepared recently by *Bartlett* and *Sladky* [13] by the reaction of XeF_2 with IrF_5 in BrF_5 and which probably is $XeF^+[Ir_2F_{11}]^-$. Furthermore, the faint pattern that frequently appears in X-ray photographs of $Xe(PtF_6)_x$ (x = 1–2) has been identified as that of XeF_2, PtF_5. This compound is structurally very closely related to the 1:1 adduct XeF_2, IrF_5, which is probably the salt $XeF^+[IrF_6]^-$ [13]. Incidentally, IrF_6 does not interact with xenon under the conditions of $Xe(PtF_6)_x$ formation.

Earlier work [8] had shown that the $Xe(PtF_6)_x$ contains Pt(v), since interaction with alkali fluoride ($A[IF_6]$, A = Rb, Cs) in IF_5 solution yielded $A^+[PtF_6]^-$ salts. A separate experiment established that XeF_4 in IF_5 solution does not oxidize Pt(IV) fluoride in the presence of alkali fluoride.

There are few solvents for $Xe(PtF_6)_x$ and recrystallization of the material from a solvent has not yet been achieved. When the solid is heated above 160 °C [*] a complicated redox reaction takes place, resulting in the formation of XeF_4 and a diamagnetic material, which contains xenon, has a composition approximating to $XePt_2F_{10}$ [8,9] and gives a distinctive X-ray powder pattern.

The interaction of PtF_6 with Xe may therefore be interpreted by assuming the following reactions:

$$Xe_{(g)} + PtF_{6(g)} \rightarrow Xe^+[PtF_6]^-$$

The cation is then fluorinated by excess PtF_6:

$$Xe^+PtF_6^- + PtF_6 \rightarrow XeF^+[PtF_6]^- + PtF_5.$$

Evidently the formation of the $XeF^+[Pt_2F_{11}]^-$ salt requires thermal activation:

$$XeF^+PtF_6^- + PtF_5 \rightarrow XeF^+[Pt_2F_{11}]^-$$

The initial product $Xe^+[PtF_6]^-$ could rearrange to form $Xe_2^{2+}[PtF_6]_2^-$ but the like charges of the Xe^+ would not be expected to encourage such a union and there is no evidence to support such a formulation.

The ionization potential of krypton $I_{(Kr)}$ is 323 kcal·mole^{-1} [4] and the lattice energy $U_{(Kr^+[MF_6]^-)}$ is approximately -125 kcal·mole^{-1}; hence, a minimum electron affinity $E_{(MF_6)}$ of -198 kcal·mole^{-1} is required to effect oxidation of krypton to $Kr^+[MF_6]^-$ by MF_6. Unfortunately PtF_6 will not oxidize krypton nor will RhF_6 [8], although AuF_6, should it be prepared, could possibly do so, since $E_{(AuF_6)}$ is estimated to be > -180 kcal·mole^{-1} [11].

Although RhF_6 will not oxidize Kr it does oxidize Xe [8].

The reaction product of two experiments had a composition close to $XeRhF_6$, the combining ratio Xe: RhF_6 being 1:1.05 and 1:1.0. Very faint sharp line patterns indicate the presence of $XeF^+[RhF_6]^-$ as a minor phase; this suggests that an excess of RhF_6, like PtF_6, interacts with the Xe^+ to produce XeF^+.

Clearly PtF_6 and RhF_6 (and possibly IrF_6) ought to be capable of oxidizing radon since $I_{(Rn)}$ = 246.6 kcal·mole^{-1}. With $U_{(Rn^+[MF_6]^-)} = -115$ kcal·mole^{-1}, $E_{(MF_6)}$ would have to be considerably more exothermic than -132 kcal·mole^{-1}

3. Oxidation of NO and ONF

None of the third transition series hexafluorides other than PtF_6 proved to be capable of oxidizing xenon or oxygen [9]. Since the hexafluoride anions are large and are similar in size, the lattice energy does not vary by

S.G. = Space group (or Bravais lattice) g = gas, l = liquid, s = solid.

more than 1–2 kcal·mole^{-1} for a common cation. Furthermore, NO^+ is so similar in size to O_2^+ that the difference in lattice energy in salts of a common anion is negligible. Since the ionization potential $I_{(NO)}$ is 68 kcal·mole^{-1} less than $I_{(O_2)}$ [4], the electron affinity $E_{(MF_6)}$ for oxidation of NO need be that much less exothermic than for oxidation of O_2. On the other hand, the oxidation of nitrosyl fluoride with liberation of molecular fluorine requires a minimum $E_{(MF_6)}$ of −126 kcal·mole^{-1} (c.f. Fig 2).

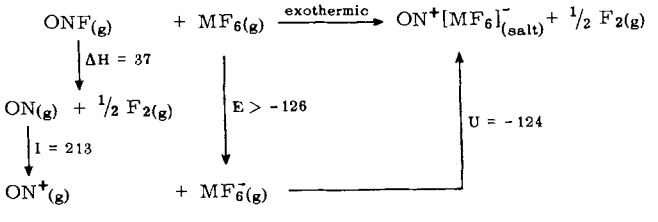

Fig. 2. A modified Born-Haber cycle for the reaction $ONF_{(g)} + MF_{6(g)} \rightarrow NO^+[MF_6]^-_{(s)} + {}^1/_2 F_{2(g)}$. (Enthalpies in kcal·mole^{-1}).

By employing NO or ONF as the reducing agent *Jha* and *Beaton* have established [2,9,11,12] a smooth increase in $E_{(MF_6)}$ in the series WF_6 to PtF_6 (cf. Table 1). Iridium hexafluoride is seen to be the only hexafluoride of this series, other than PtF_6, to be capable of oxidizing ONF to liberate fluorine. However, the ONF adduct with OsF_6 is readily reduced to $NOOsF_6$ and indeed on one occasion ONF_3 has been noted as a gaseous product. This contrasts with the marked stability of $(NO)_2ReF_8$. The nature of the products obtained by reaction of NO with MF_6 shows that WF_6 is the poorest oxidizer and that IrF_6 and PtF_6 are the best oxidizing agents. Evidently $E_{(MF_6)}$ increases (exothermally) regularly in the sequence $WF_6 < ReF_6 < OsF_6 < IrF_6 < PtF_6$ with $E_{(ReF_6)} > -90$ $E_{(IrF_6)} > -126$; and $E_{(PtF_6)} > -156$ kcal·mole^{-1} [11]. The increase in $E_{(MF_6)}$ with unit increase in atomic number of M appears to be ~ −20 kcal·mole^{-1}.

The change in volume of MF_6^-, indicated by the relative formula-unit volumes in the cubic crystalline $NO^+[MF_6]^-$ salts [2,9,11,12] is as follows: Ta, 133.4; Re, 130.7; Os, 129.8; Ir, 129.3; Pt, 129.2 Å^3.

The volume of the PtF_6 group is close to a limiting volume. The unit cell volumes of both the orthorhombic and cubic forms of the hexafluorides [16] reveal a similar limiting volume behavior (cf. Table 3). Presumably, therefore, $V_{(AuF_6)}$ ought to be similar in magnitude to $V_{(PtF_6)}$; however, the fluorine ligand electrons of the former would be more highly polarized than in the latter and consequently spontaneous liberation of fluorine would be more likely to occur. Undoubtedly the AuF_6 molecule would be more strongly oxidizing than PtF_6 and $E_{(AuF_6)}$ would probably be > −180 kcal·mole^{-1}. It is unlikely that it would be powerful enough to oxidize molecular nitrogen ($I_{(N_2)}$ = 358 kcal·mole^{-1} [4]) since this requires an $E_{(AuF_6)}$ greater than −233 kcal·mole^{-1}, but the oxidation of Kr (cf. Section 2) could be within range.

The products obtained on reaction of ONF with MF_6 not only reveal an increase in electron affinity from WF_6 to PtF_6 but also demonstrate a marked decrease in F^- acceptor ability – at least from ReF_6 to PtF_6. Although WF_6 cannot oxidize NO, it readily adds F^-:

$$ONF + WF_6 \rightarrow NOWF_7$$
$$2\,ONF + WF_6 \rightarrow (NO)_2WF_8$$

The $NOWF_7$ complex is simple cubic and must be a plastic crystal, the WF_7^- being rotationally disordered. The $(NO)_2WF_8$ salt is isomorphous with $(NO)_2ReF_8$

[14] *J. R. Gleichmann, E. A. Smith, S. S. Trond,* and *P. R. Ogle,* Inorg. Chem. *1*, 661 (1962).

[15] *F. P. Gortsema* and *R. H. Toeniskoetter,* Inorg. Chem. *5*, 1217 (1966).

[16] *S. Siegel* and *D. A. Northrop,* Inorg. Chem. *5*, 2187 (1966).

and it is probable that both contain MF_8^{2-} ions. Interestingly, although there is evidence that $NOReF_7$ can be prepared at temperatures lower than −30 °C, the compound dismutates below room temperature [12]:

$$ONF + ReF_6 \rightarrow [NOReF_7] \rightarrow ReF_6 + (NO)_2ReF_8$$

The interaction of NO with ReF_7 [12] involves the same intermediate:

$$2\,NO + ReF_7 \rightarrow NO + [NOReF_7] \rightarrow NOReF_6 + (NO)_2ReF_8$$

It seems that the enthalpy of the addition reaction $F^-_{(g)} + MF^-_{7(g)} \rightarrow MF^{2-}_{8(g)}$ is more exothermic for ReF_7^- than for WF_7^-; all other factors being neglected, this is at least consistent with the greater electron affinity of Re^{VI} over W^{VI}. The inability of OsF_6 to form $(NO)_2OsF_8$ is therefore ascribed to the greater ligand crowding in the Os^{VI} species. Presumably in ReF_7^- the ligands are not so tightly crowded as in OsF_7^-. The unimolecular unit cell volume of $NOWF_7$ (140.4 Å^3 [11,12]) is certainly much greater than in $NOOsF_7$ (136 Å^3); also, the latter volume is only 14 Å^3 greater than the molecular volume in the cubic OsF_6 (122 Å^3).

With IrF_6 the marginal ability to add F^- and the ability to oxidize F^- to $^1/_2F_2$ combine to render it a most effective oxidative fluorinating agent. When ONF and IrF_6 are mixed in approximately equimolar quantities at 20 °C, a reaction occurs, the overall stoichiometry of which approximates to

$$ONF + IrF_6 \rightarrow NOIrF_6 + {}^1/_2F_2$$

Some nitrogen oxide trifluoride [11,17–19] is formed, the yield of which is increased greatly when the ratio of ONF to IrF_6 is increased; with a 3:2 molar ratio, more than 60% of the theoretical yield of ONF_3 is obtained:

$$3\,ONF + 2\,IrF_6 \rightarrow 2\,NOIrF_6 + ONF_3$$

Since ONF will not interact with F_2 at ordinary temperatures and pressures without excitation [17], and since IrF_6 does not interact with ONF_3 [18], it is reasonable to suppose that these reactions involve an intermediate, probably $NOIrF_7$. Presumably this short lived complex salt can eliminate molecular F_2 concertedly.

$$2\,NOIrF_7 \rightarrow 2\,NOIrF_6 + F_2$$

Alternatively, it could interact with an excess of nitrosyl fluoride in a two step process.

$$ONF + NOIrF_7 \rightarrow ONF_2^{\bullet} + NOIrF_6$$
$$ONF_2^{\bullet} + NOIrF_7 \rightarrow ONF_3 + NOIrF_6$$

The ONF_2 radical reported by *Fox et al.* [18] is unlikely to be free in this reaction but is more likely to be fluorinated before it can leave the $NOIrF_6/NOIrF_7$ surface.

There is no evidence to suggest that a salt-like adduct is formed by the interaction of PtF_6 and ONF; such an intermediate – if it were formed – would have an extremely short lifetime, since, no matter what the concentration of ONF, the overall reaction is close to that represented by the equation:

$$ONF + PtF_6 \rightarrow NOPtF_6 + {}^1/_2F_2$$

Minor amounts of ONF_3 are produced [11,12]. It is a safe assumption that the ligand crowding is greater in PtF_6 than in the other hexafluorides of the third transition series, but this molecule also has the oxidizing power to liberate atomic fluorine from ONF, for which $E_{(MF_6)}$ must merely exceed −144 kcal·mole^{-1}. It is conceivable therefore that the shorter lifetime of $NOPtF_7$ compared to $NOIrF_7$ results from both the greater crowding and the ability to shed atomic fluorine.

The ability of PtF_6 to liberate fluorine on interaction with ONF was discovered independently by *Gortsema* and *Toeniskoetter* although their report [15] makes no mention of ONF_3 formation. The study by *Beaton* [11,12] gave no evidence to support the claim made by these authors that further interaction of ONF with $NOPtF_6$ takes place with liberation of more fluorine; indeed $(NO)_2PtF_6$, said to be formed in the reaction, and described as cubic, cannot be made in this way. $(NO)_2PtF_6$ is a diamagnetic salt, which has a hexagonal lattice (somewhat disordered) and can be prepared from NO (excess) + PtF_6 (cf. Table 1); it is isomorphous with $(NO)_2PdF_6$ [20].

Although the F_2 produced in these reactions is derived at normal temperatures and pressures from reagents which may be kept indefinitely at ordinary temperatures (in suitable containers), the preparation is nevertheless not a primary one. Fluorine (or presumably electrolytic syntheses) must be used to generate IrF_6 or PtF_6. Indeed there is still no definitive primary chemical preparation of this halogen.

4. Other Oxidations Involving MF_6

Attempts to oxidize Kr, N_2, NF_3, and F_2O by PtF_6 failed [9]. All are more difficult to oxidize than O_2 or Xe.

Although the lower ionization potential of hexafluorobenzene ($I_{(C_6F_6)}$ = 207.5 kcal·mole^{-1}) [21] favors its oxidation by PtF_6, it has not yet proved possible to prevent highly favored alternative reactions such as:

$$3\,PtF_6 + C_6F_6 \rightarrow 3\,PtF_4 + C_6F_{12}$$

[21] *J. R. Majer* in *M. Stacey, J. C. Tatlow*, and *A. G. Sharpe*: Advances in Fluorine Chemistry. Butterworths, London 1961, Vol. 2, p. 83.

Similarly, although CO has an ionization potential close to that of N_2 and would not be expected to yield CO^+, it interacts instantly with PtF_6 to form COF_2, PtF_4, and even Pt; the CO here assuming its normal role as a strong reducer:

$$CO + PtF_6 \rightarrow Pt + PtF_4 + COF_2$$

The oxidation of Cl_2 with PtF_6 is feasible if one considers its ionization potential $I_{(Cl_2)} = 260$ kcal·mole^{-1} [4] and its lattice energy $U_{(Cl_2^+[PtF_6]^-)}$, which was estimated to be ≈ -115 kcal·mole^{-1}. Although the gases interact immediately at $\approx 20\,^\circ C$ and no free chlorine fluorides are produced, the combining ratio $Cl_2:PtF_6$ is $\approx 1:2.5$ [9]. The investigation of this interaction is incomplete, but it is evident that the product obtained is a mixture and may well contain PtF_5 and ClF_2PtF_6 [22].

Iridium hexafluoride also proved able to oxidize Cl_2 [9]. The molar combining ratio is closer to 1:1 and, as in the case of PtF_6, no evidence has been found for free chlorine fluorides in the product. Unfortunately the product is amorphous to X-rays; the yellow solid is unstable at room temperature and decomposes [9, 23] to iridium pentafluoride [24] and a gaseous decomposition product, other than chlorine, that has not been identified. Should the Raman and infrared studies presently being carried out prove the presence of $Cl_2^+[IrF_6]^-$ in the adduct then it would follow that $E_{(IrF_6)} > -144$ kcal·mole^{-1}.

Gibler has shown [23] that WF_6, as expected, does not oxidize I_2 ($I_{(I_2)} = 214$ kcal·mole^{-1}) spontaneously. OsF_6 does, but the reaction is complex. He established that nitryl fluoride interacts with IrF_6 according to the equation:

$$O_2NF + IrF_6 \rightarrow NO_2^+[IrF_6]^- + {}^1/_2F_2$$

The nitryl salt shows the usual [26] ν_3 infrared bands at 2360 cm^{-1} and IrF_6^- ν_3 at 630 cm^{-1} [27]. The unit cell is orthorhombic, but the alternative primitive monoclinic cell $a = b = 4.99$; $c = 5.55$ Å; $\alpha = 92.3\,^\circ$ $V = 138$ Å^3, shows a clear relationship to the primitive *pseudo* cell of $NOIrF_6$, $a = 5.057$ Å, $V = 129$ Å^3. Since the dissociation enthalpy for $O_2NF_{(g)} \rightarrow NO_{2(g)} + {}^1/_2F_{2(g)}$ [25] $= 27$, $I_{(NO_2)} = 228$ [4], and $U_{(NO_2IrF_6)} = -120$ kcal·mole^{-1}, $E_{(IrF_6)}$ must be > -135 kcal·mole^{-1}, which is ~ 9 kcal more exothermic than the $E_{(MF_6)}$ requirement in the oxidation of NOF with IrF_6.

The salt $NO_2^+[OsF_6]^-$, which was prepared in a slightly impure form (contaminated with $NOOsF_6$) by *Jha* [9] from NO_2 and OsF_6, is isomorphous with NO_2IrF_6. The spontaneity of this reaction implies an $E_{(OsF_6)} > 108$ kcal·mole^{-1}.

5. Oxidizing Properties of $ReOF_5$ and $OsOF_5$

Both $ReOF_5$ and $OsOF_5$ are of C_{4v} symmetry and are nearly octahedral [33, 38]. The molecular volume of $OsOF_5$ in both the orthorhombic and cubic forms is less than that of OsF_6 (see Table 3). At 20 °C $ReOF_5$ is isomorphous with orthorhombic $OsOF_5$. The interaction of the oxide fluorides with NO produces [9, 12] 1:1 salts spontaneously at ambient temperature:

$$NO_{(g)} + MOF_{5(g)} \rightarrow NOMOF_{5(s)}$$

It seems, then, that both $OsOF_5$ and $ReOF_5$ have an oxidizing capability similar to that of the respective fluorides. Clearly $OsOF_5$ is not so powerful as IrF_6, and $ReOF_5$ is not so weak as WF_6. The salts $NO^+[MOF_5]^-$ bear a close structural relationship to their $NO^+[MF_6]^-$ relatives (cf. Table 2).

Table 2. Structural Relationships of $NOMF_6$ and $NOMOF_5$ Salts.

Salt	Bravais lattice	Bravais lattice parameters (Å)		Mols./ unit cell	Mol. Vol. (Å^3)
		a	*c*		
$NOReOF_5$	tetragonal	5.083	10.00	2	129
$NOOsOF_5$	tetragonal	5.025	10.37	2	131
$NOReF_6$	body centered cubic	10.151		8	130.75
$NOOsF_6$	body centered cubic	10.126		8	129.79

When the NO + $OsOF_5$ reaction was carried out in WF_6 solution, a cubic phase of composition $(NO)_2OsWOF_{11}$ was obtained, which proved to be isomorphous but not isodimensional with $NOOsF_6$ [$(NO)_2OsWOF_{11}$: $a = 10.152$ Å; $NOOsF_6$: $a = 10.126$ Å] [9]. The magnetic susceptibility was measured over the 77–297 °K range and showed a Curie-Weiss law obedience, with $\theta = 24\,^\circ K$; the behavior closely parallels that of $NOOsF_6$ [9]. The product is presumably a solid solution of $NOWOF_5$ in $NOOsF_6$. The magnetic moment of $(NO)_2OsWOF_{11}$ obtained on this basis was $\mu_{eff} = 3.15$ B.M. (297 °K) which compares favorably with the value of $\mu_{eff} = 3.36$ B.M. (297 °K) obtained for the pure $NOOsF_6$ salt [9]. The overall reaction in this instance was therefore:

$$2\,NO + WF_6 + OsOF_5 \xrightarrow{HF\ catalyst} NOOsF_6 + NOWOF_5$$

with the oxygen ligand exchanging partners.

It is probable that the effective catalyst was HF but this has not been established. Exchange of oxo-ligand could take place by way of an oxygen-bridged intermediate; the hypothetical oxyfluoride WOF_5 with its unsaturated oxygen valence would be a better electron acceptor than WF_6.

The course of the reaction suggests that $E_{(OsF_6)} > E_{(OsOF_5)}$, although the soundness of this conclusion must await the outcome of an investigation of the reaction mechanism.

Unlike ReF_6, $ReOF_5$ is not able to combine with 2 ONF, the sole product being $NOReOF_6$. This difference in F^- acceptance may again be ascribed to a steric cause. Similarly, although OsF_6 and ONF interact to give $NOOsF_7$, a mixture of ONF and $OsOF_5$ does not give an adduct. As is shown in Table 3, the molecular volume of $OsOF_5$ is significantly less than that of OsF_6.

The greater ligand crowding in the oxide pentafluorides compared with their hexafluoride relatives must in part be ascribed to the greater size of the oxygen ligand compared with the fluorine ligand, but there is probably an important electron configuration factor which will be referred to later.

6. Metal Hexafluorides of the Second Transition Series

Although attention has been focused upon the oxidative chemistry of the third transition series compounds it should be noted that a similar trend of increasing oxidizing power with increasing atomic number and decreasing molecular volume also occurs in the second transition series; however, information is much scarcer.

In particular, MoF_6 has been shown by *Geichmann et al.*[14] to be capable of oxidizing NO to give $NOMoF_6$, which establishes that MoF_6 is a stronger oxidizer than WF_6. *Seip*[35] determined the M—F distances in MoF_6 and WF_6 from electron diffraction studies; the values obtained were 1.820 and 1832 Å respectively. Furthermore, the MoF_6 molecular volume[16] in the orthorhombic (106.6 Å^3) and cubic (120.9 Å^3) phases is significantly less than in the case of WF_6 (Table 3).

As already mentioned, RhF_6 is capable of oxidizing Xe as also is RuF_6[39]. Both of these hexafluorides are less stable thermally than PtF_6[40] and both are much smaller than the platinum analog in size[16] (100.9 and 99.5 Å^3, respectively).

Clearly the trends noted in the third series are exaggerated in the second; however, TcF_6 is not very different from ReF_6[41,42] in its behavior toward NO or ONF since it forms $NOTcF_6$ with NO and $(NO)_2TcF_8$ with ONF, there being no indication of ONF_3 or of F_2 generation. It seems therefore that TcF_6 is not so powerful an oxidizing agent as OsF_6.

7. A Rationalization of the Properties of MF_6 and MOF_5

The relationship of oxidizing strength of MF_6 to high nuclear charge of M and to the smallness of the molecule is well established.

[42] *N. Bartlett, R. A. Naumann*, and *R. Serfass*, unpublished.

It should also be remarked that, in each series, the more powerful MF_6 is as an oxidizer the less stable it is towards dissociation [43] to a lower fluoride and fluorine. However, this does not prevent efficient synthesis. Although PtF_6 rapidly decomposes to PtF_4 and F_2 at temperatures above 260 °C [31], it is conveniently prepared in $\approx 90\%$ yield by burning platinum (≈ 1000 °C) in a F_2 atmosphere adjacent to a cold finger (−196 °C). It is probable that the average bond energies in the more powerful oxidizers are less than in the weaker oxidizers, but all are highly exothermic compounds. *Hubbard et al.* [44] have measured the enthalpies of formation of MoF_6 and WF_6, and their data indicate average bond energies of 107.4 and 121.1 kcal·mole^{-1}, respectively. These values are almost double the average bond energies in the non-transition hexafluorides of the sixth main group (SF_6, 78.5; SeF_6, 72.6; and TeF_6, 81.2 kcal·mole^{-1}) [45].

The MF_6 molecules are octahedral, although some exhibit dynamic Jahn-Teller effects [37]. Both $ReOF_5$ and $OsOF_5$ are nearly octahedral [33]. All of the hexafluorides and $OsOF_5$ are dimorphic as solids (cf. Table 3).

The orthorhombic phase approximates to a close packed fluorine ligand array, with the metal atoms in octahedral hole sites. Undoubtedly the bonded octahedra (MF_6) are smaller than the nonbonded, but it is evident that the octahedra cannot be greatly distorted since the ratio $c:b:a$ is in all cases close to $1:3:4\ \sqrt{2}/\sqrt{3}$, which is that required for a hexagonal close packing with an *abac* layering sequence along *a*.

In the cubic phase there is plastic crystal disorder and as *Weinstock* has pointed out [40] the entropy of fusion of this phase is not very different from the value of 3.3 e.u. found for the noble gases.

In keeping with the rotational disorder in the cubic phase, its volume is greater than that in the orthorhombic form. There is, however, a significant decrease in volume across the series for each phase. Presumably this results from a decrease in the size of MF_6 with z rather than from an increase in the van der Waals forces. If so, the volume decrease may be due *either* to a M–F bond shortening *or* to a decrease in the ligand van der Waals radius, *or* both.

Results of electron diffraction investigations of gaseous MF_6 by *Schomaker* and *Weinstock* (Table 3) indicate that the M–F bond length remains approximately constant. This implies a significant decrease in the van der Waals ligand radii in this series of compounds. It is, furthermore, somewhat surprising at first sight that the totally symmetric MF_6 (A_{1g} symmetry) mode decreases along the series.

There is little reason to doubt the main conclusions of *Moffitt et al.* [46] that the *d* electron configurations in MF_6 in the ground state and in the low excited state are as given in Table 3. Excited states involving configurations $dt_{2g}^{n-x}e_g^x$ were assigned to expanded molecule states, since only the e_g^x electron density effectively screens the ligands from the nuclear charge. Since the t_{2g} electrons are ineffective in their screening, an increasing polarization of the F ligand σ bonding electrons will occur with increase in atomic number *i.e.* from WF_6 to PtF_6. Moreover, if π bonding occurs it is clear that its contribution to the total bonding will decrease with increase in the population of the t_{2g} orbitals (*i.e.* as the antibonding π orbitals are filled). Therefore, F ligands in WF_6 are more likely to be multiply bonded than in PtF_6 and because of the greater z and smaller π bonding in the latter, the σ bond electrons will be very strongly polarized towards the Pt atom. This last feature may well lead to a diminution of the electron density on the outside of the F ligands and in this way to a decrease in the van der Waals radius of the ligand. If this picture is true the approximate constancy of the M–F bond lengths in the series must arise from a coincidental matching of the lengthening due to loss of multiple bond character with a shortening from the transition series contraction.

This explanation would also account for the greater readiness of the F ligands in RuF_6, RhF_6, and PtF_6 to lose M–F bonding electrons, as required for the dissociation:

$$MF_6 \rightarrow MF_{(6-x)} + {}^{x}/_{2}F_2$$

It seems that the decrease in F^- acceptor ability with increase in z is associated with the decrease in t_{2g} orbital availability. As these orbitals are populated the MF_7^- and MF_8^{2-} ions become less favorable. Each added F^- requires one of the t_{2g} orbitals, and this further severely curtails M–F π bonding. As the π bonding becomes limited, so the polarization of the σ electrons increases. Simultaneously the repulsive interaction of neighboring F ligands will also increase as those F ligand electrons previously involved in π bonding become "nonbonding". The electron affinity can, of course, be simply attributed to the need of the F ligands to replace electron density lost to the highly polarizing central atom.

The oxide pentafluorides are significantly smaller than their related fluorides. This may in part be ascribable to the dipole moment, but the major factor must lie elsewhere – perhaps in increased π bonding. Since the t_{2g} electrons have a small screening effect on the ligands, the difference in the *d* electron configurations of $OsOF_5$ (d^1) and OsF_6 (d^2) is not expected to have a large effect on the polarization of the ligand σ electrons. The $OsOF_5$ ligands have a greater opportunity to π bond, therefore the polarization of the σ electron density will, on the whole, be less than in OsF_6. On this basis $OsOF_5$ would have less affinity than OsF_6 for an electron.

It is evident from the foregoing that much more research of a quantitative nature will have to be done before the many questions posed by these remarkable compounds can be adequately answered.

Nitrogen Oxide Fluorides

BY R. SCHMUTZLER [*]

Dedicated to Professor H. J. Emeléus on the occasion of his 65th birthday

Oxyfluorides of nitrogen, i.e. compounds containing the grouping F–N–O, have been known for many years in the form of simple compounds, such as NOF and NO_2F. Detailed studies of physical, structural, and chemical aspects of this class of compounds have been conducted only in recent years, after the potential of N–F compounds as rocket propellants had been recognized. Several novel types of oxyfluorides of nitrogen, such as difluorohydroxyl amines, $RO-NF_2$, or trifluoroamine oxide, F_3NO, have been discovered recently. A further major development in O–N–F chemistry is indicated by the discovery that compounds of great chemical potential are formed between HF and NOF or NO_2F, respectively.

The compound O_2NOF, although not an oxyfluoride of nitrogen, will also be discussed in this review, because of its particular chemical relationship to NO_2F.

A. Introduction

Although the simplest oxyfluorides of nitrogen, NOF [1] and NO_2F [2], have been known for over 60 and nearly 40 years, respectively, the chemistry of these compounds has not been studied in any depth until very recently [3,4]. For a long time after their discovery NOF and NO_2F remained academic curiosities. It was not until the potential of such compounds as rocket propellants had been recognized – about 1960 – that a systematic study of the oxyfluorides was initiated. In addition to improvements in earlier syntheses of the known oxyfluorides of nitrogen, novel types of compounds were discovered, perhaps the most noteworthy being trifluoroamine oxide F_3NO, which was reported nearly simultaneously by several research groups in 1966/67.

B. Nitrogen Oxide Fluorides

1. Nitrosyl Fluoride, NOF

1.1. Preparation

NOF was first prepared by *Ruff* by the fluorination of NOCl with silver fluoride at room temperature [1]. *Ruff* also discovered that NOF is formed in the gas phase reaction between nitric oxide and fluorine [2]. This direct synthesis is usually conducted in reactors made of polytetrafluoroethylene, copper, or nickel [2,5,6]; the extremely fast and quantitative reaction [7]

$$2\,NO + F_2 \rightarrow 2\,NOF,\ \Delta H^0_{298} = -74.8\ \text{kcal/mole}\ [8]$$

takes place with emission of visible light [9]. The spectrum of ONF is continuous with a maximum at 6095 Å [8]. The following mechanism has been suggested [9]:

$$NO + F_2 \rightarrow ONF + F^{\cdot}\ (\text{slow})$$

$$NO + F^{\cdot} \rightleftharpoons [ONF]^{*} \rightarrow ONF + h\nu$$

$$[ONF]^{*} \xrightarrow{M} ONF\ [8,10]$$

Further methods of synthesis of NOF are based on the reaction of some readily accessible nitrosyl salts with alkali fluorides at high temperatures (200–300 °C) according to

$$[NO]^+X^- + F^- \xrightarrow{\Delta} ONF + X^-$$

where X = $[BF_4]^-$ [11] (c.f. also [7,12]), $[SbF_6]^-$ [13], $[S_2O_7]^{2-}$ [6]. N_2O_4 ($\approx [NO]^+[NO_3]^-$) also fits this scheme; it gives NOF upon interaction with $[N(CH_3)_4]F$ [14], KF, or CsF [15].

NOF is obtained as the major product in a synthesis of tetrafluorohydrazine [16–19], which is represented by

$$2\,NF_3 + 2\,NO \rightarrow N_2F_4 + 2\,ONF$$

and which is carried out at 500–800 °C in a flow system.

Equimolar amounts of NOF and NF_3 are produced in the reaction of nitrous oxide N_2O with fluorine [20, 21], which may be conducted in the 300 to 800 °C range

$$N_2O + 2\,F_2 \rightarrow NF_3 + ONF$$

The reaction of N_2F_4 with nitrates, such as KNO_3 or $AgNO_3$, or with nitrites at elevated temperatures [22],

$$KNO_3 + N_2F_4 \rightarrow KF + 3\,ONF$$

$$2\,NaNO_2 + N_2F_4 \rightarrow 2\,NaF + 2\,ONF + 2\,NO$$

leads to the formation of NOF in 41–76 % yield.

The most economical method for the preparation of NOF is expected to be the dehydrofluorination of NOF/HF complexes which may be effected by passing these complexes as a vapor through NaF or KF; HF can be recovered by heating NaF·*x* HF or KF·*x* HF to 265–350 °C [23–28].

NOF is formed in a number of other reactions, most of which cannot be considered as synthetic methods. The following examples are representative:

$OF_2 + NO \rightarrow ONF\,(+\,O_2NF)$ [29–31]

$COF_2 + NO \rightarrow ONF\,(+N_2F_2,\ NF_3,$ and other products) [32]

$2\,N_2F_4 + OF_2 \rightarrow ONF + 3\,NF_3$ [33]

$N_2F_2 + NO \rightarrow ONF\,(+N_2O,\ NO_2,$ and other products) [34]

"$N_2O_5W_3F_{11}$" (from $WF_6 + N_2O_4$) $\rightarrow$ $ONF + ([NO][WOF_5],$ and other products) [35]

$3\,N_2O_4 + 2\,WF_6 \rightarrow ONF + 2\,[NO][WOF_5] + O_2NF + N_2O_5$ [35]

Nitrosyl fluoride is one of the products formed in a number of pyrolytic reactions of fluorocarbon derivatives, *e.g.* $C_3F_7NO_2$ [36], $O_2N(CF_2)_2ONO$, O_2NCF_2COF, $O_2N(CF_2)_2NO_2$, and $O_2NCF_2C(ONO)FCF_3$ [37].

Formation of NOF as an oxidation product of N_2F_4,

$$N_2F_4 + {}^1/_2O_2 \rightarrow ONF + NF_3$$

has been reported [38]; however, it has been shown in independent work that there is no direct reaction between N_2F_4 and O_2 [39]; the above observation must therefore be due either to wall reactions or to impurities.

NOF is also formed in the reaction of XeF_4 and XeF_2 with NO (130–180 °C, 0.1 to 30 torr) [40].

Formation of oxyfluorides of nitrogen, mainly NOF and NO_2F, upon irradiation of mixtures of numerous nitrogen- and oxygen-containing compounds with ionizing radiation between –196 °C and room temperature has been detected by mass spectroscopy. Examples for such systems include NF_3/O_2, NF_3/N_2O, NF_3/NO, NF_3/N_2O_4, OF_2/N_2F_4, OF_2/N_2, OF_2/N_2O, OF_2/NO, *etc.* [41]. Similar irradiation of NOF possibly gives rise to novel O–N–F systems.

1.2. Structure and Physical Properties

The structure of NOF is well established from its IR spectrum [42–46] and its microwave spectrum [43, 51]. IR fundamentals have been determined not only for $^{16}O^{14}NF$, but also for $^{16}O^{15}NF$, $^{18}O^{14}NF$, and $^{18}O^{15}NF$ [46]. According to these studies, NOF is a bent, unsymmetrical molecule (cf. Table 1).

Dissociation Energy (kcal·mole^{-1}) ONF → NO + F	$+55.4$	[8]
σ (Ω^{-1}·cm^{-1}) [f, g]	5.4×10^{-5}	[56]
	5.3×10^{-5}	[57]

[a] In the temperature range -125 to -67 °C. [b] At -59.9 °C. [c] In the NOX series (X = F, Cl, Br) $f_{NF} > f_{NCl} > f_{NBr}$. [d] The intrinsic dipole moment μ(N–F) = 2.72 D [52]. [e] Measured on liquid NOF (-70 ± 1 °C) relative to CCl_3F as external standard. [f] At -79 °C. [g] The temperature dependence of σ was determined for pure NOF and for solutions of NOF in BF_3, PF_5, and AsF_5 [58].

It was concluded from vibrational force constant calculations that the N–O bond order in NOF is 1.98 (*i.e.* very nearly the same as for NOCl or NOBr) [59]. Other evidence, such as the dipole moment [60], the very low N–F force constant [49], and the long N–F bond distance [48], suggests that the N–F bond has ionic character. This is also borne out by the fact that rapid exchange of fluoride ions with the solvent is observed in solutions of NOF in liquid HF [53]. Peculiarly, NOF shows one of the lowest ^{19}F chemical shifts ever reported in the NMR (well below F_2) and a large paramagnetic contribution to the shielding of the fluorine nucleus in NOF must be invoked to rationalize this finding [53]. A special technique has been developed to handle NOF in polytetrafluoroethylene NMR tubes [61].

In terms of MO theory, NOF is viewed as a loosely bound combination of a fluorine atom and a NO radical [62, 63]. This is also reflected, for example, in the low N–F force constant [46] and in the N–O force constant for NOF, which is virtually the same as in free NO; furthermore, recent SCF–MO calculations suggest that the values of the ONF equilibrium angle and of the N–F bond distance in NOF must be slightly revised [63].

1.3. Chemical Properties

Pure nitrosyl fluoride is a colorless gas which attacks glass, especially in the presence of moisture [1], and exhibits strongly corrosive properties towards various metals; tin, lead, and certain kinds of steel being particularly readily attacked [6]. The compound is tractable, however, in apparatus made of copper, nickel, or some nickel alloys [6].

As an acid fluoride, NOF is hydrolyzed as follows [1, 6, 11]:

$$\text{neutral: } 3\,ONF + 2\,H_2O \rightarrow 3\,HF + 2\,NO + HNO_3$$

$$\text{basic: } ONF + 2\,OH^- \rightarrow NO_2^- + F^- + H_2O$$

P_4O_{10} reacts with NOF to give POF_3 [11].

NOF is a strong oxidizing agent and reacts with a great variety of elements, both metallic and nonmetallic, but it is distinctly less reactive than elemental fluorine. Qualitative observations about such reactions, far too numerous to be listed here, have been reported since the first discovery of NOF [1, 2, 11]. Nitric oxide is formed as well as the respective fluoride in such reactions; however, the possibility exists of further reaction between NOF and the fluoride of the element concerned if the latter has acceptor properties (see Section B.3.). While some elements, such as B, Si, P, As, react with NOF with incandescence, others react only upon heating (*e.g.* Mg, Zn, Fe, W) or not at all (I_2, Br_2, C, O_2) [1, 2]. Chloryl fluoride will oxidize NOF to NO_2F quantitatively at room temperature [22]. A 10 % yield of N_2O is obtained in the reaction of NOF with azide ion, thus suggesting the formation of nitrosyl azide as an unstable intermediate [64].

NOF is presumably involved as an intermediate in a number of reactions of NF_3 [65], *e.g.*

$$SO_2 + NF_3 \rightarrow SOF_2 + ONF$$

$$SO_2 + 2\,ONF \rightarrow SOF_2 + NO + NO_2$$

SeO_2 behaves in an analogous fashion, $SeOF_2$ being the product. Nitrosyl salts of fluoroacids, $[NO]^+[MF_n]^-$ are obtained in similar reactions of NF_3 if the intermediate NOF can act as a fluorinating agent, giving rise to the formation of an acceptor fluoride which will then take up further NOF (see Section B.3. [65]).

The reaction of NOF with SO_2 to give a 1:1 adduct (SeO_2 does not react) has long been known [11, 14, 66]. The adduct melts at −79 °C (+8 °C/3100 torr) and it is dissociated to an extent of 70 % at 19 °C. Chemically, $NOF{\cdot}SO_2$ behaves as a mixture of its components, *e.g.*

$$NOF{\cdot}SO_2 + BF_3 \rightarrow [NO][BF_4] + SO_2$$

$$NOF{\cdot}SO_2 + SO_3 \rightarrow [NO][SO_3F] + SO_2.$$

Like NOF itself, the adduct may act as a fluorinating, oxidizing, and complexing agent at the same time [14], *e.g.*

$$MCl_3 + 6\,NOF{\cdot}SO_2 \rightarrow [NO][MF_6] + 2\,NO + 3\,NOCl + 6\,SO_2\ (M = P, As)$$

No structural data on $NOF{\cdot}SO_2$ are available.

At high temperatures (125–600 °C), especially in the presence of an activated charcoal catalyst, SO_2F_2 is formed from SO_2 + NOF [67–70]. NOF also reacts with SCl_2 at ~50 °C to give SOF_2 [23, 71–74].

As a result of the strongly oxidizing character of NOF the scope of its organic chemistry is limited. Apart from a few qualitative observations [2], this field has only recently been investigated, the largest amount of work being concerned with the addition of NOF across double bonds, especially in perfluorinated systems. These reactions will be considered separately in Section B.4.

NOF is suitable as a gas phase fluorinating agent for CCl_4 or CH_2Cl_2, for example, giving rise to formation of chlorofluoromethanes [23, 75], sometimes in the presence of a CoF_2 catalyst [23, 76–80].

A potentially important type of reaction of NOF in organic chemistry involves its addition to steroids having olefinic bonds, such as cholesterol and some of its derivatives. Smooth reactions were observed between NOF and various such compounds in a CH_2Cl_2 or CCl_4 medium at 0 °C, with fluorine entering the 5-position, while either a nitrimine (=N–NO_2) group (from cholesteryl acetate and chloride) or a carbonyl group (from cholesterol) was in the 6-position of the steroid after working up [81].

1.4. The Hydrogen Fluoride – Nitrosyl Fluoride System

A very important development has arisen in recent years through the work of *Seel*, as well as that of research groups at Allied Chemical Corporation and at Brookhaven National Laboratory, in the study of the NOF/HF and NO_2F/HF systems. The existence of solvates such as $NOF{\cdot}3$ HF and $NO_2F{\cdot}5$ HF has been established. These compounds are potentially cheap sources of the oxyfluorides of nitrogen and may permit their use on a large scale.

The NOF/HF system has been dealt with in a review by *Seel* [54], and its discussion will be restricted here, attention being focused on recent developments.

Seel et al. [82, 83] found that solutions of N_2O_3, NOF, or alkali metal nitrites in liquid HF contain a species, $[NO]^+[F(HF)_x]^-$, from which defined products, especially $NOF{\cdot}3$ HF may be obtained. A cryoscopic study of the system NOF/HF revealed the existence of the complexes, $NOF{\cdot}HF$, 3 $NOF{\cdot}5$ HF, 2 $NOF{\cdot}5$ HF, $NOF{\cdot}3$ HF, and $NOF{\cdot}4$ HF, with melting points ranging in the −10 to +10 °C region [86, 87].

A seemingly homogeneous product of apparent composition $NOF{\cdot}6$ HF was reported by a number of workers [24–28, 85, 86, 88]. Later, however, it was shown that "$NOF{\cdot}6$ HF" has the composition $N_2O_3{\cdot}12.8$ HF or $NOF{\cdot}5.4$ HF$\cdot 0.5\ H_2O$ [54, 87]; its specific conductivity of 0.0129 Ω^{-1} cm^{-1} is comparable to that of a fused salt [24–28, 54].

A reaction has also been observed between N_2O_4 and liquid HF. Fractionation gave a product of constant b.p. 52 °C which corresponds to the composition N_2O_4 + 7.0 HF + 0.87 HNO_3 (or NOF + 6 HF + 1.87 HNO_3), along with $NOF{\cdot}3$ HF [54, 86, 89].

1.4.1. Preparation and Properties of NOF–HF Adducts.

The preparation of NOF·3 HF and "NOF·6 HF" is described in numerous reports, especially in the patent literature [23, 67–70, 72, 75, 90–97]. Usually, mixtures of HF and NOCl (molar ratio ≈ 6:1) were passed through a nickel reactor during 4 h, (contact time 18 sec). Fractional distillation of the reaction products gave "NOF·6 HF" (b.p. 68 °C) and NOF·3 HF (b.p. 95 °C).

The reaction of NOCl with HF may also be conducted in the liquid phase in polyethylene bottles; reaction commences at −40 °C. The HCl formed is finally removed by heating the system to +50 °C. Subsequent fractionation of the products must, because of their aggressive nature, be conducted in a nickel, gold, platinum, or polytetrafluoroethylene apparatus [84, 88, 91]. Although the standard free energy change for the gas phase reaction $NOCl + HF \rightarrow NOF + HCl$ is unfavorable, the reaction proceeds in the liquid phase because of complex formation between NOF and HF [54, 88]. Instead of NOCl, mixtures of $NO + Cl_2$ (or of $NO + Br_2$) may also be employed. Likewise, $NOCl{\cdot}AlCl_3$ or $[NO]^+[HSO_4]^-$ may serve as a source of NO [84, 88, 91].

NOF·3 HF is a colorless, hygroscopic liquid (b.p. 94–95 °C/760 torr; m.p. 1–5.6 °C [54, 84, 85, 88]; $d_4^{25} = 1.6$ [84, 85, 88]; $\sigma = 0.0503\ \Omega^{-1}cm^{-1}$ [24–28]) which may be stored in containers made of nickel or polytetrafluoroethylene.

A liquid of composition NOF·2.67 HF (m.p. 4.7 °C) is obtained when HF is pumped off from NOF·3 HF at room temperature. When heated, NOF·2.67 HF gives off NOF until finally NOF·3 HF distills. This observation suggests the existence of several nitrosyl fluoride-hydrogen fluoride complexes, which are in equilibrium with each other in the liquid and gas phase [54].

Very little is known concerning the structure of these products. *Seel et al.* suggested the possibility that the hydrogen fluoride in NOF·3 HF is present in the form of the cyclic associated trimer, and that NOF molecules are embedded between layers made up of such rings [88].

^{19}F–NMR spectra suggest that NOF·3 HF represents a highly associated system, in which all fluorine atoms are completely and rapidly exchanging, and that they have an environment more similar to that in HF than in NOF. The same is true for the products NOF·2.67 HF and $N_2O_3{\cdot}12.8$ HF [53, 54, 86].

Density determinations on the liquid phase in the NOF–HF system as a function of temperature and composition showed that a very remarkable volume shrinkage takes place on mixing of the pure components; in some ranges the volume of the complex mixture is very nearly the same as that of hydrogen fluoride [86, 87].

The N=O absorption in the IR spectrum of liquid NOF·3 HF (1797–1804 cm^{-1}) is shifted only slightly, compared to gaseous NOF (1844 cm^{-1}); no absorption due to $[N{\equiv}O]^+$ is detectable [88].

1.4.2. Chemistry of NOF·3 HF

NOF·3 HF is a versatile chemical reagent, whose chemical behavior is determined by both of its components, NOF and HF. It displays powerful oxidizing properties towards a great variety of nonmetallic and metallic elements. Whenever the fluoride, XF_n, formed has acceptor character, it is obtained in the form of a nitrosyl salt, $[NO]^+[XF_{n+1}]^-$ [54, 84, 88, 99]. The oxidative fluorination of certain metals, *e.g.* Mo and W, by their smooth and quantitative reaction with NOF·3 HF, can be directed so as to provide a straightforward synthesis of the hexafluorides [94, 97],

$$M + 6\ NOF{\cdot}3\,HF \rightarrow MF_6 + 6\ NO + 18\ HF$$

The oxides of all metals that react with NOF·3 HF will also react with this reagent to give fluorides, NO, and NO_2 [88]

$$MO + 2\ NOF{\cdot}3\,HF \rightarrow MF_2 + NO + NO_2 + 6\ HF$$

Particularly noteworthy is the rapid reaction of NOF·3 HF with quartz or natural silicates *e.g.* beryl,

$$Be_3Al_2[Si_6O_{18}] + 42\ NOF{\cdot}3\,HF \rightarrow$$
$$3\ [NO]_2[BeF_4] + 2\ AlF_3 + 6\ SiF_4 + 18\ (NO + NO_2) + 126\ HF$$

The significance of $NOF{\cdot}(HF)_n$ as a source of NOF, by its reaction with HF acceptors such as F^- (alkali fluorides), has already been mentioned,

$$NOF{\cdot}(HF)_n + F^- \rightarrow [F(HF)_n]^- + ONF$$

Lewis acids, such as BF_3, BrF_3, AsF_5, and SbF_5, will react with the NOF component, *e.g.*

$$NOF{\cdot}(HF)_n + BF_3 \rightarrow [NO][BF_4] + nHF$$

NOF·3 HF and other products obtained by dissolving NO, N_2O_3, N_2O_4 in HF will react with various metals and compounds which are of importance in nuclear technology (*e.g.* U, Pa, UO_2, UC, Zr, Fe, ceramics) to give the corresponding fluoro complexes, NO $[UF_6]$, $(NO)_2[ZrF_6]$, *etc.* [85, 86, 98, 101]. Such reactions are of practical significance in the recovery of uranium from spent fuel elements and in the separation of certain fission products. The complex $NO[UF_6]$ is volatile at 400 °C in the presence of NOF gas. Separation of uranium from other elements such as Pu, Nb, Mo, Te may be effected by virtue of the differences in volatility of the various complexes. Uranium may be recovered, ultimately, as UF_6, after treatment of $NO[UF_6]$ with a halogen fluoride [101].

In the electrolysis of the NOF–HF system the initial products are F_2 at the anode and NO at the cathode;

however, the two products will react with each other unless separated in the gas phase [100].

Finally it may be mentioned that NOF·3 HF (and also "NOF·6 HF") will convert the lower sulfur chlorides, SCl_2 and S_2Cl_2, to thionyl fluoride, SOF_2 [23, 71–74]. Sulfur dioxide reacts with NOF·3 HF to give sulfuryl fluoride [67–70].

NOF·3 HF and "NOF·6 HF" have some potential in organic chemistry (cf. [54]), *e.g.* in metathetical reactions involving exchange of fluorine for chlorine. A particular advantage over the use of pure HF is that such fluorination reactions may be conducted at higher temperatures without the necessity of employing sealed reaction vessels. The chlorine-fluorine exchange proceeds particularly smoothly if the chlorine is activated.

A typical example is the fluorination of halogenated benzene derivatives, a CoF_2 catalyst usually being employed [23, 76–80]. Chlorine-fluorine exchange has also been effected in aliphatic compounds, such as CCl_4 or CH_2Cl_2, which can be converted to chlorofluoromethanes [75, 93]. Unsaturated halogen compounds, such as tetrachloroethylene can also be fluorinated, the double bond not being affected [75, 93].

In some cases, oxidation of primary alcohols to aldehydes by NOF–HF complexes has been observed [54]. Especially noteworthy is the utilization of NOF–HF complexes in a Schiemann-type reaction with aromatic amines in a non-aqueous medium, whereby fluoroaromatic compounds can be prepared easily, and in high yields [23, 54, 88, 90, 92, 95, 96], *e.g.*

$$\text{Aryl–NH}_2 \xrightarrow{\text{NOF·(HF)}_n} \text{Aryl–F} + \text{N}_2$$

The diazonium compounds which are formed initially decompose in a readily controllable fashion at, or slightly above, room temperature.

2. Nitryl Fluoride, NO_2F

2.1. Preparation

Nitryl fluoride is believed to have been first obtained by *Moissan* by the reaction of NO with fluorine [102–104]. The compound was first characterized adequately by *Ruff* [2, 105] (cf. also [5]) who prepared it by the direct combination of NO_2 with fluorine. Here as well as in a number of other cases, the preparative methods for making NO_2F closely resemble those for making NOF; for example, in the reactions which involve heating a nitryl salt with alkali fluoride,

$$NO_2[X] + F^- \rightarrow O_2NF + [X]^-$$

X = BF_4, SiF_6 [12, 106–108], ClO_4 [109], PF_6 [110]. Syntheses of this type are attractive because elemental fluorine is not required. PF_5, for example, may be regenerated by heating $[PF_6]^-$ to 400–600 °C; since $NO_2[PF_6]$ is prepared from fuming nitric acid and PF_5, the above synthesis of NO_2F corresponds to the net reaction of NaF with HNO_3 [110].

The kinetics of the direct reaction of NO_2 with fluorine [108] was found to be first order both in NO_2 and F_2. The following two steps were proposed [111],

$$NO_2 + F_2 \rightarrow NO_2F + F^\bullet \text{ (slow)}$$

$$NO_2 + F^\bullet \xrightarrow{M} NO_2F + M \text{ (fast)}$$

A useful synthesis of NO_2F involves oxidation of N_2O_4 with CoF_3,

$$2\,CoF_3 + N_2O_4 \rightarrow 2\,O_2NF\ (90\%) + 2\,CoF_2$$

CoF_3 may be regenerated by reaction of CoF_2 with F_2 [112, 113]. CeF_4, MnF_3, and AgF_2 react with NO_2 at room temperature [113].

A further important method of preparation of NO_2F is based on the reaction of nitrite with fluorine [114, 115],

$$NO_2^- + F_2 \rightarrow O_2NF + F^-$$

which proceeds at temperatures slightly above room temperature. Elemental fluorine is avoided in a related synthesis, which involves the reaction of N_2O_5 with sodium fluoride [116],

$$F^- + N_2O_5\ (\approx NO_2[NO_3]) \rightarrow O_2NF + NO_3^-$$

N_2O_5 is the precursor of NO_2F in some other reactions, *e.g.*

$$BrF_5 + 2\,N_2O_5 \rightarrow BrO_2F \rightarrow 4\,O_2NF \quad [117]$$

$$BrF_3 + 3\,N_2O_5 \rightarrow Br(NO_3)_3 + 3\,O_2NF \quad [118]$$

Ruff's first successful synthesis of NOF, which involved fluorination of NOCl with silver fluoride, proved to be very unsatisfactory when applied to NO_2Cl; passage of NO_2Cl through AgF in a platinum tube at 240 °C leads to the formation of NO_2F in only 5 % yield [106, 107].

A potentially very cheap source of NO_2F is provided in the dehydrofluorination of the readily available compound, $NO_2F \cdot 5\,HF$ [119–123] with KF, NaF, or $KF \cdot xHF$,

$$NO_2F \cdot 5\,HF + y\,(KF \cdot xHF) \rightarrow$$

$$O_2NF + y\,KF \cdot (x + \tfrac{5}{y})HF$$

$$\downarrow \Delta$$

$$y\,(KF \cdot xHF) + 5\,HF$$

Finally, there are a number of reactions which also yield NO_2F but which cannot be considered suitable methods for the preparation of the compound [22, 29, 35, 36, 124–129].

The reaction of NO_2 with O_2F_2 to form NO_2F [129] might be expected to serve as a source of OF radicals which then might combine with NO_2 to form O_2NOF; however, formation of O_2NOF has not been observed.

NO_2F is also produced in the reaction of NO_2 with OF_2 [130].

2.2. Structure and Physical Properties

Nitryl fluoride, like nitrosyl fluoride, is a reactive, colorless gas at room temperature; both gases also exhibit a similar degree of volatility. A number of physical data for NO_2F are listed in Table 2.

The structure of NO_2F has been well established by a number of techniques. The ^{19}F–NMR spectrum consists of a 1:1:1 triplet (coupling between ^{19}F with nuclear spin $I = 1/2$, and ^{14}N with $I = 1$), with $J_{N-F} = 112.5$ Hz. The observation of N–F coupling of this order of magnitude proves the presence of a direct N–F bond [116]. The microwave spectrum of NO_2F [134] points to a planar molecule of point group C_{2v}; the pertinent bond parameters are listed in Table 2. The structure of NO_2F in terms of C_{2v} symmetry has been confirmed by a study of its vibrational

order of magnitude as that for NOF, 55.4 kcal/mole[8]. Likewise, the N–O bond strengths in the two nitryl halides, NO_2F and NO_2Cl, are comparable (69.66 *vs.* 68.79 kcal/mole, respectively[133]).

2.3. Chemical Properties

The chemical characteristics of NO_2F are similar to those of NOF. Because of its high reactivity, NO_2F is best handled in apparatus made from quartz or nickel alloys.

As the fluoride of nitric acid, NO_2F is hydrolyzed quantitatively by 10 % NaOH[2].

$$O_2NF + 2\,OH^- \rightarrow F^- + NO_3^- + H_2O$$

The reactions of NO_2F with numerous elements were first studied qualitatively by *Ruff*[2] and, in much more detail, by *Aynsley*, *Hetherington*, and *Robinson*[114]. Like NOF, NO_2F may act both as a powerful oxidizing agent and as a fluorinating agent. Interaction of NO_2F with metals leads to the formation of either a mixture of oxide and fluoride, or of an oxyfluoride[114], *e.g.*,

$$2\,Zn + 2\,O_2NF \rightarrow ZnF_2 + ZnO + N_2O_3$$

$$Cr + 2\,O_2NF \rightarrow CrO_2F_2 + 2\,NO$$

A few metals, such as Be, Mg, Ca, Au do not react with NO_2F at temperatures up to 300 °C[115].

In the case of nonmetallic elements, formation of the nitryl salts of the corresponding fluoroanion is frequently observed. Presumably, the fluoride of the element is formed first and then reacts with NO_2F as a fluoride donor[114] (cf. Section B.3.).

As an acid fluoride, NO_2F will react with various oxides[114,115] thus

$$O_2NF + SO_3 \rightarrow [NO_2][SO_3F]$$

NO_2F behaves as an acid fluoride in the expected fashion towards ammonia or secondary amines[145]; nitramides are formed, both in the gas phase and in an inert solvent.

$$O_2NF + NH_3 \rightarrow O_2NNH_2$$

$$O_2NF + HNR_2 \rightarrow O_2NNR_2$$

A reaction has been observed between NO_2F and $BrO_2[NO_3]$ at −78 °C in CCl_3F[117].

$$O_2NF + BrO_2[NO_3] \rightarrow N_2O_5 + O_2BrF$$

The following reaction has also been observed to occur quantitatively[146],

$$O_2NF + Cl_2F[AsF_6]^- \rightarrow NO_2[AsF_6] + 2\,ClF.$$

[145] *H. C. Mandell*, US-Pat. 3071438 (Jan. 1, 1963), Pennsalt Chem. Corp.

[146] *K. O. Christe*, private communication.

O_2F_2 is very soluble in NO_2F but there is no reaction at −78 °C[31].

NO_2F reacts exothermally and irreversibly with sulfuric acid, with formation of a clear colorless liquid. At concentrations >70 mole-%, colorless crystals, believed to be $NO_2[HSO_4]$, are precipitated[147]. On the basis of electrical conductivity, density, viscosity, cryoscopic, and Raman-spectroscopic data[115,147], the following two steps are proposed for this reaction:

$$O_2NF + H_2SO_4 \rightarrow NO_2^+ + HF + HSO_4^-$$

$$HF + 2\,H_2SO_4 \rightleftharpoons H_3O^+ + HSO_3F + HSO_4^-$$

Selenic acid also absorbs NO_2F (>2 mole/mole acid), as does H_3PO_4; however, the reactions involved have not been investigated completely[115,147].

Reactions of NO_2F with a number of organic compounds have been studied. Aromatic hydrocarbons, for example, undergo fairly smooth nitration. Deactivated aromatic compounds such as $C_6H_5NO_2$, C_6H_5COOH, C_6H_5CHO remain largely unchanged, whereas highly reactive compounds, *e.g.* aniline, anisole, furan, *etc.*, give only tars. Ethanol reacts with formation of $C_2H_5ONO_2$, CH_3CHO, CH_3COOH[115,148].

Nitryl fluoride is much more powerful a nitrating agent than NO_2Cl and is of interest in mechanistic studies[149,150]. Nitration reactions involving NO_2F are strongly promoted by the addition of Lewis acid catalysts, *e.g.* BF_3, PF_5, AsF_5, SbF_5, all of which facilitate the heterolytic reaction

$$O_2NF + MF_n \rightarrow [NO_2]^+[MF_{n+1}]^-$$

by generating $[NO_2]^+$ ion. Reaction media employed include sulfolane and *sym*-difluorotetrachloroethane[149–151]. Nitration of benzotrifluoride with NO_2F at −100 °C leads to the formation of a 1:1:1 complex of NO_2F, $C_6H_5CF_3$, and BF_3, which decomposes at −50 °C without melting and with evolution of BF_3[149,151]. (For an account of the interaction of NO_2F with Lewis acids see Section B.3.)

Considerable attention has been given to the study of addition reactions of NO_2F across multiple bonds; these will be discussed, along with analogous reactions of NOF, in Section B.4.

2.4. The Nitryl Fluoride–Hydrogen Fluoride System

A compound having the composition $NO_2F \cdot 5\,HF$ (m.p. < −78 °C; b.p. ~ 62 °C) was found to be formed upon reaction of nitryl chloride with hydrogen

[147] *G. Hetherington*, *D. R. Hub*, and *P. L. Robinson*, J. chem. Soc. (London) *1955*, 4041.

[148] *G. Hetherington* and *P. L. Robinson*, J. chem. Soc. (London) *1954*, 3512.

[149] *G. Olah*, *L. Noszko*, and *A. Pavlath*, Nature (London) *179*, 146 (1957).

[150] *S. J. Kuhn* and *G. A. Olah*, J. Amer. chem. Soc. *83*, 4564 (1961).

[151] *G. A. Olah* and *S. J. Kuhn*, J. Amer. chem. Soc. *80*, 6541 (1958).

fluoride (molar ratio *ca.* 1:5 to 1:6; at −17 °C in the liquid phase, or at 30–100 °C in the gas phase) [119–123].

$$NO_2Cl + 6\,HF \rightarrow NO_2F{\cdot}5\,HF + HCl$$

Pure $NO_2F{\cdot}5$ HF does not conduct electricity; the electric conductivity observed in the presence of moisture is ascribed to formation of $[NO_3H_2]^+[F(HF)_n]^-$ [120].

Chemically, $NO_2F{\cdot}5$ HF behaves as a mixture of its constituents, the simplest type of reaction being with the Lewis acid SbF_5 or with the Lewis base, F^- [120].

$$NO_2F{\cdot}5\,HF + SbF_5 \rightarrow NO_2[SbF_6]$$

$$NO_2F{\cdot}5\,HF + F^- \rightarrow NO_2F + [F(HF)_n]^-$$

Like $NOF{\cdot}3$ HF, $NO_2F{\cdot}5$ HF is a powerful fluorinating and oxidizing agent, its reactions often being more complicated than those of the former because of secondary transformations, such as $2\,NO_2 + 4\,HF \rightarrow NOF{\cdot}3\,HF + HNO_3$, or NO_2Cl (formed as a product) $\rightarrow NO_2 + {}^1/_2\,Cl_2$, *etc.* [120].

Worthy of particular mention is the reaction of $NO_2F{\cdot}5$ HF with gold(I) iodide which affords elemental gold (while $NOF{\cdot}3$ HF does not react with AuI). The following overall reaction is envisaged [120],

$$5\,NO_2F{\cdot}5\,HF + AuI \rightarrow Au + IF_5 + 5\,NO_2 + 25\,HF$$

In summary, the system NO_2F/HF has not been studied extensively, and further work is clearly indicated.

3. Reactions of NOF and NO_2F with Acceptor Fluorides

NOF and NO_2F interact in a characteristic manner with a great variety of acceptor (Lewis acid) fluorides, the majority of these reactions involving the heterolytic cleavage of the N–F bond and formation of the corresponding fluoro anion,

$$O_nNF + XF_m \rightarrow [O_nNF{\cdot}XF_m] \rightarrow [NO_n]^+[XF_{m+1}]^-$$

The reactions take place under mild conditions, often at dry ice temperature. The interaction with acceptor fluorides, such as BF_3, PF_5, AsF_5 is also responsible for the increase in conductivity of liquid NOF or NO_2F when these fluorides are present [58, 152]. Nitrosyl and nitryl salts are formed upon interaction of NOCl or NO_2Cl, respectively, with acceptor fluorides and hydrogen fluoride in polar media such as liquid sulfur dioxide or nitroalkanes [153]

$$O_nNCl + XF_m + HF \rightarrow NO_n[XF_{m+1}] + HCl$$

The reaction probably proceeds *via* the NOF- or NO_2–HF complex.

In some instances, nitric oxide has been found to react with strongly oxidizing fluorides with formation of the corresponding nitrosyl fluoro salts as the ultimate products, and it seems reasonable to assume that NOF occurs as an intermediate and that *e.g.* the reaction:

$$3\,NO + 4\,BrF_3 \rightarrow 3\,NO[BrF_4] + {}^1/_2Br_2$$

takes place in two steps [154],

$$3\,NO + BrF_3 \rightarrow 3\,NOF + {}^1/_2Br_2$$

$$3\,ONF + 3\,BrF_3 \rightarrow 3\,NO[BrF_4].$$

Further, the reactions

$$NO + TcF_6 \rightarrow NO[TcF_6]\ [57]\ \text{and}$$

$$NO + UF_6 \rightarrow NO[UF_6]\ [155]$$

may well proceed *via* formation of NOF which then reacts with the pentafluoride, TcF_5 or UF_5. Similar considerations probably apply to the well-investigated reactions of NO with WF_6, ReF_6, OsF_6, IrF_6, and PtF_6; in all reactions except that of NO with WF_6, nitrosyl salts of the various fluoro acids are obtained [156]. An interesting trend in the reactivity of the same hexafluoride series towards NOF has also been observed [156]. A regular increase in the oxidizing power of these fluorides is reflected in the observation that for WF_6 and ReF_6 the sole products formed are the adducts (1:1 and 1:2 for WF_6, 1:2 for ReF_6) while in the case of OsF_6 a trace of ONF_3 (see Section B.5.) is obtained. IrF_6 gives $NO[IrF_6]$, besides F_3NO and F_2, while $NO[PtF_6]$ and F_2 result from PtF_6 + NOF. $[PtF_7]^-$ is not formed, even in the presence of an excess of fluorine [156, 157].

In the case of NO_2F, a mode of reaction with oxides is known in which the ultimate product is the nitryl salt of a fluoro acid [114, 115], undoubtedly as a result of Lewis acid-base interaction between NO_2F and an intermediate acceptor fluoride. The following example is typical:

$$V_2O_5 \xrightarrow{NO_2F} VOF_3$$

$$VOF_3 \xrightarrow{NO_2F} NO_2[VOF_4]$$

The role of NOF as an intermediate which subsequently acts either as a fluoride ion donor or as an oxidizing agent, is also evident in numerous reactions of NF_3 [65], as illustrated in the following example,

$$B_2O_3 + 3\,NF_3 \rightarrow 2\,BF_3 + 3\,NOF$$

$$B_2O_3 + 6\,NOF \rightarrow 2\,BF_3 + 3\,NO + 3\,NO_2$$

$$BF_3 + NOF \rightarrow NO[BF_4]$$

Likewise, $(NO)_2[SiF_6]$, $NO[PF_6]$, and $(NO)_2[S_2O_5F_4]$ are the ultimate products of the reaction of NOF with SiO_2, P_2O_5, and SO_3, respectively [65].

[155] *J. R. Geichman*, *E. A. Smith*, *S. S. Trond*, and *P. R. Ogle*, Inorg. Chem. *1*, 661 (1962).

[156] *N. Bartlett*, *S. Beaton*, and *N. K. Iha*, Chem. Commun. *1966*, 168.

[157] *F. P. Gortsema* and *R. H. Toeniskoetter*, Inorg. Chem. *5*, 1217 (1966).

A further case in this connection is the light-induced reaction of POF_3 with N_2F_4, in which NOF is believed to occur as intermediate [158]

$$POF_3 + F^{\cdot} \longrightarrow F_4PO^{\cdot} \xrightarrow{{}^{\cdot}NF_2} F_4PONF_2$$

$$F_4P(O)(O)N(F)F \longrightarrow PF_5 + ONF \longrightarrow NO[PF_6]$$

NO_2 may react with an oxidizing fluoride such as UF_6 in an entirely analogous way to that of NO and thus give the nitryl salt of a complex fluoro acid; the occurrence of NO_2F as an intermediate is indicated by the observation that identical compounds are obtained from the two reactions, $UF_5 + NO_2F$ and $UF_6 + NO_2$ [159].

$$NO_2 + UF_6 \rightarrow [O_2NF + UF_5] \rightarrow NO_2[UF_6] \rightarrow O_2NF + UF_5$$

A fairly general method of preparation of the nitryl salts of non-metals (as fluoro anions) involves the reaction of the element with NO_2F, which almost certainly proceeds *via* the fluoride of the respective element [115], *e.g.*

$$B + 3\,O_2NF \rightarrow BF_3 + 3\,NO_2$$

$$BF_3 + O_2NF \rightarrow NO_2[BF_4]$$

Other elements behaving similarly include Si, Ge, P, As, Sb, Se, I_2, Te, *etc.* [115].

While NOF and NO_2F evidently often behave in an identical fashion towards Lewis acid acceptor molecules, a notable difference has been observed for $C_6H_5PF_4$ as the acceptor fluoride.

At temperatures as low as −78 °C, NOF forms a 1:1 adduct with $C_6H_5PF_4$ in a Freon ® medium. This adduct decomposes irreversibly at ~ 0 °C. Chemical evidence suggests it to be the expected nitrosyl salt, $NO[C_6H_5PF_5]$. In contrast to NOF, NO_2F will attack the aromatic ring of $C_6H_5PF_4$ at −30 °C (in Freon ®) to give a nitrophenyltetrafluorophosphorane which upon hydrolysis gives *p*-nitrophenylphosphonic acid; this is contrary to the expectation that the PF_4 group should be *meta*-directing [160],

$$ONF + C_6H_5PF_4 \rightarrow [NO][C_6H_5PF_5]$$

$$O_2NF + C_6H_5PF_4 \xrightarrow{-HF} O_2NC_6H_4PF_4 \xrightarrow{H_2O} p\text{-}O_2NC_6H_4P(O)(OH)_2$$

The known reactions between NOF or NO_2F and acceptor fluorides are summarized in Tables 3 and 4.

The great majority of the NO_nF-acceptor fluoride adducts are stable salts at room temperature and contain the $[NO]^+$ or $[NO_2]^+$ cation; however, the possibility of the existence of molecular complexes, $NO_nF{\cdot}XF_m$, must be considered in some instances.

Table 3. Reactions of nitrosyl fluoride with acceptor fluorides.

Fluoride	Product	Ref.
BF_3	$NO[BF_4]$	[11]
$C_6H_5PF_4$	$NO[C_6H_5PF_5]$	[160]

a C=N bond (in $CF_3-N=CF_2$) is also known [171]. NOF and NO_2F are usually employed as such; however, NOF, for example, may also be generated *in situ* by treating a fluoroolefin with a mixture of N_2O_4 ($\approx NO[NO_3]$) and KF in sulfolane [172].

4.1. Fluoroolefins and Alkoxyfluoroolefins

Addition of NOF to fluoroolefins with formation of the corresponding perfluoronitroso compound *e.g.*,

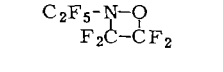
$$CF_3-CF=CF_2 + ONF \rightarrow CF_3-CF(NO)-CF_3$$

has been observed in a number of cases (cf. Table 5), yields and reaction conditions being very variable. Sometimes the perfluoronitroso compound occurs as by-product only, and there are numerous side reactions as a result of oxidation, fluorination, and nitration of the fluoroolefin; this is particularly true for the simplest fluoroolefin, $CF_2=CF_2$.

Table 5. Addition of nitrosyl fluoride to fluoroolefins.

Fluoroolefin	Product	Ref.
$CF_2=CF_2$	CF_3CF_2NO	[174]
$CF_2=CFCl$	$CF_3CF(NO)Cl$	[172, 176]
$CF_3CF=CF_2$	$CF_3CF(NO)CF_3$	[171–173, 175]
$(CF_3)_2C=CF_2$	$(CF_3)_3CNO$	[171, 173]
F_2C-CF F_2C-CF	$F_2C-CF(NO)$ F_2C-CF_2	[172, 175]
Cf. $CF_3N=CF_2 + ONF \rightarrow$	$(CF_3)_2NNO$	[171]
$CF_3N=CF_2 + O_2NF \rightarrow$	$(CF_3)_2NNO_2$	[171]

In the first study of the C_2F_4/NOF reaction (in a glass tube at −78 or −100 °C), *Barr* and *Haszeldine* [174] observed a multitude of products, C_2F_5NO being only a minor by-product (1%). The main products at −100 °C were O_2NCF_2CFO (17%), *N*-perfluoroethyltetrafluorooxazetidine



(13%), $(CF_2NO_2)_2$ (7%), and $C_2F_5NO_2$ (1%). A small amount of polymer, $[-N(C_2F_5)-O-CF_2CF_2-]_n$, was also formed.

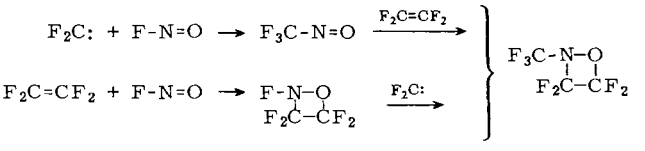
The formation of these products was rationalized on the assumption of C_2F_5NO being the primary product; however, the possibility must be considered that, as a result of attack of NOF on glass, nitrogen oxides were present which could also give rise to products such as $(CF_2NO_2)_2$ and O_2NCF_2CFO [171].

N-pentafluoroethyltetrafluorooxazetidine was also found as a major product in *Knunyants'* independent study [173], under rather different conditions, which involved heating the C_2F_4/NOF mixture over activated carbon/$CaSO_4$ at 70–80 °C for 10 hours. Upon aqueous workup, by-products such as O_2NCF_2COOH and C_2F_6 were detected. *Andreades* [171, 177] obtained *N*-pentafluoroethyltetrafluorooxazetidine in 55% yield by heating C_2F_4 and NOF (molar ratio 2:1) at 100 °C in an autoclave. It was concluded that the initial addition of NOF to C_2F_4 is rate-determining since no more than trace amounts of C_2F_5NO can be isolated. Also, it is known that the addition of the primary C_2F_5NO to C_2F_4 occurs rapidly at low temperatures in the absence of light.

A major by-product in the 100 °C reaction was perfluorocyclobutane; small amounts of polymerization products of the type already mentioned were also formed [171, 177].

The main products of the reaction at 200 °C were COF_2 and $CF_2NC_2F_5$, the latter presumably originating from the initial rupture of the N–O bond of the oxazetidine [171, 177].

Evidence for the insertion of CF_2 (originating from C_2F_4) into an N–F bond has been obtained in a study of the reaction of C_2F_4 with NOF under UV irradiation [178]. One of the products was found to be *N*-trifluoromethyltetrafluorooxazetidine which may be formed in either of two ways:

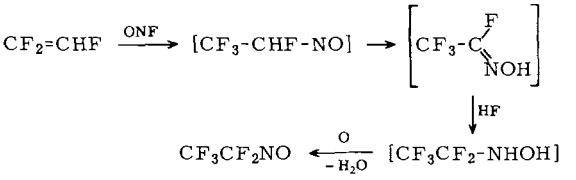


Hexafluoropropane was also observed. Neither the oxazetidine nor C_3F_6 are formed in the absence of UV irradiation [178].

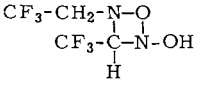
When NOF and higher fluoroolefins or chlorofluoroolefins are heated under pressure at 120 °C for long periods the major product is usually a perhalogenated derivative of 1-oxa-2-azacyclohexane [171, 177]. The positions of the substituent groups in these compounds have not yet been established [177].

When the reaction of NOF with $CF_3CF=CF_2$ is carried out at 200 atm, $(CF_3)_2CFONO$, $(CF_3)_2CO$, and $(CF_3)_2C=NCF(CF_3)_2$ are the main products formed [171].

The reaction of a hydrogen-containing olefin, *e.g.* trifluoroethylene, with NOF [173] takes a different course, the final product being C_2F_5NO. This may be accounted for by the following sequence,



The reaction between vinylidene fluoride and NOF [173] is still more complex, and a product of b.p. 80 °C, believed to have the following structure, has been isolated.



Both $CF_2=CClF$ and $CF_2=CH_2$ react explosively with NOF, and the reaction must therefore be conducted in an inert solvent.

The addition of NOF and NO_2F to alkyl perfluorovinyl ethers in the absence of catalysts proceeds smoothly and with high yields [176, 179, 180] (cf. Table 6).

$(CF_3)_2C=CFOC_2H_5$	$(CF_3)_2C(NO)CF_2OC_2H_5$	[179]	$(CF_3)_2C(NO_2)CF_2OC_2H_5$	[180]
$CFCl=CF_2OCH_3$			$CF(NO_2)ClCF_2OCH_3$	[180]
$CFCl=CF_2OC_2H_5$			$CF(NO_2)ClCF_2OC_2H_5$	[180]

As was suggested by *Knunyants* [182], observations on the addition of NOF and NO_2F to various other derivatives of fluoroolefins provides an insight into the mechanism of this reaction. An inversion of reaction mechanism from electrophilic to nucleophilic is observed as the electron-accepting properties of the double bond increase. Thus, addition of NOF to fluoro derivatives of ethylene (including perfluorovinyl ethers) proceeds by an electrophilic mechanism and, accordingly, is catalyzed by Lewis acids, such as BF_3 in a sulfolane medium [172, 175, 176]. Starting with perfluoropropene, the reaction mechanism becomes nucleophilic and is catalyzed by fluoride ion.

$$CF_3\text{-}\overset{\delta-}{C}F=\overset{\delta+}{C}F_2 \xrightarrow{F^-} [CF_3\text{-}\overset{\ominus}{C}F\text{-}CF_3] \xrightarrow[-F^-]{ONF} (CF_3)_2CFNO$$

A similar inversion of reaction mechanism is known to occur in other reactions of fluoroolefins and their derivatives, *e.g.* in halogenation, hydrohalogenation, acylation, *etc.* [182].

The addition of nitrosyl fluoride and nitryl fluoride to difluoromethylenetrifluoromethylamine (cf. Table 5) proceeds rapidly and quantitatively at low temperature, presumably by a nucleophilic mechanism *via* the resonance-stabilized anion, $CF_3-\overset{\ominus}{N}-CF_3$ [171].

4.2. Fluoroketones and -ketenes

A few reactions of this type are listed in Table 7. At low temperature, the equilibrium

$$\text{>}C=O + ONF \rightleftharpoons F-\overset{|}{C}-ONO$$

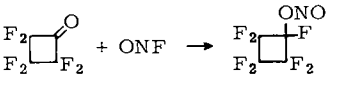
is rapidly established, the stability of the α-fluoronitrite thus formed depending markedly upon the nature of the substituents and upon the temperature [12, 183]. $(C_3F_7)_2C=O$, for example, at 0 °C absorbs an equimolar amount of NOF; the mixture shows the characteristic nitrite absorption band in the IR spectrum. At 20 °C, however, the mixture reverts to the starting compounds [12, 183]. Likewise, the compounds $(ClCF_2)_2C(F)ONO$ and $(ClCF_2)_2C(F)ONO_2$ revert to $(ClCF_2)_2C=O$ and NOF or NO_2F, respectively, on warming to room temperature [183].

The most stable fluoronitrite thus prepared is heptafluorocyclobutyl nitrite.

Table 7. Addition of nitrosyl fluoride and nitryl fluoride to fluoroketones and -ketenes.

Reaction	Product	Ref.
$(CF_3)_2C=O + ONF$	$(CF_3)_2CF(ONO)$	[12]
$CF_3(CF_2NO_2)C=O + ONF$	$CF_3CF(ONO)CF_2NO_2$	[186]
$(ClCF_2)_2C=O + ONF$	$(ClCF_2)_2CF(ONO)$	[183]
$F_2C(-CF_2)C=O + ONF$	$F_2C(-CF_2)CF(ONO)$	[12, 183]
$F_2C(-CF_2)C=O + O_2NF$	$F_2C(-CF_2)CF(ONO_2)$	[12, 183]
$(CF_3)_2C=C=O + ONF$	$(CF_3)_2C(NO)CFO$ [a]	[184]

[a] Also obtained by the addition of NOF to $CF_2=C(CF_3)CFO$ [185].



Perfluorocyclobutanone also reacts readily at low temperature with NO_2F to give heptafluorocyclobutyl nitrate, the first example of a fluoroalkyl nitrate. The NOF and NO_2F addition products of fluoroketones not only decompose readily into their components but also undergo a variety of secondary reactions, such as thermal ring opening in the case of heptafluorocyclobutyl nitrite and nitrate. The ring-opening products are 4-nitroso- or 4-nitrohexafluorobutyryl fluoride which can be made directly if the reaction between perfluorocyclobutanone and NOF or NO_2F is conducted at 100 °C, instead of at or below room temperature [183].

5. Trifluoroamine Oxide, F_3NO

Trifluoroamine oxide is the most recently discovered compound containing the O–N–F grouping. It was first disclosed in 1966/67 by several independent research groups, its synthesis having been achieved by a number of approaches [187–192], most of which involve

the oxidative fluorination of either NO or NOF (the latter being the initial reaction product between NO + F_2), *e.g.*

$$3\,NOF + 2\,IrF_6 \rightarrow 2\,[NO][IrF_6] + ONF_3$$

$$NF_3/O_2 \xrightarrow[-196\,^\circ C]{\text{electr. discharge}} ONF_3$$

$$2\,NO + 3\,F_2 \rightarrow 2\,ONF_3$$

$$ONF + F_2 \rightarrow ONF_3$$

$$N_2/F_2/O_2 \xrightarrow{\text{electr. discharge}} ONF_3$$

Pyrolysis of $(NO)_2[NiF_6]$ (prepared from NiF_2, F_2, and NOF) at 350 °C in an atmosphere of fluorine also gives rise to formation of ONF_3 [187]. Finally, according to as yet unpublished work by *Pilipovich et al.* (quoted in [193]) ONF_3 is obtained by the action of a mixture of ClF_3/ClO_2 on HNF_2.

In comparison with the starting materials required for its synthesis, ONF_3 is chemically very inert and somewhat similar to carbon tetrafluoride, CF_4, with which it is isoelectronic. ONF_3 is stable towards glass and many metals at room temperature and its reaction with water is only very slow. When heated in nickel or Monel® vessels, ONF_3 is thermally stable up to 300 °C [188, 192]. It is a strong oxidizing agent towards various organic and inorganic materials [188].

The structure of ONF_3 could be established quite readily from its IR [187, 188, 193] and ^{19}F–NMR spectra (Table 8), both ruling out a hypofluorite, F_2NOF formulation. IR fundamentals have been assigned in terms of C_{3v} symmetry.

Table 8. Physical properties of trifluoroamine oxide.

	−85	[188]
^{19}F–NMR	1:1:1 Triplet, J_{NF} = 136 Hz, $\delta_F(CCl_3F)$ = −363 ± 2 ppm (liquid at −90 °C)	[188]
	1:1:1 Triplet, J_{NF} = 135.5 Hz, $\delta_F(CCl_3F)$ = −365.7 ± 0.2 ppm (solution in CCl_3F at −82 °C)	[187]
IR		[187, 188, 193]
Thermodynamic Data		[193]

Little is known, as yet, about the chemistry of ONF_3. Addition reactions with fluoroolefins lead to the formation of $RONF_2$ derivatives [188]. The radical, F_2NO is produced in the photolysis of ONF_3 (at −196 °C) and is identified by its ESR spectrum [188].

Trifluoroamine oxide reacts with acceptor fluorides, such as BF_3 [194, 195], AsF_5 [187, 188, 195], or SbF_5 [188, 195]. Formation of the $F_3NO{\cdot}BF_3$ adduct has been claimed as a means of purifying ONF_3, removing impurities such as N_2O, SiF_4, NO_2F, NOF, NF_3, *etc.* The $F_3NO{\cdot}BF_3$ adduct dissociates quantitatively into its components on warming to room temperature [194]. At −126 °C formation of a 2:1 adduct between BF_3 and F_3NO has been observed [195]. The thermal stability of these adducts decreases in the order $F_3NO{\cdot}SbF_5 > F_3NO{\cdot}AsF_5 > F_3NO{\cdot}BF_3 > F_3NO{\cdot}2\,BF_3$ [187, 188, 195]. Hydrolysis of $F_3NO{\cdot}AsF_5$ leads to formation of $[NO_2][AsF_6]$. According to IR and ^{19}F–NMR spectra the solid 1:1 adducts are ionic and contain the $[F_2NO]^+$ cation (point group C_{2v}) whose structure is similar to that of the isoelectronic COF_2 [195].

IR spectra of thin films of the complexes exhibit strong bands at 1857, 1162, and 905 cm^{-1} which are assigned to ν(NO), ν_s(NF), and ν_{as}(NF) [188] for the ion $[F_2NO]^+$; this is supported by ^{19}F–NMR spectra for the solution state, of $F_3NO{\cdot}AsF_5$ and $F_3NO{\cdot}SbF_5$ (HF solvent). The compounds are apparently ionic and have the formulation $[F_2NO]^+[MF_6]$; in both cases, a 4:5:4 triplet N–F resonance at −331 ± 3 ppm (from CCl_3F) with J_{N-F} = 250 Hz, as well as the high field resonance of $[AsF_6]^-$ (+60 ppm.) or $[SbF_6]^-$ (+135 ppm.), is observed [188].

A high-yield fluorination reaction for haloolefins under mild conditions is based on the following reaction of F_3NO-Lewis acid adducts,

$$F_3NO \cdot BF_3 + \rangle C{=}C\langle \rightarrow \underset{|}{\overset{|}{F\overset{|}{C}-\overset{|}{C}F}} + NO[BF_4]$$

6. Oxydifluoroamines (*N,N*-Difluorohydroxylamines), $RONF_2$

A few members of a new class of compounds, containing the oxydifluoroamine grouping, $-ONF_2$ have been reported in recent years. Tetrafluorohydrazine, F_2NNF_2 or, sometimes, NF_3, CF_3NF_2, and $SO_2(F)NF_2$ served as a source of NF_2 radicals in their preparation. UV irradiation was required to initiate some of the reactions while others, *e.g.* $F_5SOF + N_2F_4 \rightarrow F_5SONF_2 + NF_3$, start immediately upon mixing the reactants. Since compounds such as F_5SOF, CF_3OF, CF_3OOCF_3, *etc.* may act as oxidative fluorinating agents towards N_2F_4, numerous by-products (NF_3, NO, SF_6, SO_2F_2, SOF_4, NO_2, COF_2, CF_4, *etc.*) are frequently formed, and an involved separation procedure, *e.g.* by VPC, may be required.

Fully characterized compounds containing the $-ONF_2$ grouping are listed in Table 9. A number of further compounds have been obtained by reaction of CF_3O radicals (generated by fission of CF_3OOCF_3) with N_2F_4; characterization of these compounds was by mass spectroscopy and IR only [199].

Mention has been made of the formation of $RONF_2$ by reaction of F_3NO with fluoroolefins [188], but no details are available, as yet.

The reaction of N_2F_4 with $(FSO_2)_2O_2$, which is homogeneous and proceeds without change in pres-

$(CF_3)_2NONF_2$	$(CF_3)_2NOH + NF_2Cl/CsF$	[a]	^{19}F–NMR	[205]

[a] Not determined, since product cannot be separated from accompanying $(CF_3)_2NO$.

sure, has been studied kinetically at temperatures between −15 and +15 °C. The following steps are proposed [199]:

$$(FSO_2)_2O_2 \rightarrow 2\ FSO_2O^{\bullet} \text{ (rate-determining)}$$

$$FSO_2O^{\bullet} + N_2F_4 \rightarrow FSO_2ONF_2 + {}^{\bullet}NF_2$$

$$N_2F_4 \rightleftharpoons 2\ {}^{\bullet}NF_2$$

FSO_2ONF_2 is also formed in the reaction of FSO_2OF with N_2F_4 by a similar radical mechanism [199].

Only a few reactions of oxydifluoroamines have been described as yet. Thus, the compound FSO_2ONF_2 undergoes an addition reaction which can be initiated thermally with fluoroolefins such as tetrafluoroethylene or hexafluoropropene [197].

$$F_2NOSO_2F + CF_2{=}CF_2 \rightarrow F_2NCF_2CF_2OSO_2F$$

$$F_2NOSO_2F + CF_3{-}CF{=}CF_2 \rightarrow CF_3CF(OSO_2F)CF_2NF_2 + CF_3CF(NF_2)CF_2OSO_2F$$

A few oxydifluoroamines react with both electrophilic and nucleophilic reagents [200] *e.g.*

$$F_2NOSF_5 + BF_3 \rightarrow SF_6 + NO[BF_4]$$

However, FSO_2ONF_2 does not react with BF_3.

A differentiation between F_5SONF_2 and FSO_2ONF_2 with regard to their reactivity towards nucleophiles is also evident: F_5SONF_2 is not attacked by Cl^- or F^- at 150 °C; however, FSO_2ONF_2 reacts with Cl^- (90 % yield).

$$F_2NOSO_2F + Cl^- \rightarrow FSO_3^- + F_2NCl$$

F^- reacts with FSO_2ONF_2 in a different fashion [200].

$$FSO_2ONF_2 + F^- \rightarrow FSO_2F + ONF$$

C. Nitryl Hypofluorite (Fluorine Nitrate), O_2NOF

Cady [206, 207] obtained O_2NOF in the reaction of dilute nitric acid with elemental fluorine. He noted that both concentrated and very dilute HNO_3 gave rise to explosions while the reaction proceeded fairly safely when 4 N HNO_3 was employed. Subsequently, other authors reported that it was safer to pass elemental fluorine at room temperature into conc. HNO_3 [208] or even into 100 % HNO_3 [209]; a detailed preparative procedure for NO_3F has been given by *Kwasnik* [210]. A further synthesis of NO_3F involves reaction of KNO_3 with fluorine [211, 212].

Varying amounts of NO_3F are produced in the reaction of OF_2 with NO_2 [130]. Finally, formation of NO_3F has been observed upon electrolysis of mixtures of HF with NO or N_2O, using nickel electrodes. NO_3F is formed at the anode at lower potentials while OF_2 is the predominant product at higher potentials [100, 213, 214].

Structure: Although the hypofluorite structure O_2NOF was proposed on the basis of chemical evidence, early parachor studies [208] led to the suggestion of a cyclic structure,

However, an electron diffraction study [215], reported at about the same time, gave the following structure and bonding parameters.

More recently, the IR spectrum of NO_3F has been analyzed and compared with that of NO_3Cl [216, 217] (see also [126]). Eight out of the expected 9 fundamentals could be observed. A planar structure of symmetry C_s (see above) is believed to be most likely, and the presence of an N–F bond can be ruled out with certainty on the basis of the spectroscopic evidence.

Physical and *chemical properties*: Various physical data pertinent to NO_3F are set out in Table 10.

Fluorine nitrate is a toxic, colorless gas which is dangerously explosive in the gaseous, liquid, and solid state [206, 207, 209, 211]. NO_3F is a powerful oxidizer, and spontaneous explosions occur upon its contact with various organic compounds, such as ethanol, ether, aniline, *etc*; however, it does not attack dry glass. NO_3F is moderately soluble in water and on dissolution oxygen is evolved slowly; oxygen formation is more rapid in aqueous alkali [206, 207, 209].

$$O_2NOF + 2\,OH^- \rightarrow {}^1/_2\,O_2 + F^- + NO_3^- + H_2O$$

The following reaction takes place in aqueous solutions of iodide:

$$O_2NOF + 3\,I^- \rightarrow I_3^- + F^- + NO_3^-$$

NO_3F reacts with Ag^+ to form a black precipitate, formulated as "Ag_2O_3". In the presence of Ag^+, Mn^{2+} is oxidized to MnO_4^- [211].

Yellow solid addition compounds of unknown structure are formed on reaction of NO_3F with $TiCl_4$ or $SbCl_5$ [209].

In a recent study of the chemistry of NO_3F [219] it was found that the compound appears to add across the double bond of ethylene to give what is believed to be $FCH_2CH_2ONO_2$. The reaction of NO_3F with tetrafluoroethylene leads to the formation of COF_2 and CF_3NO_2; these products possibly originate from an unstable species $C_2F_5ONO_2$. A variety of products, including SF_6, NO_2F, SOF_2 NO_2, O_2, SiF_4, but not F_5SONO_2, are formed in the thermal or UV-initiated reactions of SF_4 with NO_3F. NF_3, NO_2, NO_2F, and NOF are obtained on reaction of NO_3F with N_2F_4 [219].

Considerable attention has been given to the study of the thermal decomposition of NO_3F which, as has been pointed out, forms the link between NO_3F and the simple oxyfluorides of nitrogen, NOF, and especially NO_2F. NO_3F decomposes into NO_2F and oxygen at temperatures between 80 and 130 °C, and at pressures varying between 0.6 and 400 torr [125–127]. The reaction is homogeneous and monomolecular; its rate varies with the addition of various foreign gases, such as Ar, N_2, O_2, CO_2, NO_2, OF_2, *etc.*

The primary process and rate-determining step during the thermal decomposition of NO_3F is believed to be the cleavage of the O–F bond [125–127, 130].

$$O_2NOF \rightarrow NO_3^\bullet + F^\bullet$$

The activation energy of this reaction which is a measure of the strength of the O–F bond in NO_3F, has been reported as 29.7 kcal/mole [125, 126] and 32.3 kcal/mole [127]. The subsequent, relatively fast steps are [125–127]

$$NO_3^\bullet + NO_3^\bullet \rightarrow 2\,NO_2 + O_2$$

$$NO_2 + F^\bullet \xrightarrow{M} O_2NF$$

In an earlier study of the kinetics of this reaction [220], the primary process was formulated as

$$O_2NOF \rightarrow NO_2 + {}^\bullet OF$$

followed by

$$O_2NOF + NO_2 \rightarrow O_2NF + NO_3^\bullet$$

$$NO_3^\bullet + {}^\bullet OF \rightarrow O_2NF + O_2$$

Further kinetic studies on the bimolecular reaction of NO_3F with NO_2 [221] have been carried out at temperatures between 80 and 100 °C.

$$NO_2 + O_2NOF \rightarrow O_2NF + NO_3^\bullet \text{ (rate-determining)}$$

$$NO_2 + NO_3 \rightleftharpoons N_2O_5 \rightarrow 2\,NO_2 + {}^1/_2\,O_2$$

The above study was conducted after the effect of added NO_2 upon the rate of the unimolecular decomposition of NO_3F had been observed [127]. For the same reason, the effect of added fluorine upon the decomposition of NO_3F was studied between 90 and 110 °C at partial pressures of 0.3–400 torr and 25–100 torr for fluorine and for NO_3F, respectively. Fluorine is believed to produce OF radicals which immediately react with further NO_3F [222].

[222] *J. E. Bolzan, J. E. Sicre*, and *H. J. Schumacher*, Z. physik. Chem. N.F. *41*, 101 (1964).

$$F_2 + O_2NOF \rightarrow NO_2F + F^\bullet + {}^\bullet OF$$

$$^\bullet OF + O_2NOF \rightarrow O_2NF + F^\bullet + O_2$$

$$F^\bullet + F^\bullet \xrightarrow{M} F_2$$

Addition of small quantities of F_2 (as little as 0.1 torr) was found to double the rate of decomposition of NO_3F.

Finally, the kinetics of the reaction between NO and NO_3F were investigated in the range −110 to +42 °C; the reaction is essentially second order and homogeneous, especially at high temperatures. The sole products are NOF and NO_2.

$$O_2NOF + NO \rightarrow ONF + NO_3^\bullet \text{ (rate-determining)}$$

$$NO_3^\bullet + NO \rightarrow 2\,NO_2 \rightleftharpoons N_2O_4$$

D. Uses of Oxide Fluorides of Nitrogen

Numerous examples illustrating the chemical significance of the oxyfluorides of nitrogen have already been discussed in the previous Sections. The role of these compounds as oxidizers in rocket propellants is of particular importance, and it is safe to assume that much relevant information is still classified. Attention has been focused on the potential of NOF, NO_2F[223,224] (and NO_3F[189,190]) in this field[223], since as far back as 1950.

Furthermore, it has been suggested that NOF might be used as a stabilizing agent for liquid SO_3 (in the α-form) against polymerization, small amounts of NOF (0.1–3 %) being sufficient[225]. NOF has also been claimed as a nitrosating agent for cycloaliphatic hydrocarbons in the presence of UV irradiation[226,227], but this has not been confirmed by other authors[4].

It has been reported that oxydifluoroamines, $RONF_2$, act as polymerization initiators, especially in the case of fluoroolefins[198].

Finally, it may be noted that one of the more curious uses proposed for NO_3F is as a war gas[228].

A Versatile Method for Preparation of *C*-Deuterated Compounds

By *K. Kühlein, W. P. Neumann,* and *H. Mohring* [*] [1]

Dedicated to Professor Fritz Kröhnke on the occasion of his 65th birthday

The possibilities for preparation of specifically deuterated compounds are limited[2]. Organotin deuterides have been used for deuteration of individual alkyl and cycloalkyl halides[3,4] and have been added to alkynes[5], but the need to use $LiAlD_4$[3] or R_2AlD[6] in their preparation has restricted their wider application.

We have now found a simple and prolific method of preparing organotin deuterides, namely, by preparing stannyl alkali compounds from distannanes by means of naphthalene sodium and treating the products with D_2O.

$$R_3SnNa + D_2O \rightarrow R_3Sn{-}D + NaOD$$

$$R_2SnNa_2 + 2\,D_2O \rightarrow R_2SnD_2 + 2\,NaOD$$

$R = CH_3, C_2H_5, C_3H_7, C_4H_9$, *sec*-$C_4H_9$, C_6H_5, cyclo-C_6H_{11}

Whether the resulting deuterides contain also Sn–H groups depends only on the purity of the D_2O used.

This result and the numerous possibilities of transferring hydrogen to carbon by using organotin hydrides in radical or

$$RR^1C{=}O + R_3^2Sn{-}D \longrightarrow RR^1CD{-}OSnR_3^2$$

$$RR^1CD{-}OSnR_3^2 \xrightarrow[-1/2\,(R_3^2Sn)_2O]{+1/2\,D_2O} RR^1CD{-}OD \quad (a)$$

$$RR^1CD{-}OSnR_3^2 \xrightarrow[-1/2\,(R_3^2Sn)_2O]{+1/2\,H_2O} RR^1CD{-}OH \quad (b)$$

$$RR^1C{=}O + R_2^2SnD_2 \longrightarrow RR^1CD{-}OD + 1/n\,(R_2^2Sn)_n \quad (c)$$

Carbonyl compound	Deuteride	Catalyst	Route	Conditions (h/ °C)	Deuterated alcohol [a]	ν_{C-D} (cm^{-1})

[a] The products have no measurable optical activity.

polar additions or substitutions[7] induced us to test the wider use of organotin deuterides for deuteration.

Using powerful catalysts such as Raney nickel, palladium, platinum[8], or anhydrous $ZnCl_2$[9], we obtained both *C*-deuterated and *C,O*-bisdeuterated alcohols smoothly from organotin deuterides and aldehydes or ketones. To save deuteride we liberated the alcohol by deuterolysis (a) or hydrolysis (b), as required. However, a second equivalent of deuteride also effects this liberation, and is best used in the form of the more active compounds $R^2_2SnD_2$ which react in one step (c).

Working up is by fractional distillation. Yields are 70–95%.

Alkyl chlorides, bromides, and iodides, aryl iodides, and acid chlorides can be deuterated even without a catalyst. Carbonyl, nitro, and nitrile groups, which are often attacked by the usual deuterating agents, are unchanged in this reaction. Acid chlorides afford [1-D]aldehydes[10], and also the dideuterated esters. The ratio of the yields [1-D]aldehyde:ester can be varied according to the experimental technique and the concentration of the reactants, as is recorded[7,11] for the analogous reaction with hydrides.

[a] By use of $(C_6H_5)_3SnD$. — [b] Since the product is formed in a radical reaction no optical activity is to be expected. — [c] By use of $(C_2H_5)_3SiD$.

As shown for the case of *p*-nitrobenzoyl chloride, even the more sluggishly reacting $(C_2H_5)_3SiD$ [easily obtained from the bromide and $(C_6H_5)_3SnD$ by distillation from the equilibrium mixture] acts as deuterating agent for particularly reactive starting materials.

The deuteride is usually added dropwise to the other reactant. The resulting products have been characterized by m.p. or b.p., elemental analysis, NMR spectra, ν_{C-D}, and sometimes ν_{O-D} in the IR spectra.

A New Route to 1,1-Disubstituted Cyclopropanes

By *J. Gosselck* and *G. Schmidt*[*]

Dedicated to Professor F. Kröhnke on the occasion of his 65th birthday

Treatment of substituted dimethylvinylsulfonium salts with the sodium salts of CH-acidic compounds in anhydrous ethanol leads stereospecifically to H^1,H^2-*trans*-cyclopropanes[1]. We have postulated a 1,4-sulfonium betaine as intermediate which closes the three-membered ring in a S_Ni reaction with loss of dimethyl sulfide. To test this assumption we synthesized the sulfonium salts *(1)* and treated them in anhydrous ethanolic solution or suspension with an equivalent amount of sodium ethoxide. Dimethyl sulfide was split off even at 20 °C. After 2–15-hours' stirring, the mixture was treated with ice and dilute sulfuric acid and then extracted with ether; the extract was worked up by distillation [*(2a)–(2d)*] or recrystallization [*(2f)*].

As expected, 1,1-disubstituted cyclopropanes *(2)* were obtained. They were identified by analysis of their NMR spectra, by gas-chromatographic studies, and by comparison of the results with recorded data.

1,1-Dibenzoylcyclopropane *(2f)* was a new compound. It crystallized from 4 parts of ethanol at −50 °C as pale yellow crystals (m.p. 56–58 °C).

As a result of alcoholysis of one nitrile group, *(1d)* (R = R^1 = CN) affords *(2c)* (R = $COOC_2H_5$, R^1 = CN) and not the dinitrile *(2d)*. To obtain *(2d)*, *(1d)* must be suspended in anhydrous ether and refluxed for 24 h with an equivalent amount of *N*-ethyldiisopropylamine.

In order to prepare the sulfonium salts *(1)* we first synthesized the β-substituted ethyl sulfides *(3)* by adding 2-(methylthio)-ethyl bromide[5] dropwise to a suspension of the potassium salts of CH-acidic compounds in *tert*-butyl alcohol[6]. The mixture was boiled until neutral (1–3 h). After removal of the

tert-butyl alcohol under vacuum the residue was treated with ice and dilute sulfuric acid and extracted with ether; the extract was then fractionated.

The sulfides *(3)* were treated with the calculated amount of methyl iodide and set aside at 0 °C for 1—8 days. This afforded the sulfonium salts in almost quantitative yield. They were purified by washing with anhydrous ether and were analyzed as iodides, picrylsulfonates, or tetraphenylborates.

	R	R¹	Reaction time (days)	M.p. (°C) [b]
(1a)	$COOC_2H_5$	$COOC_2H_5$	8	152 (P) [a], 129 (T)
(1b)	$COOC_2H_5$	$COCH_3$	3	146 (P)

(1d)	$C\equiv N$	$C\equiv N$	2	142—144 (P), 108 (I)
(1e)	C_6H_5CO	C_6H_5	2	151—153 (P), 130—131 (I)
(1f)	C_6H_5CO	C_6H_5CO	1	123—124 (P)
(1g)	C_6H_5CO	$COOC_2H_5$	4	127 (P)
(1h)	CH_3CO	CH_3CO	2	165 (P), 125—126 (I)

[a] M.p. of the picrylsulfonate given in [11] is 168—169 °C.
[b] P = picrylsulfonate, T = tetraphenylborate, I = iodide.

The procedure described here has the advantage over synthesis of 1,1-disubstituted cyclopropanes from CH-acidic compounds and ethylene dibromide that the products are obtained in appreciably purer form. Further, the reaction occurs under very mild conditions.

As expected, 1,1-disubstituted cyclopropanes *(2)* are also formed on treatment of dimethylvinylsulfonium bromide *(4)* with the sodium salts of CH-acidic compounds in anhydrous ethanolic solution. Reaction of 2-bromoethyldimethylsulfonium bromide *(5)* with one equivalent of a CH-acidic compound and two equivalents of sodium ethoxide or *N*-ethyldiisopropylamine as proton acceptor also leads to cyclopropanes *(2)*. However, yields are lower in these two reactions.

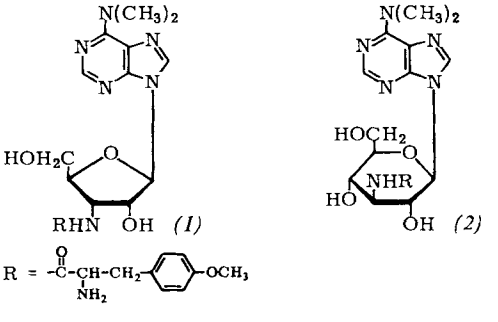
Synthesis of a Puromycin Analog[1]

By *F. W. Lichtenthaler* and *H. P. Albrecht*[*]

Dedicated to Professor F. Kröhnke on the occasion of his 65th birthday

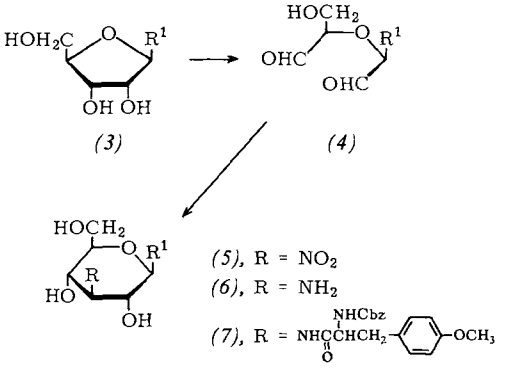
Attempts to improve the pharmacological properties of the nucleoside antibiotic puromycin *(1)*[2] have led to the synthesis of analogous compounds[3] largely based on the principle that the biological activity is due to the presence of an aminopentofuranose unit[4].

Although the activity of the puromycin analog *(2)* that is derived from 3-amino-3-deoxy-D-glucopyranose and whose



synthesis we describe below is not comparable with that of puromycin against *E. coli* and *S. faecalis*, it interferes with the transfer of [^{14}C]phenylalanine from t-RNS to the polypeptide (Nierenberg system)[5].

On cyclization with nitromethane in the presence of sodium methoxide in methanol and subsequent neutralization the nucleoside dialdehyde *(4)* that is obtained by periodate oxidation of 6-(dimethylamino)-9-(β-D-ribofuranosyl)purine *(3)*[6] affords a crystalline mixture of isomers (75 % yield), whence (3-deoxy-3-nitro-β-D-glucopyranosyl)-6-(dimethylamino)purine can be separated by fractional crystallization from methanol/water in 23 % yield [calculated on *(3)*] m.p. 202–204 °C (decomp.), $[\alpha]_D^{20} = -13°$ (c = 0.6, CH_3OH)[7]. Hydrogenation over 10 % palladium-animal charcoal affords 9-(3-amino-3-deoxy-β-D-glucopyranosyl)-6-(dimethylamino)purine *(6)*, m.p. 145–147 °C, $[\alpha]_D^{20} = -10°$ (c = 0.5, CH_3OH). This is converted by acetic anhydride/pyridine into the tetraacetate, m.p. 235–237 °C, $[\alpha]_D^{20} = -43°$ (c = 0.5, CH_3OH), whose NMR spectrum measured in $(CD_3)_2SO$ [9-Hz doublet for H-1′ at τ = 4.00, acetyl resonances at τ = 8.00, 8.03 (C-4′- and C-6′-OAc, respectively), 8.25 (NHAc), and 8.33 (C-2′-OAc)] proves the *gluco* configuration[8].



R^1 = 6-Dimethylaminopurin-9-yl

Treatment of *(6)* in dimethylformamide with the mixed anhydride prepared from *N*-(benzyloxycarbonyl)-*p*-methoxy-L-phenylalanine and ethylchloroformate/triethylamine[9] affords the amide *(7)*, m.p. 205–207 °C, $[\alpha]_D^{20} = +14°$ (c = 0.6, DMF), in 72 % yield. Hydrogenolysis of the benzyloxycarbonyl group over 10 % palladium-animal charcoal leads to the puromycin analog *(2)*, m.p. 135–137 °C, $[\alpha]_D^{20} = -26°$ (c = 0.8, CH_3OH), in 86 % yield. Its dihydrochloride crystallizes in well-formed needles of m.p. 188–190 °C.

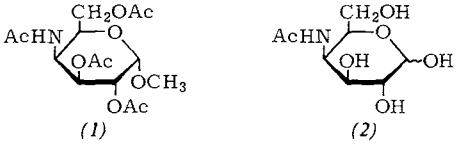
Synthesis of Derivatives of 4-Amino-4-deoxy-D-galactose

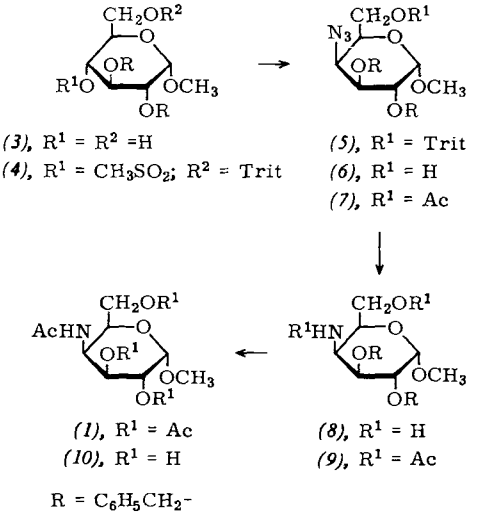
By *F. W. Lichtenthaler* and *P. Heidel*[*]

The structure proposed[2] for the nucleoside antibiotic gougerotin[1] is based on studies of periodate oxidation and some NMR data, and particularly on the physical constants of two degradation products *(1)* and *(2)*[2,3] to which the 4-amino *galacto* configuration is ascribed[2].



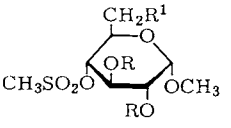
The syntheses described below afford compound *(1)* as a syrup with $[\alpha]_D^{25} = +119°$ in $CHCl_3$. Since the gougerotin degradation product has other constants (m.p. 193 °C, $[\alpha]_D^{20} = +87°$ in $CHCl_3$), the validity of the 4-amino-*galacto* structure is doubtful.

The 4-*O*-methanesulfonate *(4)*, m.p. 146–147 °C, $[\alpha]_D^{25} = +24°$ (c = 0.5 in $CHCl_3$), is obtained in 79 % yield from methyl 2,3-di-*O*-benzyl-α-D-glucopyranoside *(3)*[4] by tritylation and subsequent methanesulfonylation; it is converted into the 4-azido galactoside *(5)*, m.p. 50–52 °C, $[\alpha]_D^{25} = +13°$ (c = 2 in $CHCl_3$), when heated with sodium azide in dimethylformamide for 30 h at 100 °C (yield 93 %). Detritylation by acid affords *(6)*, which does not crystallize but can be characterized as the 6-*O*-acetate *(7)*, m.p. 76–78 °C, $[\alpha]_D^{25} + 8°$ (c = 0.7 in $CHCl_3$). $LiAlH_4$ reduces *(6)* to the 4-amino galactoside *(8)* (a syrup, $[\alpha]_D^{25} = +49°$, c = 1 in $CHCl_3$), and acetylation then yields the diacetyl derivative *(9)* (a syrup, $[\alpha]_D^{25} = +51°$, c = 1 in $CHCl_3$). After thin layer chromatography on silica gel PF_{254} [development with ethyl acetate-ethanol-water (15:2:1) or chloroform-ethyl acetate-ethanol (10:2:1)] both these products were analytically pure (combustion analysis) and gave the expected NMR values. Reaction of *(6)* with sodium in liquid ammonia and subsequent acetylation led to the tetraacetate *(1)*, which after column chromatography on silica gel [elution with ethyl acetate-ethanol-water (15:2:1)] is obtained analytically and chromatographically pure, as a syrup, R_F = 0.6[5], $[\alpha]_D^{25} = +119°$ (c = 1 in $CHCl_3$), in 43 % yield calculated on *(6)*. Removing the *O*-acetyl groups by methanolic ammonia affords the *N*-acetate *(10)*, which crystallizes as needles, m.p. 203–205 °C, $[\alpha]_D^{25} = +182°$ (c = 1 in CH_3OH).



(10) can also be synthesized in five steps from methyl 2,3-di-*O*-benzoyl-4,6-di-*O*-mesyl-α-D-glucopyranoside *(11)*[6a] [m.p. 150–151 °C, $[\alpha]_D^{25} = +143°$ (c = 2, $CHCl_3$)]. In com-

pound *(11)*, the primary *C*-6 mesyloxy group can be solvolyzed selectively: sodium azide in dimethylformamide (3 h, 75 °C) gives the 6-azido compound *(12)* [m.p. 148–150 °C, $[\alpha]_D^{25} = +162°$ (*c* = 1, $CHCl_3$), yield 84 %]; similarly, sodium benzoate in dimethylformamide (5h, 80 °C) gives analytically and chromatographically[5] pure methyl 2,3,6-tri-*O*-benzoyl-4-*O*-mesyl-α-D-glucopyranosyl *(13)* in amorphous form [$[\alpha]_D^{25} = +139°$ (*c* = 1, $CHCl_3$), yield 92 %]. Solvolysis of the *C*-4 mesyloxy group in *(13)* by heating with sodium azide in dimethylformamide (60 h, 100 °C) and subsequent de-*O*-benzoylation with methanolic ammonia affords methyl 4-azido-4-deoxy-α-D-galactopyranoside *(6)*, R = H [m.p. 153–155 °C, $[\alpha]_D^{25} = +120°$ (*c* = 0.5, CH_3OH), yield 64 %]. Hydrogenation of *(6)*, R = H, followed by *N*-acetylation yields a product whose melting point, $[\alpha]_D$, and IR spectrum are identical with those of *(10)*.



(11), $R^1 = OSO_2CH_3$; R = C_6H_5CO
(12), $R^1 = N_3$; R = C_6H_5CO
(13), R^1 = R = C_6H_5CO

The *galacto* configuration of *(1)* and *(5)–(10)* follows from the method of preparation[6b] and from NMR spectroscopic data. The acetyl resonances obtained for *(1)* [τ = 7.91, 7.94 (2), and 8.01 in $CDCl_3$; 7.96, 7.98, and 8.08 (2) in [D_6]-DMSO] indicate[7] the absence of axial acetoxy and equatorial acetylamino groups. Analysis of the ring CH protons effected at 100 MHz in $CDCl_3$[8] gave for H-4 at τ = 5.27 a quartet with J_{34} = 4.0 and J_{4NH} = 10.0 Hz, each line being broadened by coupling with H-5 ($J_{45} \approx 1$ Hz). This quartet is simplified to a 4-Hz doublet by irradiation at the resonance frequency of the NH doublet (τ = 3.61, 10 Hz) and to a 10 Hz doublet by irradiation at the resonance frequency of the H-3 quartet (τ = 4.72).

Attempts to obtain *(2)* by acid hydrolysis of *(1)* or *(10)* [4 N HCl, 100 °C] and subsequent *N*-acetylation have so far failed. Apparently ring contraction giving the pyrrolidine sugar occurs under the conditions necessary for glycoside cleavage[9].

Ethynylogous Amides and Urethanes[**]

By *K. Hafner* and *M. Neuenschwander*[*]

Vinylogous amides have proved useful as starting compounds for the preparation of polycyclic conjugated, nonbenzenoid π-electron systems[1]. The hitherto unknown ethynylogous amides should provide a synthetic route to novel unsaturated ring systems; the study of the chemical and physical properties of these compounds was therefore of interest.

Ethynylogous amides and urethanes can be prepared easily and in good yields from the corresponding vinylogous compounds *(1)*. The bromination of 3-(dimethylamino)prop-

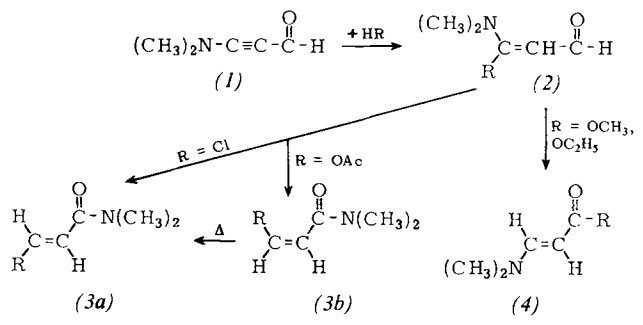
A New Rearrangement of Substituted 3-Aminopropenals[**]

By *M. Neuenschwander* and *K. Hafner*[*]

3-(Dimethylamino)prop-2-yn-1-al *(1)* reacts with an equimolar quantity of HCl in anhydrous tetrahydrofuran at 0 °C to give the reactive aldehyde *(2)*, R = Cl[1], which rearranges during isolation to form isomer-free[2] *trans*-3-chloro-*N,N*-dimethylacrylamide *(3a)*, R = Cl (yield 80 %)[3]. The strong band in the UV spectrum of *(3a)*, R = Cl, occurs at 216 nm (*n*-hexane), a position characteristic of amides of similar structure, and the AB system of the vinyl protons in the NMR spectrum occurs at τ = 2.77 and 3.32 (J = 13 Hz[4]); hydrogenation of *(3a)*, R = Cl, with Pd black (20 °C in benzene) yields *N,N*-dimethylpropionamide. The aldehyde *(2)*, R = OAc, cannot be isolated in the analogous reaction of *(1)* with glacial acetic acid; the product obtained (80 % yield) is isomer-free[2] *cis*-3-acetoxy-*N,N*-dimethylacrylamide *(3b)*, R = OAc [NMR in $CDCl_3$: τ = 2.58/D (J = 7.5 Hz)/1 H; τ = 4.43/D/1 H; τ = 6.90 and 6.94/2S/6 H; τ = 7.75/S/3 H], which rearranges when heated to 60 °C to give the thermodynamically more stable *trans* isomer *(3a)*, R = OAc [NMR in $CDCl_3$: τ = 1.73/D (J = 12 Hz)/1 H; τ = 3.73/D/1 H; τ = 6.93/S/6 H; τ = 7.79/S/3 H]. Compound *(3b)*, R = OAc, can be converted into 3-acetoxy-*N,N*-dimethylpropionamide by hydrogenation (Pd/H_2, 20 °C in benzene).

Compound *(1)* reacts highly stereoselectively[6] with an equimolar quantity of diethylamine or with an excess of methanol or ethanol[5] to give the aldehydes *(2)*, R = $N(C_2H_5)_2$, OCH_3, and OC_2H_5 respectively, which can be isolated since their tendency toward rearrangement is less pronounced than that of the adducts of *(1)* with HCl or acetic acid, and decreases in the order OCH_3 > OC_2H_5 > $N(C_2H_5)_2$.



Whereas only traces of 3-(diethylamino)-3-(dimethylamino)-prop-2-en-1-al *(2)*, R = $N(C_2H_5)_2$, rearrange at 60 to 80 °C, 3-methoxy-3-(dimethylamino)prop-2-en-1-al *(2)*, R = OCH_3, [yellow oil, yield 90 %, NMR in $CDCl_3$: τ = 0.72/D (J = 8 Hz)/1 H; τ = 5.46/D/1 H; τ = 6.16/S/3 H; τ = 7.06/S/6 H] is converted when heated at 60 °C in $CHCl_3$ into the isomeric methyl *trans*-3-(dimethylamino)acrylate *(4)*, R = OCH_3 [57 % yield, m.p. 46–47 °C, λ_{max} in CH_2Cl_2: 278 nm, log ε = 4.28, NMR in $CDCl_3$: τ = 2.57/D (J = 13 Hz)/1 H; τ = 5.50/D/1 H; τ = 6.35/S/3 H; τ = 7.09/S/6 H], the constitution of which was verified by comparison with *(4)*, R = OCH_3, prepared from methyl propiolate and dimethylamine.

The new rearrangement of 3-aminopropenal derivatives *(2)* evidently proceeds with high stereoselectivity; a four-membered ring intermediate or a corresponding transition state is probably involved. The configuration of the aldehyde *(2)*, which is important for the elucidation of the mechanism[7], cannot be established from the above results. We are now proceeding with the further study of this reaction.

[**] *M. N.* is grateful to the *Schweizerische Stiftung für Stipendien auf dem Gebiete der Chemie* for a grant. We thank Fräulein *M. Ruppert* for her skilful experimental assistance.

[1] The aldehyde *(2)*, R = Cl, can be obtained in the impure state by careful working-up [UV in CH_2Cl_2: λ_{max} = 297 nm; NMR in $CDCl_3$: τ = 0.45/D/1 H and τ = 4.80/D (J = 7 Hz)/1 H; τ = 6.81/S/6 H].

[2] Purity checked by NMR spectra.

[3] Similarly, the addition of HCl to 3-(*N*-methylanilino)prop-2-yn-1-al (NMR in $CDCl_3$: τ = 0.73/S/1 H; τ approx. 2.75/M/5 H; τ = 6.62/S/3 H; IR in CCl_4: $\nu_{C\equiv C}$ = 2170 cm^{-1}) leads by rearrangement to *trans*-3-chloro-*N*-methylacrylanilide [NMR in $CDCl_3$: τ = 2.3–2.9/M/6 H, including τ = 2.64/D/(J = 13 Hz); τ = 3.78/D (J = 13 Hz)/1 H; τ = 6.63/S/3 H].

[4] For coupling constants of similar compounds, cf. *E. Winterfeldt* and *H. Preuss*, Chem. Ber. *99*, 450 (1966).

[5] Since the reaction rate in dilute equimolar solutions is too slow, the reactions was carried out in the corresponding alcohol.

[6] According to the NMR spectra, the adducts *(2)*, R = $N(C_2H_5)_2$, OCH_3, OC_2H_5, are formed with a stereoselectivity of about 90 %.

[7] For the steric course of additions to C≡C bonds, cf. *R. Huisgen*, *B. Giese*, and *H. Huber*, Tetrahedron Letters *1967*, 1883 (further references cited); *E. Winterfeldt*, Angew. Chem. *79*, 389 (1967) (further references cited); Angew. Chem. internat. Edit. *6*, 423 (1967).

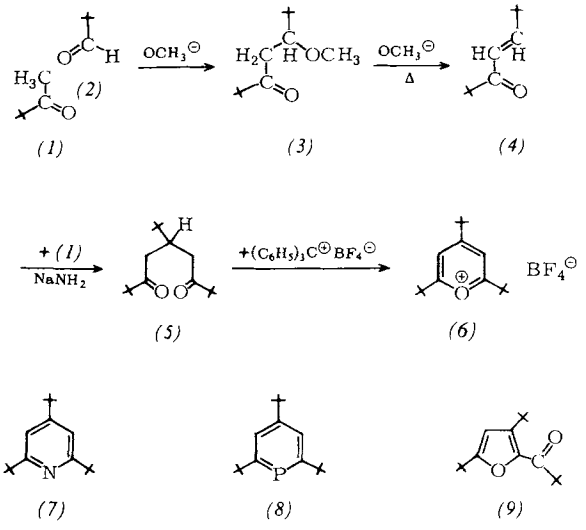
Preparation of 2,4,6-Tri-*tert*-butylpyrylium Tetrafluoroborate, 2,4,6-Tri-*tert*-butylpyridine, and 2,4,6-Tri-*tert*-butylphosphorin

By *K. Dimroth and W. Mach*[*]

Pyrylium salts substituted by *tert*-butyl groups in the 2,4,6-positions have not previously been known. The synthesis of such a salt, which we describe here, made possible the prepa-

ration of 2,4,6-tri-*tert*-butyl-pyridine and 2,4,6-tri-*tert*-butyl-phosphorin, the first phosphorin derivative containing only aliphatic substituents.

We obtained 2,4,6-tri-*tert*-butylpyrylium tetrafluoroborate *(6)* in a total yield of 42% by the route shown in the following scheme. The methoxy ketone *(3)* is converted mainly into the unsaturated ketone *(4)* when boiled in a basic medium, whereas it is converted by acids into a cyclic carboxonium salt[1].



(1) *(3)* *(4)*

(5) *(6)*

(7) *(8)* *(9)*

2,4,6-Tri-*tert*-butylpyridine *(7)*, m.p. 69 °C, is formed quantitatively by the action of alcoholic ammonia on the pyrylium salt *(6)*. NMR: singlet $\delta = -7.02$ ppm (2 H), $\delta = -1.34$ ppm (18 H), and $\delta = -1.30$ ppm (9 H). The base *(7)* can be isolated and purified by recrystallization from ethanol/water.

Tri-*tert*-butylphosphorin *(8)*[2] is formed in 37% yield from *(6)* and $P(CH_2OH)_3$; it has m.p. 88 °C, and in the NMR shows $\delta = -7.77$ ppm (2 H), $J_{P-CH} = 6$ Hz, doublet $\delta = -1.46$ ppm (18 H), $J_{P-CH} = 2$ Hz, singlet $\delta = -1.37$ (9 H) *(8)* is isolated and purified by recrystallization from methanol/water.

With H_2O_2 in ethanol[3], compound *(8)* affords a 30% yield of *tert*-butyl 3,5-di-*tert*-butyl-2-furyl ketone *(9)*, which can also be obtained from *(6)* by use of hydroxylammonium chloride.

Experimental:

Compounds *(2)* (86 g, 1 mole) and *(1)* (100 g, 1 mole) are boiled for 4 h in 10% $NaOCH_3$ solution (540 g, 1 mole of $NaOCH_3$), whereupon *(3)* and *(4)* are formed in approximately equal amounts in a total yield of about 67%. To 18.2 g of this mixture and 10 g of *(1)* (0.1 mole) is added 20 g of a 30% sodamide suspension in benzene (0.15 mole of $NaNH_2$). Compound *(5)*, m.p. 53 °C, is formed in 85% yield; this is boiled with an equimolar amount of triphenylmethyl tetrafluoroborate in glacial acetic acid, then treated with ether, whereupon the salt *(6)* crystallizes in 75% yield. It is recrystallized from ethylene dichloride/ether. M.p. 216 °C. NMR: $\delta = -7.82$ ppm (2 H), $\delta = -1.46$ ppm (9 H), $\delta = -1.53$ ppm (18 H).

Independently of us, *W. Rundel* (Tübingen) has prepared 2,4,6-tri-*tert*-butylpyrylium perchlorate by a different route[4].

Stable Cyclic Carboxonium Salts

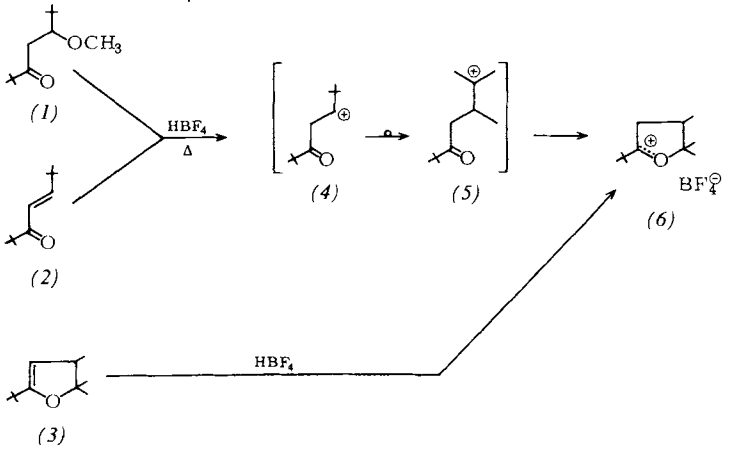
By *K. Dimroth* and *W. Mach*[*]

Whereas carbonium salts having two ethereal oxygen atoms in the α-position are known to exist as stable carboxonium salts[1], the corresponding cyclic carboxonium salts with only one ethereal oxygen in the α-position have hitherto only been detected kinetically or by NMR measurements at low temperature[2].

We have now succeeded in isolating the carboxonium salt *(6)*, whose stability can be ascribed to the formation of a heterocyclic five-membered ring. There are three ways in which this salt can be synthesized: a) by cleavage of methoxide from 5-methoxy-2,2,6,6-tetramethyl-3-heptanone *(1)*[3]; b) by addition of a proton to 2,2,6,6-tetramethyl-3-hepten-5-one *(2)*[3]; and c) by addition of a proton to 2-*tert*-butyl-4,5,5-trimethyl-4,5-dihydrofuran *(3)*.

In methods a) and b) the formation of *(6)* takes place on boiling the reactants with a 50% solution of water-free HBF_4 in 1,2-dichloroethane; the carbonium ion *(4)* is probably formed first, and migration of a methyl group leads to the formation of *(5)* and subsequently to *(6)*. Compound *(6)* can be isolated by precipitation with ether (yield 75%).

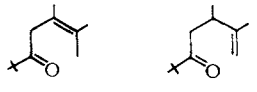
In method c) the cyclic carboxonium salt *(6)* is formed immediately, in quantitative yield, on addition of ethereal HBF_4 in the cold.



(1) *(2)* *(3)* *(4)* *(5)* *(6)*

The new carboxonium salt *(6)* melts, with decomposition at 190 °C (sealed tube). It is non-hygroscopic; however, on standing for a few days it changes color. Repurification can be achieved by recrystallization from 1,2-dichloroethane with ether. Its constitution is established by elemental analysis and from its NMR data (in liquid SO_2 at −30 °C): multiplet (AB part of an ABX spectrum) at $\delta = -3.27$ ppm (2H); multiplet at $\delta = -2.25$ ppm (1H); singlets at $\delta = -1.32$ ppm (3H), $\delta = -1.08$ ppm (3H), $\delta = -0.90$ ppm (9H); doublet at $\delta = -0.62$ ppm [$J = 7$ Hz, (3H)].

If potassium *tert*-butoxide or sodium methoxide is added to a solution of *(6)* in *tert*-butanol at room temperature, compound *(3)* is formed almost exclusively; on warming, a mixture of *(3)*, *(7)*, and *(8)* is formed that can be resolved into its components by gas chromatography (ratio *(3)*:*(7)*:*(8)* = 9:2:3).



(7) *(8)*

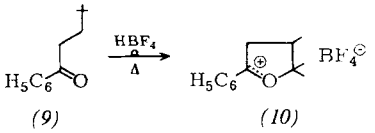
The constitution of each of these compounds is established by CH analysis, by mass spectrometry, and from the following NMR spectroscopic data:

(3): Doublet at $\delta = -4.27$ ppm [$J_1 = 3$ Hz, (1H)]; octet at $\delta = -2.54$ ppm [$J_1 = 3$ Hz, $J_2 = 7$ Hz, (1H)]; singlets at $\delta = -1.24$ ppm (3H), $\delta = -1.03$ ppm (9H), $\delta = -1.15$ ppm (3H); doublet at $\delta = -0.88$ ppm [$J_2 = 7$ Hz, (3H)].

(7): Singlets at $\delta = -3.15$ ppm (2H), $\delta = -1.68$ ppm (3H), $\delta = -1.56$ ppm (6H), $\delta = -1.13$ ppm (9H).

(8): Multiplets at $\delta = -4.65$ ppm (2H), $\delta = -2.46$ ppm (3H), $\delta = -1.70$ ppm (3H); singlet at $\delta = -1.10$ ppm (9H); doublet at $\delta = -0.95$ ppm [$J = 7$ Hz, (3H)].

The ketone *(9)* [4] can be converted into the phenyl-substituted tetrafluoroborate *(10)* if subjected to the same treatment as that described for methods a) and b). The yellow crystals of *(10)*, which melt at 123 °C, are stable at room temperature. Dissolution in methylene chloride, trifluoroacetic acid, or SO_2 leads to an intensive blue fluorescence.



(9) *(10)*

The constitution of *(10)* is confirmed by elemental analysis and by its NMR spectrum. NMR (in trifluoroacetic acid): Multiplet at $\delta = -8.1$ to -7.15 ppm (5H); multiplet (AB part of an ABX spectrum) at $\delta = -3.75$ ppm (2H); multiplet at $\delta = -2.50$ ppm (1H); singlet at $\delta = -1.52$ ppm (3H); singlet at $\delta = -1.29$ ppm (3H); doublet at $\delta = -0.90$ ppm [$J = 7$ Hz, (3H)]. UV spectrum (in methanol): $\lambda_{max} = 390$ nm; $\varepsilon = 735$.

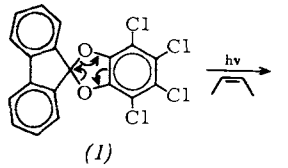
New Precursors for Arylcarbenes[1]

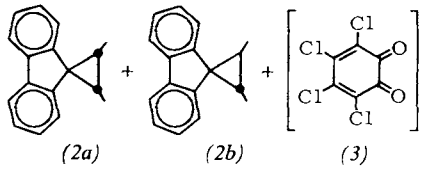
By *R. M. G. Nair*[*], *E. Meyer*[**], and *G. W. Griffin*[*]

We have found that photolysis [2] (24 h) of 4,5,6,7-tetrachlorospiro-[1,3-benzodioxole-2,9′-fluorene] *(1)* (10^{-3} mole)[3] in *cis*-2-butene (75 ml) leads to a mixture of *cis*- and *trans*-2,3-dimethylspiro[cyclopropane-1,9′-fluorene] *(2a)* and *(2b)*, respectively, in 23 % yield[4]. The formation of 3,4,5,6-tetrachloro-*o*-benzoquinone *(3)* was confirmed in rigid matrices by detection of typical oxidation processes by this compound. It was not isolated in *cis*-2-butene because of formation of adducts.

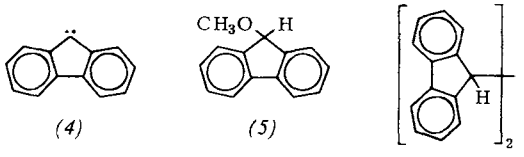
We propose that photolysis of *(1)* affords fluorenylidene *(4)*. Since *(2a)* and *(2b)* are interconverted when subjected to UV irradiation[4,5], no significance may be attached to the apparent nonspecificity of addition of *(4)* to *cis*-2-butene, which was used because of the lower solubility of *(1)* in the *trans*-isomer.



(1)



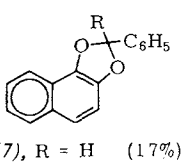
(2a) *(2b)* *(3)*



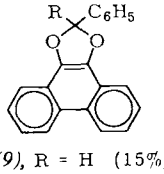
(4) *(5)* *(6)*

Our recent work with oxiranes leaves no doubt that carbenes are implicated in the photofragmentation of epoxides[5] and lends credence to our contention that fluorenylidene is the chemically significant species involved in the conversion of *(1)* to *(2a)* and *(2b)*. Corroborative evidence is provided by the photolysis (24 h) of *(1)* (10^{-3} mole) in methanol (90 ml), which yields fluorenyl methyl ether *(5)* in 30 % yield. *Kirmse* and *Horner*[6] have previously used alcohols to intercept arylcarbenes. 9-Diazofluorene, the accepted fluorenylidene precursor, also gives *(5)* under similar conditions. *(1)*, like diazofluorene[6], also gives 9,9′-bifluorenyl *(6)* in high yield (38 %) upon photolysis in cyclohexane (90 ml, 10^{-3} mole, 48 h).

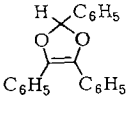
The following compounds also fragment to arylcarbenes which have been trapped with methanol (yields of methyl ethers in parentheses):



(7), R = H (17%)
(8), R = C_6H_5 (11%)



(9), R = H (15%)
(10), R = C_6H_5 (5%)



(11), (16%)

All products were separated by gas and elution chromatography and identified by comparison with authentic samples [7].

[1] We gratefully acknowledge financial support from the Petroleum Research Fund of the American Chemical Society.

[2] The solutions were carefully degassed and irradiated in a sealed quartz vessel at 40–70 °C. The radiation source was an air-cooled Rayonet RPR-100 Chamber Reactor (from The Southern New England Ultraviolet Co., Middletown, Conn. U.S.A.) containing sixteen 8-watt low-pressure mercury lamps, or the larger preparative RPR-208 model. The yields reported are based on reactions performed in the latter unit.

[3] This compound (m.p. 281 °C) was obtained in 81 % yield by addition of diazofluorene to 3,4,5,6-tetrachloro-*o*-benzoquinone in ether under a nitrogen atmosphere. The solution was then heated under reflux until nitrogen evolution ceased whereupon the solvent was removed and the residue recrystallized from ethanol/acetonitrile.

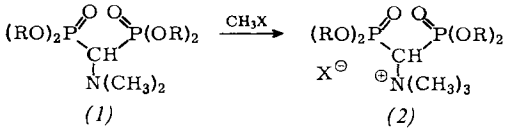
Bis(diethoxyphosphinyl)(trimethylammonio)-methylide, a Stable *N*-Ylide

By *H. Gross* and *B. Costisella* [*]

[Bis(diethoxyphosphinyl)methyl]dimethylamine *(1)* [1], which is readily accessible from formamide dimethyl acetal and diethyl phosphite is smoothly converted by reaction with dimethyl sulfate or methyl iodide in dioxane at room temperature into the quarternary salts *(2a)* and *(2b)*, respectively, which are obtained pure when washed several times



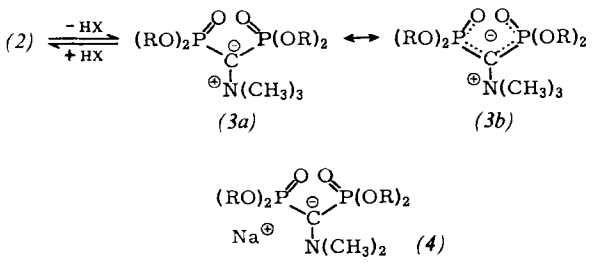
(1) *(2)*

R = C_2H_5

(a), $X^{\ominus}$ = $CH_3OSO_3^{\ominus}$
(b), $X^{\ominus}$ = $I^{\ominus}$
(c), $X^{\ominus}$ = $ClO_4^{\ominus}$

with ether [*(2a)*: yield 76 %, m.p. 105–106 °C; *(2b)*: yield 85 %, m.p. 116–118 °C, NMR spectrum $\tau_{CH_3-CH_2-}$ = 8.58 triplet (J = 7 Hz), 5.65 multiplet (J = 8 Hz, $\tau_{-N(CH_3)_3}$ = 6.10 singlet, $\tau_{>CH-}$ = 4.12 triplet (J = 20 Hz)]. When treated with silver perchlorate in an aqueous medium, *(2a)* gave the perchlorate *(2c)*, m.p. 134–135 °C, in 90 % yield.

The phosphonate proton of *(2)*, like that of *(1)* [1], is very strongly acidic. If *(2a)* is stirred for *ca.* 30 min with saturated aqueous potassium carbonate solution and then shaken with benzene, subsequent separation of the organic phase leads, after drying and evaporation in a vacuum, to a colorless crystalline compound of m.p. 38–40 °C, which according to its elemental analysis and spectral properties has the structure of an *N*-ylide *(3)*, namely, bis(diethoxyphosphinyl)(trimethylammonio)methylide. ^{1}H–NMR spectrum: $\tau_{CH_3-CH_2-}$ = 8.74 triplet (J = 7 Hz), 6.07 multiplet (J = 4 Hz), $\tau_{-N(CH_3)_3}$ = 6.47 singlet. The signal of the phosphonate proton that



(3a) *(3b)*

(4)

appeared as a triplet at τ = 6.80 or 4.12, respectively, for *(1)* [1] and *(2)* is not present in the spectrum of *(2c)*. The ^{31}P–NMR spectra [2] of the compounds *(1)–(3)* and of *(4)* [Na salt of *(1)*] [3] contain the following signals: *(1)* −18 ppm, *(2)* −11 ppm, *(3)* −28 ppm, *(4)* −33 ppm; the appreciably more negative shift of *(3)* compared with that of *(2)* indicates delocalization of the free electron pair of the carbanion as shown in *(3b)*; this presumably accounts for the stability of the ylide [4]. The same delocalization is shown on comparison of the chemical shifts of *(1)* and *(4)*.

The ylide *(3)* is readily soluble in water from which it can be recovered unchanged by evaporation or extraction. Addition of perchloric acid to a solution of *(3)* in dioxane followed by addition of ether leads to regeneration of the perchlorate *(2c)*.

[3] Compound *(4)* is obtained from *(1)* and NaH in dioxane.

[4] An analogous effect was assumed to explain the stability of the dicyano(trimethylammonio)methylide described by *Z. Arnold*, Chem. and Ind. *1960*, 1470; Coll. czech. chem. Commun. *26*, 1113 (1961).

Synthesis of Both Hexobarbital Enantiomers and of (+)-Thiohexobarbital from (+)-Methyl 2-Cyano-2-(1-cyclohexenyl)propionate [1]

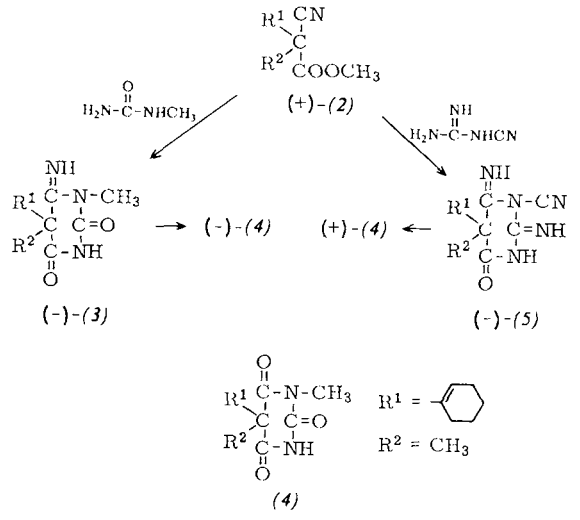
By *J. Knabe* and *D. Strauss* [*]

Since the enantiomers of hexobarbital [2] have different pharmacological properties [3] and resolution of the racemate is difficult on a large scale [2], we sought an alternative route for their synthesis.

We have found that the two hexobarbital enantiomers can be prepared in good yields from (+)-methyl 2-cyano-2-(1-cyclohexenyl)propionate [(+)-*(2)*]: (−)-hexobarbital [(−)-*(4)*] is obtained *via* (−)-iminohexobarbital [(−)-*(3)*] by condensing (+)-*(2)* with *N*-methylurea and (+)-hexobarbital [(+)-*(4)*] is obtained by condensing (+)-*(2)* with dicyanodiamide; in the last-mentioned reaction (−)-cyanodiiminobarbital [(−)-*(5)*], which is first formed, gives [(+)-*(4)*] on methylation with dimethyl sulfate and subsequent hydrolysis.

The formation of optically active hexobarbital from (+)-*(2)* and *N*-methylurea in about the same optical purity as is obtained by resolution of the racemate [2] confirms previous findings [4] that condensation of disubstituted cyanoacetic esters with *N*-methylurea is stereoselective [5]. We have found this also to be the case with *N*-methylthiourea, since we obtained (+)-thiohexobarbital from (−)-2-cyano-2-(1-cyclohexenyl)propionic acid [(−)-*(1)*] and *N*-methylthiourea.

The (+)-form of *(2)* is easily obtained from racemic *(1)* by resolution and subsequent esterification [6].



Experimental:

Synthesis of (−)-*(4)*: 5.7 g of (+)-*(1)*, $[\alpha]_D$ +32.76°, which was obtained from racemic *(1)* by way of the diastereoisomeric quinine salts, was esterified with diazomethane and the resulting ester was distilled. Yield 4.8 g of (+)-*(2)*, $[\alpha]_D$ = +45.27°, b.p. 114°C/2.3 torr. Condensation with *N*-methylurea in methanolic $NaOCH_3$ gave 3.0 g of (−)-*(3)*, which after recrystallization from ethanol had $[\alpha]_D$ = −12.29°, m.p. 160–161°C. (−)-*(3)* was hydrolyzed quantitatively by 25% H_2SO_4 to (−)-*(4)*, $[\alpha]_D$ = −11.64°, m.p. 153°C.

Synthesis of (+)-*(4)*: 3.5 g of (+)-*(1)*, $[\alpha]_D$ = +29°, was esterified with diazomethane to yield (+)-*(2)* which was condensed with dicyanodiamide in methanolic $NaOCH_3$ to give (−)-*(5)*, $[\alpha]_D$ = −58.67°, m.p. 252–254°C (decomp.) (yield 4 g). Methylation of 3.25 g of (−)-*(5)* with dimethyl sulfate and subsequent hydrolysis gave 2 g of (+)-*(4)*, $[\alpha]_D$ = +10.64°, m.p. 151–153°C.

Synthesis of (+)-Thiohexobarbital: 3.7 g of (−)-*(1)*, $[\alpha]_D$ = −31.44°, was esterified with diazomethane to give (−)-*(2)* and this was condensed with *N*-methylthiourea in ethanolic $NaOC_2H_5$, and the product was hydrolyzed with 10% H_2SO_4, yielding (+)-thiohexobarbital (0.9 g), m.p. 144 to 145°C (from ethanol), $[\alpha]_D$ = +38.28°.

Values of $[\alpha]$ refer to solutions in anhydrous ethanol at 20°C.

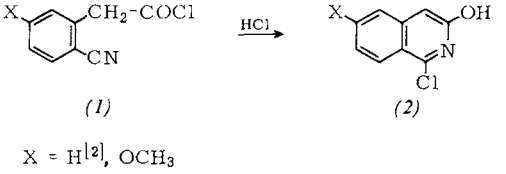
Synthesis of Derivatives of Isoquinoline, of 1,3-Benzoselenazin-4-one, and of 1*H*-2-Benzazepin-1-one

By *G. Simchen*[*]

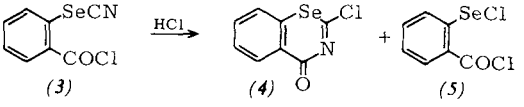
In continuation of our work on cyclizing acylation of imidoyl halides[1] we obtained nearly quantitative yields of 1-chloroisoquinolin-3-ols *(2)* from *o*-cyanophenylacetyl chlorides *(1)* and hydrogen chloride. UV spectroscopic studies show these products to exist in the lactim form independently of the solvent.



(1) *(2)*

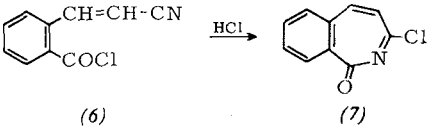
X = H[2], OCH_3

Although hydrogen halide adducts of selenocyanates are extremely unstable, we have succeeded in cyclizing *o*-selenocyanatobenzoyl chloride *(3)*[3] by hydrogen chloride at 60°C to 2-chloro-1,3-benzoselenazin-4-one *(4)*; *o*-(chloroformyl)-benzeneselenyl chloride *(5)*[5] is formed in a side reaction.



(3) *(4)* *(5)*

In analogous syntheses we obtained larger ring systems, namely, 3-chloro-1*H*-2-benzazepin-1-one *(7)* on treating 2-(chloroformyl)-*cis*-cinnamonitrile *(6)*[4] with hydrogen chloride. Further study is under way to show how far this ring system can be considered an azologous 2,3-benzotropone.



(6) *(7)*

1-Chloroisoquinolin-3-ols (2): 0.01 mole of (*o*-cyanophenyl)- or (2-cyano-5-methoxyphenyl)-acetyl chloride *(1)* [from the corresponding (*o*-cyanophenyl)acetic acid and PCl_5 in ether] is dissolved in 30–40 ml of di-*n*-butyl ether, HCl is passed in to saturation, and the mixture is warmed to 60°C for 4 h. Pure *(2)*, which precipitates on cooling, is filtered off, washed with benzene, and recrystallized from ethanol. X = H: yield 97%, m.p. 205°C[2]. X = OCH_3: yield 92%, m.p. 211°C.

2-Chloro-1,3-benzoselenazin-4-one (4): 2.2 g (0.009 mole) of *o*-selenocyanatobenzoyl chloride *(3)* [from *o*-selenocyanatobenzoic acid[5] and PCl_5 in ether at 0°C] was dissolved in 60 ml of dioxane pre-saturated with HCl and the mixture warmed at 60°C for 5 h. The dioxane was then distilled off in a vacuum, and the residue treated with hexane [to remove *(5)*] and subsequently sublimed at 80°C/10^{-2} torr. Yield 1.3 g (59%) of *(4)*, m.p. 125–126°C. The hexane solution was evaporated to dryness in a vacuum and the residue sublimed at 40°C/10^{-2} torr. Yield 0.6 g (26%) of *(5)*, m.p. 65–66°C.

3-Chloro-1H-2-benzazepin-1-one (7): 5.8 g (0.03 mole) of 2-(chloroformyl)-*cis*-cinnamonitrile *(6)*[4] (from 2-nitroso-1-naphthol and PCl_5 in hexane in 73% yield) was dissolved in 30 ml of dioxane. HCl was passed in at 70°C for 5 h. After removal of the dioxane in a vacuum the residue was treated with ether and then sublimed at 80–85°C/10^{-2} torr. Yield 2.6 g (45%) of *(7)*, m.p. 117°C.

Simplified Process for Preparation of Anhydrides of Aromatic Acids

By *P. Rambacher* and *S. Mäke* [*]

Anhydrides of aromatic carboxylic acids are prepared by reaction of an acid chloride with the sodium salt of the same or another acid [1], or by treating the acid chloride with pyridine and decomposing the reaction mixture with water [2]. The procedure becomes appreciably simpler if the acid chloride is allowed to react with a solution of sodium hydrogen carbonate to which a small amount of a weak tertiary base such as pyridine has been added. Use of a water-insoluble base or alkali hydroxide in place of the hydrogen carbonate leads to considerably lower yields [3]. The reaction is also suitable for preparation of large amounts of anhydride in very good yield and high purity.

o-Ethoxybenzoic anhydride: 16.8 g (0.2 mole) of sodium hydrogen carbonate is dissolved in 300 ml of water. 4 ml of pyridine is added, then 36.9 g (0.2 mole) of *o*-ethoxybenzoyl chloride is added dropwise during 30 min. The temperature is kept at 20 °C by cooling. 29.1 g (92.7%) of the anhydride (m.p. 74–75 °C) is isolated after 1 hour's stirring. Recrystallization from benzene/ethanol gives rod-shaped crystals of m.p. 77.5 °C.

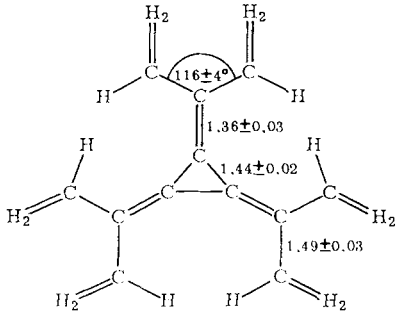
Crystal Structure of Triisopropylidenecyclopropane

By *H. Dietrich* and *H. Dierks* [*]

Triisopropylidenecyclopropane (prepared by *Köbrich et al.* [1]) crystallizes in the space group $P\,6_1$ (C_6^2) with $a = 9.39$ Å, $c = 21.36$ Å, $V = 1631$ Å^3, $n = 6$, and X-ray density 0.9912 g cm^{-3}. The space group and unit cell were determined previously by *Dunitz* and *Mugnoli* [2] who, however, found different cell dimensions and a much greater density.

We used three-dimensional X-ray diffraction data (filtered Cu–K_α radiation, multifilm technique), the intensities of reflections being estimated visually with the aid of comparison scales.

The molecules are arranged in flat sheets perpendicular to the *c*-axis, as concluded previously by *Dunitz* and *Mugnoli* from the high intensity of the (001) reflections. In crystals obtained by recrystallization from ethanol these layers are apparently stacked irregularly, as can be recognized in the diffraction diagrams from extension of the reflections along the length *c**. This disorder could be removed, as suggested by *Köbrich*, by tempering the crystals for 24 h at 120 °C.



The Figure shows the bond lengths and bond angles at the present stage of refinement ($R = 0.16$). The figures given are the mean values of chemically equivalent bonds and angles and their double standard error ($\pm 2\sigma$), calculated from the scatter of the individual values. The bonds in the cyclopropane ring are remarkably short, a fact which is probably due to the interaction between the three neighboring double bonds.

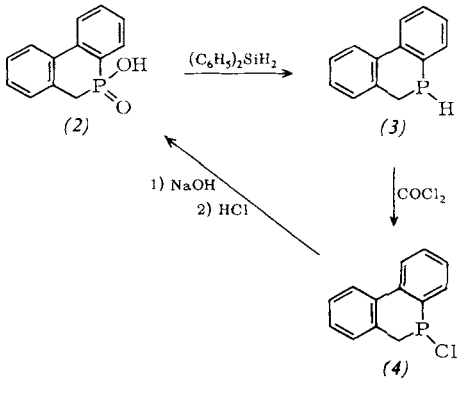
Dibenzo[*b,d*]phosphorin

By *P. de Koe*, *R. van Veen*, and *F. Bickelhaupt* [*]

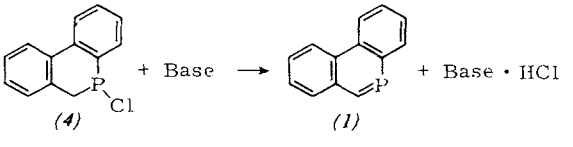
As part of our studies of aromatic compounds containing tervalent pπ-hybridized phosphorus as heteroatom we prepared the linearly annelated dibenzo[*b,e*]phosphorin [1]; we now report the preparation of dibenzo[*b,d*]phosphorin (= 9-phosphaphenanthrene) *(1)* in solution.

As starting material we used 5,6-dihydro-5-hydroxydibenzo[*b,d*]phosphorin-5-one *(2)* [2], which was reduced to 5,6-dihydrodibenzo[*b,d*]phosphorin *(3)* [4], b.p. 132 °C/0.01 torr, in 92% yield by diphenylsilane [3]. 20.15 g of *(3)* in 350 ml of methylene chloride was stirred under nitrogen with 7.3 ml of phosgene for 1/2 h at −30 °C and then for 1/2 h at room temperature [5]. The residue obtained on evaporation under vacuum gave, on molecular distillation (bath temperature 160 °C, 0.001 torr), 5-chloro-5,6-dihydrodibenzo[*b,d*]phosphorin *(4)* [4], m.p. 58–62 °C, as main fraction in a yield of 35%.



Removal of HCl was achieved by treating 490.6 mg of the product *(4)* in 90 ml of anhydrous, degassed ether at −196 °C with 394.6 mg of 1,5-diazabicyclo[5.4.0]undec-5-ene *(5)* [6] (23% excess) and, after the vessel had been sealed in a vacuum, warming the mixture to room temperature. A yellow precipitate was formed [after 3 h, 368.5 mg, of which 291.9 mg was hydrochloride of *(5)* (= 73% yield)]; for determination of the UV spectrum the colorless solution was filtered from the precipitate into a glass-to-glass sealed 0.1 cm cuvette.

The spectrum obtained (Fig. 1), which we ascribe to compound *(1)*, reached maximum intensity after 3 hours (extinction $E = 0.45$ at $\lambda = 372$ nm). When compared with the



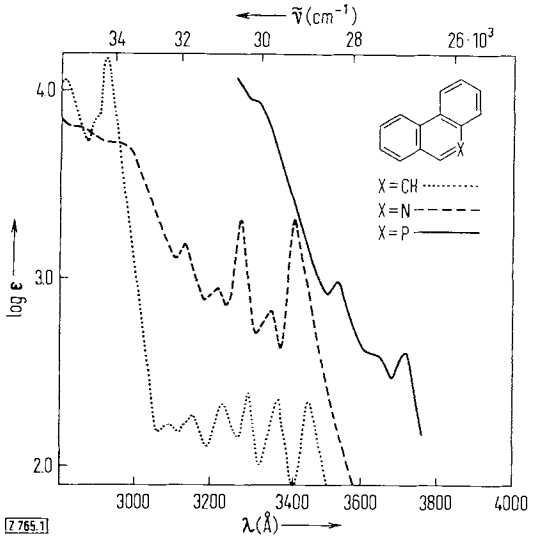


Fig. 1. UV spectra of phenanthrene (in cyclohexane), phenanthridine (in cyclohexane), and *(1)* (in ether). (The height of the curve for *(1)* is arbitrary.)

spectra of phenanthrene and phenanthridine it shows the known bathochromic shift ($\Delta\tilde{\nu}$ = 1950 cm^{-1} or 2350 cm^{-1}, resp.), which is less than for other heterocyclic aromatic phosphorus compounds[1,7]. In contrast to results in the anthracene series[1] the shape of the spectrum of *(1)* resembles that of the nitrogen analog more than that of the carbon analog. Dibenzo[*b,d*]phosphorin *(1)* could not so far be isolated in pure form. Its stability appears comparable with that of dibenzo[*b,e*]phosphorin: the intensity of the UV absorption of an ethereal solution of *(1)* decreases to about a half of its original value in three days and decreases irreversibly on cooling to −196 °C. *(1)* is unstable towards air.

In the mass spectrum of *(4)* the singly and doubly charged ions of *(1)* are prominent: *m/e* = 232, 28%, *(4)*$^+$; *m/e* = 196, 100%, *(1)*$^+$; *m/e* = 165, 37%, fluorenyl$^+$; *m/e* = 152, 7.5%, biphenylene$^+$; *m/e* = 98, 8.2%, *(1)*$^{2+}$[8].

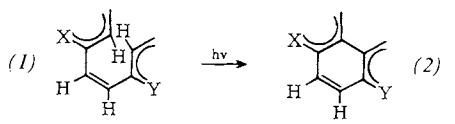
Photochemical Cyclodehydrogenations in the Indole Series[1]

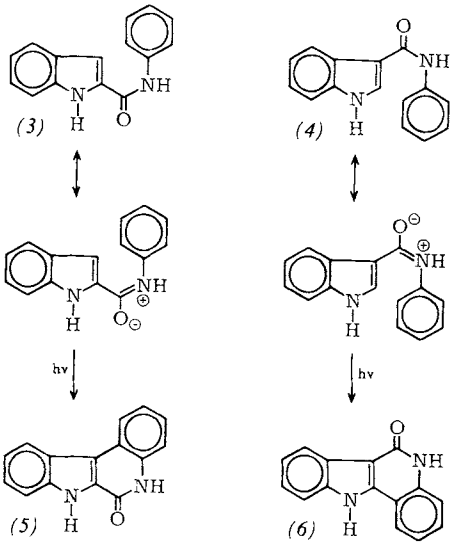
By *E. Winterfeldt* and *H. J. Altmann*[*]

Photocyclization of stilbene derivatives *(1)* affords highly condensed aromatic compounds *(2)* in a simple manner[2]. The benzene ring may be replaced by heterocycles[3].



As the amide group has a certain amount of double bond character (hindrance of rotation), this group can also be used to link the aromatic rings, as was demonstrated by means of benzanilide[4].

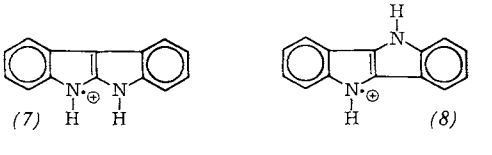
We have now irradiated the anilides *(3)* and *(4)* of α- and β-indolecarboxylic acid and have obtained the cyclization products *(5)* and *(6)* as the main products of a smooth reaction; they are readily recognized by means of their UV spectra. Further, absence of the signal of the α- or β-indole proton in the NMR spectrum proves completion of the cyclization.



(5): melts from 280 °C with sublimation	*(6)*: melts from 280 °C with sublimation
UV: λ_{max} (ε) 245 (36200), 268.5 (14900), 292 (4270), 305 (6400), 320 (5620), 333 (10200) 349 nm (11500).	UV: λ_{max} (ε) 222 (47500), 246 (49000), 293 (6590), 306 (7300), 322 (13900), 337 nm (19000).
IR: 1530, 1565, 1585, 1610, 1650 cm^{-1}.	IR: 1550, 1580, 1610, 1635 cm^{-1}.
NMR: τ = −2.4 (1), −1.9 (1), 1.5 (2), 2.5 (6).	NMR: τ = −2.6 (1), −1.5 (1), 1.75 (2), 2.5 (6).
MS: 234 *m/e* (100%) → 216 *m/e* (8%) M$^+$ 199.4 234 *m/e* (100%) → 205 *m/e* (19%) M$^+$ 180.5 117 *m/e* (8%) 103 *m/e* (12%)	MS: 234 *m/e* (100%) → 205 *m/e* (12%) M$^+$ 180 117 *m/e* (11%) → 103 *m/e* (15%) M$^+$ 90.5 102.5 *m/e* = 205/2 68.33 *m/e* = 205/3

The two products have been prepared previously by a more difficult route[4,5]; however, compound *(6)* could not be isolated in pure form. These compounds are conveniently accessible by the cyclodehydrogenation.

For both substances the molecular ion is the base peak in the mass spectrum, and conversion of this ion into the fragment *(7)* or *(8)* with loss of CO − proved by a metastable peak at 180 − is characteristic.



Experimental:

A solution of the anilide (100 mg) in dioxane (10 ml) and acetone (1 ml) is irradiated in a quartz vessel with a 500-watt medium-pressure mercury-quartz lamp for 60 hours. The cyclized products are eluted with methylene chloride acetone (1:1 v/v). Yield 15%.

Separation and Properties of the *cis-trans*-Isomers of *N*-Alkylthioformamides

By *W. Walter, E. Schaumann*, and *K.-J. Reubke*[*]

Since the thioamide system is planar by mesomerism, two isomers *(a)* and *(b)* may occur when $R^1 \pm R^2$.

(a) *(b)*

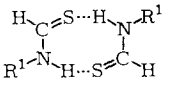
(1), R = R^2 = H, R^1 = $CH(CH_3)_2$
(2), R = R^2 = H, R^1 = CH_2-$CH(CH_3)_2$
(3), R = R^2 = H, R^1 = CH_2-C_6H_5

The rational isomers have proved separable so far only for *N,N*-dialkyl compounds[1] in the thioamide series and, among the secondary amides, for 2,4,6-tri-*tert*-butylacetanilide, in which rotation is sterically strongly hindered[2]. For *N*-alkylthioformamides (R = R^2 = H) there exist only ^{1}H–NMR investigations of the equilibrium position (pure liquid or solution in $CHCl_3$), but these show that, except for *N*-*tert*-butylthioformamide, the sterically unfavorable *trans*- or *Z* form[**] predominates over the *cis*- or *E* form[**][3,4].

By preparative thin-layer chromatography on silica gel (Merck PF 254) at –15 °C with acetic ester:hexane:diethylamine (4:10:1 v/v), applied five times successively, we have succeeded in isolating the forms *(a)* and *(b)* of the thioamides *(1)*, *(2)*, and *(3)*. After separation from the silica gel, the isomers of *(1)* and *(2)* were obtained as brownish liquids and those of *(3)* were obtained as brownish solids, each of these containing not more than 10% of the other isomer. Identification was effected by the ^{1}H–NMR spectrum[3] and by IR spectroscopy for the NH stretching modes (2×10^{-3} M solution CCl_4). The isomers had little stability at room temperature; the half-time for establishment of equilibrium at –15 °C is about four weeks. Thus the success of the separation is due less to a high activation energy than to a distinct difference in polarity of the isomers.

The IR spectra of *(a)* and *(b)* differ appreciably [film, *(3)* in KBr]. Noteworthy are the high intensities of the thioamide *B*-bands and their shift to higher wave numbers in the *E*-isomers *(a)* in comparison with the *Z*-isomers *(b)*: for *(a)* 1555 to 1565 cm^{-1} were found, and for *(b)* 1520 to 1530 cm^{-1}.

The changes in the IR spectrum of the *E*-isomers above 3000 cm^{-1} in comparison with the *Z*-forms and the equilibrium mixtures, and in particular the appearance of a new band at 3070 cm^{-1}, are ascribed by us to occurrence of cyclic dimers of type *(4)*.



(4)

In the UV spectrum the absorption maximum of the $\pi \rightarrow \pi^*$ transition is observed at longer wavelength for the *E*-isomer *(a)* than for the *Z*-isomer *(b)* (276 compared with 266 nm, in $CHCl_3$).

The isomers differ also in the rate of complex formation with cupric acetate; this should be possible only with the *E*-form *(a)*. In fact, 50% reaction (room temperature, $CHCl_3$) of *(a)* requires only a few minutes, but of *(b)* requires about 2 hours because of the need for conversion into the other form – the reactions can be followed by disappearance of the $\pi \rightarrow \pi^*$ bands.

The predominance of *Z*-isomers *(b)* in the equilibrium mixture can be understood on the basis of the dipoles: for form *Z (b)* there is considerable compensation *(6)*, but for form *E (a)* there is addition *(5)*, whereby *(a)* becomes electrostatically disfavored.

(5) *(6)*

Very marked electron delocalization within the thioamide system occurs in order to offset this disadvantage of the *E*-form *(a)*, and this may explain the short-wave shift of the thioamide *B*-bands (larger C–N double-bond character) and the bathochromic shift of the $\pi \rightarrow \pi^*$ transition.

Acid-catalyzed Rearrangements of Hexamethylprismane and Hexamethyl-Dewar-benzene

By *R. Criegee* and *H. Grüner*[*]

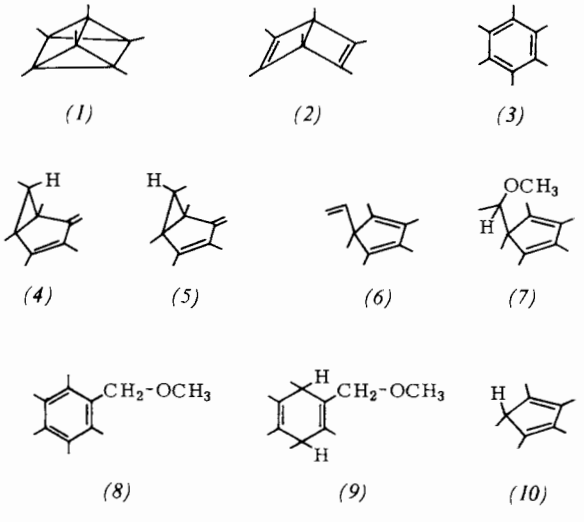
On thermal and metal-catalyzed decomposition, hexamethylprismane *(1)* gives variable amounts of hexamethyl-Dewarbenzene *(2)* and hexamethylbenzene *(3)*[1–3]. On the other hand, after reaction of *(1)* with 2% of *p*-toluenesulfonic acid (TsOH) in CCl_4 at 35–40 °C for 69 h the NMR spectrum shows that the sole product besides 10–20% of *(3)* is the 1,2,3,5,6-pentamethyl-4-methylenebicyclo[3.1.0]hex-2-ene *(4)* that was previously obtained by *Schäfer* and *Hellmann*[4] by another route. Product *(4)* was, however, isolated in only 37% yield because of its ready polymerization. The position of the methyl doublet (τ = 9.08) and of the quartet for the

single proton ($\tau = 9.40$) indicate the *exo*-position for the methyl group on the three-membered ring.

When *(4)* is warmed at 105 °C for 2 h with 2% of TsOH in benzene an equilibrium mixture – attainable from both sides – is formed containing approximately equal amounts of *(4)* and its *endo*-methyl isomer *(5)*, which was also obtained by *Schäfer* using a different method[5]. In the NMR spectrum of *(5)* the signals for the methyl group on the three-membered ring and for the single proton are at $\tau = 9.34$ and 9.25, respectively.

In the presence of 2% of TsOH in *o*-dichlorobenzene at 110 °C the compounds *(4)* and *(5)* rearrange almost quantitatively to 1,2,3,4,5-pentamethyl-5-vinylcyclopentadiene *(6)*[4], whose constitution follows from, *inter alia*, the UV spectrum (in hexane, $\lambda_{max} = 242$ nm, $\log \varepsilon = 3.82$) and the NMR spectrum [CCl_4; quart. methyl $\tau = 9.00$ (singlet), methyl on the double bonds $\tau = 8.33$ (singlet) and 8.23 (singlet), and vinyl protons recognizable only after addition of benzene as a multiplet at $\tau = 4.93$]. Compound *(6)* gives an adduct with maleic anhydride and when boiled with 1% methanolic sulfuric acid is partly converted into the ether *(7)*.

When compound *(2)* is boiled for 40 h with 0.03% sulfuric acid in methanol there is formed, as well as 13% of *(3)*, a mixture (separable by gas-chromatography or by distillation through a rotating-band column) containing 55% of 5-(1-methoxyethyl)-1,2,3,4,5-pentamethylcyclopentadiene *(7)*, 24% of 5-(methoxymethyl)-1,2,3,4,6-pentamethyl-1,4-cyclohexadiene *(9)*, and 4% of 1,2,3,4,5-pentamethylcyclopentadiene *(10)*. In hexane the ether *(7)* has $\lambda_{max} = 260$ nm ($\log \varepsilon = 3.58$) and in the NMR spectrum (CCl_4) gives signals at $\tau = 9.45$ (doublet, $J = 6$ Hz), 9.02 (singlet), 8.33 (multiplet), 6.93 (quartet, $J = 6$ Hz), and 6.73 (singlet) in the ratio 3:3:12:1:3 [6].



(1) *(2)* *(3)* *(4)* *(5)* *(6)* *(7)* *(8)* *(9)* *(10)*

With maleic anhydride compound *(2)* gives an adduct of m.p. 159–161 °C. The constitution of the isomeric ether *(9)* follows from absence of a UV maximum and from the NMR spectrum (CCl_4) which contains two doublets at $\tau = 9.02$ and 8.92 ($J = 7$ Hz) and the multiplet corresponding to the single proton at $\tau = 7.66$, also singlets for the methyl groups on the double bonds at $\tau = 8.38$ and 8.32, for the methoxy group at $\tau = 6.83$, and for the methylene group at $\tau = 6.15$ ppm with the expected intensity ratios. When heated for 27 h in a sealed ampoule at 270 °C compound *(9)* loses water and gives (methoxymethyl)pentamethylbenzene *(8)* of m.p. 63–65 °C, identical with a product synthesized from (chloromethyl)-pentamethylbenzene[7]. On catalytic hydrogenation it is converted into *(8)* and *(9)*.

Pentamethylcyclopentadiene *(10)*[8] [b.p. 39–40 °C/5 torr; λ_{max} (hexane) = 266, 250, 230 nm ($\log \varepsilon = 3.43$, 3.42, 3.37); NMR (CCl_4) $\tau = 9.04$ (doublet, $J = 7.5$ Hz), 8.25 (multiplet and 7.72 (multiplet) in proportions 3:12:1] gives a maleic anhydride adduct of m.p. 131–134 °C and is to be regarded as a fragmentation product of *(7)*, from which it is formed on 120-hours' heating with 0.1% methanolic sulfuric acid.

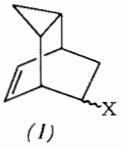
Valence Isomerizations of C_9H_{10} Hydrocarbons[1]

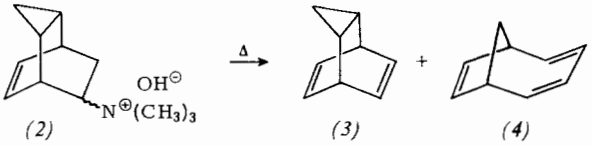
By *J. Daub* and *P. v. R. Schleyer*[*]

Quickening interest in the preparation, the interconversions, and other special properties of C_9H_{10} hydrocarbons and related systems[2–9] reflects the fascinating potential of these molecules. An hitherto unreported member of the C_9H_{10} family, tricyclo[3.2.2.0^{2,4}]nona-6,8-diene *(3)*, is the focus of attention of this communication.



(1)

(a), X = CN *(d)*, X = $NHCOOCH_3$
(b), X = COOH *(e)*, X = $NHCH_3$
(c), X = NCO *(f)*, X = $N^{\oplus}(CH_3)_3I^{\ominus}$

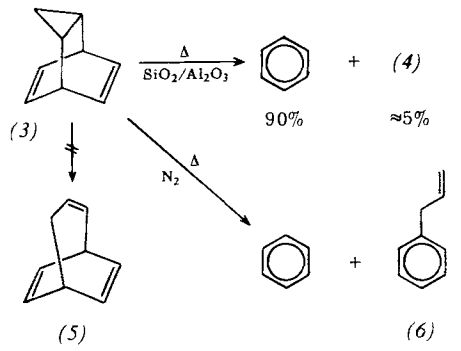


(2) *(3)* *(4)*

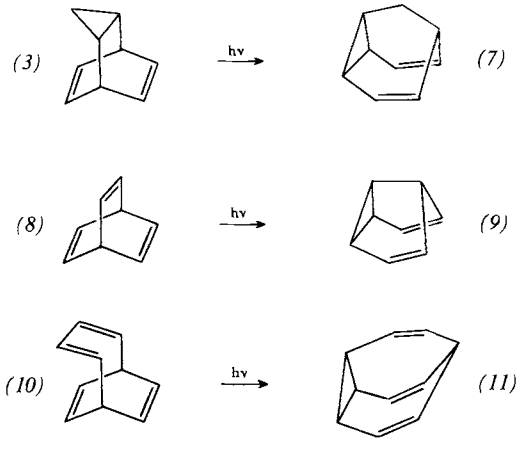
The Diels-Alder adduct of cycloheptatriene and acrylonitrile *(1a)*, a 60:40 mixture of *endo* and *exo* isomers, could be prepared in 44% yield at 170 °C. Conversion of *(1a)* to *(3)* followed a standard sequence involving intermediates *(1b)* through *(2)*[10]. The final step, the pyrolysis of quartenary salt *(2)*, gave a 55% yield of a C_9H_{10} fraction (b.p. 83–86 °C/40 torr) which proved to be a 4:1 mixture of *(3)* and an isomerized product *(4)*, bicyclo[4.2.1]nona-2,4,7-triene[4,6–8]. We think it likely that the latter arose by a cationic rearrangement route.

After purification by preparative gas chromatography[11], *(3)* was characterized spectroscopically: IR in CCl_4: 3050, 3005, 2955, 1630, 1580, 1435, 1355, 1250, 1215, 1095, 1040, 1020, 965, 900, 710, and 670 cm^{-1}; MNR in CCl_4: multiplets at $\tau = 9.4$ and 8.9 (secondary and tertiary cyclopropane hydrogens, respectively), $\tau = 6.4$ (bridgehead hydrogens), and quartets due to the two types of vinyl hydrogens at $\tau \approx 4.1$ and 3.55. When *(3)* was reduced with an uptake of 2 moles of hydrogen, tricyclo[3.2.2.0^{2,4}]nonane[12] was formed.

When *(3)* was pyrolyzed under nitrogen in the presence of silica-alumina catalyst at 240 °C, benzene was produced in

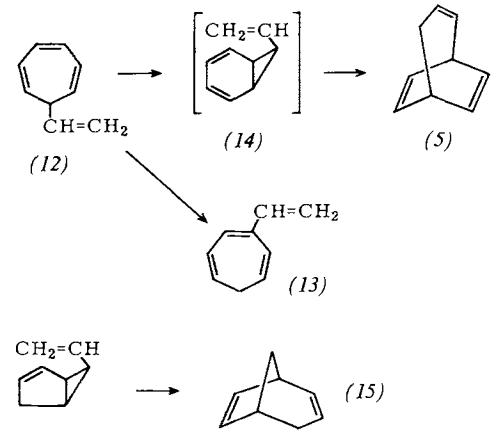


90 % yield. The desired ring-opening to give bicyclo[3.2.2]-nona-2,6,8-triene *(5)*[7] was not observed, but a small amount of by-product, tentatively identified as *(4)*, was formed. Pyrolysis of *(3)* in a nitrogen stream over Raschig rings at 310 °C gave benzene and allylbenzene *(6)* in a 2:1 ratio. Under these conditions neither *(4)* nor *(5)* was produced. The formation of benzene as the major product in these reactions suggests that cyclopropene was also formed, but we did not establish this possibility experimentally.



Photolysis of *(3)* (1 % solution in pentane/acetone (1:1 v/v); 450 W Hanovia Lamp, no filter) proceeded to give yet another product, tricyclo[3.3.1.$0^{2,8}$]nona-3,7-diene ("barbaralane") *(7)*, whose NMR spectrum agreed well with that reported[9]. Barbaralane *(7)* was not stable under these conditions; the yields were much higher at low conversions than at higher ones. This photolysis isomerization of *(3)* is reminiscent of the similar conversion of barrelene *(8)* to semibullvalene *(9)*[13] and of bicyclo[4.2.2]deca-2,4,8,9-tetraene *(10)* to bullvalene *(11)*[14]; perhaps the mechanisms of these transformations[13] also are analogous.

When 7-vinylcycloheptatriene *(12)*[15] was heated to 150 °C under a nitrogen atmosphere for 13.5 hours only a 13 % yield of a C_9H_{10} fraction (b.p. 55–57 °C/10 torr) was recovered by distillation from the higher boiling residue. Gas chromatography showed the volatile fraction to consist of 75 % bicyclo[3.2.2]nona-2,6,8-triene *(5)*[7] and 25 % 3-vinylcycloheptatriene *(13)*[15]. The IR spectrum of *(5)* was identical with that reported[7]; the NMR spectrum in CCl_4 showed absorptions at $\tau = 7.9$ (CH_2 group, complex quartet), $\tau = 7.05$ (bridgehead protons, multiplet), $\tau = 5.2$ and 4.2 (protons on the three carbon bridge, tripled AB spectrum with $J_{AB} = 11$ Hz), $\tau = 3.95$ and 3.55 (two olefinic protons each, complex triplet).



The formation of *(5)* evidently proceeded through the vinylnorcaradiene derivative *(14)* as intermediate. A similar reaction has recently been reported by *Goldstein* and *Odell*[16]; we have utilized an analogous vinylcyclopropane rearrangement for the synthesis of bicyclo[3.2.1]octa-2,6-diene *(15)*[17].

Structure of Dimethylnitrosaminecopper(II) Chloride[1]

By *U. Klement* and *A. Schmidpeter*[*][2]

Nitrosamines form addition compounds with metal halides and non-metal halides. Potentially each of the three atoms of the nitrosamine skeleton possesses a donor function. In the case of halides having a prominent Lewis acid character coordination of the amino nitrogen was first assumed[3]; later, ^{1}H–NMR spectroscopic studies revealed coordination of the nitroso oxygen atom[4]. The IR spectra of nitrosamine complexes of the transition metal halides likewise indicate the presence of bonding to the oxygen atom[4, 5]; however, the nature of the bonding is unclear as yet since the stoichiometry of the 1:1 complexes with metal(II) halides suggests that they contain the nitrosamine not only as unidentate ligand.

We have examined X-ray spectrographically the well developed, but easily cleavable, red crystals of $(CH_3)_2N{-}NOCuCl_2$ *(1)*. The lattice constants (in Å) have the following values: $a = 6.376$, $b = 14.685$, $c = 7.265$; the space grouping is D_{2h}^{16}–*Pnam*. According to the density, 2.07 g/cm^3, the unit cell contains four formula units. 730 reflections were measured (counting tube) and corrected for absorption and the Lorentz polarization factor. Isotropic refinement of the values by the method of least squares led to an R value of 15%; further refinements are being carried out.

The structural skeleton is formed by slightly puckered $CuCl_2$ chains which run through the crystal parallel to the x-axis and in which the copper atoms are coupled by double chlorine bridges.

The distance between neighboring chains is 7.34 Å in the y-direction and 3.6 Å in the z-direction. In the x-direction the chains are shifted by about 0.5 Å with respect to one another. The nitrosamine molecules are perfectly planar and arranged alternately on both sides of a chain and with the copper atoms situated in the same plane paralled to (001). They direct thereby the nitroso group, which is approximately aligned with the axis of the chain, to the chain. The nitrosamine molecules of neighboring chains lie inverted above each other. The planarity was first proved independently of the space group symmetry, in that calculations were made for the noncentrosymmetric sub-group C_{2v}^9–*Pna*2$_1$. Further refinement and the reflection statistics showed a centrosymmetric space group and that all atoms except chlorine lie in the mirror plane. The layer structure appears also in the extreme cleavability parallel to (001).

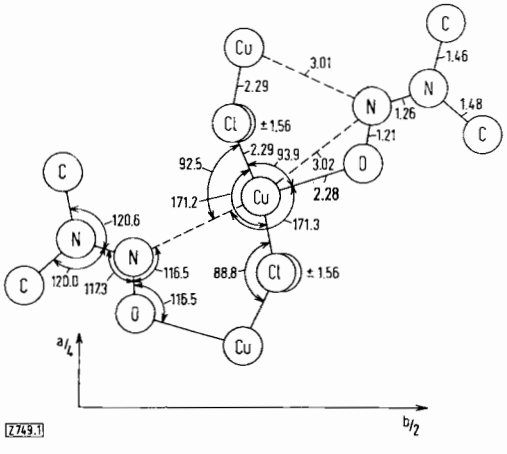

Fig. 1. (001)-Projection of two formula units of *(1)* with bond lengths (Å) and angles.

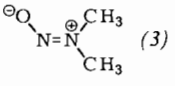
The structure found is reminiscent of that of the 1,2,4-triazolecopper(II) chloride *(2)*[6]. In both cases the copper atom is approximately octahedrally surrounded by four chlorine atoms and two donor functions of two molecule ligands situated *trans* to each other. In *(1)* the nitroso group appears in place of the neighboring nitrogen atoms of the ring in *(2)*. In both cases the $CuCl_2$ chain is folded as a result of the bridging of the copper atoms *via* the ligating molecules. In detail, however, the structures *(1)* and *(2)* are fundamentally different. In *(2)* and in the compound L_2CuCl_2 (L = H_2O[7], pyridine[8]) the chlorine atoms round a Cu atom form a rhombus with two short Cu–Cl distances of 2.28 to 2.34 Å and two long distances of 2.77 to 3.05 Å; in *(1)* on the other hand they form a square with uniformly short Cu–Cl distances. Whilst in *(2)* two chlorine atoms lie in the direction of the Jahn-Teller distortion, in *(1)* these positions are clearly occupied by the donor atoms of the ligands. Correspondingly the distances Cu–O and Cu–N are here considerably longer than in $(H_2O)_2CuCl_2$ (with 2.01 Å[7]) and in $(C_5H_5N)_2CuCl_2$ (with 2.02 Å[8]).

However, the distance Cu–O is shorter and the distance Cu–N much longer than one would expect to be the case along the axis of the Jahn-Teller distortion (both about 2.6 Å). The bonding of the copper to the nitrosamine is thus mainly *via* the oxygen. The nitroso nitrogen is equidistant from two neighboring copper atoms of a chain. The difference between the Cu–O and Cu–N distance is made possible by the fact that the Cu protrudes about 0.2 Å from the plane of surrounding chlorine atoms in the direction of the oxygen. A transition from octahedral to square pyramidal environment is therefore suggested.

The complexed nitrosamine is best described by the limiting formula *(3)*.



(3)

This formula also makes the weak bonding of the nitroso nitrogen understandable; the use of its lone pair leads to adjacent partial positive charges. The bond lengths of the free dimethylnitrosamine are not known. The best indication is provided by the values of methyl nitrite[9]; if one considers the spectroscopically verified stronger participation of the free lone pair of the amino nitrogen then for the nitrosamine N–O of 1.27 Å and N–N of 1.37 Å can be estimated. Compared with these values the N–N distance in *(1)* is, as expected, considerably shortened; remarkably, however, the N–O distance is also shortened.

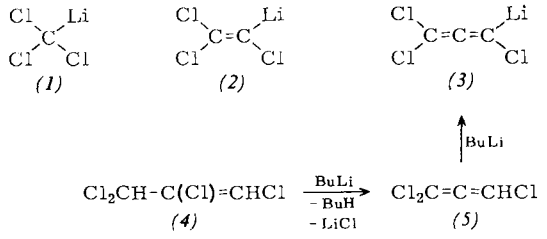
Cycloadducts from Trichloroallenyllithium[1]

By *G. Köbrich* and *E. Wagner*[*]

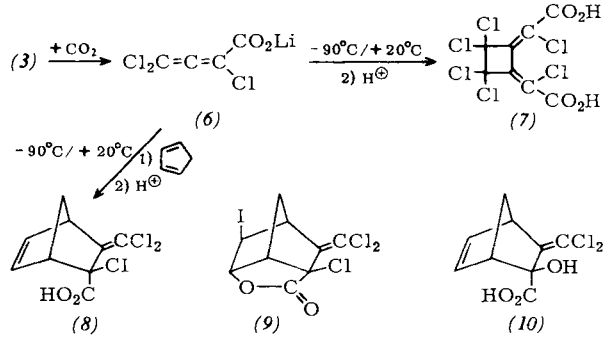
Trichloroallenyllithium *(3)* is interesting as a homolog of the known carbenoids *(1)* and *(2)*[2]; further, lithioallenes have hitherto been known only as intermediates[3].

We obtained stable solutions of *(3)* on treating trichloroallene *(5)*[4] or, better, 1,2,3,3-tetrachloro-1-propene *(4)* (*cis* and/

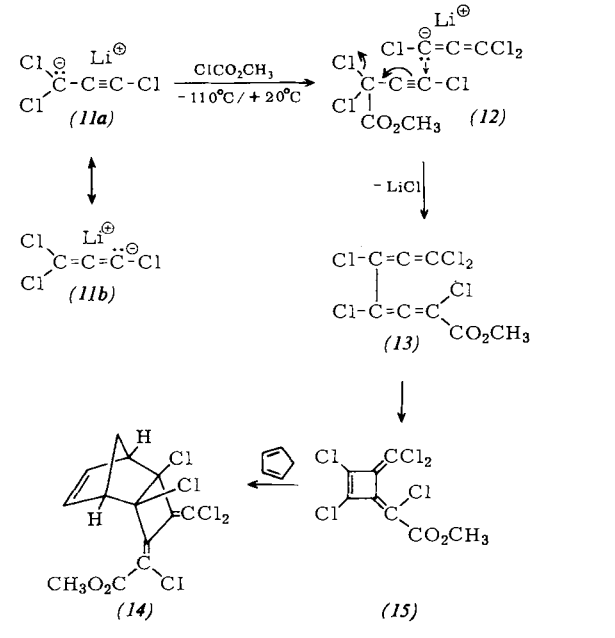


or *trans*)[5] with one or two molecular equivalents of *n*-butyllithium, respectively, in Trapp mixture[6] at −110 °C.

Trichloroallene *(5)* is metalated faster than it is formed from *(4)*, since only *(4)* is obtained alongside *(3)* if a sample of *(4)* is treated with less than 2 molecular equivalents of *n*-butyllithium. Carboxylation of *(3)* affords a mixture of dimeric carboxylic acids in 90% yield. About half of this mixture consists of *(7)*[4], which can be separated as the dimethyl ester (m.p. 161.5–163.5 °C)[7]. Proof that formation of monomeric trichloroallenyllithium from *(4)* is almost quantitative is provided by the diene reaction of the primary product *(6)* of carboxylation with cyclopentadiene (added at −90 °C), which gives a structurally homogeneous adduct $C_9H_7Cl_3O_2$ of m.p. 141–143 °C [yield 91% calculated on the amount of *(4)* used]. Of the four theoretically possible isomers the iodolactone reaction[8] decides in favor of *(8)* since it gives the tricyclic compound *(9)* (m.p. 157–158 °C; $\nu_{C=O}$ = 1800 cm^{-1}). In hot $NaHCO_3$ solution compound *(8)* forms *(10)* (m.p. 111–112 °C) instead of a tricyclene[8].



The deep violet color of trichloroallenyllithium indicates an ion-pair structure with the limiting forms *(11a)* and *(11b)*. The reasonable ambivalence is realized, at least formally, on treatment with methyl chloroformate which attacks at C-3 in contrast to carboxylation; surprisingly, the sole defined product is the unstable dimethylenecyclobutene *(15)* (m.p. 71–73 °C), which we consider to arise from the primary product *(12)* and an excess of *(3)* by way of the diallene *(13)* with subsequent cyclization.



Compound *(15)* and cyclopentadiene give the adduct *(14)* (m.p. 143-144.5 °C), whose NMR spectrum shows different τ values (6.44 and 6.66, each a quartet with J = 1.8–2.0 Hz) for the two bridgehead protons. This must be due to the influence of the ester group, which, therefore, is probably spatially close to a bridgehead and thus assumes in *(15)* a position remote from the second exocyclic double bond.

Thermolysis of *(3)*, which begins at −90 °C, gives neither tetrachlorohexapentaene nor the product of a dimerizing α-elimination, and no cyclopropane derivative if cyclohexene is added, but, instead, soot-like polymers are formed.

Experimental:

Preparation of *(3)*: A solution of 20 mmoles of *(4)* in 48 ml of Trapp mixture is treated dropwise under N_2 at −110 °C within 10–15 min with 40 mmoles of *n*-butyllithium in 20 ml of petroleum ether, and the mixture is stirred for a further 40–45 min at −110 °C.

Preparation of *(8)*: Compound *(3)* is carboxylated with an excess of pre-cooled powdered dry-ice[9], 24 ml of distilled cyclopentadiene is added and the mixture is allowed to come to room temperature within 24 h. On working-up by the usual technique[9], 4.61 g (91%) of *(8)*, m.p. 141–143 °C (after crystallization from CCl_4 and sublimation at 110 °C/1 torr), is obtained as acidic portion.

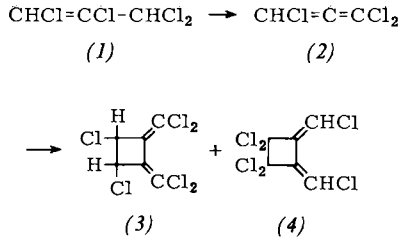
Preparation and Dimerization of Trichloroallene[1]

By *A. Roedig* and *N. Detzer*[*]

Treating 1,2,3,3-tetrachloro-1-propene *(1)* (*cis* and/or *trans*)[2] in a propane-ammonia mixture with sodamide gives trichloroallene *(2)* as an almost colorless liquid, which gradually solidifies (yield 76.5%). If recorded immediately after removal of a sample from the cooling bath, the IR spectrum (capillary layer) of this compound shows the bands at 1940 and 760 cm^{-1} typical of an allene, but warming causes these to change rapidly to the bands of the dimers *(3)* and *(4)*. Undiluted *(2)* decomposes explosively at room temperature. In petroleum ether, dimerization is complete in 3 days at 20 °C.



(1) (2) (3) (4)

The dimer mixture is not separable by distillation; its ^{1}H–NMR spectrum contains signals at $\tau = 5.08$ (very strong) and at 4.59, 3.03, and 2.97 (all weak). Calculation by the additivity scheme [3], which, however, does not permit differentiation of *cis*- from *trans*-isomers, gives $\tau = 5.10$ for *(3)* [4]. Since *trans* ring-protons usually have higher τ values than *cis* ring-protons [5], it is to be assumed that *(3)* exists mainly in the *trans*-form. The signals of the olefinic protons do not, however, permit a decision whether *cis-cis-* and *trans-trans-(3)* or only *cis-trans-(3)* is present in the mixture.

Experimental:

Trichloroallene *(2)*: 18 g of 1,2,3,3-tetrachloro-1-propene *(1)* is cooled to −75 °C in an N_2 atmosphere with rigid exclusion of moisture. 300 ml of propane and 50 ml of ammonia are condensed into this substance within $^1/_2$ h at the same temperature with stirring. Next, 5 g of water-free and benzene-free sodamide is added in small portions during 5 h and the mixture is stirred for a further 15 h at −75 °C. The resulting pale yellowish-green propane layer is then decanted from the dark ammonia layer and sucked through a fritted glass filter (externally cooled in dry ice), with exclusion of moisture, on to 50 g of a mixture (1:1) of active charcoal and silica gel that is placed in a flask cooled to −75 °C. The ammonia layer is washed again with three 50-ml portions of liquid propane. The united propane solutions are evaporated in a rotary evaporator at −70 °C at 12 torr and then at 0.1 torr, leaving the product *(2)* as a liquid that gradually solidifies to a white powder. Yield 11.0 g (76.5%).

Dimerization of *(2)*: 18.4 g of *(2)* in 45 ml of anhydrous petroleum ether (b.p. 30–50 °C) is kept at room temperature for 72 h with exclusion of moisture. After removal of the solvent in a vacuum the yellow oil is fractionated. 4.8 g of *(2)*, b.p. 42 °C/2 torr and a total of 13 g of mixed isomers *(3)* and *(4)*, b.p. 84 °C/0.01 torr, $n_D^{20} = 1.6051$ (after several distillations), are obtained.

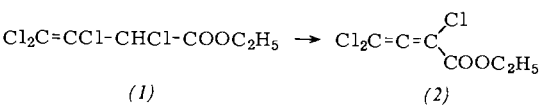
Preparation and Dimerization of Ethyl Trichloroallenecarboxylate [1]

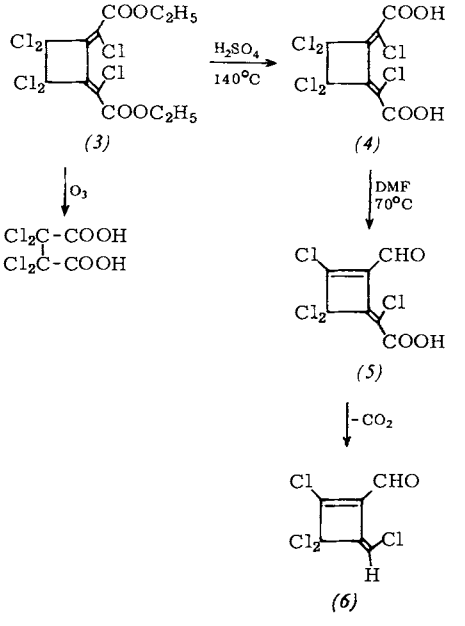
By *A. Roedig* and *N. Detzer* [*]

Reaction of ethyl 2,3,4,4-tetrachloro-3-butenoate *(1)* [2] and lithium *tert*-butoxide at −75 °C affords ethyl trichloroallenecarboxylate [trichloro-2,3-butadienoate] *(2)* as an almost colorless oil in 86% yield.



(1) (2)

The allenic ester *(2)* is less stable thermally than perchloroallene [3]. The intensity of the typical allene bands of the IR spectrum at 1953 cm^{-1} (capillary film) decreases very rapidly with increasing temperature. In contrast to that of trichloroallene [1], dimerization of *(2)* proceeds homogeneously in one direction; in light petroleum at room temperature it is complete in 20 h, affording a 100% yield of a crystalline dimer of m.p. 111–112 °C. Ozonization (0 °C, anhydrous methanol) of the dimer and oxidative hydrolysis (formic acid/perhydrol) give tetrachlorosuccinic acid, which was identified by IR-spectroscopical comparison with an authentic sample [4]. Thus the ethoxycarbonyl groups of the dimer are situated on the exocyclic methylene C atoms [5], but it has not been decided which stereoisomer is present: we assume that it is the *trans,trans*-form [6].



(3) (4) (5) (6)

The dicarboxylic acid *(4)* (decomp. 248 °C) corresponding to the diester *(3)* is decarboxylated in dimethylformamide at 70 °C, probably with allylic rearrangement by way of a kind of "Vilsmeier complex" that on hydrolysis yields the aldehydo acid *(5)* (decomp. 130 °C; yield 83%). The ^{1}H–NMR spectrum of *(5)* contains signals at $\tau = 1.94$ (aldehyde protons) and −0.70 (carboxyl protons). The acid *(5)* loses a further equivalent of CO_2 at about 100 °C with formation of the monoaldehyde *(6)*. Reaction of *(5)* with 2,4-dinitrophenylhydrazine solution at room temperature leads directly to the 2,4-dinitrophenylhydrazone (decomp. 238 °C) of *(6)*.

Experimental:

Ethyl trichloroallenecarboxylate *(2)*: The ester *(1)* (2.5 g, 10 mmoles) is cooled to −75 °C in a N_2 stream with rigid exclusion of moisture, propane (150 ml) is condensed in, and the whole is treated with lithium *tert*-butoxide (1.2 g, 15 mmoles) with stirring during 5 h. After a further 4 h at −75 °C the mixture is filtered rapidly into a vessel pre-cooled to −75 °C, and the propane is removed at −70 °C, first at 12 torr and then at 0.01 torr, leaving a colorless oil (yield 1.8 g, 86%). Diethyl 3,3,4,4,α,α′-hexachloro-$\Delta^{1,2}$-cyclobutanediacetate *(3)*: A solution of *(2)* (1.8 g) in 30 ml of dry light petroleum (b.p. 30–50 °C) is set aside for 20 h at room temperature with exclusion of moisture. Then, after removal of the solvent in a

vacuum there remains 1.8 g of *(3)* as almost pure, white crystals, m.p. 111–112 °C (from ethanol).

Synthesis of Oligonucleotides on a Polymeric Carrier[1]

By *F. Cramer* and *H. Köster*[*]

For the synthesis of oligonucleotides on polymeric carriers, soluble[1,2] and cross-linked[3] polystyrenes have been used in which a mono- or a di-methoxytrityl group or a benzoyl group[4] acts as anchor for the growing chain.

The polymeric carriers used previously all swell to some extent, thereby giving rise to the following problems:

1. Reactions can be effected only in solvents that can swell. Only a limited number of solvents can be used to wash out by-products and excess of reagents.

2. Many substances are tenaciously retained by the gel, so that time-consuming washing with large quantities of solvent is necessary. In this respect, a soluble polystyrene is better than a polystyrene that is cross-linked with 1–2% of divinylbenzene (Merrifield type) since it can be purified by reprecipitation[1].

3. Use of aqueous systems for selective removal of protecting groups[5] is not always possible.

4. In syntheses by the diester method the growing chain has one charge per phosphodiester bond. The existence of an ionic species in a non-polar solvent cage may be one reason why, with increasing chain length, cleavage of the oligonucleotides from the polymeric carrier becomes increasingly difficult, as we found both with soluble polystyrene and with polystyrene cross-linked with 1–2% of divinylbenzene. Cleavage conditions had to be chosen that partially destroyed the labile *N*-glycosidic linkage of the purine nucleotides.

After systematic testing of various insoluble polymer types[6], we now use as polymeric carrier a highly cross-linked, rigid polystyrene-divinylbenzene copolymer whose porosity can be varied within wide limits. It can be obtained as beads that do not swell and has the following advantages:

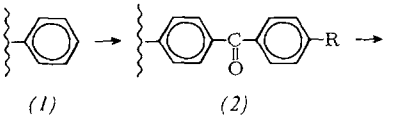
1. Aqueous solvents can be used; the carrier can be washed with all solvents without use of a gradient and can be freed from soluble impurities.

2. The condensation reactions occur as fast as in carrier-free systems.

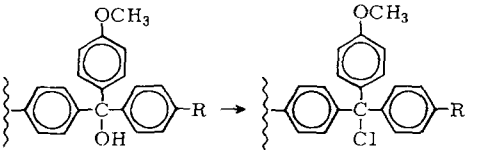
3. Removal of the oligonucleotide chains becomes easier rather than harder with increasing length.

4. On account of its bead form and rigidity the polymer is mechanically stable and easy to handle.

The copolymer *(1)* from styrene and divinylbenzene was subjected in nitrobenzene to a Friedel-Crafts reaction with benzoyl or *p*-methoxybenzoyl chloride and the polymeric ketone *(2)* thus obtained was then subjected to a quantitative Grignard reaction with *p*-bromoanisole. The resulting product, compound *(3)*, was then boiled with benzene/acetyl chloride under reflux or was treated with acetic anhydride/HCl at 0 °C, thereby giving the chloride *(4)*. In the statistical mean the polymer contains one trityl chloride group per 19 styrene units.



(1) *(2)*



(3) *(4)*

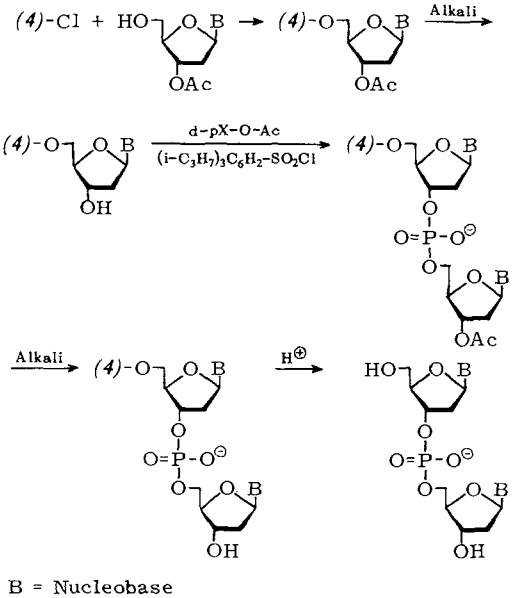
R = H, $-OCH_3$

A polymeric dimethoxytrityl alcohol of type *(3)* was also obtained by copolymerization of styrene, divinylbenzene, and bis-(*p*-methoxyphenyl)-(*p*-vinylphenyl)methanol, but we did not use it in the experiments now described.

The polymeric dimethoxytrityl chloride *(4)* R = OCH_3[7], could be loaded up to 50–60% with 3'-*O*-acetyldeoxythymidine (d-T–O–Ac) (0.2 mmole of d-T per g of polymeric carrier) and up to 5–10% with d-TpT–O–Ac (0.02 mmole of d-TpT per g of polymeric carrier) (pyridine, 48 h, 70 °C). Removal of the acetyl groups is effected with 0.1 N tetramethylammonium hydroxide in isopropyl alcohol (3 h, room temperature) or with a mixture of dimethylformamide, pyridine, and 1 M sodium ethoxide (5:4:1 v/v) (1 h, room temperature).

The synthesized oligonucleotide chains are removed from the carrier by treatment with 80% acetic acid for 1 h at 70 °C or for 6 h at room temperature; removal can also be effected by a pyridine-acetic acid buffer (pyridine:acetic acid:water = 3:10:3 v/v) in 48 h at room temperature. Since deoxyadenosine 5'-monophosphate is stable in 80% acetic acid for at least 24 hours and in the pyridine-acetate buffer for at least four weeks purine nucleotides can also be used.

The carrier can be loaded with pre-formed oligonucleotide and this can be lengthened by a single dinucleotide unit (block condensation). This process enables longer, biochemically interesting chains to be synthesized.



B = Nucleobase

	Nucleoside components	Phosphate components [a]	Yields (%) calculated on total amount of eluted nucleotide material [b]			
			d-TpT	d-TpTpX	d-TpTpTpT	d-TpTpTpTpTpT
I	*(4)*-d-T	d-pT—O—Ac	49.5			
II	*(4)*-d-TpT	d-pT—O—Ac	33.0	67.0		
III	*(4)*-d-TpT	d-pT—O—Ac	32.0	34.0	34.0 [c]	
IV	*(4)*-d-TpT	d-pTpT—O—Ac	36.2		33.3	30.6 [c]
V	*(4)*-d-TpT	d-pC(N^6—Ac)—O—Ac	58.7	41.3		
VI	*(4)*-d-TpT	d-pA(N^6—Ac)—O—Ac	70.1	29.9		
VII	*(4)*-d-TpT	d-pG(N^2—Ac)—O—Ac	74.1	20.9		

[a] A 50—100 fold excess of nucleotide was used. In experiment I a 10 fold excess gave the same yield.

[b] IR spectra indicate that all fissions occurred with at least 97% yield. For VI, λ_{max} of d-TpTpA = 262 nm (ε = 33400 was used). For VII, λ_{max} of d-TpTpG = 258 nm (ε = 30600 was used).

[c] After two condensations with the phosphate components.

Attachment of the nucleotide bond was effected by triisopropylbenzenesulfonyl chloride in pyridine (4 h or 6—8 h for block condensation).

Contrary to usual practice, water is not added after the condensation but the reaction is stopped by precipitation with anhydrous ether. Thorough washing with ether removes the excess of triisopropylbenzenesulfonyl chloride, and the excess of nucleotide is eluted with 20% aqueous pyridine. This method of working up saves time and regenerates the excess of nucleotide almost without loss and in such a form that, after removal of the water, it can be used directly for renewed condensation.

In this manner a condensation step can be carried out comfortably in one day, so that synthesis of d-TpTpTpTpTpT including loading and working up does not take more than a week.

The oligonucleotides synthesized can be degraded quantitatively with snake-venom phosphodiesterase to yield the required proportions of d-T and d-pT or d-T, d-pT and d-pX (X = A, C, G).

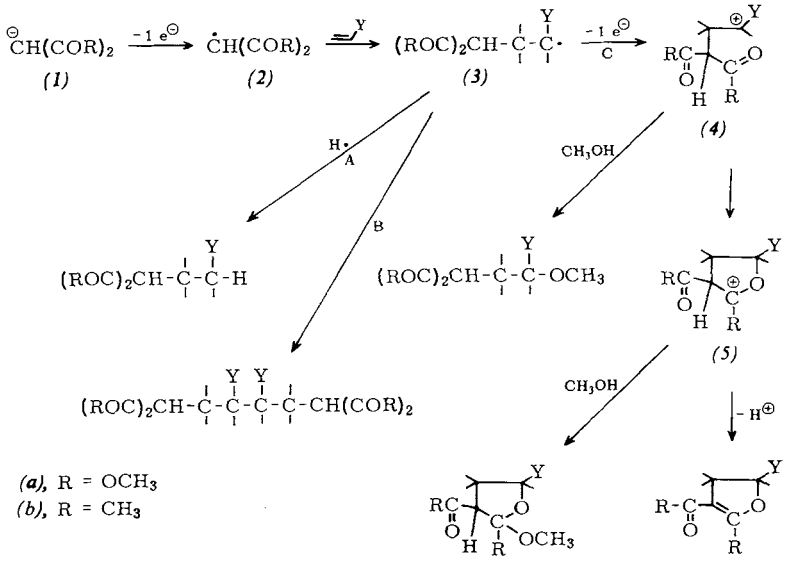
Oxidative Addition of Dimethyl Sodiomalonate and Sodioacetylacetone to Olefins[1]

By *H. Schäfer* and *A. Alazrak*[*]

We are engaged in a study of whether various organic anions can be added to non-activated olefins by way of radical intermediates.

When we oxidized dimethyl sodiomalonate *(1a)* or sodioacetylacetone *(1b)* anodically in the presence of cyclohexene, ethyl vinyl ether, styrene, or butadiene, we obtained the products named in the Table[2]. The anode voltage was controlled by a potentiostat and was always less than the polarographically determined half-wave potential of *(1a)* ($E_{1/2} \approx +0.89$ V against Ag/AgCl) or *(1b)* ($E_{1/2} \approx +0.8$ V). Usually, *ca.* 100 mmoles of *(1a)* or *(1b)* in an olefin/methanol mixture (1:2 to 1:1 v/v) were electrolyzed, in a cell without a diaphragm, at current densities of 0.01—0.05 A/cm².

The reactions probably begin with formation of a radical *(2)* at the anode; this radical then adds to the olefin, giving a new radical *(3)*. *(3)* can remove a hydrogen atom from the solvent or from the excess of malonic ester or acetylacetone (route A), or it can dimerize (route B), or it can be oxidized to the cation *(4)* at the anode, provided that the cation is stabilized by Y = phenyl or ethoxyl (route C). Two possibilities are open to the cation *(4)*: it may attack methanol electrophilically or it may attack the oxygen of the carbonyl



Anion	Olefin	Products	Yield (%) [a]
(1a)	Cyclohexene	Dimethyl 2-cyclohexenylmalonate	12
		Dimethyl cyclohexylmalonate	8
(1a)	Ethyl vinyl ether	Dimethyl (2-ethoxy-2-methoxyethyl)malonate	37
(1a)	Styrene	Methyl tetrahydro-2,2-dimethoxy-5-phenyl-3-furancarboxylate	43
		Tetramethyl 3,4-diphenyl-1,1,6,6-hexanetetracarboxylate	15
(1b)	Ethyl vinyl ether	4-Acetyl-2-ethoxy-2,3-dihydro-5-methylfuran [b]	36
(1b)	Styrene	4-Acetyl-2,3-dihydro-5-methyl-2-phenylfuran	30
		5-Phenyl-2-pentanone	6 [c]
		5,6-Diphenyl-2,9-decanedione	10 [c]

[a] Calculated on current consumption. — [b] IR: $\nu_{C=C}$ = 1598 cm^{-1}. [c] After ester fission of the crude product. — [d] IR: ν_{C-H} = 965 cm^{-1}.

group intramolecularly with formation of an alkoxymethyl cation *(5)*, which is then solvolyzed or deprotonated.

On the basis of this working hypothesis we attempt to influence the product distribution by variation of the anode potential and the current density.

Methyl tetrahydro-2,2-dimethoxy-5-phenyl-3-furancarboxylate:

A solution of dimethyl malonate (18 g, 136 mmoles) and sodium (1.1 g, 48 mmoles) in styrene (100 ml) and methanol (120 ml) was electrolyzed at 20 °C with an anode potential of +0.65 V (against Ag/AgCl) and a current density of 0.02 A/cm^2. After a current consumption of 16200 Cb most of the solvent was distilled off in a rotary evaporator at 60 °C, the residue was treated with saturated NaCl solution (30 ml), and the mixture was extracted with ether and worked up as usual. Distillation afforded 9.9 g (43%) of methyl tetrahydro-2,2-dimethoxy-5-phenyl-3-furancarboxylate (b.p. 114–115 °C/0.05 torr). This product gave the 2-oxo derivative (IR: $\nu_{C=O}$ = 1780, 1740 cm^{-1}) when treated with toluenesulfonic acid in 97% aqueous methanol. Chromatography of the distillation residue on silica gel with light petroleum (b.p. 40 to 60 °C):ether (3:1 v/v) yielded tetramethyl 3,4-diphenyl-1,1,6,6-hexanetetracarboxylate, m.p. (of one diastereoisomer) 131.5–132.5 °C (from benzene/light petroleum).

CONFERENCE REPORTS

Valence and Reactivity: an International Symposium of the Chemical Society (London) on d-Orbital Effects, January 9–11, 1968, in Oxford

Participation of "outer" d-orbitals (nd) in the bonding of non-metallic elements with principal quantum numbers n $\geqslant$3 is a central problem of inorganic chemistry[1]. As for the largely clarified participation of "inner" d-orbitals [(n-1)d] in transition-metal complexes, its solution would open numerous new aspects of the chemistry, spectroscopy, and quantum-chemical description of non-metal compounds.

In a general introduction to the symposium *C. A. Coulson* (Oxford) first formulated the essential questions: What is known about the energies and sizes of d-orbitals in isolated atoms? Can the "diffuse" d-orbitals in compounds be contracted by electronegative ligands, and what is the effect of such a contraction on the overlap with σ- and π-orbitals? What experimental data give valid information about d-orbital effects? Does participation of d-orbitals in π-systems lead to a conjugational barrier at the d-orbital center? Are transition states stabilized by d-orbital participation? The results of theoretical and experimental investigations of these questions were set out in 30 papers[2].

D. W. J. Cruickshank (Glasgow) reviewed the SCF calculations carried out in recent years for excited configurations of free atoms and ions. The results show that with optimal spin alignment (*e.g.* ^{7}F for S (sp^3d^2)) the radial parts of the d-orbitals shrink to the size necessary for participation in bonding. Energies of the "outer" d-orbitals of neutral atoms X are small and largely independent of the atomic number; but they are appreciably influenced by the state of ionization ($X \approx -2$ eV; $X^+ \approx -8$ eV; $X^{2+} \approx -18$ eV). By way of contrast, the energy of the "inner" d-orbitals of transition metals decreases with increasing nuclear charge ($Sc(d^1s^2) \approx -9$ eV; $Zn(d^{10}s^2) \approx -21$ eV). Calculations that take into account the "outer" d-orbitals, by means of an analytical two-term Slater function, lead – according to *T. Thirunamachandran* (London) – to the result that d-atomic orbitals are more diffuse for the d^1-configuration (*e.g.* P(sp^3d)) than for the d^2-configuration (*e.g.* S(sp^3d^2)).

C. Zauli (Bologna) summarized the bonding conditions in higher valence states where the octet rule is violated. He described the distortion of the valence orbitals by the ligand field, the energy gain on formation of the molecule, and the energy differences between excited covalent and ionic states. Since the promotion energies are generally comparable, 4s- and 4p-states must be considered as well as 3d-states. The d-orbital contraction in the ligand field can lead to participation of 3d-orbitals in the bonding, *e.g.* for sulfur compounds; the promotion energies could be compensated by electrostatic interactions. According to *K. A. R. Mitchell* (Vancouver) calculations with simple radical functions $R(r) = Nr^2e^{-\alpha r}$ with a distance of maximum probability at $r_{max} = 3/\alpha$ [a.u.] lead to exponentials $\alpha \approx 1.2$–1.5 for the orbitals of SF_6 and to $\alpha \approx 1.3$ for the d-orbitals of POF_3. Thus d-orbital participation should be considered in compounds of this type. However, for interhalogen compounds, polyhalides, and polyhalogen cations, according to *E. H. Wiebenga* (Groningen), a σ-HMO procedure without inclusion of d-orbitals suffices for prediction of the stable configurations, electronic transitions, bond distances, and non-existent compounds. The procedure uses only np-functions and, since the ionization energies, electron affinities, and bond distances are known, it requires only the resonance integrals $\beta_{\mu\nu}$ as a function of distance, these parameters being accessible spectroscopically. According to *R. J. Gillespie* (Hamilton) the qualitative model of electron-pair repulsion proves useful for predicting the geometry of simple molecules such as interhalogen or noble-gas compounds.

Molecular properties that should show the effect of d-orbital participation have been intensively investigated. *H. H. Jaffe* (Cincinnati) reported on d/π^* interactions in excited states which are particularly relevant because of the small

energy differences $E_d - E_\pi^*$. The electronic spectra of sulfones, sulfoxides, sulfonium salts, alkyl iodides, and anisoles that are *para*-substituted by acceptor groups X (X = halogen, SiR_3, GeR_3, SnR_3) were cited as examples. *D. S. Urch* (London) drew attention to the properties of inorganic compounds that can be explained by strong d/n interactions between unoccupied 3d-orbitals and free 3p-electron pairs.

According to *H. Bock* (München) simple models of d/π-, d/n-, and d/π* interactions are provided by R_3Si-substituted linear and cyclic, isoconjugated and heteroatomic π-electron systems such as polyenes, aromatic hydrocarbons, aryl ethers, ketones, and aldimines. These R_3Si-substituted π-electron systems differ significantly from R_3C- and R_3SiCH_2-substituted "standard" compounds in vertical ionization energies, charge-transfer maxima of suitable donor-acceptor complexes, half-wave reduction potentials, ESR coupling constants of the radical anions, and the electron transition energies. The energy differences can be interpreted on the basis of differing inductive polarizations ($+I_{SiR_3} > +I_{CH_2SiR_3} \gg +I_{CR_3}$) and additional back-donation of electrons $Si \leftarrow C_\pi$. The ionization energies in the photoelectron spectra of SF_6, SeF_6, and TeF_6 can be assigned, as was shown by *D. R. Lloyd* (Birmingham), on the basis of CNDO calculations only if d-terms are included.

E. A. C. Lucken (Geneva) reviewed the spectroscopic methods to measure the properties of ground states (NMR, ESR, NQR, and Mössbauer spectroscopy) and discussed the differences in determining energies (eigenvalues) and electron distributions (eigenfunctions). Unequivocal proof of d-orbital contributions that is possible by these methods is, however, limited by the assumptions required in evaluating the experimental results and by parameters introduced into the model calculations. Among other examples the (d← n)-electron back-donation in R_3SiCl (NQR), $(d/p)_\pi$-conjugation in R_3Si-substituted π-electron systems, and $(d/p)_\pi$-bonding in phosphorus compounds $R_3P{=}X$ (ESR, ^{13}C-, ^{29}Si-, and ^{31}P–NMR) were considered.

H. Zeil (Karlsruhe) discussed bond distances of acetylenes $(CH_3)_3X{-}C{\equiv}C{-}Cl$ (X = C, Si, Ge, or Sn) determined by microwave spectroscopy and electron diffraction, and the NQR, IR, and Raman spectra of such molecules. For instance, the C–Cl bond length is shorter, the force constant $f_{C\equiv C}$ smaller and f_{C-Cl} larger for the Si compound than for the *tert*-butyl derivative. This finding supports $(p \rightarrow d)_\pi$-bonding, as do also the ^{35}Cl–NQR coupling constants, which decrease in the series from C- to Sn-acetylenes. Further evidence for d-orbital effects in compounds of elements of the fourth main group may be deduced from the quadrupole splittings in the ^{119}Sn-Mössbauer spectra, as was shown by *J. J. Zuckerman* (Ithaca) and *J. D. Donaldson* (London). According to *B. Lindberg* (Uppsala) $(d/p)_\pi$-contributions for, *e.g.*, S=O bonds can be inferred from the spectra of inner electrons that result from X-ray excitation, and which may be correlated with the effective nuclear charge and the arrangement of electrons in the valence shell. In contrast to the interpretation of the preceding results, *M. P. Bogaard* (Bristol) found that the NQR spectra of polyhalide anions such as I_3^- and IBr_2^- can be interpreted on the basis of a three-center four-electron MO theory without assuming d-orbital contributions.

Mutually contradictory reports have been given about the d-orbital centers as conjugational barriers in π-electron systems, with PN rings as examples. In his review *N. L. Paddock* (Vancouver) reported thermochemical and structural studies of PX bonds in compounds of the type $R_3P{=}X$ (X = O or NR), where the effects of substituents on bond enthalpies or P=O stretching frequencies are evidence of $(d/p)_\pi$-bonds. Here two π-components at right angles to each other can be conceived, which are no longer degenerate in PN rings. Calculated HMO eigenvalue schemes for rings containing three to six P=N units show the same alternation as, *e.g.*, the measured photoionization energies. Predicted structures agree with X-ray structure analyses, as *A. J. Wagner* (Groningen) reported. However, *H. R. Allcock* (University Park/USA) reported experimental results that contradict π-delocalization in PN rings; in particular, the electron transitions ($\nu_m > 50000\ cm^{-1}$!), which are independent of the number of PN units ($n \rightarrow \infty$), and the half-wave reduction potentials of certain derivatives, which are in accord only with the Dewar PNP island model.

Transition states in reactions of Si and P compounds can be stabilized by d-orbitals with increase in the coordination number, in contradistinction from those of C compounds. The previously known material was summarized by *R. F. Hudson* (Canterbury): for Si and P derivatives inversions as well as retentions of configuration are known, depending on the reaction conditions and on the nature of the leaving group. Retention occurs particularly in cyclic transition states such as occur in the Wittig reaction. $X_3P{=}^{18}O$ compounds are hydrolyzed without exchange of ^{18}O, in contrast to carboxylic esters; however, trialkylfluorosilanes racemize in methanol without detectable hydrolysis. Numerous further examples help toward the conclusion that the transition state can be stabilized by unoccupied higher orbitals but that these need not necessarily be of 3d type. *G. Schiemenz* (Kiel) showed that Hammett constants of phosphorus substituents can be determined from ^1H–NMR data and that the σ-values obtained show a –M effect of phosphorus. *B. G. Gowenlock* (Edinburgh) reported on gas-phase reactions of silanes. Other papers on the properties and reactions of metal complexes were contributed by *C. W. Fryer* (Coventry), *J. A. McGinnety* (Evanstown), and *P. Uguagliati* (Padua), and on special methods of calculation by *R. Wratten* (Sheffield) and *W. T. Dixon* (London).

Finally *C. A. Coulson* reviewed the answers that had been given during the symposium to the questions that he put forward at its opening. d-Orbitals clearly play a larger part in π-bonding than in σ-compounds (such as the interhalogens). Ground and excited states must be considered separately. Except for compounds such as $R_3P{=}X$, the chemical evidence for d-orbital contributions is not compelling because, generally, only acceptor functions of substituents are determined and these could be due to other orbitals that have π-symmetry. The intensive attempts to clarify the "d-orbital effects", which can be reproduced in quantum-mechanical calculations, including d-orbital contraction, are, however, likely to yield decisive results in the foreseeable future.

Investigation of the Ionic Mobility of Some Copper(I) Compounds by Nuclear Magnetic Resonance

By *H. Richtering* and *G. W. Herzog* [*]

Cationic mobility of CuBr and CuI is greater in the high-temperature phases than in aqueous solutions at room temperature. The shape and width of the NMR signals of ^{63}Cu, ^{65}Cu, ^{79}Br, ^{81}Br, and ^{127}I were studied between –100 and +500 °C; for ^{63}Cu the spin-lattice relaxation time T_1 was also determined at temperatures up to 330 °C.

For the cubic low-temperature phases the width of all the signals is constant at low temperatures (1.5 to 2.5 G) and they can be used to provide the second moments, the values

derived agreeing fairly well with those obtained from the lattice structure. Between 20 and 150 °C the width of the Cu signals decreases for both compounds (to < 0.4 G), which is to be ascribed to increasing mobility of the Cu^+ ions with rising temperature; by using *Bloembergen, Purcell,* and *Pound*'s theory[1] the mean residence time of a Cu^+ ion in its lattice position is found to be $\tau_{Cu^+} \approx 5\times10^{-5}$ sec at 100 °C. In the same region the halogen signals become first narrower and then appreciably broader (>5 G). For Br the width passes through a maximum at 240 °C; this maximum occurs at the same temperature for samples of various degrees of purity but is the more pronounced the larger the number of bivalent cations (Cu^{2+}, Cd^{2+}) that are present. The maximum in signal width corresponds to a minimum in T_1, caused by quadrupole interaction[2]. Thus at 240 °C the mean frequency of interchange of defect sites in the Cu lattice (which contribute to the quadrupole interaction) is of the order 10^8 Hz, the Larmor frequency of Br nuclei in the external magnetic field (14000 G). The Cu signals become somewhat broader below the transition temperature for the change cubic → hexagonal. Here the width of the signal is already appreciably influenced by T_1; for ^{63}Cu T_1 decreases from 5–10 msec at 25 °C to *ca.* 500 μsec at 330 °C. Shortly before the transition point τ_{Cu^+} thus approaches the reciprocal Larmor frequency of the Cu nucleus (1.0×10^8 Hz).

For the hexagonal β-phases (CuBr 390–470 °C; CuI 373 to 410 °C) the Cu signals are first broader, unsymmetrical, and shifted downfield by 0.5 G (CuBr) or 2 G (CuI). The shift decreases with rising temperature, and the signals become symmetrical and narrower.

For the cubic α-phases of CuI above 440 °C the width of the signals decreases further: $\tau_{Cu^+} < 10^{-8}$ sec. Halogen signals cannot be observed for either the β-phases or the α-phases of CuI.

Oxygen Radicals and Chemiluminescence

By *J. Stauff*[*]

Weak chemiluminescence (10^3–10^8 $h\nu\cdot cm^{-3}\cdot sec^{-1}$) is observed in very many oxidations by hydrogen peroxide, hypohalite, or ozone and also by molecular oxygen. This can be traced to oxygen radicals of the type O_2H, O_3H, and O_2R (R = an organic group) arising as intermediates which on recombination afford oxygen in the singlet state ($^1\Delta$ or $^1\Sigma$), *e.g.*, $2\ O_2H \rightarrow H_2O_2 + O_2^*$ ($\Delta H = -58$ kcal/mole). The excited oxygen can pass to the ground state with emission of red light.

However, emission in the wavelength region 360–580 nm is also found spectroscopically; so processes must also occur that are resolved by collision of two excited singlet oxygen molecules, their energies then being added together. This view is supported by a quadratic dependence of the emission on the O_2 concentration in the Cu^{2+}-catalyzed oxidation of sulfites by molecular oxygen. The rate of onset of chemiluminescence produced by recombination of two O_2H radicals (from $Ce^{4+} + H_2O_2$) is very much greater than the rate of recombination of the radicals, whence it is concluded that light is emitted only on collision of two individual O_2 species, and that this does not necessarily require formation of an O_2–O_2 complex *in statu nascendi* although this may happen in other cases (*e.g.*, $O_3 + H_2O_2 \rightarrow O_4^* + H_2O$).

O_2H radicals can be determined by ESR spectroscopy in a flow apparatus; their reaction kinetics are thus known. For OH radicals and for O_3H radicals arising therefrom (*e.g.*, from Ti^{3+} and H_2O_2) complex formation with the cations produced makes quantitative interpretation of the ESR signals difficult; nevertheless, connections between radical reactions and chemiluminescence can be recognized.

The bluish-yellow chemiluminescence is an indicator for appearance of O_2H radicals and, at pH $>$ 5 or in solvents with low dielectric constants, of O_2^- radicals; furthermore, it can be used as indicator when following autoxidations and one-electron transfers to O_2, as well as in the action of O_2 on semiquinones and many other electron-donors (including biological ones). In particular, complexes of heavy-metal ions with amino acids, proteins, nucleotides, and nucleic acids in the presence of cysteine and other donors or of natural oxidases give measurable light emission when treated with oxygen, and this can be used as a means of studying their reaction mechanisms.

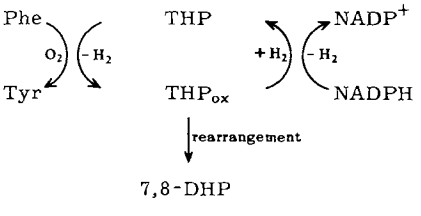
Tetrahydropterins as Coenzymes of Enzymatic Hydroxylation

By *M. Viscontini*[*]

S. Kaufman[1] has shown that the coenzyme of an enzymatic hydroxylation system is a tetrahydropterin. This system operates in a fairly complicated manner with formation of an oxidized tetrahydropterin (THP_{ox}) as well as of a 7,8-dihydropterin (7,8-DHP) in the presence of the redox coenzyme

$$NADP^+ \underset{-H_2}{\overset{+H_2}{\rightleftharpoons}} NADPH$$

The mechanism of enzymatic hydroxylation of phenylalanine to tyrosine can be represented as in Scheme 1.



In order to study the course of the hydroxylation we first prepared pure tetrahydropterins and investigated the chemical properties of these particularly unstable substances. We have been able to show that the tetrahydropterins are oxidized to 7,8-dihydropterins under physiological conditions (pH 6.8, atmospheric oxygen). A very unstable quinonoid dihydropterin *(11)* is formed as intermediate, its UV spectrum being the same as that of *Kaufman*'s "oxidized tetrahydropterin".

Phenylalanine and tryptophan can be hydroxylated under physiological conditions in the presence of tetrahydropterins and Fe^{III} (yield 3–5 %). The Fe^{III} takes up an electron from the tetrahydropterin which is converted into a radical cation. Then the Fe^{II} thus formed adds an O_2 molecule and passes the electron on to it; a proton finally migrates from the radical cation to the negatively charged oxygen. An analogous transfer of an electron and a proton from a second tetrahydropterin molecule leads to a complex *(6)* consisting of THP radicals, Fe^{III}, and hydrogen peroxide, which can hydroxylate aromatic compounds.

On the basis of these results we propose Scheme 2 as a model for enzymatic hydroxylation [2]:

Cooperative Conformational Changes of the Helix Structures of Biopolymers and Analogous Model Substances in Solution

By *Th. Ackermann* [*]

Under suitable experimental conditions (temperature, solvent composition, pH value), and even in the dissolved state, polypeptides and polynucleotides adopt a secondary structure that corresponds largely to the model of the Pauling α-helix and to the Watson-Crick model of the DNS double helix. Alteration of the experimental conditions can convert the molecules of the dissolved biopolymer from the ordered helix state into the statistically disordered state of a bundle; this conversion is often referred to as the helix-random coil transition.

Experiments with a series of model systems (*e.g.*, poly-γ-benzyl L-glutamate dissolved in a mixture of dichloroacetic acid and 1,2-dichloroethane or an equimolar mixture of salts of polyribouridylic acid and polyriboadenylic acid in aqueous buffer solutions) have shown the helix-coil transition to be a reversible cooperative process that proceeds almost completely within a relatively narrow temperature range. The transition is clearly detectable by characteristic changes in physical properties of the solutions; these may be studied by, *e.g.*, measurement of optical rotation, viscosity, UV absorption, IR absorption, and the chemical shift of the nuclear resonance signals of α-CH protons of polypeptides in relation to temperature or solvent composition.

The stability of the helix structures in the dissolved state is influenced, not only by the intramolecular hydrogen bonds, but also by solvation effects and by the energetic interaction of the ring systems of the heterocyclic bases present in the polynucleotides. Thermodynamic parameters of such systems can be determined by exact measurement of the temperature relation of the heat capacity by means of recording adiabatic calorimeters.

Not only the transition enthalpies but also the characteristic cooperative parameters can be found by such measurements. Comparative measurements on DNS samples with various base compositions permit statements about the influence of the base pairs adenine-thymine, adenine-uracil, and guanine-cytosine on the thermal stability of the helix structures [1–3].

Investigations of Roman Wall Paintings

By *R. Giovanoli* [*]

According to *W. Klinkert* [1], Roman wall painting differs from modern frescoes in the way in which it was made. Since we can expect little appreciably new as addition to our knowledge of the "fresco buono" technique of wall painting, our investigations were directed mainly to testing the more recent methods of study that have not yet found wide application in archaeometry. The first comprehensive application was that by *U. Hofmann* [2] to Attic ceramics.

In our study of fragments of wall painting (from the frigidaria of two Roman villas in Switzerland), we used X-ray diffraction, X-ray fluorescence spectrometry, electron diffraction, and electron microprobe techniques, and we recognized the various color tones as resulting from blue, wine red, pale green, and yellow pigments, and from the white of the plaster.

X-Ray fluorescence analysis disclosed the following element contents:

- In the plaster Ca (secondary element Sr) and Si
- In blue pigment layers Cu, Ca, and Si
- In red pigment layers Fe, Si, Ca, and some Cu
- In green and in yellow layers traces of Fe, otherwise as for the plaster.

Use of X-ray and electron diffraction led to recognition of the crystal species α-Fe_2O_3 (hematite) and $CaCuSi_4O_{10}$ (the ancient synthetic pigment "Egyptian blue"), as well as calcium carbonate, but other colored material lay below the limits of detection. However, the fine structure of the electron diffraction of extracts from surface prints of green fragments and yellow fragments gave indications of the presence of clay mineral structures.

Ground sections showed their layer structure in the electron microprobe. Element concentration profiles confirmed the X-ray findings and led to the additional conclusions that the colored bodies in the green pigment layers were glauconite and that those in the yellow pigment layers were an ocher (kaolinite with α-FeOOH).

From the thickness of the pigment layers of the various fragments it was further concluded that the blue layers were purposely applied more thickly, so that the full color tone of the coarsely crystalline Egyptian blue became clearly evident; our imitation of Egyptian blue, when powdered in a mortar, is pale blue and does not possess the deep color tone of the crude product. Such fragments thus cannot be deemed "fresco buono" in the strictest sense.

The instrumentation used has proved useful for characterization of the composition and intimate structure of such fragments of paintings and similar objects.

Porphin Derivatives as Experimental Models for Mass-spectroscopic Fragmentation Reactions

By *H. Budzikiewicz* [*]

As a result of the concept that decomposition of a molecule during mass-spectroscopy is induced by a localized positive charge, such study of organic compounds has in recent years concerned mainly the influence of various functional groups and structural units on the fragmentation pattern. To obtain a more general picture it is necessary to test the available results for applicability to complex systems and for their limitations. Porphin derivatives are suitable as experimental models because in all their decomposition reactions the positive charge is localized preferentially in the π-system of the macrocycle whilst fragmentation occurs in the side chain.

In the case of 1,2,3,4,5,6,7,8-octaethyl-1,2,5,6-tetrahydroporphin the preferential formation of even-numbered electron systems in the singly and doubly charged regions can be demonstrated by comparing the relative intensities of the daughter ions formed by successive loss of ethyl radicals; this is also indicated by the preferred course of the McLafferty rearrangement which affords ions with even numbers of electrons. The mass spectra of porphyrins and chlorins that are not substituted in the *meso*-position confirm the principle of benzyl cleavage observed with simple aromatic compounds whilst the mutual steric hindrance of the side chains in 6,7-substituted compounds causes fission of the bonds leading directly to the aromatic ring and also leads to simultaneous loss of two substituents with formation of a metastable peak. The last-mentioned observation is of particular importance for the theory of metastable transitions. Comparison of the mass spectra of 10-methoxy- and 10-isopropoxy-methylpheophorbide indicates the limits within which analogies may be drawn on purely empirical application of mass spectroscopy: the differing behavior of the two types of compound can be explained by the fact that the energetics of cleavage of various bonds proceeding from the same center (C-10) may be more or less favorable according to the nature of the substituents.

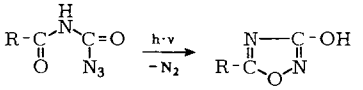
New Investigations of Heterocumulenes[**] and their Derivatives

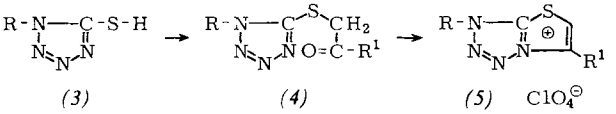
By *R. Neidlein* [*]

N-Acylcarbamoyl azides *(1)* are converted by loss of nitrogen



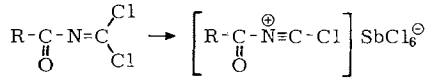
(1) *(2)*

into 1,2,4-oxadiazol-3-ols *(2)*, whose structure is proved by degradative reactions and by IR and ^{1}H–NMR spectroscopy, as well as by synthesis of their methyl ethers by another route. The tetrazole-5-thiols *(3)*, that can be obtained



(3) *(4)* *(5)* $ClO_4^{\ominus}$

from isothiocyanates and hydrazoic acid with subsequent rearrangement, are converted by way of the intermediate *(4)* into the quasiaromatic thiazolo[3,2-*d*]tetrazolylium salts [isolated as perchlorate *(5)*], whose properties and reactions have been intensively studied.



(6) *(7)*

Whereas reaction of *N*-(dichloromethylene)carboxyamides *(6)* with electrophilic metal chlorides such as $SbCl_5$ gives *N*-acylchloroformonitrilium salts *(7)*, only addition products can be obtained from *N*-(dichloromethylene)sulfonamides and electrophilic metal chlorides. Also, *N*-[(alkylthio)chloromethylene]sulfonamides cannot be converted into the corresponding nitrilium salts but decomposition reactions occur in which are formed sulfonyl chlorides and adducts of the electrophilic metal chlorides to the alkyl thiocyanates that are split off. Further syntheses with *N*-(dichloromethylene)-sulfonamides lead to substituted 1,3,4-oxadiazoles, 1,3,4-thiadiazoles, tetrazoles, 1,2,4-oxadiazoles, 1,2,4-triazoles, *etc.*

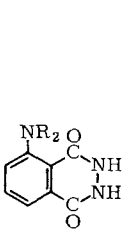
[**] By heterocumulenes are meant compounds having cumulated double bonds, and whose C atoms are replaced by heteroatoms, *e.g.* isocyanates, carbodiimides, thionylimines, *etc.*; cf. *H. Ulrich*: Cycloaddition Reactions of Heterocumulenes. Academic Press, New York-London 1967.

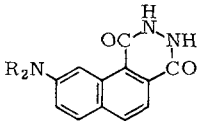
Chemiluminescence of Cyclic Diacylhydrazides and Diazaquinones

By *K.-D. Gundermann* [*]

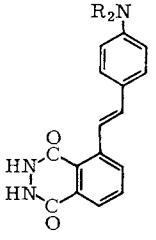
Dialkylamino groups in the 3-position of the phthalhydrazide system are sterically resonance-hindered, and thus compounds of type *(1)* show only very weak chemiluminescence on hemin-catalyzed oxidation in aqueous-alkaline H_2O_2.



(1)

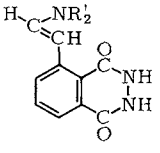


(2)

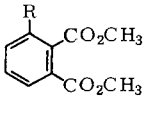


(3)

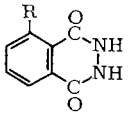
Compounds of type *(2)* [1] [vinylogs of *(1)* in the wider sense] are more effective than luminol (3-aminophthalhydrazide) in purely aqueous systems. However, in mixtures of DMSO and water, hydrazides of type *(3)* [1] and *(4)* [vinylogs of *(1)* in, respectively, the wider and the narrower sense] are much superior to luminol and hydrazides of type *(2)*. Compound *(4)* with R′ = cyclohexyl and *n*-pentyl was synthesized from dimethyl 3-methylphthalate *(5)* by way of the steps *(6)*–*(11)*.

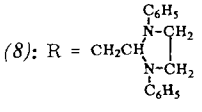


(4)

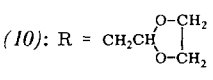


(5): R = CH_3
(6): R = CH_2Br
(7): R = CH_2CN

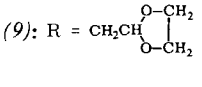




(8): R =



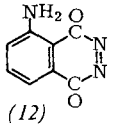
(10): R =



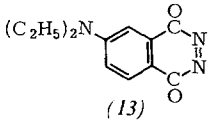
(9): R =

(11): R = CH_2CHO

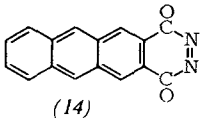
Dehydrogenation of the monosodium salts of the corresponding hydrazides with *tert*-butyl hypochlorite in dimethyl ether leads to the azaquinones *(12)*–*(14)*.



(12)



(13)



(14)

Compounds *(13)* and *(14)* are deep violet in the crystalline state and chemiluminesce when their acetone solutions are mixed with aqueous sodium hydroxide. The light yield is a function of the amount of H_2O_2 present, which, however, can also be replaced by oxygen [2]. The quantitative findings support the mechanism proposed by *Rauhut* [3] for the chemiluminescence of luminol and related compounds, which postulated decomposition of a peroxide of type *(15)* as energy-releasing step.

The Behavior of Modifications of Arsenic Sesquioxide

By *I. N. Stranski* [*]

The behavior of arsenolite (cubic) and claudetite (monoclinic) offends against some of the rules for polymorphic substances, *e.g.*, against the rule that crystals cannot be heated above their transition point (or melting point) and also against Ostwald's stepwise rule. The fundamental assumption [1–5], which has been confirmed by structural analysis of claudetite, is that the two forms differ basically in the nature of the lattice components and in their mode of union: claudetite has a layer lattice with cross-linkage by primary valences within the layers and by van der Waals bonding between the layers; arsenolite, however, contains a molecular lattice of diamond type formed from saturated, isolated As_4O_6 molecules.

All the anomalies in the phase transitions (evaporation, condensation, dissolution, crystallization, melting, and solidification) are caused by the fact that the units of the initial phase must be rearranged to units of the product phase. Appreciable activation energies are required in practice for this process, and particularly so when primary valences have to be cleaved.

The condensation as arsenolite instead of as the stable claudetite that is observed above and below the transition point (*ca.* −30 °C) results because up to *ca.* 800 °C arsenic oxide vapor consists almost exclusively of saturated As_4O_6 particles, whose bonding must be at least partly destroyed before incorporation into the claudetite lattice. Correspondingly, the evaporation of claudetite is hindered in comparison with that of arsenolite, and its rate of evaporation at comparable vapor pressure is lower by many powers of ten, because only secondary valences need to be broken during destruction of the claudetite lattice.

For dissolution and for crystallization from solutions the decisive factor is whether the solvent can (*e.g.*, H_2O) or cannot (*e.g.*, $AsBr_3$) set up an equilibrium between the units composing the various phases. In the negative case measurements of solubility can lead to totally false conclusions about the transition point. That arsenolite can be heated unchanged, not merely above its transition point, but even above its melting point, arises because the melt has a claudetite-like structure, so that cleavage of the lattice is necessary also for conversion into the molten state. Whereas in many cases the activation energy can be lowered catalytically (*e.g.*, by entry of H_2O into the action), it is often added as thermal energy or ion impact in enforced condensations. However, in such cases amorphous, glassy condensates usually result, and

crystalline claudetite is formed only under special experimental conditions.

The modifications of arsenic oxide provide a clear model system for the study of phase transitions that are influenced by structure.

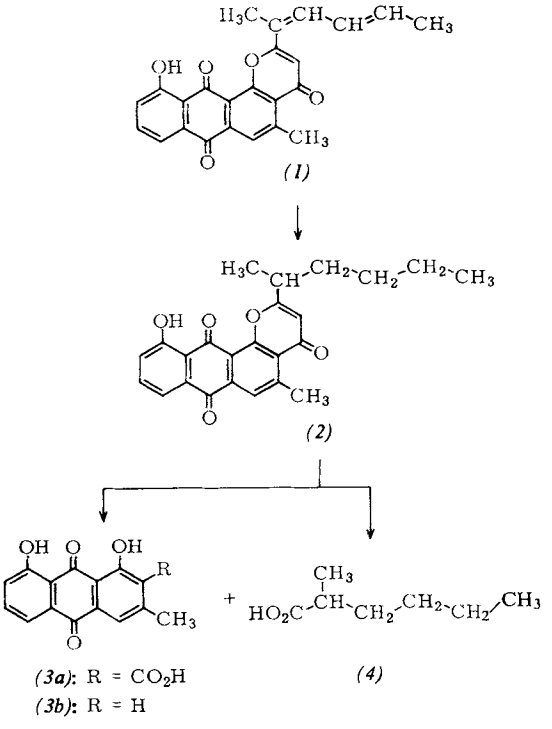
Indomycins and Indomycinones

By *H. Brockmann* [*]

From the mycelium of *Streptomyces* sp. *Ind.* 927, *J. Schnell* [1] has isolated: indomycin A, yellowish-red, provisional molecular formula $C_{40}H_{52}N_2O_{10}$ [6 C–CH_3, NH–CH_3, $N(CH_3)_2$, 5 active H atoms], $[\alpha]_D^{20} = +345°$ ($CHCl_3$), bacteriostatic against *B. subtilis* to a dilution of $1:2.5 \times 10^5$, carcinostatic against Ehrlich ascites tumor at 2 mg/kg mouse; indomycin B, brownish-yellow, provisional formula $C_{38}H_{48}N_2O_{10}$ [5 C–CH_3, NH–CH_3, $N(CH_3)_2$, 5 active H atoms], $[\alpha]_D^{20} = +319°$ ($CHCl_3$), bacteriostatic against *B. subtilis* to $1:2.5 \times 10^6$, carcinostatic against Ehrlich ascites tumor at 2 mg/kg mouse; and indomycin C, brownish-red crystals, provisional formula $C_{41}H_{52}N_2O_{11}$ [6 C–CH_3, NH–CH_3, $N(CH_3)_2$, 7 active H atoms], $[\alpha]_D^{20} = +254°$ ($CHCl_3$), carcinostatic against Ehrlich ascites tumor at 30 mg/kg mouse.

The indomycins have a bitter taste, are yellowish-red in organic solvents, violet in methanolic alkali hydroxide, and red in concentrated sulfuric acid, give a red vat with dithionite, and contain a quinone group with a chelated hydroxyl group. Further, biologically inactive, yellow indomycinones were also isolated from the mycellium; these are either the indomycin chromophores or compounds resembling them very greatly in structure.

The constitution of the yellow crystalline, optically inactive α-indomycinone *(1)* was proved by *K. H. Dahm* [2], by ozone degradation of dihydro- and tetrahydro-α-indomycinone *(2)* to 9,10-dihydro-1,8-dihydroxy-3-methyl-9,10-dioxo-2-anthracenecarboxylic acid, chrysophanic acid *(3b)*, and



(1)

(2)

(3a): R = CO_2H
(3b): R = H

(4)

2-methylhexanoic *(4)* or butyric acid respectively, supplemented by ^1H–NMR and mass spectra of *(2)*, of dihydro-α-indomycinone, and of their acetates. The configuration of the side chain has not yet been established.

Lecture at Clausthal-Zellerfeld (Germany) on January 26, 1968 [VB 156 IE]

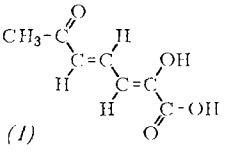
SELECTED ABSTRACTS

Olefins were converted into aldehydes by *H. C. Brown, R. A. Coleman,* and *M. W. Rathke* by hydroboronation of the olefins, treatment of the trialkylboranes with CO and $LiAlH(OCH_3)_3$ at atmospheric pressure and room temperature, and subsequent careful oxidation. Examples: 1-hexene → heptanal (yield 98 %); isobutene → 3-methylbutyraldehyde (91 %); norbornene → 2-norbornanecarbaldehyde (87 %). / J. Amer. chem. Soc. *90*, 499 (1968) / –Kr.

[Rd 840 IE]

Microbiological conversion of 3-methylpyrocatechol into 2-hydroxy-6-oxo-*trans*-2-*trans*-4-heptadienoic acid *(1)* is described by *D. Catelani, A. Fiecchi,* and *E. Galli.* After incubation of 3-methylpyrocatechol with a *Pseudomonas desmolyticum* culture in phosphate buffer of pH = 7, a yellow



(1)

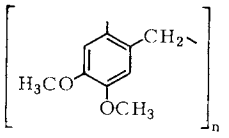
compound of m.p. 122–124 °C (decomp.) could be isolated from the culture liquid; this product was identified as *(1)*. / Experientia *24*, 113 (1968) / –Ma.

[Rd 850 IE]

Exchange of oxygen and hydrogen atoms of *o*-nitrotoluene was observed by *E. K. Fields* and *S. Meyerson.* On pyrolysis of a solution of *o*-nitrotoluene in methanol at 600 °C (11 sec contact time) methyl anthranilate was formed as principal

product (48 mole-% yield). Intramolecular oxidation and reduction yields anthranilic acid which in absence of methanol loses the COOH group and gives aniline. Nuclear-substituted *o*-nitrotoluenes such as 4-fluoro-2-nitrotoluene, 4-chloro-2-nitrotoluene, 3-nitro-*o*-xylene, and nitro-*p*-xylene give 4-fluoro-, 4-chloro-, and 3-methyl- and 4-methyl-anthranilate, respectively, in *ca.* 35 mole-% yield. / Tetrahedron Letters *1968*, 1201 / –Ma. [Rd 851 IE]

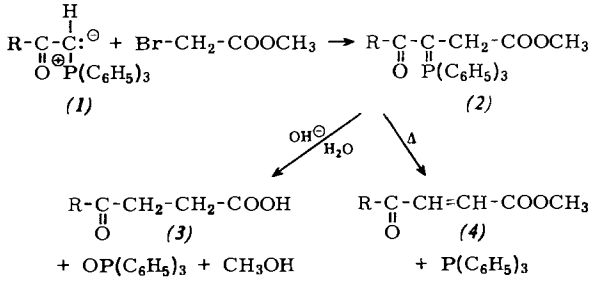
Cyclotetraveratrylene *(1)*, the first derivative of the symmetrical cyclododecatetraene system, was obtained alongside the known cyclotriveratrylene *(2)*, by *J. D. White* and *B. D. Gesner*, when they warmed a solution of 2,4-dimethoxybenzyl alcohol in glacial acetic acid with a few drops of concentrated H_2SO_4 at 90 °C [68 % of *(2)*, 16 % of *(1)*] or treated veratrole in 70 % H_2SO_4 with aqueous formaldehyde at 0 °C.



(1), n = 4
(2), n = 3

In contrast to the rigid crown conformation of *(2)*, the product *(1)* is flexible and provides the possibility of pseudorotation around the methylene-C atoms. At low temperatures the mobile molecule can be frozen in a single conformation (chair or saddle form). / Tetrahedron Letters *1968*, 1591 / –Ma. [Rd 855 IE]

A new synthesis of esters of γ-keto acids and of β-acylacrylates has been described by *H.-J. Bestmann, G. Graf*, and *H. Hartung*. Triphenylphosphineacylmethylenes (β-oxoalkylidenetriphenylphosphoranes) *(1)* react with ethyl bromoacetate in a molar ratio of 2:1 to give triphenylphosphineacylmethoxycarbonylmethylmethylenes (β-oxoalkylidenemethoxycarbonylmethyltriphenylphosphoranes) *(2)* in a yield of about 70 %.



Alkaline hydrolysis of *(2)* in aqueous methanol leads to removal of triphenylphosphine oxide and methanol, with smooth formation of γ-keto acids *(3)* (R = CH_3, 69 %; R = C_3H_7, 45 %; R = C_6H_5, 94 %). The methylene H atoms in the ylides *(2)* are activated by the adjacent ester group. Consequently when the compound is heated to 150–180 °C, it decomposes into triphenylphosphine and the β-acylacrylate *(4)* (R = CH_3, 30 %; R = C_3H_7, 62 %; R = C_6H_5, 85 %). / Liebigs Ann. Chem. *706*, 68 (1967) / –DK. [Rd 798 IE]

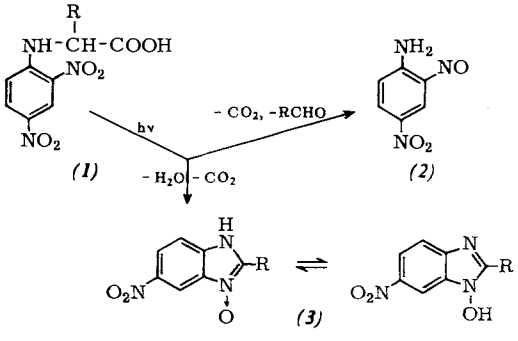
Dimethylaminotrimethylstannane *(1)* **is an efficient dehydrochlorinating agent,** as was found by *D. J. Cardin* and *M. F. Lappert*:

$(CH_3)_3Sn{-}N(CH_3)_2 + Cl{-}A{-}H \longrightarrow (CH_3)_3SnCl{\cdot}HN(CH_3)_2 + A$
(1) *(2)*

The reaction proceeds under mild conditions and almost quantitatively. Compound *(2)* is easily separated because of its low solubility. The efficiency of the reagent is thought to be partly due to the weak, strongly polar Sn–N bond, the high basicity of *(1)*, the high heat of formation of crystalline *(2)*, and in inorganic reactions, the intermediate formation of metal-Sn bonds. Other amido compounds, such as $[(CH_3)_3Sn]_3N$ and derivatives of the more strongly electropositive elements, should behave in a similar manner. Examples: $IrHCl_2(PPh_3)_3$ and $IrH_2Cl(PPh_3)_3$ are dehydrochlorinated in xylene at 80–100 °C within 2 hours and 1.5 hours respectively, with formation of $IrCl(PPh_3)_3$ and $IrH(PPh_3)_3$. At 40 °C *n*-C_4H_9Cl gives 5.2 % *cis*- and 88.5 % *trans*-$CH_3{-}CH{=}CH{-}CH_3$, together with 6.3 % $CH_3{-}CH_2{-}CH{=}CH_2$. / Chem. Commun. *1967*, 1034 / –Ma. [Rd 819 IE]

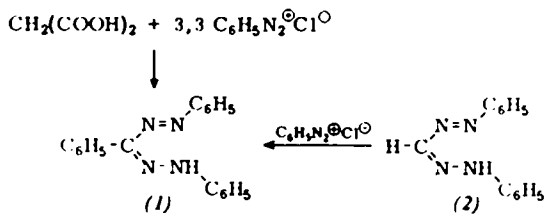
New technetium compounds have been prepared by *J. H. Holloway* and *H. Selig*. When an excess of NO, NOF, or NO_2F was condensed at –195 °C on TcF_6 they obtained the nonvolatile compounds $NOTcF_6$ *(1)* (yellow), $(NO)_2TcF_8$ *(2)* (off-white), and NO_2TcF_7 *(3)* (yellow), respectively. $(NO)_2TcF_8$ has the same structure as $(NO)_2WF_8$ and $(NO)_2ReF_8$, which can be prepared analogously. The magnetic moment of *(2)* (1.72 BM.) is in accord with octacoordinated Tc(VI), but that of *(1)* (2.82 BM.) is too high for this. *(3)* has a magnetic moment of 1.62 BM. / J. inorg. nuclear Chem. *30*, 473 (1968) / –Kr. [Rd 842 IE]

The photolysis of *N*-(2,4-dinitrophenyl)-α-amino acids *(1)* (DNP-amino acids) yields 4-nitro-2-nitrosoaniline *(2)* and/or 2-substituted 6-nitrobenzimidazole 1-oxides *(3)*. *D. J. Neadle* and *R. J. Pollit* studied the well known light-sensitivity of DNP-amino acids and found that *(2)* is generally formed from DNP-amino acids having an α-hydrogen atom. Photolysis of DNP-α-alanine leads to *(3)*, R = CH_3, in a yield that varies in a complex manner with the pH value of the solution.



The photolysis of DNP-threonine leads, as expected, to *(3)* with R = $CHOH{-}CH_3$, and also to *(3)* with R = H; the authors attribute the formation of the latter product to a retroaldol-like reaction. / J. chem. Soc. (London) *C 1967*, 1764 / –DK. [Rd 797 IE]

Triarylformazanes have been obtained by *F. A. Neugebauer* and *B. Küchler*. For example, 1,3,5-triphenylformazane *(1)* was obtained in 44 % yield from 1 mole of malonic acid and 3.3 moles of benzenediazonium chloride in DMF/pyridine (dec. p. 176–177 °C). 1,5-Diphenylformazane *(2)* is converted into *(1)* under the same conditions, so that *(2)* may be assumed to be an intermediate in the formation of *(1)*. The new method is useful for the preparation of substituted triarylformazanes. For example, only 4-fluoroaniline is required for the preparation of 1,3,5-tris(4-fluorophenyl)formazanes,



whereas 4-fluorobenzaldehyde and 4-fluorophenylhydrazine were also required in the old method. Liebigs Ann. Chem. *706*, 104 (1967) DK. [Rd 795 IE]

On electrophilic substitution of monosubstituted [2.2]paracyclophanes *(1)* *H. J. Reich* and *D. J. Cram* found the values given in the table. Compounds *(1a)*-*(1f)* were treated with

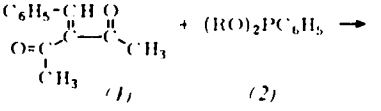
[Rd 845 IE]

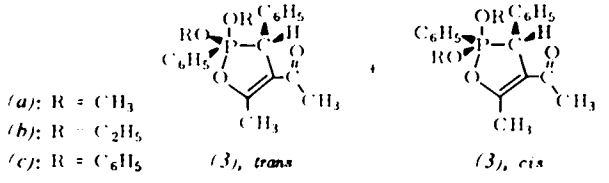
Adsorption of alkali salts onto silica gel from acetone solution was studied by *R. Maatman et al.* for the cases of LiCl, $LiNO_3$, and NaI. Cations and anions are reversibly adsorbed to equal extents (without ion exchange); on addition of small amounts of water (< 2 vol-%) the extent of adsorption increases, but with larger amounts of water decreases again. Langmuir isotherms were used for finding the equilibrium constants for formation of surface species of LiCl ($2-6 \cdot 10^2$ l mole^{-1}) and for $LiNO_3$ and NaI (both ≈ 10 l mole^{-1}). The concentration of the adsorption centers of silica gel varies according to the water content between 0.2 and 0.6 mmole g^{-1} (8×10^{13} cm^{-2}; distance between the centers on regular distribution over the surface ≈ *ca.* 35 Å). No adsorption of salt was found when *n*-propyl, *n*-butyl, or isopentyl alcohol was used as solvent. / J. physic. Chem. *72*, 97 (1968) / -Hz. [Rd 856 IE]

The cause of superconductivity is suggested by *H. Krebs* as being that orbitals of the solid overlap in such a way that electrons are able to move in at least one direction without having to pass through a planar or conical atomic nodal plane. This is verified for the simplest case when the s orbitals form a band that is energetically separated from others in a lattice. This hypothesis is discussed with reference to the bonding in many metallic-conducting inorganic compounds for which superconductivity has been observed. Z. Naturforsch. *23a*, 332 (1968) Hz. [Rd 857 IE]

Stereoisomerism at the P atom of cyclic oxyphosphoranes has been observed by *F. Ramirez, J. F. Pilot, O. P. Madan,* and *C. P. Smith.* From 3-benzylidene-2,4-pentanedione *(1)* and the phosphonite esters *(2a)* *(2c)* they obtained the 1,2-oxa-P^V-phospholenes *(3a)* *(3c)*, which according to the ^{31}P NMR spectra in CH_2Cl_2 at 25 °C exist in two diastereoisomeric forms.



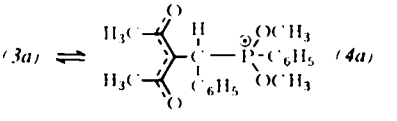
(1) *(2)*



(a): R = CH_3
(b): R = C_2H_5
(c): R = C_6H_5

(3), *trans* *(3)*, *cis*

The phospholene ring of *(3)* occupies an apex and a corner of the basal plane of a trigonal bipyramid, and the P-phenyl ring and an alkoxy group occupy the other two equatorial positions. The other alkoxy group forms the second apex of the pyramid. Interchange between CH_3O and C_6H_5 begins at about 52 °C, and at still higher temperature *(3a)* passes reversibly into the open-chain dipolar form *(4a)*.



(3a) *(4a)*

On reaction of the phosphinite esters $ROP(C_6H_5)_2$ (R = CH_3, C_2H_5, C_6H_5) with *(1)* there is formed only a single compound analogous to *(3)* (containing two equivalent phenyl groups) which also decomposes to a dipolar ion at elevated temperatures. / J. Amer. chem. Soc. *90*, 1275 (1968) / -Kr. [Rd 843 IE]

An eight-membered gold-oxygen ring (with four μ-hydroxo groups) is present, according to *G. E. Glass, J. H. Konnert, M. G. Miles, D. Britton,* and *R. S. Tobias,* in dimethylgold(III) hydroxide, which is tetrameric in the crystalline state and in all the solvents studied. The orthorhombic unit cell contains 32 (monomeric) formula units (space group Pbca, *a* = 19.35, *b* = 9.65, *c* = 19.59 Å). The rings are stacked one above the other and are held together by strong intramolecular hydrogen bonds. The close packing of this stack leads to a very dense structure. Even in solution, $[(CH_3)_2AuOH]_4$ is clearly very rigid; two kinds of methyl protons can be distinguished by NMR spectroscopy up to at least 94 °C. There may be several crystalline modifications of this substance. / J. Amer. chem. Soc. *90*, 1131 (1968) / -Kr. [Rd 844 IE]

Handbuch der theoretischen Chemie (Handbook of Theoretical Chemistry). By *Leopold Gmelin*. Facsimile reprint of the 1st edition of 1817. Verlag Chemie, Weinheim/Bergstr. Vol. 1: 382 pages, Vol. 2: 588 pages, Vol. 3: 664 pages. All three volumes in a cassette, DM 260.–.

At the time when *Leopold Gmelin* first wrote his "Handbuch der theoretischen Chemie" 48 elements had been discovered. Nevertheless, his preface opens with words which could well be read in books published in our own day: "The great advances made in chemistry in recent times, which have rendered worthless otherwise excellent handbooks of chemistry . . . , justify the present author in writing this work." 150 years have passed, and "Gmelin" has grown steadily, both in volume and in stature.

To celebrate this jubilee the Gmelin Institut has issued a facsimile reprint of the long unobtainable first edition of this handbook. The three modest volumes (their binding also follows the style of the original) will impress everyone possessing a sense of history. Few people no doubt are aware that Gmelin's handbook originally embraced inorganic, organic, and, to a lesser extent, physical chemistry. *Berzelius* wrote to *Gmelin* in 1830: "Now that we have your handbook it is no longer any achievement to become a learned chemist, because everyone who acquires and uses a copy is up-to-date with his science." It is fascinating to learn what it was to be up-to-date 150 years ago. The chapter on electricity in *Gmelin* begins "Electricity is sometimes taken to denote 2 unweighable fluids with very many analogous properties but directly opposed in their behavior toward each other, and sometimes only one, the relative excess or deficiency of which produces the manifestations of positive or negative electricity." These words are typical of the outstanding characteristics of this work: its strict, systematic approach, and the efforts of the author to embrace the state of knowledge objectively and exhaustively.

What in 1817 seemed a virtue was no longer so less than 30 years later. *Gmelin* himself, in 1844, wrote in his "Textbook of 'unorganic' chemistry": "The greater my efforts to make my handbook of chemistry more complete with each new edition, the less suitable it becomes for teaching the rudiments owing to the excess of detail. This state of affairs has troubled me so much with the fourth edition, on which I am at present engaged, that I have felt obliged to compile the present textbook for my lectures . . . The essence has been to include only the precepts and facts that are of general theoretical or practical importance". The problem of comprehensiveness *versus* critical selection is thus practically as old as the handbook itself.

The Gmelin Institut deserves our gratitude for the idea of the facsimile reprint, not only because it grants us access to a piece of history, but also, and especially, because the three modest volumes, which represent the entire state of knowledge of their time, encourage us to reflect on the present state of chemistry and on chemical literature from its inception.

H. Grünewald [NB 688 IE]

Gelchromatographie (Gel chromatography). By *H. Determann*, Springer-Verlag, Berlin-Heidelberg-New York 1967, 1st Edit., xii, 204 pages, 40 figures, DM 32.–.

The method of gel chromatography has within a short space of time become a valuable technique used in many chemical and medical laboratories. Its wide scope explains why most reviews describe only parts of the field, or fail to give a comprehensive account of experimental details. The present book closes this gap.

Five chapters describe the present state of gel chromatography. The practical section which describes the gels, the apparatus, and the experimental techniques will be most useful to the novice. Little is as yet known about the fundamentals of gel chromatographic separation, not least because our knowledge concerning the state and properties of cross-linked systems is still very limited. In the theoretical section, the attempt by the author to compare critically the different postulates about gel chromatography will stimulate the reader to reflect our ideas concerning the method and to carry out further experiments.

The sections on principles of application and results show how difficult it is to follow work published in periodicals devoted to different subjects. The detailed descriptions and the numerous literature references make this book a valuable guide for all faced by fresh problems in this field.

It is to be hoped that this book will receive the attention it deserves by workers engaged in the study of those disciplines in which this technique can be used. *W. Heitz* [NB 709 IE]

Acryl- und Methacrylverbindungen (Acrylic and Methacrylic Compounds). By *H. Rauch-Puntigam* and *T. Völker*. Springer-Verlag, Berlin-Heidelberg-New York 1967. 1st Edit., xx, 429 pages, 24 figures, DM 89.–.

The technical development of acrylic and methacrylic compounds began in Germany at the end of the nineteen-twenties and beginning of the thirties. The result was not only Plexiglas and the important polymer dispersions, but also acrylonitrile fibers and polyvinyl chloride *via* the acrylate copolymers. A presentation of this field was therefore urgently indicated, though more difficult than that of individual compounds such as vinyl chloride or styrene.

The large number of possible functional derivatives of the carboxyl group, *e.g.* acids, salts, esters, amides, nitriles, chlorides, and aldehydes, and the manufacture, properties, and uses of the polymers are manifold; furthermore, acrylic compounds readily polymerize and have the ability to copolymerize with one another and with all other vinyl compounds – a host of possibilities which provided a strong stimulus to the development of the field from the very beginning, but which renders the task of making a clear overall survey somewhat difficult.

The authors, evidently themselves active in this field, have accomplished this task successfully.

They begin with a detailed description of the monomers, their preparation, chemical reactions, physical properties, and analysis. α-Substitution products other than the α-methyl derivatives have not been forgotten.

Subsequent chapters deal with polymerization and, in a clear and comprehensive manner, bring the reader up-to-date with the state of affairs in this field.

The sections on the preparation, properties, and application of the polymers, Plexiglas and the methacrylate polymers in general, have been given particular attention. In addition to water-soluble polymers, nitrile polymers, and above all polyacrylonitrile fibers, bead polymerization, and emulsion polymers, the latest developments such as reactive polymers and reactions on polymers are presented in detail.

This excellently produced book concludes with a compilation of the analytical procedures used for characterizing polymers. It will be highly useful to all plastics chemists as an introduction, an all-embracing means of orientation, and a reference work. *H. Fikentscher* [NB 715 IE]

Praktische Chemie für Mediziner (Practical Chemistry for Doctors and Medical Students). By *H.-G. Henning*, *W. Jugelt*, and *G. Sauer*. Verlag Volk und Gesundheit, Berlin 1966, 364 pp., numerous figures, DM 22.40.

In contrast to most textbooks in current use the present work is built up deductively, *i.e.* special cases are treated secondarily and are derived from the general laws. For instance, the

authors assume atoms and chemical bonds to be axiomatic and subsequently derive the laws of stoichiometry and compound formation as a logical consequence.

In place of a senseless enumeration of countless substances, the book concentrates on reactions and compounds important to an understanding of theoretical chemistry. The theory of electronegativity is used to discuss the most important main and subgroup elements. In view of the fact that the book is intended for medical students, it is surprising that theoretical problems are dealt with in such detail. More difficult subjects such as orbital models, energy problems in chemical reactions, kinetics, *etc.* are represented without mathematical ballast but are nonetheless plausible and clear. Selected subjects from the fields of kinetics, electrolytic dissociation (pH, p*K*, titration, buffers, *etc.*), and catalysis are discussed in particular detail, since a knowledge of such topics is indispensable to the biochemist and doctor. The preferential treatment of theoretical problems is particularly welcome.

In the section dealing with organic chemistry the clear presentation and the strict classification of the principal types of compounds and functional groups are a characteristic feature. The modern way of writing organic reaction mechanisms is demonstrated clearly.

The chapter on analytical chemistry is likewise praiseworthy. There is no accumulation of widely varying and rarely occurring ions to overwhelm, plague, and bore the reader, and he is not asked to analyze a blown-up pharmacy. He is, on the other hand, made familiar with modern methods such as photometry, polarimetry, ion exchange, paper chromatography, thin-layer chromatography, *etc.*

W. Littke [NB 694 IE]

Handbuch der Kolorimetrie; Band III: Kolorimetrie in der Biologie, Biochemie und Medizin (Handbook of Colorimetry; Vol III: Colorimetry in Biology, Biochemistry, and Medicine) Part B: Inorganic Part. By *B. Kakáč* and *Z. J. Vejdelék*. Translated by *E. Hachová*. Gustav-Fischer Verlag, Jena. 1966. 1st Edit., xiii, 510 pp., 44 figures, DM 49.60.

The inorganic part of Volume III of this handbook [*] deals with the quantitative analysis of inorganic components in biological substances by means of their light absorption in the visible region. The arrangement of the book follows that of the periodic table. In addition to normal salt-like constituents of vegetable and animal tissues or liquids, it is necessary to determine chemically bound metals such as iron, magnesium, cobalt, zinc, and also the toxicologically important elements arsenic, lead, mercury, chromium, *etc.* The preparation of the material to be analyzed is described in detail, especially the "mineralization" necessary in many instances. As in previous volumes, detailed instructions and critical comments regarding sensitivity, reproducibility, and sources of error constitute a most valuable aid to the user. The now complete work unquestionably fills a gap, and is likely to prove indispensable in biological, medicinal, and pharmaceutical laboratories, where photometric determinations are frequently carried out. It provides an effortless and yet reliable guide to the available methods.

H. Böhme [NB 723 IE]

The Organic Chemistry of Nitrogen. By *N. V. Sidgwick*. Edited by *I.T. Millar* and *H. D. Springall*. Oxford University Press, London 1966, 3rd Edit., xii, 909 pages, numerous illustrations, bound, 168 s.

The well known book by *N. V. Sidgwick* (1873–1952) published in 1910, the 2nd edition of which was rewritten in 1937 by *T. W. J. Taylor* and *W. Baker*, has been completely revised for the 3rd edition by *I. T. Millar* and *H. D. Springall* of Keele University. Its size has been increased by about 50 % in comparison to the 1937 edition. In 1910 *Sidgwick* (the reviewer is happy to record the presence of a detailed biography) may have found it attractive to classify the organic chemistry of nitrogen separately from the rest of the material. In 1937 such an arrangement was already problematic, not only because of the interim growth of the material, but above all because by then the "nitrogen part" of organic chemistry had become so interwoven in the general subject that its isolation in the form of a textbook must have been recognized as a risky undertaking.

The introduction to the third edition, appearing a whole generation later, indicates that the new authors have been conscious of this problem. The arrangement of the book leads one to conclude that the last chapter, Nucleic acids (44 pages), is intended to be the great climax for which the other chapters prepare the way; it is surely for this reason too, that Diazines (40 pages) have been restored. Unhappily, it is in the field of nucleic acids more than in any other that progress is so rapid that to talk of the state of knowledge in 1964 – representing the scope of the book – is rather like discussing olden days. In fact, descriptions such as those given on pages 834, 849 and 864 were already out-of-date at the time of publication.

In the 28 preceding chapters it is in many instances precisely the highlights of organic nitrogen chemistry since 1937 which have fallen victim to mere reference to other monographs. What remains is pure textbook chemistry on subjects about which good reviews have long existed in most languages, albeit not, as here, in the straitjacket of the nitrogen aspect. Is there any point in describing acid amides, nitriles, and amines in textbook form without mentioning carboxylic acids and alcohols?

The present book suggests an unequivocal negative.

The chapter on Amides (pp. 223–250) makes no reference to *Meerwein*'s work on acid amide acetals, which set a new landmark in this field. The Vilsmeier-Haack method is no more mentioned than is its elegant extension by *C. Jutz*. The names *B. N. Menschutkin, T. Zincke, W. König, N. J. Leonard* and many others are conspicuous by their absence. For a mention of the great champion of nitrogen chemistry, *Theodor Curtius*, one might have been prepared to sacrifice the somewhat less important and unsupported historical references, such as (p. 796) "*Baeyer* named the product after a girl called Barbara, with whom he was in love at the time". In the discussion of azo compounds there is no mention of *S. Hünig*'s method of oxidative azo coupling, a surprising omission in an allegedly exhaustively investigated subject. The immonium-carbonium mesomerism which illuminates so many reactions of organic nitrogen compounds is not dealt with. In addition, it hardly seems proper to scorn all mention of spectroscopic data and discussion.

Other important subjects are dismissed too summarily, *e.g.* the enamines (pp. 132–134) whose essential character is not elucidated. The esters of cyanic acid, like the pentazoles, receive only a few lines, though these chapters do not yet appear in conventional textbooks.

These are just a few examples. The expert knowledge in the chapter by *R. McWeeny*, Quantum Theory of Valence, has not rubbed off on any of the remaining chapters.

Most important of all, in view of the book's basic construction, the fundamental question to be asked about any book – to what circle of readers should the book be recommended – is unanswerable.

Synthetic Methods of Organic Chemistry, Vol. 21. By *W. Theilheimer*. S. Karger, Basel-New York 1967. 1st Edit., xx, 540 pp., numerous figures and tables, SFr 195.–/DM 195.–/ $ 46.80.

Volume 21 continues the well-known and proven series in the accustomed manner [1]. Classification and selection therefore

[*] Cf. Angew. Chem. *79*, 328 (1967); Angew. Chem. internat. Edit. *6*, 380 (1967).

[1] Cf. Angew. Chem. *79*, 283 (1967); Angew. Chem. internat. Edit. *6*, 277 (1967).

need no explanation. There are 462 pages, containing almost 1000 examples selected from the literature between 1964 and 1966. The value as specifications for synthesis goes beyond that of individual cases, and can thus serve as a welcome stimulus for original work. Embraced are starting materials, products, and methods spanning the whole of organic chemistry. It is evident that the synthesis of carbocyclic and heterocyclic compounds is progressively gaining in importance. Reading the "Trends in Synthetic Organic Chemistry" (7 pages, 86 refs.) is particularly stimulating; this contains well-defined novel syntheses. A well arranged and very detailed subject index (112 pages) considerably assists orientation, especially if the classification system used is not to the readers's liking.

It is necessary once again to consider whether the mass of information compiled between the covers of the 21 volumes would not be even more accessible with the aid of a cumulative index in the form of a punched card register.

S. Hünig [NB 722 IE]

Hyperfine Interactions. Edited by *A. J. Freeman* and *R. B. Frankel*. Academic Press, New York-London 1967, 1st Edit., xvi, 758 pages, $ 16.00.

The present book is part of a report of a NATO Advanced Study Institute meeting held between the 8 and 26 August, 1966, in Aix-en-Provence, France. The reader is spared a word-for-word rendering in that each lecture has been rewritten in the form of a readily understandable report after the meeting. Thus, even the layman can obtain an insight into the complex material presented.

The book consists of 25 contributions by specialists on aspects of hyperfine interactions such as nuclear spin resonance, paramagnetic resonance, atomic radiation resonance, perturbed angle correlations, dynamic polarization and relaxation, optical hyperfine structure determinations, specific heats of nuclear spin systems, and the Mössbauer effect. Individual, more theoretical articles concern the Hartree-Fock theory of the hyperfine interaction in atoms and magnetic compounds, the calculation of the magnetic hyperfine structure constants of the ground state of light atoms and also the conductivity electron density and spin density effects of dislocations and localized moments in metals.

The discussion concentrates on hyperfine interactions in inorganic solids and in individual atoms. No description is given, however, of hyperfine interactions in organic molecules and radicals, which are important for chemists interested in analytical aspects. *Bleaney* presents a didactic introduction to paramagnetic resonance, *Narath* to nuclear spin resonance in solids, *Abragam* and *Kirsch* dynamic polarization and relaxation, *Mössbauer* and *Cläuser* the Mössbauer effect, and *Cohen* the perturbed angle correlations of nuclear gamma rays.

Gschwind contributes a more detailed account of the paramagnetic resonance of ions in the excited state, and of electron spin-nuclear spin double resonance (ENDOR), *Steudel* deals with optical hyperfine interaction measurements using a double Fabry-Pérot interferometer, *Budnik, Skalski,* and *Shaltiel* nuclear resonance in metals, *Dekker, de Waard, Housley, Gonser,* and *Walker* the Mössbauer effect and *Matthias, Karlsson,* and *Murnik* perturbed angle correlations.

Lounasmaa, Stone, and *Lubbers* discuss the specific heat, cooling effects, and orientation of nuclear spin systems.

This conference report provides a wide survey of the current position and problems of hyperfine interactions in solids, atoms, and ions and can therefore be confidently recommended to the solid state physicist, the physical chemist, and the inorganic spectroscopist.

The analyst working with organic materials will find it of little interest because, as mentioned above, the hyperfine interactions of organic compounds have been omitted.

F. Kneubühl [NB 707 IE]

Introduction to the Principles of Heterogeneous Catalysis. By *J. M. Thomas* and *W. J. Thomas*. Academic Press. London-New York 1967. 1st Edit., x, 544 pp., numerous illustrations and tables, 120 s.

The scientifically very stimulating and technically very important field of heterogeneous catalysis has been the subject of several large collective works and a number of periodical publications (Congress Reports, Advances) during past decades. For some time, however, no modern monograph has been published that embraces the overall field. This is all the more surprising in that research in this sector, both in academic and in industrial laboratories, has assumed very large proportions and is still growing. In addition, universally applicable results have been obtained in many of the subsidiary fields.

In view of the accumulated literature it is not merely remarkable but also in a sense praiseworthy that the two Welsh authors, both students of *K. W. Sykes*, should have undertaken to fill the gap. *J. M. Thomas* is responsible largely for the scientific, and *W. J. Thomas* for the technical chapters. The authors have succeeded in covering all the important aspects while still adhering to their avowed principle that brevity is the key to understanding: Introduction; Adsorption; Experimental Aspects; Pore Structure and Surface; Lattice Dislocations; Geometric, Electronic and Related Factors; Selective and Polyfunctional Catalysts; Mechanism of Typical Reactions; Reactor Design. In all chapters extensive reference is made to the original literature, so that the work, though intended as a textbook for undergraduates and young researchers, can also be used as a work of reference. Naturally, it is possible to disagree on the relative prominence given to various subjects, *e.g.* the overemphasis placed on adsorption at the expense of mixed catalysts, or the electronic factor; however, the book presents the most important things consisely but understandably throughout. The stimulating effect of such books has been proven by experience, and Thomas-Thomas will be of incalculable value to all who work in, or who wish to take up, this field. Printing and presentation are commensurate with the price and up to the publisher's usual standard. *G.-M. Schwab* [NB 706 IE]

Infrared Spectra of Adsorbed Species. By *L. H. Little*, supplementary chapters by *A. V. Kiselev* and *V. I. Lygin*, Academic Press. London-New York 1966. xii, 428 pages, numerous illustrations, 100 s.

Infrared Spectroscopy in Surface Chemistry. By *M. L. Hair*, Marcel Dekker Inc., New York 1967. xiii, 315 pages, several illustrations, $ 15.75.

The chemistry of solid surfaces has attracted increasing attention in recent years, owing largely to the investigation of heterogeneous catalysis reaction mechanisms and of intermediate products. Quite apart from pure scientific interest a knowledge of the state of the surface and its reactions is becoming increasingly important for other investigations, *e.g.* the study of pigments and the incorporation of fillers in polymers. IR spectroscopy furnishes a great deal of information about functional groups on surfaces, their interaction with adsorbed molecules, and about the groups formed. The same technique can be applied to the study of thin metal films and finely divided metals deposited on carriers.

Almost simultaneously, two books have appeared which aim at describing the method, its potentialities, and its limitations, as well as that which has already been achieved. Comparison of the two works reveals that *Little*'s book contains a good deal more text than is suggested by its extra hundred pages. Closer line spacing and fuller pages are responsible, but the penalty is that reading becomes much more tiring. *Little* gives a more comprehensive selection of literature references and includes many papers which contribute to the study of surface chemistry without IR measurements. Furthermore, his book reproduces many more spectra. By way of contrast,

Hair attempts to provide a coherent account at the expense of detail, and evaluates the literature according to his own concepts. This latter book is thus easier to read. Certain formulations, *e.g.* covalent −Al=O double bonds (*Hair*, p. 166) should be overlooked.

Unhappily, as so often in the past, neither author does anything like justice to literature that has appeared in languages other than English. All the more welcome, then, that *Little* has been able to get the Soviet researchers *A. V. Kiselev* and *V. I. Lygin* to contribute their own wide-ranging experience and the abundant Russian literature. The use of IR spectroscopy in the study of surfaces can be traced back to work by *Terenin* in the early nineteen-forties.

As an introduction *Hair* provides several chapters on adsorption and IR spectroscopy which *Little* assumes to be already familiar. *Little* describes the experimental technique in greater detail and more thoroughly. Both authors give special treatments of the OH groups on oxide surfaces, above all on silica, and the surface acidity of silica-alumina adsorption on zeolites, and the chemisorption of carbon monoxide on metals and metal oxides. *Little* deals in detail with the adsorption of hydrogen and hydrocarbons. The literature up to about 1966 has been taken into account, and *Little* appends a list of the most important articles published after his book had gone to print.

Both books can be recommended. *Hair* provides a good survey of, and the results obtained with, the technique, while *Little* gives more information about special problems and is, moreover, less expensive. *H. P. Boehm* [NB 719 IE]

The Palladium-Hydrogen System. By *F. A. Lewis*, Academic Press, London-New York 1967, 1st Edit., xii, 178 pp., numerous illustrations, 45 s.

The well-known monographs on hydrogen in metals by *Smith* and by *Gibb* have, to some extent, been superseded by recent developments. The present book, by *Lewis*, reviews the present state of research specifically in regard to the system palladium-hydrogen. This system is of particular theoretical interest as the prototype of a simple alloy, but it is also of practical interest as a membrane material for fuel cells and for the purification and isotopic separation of hydrogen.

The results of both old and recent work on the thermodynamic, chemical, mechanical, electrical, and magnetic properties are presented in a thoroughly comprehensive manner; separate chapters are devoted to the absorption of hydrogen in palladium alloys, to diffusion, and to isotopic separation. A short chapter deals with attempts to provide a theoretical insight into hydrogen absorption by means of model representations.

No final picture can be expected of a field which is in a state of such intensive development, with active research being conducted in numerous laboratories. It is precisely in such laboratories that this book will be of great help because of its complete literature survey, a factor which should also ensure it a wide distribution.

H. Brodowsky [NB 699 IE]

Fractional Solidification. Vol. 1. Edited by *M. Zief* and *W. R. Wilcox*. Marcel Dekker, Inc., New York 1967, 1st Edit., xvi, 714 pages, numerous illustrations and tables, $ 28.75.

Research and production processes involving solvent-free recrystallization from the melt are becoming progressively more important. The editors, well known from their own work in this field, and twenty specialists chosen by them have succeeded in unifying the individual methods of separation in an all-embracing work, thus finally closing the gap between detailed individual works (*e.g.* about zone melting) and review articles.

Part I lays down the thermodynamic basis of fractionating crystallization from the melt, Part II deals with laboratory apparatus (normal solidification, discontinuous and continuous zone melting with modifications, column crystallization, zone reprecipitation as a transition from recrystallization from solution), and Part III outlines industrial techniques (particularly multiple crystallization by means of cooled drums and the Phillips process). Industrial desalination of sea water brings us to the applications section (Part IV), which deals especially with electronics (semiconductors *etc.*), ultrapure pharmaceutical preparations, analysis, and special techniques. Part V deals briefly with economic aspects. About 1500 literature references, 40 tables, and 266 illustrations in the form of photographs, technical drawings, or diagrams ensure comprehensive evaluation of the material. Part VI consists of a tabular appendix of about 130 inorganic elements, compounds, and systems (298 references), about 110 organic compounds, individual data for 250 organic substances (126 references), and 71 patents to aid the chemist or metallurgist in his investigation. *K. Maas* [NB 701 IE]

Soil Biochemistry. Edited by *A. D. McLaren* and *G. H. Peterson*. Marcel Dekker Inc.. New York 1967. 1st Edit., xiii, 509 pp., numerous figures, $ 22.75.

This monograph represents a collective effort by 25 English-speaking authors. The book is in three parts: I. Isolation and characterization of biochemical components of the soil, *i.e.* nitrogen compounds, nucleic acids and derivatives, organic phosphates, carbohydrates, organic acids, and free radicals. Part II deals with metabolisms, energetic relationships such as photosynthesis, respiration, enzymatic and chemoautotropic reactions, nitrogen-, phosphate-, and sulfur cycles, lignin degradation and humic acid formation, microbial decomposition of phenol, decomposition of herbicides and surface-active agents, and enzyme reactions in the soil. Part III presents microbiological and biochemical aspects of the rhizosphere, and, finally the discussion even extends to the exploration of the surface of planets.

The number of publications, experimental results, and interpretations in the complex field of soil biochemistry has become so vast that no individual can now embrace them all. The authors deserve our gratitude for going to the trouble of sifting the literature of the past 70 years (in some parts of the book up to 1966) and for summarizing and interpreting 2147 publications. The inclusion of not only the English-language literature but also of important references in other languages is particularly welcome. The book, which is entirely up-to-date, introduces the reader to the problems involved in a succint and pregnant manner.

Despite the number of contributors involved, the book is written in a remarkably uniform style. Its content is very well balanced and the work can claim considerable scientific and didactic merit. The first chapter "Introduction to the Biochemistry of Terrestrial Soils" could, it is true, have been omitted without loss, as it contains an arbitrary and not always skilful enumeration of a number of processes and facts which are dealt with again much more soundly in later chapters. A number of misprints will have to be eliminated from subsequent editions.

The two editors are to be warmly congratulated for a book which is recommended to all interested in the chemistry and biology of soil. *F. Scheffer* [NB 725 IE]

Richard Kuhn in Memoriam [*]

BY O. WESTPHAL [**]

"You may call me an 'experimental philosopher' who endeavors to get at the root of things not only by cogitation but also by experimenting." (*R. Kuhn* [1])

Richard Kuhn was born on December 3, 1900, in Vienna-Döbling (Fig. 1). His father, Councillor *Richard Clemens Kuhn*, was a hydraulic engineer in the Austrian Government Service. It is reported that he

Fig. 1. Birthplace of *Richard Kuhn*, where he also spent his youth.

was held in general esteem and had carried out important projects such as the reconstruction and modernization of Trieste harbor and the planning of the Oder-Danube Canal. He liked music and was an accomplished pianist. His mother, *Angelika* née *Rodler*, was a primary school teacher and retained her profession after the birth of the two children, *Angelika*, and a year later *Richard* (Fig. 2).

Richard Kuhn received an unusual schooling. His mother taught him at home for several years, covering the entire primary school curriculum. He only had to

Fig. 2. The parents, with daughter *Angelika* and son *Richard* in 1907.

report once a year for examinations and was told: "Good, carry on." He started his first regular schooling in 1909 when he entered the Döbling Gymnasium. There he spent eight years together with his friend *Wolfgang Pauli*, who later became a renowned physicist. *Pauli* and *Kuhn* remained lifelong friends, and would often recollect exciting hours spent with their physics and mathematics teacher *Kottenbach*, who, many years later, at the age of 85 was still being visited by *Kuhn* in Austria.

When only 12 years of age *Richard Kuhn* was greatly influenced by a friend of the family, Professor *Ernst Ludwig*, who was Director of the Institute of Medical Chemistry of Vienna University. *Ludwig* took his teaching duties very seriously, especially the demonstration of experiments, and when he was preparing his lectures over the weekend the young *Richard Kuhn* was allowed to accompany him and to take part in preparing the experiments. "There were many wondrous things indeed: mercury solidifying in liquid air,

[1] *R. Kuhn*, From the address delivered on the occasion of the conferring of the honorary degree of Doctor of Philosophy by Vienna University, December 13, 1960.

metals precipitated from solutions by electric current, and vast quantities of rowan berries which were used in those days for extracting malic acid" [1]. *Ernst Ludwig* made him a present of his "Lehrbuch der Chemie für Aspiranten der Pharmazie", which *Kuhn* studied avidly every evening. *Kuhn*'s graduation was also unusual. It was the end of 1917, the war was approaching its climax, and young men were being mobilized. *Kuhn* was also called up and found fit. "At the Gymnasium they thrust my graduation certificate into my hand without any written or even oral examination ... and next day I was reporting to the Signals Regiment in St. Pölten." At St. Pölten he had to take part in security duties during those troubled days, particularly towards the end of the war, and lived through some rather difficult times. On November 18, 1918, he was discharged "until further notice" and, as he once remarked later, remained in that status all his life.

A few days later, on November 22, 1918, he was already eagerly seeking admission to Vienna University. There is a photograph of him, which he had taken for his parents for Christmas of that year (Fig. 3).

Fig. 3. *Richard Kuhn* in Vienna, end of 1918.

It was very difficult to obtain working space in a laboratory in Vienna in those days but, with the help of his godfather, Professor *Richard Paltauf*, Director of the Institute of Pathology, *Kuhn* obtained a laboratory position at the Institute of Medical Chemistry under Professor *Hans Fischer*, who had in the meantime succeeded *Ernst Ludwig*. His actual teachers, however, were *Wilhelm Schlenk* and *Rudolf Wegscheider*. *Kuhn* recalled that *Wegscheider* always used to lecture around 3 P.M. and that this may have been the reason for poor attendance by students; *Kuhn* regretted this very much because he was deeply influenced by *Wegscheider*'s lectures on physical chemistry. He also studied analytical chemistry very seriously under *A. Franke*.

After three semesters and two excellent intermediate examinations under *Schlenk*, *Kuhn* moved from Vienna to Munich. He was aware of the world renown of *Richard Willstätter* (Fig. 4) and had heard of his famous lectures.

Fig. 4. A lecture by *Richard Willstätter*, Munich, 1921.

Kuhn was attracted by *Willstätter*'s virtuosity in organic synthesis and especially by his mastery of research into plant dyestuffs. *Kuhn* found great aesthetic joy in beautiful colors, and, with an early developed appreciation of formulas, he soon admired and was attracted by *Willstätter*'s work. He worked in Munich at an accelerated pace. He was frequently tested, and was progressively given more and more laboratory exercises and assignments. He carried out analyses under Professor *Lecher* so quickly and accurately that it was often thought that something must be amiss; ever more difficult analyses were presented to him, but he mastered them all. Thus, after only six semesters, he was allowed to begin his doctor's thesis under *Willstätter* on the "specificity of enzymes in carbohydrate metabolism". On November 22, 1922, four years to the day after he entered Vienna University, *Kuhn* obtained his Doctorate with the highest marks that could be given.

In the course of the work on the doctorate thesis, *Willstätter* suggested to the young *Kuhn* that he should study seriously the most advanced methods of analytical chemistry. In those days, microanalysis had been developed in Austria to a high level of perfection and accuracy. *Kuhn* interrupted work on his doctorate and returned temporarily to Vienna to study organic analysis under Professor *E. Philippi*. He later wrote that he owed *Philippi* particular gratitude because "most of the work which I undertook later would have been impossible, owing to the very small quantities of substances available, without the techniques which I learned from him. The extent of his influence on me may be assessed from the fact that later, not only as a lecturer in Munich but even for some time as Professor in Zurich, I carried out with my own hands innumerable microanalyses for my doctorate students and assistants" [1].

The remarkable photograph (Fig. 5), dated 1922, symbolizes the exceptional esteem of the great teacher *Willstätter* for his student *Richard Kuhn*. In turn, *Kuhn* was obviously deeply influenced by *Willstätter*. Among other things, *Kuhn*'s later brilliant lectures had many features in common with *Willstätter*'s fascinating art of lecturing.

Kuhn's early life in Munich was very primitive. He was several times evicted by the City Fathers as an "undesirable alien" from the central part of the city where there was an acute shortage of accommodation, so that he had to live a considerable distance from the Institute, which he covered on foot.

Fig. 5. *Richard Willstätter* and *Richard Kuhn* in Munich in 1922.

Once he forgot to shut the skylight in his attic, and on his return found snow covering his habilitation thesis which, in those days, was still written by hand. Many pages were completely disfigured. After the first shock, *Kuhn* accepted the mishap with good grace and rewrote the spoiled pages in his fine hand. There are still in existence some yellowed manuscripts, never handed in, on investigations which he obviously thought unsuitable for publication, which show how very clearly, with only a few alterations and minor corrections, the entire concept was already formed in his mind.

A few months before *Kuhn*'s doctorate, in August 1922, *Willstätter* requested for his 50th birthday that the festive address at the Munich Arts Gallery be read by his favorite student. *Willstätter*'s esteem for *Kuhn* was enormous; he recognized a promising talent and did all he could to foster it. We know of how, in the difficult days of inflation, he provided funds for *Kuhn* to attend a Congress in Edinburgh by casually slipping dollars into his pocket, and of other such instances of help to the young student. *Willstätter*'s Memoirs[2] contain vivid descriptions of life in Munich in the early 1920's, with its political and economic chaos.

Even in those early days *Kuhn* was distinguished by rapid comprehension, enormous powers of insight and imagination, and very high precision and discipline in his work. *Kuhn* came to Munich at a time when *Willstätter* was switching over from classical organic chemistry to the chemistry of enzymes (see[2], pp. 331–332). One of the first, and particularly significant, accomplishments of the young *Richard Kuhn* was that he convinced *Willstätter* of the importance of quantitative physicochemical methods of identification and of accurate kinetic measurements in enzyme chemistry. He introduced such methods for accurate measurement of reaction rates, for determining activities, and for following quantitatively enzyme enrichment and purification processes. *Willstätter* was very impressed and mentioned this to many leading chemists of the day. Thus, he suggested to his friend *Fritz Haber* that there should be more properly organized physical chemistry departments in Germany.

These early enzyme studies also involved absorption and elution methods with carrier substances, which were to become so important later. As substrates for enzyme studies, *Richard Kuhn* used glucosides, oligosaccharides, and polysaccharides, *i.e.* sugar derivatives. Specificity studies led him inevitably into stereochemistry where he found his first great field of independent work. Together with *Friedrich Ebel*, his first doctorate student, he studied the optical activity of substances obtained by addition to ethylenic double bonds, *e.g.* by addition of hypochlorous acid to fumaric and maleic acids; the chloromalic acids and their ring closure to ethylene oxide dicarboxylic acids[3]. *Ebel* obtained his doctorate with "*summa cum laude*", and this greatly increased the influx of doctorate students to the 23-year old *Kuhn*. Using the classical example of the Walden inversion, *Kuhn* and *Theodor Wagner-Jauregg* determined the stage of the reaction at which the steric rearrangement of the substituents takes place[4].

For his habilitation, which took place on March 3, 1925, in Munich, *Kuhn* presented a paper on the "Mechanism of Action of Amylases"[5] and gave a lecture on "The Role of Theory in Organic Chemistry" In addition, he put forward twelve theses (Fig. 6).

Habilitations-Schrift:

Der Wirkungsmechanismus der Amylasen; ein Beitrag zum Konfigurations-Problem der Stärke.

Probe-Vorlesung:

Die Stellung der Theorie in der organischen Chemie.

Thesen:

1. Bei den Phosphor-molybdänsäuren wird die Vereinigung von mehr als 12 MoO_3 mit 1 P durch gleichzeitigen Einbau von Schwefelsäure-, Selensäure- und Tellursäure-Resten in das Kristallgitter ermöglicht.
2. Es ist zu erwarten, daß Chlordioxyd paramagnetisch ist.
3. In den Grundgleichungen der chemischen Kinetik ist, soweit sie sich auf die Reaktion zwischen ungeladenen Molekülen und Jonen in wässriger Lösung beziehen, die Annahme der Proportionalität zwischen Reaktionsgeschwindigkeit und Konzentration der reaktionsvermittelnden Molekülgattungen aufzugeben.
4. Die Abhängigkeit katalytischer Hydrierungen vom Sauerstoffgehalt des Platins bezw. Wasserstoffs steht mit dem Einfluß des Sauerstoffs auf die Intensität der Balmer-Serie in Einklang.
5. Bei Alkyl-halogeniden findet der Ersatz von Halogen durch die SH-Gruppe ohne intermediäre Bildung des entsprechenden Olefins statt.
6. Die Spannungstheorie A. v. Baeyers hat die Entwicklung unserer Kenntnisse von den höheren Polymethylenen und ihrer Derivate entscheidend gehemmt.
7. *Es liegt kein Beweis für die Richtigkeit der Zuckerformeln E. Fischers in der nach B. Tollens* üblichen Modifikation vor.
8. Das Gaultherin stellt das einfachste bisher bekannte natürliche Derivat des Traubenzuckers dar, das keinen butylenoxydischen Sauerstoffring besitzt.
9. Aus der Affinität einer Malzamylase zur Stärke läßt sich auf die Lage der Verzuckerungsgrenze schließen.
10. Die meist weitgehende Dissoziation der Enzym-Co-enzymbindung (Zymase-Cozymase, Trypsin-Enterokinase, Amylasen-Neutralsalze) bedeutet für die Organismen eine wichtige doppelseitige Regulierungsmöglichkeit ihrer fermentativen Funktionen.
11. In der Erholungsphase des Muskels findet neben der Verbrennung von Milchsäure ein Wiederaufbau von Kohlehydraten aus Milchsäure statt.
12. Der Insulintod, in vielen äußeren Symptomen dem Hungertode gleichend, stellt einen Erschöpfungstod in Bezug auf die Zucker-Reserven dar.

A 631.6 — Universitäts-Buchdruckerei Dr. C. Wolf & Sohn, München.

[*] The author is indebted for a copy of the printed invitation to Dr. *Leonhard Schuler*, Heidelberg, who was at that time a chemist in Munich.

Some of the theses were rather provocative for Munich, especially Thesis No. 6 (Fig. 6) which criticized Baeyer's strain theory. *Adolf von Baeyer*, *Willstätter*'s predecessor at the Department of Organic Chemistry, was for many years regarded in Munich as the high priest of organic chemistry. *Kuhn* claimed that the hydroaromatic rings should not be considered planar, as assumed by *von Baeyer*, but puckered, thus making it possible to explain in a simple way the stability of rings with seven or more methylene groups. In this, *Kuhn* considered himself a disciple of *van't Hoff* and of his concept of a tetrahedral carbon atom with its four valences.

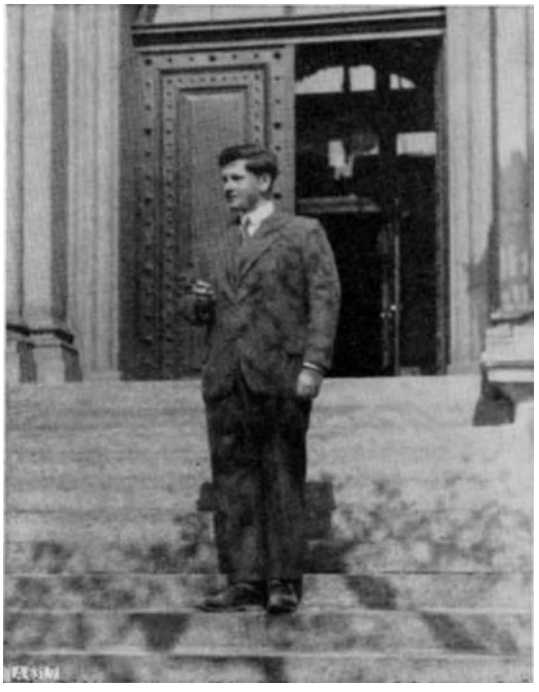

Fig. 7. *Richard Kuhn*, as a 27-year old ordinary Professor of Organic and Analytical Chemistry, at the gate of the Chemical Institute of the ETH in Zurich.

Only eighteen months after his habilitation, following a special recommendation by *Willstätter* [6] (who had himself declined the invitation), *Kuhn* was invited to take over the Department of General and Analytical Chemistry at the Federal Technical University of Zurich. In his inaugural lecture [7] on June 18, 1927, *Kuhn* developed a kind of program for the chemistry of those days, and said that it follows three paths. One path leads to *theoretical research*, governed by numbers and measurements. A second path leads to *technology* and here *Kuhn*, an Austrian by birth, was singing to his Swiss audience in the year 1927 a hymn to German chemical technology, of which he remained a lifelong admirer. A third path leads to *biology*. In a remarkable train of thought, he added that, in the final analysis, the triad which he was endeavoring to express might well be rooted in the very psyche of man and might correspond to an age-old nostalgia: dreams on the nature and the origin of things, the dream of gold, and the dream of eternal youth.

One of his enthralled listeners in Zurich was *Daisy Hartmann*, a student of pharmacy. They were married in 1928 and had two sons and four daughters.

The three years from October 1926 to October 1929 saw the beginning of many investigations of particular importance in his life's work. Among the problems which *Richard Kuhn* tackled in Zurich, and which originated in his stereochemical investigations was the restricted rotation around carbon-carbon bonds in biphenyl derivatives. He was especially interested in the *ortho*-substituted biphenyls showing restricted rotation. In those days, however, the formulas [8] of the two enantiomorphs shown in Fig. 8 were by no means proved.

Fig. 8. Mirror image forms of *ortho*-substituted biphenyl derivatives [8].

For a long time, the folded form *(1)* (see Fig. 9) was also considered as a possible conformation for biphenyl derivatives and was based on the concepts of *Kaufler* [9]. Together with *Zumstein* [10], *Kuhn* was the first to show clearly that the distance between the two amino groups of benzidine cannot be of the order of 1.5 Å as in formula *(1)* but must be of the order of 10 Å as in the stretched formula *(2)* shown in Fig. 9. Only the stretched shape can explain the restricted rotation observed in so many *ortho*-substituted biphenyls.

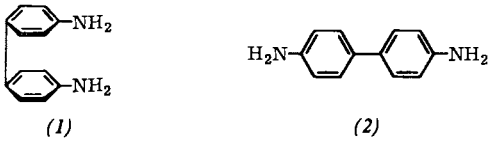

Fig. 9. The two space formulas of benzidine [8].

A short time earlier, *Bjerrum* [11] had shown that the distance between charged groups can be established by determining the ratio of the respective dissociation constants. *Kuhn* applied *Bjerrum*'s quantitative theory to his problem and found unambiguously [10] that form *(2)* and not form *(1)* corresponds to reality.

One of the first quantitative determinations of the activation energy for the rotation of *ortho*-substituted diphenic acids was published by *Kuhn* and *Albrecht* as early as 1927 [12, 13].

While the *o,o'*-dinitrodiphenic acid antipodes cannot be racemized, even under vigorous conditions, the *o,p'*-dinitrodiphenic acid is racemized with an activation energy of 26 kcal/mole. This work was followed by several similar investigations by other authors, especially *Roger Adams* in the USA, in which the space requirements of substituents were determined quantitatively for the first time. In *Karl Freudenberg*'s "Stereochemie", under the title "Molecular Asymmetry", *Kuhn* introduced the concept of atropisomerism (Atropisomerie)[8]: "Compounds that have an isomerism which is based on restricted rotation of single bonds are called atropisomers for short" (atropos = incapable of rotation).

In further studies of the atropisomerism of biphenyls, to which the quite different atropisomerism of *Ansa* compounds was added in 1940 (*A. Lüttringhaus*), the concept of atropisomerism was at first used in a much narrower sense and was applied only to systems in which intramolecular rotation was hindered by atoms or by bulkier substituents. It had been forgotten that *Kuhn*'s original definition includes cases without any substituents. For example, the cycloalkene ring in simple *trans*-cyclooctene (Fig. 10) is so rigid that a few years ago *Cope*[14] succeeded in separating it into two enantiomorphs, both with a relatively high optical stability. In a paper dedicated to *Richard Kuhn* for his last birthday[15], *Lüttringhaus* wrote: "*Richard Kuhn* coined the concept of atropisomerism in 1933, *i.e.* several years before the concepts of conformation or constellation had acquired a definite meaning. It is often overlooked that *Kuhn* had far-sightedly defined atropisomerism in such a manner that it coincides fully with what we now call conformation isomerism, and especially rotational isomerism ...".

Fig. 10. The enantiomorphs of *trans*-cyclooctene [14].

All these studies of the spatial location of atoms in molecules go back to *van't Hoff*'s concept of the tetrahedral nature of carbon compounds. We know of many examples of *Kuhn's* veneration of this earlier genius. For example, *Kuhn* published in 1961 a biographical study[16] of *van't Hoff* on the occasion of the 50th anniversary of his death. Similarly to *van't Hoff*, *Kuhn* had an extraordinary grasp of stereochemical problems. He could clearly visualize the most complex spatial formulas, and he played with them in his imagination.

Further work, started in Zurich, concerned –C=C bonding. Investigations carried out with *F. Ebel* and others gave *Kuhn* the idea of synthesizing polyenes, *i.e.* compounds with several conjugated double bonds. In his first paper with *Alfred Winterstein*[17], *Kuhn* wrote: "It is a delightful task of organic chemistry to make use of the bonding capacity of carbon for the artificial construction of compounds in which a given structural group is repeated uninterruptedly". *Richard Kuhn* enjoyed this mixture of playing with atoms and molecules and of the urge for theoretical understanding. He synthesized the diphenylpolyenes shown in Fig. 11, first only as far as 1,16-diphenylhexadecaoctaene [18], and found to his surprise that even the lower members of the series are colored. These were the first hydrocarbons proved with certainty to be colored, and it was just this property that inspired *Kuhn* to prepare increasingly higher polyenes. In 1938, jointly with *Kurt Wallenfels*[19], *Kuhn* succeeded in synthesizing the violet-black 1,22-diphenyldocosaundecaene, and finally the virtually insoluble green-black 1,30-diphenyltriacontapentadecaene, *i.e.* a compound with 15 conjugated double bonds. According to *Kuhn*[20], it is hardly possible to make still higher polyenes in the pure state because of their extreme insolubility.

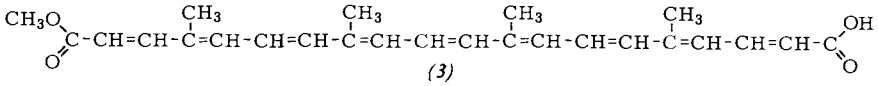
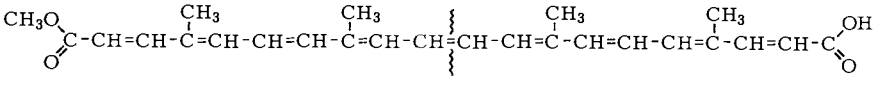
His work with *Winterstein* led logically to new fields, notably to the study of carotenoids and to physicochemical investigations of constitution and color. In February 1928 at the Zurich Chemical Society, *Paul Karrer* read a paper on crocetin, a C_{20} dyestuff pigment extracted from saffron, but could give no plausible explanation of the colored nature of this dicarboxylic acid. At the same time, *Kuhn* and *Winterstein* had seen the analogy between natural pigments such as crocetin (C_{20}) or bixin (C_{24}) and the synthetic diphenylpolyenes, and supposed that in the natural pigments the two phenyls were replaced by carboxyl groups. For bixin, the red pigment of bixa seeds, which is well known because of its use in coloring Edam cheese, *Kuhn* and *Winterstein* [21] proposed a polyene structure



(3)



(4)

Fig. 12. Proposed structures for bixin, November 1927 *(3)* and 1932 *(4)* [21,22].

(3) (Fig. 12), which they corrected a few years later [22] to the now fully accepted symmetrical structure *(4)*.

The gap between theoretically interesting synthetic compounds and natural substances had now been bridged, thus opening the way for a major advance in the field of vitamins – in the same year *H. von Euler* [23] reported from Stockholm that vitamin A is a polyene and that carotene exerts vitamin A action in vitamin A-deficient animals. It was thus demonstrated that *Kuhn*'s polyenes also occur in nature. The fact that a vitamin had entered this field of study considerably strengthened *Kuhn*'s interest in this line of research. He had always been particularly interested in the biological aspects of chemistry, and upon hearing *Adolf Windaus* read a paper on vitamin D and on its formation from ergosterol by irradiation that same year (1929) in Zurich, Kuhn decided that he too wanted to devote himself increasingly to the study of vitamins.

Toward the end of 1929, on the initiative of *Ludolf von Krehl*, *Kuhn* was invited to Heidelberg as Director of the Chemistry Division of the newly founded Kaiser Wilhelm Institute for Medical Research. Later, *Kuhn* wrote a memorial article for the birthday centenary of *Ludolf von Krehl* [24]; the draft, in *Kuhn*'s characteristic hand, was found among his papers (Fig. 13).

The new Institute was built on the Neckar. It had four wings, which housed the four divisions for chemistry,

Das Kaiser-Wilhelm-Institut für Medizinische Forschung, das 1930 in Heidelberg gegründet wurde, verdankt seine Entstehung vor allem Gedanken von L. von Krehl: Seine Überzeugung war es, daß die theoretischen Grundlagen der Medizin auf den Gebieten der Physik, Chemie, Physiologie und Pathologie besonderer Förderung bedürften.

physics, physiology, and pathology. These wings are connected by a centrally located library (Fig. 14); it was an ideal conception, a place where one could work at one's best and virtually undisturbed.

Fig. 14. The Kaiser Wilhelm Institute for Medical Research, Heidelberg, in the thirties.

There were two great creative periods in the life of *Richard Kuhn*, one starting in the thirties, the other in the middle fifties. These periods of greatest productivity can also be recognized by arranging in chronolog-

ical order the approximately 700 papers which *Kuhn* published together with about 150 co-workers (Fig.15). The diagrams in Fig. 15 also show the main subjects on which *Kuhn* and his students have worked.

Many young co-workers joined *Kuhn* in Heidelberg. Some, *e.g. I. Löw*, *H. Trischmann*, and *E. F. Möller*, remained with the master until his death. A photograph from that period (Fig.16) shows *Kuhn* and his wife, *Brockmann* and his wife, *Hoffer* and *Wassermann*, farther to the left *Grundmann*, *Wagner-Jauregg*, and *Trischmann*, and, in the background, *E. Lederer*, *Roth*, *Möller*, and others.

Fig. 16. *Kuhn*, his wife, and his associates in Heidelberg (1932).

This was a circle of people who worked with great intensity of purpose and enthusiasm, initially on polyenes and carotenoids.

There were also many discussions, especially during the daily coffee-break around 5 P.M. *Kuhn* not only took part in these discussions but also unobtrusively examined his students. It was his habit to take all journals on the day of their appearance and to read them the same evening. He not only immediately incorporated the essential contents into his mental armoury but also, as a kind of hobby, picked out with a very sure eye any misprints in the papers; the next day he frequently checked whether his coworkers had also noticed these misprints. In this and similar ways all his students acquired with almost no effort an extensive knowledge of the literature. *Kuhn* used to say: "What I read in the evening I know by heart next morning, it sediments by itself". *Kuhn*'s phenomenal memory for formulas, numbers, and data, and for people and their histories, was one of his outstanding characteristics, which was also reflected in his dealings with students. He advised them: "Take the Zentralblatt für Chemie, it should always be on your bedside table".

Kuhn was an outstanding chess player with great combinatorial talent and he enjoyed playing chess, not only with his co-workers (Fig. 17).

Fig. 17. *Kuhn* and *Winterstein* playing chess, with *Ursula Ehrenberg* lookin on (1932).

Bogoljubov, former Russian world champion, lived in Heidelberg at the time; *Kuhn* liked playing with him and often won. Another frequent opponent was Herr *Schmauss*, landlord of the "Goldene Rose" in Heidelberg. *Kuhn* was also a keen follower of sports, particularly of soccer. At the beginning of each week he would know the results of many games, particularly of the Vienna teams. He enjoyed playing tennis, both in Zurich and later in Heidelberg. For many years, together with sports-inclined associates, he played volley-ball at the University sports grounds located near the Institute.

Together with *Edgar Lederer* and *Hans Brockmann*, *Kuhn* now turned his attention to chromatography, which he had already used as a method of separation during his time with *Willstätter*. New improved media were found for the absorption and elution of pigments, and several pigment mixtures were separated on columns. The first result was the separation of carotene into α- and β-carotene. Both purified substances were obtained as beautiful crystals[25] (Fig. 18), which satisfied *Kuhn*'s aesthetic sense. This was followed by

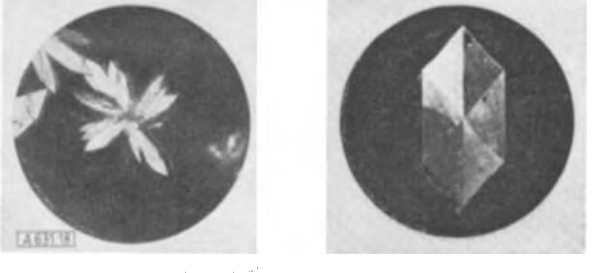

Fig. 18. Crystals of α- (left) and β-carotene (right) (both from solution in benzene-methanol mixture) between crossed nicols. Magnification × 225 in the original publication [25], about × 90 in this reproduction.

identification of γ-carotene[26], which occurs in small quantities in many plants together with the other carotenes. Structural studies then clarified the relationship of carotene to vitamin A[27]. Vitamin A,

In vivo: $C_{40}H_{56} + 2\,H_2O \longrightarrow 2\,C_{20}H_{30}O$

Fig. 19. The structural relationship of β-carotene (provitamin A) *(5)* to vitamin A *(6)*.

$C_{20}H_{30}O$, was shown to be a hemi-derivative of β-carotene, $C_{40}H_{56}$, and *Kuhn* suggested that the cleavage occurs *in vivo* by a type of hydrolysis (Fig. 19). β-Carotene was thus recognized as provitamin A, after English researchers had already expressed the same idea.

In 1933 *Kuhn* reported to the Royal Society in London [28] the concept that carotenoids in plants may undergo cleavage of the C_{40} arrangement and be transformed into diverse polyenes, *e.g.* into lower pigments such as bixin (C_{24}), crocetin (C_{20}), or azafrin (C_{27}), into odoriferous substances such as methylheptenone or ionone, or into bitter substances such as saffronal which is formed from picrocrocin (Fig. 20).

Important work on constitution and color [29] was carried out by *Kuhn* jointly with Professor *Karl Wilhelm Hausser*, the physical chemist who was the first Director of the Physics Division of the Kaiser Wilhelm Institute. Shortly before his premature death (June 4, 1933), *Hausser* showed at a colloquium at the Institute in November 1932, that these studies had resulted in the formulation of the first quantitative relationship between light absorption and the number n of double bonds in vinylogous series, *e.g.* in diphenylpolyenes (see Fig. 11). An important finding was the relationship between the location of the longest-wave absorption maximum λ_1 and the square root of the number n of double bonds (see Fig. 21):

$$\lambda_1 = K' \cdot \sqrt{n} + K''$$

The absorption spectra found for synthetic polyenes were of considerable importance for structural investigations on natural carotenoids.

Another wide field of work opened up in connection with water-soluble vitamins. It was fortunate that *Paul György* worked at that time at the Heidelberg

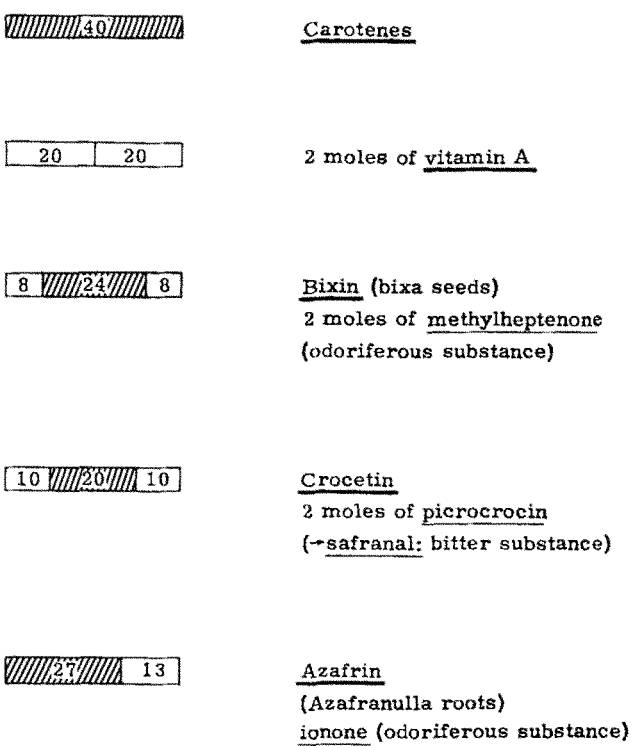

Fig. 20. Biochemical cleavage reactions of carotenes, after *R. Kuhn* [28].

Children's Clinic. He was interested in problems of infant nutrition, and saw clearly that vitamins are of decisive importance for the growing child. How many and which vitamins important for life could be present in milk? Together with *György* and *E. Lederer*, *Kuhn* tried to isolate the antiseborrheic skin factor (vitamin H) described by *György*. It seemed worthwhile to work on this skin factor in order to distinguish it from vitamin B_2 which was considered in those days as a substance preventing pellagra. *Wagner-Jauregg*, who had just completed his habilitation thesis, volunteered to undertake this work. He soon observed that B_2 concentrates are always yellow and exhibit green fluorescence. Starting from very large quantities of whey and using many refining stages, he isolated a crystalline substance, lactoflavin, which was shown to be pure vitamin B_2 [30, 31]. This was the first step in the chemistry of flavins.

In connection with *Otto Warburg*'s work on oxidation enzymes, *Kuhn* and his co-workers showed that lactoflavin was a component of *Warburg*'s yellow ferment. Together with *Hermann Rudy*, *Friedrich Weygand*, and *Wagner-Jauregg*, *Kuhn* determined the structure and carried out a synthesis of lactoflavin [32] and then prepared lactoflavin phosphate [33]. Combining the protein carrier of the yellow enzyme from yeast with synthetic lactoflavin phosphate, *Kuhn* and *Rudy* [34] succeeded in synthesizing *Warburg*'s yellow oxidation enzyme (Fig. 22) in 1935/1936. This proved to be fully effective enzymatically, and was thus the first

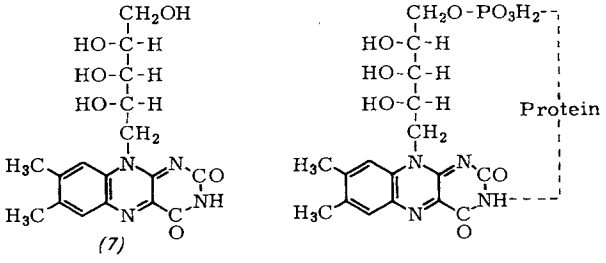

Fig. 22. Vitamin B_2 (lactoflavin) and its relationship to the yellow oxidation enzyme [34].

instance of partial synthesis of an enzyme. A photograph of *Richard Kuhn* taken in those days is shown in Fig. 23.

Those who had an opportunity at that time to hear *Richard Kuhn* lecturing on his work were held irresistibly by the magic of his personality. This was particularly so at the Heidelberg Chemical Society. He never tried to disguise his Viennese accent; his vocal powers ranged from a factual mezzo piano to

Fig. 23. *Richard Kuhn* in Heidelberg in 1935.

a mighty, almost theatrical, forte. He polished his lectures with great care, so that they became almost works of art. During the lectures his imagination was at full pitch – one could almost see the thoughts seething in his mind. The author also came under the influence of such lectures, which provided for many young scientists the frequently decisive contact with genius, and decided to strive for the privilege of working under *Richard Kuhn*.

In connection with the synthesis of lactoflavin and of many lactoflavin analogs, the need arose to study *N*-glycosides; this led to important work with *Weygand* and *L. Birkofer* on the Amadori rearrangement and its mechanism [35].

In 1937 *Richard Kuhn* and *Rudolf Ströbele* published a fundamental paper on the action of lactoflavin as an oxidation catalyst [36] entitled "On verdo-, chloro-, and rhodoflavins". On the basis of the red reduction stage of lactoflavin as described by *Kuhn* and *Wagner-Jauregg* [36], *Kuhn* and *Ströbele* succeeded in isolating intermediate stages of the oxidation-reduction system flavin $\rightleftarrows$ leukoflavin as crystals of brilliant deep colors and definite compositions. It was shown that these could be reconverted into lactoflavin by 0.25, 0.5, and 0.75 moles of O_2 respectively, and the intermediate oxidation stages were characterized as dimers with different paramagnetic properties (Fig. 24). The paramagnetism is due to the 1:1 ratio of monohydroflavin (semiquinone) and of the fully oxidized or fully reduced stage in molecular compounds of the type of quinhydrone. The biological significance of these two basic chemical principles – formation of quinhydrone-type complexes on the one hand and of radical ions on the other – ensuring stabilization of the intermediate stages was clearly recognized. The yellow enzyme can only be hydrogenated in four stages if two flavin molecules are associated in the enzyme complex. Only in this manner can the energy of the $^1/_4$-quinone and

of the $^3/_4$-quinone be distributed over the two halves of the molecular compound.

We are only now beginning to understand the mechanism of the cooperation of the protein-bound coenzyme molecules of different reduction stages, postulated by *Kuhn* in a stroke of genius as far back as 1937. One of the highlights of the 1967 International Biochemistry Congress in Tokyo was the demonstration by *Kunio Yagi*[37] of crystallized intermediate stages of the anaerobic reduction of D-amino acid oxidase. These are exactly the compounds discussed in the paper by *Kuhn* and *Ströbele*[36] published 30 years earlier. What *Kuhn* called "distribution of energy" is now called "complex formation by electron transfer between two molecules of flavin of different oxidation levels (charge transfer complexes according to *Mulliken*, 1950) and formation of semiquinone".

This example is one of many illustrating *Richard Kuhn*'s powers of conception and comprehensive foresight.

From here the path led to the vitamin B group. Vitamin B_6 (pyridoxin) – which *Kuhn* called "Adermin" because it cured a dermatitis in deficient rats – was concentrated from yeast and rice bran, and was obtained in the crystalline state by *G. Wendt*[38]. The structural formulation (Fig. 25) and the synthesis were achieved by *Wendt* jointly with *K. Westphal* and *O. Westphal*[39].

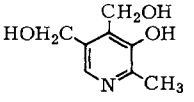

Fig. 25. Vitamin B_6.

Pantothenic acid was isolated, and was synthesized by *Theodor Wieland*[40]. The growth factor vitamin H' was identified as *p*-aminobenzoic acid[41]. Numerous analogs of all these vitamins or growth factors were synthesized, *e.g.* dichlorolactoflavin and flavins with other polyol residues such as ribital; derivatives were prepared of *p*-aminobenzoic acid, among them 4,4'-diaminobenzil (Fig. 26), and of salicil, *e.g.* dibromosalicil. Several of these substances exhibited growth-promoting vitamin effects, others were ineffective, but some analogs, tested in bacterial growth experiments, exhibited antagonistic effects with respect to the corresponding natural growth factors, *i.e.* acted as antivitamins[42,43].

A short time earlier, British workers had postulated antagonism between *p*-aminobenzoic acid and sulfanilic acid. *Kuhn* showed that sulfanilic acid and some of its derivatives do indeed strongly inhibit the growth-promoting action of *p*-aminobenzoic acid [42] (Fig.26)

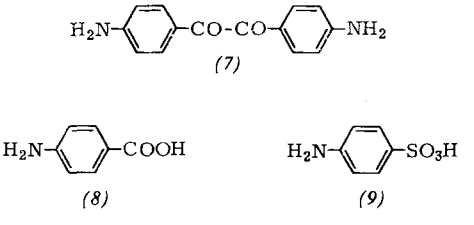

Fig. 26. On the vitamin/antivitamin antagonism. Antagonists of *p*-aminobenzoic acid [42]: *(7)*, 4,4'-diaminobenzil (→ salicil derivatives) (inhibitors); *(8)*, *p*-aminobenzoic acid (growth factor), *(9)*, sulfanilic acid (sulfonamides).

and that this inhibition explains the bacteriostatic effectiveness of sulfonamides: the antivitamin displaces the vitamin from its natural acceptor (*e.g.* an enzyme protein) in a specific manner, thus inhibiting the metabolic process concerned, and this inhibition may often be reversibly counteracted by increased doses of the vitamin. *Kuhn* pioneered these concepts, and the principles which he formulated are valid for almost all the antibiotics discovered since then.

On November 9, 1939, the Nobel Committee in Stockholm decided to award *Richard Kuhn* the Nobel Prize in chemistry "for his work on carotenoids and vitamins".

When the award of this highest scientific distinction was announced, *Richard Kuhn*, similarly to *A. Butenandt* and *G. Domagk*, was forced by the German National-Socialist Government, under threat of sanctions, to decline the prize. The Swedish Academy later acknowledged that the refusal was made under duress, and accepted it as null and void.

In the field of carotenoids there is a chapter which later caused *Richard Kuhn* much pain. The biologist *Max Hartmann*, of Berlin-Dahlem, suggested studies on the copulation substances of the green alga *Chlamydomonas eugametos*. He strongly recommended to *Kuhn* his student, *Franz Moewus*, to carry out these studies. In their experiments, *Moewus* and his wife proclaimed the effectiveness of a series of carotenoids purportedly isolated from green algae. On this basis an extensive theory of the "relative sexuality" and the effectiveness of light was constructed for these unicellular organisms. However, detailed and careful checks carried out by several researchers after the war, some of them in *Moewus*' presence, invariably gave totally negative results. Several biologists held it against *Kuhn* that it was not until 1960 that he publicly dissociated himself from *Moewus*' assertions and results [44]. In this disclaimer it was stated that *Moewus*' claims to the effect that crocin, the dimethyl ester of crocetin, rutin, quercetin, isorhamnetin and peonin, which had been isolated in Heidelberg from other plant material, were also formed by *Chlamydomonas*, were unverified and in fact doubtful. The alleged biological effectiveness of picrocrocin and safranal, crocin, the dimethyl esters of *cis*- and *trans*-crocetin, a flavonol glycoside from crocus, isorhamnetin, boric acid, and other substances on *Chlamydomonas* cells was also declared as unverified. Nevertheless, *Kuhn* and *Löw* concluded the disclaimer with the sentence: "It should be noted that the purely chemical results of this work, relating to methods of isolation, crystallization, and structural formulation, are free of the reservations expressed above" [44].

As *Max Hartmann* and *Franz Moewus* are no longer alive, this chapter should be closed at this point, but only after stating that *Kuhn*'s trust in the two biologists had remained unshaken for a long time.

In nearly 30 years of belonging to *Kuhn*'s working circle, *Irmentraut Löw* distinguished herself by purifying and crystallizing numerous plant glycosides. She has contributed substantially to clarifying the structures of flavonol and alkaloid glycosides, as well as of oligosaccharides from *crocus*, *Solanum* species, *Forsythia*, and *lycopersicum*, and was also a chemical partner of *Hartmann* and *Moewus*' biological group. This part of the work yielded many interesting new natural products.

Work on carotenoids and polyenes led to the cumulenes, again as a result of a simple thought: synthesis of substances with the highest possible cumulation of double bonds. In this context, on the occasion of being awarded the 1942 Goethe Prize of the City of Frankfurt, the first time this prize was awarded to a natural scientist, *Kuhn* said [45]: "It is only gradually that a student of nature, and especially a chemist working on syntheses, comes to discover the natural laws and then, following his intuition, to go beyond that which he finds in nature. He thus becomes in a certain sense an artist developing freely within the limits drawn by nature". He was again referring to *van't Hoff*, who had postulated at the turn of the century that in the case of an isolated double bond one may expect *cis-trans* isomerism but that, with two cumulated double bonds, one should expect right-handed and left-handed isomers, *i.e.* d,l isomers (Fig. 27). In general,

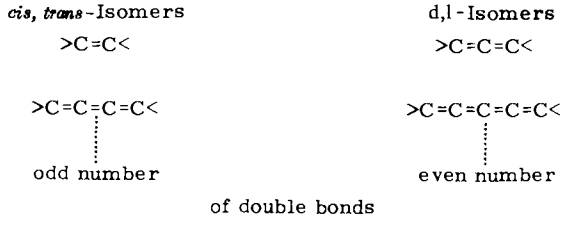

Fig. 27. d,l and *cis-trans* isomerism depending on the number of cumulated double bonds (after *J. H. van't Hoff* [46]).

one should expect *cis-trans* isomerism with an odd number of cumulated double bonds, and d,l isomerism with an even number, as implied by the tetrahedral form of carbon.

Syntheses of cumulenes were started in 1938. *Kurt Wallenfels* distinguished himself greatly by preparing such substances starting from diacetylene [47,48]; substances with cumulated double bonds were thus obtained, which were stabilized *e.g.* by phenyl residues at the ends.

It was shown, for example, that it is possible to obtain from diacetylenedimagnesium bromide and acetophenone a high yield of 1,1,6,6-tetraphenyl-2,4-hexadiine-1,6-diol [47], [Fig. 28, formula *(10)*], and from this, with HCl and $CrCl_2$ in ether [48], also a virtually quantitative yield of tetraphenylhexapentaene [48,49] [Fig. 28, formula *(11)*].

The second world war caused an increasingly severe curtailment of scientific effort at almost all German Institutes. *Kuhn*'s creative work was also severely cut. He nevertheless fought behind the scenes in high places, as can be seen from numerous letters. He fought for the preservation of German chemical literature, especially for the authors of important books regardless of personalities, only according to quality. He was concerned with preserving what he called the "100000 man army" of chemists, so that after the war Germany could immediately begin reconstruction as in 1918.

Many letters preserved from the years 1936/1944 show that *Kuhn* was motivated by a great admiration and love for Germany. He now acted for the Germany of the open-minded spirit of research so rich in tradition, of the great chemical and technological achievements which he had praised in his inaugural lecture in Zurich in 1927[7]. He had welcomed Austria's unification with Germany from a deeply felt sense of togetherness of the two German-speaking nations with so much common history. But he was undemonstrative and disliked heroics. He was essentially an introvert and a sensitive man who revealed himself seldom and then only to a few friends. He could be described as a "master of silence". Subsequent accounts of his relations with the regime of those days, particularly in various English-speaking scientific circles, had frequently done him injustice.

The work on cumulenes was resumed after the war (1951). While the earlier investigations[47,48] were performed mostly from a preparative point of view, more stereochemical aspects now came to the fore with *H. Jahn*, *K. L. Scholler*, *D. Blum*, and especially *Herbert Fischer* and *B. Schultz*. *Cis-trans* isomerism was demonstrated, for example, for mixed phenylated and nitrophenylated butatrienes[49,50], using dipole measurement techniques. *Cis* (m.p. 142–143 °C) and *trans* (m.p. 127–128 °C) isomers of 1,4-diphenyl-1,4-di-*tert*-butylbutatriene, [Fig. 29, formula *(12)*] were separated by column chromatography[51]. In contrast, 1,6-diphenyl-1,6-di-*tert*-butylhexapentaene [Fig. 29, formula *(13)*][52], could not be separated by laboratory methods, but the nuclear resonance spectrum in [D_6]-dimethyl sulfoxide showed two sharp bands at 100 MHz, corresponding to the two *tert*-butyl groups of the *cis* and the *trans* forms. From the coalescence point (coalescence temperature 100 °C) of the two bands, the free activation enthalpy of the *cis-trans* transformation in dimethyl sulfoxide was assessed at $\Delta G^{\ddagger} = 20$ kcal/mole[52], the $\Delta G^{\ddagger}$ of the butatriene *(12)* at about 30 kcal/mole. It follows, as theoretically predicted, that the stability of the steric arrangement decreases with increasing number of cumulated double bonds. *R. Kuhn* and *H. Zahn*[53] also obtained tetraphenylated octaheptaenes

$$Ar_2C{=}C{=}C{=}C{=}C{=}C{=}C{=}CAr_2$$

by transforming triacetylene with benzophenone, or with fluorenone, into octatriinediols and reducing these with P_2I_4.

In the series of compounds with an even number of cumulated double bonds, *Kuhn et al.*[54]

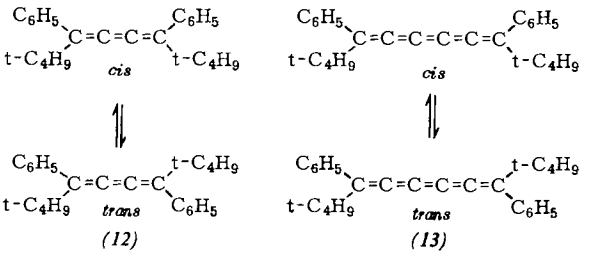

Fig. 29. Diphenyl-di-*tert*-butylbutatriene *(12)* and diphenyl-di-*tert*-butylhexapentaene *(13)*.

could only reach tetraphenylated pentatetraenes. A number of sketches were found among *Kuhn*'s papers, including one for a lecture on problems of cumulenes (Fig. 30).

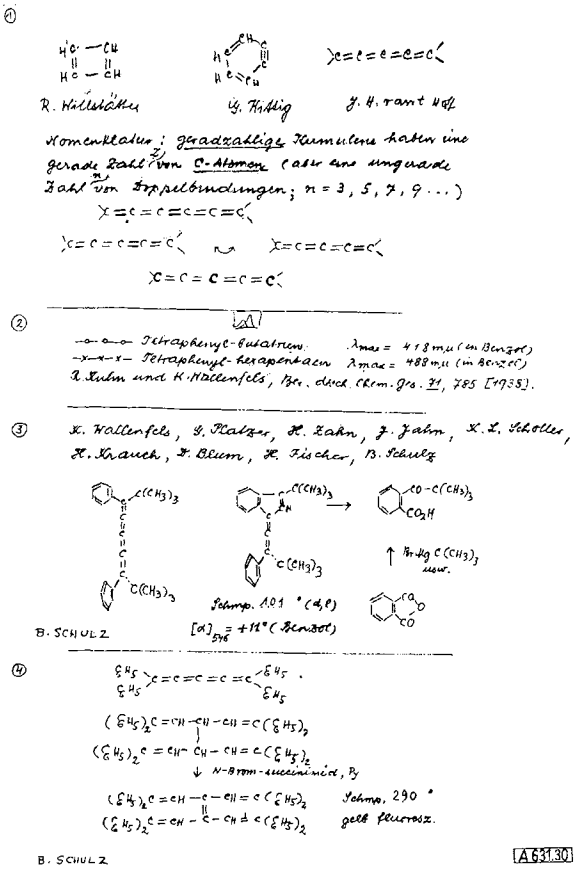

Fig. 30. Sketches by *R. Kuhn* (1963) regarding problems of cumulenes; cf. [55].

Closely related to the work on cumulenes were the investigations on highly acidic hydrocarbons which started in 1961[56] and which were conducted mainly in collaboration with *Herbert Fischer* and *Franz Neugebauer*. The colorless 1,5-bis-(2,2′-biphenylylene)-1,4-pentadiene [Fig. 31, formula *(14)*], which forms a deep blue salt in aqueous NaOH[57], may be cited as a

typical example[57]. *Kuhn* could not deny himself the pleasure of demonstrating this colorful experiment during his *van't Hoff* lecture[58].

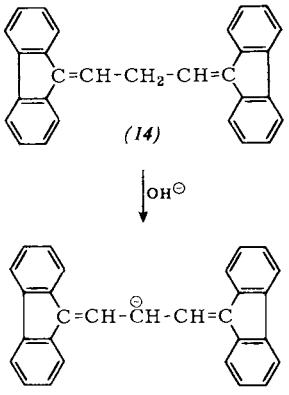

Fig. 31. 1,5-Bis-(2,2'-biphenylylene)-1,4-pentadiene [bis-(9-fluorenylidene)propane] *(14)*.

The anions of highly acidic hydrocarbons can be discharged into free paramagnetic radicals by oxidizing agents. For example, the colorless hydrocarbon *(15)* (Fig. 32) changes in aqueous NaOH into the red anion *(16)*, which is discharged by potassium hexacyanoferrate(III) to give the dimeric hydrocarbon *(17)* obtainable as colorless crystals. In solution, however, this dimer dissociates into yellow free radicals *(18)*[57,58], which are very stable, for example, to oxygen, due to delocalization of the radical electron, as has also been demonstrated by ESR. This delocalization is related to mesomeric stabilization, corresponding to stabilization of the anions of the corresponding highly acidic hydrocarbons.

Nitrogen-containing radicals[59] such as the tetraazapentenyl radical[60]

$$Ar_2N-N=CH-\dot{N}-NAr_2$$

were prepared from aza-isologs of highly acidic hydrocarbons. The green "verdazyls"[61] discovered jointly with *H. Trischmann* are similar N-radicals. The stability of such verdazyls was demonstrated, more or less as a game, by preparing the deep green triradical 1,3,5-tris(1,5-diphenylverdazyl-3-yl)benzene[62] containing ten conjugated six-membered rings.

Verdazyls are derived from triphenylformazan (Fig. 33), which was used by *Kuhn* and *D. Jerchel*[63] as early as 1941 as an intermediate product in the synthesis of triphenyltetrazolium chloride. Within the framework of joint investigations with *H. J. Bielig*, *D. Jerchel*, and *O. Westphal* on the so-called invert soaps and their biological properties[64], several surface-active ammonium salts were synthesized, including some with N-containing heterocycles, such as triazolium[65] and tetrazolium[63] salts. Of these, triphenyltetrazolium chloride (TTC) proved to be particularly interesting because it can be used as a biological reduction indicator[66]. For example, if TTC is introduced into the nutrient solution of germinating plants, the cotyledons appear deep red owing to the presence of formazan formed by reduction. As *Kuhn* and *Trischmann*[61] found in 1964, triphenylformazan is easily transformed by dimethyl sulfate, methyl iodide, or formaldehyde into the green radical called verdazyl (Fig. 33).

Kuhn's colleagues report an episode from the difficult days after the end of the war, at a time when there was an acute danger of the Institute being closed by US forces and when an

ordinance was in force that "by order of the Headquarters of the Military Government, all Austrian citizens must be repatriated forcibly to Austria with 50 kg of luggage each". One day, an American colonel appeared in this connection and was engaged in conversation by *Kuhn*. It transpired that the colonel's wife, back in the States, was an enthusiastic amateur gardener. *Kuhn* told the colonel that he could, in a simple way, turn green plants a gorgeous red. The colonel was sceptical, but decided to send his wife a sample of TTC... with resounding success. By return of mail came the news that the lady's friends invited to witness the experiment were highly delighted, and that more of the wonder drug should be sent. *Kuhn*'s imminent repatriation was postponed.

The 1950's saw the second period of great creative activity in the life of *Richard Kuhn* (Fig. 15) connected with investigations on resistance factors[67] and with the related work on oligosaccharides of human milk and gangliosides of the brain. Among the first investigations after the end of the war was *Kuhn*'s work on the resistance of certain *solanum* species to attack by the Colorado beetle. In 1947, *Kuhn* together with *I. Löw* isolated demissin, an alkaloid glycoside from *solanum demissum*[68]. In collaboration with *A. Gauhe*[69] he demonstrated the importance of this substance for resistance against the Colorado beetle larva. During the following ten years, *Kuhn*, together with *I. Löw* and *H. Trischmann* carried out extensive studies[70] on the structure of demissin and other closely related alkaloid glycosides.

Work on resistance factors led again to processing of the contents of milk. *Paul György*, in Philadelphia since 1936, resumed contact with *Kuhn*, and thus the two working groups found themselves, some 30 years after the first joint work on lactoflavin, working together again on the old question of the importance of mother's milk (compared to cow's milk) with regard to the resistance of the infant to infections. On the basis of investigations on *bifidus* factors and on the virus-inhibiting properties of mother's milk[71], *Kuhn* concentrated his interest (together with *H. H. Baer* and *Adeline Gauhe*, and later also with *R. Brossmer*) on the oligosaccharides. From 1954 onwards, numerous lacto-oligosaccharides were prepared in pure form and defined structurally with masterly skill. A key substance proved to be lacto-*N*-tetraose (Fig. 34) which was isolated in 1954[72] and whose structure was established in 1956[73]. The isomeric lacto-*N*-neotetraose (Fig. 34) was defined in 1962[74]. Both tetrasaccharides consist of glucose, galactose, and *N*-acetylglucosamine in the ratio of 1:2:1, the galactose at the non-reducing end being bound β-1,3 in lacto-*N*-tetraose and β-1,4 in lacto-*N*-neotetraose.

In the course of investigations on gangliosides undertaken in 1960, the key substance ganglio-*N*-tetraose[75] was isolated from these glycolipids, which proved to be structurally very similar to the two tetraoses from human milk (Fig. 34) inasmuch as the only difference is that galactosamine, instead of glucosamine, is the amine found in ganglio-*N*-tetraose (bound β-1,4 to the median galactose). All three tetrasaccharides are derivatives of galactosido-β-1,4-glucose (Fig. 34). It remained *Kuhn*'s unfulfilled wish to study the genetic background of these relationships.

of correspondingly low oligosaccharides, *e.g.* lactose, or can be obtained from the tetraoses shown in Fig. 34 by substitution with fucosyl or lactaminyl residues (Fig. 35 and Table 1).

Among the substances which were isolated and identified were fucosidolactose [78], lactodifucotetraose [79], lacto-*N*-fucopentaose I (LNFP I) and II (LNFP II) [80], lacto-*N*-difucohexaose, and a (crystallized) hexasaccharide with two fucosyl residues [81] which showed strong Le^a blood group activity. A list of all the oligosaccharides which were isolated or prepared for comparison up to 1957 is given in the synopsis on amino sugars [76]. The finding that lactaminic acid-containing oligosaccharides are cleaved by influenza virus [82,83] was of great interest. The simplest cleavable oligosaccharides were found to be the 3'- and 6'-lactaminyl-lactoses [84,85]. It was shown that influenza virus, as well as the so-called receptor-destroying enzyme (RDE) of cholera vibrios split the glycosidic bond of lactaminic acid derivatives, *i.e.* possess α-ketosidase activity. Lactaminyl oligosaccharides were identified

as receptors for influenza virus, thus explaining[86,87] the virus-inhibiting effectiveness of human milk. In his lecture on resistance problems[67], given at the 100th Meeting of the Gesellschaft Deutscher Naturforscher und Ärzte in 1958 in Wiesbaden, *Kuhn* suggested that cells that do not form such lactaminyl-oligosaccharide structures on their surfaces must be resistant to influenza virus. A note from that time found in *Kuhn*'s papers (Fig. 36) shows the structure of the oligosaccharides obtained and their substrate effectiveness toward influenza virus and RDE.

Lactaminic acid was found to be identical with *N*-acetylneuraminic acid (sialic acid)[88]; it may therefore be considered as a condensation product of *N*-acetyl-D-mannosamine with pyruvic acid (Fig. 36). Lactaminic acid was synthesized in 1962 by *Kuhn* and *G. Baschang*[89].

Gangliosides are oligosaccharide derivatives of sphingosin with a long-chain fatty acid (Fig. 37). The gangliosides I, II, III, and IV isolated from brain by *Kuhn*, mainly in collaboration with *H. Wiegandt*, are derivatives of ganglio-*N*-tetraose (Fig. 34) with one, two, or three lactaminyl residues, as shown in Fig. 38; the higher substituted gangliosides IV, III, and II are transformed by influenza virus into ganglioside I, as shown by the arrows[91].

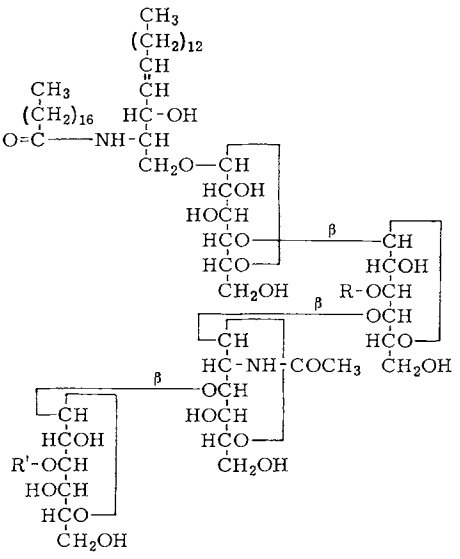

Fig. 37. Structural principle of gangliosides [90]. Ganglioside G_I: R = lactaminic acid, R' = H; Ganglioside G_{II}: R = R' = lactaminic acid.

These results were obtained at the beginning of a large program of detailed research on gangliosides, and are of a provisional nature[92,93]. *Kuhn* did not live to see

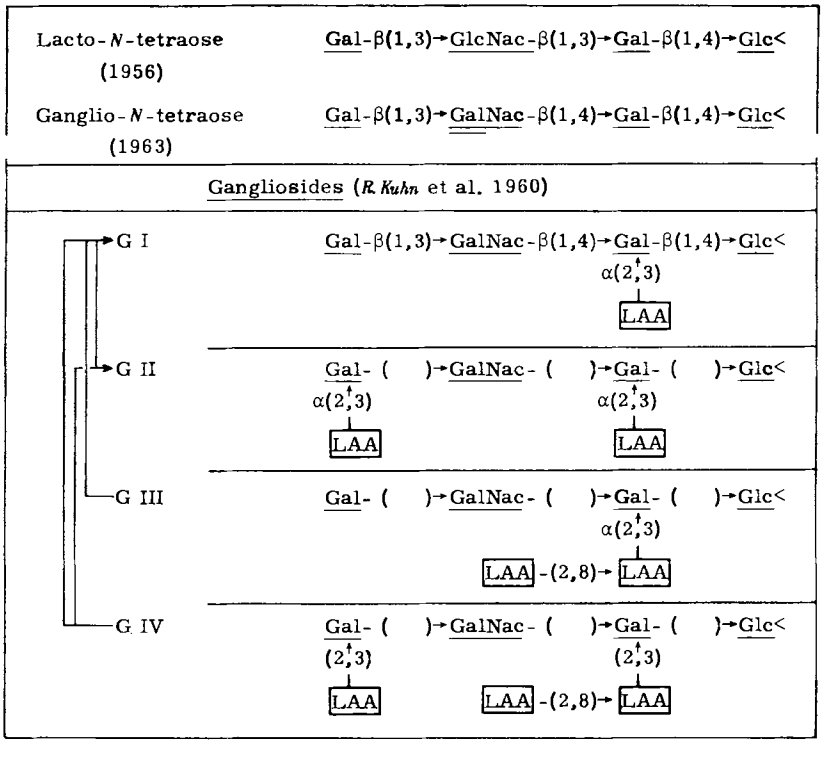

Fig. 38. The acidic oligosaccharides of gangliosides I, II, III, and IV (see [91]).

the fulfilment of the great expectations he had of further ganglioside and brain research[93a].

"We live in an age of electronics. Electronic computers, or electronic brains as they are also called, can perform with

lightning speed computations that would require scarcely imaginable times with a pencil and log tables. Research on the human brain has not kept pace with the rapid development of electronics" [94].

A method frequently used for the detection and quantitative determination of *N*-acetylamino sugars is the Morgan-Elson reaction [95]. After treatment with dilute caustic soda, *p*-dimethylaminobenzaldehyde (Ehrlich's aldehyde) is added to the acidified solution, resulting in a purple coloration. *Kuhn* and *G. Krüger* [96] elucidated the mechnism of this important color reaction and defined the structural conditions required for the formation of the chromogen (splitting off of two molecules of H_2O from the acetylaminohexose and closure of the furan ring); they also determined the structure of "chromogen III", which was identified as D-5-dihydroxyethyl-3-acetaminofuran (Fig. 39). They showed that, in the formation of the chromogen, the *N*-acetylhexosamine reacts in its furanose form and that consequently the hydroxyl groups on carbons 1 and 4 must be free. The above assumptions make it possible to apply this color reaction to structural studies of hexosamine derivatives.

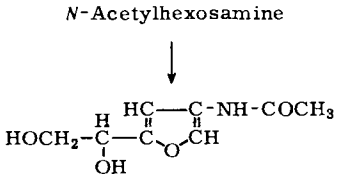

Fig. 39. The "chromogen III" of the Morgan-Elson reaction [96,97].

In connection with research on lacto- and ganglio-*N*-oligosaccharides and on their amino sugar-containing cleavage products, it became necessary to improve the methods available for the synthesis of amino sugars and derived disaccharides, *etc.* Together with *W. Kirschenlohr*, *W. Bister*, *G. Baschang*, and others, *Kuhn* did a considerable amount of work on syntheses of amino sugars [97].

The well known synthesis, due to *E. Fischer* and *H. Leuchs* [98], in which a 2-amino sugar is built up from a sugar containing one less carbon atom by conversion with ammonia and HCN into the corresponding aminonitrile, then transformation of the aminonitrile into the acid and its lactone, and reduction of the lactone to the amino sugar with Na amalgam (which gives only a 1 to 2% overall yield) was decisively improved [97] by introduction of semihydrogenation of aminonitriles [99] as well as of arylamino- and benzylaminonitriles [100]. In less than ten years, 25 papers were published on syntheses of amino sugars. Among the substances synthesized were the eight possible 2-amino-2-deoxyhexoses (hexosamines) of the D-series [101], the four 2-amino-2-deoxypentoses [102], and the two 2-aminotetroses (D-threosamine and D-erythrosamine) [103]. L-Fucosamine [104] and other amino sugars of the deoxy series also became easily accessible. A very elegant synthesis based on the same principle was that of the disaccharide *N*-acetyllactosamine from lactose (galactosyl-β-1,4-glucose) [105]. Lactose is first degraded to galactosyl-β-1,3-arabinose, which is then transformed into lactosamine *via* the aminonitrile.

The cyanohydrin reaction was also developed for a substantially improved synthesis of L-glucose and L-mannose starting from L-arabinose [106].

Kuhn's amino sugar syntheses have enriched considerably the preparative chemistry of carbohydrates.

In the last years of his life and in keeping with his position as President of the Gesellschaft Deutscher Chemiker *Richard Kuhn* did considerable biographical work, in which he occupied himself with the great men of chemistry, especially with those whose thoughts and theories had permanently influenced progress in chemistry. He was interested in their letters and had an extraordinary memory for everything he could find out about them. Thus arose some delightful documents, such as the commentary [107] to the reprint of *J. H. van't Hoff*'s inaugural lecture on "Imagination in Science", delivered on the occasion when *van't Hoff*, like *Kuhn*, became a Professor at the age of 26 (1878 in Amsterdam). *Kuhn* was always working on this theme, which fascinated him because he too had a great gift of imagination [*]. Imagination is of immense importance in scientific work, and it is the teacher's duty to stimulate it in his students.

The papers left by *Kuhn* include innumerable sketches, beautifully written formulas – virtually works of art – reflecting his thoughts.

Kuhn has exerted great attraction on many people and was often in touch with important men. He enjoyed the meetings of Nobel Prize winners at Lindau. We find

again and again the expression of his interest in thinking and creative people.

The years 1944/1945, when *Theodor Heuss* left the increasingly unsafe Berlin after the July 1944 plot and came to quieter Heidelberg, saw the development of a warm friendship; *Heuss* and *Kuhn* sought and found mutual contact (Fig. 40). On the occasion of BASF president *Carl Wurster*'s 60th birthday, on December 2, 1960, in Ludwigshafen, *Heuss* learned that *Kuhn*'s 60th birthday was on the following day. On his return to Stuttgart, *Heuss* sent *Kuhn* a handwritten letter which he posted in the small hours "as an experiment on whether they manage it in time". A few lines may be quoted ... "You, my dear Herr *Kuhn*, have a refreshingly meager talent for getting excited. My greatest pleasure in your company is the relaxed serenity of your observant eyes. May this searching look serve you for many years to discover that which is hidden and to enjoy your discoveries. With best wishes, *Theodor Heuss*".

In September 1965, at the Kekulé festival in Bonn, *Kuhn* was told by doctors that he was incurably ill. Those who had the privelege of being near him during the last period of his life know with what inner and outer discipline, spiritually unbroken to the last, he put his affairs in order, and with what passionate dedication he made arrangements for the future of his Institute and of his colleagues. We remember him as he appears in a photograph in 1965 (Fig. 41) gazing at distant horizons, in the background his devoted wife who stood by his side in both good and bad times, and especially in the last two years of his life. All his students and friends know how much she did for him in her quiet way.

Richard Kuhn died on July 31, 1967, in Heidelberg. It will take time to appreciate fittingly the life's work of this great chemist. In numerous discussions with former students, *Friedrich Ebel*, *Heinz Staab*, *Theodor Wagner-Jauregg* and *Kurt Wallenfels* (to whom, as well as to *A. Lüttringhaus*, the author is indebted for

Fig. 41. *Richard Kuhn* and his wife at the 75th Anniversary of the Deutsche Pharmazeutische Gesellschaft, Berlin, in October 1965. (Copyright by Raillon & Baldenins, Berlin).

advice and discussion), who assisted in assembling the biographical data and particulars of *Kuhn*'s work, it became very obvious that the task of appraising the work of *Richard Kuhn* is beyond the capacity of any one individual, at least at the present time. This is a task for future research. We, however, will always retain the indelible impression of *Kuhn*'s unique personality. We, his students, often used to say of him: You can only love him, or else you do not understand him. Let us take earnestly his precept that our most precious possession is man's creative force directed to beauty and progress. "The greatest happiness is to observe the birth of new ideas, and to foster and stimulate them, because they shape the future" [7]. The memory of *Richard Kuhn* binds us all to this precept. His achievements are part of the history of natural science.

Free Radical Studies at Low Temperatures

BY B. MILE[*]

Free radicals can be produced in the gas phase and then condensed together with the molecules of an inert gas; they can also be generated and trapped in isolated sites in rigid solids. IR and ESR spectra of trapped radicals provide information concerning their structure and chemical properties. The techniques employed for producing and studying radicals are reviewed and a number of recent IR and ESR investigations of trapped radicals are discussed. The last part of the article deals exclusively with the applications of the rotating cryostat to the study of the ESR spectra and reactions of trapped radicals at low temperatures.

1. Introduction

Free radicals (molecular fragments containing an unpaired electron) are active participants in a wide variety of systems undergoing chemical change [1]. For example, the pyrolysis and combustion of organic materials involve highly reactive free radicals and the extensive conversions that occur are due to the high efficiency of the reactions between radicals and molecules. The high reactivity of free radicals can also result in extreme complexity since the conversion of reactants to products occurs through a maze of numerous, very fast radical-molecule reactions taking place in sequence and in parallel. The very efficient reaction between two radicals to form molecular products also causes the concentration of radicals in most systems to be so low that, not only have the concentrations not been measured, but even the presence of radicals in the system has usually been inferred from the nature of the products and has not been directly demonstrated.

The fact that the radical concentrations have not been measured inevitably means that there are more reaction steps than there are products and that, consequently, there is uncertainty both in the reaction scheme adopted and in the rate constants assigned to the assumed reaction steps. The consistency of the data for the same radical reaction studied in entirely different systems does, in most cases, lend support to the reaction steps proposed and to the existence of the radicals postulated; but, clearly, these proposed reaction mechanisms would be put on a firmer basis if the radicals postulated could be shown to exist and if the reactions could be observed directly and in isolation. Of equal, if not greater, importance is the fact that the physical and thermodynamic properties of radicals (*i.e.*, the orbital of the unpaired electron, the vibration frequencies, *etc.*) must be known before any reliable theory of radical-molecule reaction rates can be formulated. Thus, there are strong arguments for attempting to obtain sufficient concentrations of free radicals in a high state of purity so that their physics and chemistry can be studied more directly.

There are two ways of producing radicals in sufficient concentrations to be detected by physical techniques such as ESR spectroscopy: (a) the rate of radical generation can be increased; this is done in flash photolysis [2], pulse radiolysis [3], and recently in the radiolysis of liquid hydrocarbons [4]; (b) the rates of radical-radical termination reactions can be reduced; this is the approach adopted in the study of trapped radicals at low temperatures, and it is with this method that this review is concerned. The collision between radicals, which is the prerequisite of reaction, is reduced to a very small value by forming and trapping the radicals in isolated sites in rigid solids at low temperatures. The rates of diffusion of the radicals through the solid matrix can be made so low that the radicals can be preserved for years without any significant decrease in their concentration.

Work on trapped free radicals was begun by *G. N. Lewis* and his students [5] in the early 1940's. They showed that photolysis of frozen solutions of aromatic hydrazines with ultraviolet light resulted in the formation of free radicals which could be kept for long periods of time. In 1951, *Rice* and *Freamo* [6] demonstrated another way of generating trapped radicals when they decomposed hydrazoic acid by passing it through a heated tube at low pressures, and trapped out reactive intermediates from the gas phase onto a surface cooled with liquid nitrogen. (For reviews and details of work carried out on this topic up to 1960 see [7].)

The article will be divided into four sections dealing with: (1) experimental methods, (2) the infrared

2. Experimental Methods of Preparing and Trapping Radicals

2.1. Matrices: The Matrix Isolation Technique[8]

It is impossible to prevent collisions between radicals in the liquid and gas phases (except in the extremely dilute regions of a molecular beam) and it is only in inert solids that radicals can be kept apart. The solid matrix used for holding the radicals in dispersed sites several molecules apart should satisfy the following requirements.

Rigidity – Clearly the matrix must be sufficiently rigid to prevent radicals diffusing and this is usually ensured by working at low temperatures. However, some work has been done with ionic solids containing trapped radicals as, for instance, in studies of γ-irradiated single crystals of carboxylic acids and their salts[9]. It is worthwhile noting that radical diffusion occurs at a temperature well below the melting point of the matrix; usually the radicals begin to disappear when the temperature rises to between one-tenth and one-third of the melting point (°K).

Inertness – The matrix must not react with the free radicals being studied. Otherwise, not only will radicals from the matrix be generated rather than the radicals of interest, but there is also the possibility of "chemical" diffusion whereby the free valences migrate through the matrix by a series of atom-transfer reactions between adjacent molecules. Additionally, the matrix must not be decomposed by the light which is used to photodissociate the guest reagent molecules into radicals.

Transparency – For visible, ultraviolet, and infrared spectroscopic studies, ideally the matrix should not absorb radiation in the same wavelength regions as the radicals do. The rare gases are obviously the most suitable matrices from this viewpoint. In the case of electron spin resonance spectroscopy, the spectra are often considerably better resolved if the radicals are trapped in sites in which they can undergo extensive "tumbling" motion. This helps to average out the effects on the spectrum of the orientation of the free radical in the magnetic field. (In most trapped radical studies, amorphous solids are used so that if the free radicals are in a fixed orientation, there is an overall random distribution of all possible orientations with a consequent broadening of the lines.) Thus, the best matrix would be one having large cavities in which the radicals can be trapped and still rotate in three dimensions, as well as having sufficient rigidity to prevent translational motion of the radicals.

Volatility – Apart from those cases where solutions are frozen and then irradiated, most of the techniques require that the matrix be deposited from the vapor phase onto a cooled surface. The matrix must therefore have sufficient volatility ($\approx$1 torr) at temperatures below those at which the matrix molecules decompose. The rare gases are the most commonly used matrices but hydrocarbons, fluorocarbons, and even water have also proved useful.

2.2. Formation of Radicals Prior to Trapping

There are two distinct ways of preparing the radicals that are to be trapped: (a) the radicals can be formed in the gas phase and subsequently trapped in the solid phase by co-condensing the radicals with molecules of inert gas; (b) the radicals can be both formed and trapped in the solid phase.

2.2.1. Formation of Radicals in the Gas Phase

Electric discharges are most frequently used for dissociating gaseous molecules (especially for making simple radicals, like H, NH, *etc.*). The gas mixture, consisting mainly of a rare gas with a small amount of the compound to be dissociated, is passed through either an electrodeless discharge or a discharge employing electrodes (Woods tube) and the resulting dissociated mixture is then quickly condensed onto a cold surface located close to the end of the discharge. This technique is simple and straight-forward to use, but it suffers from the disadvantage that the processes occurring in the discharge are complex and the identity and degree of purity of the radicals produced are sometimes uncertain.

Gaseous molecules can also be dissociated by pyrolysis[6]. *Klein* and *Scheer*[10] have studied the reactions of dissociated hydrogen atoms by heating a tungsten filament to a high temperature (2000 °K) in a stream of hydrogen and then bombarding frozen solid olefins with the partially dissociated gas. Atoms and small molecules of carbon can also be generated by thermal methods[11]. These methods are more useful for producing atoms by the dissociation of diatomic molecules than for producing polyatomic free radicals.

Only atoms and simple radicals such as OH, CH, C_2, NH_2, and PH_2, have been trapped from the gas phase and there is a simple reason for this. The combination of atoms and simple radicals can only occur in the presence of a third molecule which can remove some of the energy released on combination. (If this energy is not removed the nascent molecule will dissociate at the end of the first vibration.) Because of this third-body requirement, the rate of combination of atoms in the gas phase can be reduced considerably by reducing the pressure and thus sufficient concentrations of atoms can be built up to ensure the trapping of ap-

[11] *R. L. Barger* and *H. P. Broida*, J. chem. Physics *43*, 2364, 2371 (1965).

preciable numbers when the gas is condensed. More complex radicals with a larger number of bonds to absorb the energy released on combination do not require a third body for combination so that it is very difficult to achieve sufficiently large concentrations of these radicals in the gas phase. The condensation process itself probably results in extensive combination since the gaseous molecules and radicals are brought much closer together as they form the solid phase. Nevertheless, it would be of considerable interest to be able to trap and identify radicals from complex gaseous systems where, for example, pyrolysis or oxidation occurs. Possibly the use of techniques similar to those used for the mass spectrometric [12] examination of free radicals might be helpful in this connection.

2.2.2. Formation of Radicals in the Solid Phase

The molecules to be dissociated are dispersed widely in the inert matrix by condensing the reagent and the inert matrix on a cold surface from the gas phase. The frozen solid is then irradiated with visible or ultraviolet or far-ultraviolet light, which causes photodissociation of the reagent molecules into free radicals. Radiolysis can also be used but the reagent itself must then serve as the matrix since the absorption of ionizing irradiation is non-selective. Photolysis of well-chosen molecules can be clean and can result in the formation of one or only a small number of radicals.

The major problem with this method is the possible occurrence of the "cage" effect which can reduce the quantum yield of radical formation to very low values. Photolytic dissociation of a molecule always results in the formation of two radicals (of opposite spin) and not one, and these radicals must separate from each other if they are not to recombine to form the parent molecule. This separation can be difficult in the solid phase where the two radicals are "caged" together and prevented by surrounding molecules from diffusing apart. Although the cage effect can be an important factor, it can be overcome by a suitable choice of conditions [13, 14]. For instance, if a molecule dissociates to give one small fragment that can move readily through the matrix, then the other larger fragment will be trapped. A simple reorientation of the radicals can also result in stabilization [15].

A hybrid of the two methods of gas and solid phase formation of radicals has also been employed. In this method the sample is photolyzed while it is being condensed and in some cases there is a considerable enhancement in yield over the simple photolysis of the condensed solid solution [16]. This may be due both to a reduction in the cage effect and to the fact that every region of the deposit has been irradiated and not merely the surface layers. (Absorption of a large amount of light in the first few layers of a solid can lead to the generation of a large number of radicals in close proximity with resultant loss of the radicals by combination.

Once the radicals have been formed and trapped, a variety of techniques can be used for their identification and characterization. Emission and absorption spectrometry, X-ray diffraction, calorimetry, infrared spectrometry, and electron spin resonance spectrometry have all been used for this purpose. Only the latter two techniques will be discussed in this article.

3. Infrared Spectra of Trapped Radicals

The characteristics of the ultraviolet and visible absorption spectra of trapped small radicals are well known, but it is only recently that it has been possible to obtain the infrared spectra of radicals [17]. The problem has been one of obtaining sufficiently high concentrations of radicals so that infrared absorption by the radicals is detected above the background absorption by the matrix.

The infrared spectrum of a radical can yield information about the frequencies of the various vibrations in the radical and also about the structure and thermodynamic properties of the radical. For instance, it is often possible to decide whether a radical is planar or non-planar, or whether two atoms of the same element are equivalent or non-equivalent. Thermodynamic functions such as the entropy and heat capacity can be calculated by statistical mechanics if the vibration frequencies and the bond lengths and angles of the radicals are known. The frequencies can be obtained from the infrared spectra but in most cases the bond lengths and angles have to be guessed – this is a serious gap in our knowledge and can only be removed by observation of rotational fine structure in the infrared spectra or by the observation of the microwave spectra of radicals.

3.1. Infrared Cells Used for Trapped Radical Studies

Most of the infrared work has been carried out in a cell similar to that first described by *Becker* and *Pimentel* [8] and shown schematically in Figure 1. A Dewar vessel containing the refrigerant, liquid hydrogen, helium, or nitrogen, is sur-

rounded by another Dewar vessel containing liquid nitrogen, this outer Dewar serving as a radiation shield. A copper rod protrudes from below into the refrigerant in the inner Dewar and to the lower end of this rod is attached a copper block holding a silver iodide window (or other window transparent to infrared radiation). The silver iodide window is thus cooled *via* the copper block and rod. The matrix and substance under examination are co-condensed on the window, photolyzed with ultraviolet radiation, and investigated infrared spectroscopically.

3.2. Infrared Spectra

3.2.1. The Formyl Radical, HCO

The formyl radical (see also Section 4.2.1) was the first radical whose infrared spectrum was recorded. *Ewing*, *Thompson*, and *Pimentel*[17] ingeniously avoided the cage effect by using a reactive matrix. HI or DI molecules were dispersed in solid carbon monoxide and the hydrogen or deuterium atoms produced by photodissociation reacted with the carbon monoxide to form formyl radicals, HCO or DCO. The radicals were detected by their absorption bands in the visible spectral region.

Subsequently, *Milligan* and *Jacox*[18] were able to produce much larger concentrations of HCO or DCO by the simultaneous condensation and photolysis of mixtures of H_2S or D_2S and CO. These workers assigned the following frequencies: C=O stretching frequency of 1861 cm^{-1} in HCO and 1800 cm^{-1} in DCO; C–H and C–D stretching frequencies of 2488 and 1937 cm^{-1}, respectively; and C–H and C–D bending frequencies of 1090 and 852 cm^{-1}, respectively. Perhaps the most interesting feature of the spectra is the very low value of the C–H stretching mode at 2488 cm^{-1} (C–H stretching frequencies in normal molecules occur at *ca.* 3000 cm^{-1}). This indicates strongly that the C–H bond in HCO is considerably weaker than that in H_2CO and this is entirely in accord with kinetic evidence which indicates that $D_{(CO-H)}$ is 18 kcal per mole compared with a value of 88 kcal per mole for $D_{(HCO-H)}$[19]. The electron spin resonance spectrum of HCO also provides evidence of a very weak C–H bond (see Section 4.2.1).

The thermodynamic functions of the formyl radical can now be calculated fairly accurately since the bond angles and bond lengths of this radical are known from the absorption spectrum of the radical in the gas phase[20,21].

3.2.2. The Hydroperoxyl Radical, HO_2

The HO_2 radical, believed to be one of the most important intermediates in oxidation systems, has proved to be one of the most elusive radicals to trap and identify. *Milligan* and *Jacox*[22] finally succeeded in obtaining its infrared spectrum in argon at 4 °K by employing a technique similar to that used for the study of the formyl radical. Argon, hydrogen iodide, and oxygen were deposited onto a cooled cesium bromide window with simultaneous photolysis of the cold film. Argon was used as a diluent to prevent possible reaction between HO_2 and the iodine atom also produced by photodissociation of the HI. Three absorption bands were obtained for $H^{16}O_2$ and these were assigned to the H–O_2 stretching mode (3414 cm^{-1}), the O–O stretching mode (1101 cm^{-1}), and the H–O_2 bending mode (1389 cm^{-1}). The values of the OH stretching and bending mode frequencies are near to those for these modes in H_2O_2 indicating a tightly bound hydrogen atom in the HO_2 radical. This is in accord with the recent estimation of $D_{(H-O_2)}$ = 47.1 ± 2 kcal/mole compared to $D_{(HO_2-H)}$ = 89.6 ± 2 kcal/mole[23]. The O–O stretching frequency is intermediate between that in H_2O_2 (880 cm^{-1}) and that in O_2 (1580 cm^{-1}). The spectra of $H^{16}O^{18}O/H^{18}O^{16}O$ mixtures are interesting in that they show that the two oxygen atoms are not equivalent. This contradicts theoretical calculations which indicate that HO_2 has the configuration of an isosceles triangle[24].

3.2.3. The Methyl Radical, CH_3

Although much effort has been expended in the search for the infrared spectrum of the simplest alkyl radical, the methyl radical, it is only very recently that an absorption due to the out-of-plane bending mode has been observed by *Andrews* and *Pimentel*[25]. The methyl radicals were generated by condensing methyl iodide in argon simultaneously with a beam of lithium atoms. Although bands attributable to lithium iodide and methyllithium were detected, an additional absorption at 730 cm^{-1}, which decayed on warming, was also observed. From a comparison of the corresponding band obtained when deuterated methyl iodide was used, the authors assigned the observed frequency to an out-of-plane bending mode and calculated a force constant of 0.2527 mdyn/Å. This is close to force constants for the same mode in BBr_3 (0.29) and BI_3 (0.24) and thus provides some support for the planar structure of the methyl radical. No infrared spectra of any other alkyl radicals have yet been reported (see also Section 4.3.1.).

3.2.4. The Trifluoromethyl Radical, CF_3

Milligan, *Jacox*, and *Comeford*[26] have succeeded in recording the spectrum of CF_3 in a variety of matrices. The radical was prepared by a number of different

methods but the infrared spectra from the deposits had three features in common and all these features decayed on warming. The three bands occur at 703 cm^{-1}, 1084 cm^{-1}, and 1250 cm^{-1} and have been assigned to an umbrella mode, to a symmetric, and to an asymmetric stretching mode respectively. The finding of two absorptions (1084 cm^{-1} and 1250 cm^{-1}) in the region of the C–F stretching fundamentals is very important since it shows that the CF_3 radical is non-planar. (In a planar molecule only the asymmetric stretching mode would be seen since the symmetric mode would involve no change in dipole moment.) In the case of CF_3 a direct comparison is possible between results in the gas phase and those in the solid phase since *Carlson* and *Pimentel* [27] have also succeeded in obtaining the infrared spectrum of the CF_3 radical in the gas phase by using rapid-scan infrared techniques in conjunction with flash photolysis. Transient absorption bands were observed whose positions were nearly identical with those observed for the trapped CF_3 radicals. Recent examination of the electron spin resonance spectrum of CF_3 has also shown that the radical is non-planar (*vide infra*).

3.2.5. Other Radicals

The foregoing should suffice to illustrate the application of infrared spectroscopy to trapped radicals. The spectra of the following radicals have also been observed and interpreted but will not be described in detail here: NH_2 [28,29]; NH [29,30]; NF_2 [31]; NF, NCl and NBr [32]; NCN [33]; CCO [34]; FCO [35]; ClCO [36]; CF_2 [37]; and the radical anion CO_2^- [38].

4. The Electron Spin Resonance Spectra of Trapped Radicals

Electron spin resonance spectroscopy has several advantages for the study of radicals: it only "sees" species containing free electrons so that matrix transparency is not a problem; it "sees" the very part that causes the high reactivity of the free radical; and it is extremely sensitive and can detect free radical concentrations as low as 10^{-8} molar (cf. [39,40]).

The technique depends on the fact that the electron has a magnetic moment (associated with its spin) which can lie either parallel or antiparallel to a magnetic field in which the electron is placed. In a sample containing many free electrons those with magnetic moments lying parallel to the field have a slightly lower energy than those lying anti-parallel to it, the relative numbers in each state (N_p and N_{ap} respectively) being given by the Botzmann equation:

$$N_{ap}/N_p = \exp(-\Delta E/kT)$$

where ΔE is the energy of separation which is equal to $g\beta H$, g is a dimensionless number (g-factor) having the value of 2.0023 for a free electron, β is the Bohr magneton, and H is the field strength in gauss (G). When electromagnetic radiation of the correct frequency falls on the sample ($h\nu = g\beta H$) it is absorbed and some of the electrons in the low energy state are raised to the high energy state. (ν is in the microwave region, 9000 MHz, when fields of 3000 G are used.) Of great interest to the chemist is the fact that nuclei close to the electron can cause hyperfine structure in the absorption if these nuclei themselves possess a magnetic moment. For example, in a hydrogen atom (nuclear spin quantum number, $I = 1/2$) the magnetic moment of the nucleus, like that of an electron, can lie parallel or anti-parallel to the field and these different orientations will result in the magnetic field experienced by the electron being either greater or less than the externally applied field. Two absorption lines are thus observed

$$h\nu_1 = g\beta\,(H + H_p) \text{ and } h\nu_2 = g\beta\,(H - H_p).$$

For hydrogen atoms, H_p, the effective field due to the proton at the electron, has a value of about 250 G. The presence of more than one proton in the vicinity of the electron, as in alkyl radicals, causes further splitting of these lines and clearly this hyperfine structure gives direct information about the environment of the unpaired electron and hence about the orbital which it occupies.

The interaction of the free electron with neighboring nuclei is of two types, isotropic and anisotropic. The latter is simply the dipole-dipole interaction between the magnetic moments of the electron and that of the nucleus, and its magnitude is inversely proportional to the cube of their separation and also dependent on the relative orientation of the two spins and hence on the orientation of the radical in the magnetic field. If the radicals are rigidly held and their orientations are random, this interaction can lead to considerable broadening of the hyperfine lines with consequent loss in resolution. A "tumbling" motion of the radicals in their sites results in the anisotropic interaction being averaged out to zero. The isotropic interaction, or the Fermi contact interaction [41], only occurs when there is a finite unpaired electron density at the neighboring nucleus. This isotropic interaction is not averaged out to zero by molecular motion and it is this interaction which is usually measured in the spectra of randomly orientated trapped radicals.

ESR experiments can be carried out in a similar way to infrared experiments. The copper rod and windows (Figure 1) are replaced by a non-conducting sapphire rod (electric insulator) and this rod is located in a microwave cavity between the pole

pieces of a powerful magnet. Alternatively, the free radicals can be formed and trapped in samples outside the spectrometer and then subsequently placed in the cavity. The samples must, of course, be prepared, transferred, and measured at low temperatures and silica glass Dewars are used for these purposes.

4.1. σ and π-Radicals

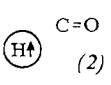
The classification into σ and π-radicals is dependent on the structure and symmetry of the orbital of the free electron; it also has important chemical implications. In σ-radicals the free electron is in an sp-hybridized orbital with contributions from both the s and p orbitals of the atom at which the free valence formally occurs; this usually results in the free electron orbital being non-perpendicular to the bonds attached to the free valence atom. In π-radicals the free electron orbital has a contribution from only the p orbital of the free valence atom and is perpendicular to the bonds to this atom; these bonds may themselves be sp-hybrid bonds and may be either co-linear or co-planar.

4.2. σ-Radicals

4.2.1. The Formyl Radical, HCO

The formyl radical could be either linear, $H-\overset{|}{C}=O$ (π-radical), or bent, $\overset{H}{\diagdown}C=O$ (σ-radical). *Adrian*, *Cochran*, and *Bowers*[42] produced the radical by reaction of hydrogen with solid carbon monoxide and also by photolysis of solid formaldehyde and methyl alcohol. The most striking feature of this work is the large proton hyperfine interaction of 137 G observed. (Since the resonance frequency ν and the magnetic field H are related by $h\nu = g\beta H$, the hyperfine interaction or splitting constant can be expressed in gauss or in megahertz.) This large interaction together with the pronounced anisotropy of the g-factor show that the formyl radical is a σ-type radical with the bent structure, *(1)*.

(1)



(2)

The other canonical form, *(2)*, with a loose interaction between a free hydrogen atom and a carbon monoxide molecule, also makes an important contribution. This is in complete accord with the information obtained from the infrared and kinetic studies (see Section 3.2.1).

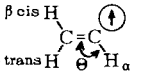
Brivati, *Keen*, and *Symons*[43] have also observed the ESR spectrum of the formyl radical and come to similar conclusions.

Recently *Cochran*, *Adrian*, and *Bowers*[44] have observed the ^{13}C hyperfine splittings in the HCO radical, and have determined the HCO angle as 125 °, thus confirming the bent structure.

4.2.2. The Ethynyl and Vinyl Radicals, $HC\equiv C\bullet$ and $H_2C=\dot{C}H$[16]

Photolysis of acetylene while being co-deposited with argon results in the formation of the ethynyl radical, $HC\equiv C$. The ESR spectrum shows a hyperfine interaction of 16.1 G with the proton. Unfortunately, the interpretation of this interaction in terms of the structure of the radical is complex but it does seem likely that the radical is of σ- and not π-type. Observation of the ^{13}C interactions (^{13}C has a magnetic moment, ^{12}C does not) would provide more information about the structure of the radical.

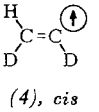
Vinyl radicals, $CH_2=\dot{C}H$, were formed by addition of hydrogen atoms to acetylene diluted with argon (analogous to the system used to generate HCO). The ESR spectrum showed that the unpaired electron interacted with three non-equivalent protons and from the effect of deuteration and from theoretical considerations it



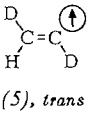
(3)

was shown that the hyperfine splitting constants could be assigned as follows: $a_{H\alpha} = 16.0$ G; $a_{Hcis} = 34$ G; $a_{Htrans} = 68$ G. *Cochran*, *Adrian*, and *Bowers*[16] calculate the Θ angle to be between 140 ° and 150 °.

In the formyl radical the α proton interaction is considerably greater (137 G). This is explained in part by the larger resonance of the carbon monoxide molecule and in part by the fact that the interaction is greater the less the angle Θ (in $\hat{HCO}$, Θ = 125 °). An interesting finding in this work is the fact that only the *trans* isomer is found when hydrogen atoms are added to dideuterioacetylene.



(4), cis



(5), trans

This is likely to be due to the zero point vibrational energies of the two isomers being sufficiently different so that only the more stable isomer is present in detectable concentrations at temperatures below 32 °K.

The ESR spectrum of the vinyl radical has also been observed recently in liquid ethylene by *Fessenden* and *Schuler*[4] and the only significant difference between the [solid] liquid and solid phases is that in liquid ethylene the α proton is inverting from one side of the molecule to the other at such a rate that the interactions with the β protons are averaged.

[42] *F. J. Adrian*, *E. L. Cochran*, and *V. A. Bowers*, J. chem. Physics *36*, 1661 (1962).

[43] *J. A. Brivati*, *N. Keen*, and *M. C. R. Symons*, J. chem. Soc. (London) *1962*, 237.

[44] *E. L. Cochran*, *F. J. Adrian*, and *V. A. Bowers*, J. chem. Physics *44*, 4626 (1966).

Fessenden [45] has recently observed the $\alpha^{13}C$ splitting in the vinyl radical (107.57 G) and from this has calculated Θ to be 151 ° which is in the range suggested by *Cochran, Adrian,* and *Bowers.* (The magnitude of the hyperfine splitting constant of the $\alpha^{13}C$ is dependdent on the amount of s character in the hybridize orbital and this in turn will also determine the bond angle.) All the features of the ESR spectrum of the vinyl radical, especially the $\alpha^{13}C$ interaction, show conclusively that it is a σ-type radical.

4.2.3. Trifluoromethyl, CF_3, and Other Fluorinated Methyl Radicals

Fessenden and *Schuler* [46] have observed the spectra of the interesting fluorinated methyl radical trapped in inert gas matrices, and also of CF_3 in liquid C_2F_6 (see also Section 3.2.4). In solid krypton and xenon the concentrations of radicals were sufficient for the ^{13}C splitting to be detected. From the value of the ^{13}C interaction, these authors have calculated that the free electron orbital has 21 % carbon 2s character and that the radical is non-planar (there is an angle of 17.8 ° between the C–F bonds and the plane normal to the threefold symmetry axis). In CHF_2 the orbital has 10 % C 2s character and the angle is 12.7 °; the CH_2F radical is nearly planar. There is thus a slow change from a planar radical to a pyramidal radical as the hydrogen atoms of the methyl group are replaced by fluorine atoms (see Section 4.3.1). The CF_3 and CF_2H radical ara again σ-type radicals.

4.2.4. The Cyclopropyl Radical

The ESR spectrum of the cyclopropyl radical in the liquid phase has been seen only by *Fessenden* and *Schuler* [4] and although it was not possible to observe any ^{13}C interaction, it is clear from the value of the α hydrogen splitting that the three bonds to the free valence carbon atom do not lie in a plane and that the radical is of the σ-type.

4.3. π-Radicals

4.3.1. The Methyl Radical

The ESR spectrum of methyl radicals has been observed in the solid phase [47] and in the liquid phase [4].

The hyperfine interaction with the protons is 23 G and with ^{13}C is 38.5 G, indicating that the radical is nearly planar, in agreement with the conclusion based on the absorption spectrum of the radical in the gas phase [48]. The methyl radical is thus a π-type radical with the free electron located in a carbon 2p orbital, the hydrogen atoms being bound to the carbon through sp^2-hybrid orbitals. An interesting result that follows from the different values of the ^{13}C interaction in CH_3, CD_3, CD_2H, and CDH_2 has been determined by *Fessenden* [45]. These values show that there is incomplete orbital following in these species (*i.e.*, the bonding electrons lag behind the nuclei as the nuclear skeleton undergoes bending vibrations). This is thought to be due to a decrease in electron repulsions caused by the occurrence of "bent" bonds [49].

4.3.2. Other π-Radicals

Most of the alkyl radicals appear to be of this type and these are discussed in Section 6.1.1. The benzyl radical [50], $C_6H_5\dot{C}H_2$, also belongs to this type and in this case the planar configuration about the $-CH_2$ group is favored by the occurrence of overlap of the p orbital on this carbon atom with the π-orbitals of the benzene ring.

4.4. Oxygen-containing Radicals

4.4.1. Alkoxy Radicals

Unfortunately, there is a conspicuous lack of information on the ESR spectra of alkoxy radicals. The samples from the γ-irradiation of frozen ethanol [51] and ultraviolet photolysis of H_2O_2/ethanol mixtures [52], followed by annealing of the samples at 100 °K, give rise to a slightly asymmetric single-line ESR spectrum which has been assigned to ethyl and methyl alkoxy radicals. No structural information is obtainable from these spectra and the assignments cannot be regarded as certain. The electron may not have an appreciable interaction with protons in the alkyl group but much more work is needed before any conclusions can be drawn with confidence.

5. The Rotating Cryostat

5.1. Principle of the Technique

The rotating cryostat is really a means of mixing two solids together intimately at the molecular level and in a controlled fashion so that single-step chemical reactions can occur and the primary products can be preserved for further study of their chemical and phys-

ical properties. For example, the reaction between a halohydrocarbon and alkali atoms,

$$RX + Na^{\bullet} \rightarrow R^{\bullet} + NaX,$$

has been used to generate hydrocarbon radicals.

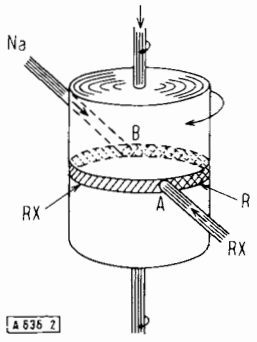

Fig. 2. Principle of the rotating cryostat.

The principle of the method is illustrated in Figure 2. Alternate layers of the two reactants are deposited from the gas phase onto the outer surface of a stainless steel drum which contains liquid nitrogen and is rotated rapidly (*ca.* 2400 r.p.m.) in a high vacuum ($<10^{-5}$ torr). The gaseous reactants are directed onto the drum from jets located close to the surface and on opposite sides of the drum so that each is deposited on a freshly formed surface of the other. The flow rates are adjusted so that about nine monolayers of halohydrocarbon are deposited per revolution but only about 1/25 of a monolayer of sodium. This "sprinkling" of the surface with sodium atoms ensures that very few alight adjacent to each other so that the radicals are formed in isolated sites. These radicals, immobilized on the surface, are then covered and trapped by the next layer of halohydrocarbon, and a small number of the surface molecules of this next layer are then converted into radicals by bombardement with further sodium atoms. This whole process is repeated many times until a solid deposit about 1 cm wide and about 1 mm thick is formed which is an interleaving spiral of a very dilute, free-radical layer and a much more dense halohydrocarbon layer. At the end of the experiment this deposit which contains about 10^{18-19} radicals per gram is transferred from the drum, still at 77 °K and under high vacuum, into a glass tube suitable for electron spin resonance measurements.

The technique can be slightly modified so that radicals can be prepared and trapped in materials other than the parent halohydrocarbon. This is achieved simply by deposition of the matrix as a third layer which forms the bulk of the deposit, the flux of halohydrocarbon being reduced to a value similar to that of sodium. In this case three jets are used instead of two. A similar modification allows the reactions of radicals with molecules to be studied. Before the radicals are covered up they are bombarded with a stream of the reactant molecules from the third jet. For example, the radicals can be bombarded with oxygen molecules, when the reaction

$$R^{\bullet} + O_2 \rightarrow RO_2^{\bullet}$$

takes place and the product radicals, RO_2, together with any unchanged R, are covered by the next matrix layer and trapped. If the ESR spectra of the reactant and product radicals differ sufficiently, the extent of the conversion can be calculated directly from the composite spectrum. Clearly, other reactions and other methods of generating radicals can be used in conjunction with the technique.

The rotating cryostat has a number of advantages over the simpler co-deposition methods where the vapors of different compounds are condensed on a stationary cold surface. The motion of the cold surface in the rotating cryostat allows the two processes of condensation and chemical reaction to be separated from each other and therefore allows more control of the system. It is also possible to study further reactions of the radicals initially formed, and this again can be done in a controlled way.

5.2. Experimental Equipment

A vertical section through the apparatus is shown in Figure 3. The drum itself is constructed from stainless steel and the parts are argon-arc-welded or vacuum-brazed together.

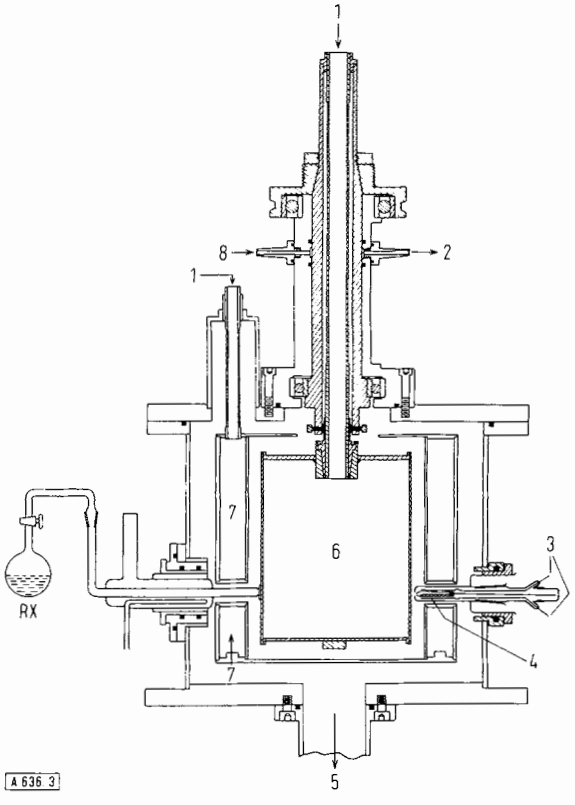

Fig. 3. General arrangement of cryostat (all hatched parts rotate; others are stationary), about 1/6 natural size.
1 — Filling tube for liquid nitrogen. 2 — Outlet for coolant. 3 — Terminals for heater windings. 4 — Sodium wire. 5 — To vacuum pumps. 6 — Spinning drum containing liquid nitrogen. 7 — Liquid nitrogen. 8 — Inlet for coolant.

The assembly is rotated by a belt-driven pulley attached to the outer tube, and it is the outer tube which carries the rotating seal. The "heart" of the apparatus is the seal around the outer shaft, which must allow the drum to be rotated at high speeds but must also seal the shaft so that pressures of less than 10^{-5} torr can be maintained in the main vessel (a high speed pump and wide-bore tubes are also used to help to maintain these low pressures). Two rubber O-rings, manufactured for rotating seals, are housed in two grooves with a 1 cm separation between them. The lower O-ring is the vacu-

um seal, while the upper one is a retaining ring which allows silicone oil to be pumped around the rotating shaft between the two O-rings. This flow of oil serves both to lubricate the seals and also to carry away the frictional heat which is generated by rotation of the shaft. (For further details see[53,54].)

6. Applications of the Rotating Cryostat

The results obtained can be divided into two categories: those that give information about the structure of the radicals and those that give direct information about the chemical reactions of radicals.

6.1. ESR Spectra and Structure of Radicals

6.1.1. Alkyl Radikals

Several radical species may be formed in the initial stages of photolysis or radiolysis and these primary radicals can either react with matrix molecules to form new radicals (the photon energy in excess of that required for bond breaking can be used for these reactions) or themselves be photolyzed into new species. With the rotating cryostat technique, the radicals are formed by the reaction

$$RX + Na\cdot \rightarrow R^{\bullet} + NaX$$

so that the position of the free valence in the radical is determined by the position of the halogen atom in the parent halohydrocarbon molecule. The ESR spectra of the deposits can therefore be assigned to definite radical species with considerable confidence.

A large number of alkyl radicals of each radical type have been prepared in a variety of matrices and the ESR spectra in each case can be interpreted in terms of the radical expected from the sodium-halohydrocarbon reaction. Some typical ESR spectra are shown in Figure 4. The results[54,55] are in general agreement with those of *Ayscough* and *Thomson*[56] who avoided some of the difficulties accompanying radiolysis by preparing the radicals by γ-irradiation of the parent halohydrocarbon. One difference is the finding of a readily interpretable spectrum for the isopropyl iodide-sodium system with the rotating cryostat, whereas a very complex spectrum was observed by *Ayscough* and *Thomson* after the radiolysis of isopropyl iodide.

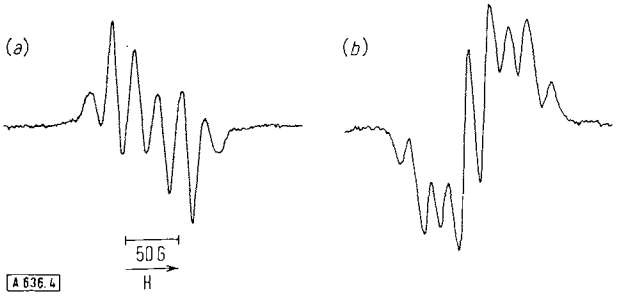

Fig. 4. The first derivative ESR spectra of: (a) *n*-heptyl radical $CH_3-(CH_2)_5-\dot{C}H_2$; (b) 4-heptyl radical $CH_3-(CH_2)_2-\dot{C}H-(CH_2)_2-CH_3$.

The spectra of the alkyl radicals can be interpreted on the following basis:

1) in all the alkyl radicals only the α and β protons (*i.e.* those attached to the free valence carbon atom and the adjacent carbon atoms) show any resolvable interaction with the unpaired electron (interaction with γ protons from 0.4 to 1.1 G can be observed in the liquid phase where the lines are narrower[4]);

2) the α protons, all three protons of a βCH_3 group and one of the protons of a βCH_2R group have similar hyperfine splitting constants of about 22 to 25 G;

3) the other proton in a βCH_2 group and the one proton in a βCH group have a hyperfine splitting constant of about 42 to 45 G.

These features can be explained by assuming that the α carbon atom adopts an sp^2 hybridization with a coplanar arrangement of the bonds around it and with the unpaired electron occupying a p-orbital whose axis is perpendicular to this plane. In order to explain the inequality of the two βCH_2R protons, it must be assumed that the hyperfine interaction depends on the orientation of the βCH bond with respect to the axis of the p-orbital. *Horsfield*, *Morton*, and *Whiffen*[9] have shown that this is so in free radicals formed by γ-irradiation of carboxylic acids and have also shown that the angular dependence of the interaction is given by

$$H_\beta = B_0 + B_1 \cos^2\Theta$$

where H_β is the β proton splitting, B_0 and B_1 are constants, and Θ is the angle between the βC–H bond and the p-orbital axis projected onto a plane perpendicular to the C–C bond. From the values of the hyperfine interaction the angles for the two β protons in alkyl radicals were calculated to be 12° (44 G interaction) and 48° (22 G interaction). The fact that the two β C–H bonds are non-equivalent shows that there is a barrier to rotation about the C–C bond. This does not necessarily mean that the molecule is fixed rigidly in any configuration but indicates that the lifetime in any of the four possible orientations which have these angles must be greater than 10^{-7} sec (the reciprocal of the hyperfine splitting).

From the chemical viewpoint the interaction with the α and β protons must mean that the α and β C–H bonds in the radical are weaker than in the corresponding alkane. In simple valence bond theory, this can be described in terms of contributions from canonical structures such as $H\cdot CH_2{=}CH_2$. For an isolated hydrogen atom the hyperfine interaction has a value of about 500 G so that a 22 G interaction can be interpreted on this basis to mean that the hydrogen is about 4% (22/500) dissociated in the radical. It is known from kinetic data that the C–H bond strengths in alkyl radicals are lower than those in the corresponding alkane (for example: $D_{(C_2H_5-H)} = 98.0$ kcal per mole while $D_{(\dot{C}H_2CH_2-H)} = 39$ kcal per mole)[19]

The results from these solid phase studies are in good accord with those obtained by *Fessenden* and *Schuler*[4] for alkyl

[54] *J. E. Bennett* and *A. Thomas*, Proc. Roy. Soc. (London) Ser. A, *280*, 123 (1964).

[55] *J. E. Bennett*, *B. Mile*, and *A. Thomas*, unpublished.

[56] *P. B. Ayscough* and *C. Thomson*, Trans. Faraday Soc. *58*, 1471 (1962).

radicals in the liquid phase. Any differences between corresponding spectra are due to effects of temperature and phase on the rates of intramolecular internal reorientation of the radicals.

6.1.2. Substituted Allyl Radicals[57]

Because the free allyl radicals can be formed with the free valence at a specific site, the rotating cryostat allows an interesting direct demonstration of the phenomenon of resonance in organic molecules. In two separate experiments sodium atoms were caused to react with 3-chloro-1-butene *(6)* and with 1-chloro-2-butene *(7)*. In the absence of resonance, radicals *(8)* and *(9)* should have quite different ESR spectra.

$$\underset{(6)}{CH_2{=}CH{-}CHCl{-}CH_3} + Na\cdot \rightarrow \underset{(8)}{CH_2{=}CH{-}\dot{C}H{-}CH_3} + NaCl$$

$$\underset{(7)}{ClCH_2{-}CH{=}CH{-}CH_3} + Na\cdot \rightarrow \underset{(9)}{\cdot CH_2{-}CH{=}CH{-}CH_3} + NaCl$$

In fact, the radicals from both chloro compounds gave identical spectra consisting, at 77 °K, of seven lines with an equal separation of 15 G. This shows that the unpaired electron is interacting equally with six equivalent protons and is entirely in accord with the generally held view that structures *(8)* and *(9)* are canonical forms of the same radical species. The one proton that does not show any interaction at 77 °K is that on C-2.

6.1.3. The Phenyl Radical[58]

The phenyl radical is considered to be one of the most reactive hydrocarbon radicals[59,60]. This radical can be prepared in a rotating cryostat from phenyl iodide and can be trapped when matrices of water, benzene, deuteriobenzene, and perfluorocyclohexane are used; however, when matrices such as camphane, hexamethylethane, and cyclohexane are used the radical abstracts a hydrogen atom from a matrix molecule to form a matrix radical. The ESR spectrum indicates that the unpaired electron interacts with the two *ortho* protons (18.1 G) and to a lesser extent with the two *meta* protons (6.4 G) but not with the *para* proton. This shows that the unpaired electron remains in an sp^2 orbital on the carbon atom at which bond scission has occurred and the radical is thus of the σ-type. The projection of the sp^2 orbital outwards from the aromatic ring helps to explain the very high reactivity of the phenyl radical since appreciable bonding interactions can occur with adjacent molecules at distances where the repulsive interactions are still low. The extreme reactivity of the phenyl radical is shown by the fact that radicals such as methyl do not attack matrices such as cyclohexane while the phenyl radical does so with great ease.

6.1.4. The $CO_2^{\ominus}$ and $CS_2^{\ominus}$ Radical Anions[61,62]

Deposition of sodium or potassium onto solid carbon dioxide or solid carbon disulfide at 77 °K resulted in the formation of ion pairs, $Na^{\oplus}CO_2^{\ominus}$, *etc.* There was a small hyperfine coupling to the alkali metal nucleus which showed that the unpaired electron was not completely transferred to the carbon dioxide or carbon disulfide molecule. Similar ion pairs can be formed by γ-irradiation of alkali formate crystals[63,64] and the differences between the hyperfine splitting constants of the alkali metal atoms in the two cases (one a molecular solid, the other an ionic solid) demonstrates the marked effect the environment can have on the unpaired electron distribution between the members of an ion pair.

6.1.5. Aliphatic Ketyl Radical Anions[65]

The ketyl radical anions *(10)* of acetone, biacetyl, cyclopentanone, and cyclohexanone were prepared by reaction of sodium (or potassium) atoms with the solid ketones at 77 °K,

$$\underset{\underset{O}{\|}}{R{-}C{-}R} + Na^{\cdot} \rightarrow \underset{\underset{O^{\ominus}}{|}}{R{-}\dot{C}{-}R} + Na^{\oplus}$$

(10)

No differences in spectra were detectable when potassium was used instead of sodium, showing that the electron had been transferred completely to the ketone molecule. From the values of the proton hyperfine splitting constants, the unpaired spin density at the carbonyl carbon was calculated to be only 70% of that in the corresponding alkyl radical in which hydrogen replaces the $O^{\ominus}$ group. This reduction is due to the occurrence of an appreciable spin density at the carbonyl oxygen atom, *i.e.*, structures such as *(11)*

$$R{-}\overset{\ominus}{\underset{\underset{O\cdot}{|}}{C}}{-}R \quad (11)$$

are important.

6.1.6. Trapped Electrons

Radiation chemistry has recently undergone a major development since it has been shown that the primary reducing species produced by the passage of ionizing

radiation through polar media such as water are solvated electrons and not hydrogen atoms[66] as was formerly supposed. A solvated electron is not associated with one molecule but is stabilized by interaction with an assembly of solvent molecules. ESR spectra of solvated electrons can be observed in liquid ammonia[66a], in frozen alkaline water, and in alcohols[67,68]. However, their spectrum is obscured by the spectra of other paramagnetic species such as $O^{\ominus}$, OH, and α-hydroxyalkyl radicals.

The rotating cryostat has been used to prepare trapped electrons as the sole paramagnetic species by the reaction of alkali metal atoms with ice and solid alcohols at 77 °K[69]. All the deposits were intensely colored and at 77 °K their ESR spectra consisted of a single narrow line. At 170 °K the spectrum Fig. 5 of trapped electrons in water became better resolved to reveal the presence of seven equally spaced lines (5.6 G apart) indicating an equal interaction with six protons of neighboring water molecules. The most likely arrangement of the water molecules around the electron is one with an octahedral disposition of the protons.

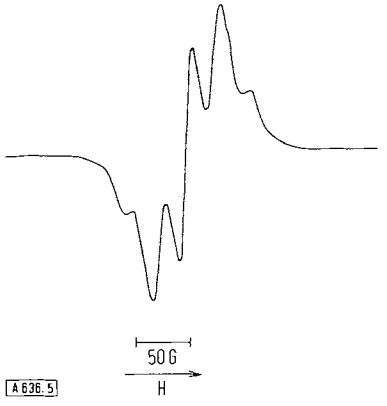

Fig. 5. The first derivative ESR spectrum of trapped electrons in ice at 170 °K.

When the samples containing trapped electrons in alcohols were either warmed slightly or exposed to visible light, the color of the samples faded and the spectrum changed to that of the corresponding α-hydroxyalkyl radical, R^1R^2COH[70]. The rate of this conversion could be measured from the change in the ESR spectrum with time, and it appeared that the rate-controlling step was a reorientation of the molecules around the electron trap into a configuration in which reaction could occur.

It is interesting that solvated electrons are not formed with hydrogen sulfide. Instead, simple negative ions $H_2S^{\ominus}$ are formed in which the electron is attached to one hydrogen sulfide molecule[71]. This marked difference between water and hydrogen sulfide is understandable because (1) the molecules in H_2S are not highly associated and have a lower dipole moment than molecules of water or alcohol and are thus less likely to form suitable electron traps; (2) the sulfur atoms has low-lying 3d orbitals which can accommodate the extra electron, whereas the oxygen does not.

6.2. Reaction Studies with the Rotating Cryostat

In these experiments the conditions under which reaction can occur are somewhat unusual in that a radical and a reactant molecule are "caged" or locked together in adjacent sites in the solid phase at 77 °K. The reactants are continually "colliding" with each other as they undergo lattice vibrations and librations of varying energy and amplitude. During the time of twenty minutes between the formation of the "caged" radical-molecule pair in the deposit and the recording of the ESR spectrum, reaction can occur when the energy in the caged region exceeds a critical activation energy with the reactants correctly orientated for reaction. If it is assumed that the energy flows in and out of the cage region with a frequency similar to that of lattice vibrations ($\nu = 10^{12}$ sec^{-1}) and that the pseudo-unimolecular reaction rate is given by $\nu P \exp(-E_A/RT)$, it can be readily shown that virtually complete reaction of all radical-molecule pairs occurs in the time available if $E_A < 5$ kcal per mole ($T = 77$ °K) and the steric factor $P = 10^{-1}$ to 10^{-4} sec^{-1}. Reactions with activation energies in excess of 5 kcal per mole cannot be conveniently studied because of the long times which would be involved.

6.2.1. Addition of Radicals to Oxygen

The reaction

$$R\bullet + O_2 + M \rightarrow RO_2\bullet + M \quad [72]$$

and the subsequent reactions of the peroxyl radicals, RO_2, are amongst the most important steps in any hydrocarbon oxidation at moderate temperatures (< 500 °C). The reaction has been investigated for a large number of radicals of widely different types (*e.g.*, alkyl, benzyl, and CF_3 radicals) by bombarding the radicals with molecular oxygen.

Since the ESR spectra of the radicals R• are usually very different from those of the corresponding peroxyl radicals, it is a relatively simple matter to estimate the extent of conversion of R• into RO_2 from a composite spectrum. The changes that occur in the case of the *tert*-butyl radical are shown in Figure 6. It is worth emphasizing that this is a direct observation on frozen radicals and does not involve the analysis of products

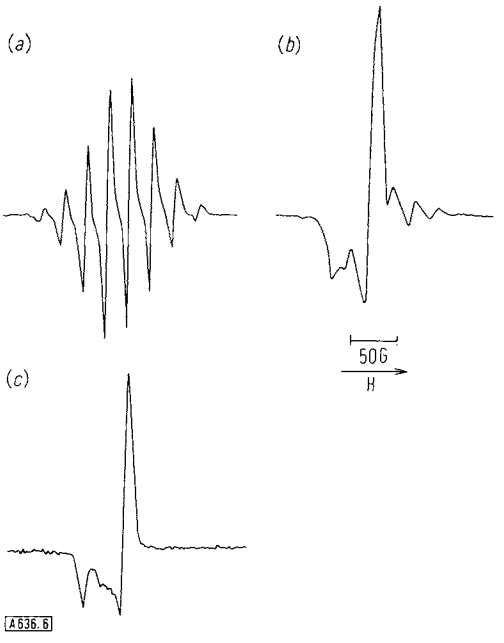

Fig. 6. Reaction between *tert*-butyl radical and oxygen at 77 °K. First derivative ESR spectra of (a) *tert*-butyl; (b) *tert*-butyl after bombardment with less than the stoichiometric quantity of oxygen; and (c) *tert*-butyl after bombardment with an excess of oxygen.

of further reaction. In all cases, even at 77 °K, complete conversion to the peroxyl radical occurred when sufficient oxygen was used, indicating a reaction of high efficiency and low activation energy. This extends to other radicals the previous conclusion about the high efficiency of this reaction made by *Dingledy* and *Calvert*, and *Hoare* and *Walsh* who studied the reactions of methyl and ethyl radicals with oxygen in the gas phase [73, 74].

The ESR spectra of the different peroxyl radicals are striking in that they are almost identical, being independent of the nature of the group R, and showing no hyperfine interaction with the protons in this group. This indicates that the free electron occupies an orbital that is confined almost entirely to the O–O region of the radical and is unaffected by the substituent group. Since the reactivity of radicals in terms of activation energy is determined principally by the orbital of the free electron it follows that all peroxyl radicals will have similar activation energies in bond-forming reactions.

6.2.2. The Addition of Radicals to Olefins

Early studies with the rotating cryostat showed [75] that not all radicals react with a particular olefin. For example, phenyl radicals react with ethylene at 77 °K, whereas *tert*-butyl and trichloromethyl radicals do not. Alkyl radicals do not react with tetradeuteroethylene at 77 °K [76]. The model used in the earlier work must be modified since it assumed that reaction occurred either on direct first collision between the radical and the alighting molecule or very soon afterwards. Subsequent work has shown that reaction can occur at any time from the collision of the molecule with the surface to the recording of the ESR spectrum of the deposit [77]. The uncertainty in time and in the value of ν (the lattice vibration frequency) means that only upper limit estimates of E_A and P can be made. It is therefore more profitable to study the site of radical addition in asymmetric olefins, than to attempt such estimates.

Phenyl radical addition to 1-hexene [76] leads to the formation of a radical the ESR spectrum of which shows that addition occurs exclusively at the terminal CH_2 group. This is a direct observation and no inferences have to be made to arrive at this conclusion. In the case of phenyl radical addition to $CH_2{=}CD_2$ [76] a secondary deuterium isotope effect could be studied since the phenyl radicals could add to the deuterium end of the olefin to give the radical $C_6H_5{-}CD_2{-}CH_2\bullet$ or to the hydrogen end to give $C_6H_5{-}CH_2CD_2\bullet$. The ESR spectra of these two radicals were different and the relative amounts of each radical could be evaluated from the composite spectrum. In this way it was found that $C_6H_5{-}CD_2{-}CH_2\bullet / C_6H_5{-}CH_2{-}CD_2\bullet = 4$ showing that the phenyl radical had a marked preference to add at the deuterium end of the olefin. This indicates that the sum of the carbon-hydrogen/deuterium vibration frequencies in the activated complex is greater than that in the ground state. This arises because, during the reaction, a soft out-of-plane bending C–H vibration in the olefinic trigonal carbon is converted into a harder bending vibration in the tetrahedral product radical.

$$C_6H_5^{\bullet} + CH_2{=}CH_2 \rightarrow C_6H_5{-}CH_2{-}\dot{C}H_2$$

trigonal tetrahedral

From the observed inverse isotope ratio of 4 and a simplified form of *Bigeleisen*'s equation [77, 78] the difference between the sum of the frequencies in the activated complex and in the ground state was calculated to be 570 cm^{-1}. The total change in the sum of frequencies for complete conversion of phenyl to phenylethyl was estimated to be 900 cm^{-1}, and a value of 570 cm^{-1} for the activated complex is a clear proof that the complex is product-like and that a strong bond exists between the phenyl radical and the olefin in the activated complex.

The advantages of the rotating cryostat for this type of study are clearly shown here; the low temperature accentuates small differences in reactivity (for instance, an isotope effect of 1.4 is predicted for this reaction at 25 °C) and the direct determination of the site of radical addition by ESR avoids difficulties that might arise because of isotope effects that can occur in product analysis.

6.2.3. Abstraction Reactions

$R\cdot + R_1H \rightarrow RH + R_1\cdot$

The activation energies for hydrogen abstraction by most radicals are too high for detectable reaction to occur at 77 °K. Phenyl, cyclopropyl, vinyl, and CF_3 radicals are the exceptions and these attack other molecules with great ease even at 77 °K [58, 76]. This clearly demonstrates their higher reactivity and it is of some interest to note that all these radicals are of the σ-type, in which the free electron is in a localized orbital projecting away from the rest of the molecule.

Modification of the Orientation of Substitution Reactions on Thiophene and Furan Derivatives

BY JA. L. GOLDFARB, JU. B. VOLKENŠTEIN, AND L. I. BELENKIJ [*]

Under normal conditions, thiophene and furan derivatives are substituted in the α position, and no convenient alternative methods for the preparation of β-substitution products have been available until now. The present article describes a method that permits the synthesis of many β-substituted thiophenes and furans. In this method, the carbonyl group in α-aldehydes or ketones of the thiophene and furan series is blocked by complex formation with an excess of aluminum chloride, so that electrophilic substitution takes place in position 4. In another useful method, the carbonyl group is blocked by acetalization. The acetals can be metalated in the ring by organolithium compounds.

1. Introduction

Though the term "aromaticity" [**] was first introduced more than a century ago, there is still no satisfactory definition or experimental test that could be applied to establish whether or not a system is aromatic. Our present ideas on aromatic systems are dominated by generalizations that follow from *Hückel*'s application of the MO theory to aromatic molecules and from the further development of this author's views. Despite the simplifications and approximations involved, the resulting physical picture enables us to explain some of the properties of such systems more or less precisely, and to predict the existence of new, similar compounds. However, questions concerning the properties of individual types of aromatic compounds were largely ignored for a long time.

Peculiarities in the behavior even of compounds that are formally very similar have in the meantime attracted considerable attention, from both the theoretical and the practical points of view. A comparison of the thiophenes with the furans shows that many properties are changed when a sulfur atom is replaced by an oxygen. Greater differences are observed on comparison of these and other heteroaromatic compounds with benzene derivatives. These differences are particularly obvious in substitution reactions; the unsubstituted heteroaromatic compounds can very often be regarded purely formally as monofunctional compounds.

One peculiarity of thiophene and furan is the strict orientation of electrophilic and protophilic substitutions, in which the substituent always becomes attached to the α position of the ring [***]. In the few cases in which β-substitution products were found, these were probably formed by isomerization of the α-substituted compound formed initially [4, 5]. Thus β-substituted products can generally be obtained only indirectly.

How can the orienting effect of the hetero atom be overcome in thiophene and furan chemistry? A solution to this problem would be valuable, since *e.g.* many natural products are β-substituted furans and thiophenes. The β-substitution products may also include physiologically active compounds.

Moscow V-334, Leninskij Prospekt 47 (USSR).

[**] The term "aromatic" is also used for heteroaromatic systems in this paper.

[***] The deuterium exchange kinetics show that the α position of thiophene reacts three orders of magnitude faster than the β position in electrophilic substitutions [1, 2] and six orders of magnitude faster in protophilic substitutions [2]. The α position in furan reacts three orders of magnitude faster than the β position in protophilic substitutions [3].

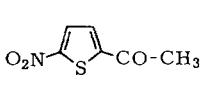
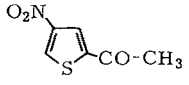
Significant work on the synthesis of 2- and 3-substituted thiophenes and their biological action in comparison with one another and with benzene derivatives has been carried out by *Campaigne et al.* [6]. Having examined the literature data (cf. *e.g.* [7]), we can agree with *Campaigne*'s opinion that the biological activity of 3-substituted thiophene cannot be estimated from the activity of the corresponding 2-substituted thiophene or of a benzene analog. Thus the β-substituted isomer should not be forgotten in the testing of thiophene analogs of biologically active benzene derivatives. There is a very high probability that this isomer is more active than the α-isomer. We know of only one case in which the antibiotic activity present in the α isomer (5-nitro-2-acetylthiophene) *(1)* does not occur in the β isomer *(2)* [8].



(1)



(2)

There is considerably less literature on the comparison of the physiological activities of α- and β-substituted furans, since β-substituted furans are much more difficult to obtain. However, many of the β derivatives again exhibit greater biological activity than the α isomer (analgesics [9], antihistaminics [10], antiseptics [11, 12]).

Four methods are available for the synthesis of β-substituted thiophenes:

1. Ring closure of bifunctional aliphatic compounds.

2. Side-chain bromination of 3-methylthiophene with *N*-bromosuccinimide.

3. Introduction of functional groups into a 2,5-disubstituted thiophene, followed by removal of the original substituents (generally halogen).

4. Reactions of 3-bromothiophene.

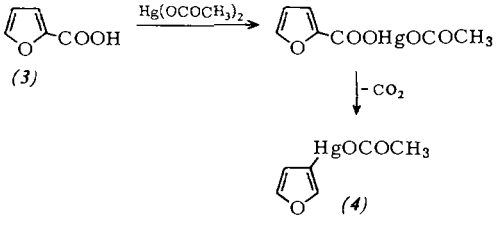
Though method 1 has been used for the synthesis of several interesting compounds, it is not very promising, since the bifunctional aliphatic compounds required as starting material are generally difficult to obtain. Moreover, thiophene derivatives can be synthesized from thiophene itself and its lower homologs, which are formed on thermal decomposition of natural raw materials or can be obtained from aliphatic hydrocarbons and sulfur or simple sulfur compounds. Quite apart from that, the tendency in thiophene chemistry is more toward the opposite course, *i.e.* the preparation of aliphatic compounds from thiophenes.

Method 2, which was proposed by *Campaigne* [13], is more feasible; however, it is fairly laborious and yields 2-bromo-3-methylthiophene as a by-product, although it has given satisfactory yields of 3-substituted thiophenes in some cases [14].

2,5-Dichloro-3-chloromethylthiophene [15], alkyl 2,5-dichloro-3-thienyl ketones [16, 17], and 2,5-dichloro-3-thiophenecarboxylic acid [18] have so far been obtained by method 3. It is very difficult in this case to eliminate the halogen atoms without alteration of the functional group introduced.

In our view the most suitable method for the preparation of 3-substituted thiophenes is that based on the use of 3-bromothiophene (method 4). The latter compound is generally obtained from 2,3,5-tribromothiophene by elimination of two bromine atoms. The simplest method of dehalogenation is that described by *Gronowitz* [19], in which zinc dust and acetic acid are used. This author also showed that the bromine in 3-bromothiophene can be almost quantitatively replaced by lithium under the action of *n*-butyllithium at −70 °C [20]. It would be difficult to overestimate the possibilities offered by 3-thienyllithium.

The range of reactions available for the synthesis of β-substituted furans is even smaller than that given for β-substituted thiophenes. We know of only two cases in which substituents were introduced directly into the β-position of a furan ring having at least one free α position. One was the reaction of mercury acetate with 2-furancarboxylic acid *(3)* to form a β-mercurated compound *(4)* [21], while the other was the formation of 4-isopropylfurfural from furfural [22] by alkylation with 2-chloropropane.



(3) *(4)*

In the first case the reaction proceeds *via* a mixed mercury salt of acetic acid and 2-furancarboxylic acid. Isomerization of 2-isopropylfurfural into the 3-isomer cannot be ruled out in the second case (cf. [5]).

In view of these difficulties, 3-monosubstituted and 2,3- and 2,4-disubstituted furans are usually obtained by cyclization of aliphatic compounds or by removal

of substituents from 2,3,5-trisubstituted furans. All these reactions proceed less readily than in the thiophene series, and the desired products are formed in lower yields.

2. Modification of the Orientation by Complex Formation

2.1. Problem

None of the preparative methods permits the direct introduction of substituents into the β-position of thiophenes or furans containing at least one free α position. We attempted to develop a direct method of β substitution suitable for at least some types of compounds of these series. As our first model we chose derivatives having a carbonyl group in one α position in the ring.

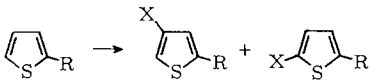
The directing influences of the ring hetero atom and of the electron-attracting substituent in position 2 of thiophene are superimposed in such a complex manner that the direction of electrophilic substitution cannot be predicted accurately for such compounds (for review see [23]).

However, it was observed some time ago [24] that the *ortho*, *meta*, and *para* positions of benzene approximately correspond to the 3, 4, and 5 positions in a 2-substituted thiophene. MO calculations [25] and dipole moment measurements [26] confirm that, to a satisfactory approximation, these positions can in fact be compared. On applying the Hammett equation to heterocycles, *Imoto et al.* [27,28] found that the constants ρ for reactions of thiophene and benzene derivatives do not differ greatly if σ_{para} is used for 2,5-disubstituted thiophenes and σ_{meta} for 2,4-disubstituted thiophenes.

Owing to the competition of the 4-directing effect of the substituent and the α-directing effect of the hetero atom, electrophilic substitutions on furan and thiophene derivatives having class II substituents in the α position practically always lead to mixtures of the 4- and 5-substitution products. The proportion of the 4 isomer formed increases with the strength of the −M effect of the substituent in position 2 [23].

Intensification of the electron-attracting properties of the substituent, *e.g.* by protonation of the carbonyl group in a strongly acidic medium, increases the percentage of the 4 isomer. Thus the 4 isomer predominates on nitration of 2-thiophenecarbaldehyde with nitric acid/sulfuric acid, whereas bromination of the aldehyde in chloroform leads almost exclusively to 5-bromo-2-thiophenecarbaldehyde [29]. Literature data relevant to this problem are listed in Table 1.

Table 1. Directing effects of class II substituents in position 2 of the thiophene ring.



(5) *(6)*

R	Reaction	Amount of *(5)* (%)	Amount of *(6)* (%)	Ref.

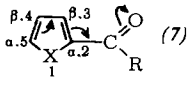
Section 1), and (iii) the reaction of methyl furoate with caproic anhydride in the presence of tin tetrachloride, which yields a mixture of the 4- and 5-caproylated products [47].

Thus to introduce an electrophilic substituent into the β position of thiophene or furan, it is necessary to reduce the mobility of the α hydrogen atom in the ring without appreciably altering the mobility of the β hydrogens. Moreover, any side chains present must not be attacked. To achieve this purpose, it seemed reasonable to make use of the conjugation resulting from the presence of an electronegative group such as the carbonyl group in the molecule [see *(7)*].

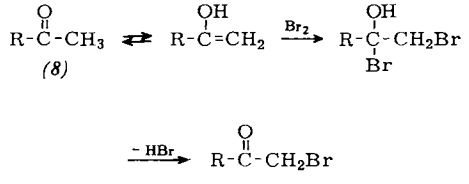


(7)

The carbonyl compound can react with an excess of a Lewis acid (particularly aluminum chloride) to form a complex in which the substituent is more strongly electron-attracting than in the free aldehyde or ketone; this increases the probability of formation of the 4-substituted, but not of the 5-substituted product. On the other hand, the complex formation hinders or prevents substitution in the side chain. Finally, the well-known catalytic effect of Lewis acids on electrophilic substitutions is particularly important for the less active β position.

It was shown as early as 1926 [48] that *m*-xylene, which gives no diketone under the usual conditions for the Friedel-Crafts reaction, reacts in the presence of 3 moles of aluminum chloride and without a solvent to give the diketone in a satisfactory yield. *Campbell* and *Spaeth* [49] obtained *m*-isopropylacetophenone by reaction of acetophenone with 2-chloropropane in a 4.5-fold molar excess without a solvent or in a 2-fold molar excess with a solvent. Practically pure 4-isopropyl-2-acetylthiophene has been prepared in a similar manner by alkylation of 2-acetylthiophene with 2-chloropropane and an excess of aluminum chloride [44].

Pearson et al. [50, 51] investigated the effect of the quantity of aluminum chloride on the direction of halogenation. It is well known that alkyl aryl ketones are normally halogenated in the side chain, α to the carbonyl group. The first step is the enolization of the ketone *(8)* [52].



In the halogenation of acetophenone and its homologs in the presence of 2–3 moles of aluminum chloride and without a solvent, *Pearson et al.* found that the halogen was introduced, not into the side chain, but into the ring position *meta* to the carbonyl group.

The main action of the aluminum chloride is probably the blockage of the carbonyl group by complex formation. The methyl group of the ketone is then no longer attacked, since enolization is practically or completely prevented in the complex. One mole of aluminum chloride is thus used for complex formation, and the remainder acts as a catalyst by participation in the formation of the attacking agent.

$$X_2 + AlCl_3 \rightleftarrows X^{\oplus} + AlCl_3X^{\ominus}$$

This assumption is confirmed by the fact that the rate of the reaction decreases when the quantity of catalyst added is reduced from 2.5–3 mole to 1.2 mole. However, the aluminum chloride also acts as a medium having a high dielectric constant, and so promotes dissociation [*].

This effect ("swamping catalyst effect") also enabled the authors to obtain satisfactory yields in the halogenation of several aromatic aldehydes and ketones [51] and several derivatives of aromatic acids [53], aniline [54], pyridine, picoline [55], isoquinoline, and quinoline [56].

2.2. Bromination of Aldehydes and Ketones of the Thiophene and Furan Series in the Presence of an Excess of Aluminum Chloride

We decided to prepare the complex of 2-acetylthiophene with aluminum chloride first, and to examine it by UV and IR spectroscopy [57], since complex formation with the hetero atom, which is possible in principle though not very probable in our case, could not be ruled out. The 600 Å increase in the wavelength of the UV absorption maximum in relation to the spectrum of the free ketone and the 70 cm^{-1} decrease in the characteristic carbonyl frequency in the IR spectrum confirm that complex formation takes place at the carbonyl group, as previously reported in the literature [58–61]. The complex is dissociated in very dilute solutions in chloroform.

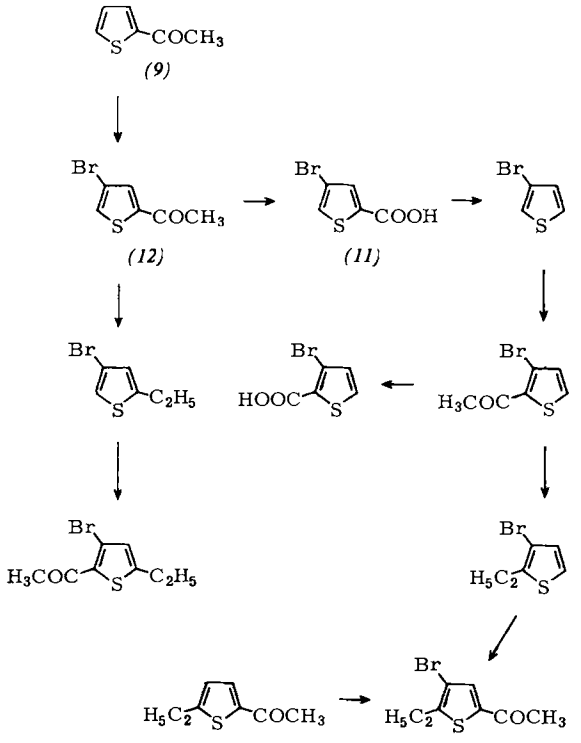
2-Acetylthiophene *(9)* [62] and other alkyl 2-thienyl ketones *(10)* [63] are brominated in the side chain in the presence of catalytic quantities of aluminum chloride in solution.

(9), R = H
(10), R = Alkyl

Bromination without a solvent and in an excess of aluminum chloride [2.5 moles per mole of *(9)* or *(10)*] yields 4-bromo-2-thienyl ketones [63,64]. Some of the reactions of 4-bromo-2-acetylthiophene *(12)* are shown in Scheme 1.



Scheme 1

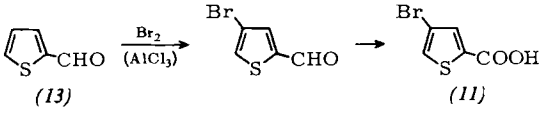
The structure of *(12)* is confirmed by chemical reactions, particularly by oxidation to the known acid *(11)*, as well as by its UV and IR spectra [65]. Polarographic measurements [66] indicate that the distilled 4-bromo-2-acetylthiophene *(12)* contains at most 0.5% of 5-bromo-2-acetylthiophene.

The only impurity isolated from *(12)* was 4,5-dibromo-2-acetylthiophene. The yield of 4-bromo-2-acetylthiophene was about 70%, that of its homologs (in the reactions of higher alkyl 2-thienyl ketones) 43–62%, and that of 4,5-dibromo-2-acetylthiophene 12%.

In view of the high reactivity of the α-methylene hydrogen in ketones, it could be assumed that the first step in the bromination is the formation of the 2-(α-bromoacyl)thiophene, independent of the reaction conditions. In the presence of more than the molar quantity of aluminum chloride, this product could isomerize to give the ring-brominated product. However, our experiments with 2-(α-bromopropionyl)thiophene and with 2-(α-bromobutyryl)thiophene in the presence of an excess of aluminum chloride and in the absence of solvent showed that a rearrangement of this type does not take place. It was also found that 5-bromo-2-acetylthiophene could be recovered unchanged after having been heated for several hours with an excess of aluminum chloride while hydrogen bromide gas was passed through the mixture.

The experiments thus show that bromine, presumably as Br^+, attacks alkyl thienyl ketones directly on C-4 of the ring.

We have also used this method for the bromination of 2-thiophenecarbaldehyde *(13)*, which is brominated almost exclusively in position 5 under normal conditions [42,43]. The bromination of the complexed aldehyde [41] leads to 4-bromo-2-thiophenecarbaldehyde (yield about 90%), the structure of which was proved by oxidation to the carboxylic acid *(11)* and by its spectra.



If the quantity of bromine is increased to 2.5–3 moles per mole of carbonyl compound, the bromination of 2-thiophenecarbaldehyde and of the alkyl 2-thienyl ketones with an excess of aluminum chloride and in the absence of solvent can be made to give very high yields of the 4,5-dibromo derivatives of the carbonyl compounds.

It was of interest to study the reaction of 2-acetylfuran *(14)* with bromine in the presence of an excess of aluminum chloride. According to *E. V. Brown*, *(14)* is brominated in the side chain when little or no catalyst is present [67]. It is also known [68–71] that in the halogenation of furan derivatives having electronegative substituents in position 2, the α-directing effect of the ring oxygen (which evidently influences the substitution direction more strongly than the sulfur in thiophene) predominates. Nevertheless, under the conditions used by *Pearson* the question of orientation in the bromination of 2-acetylfuran was difficult to decide.

We found that the action of one mole of bromine on 2-acetylfuran *(14)* at room temperature in the presence of three moles of aluminum chloride and without a solvent results in attack on the furan ring. However, this reaction, unlike that of 2-acetylthiophene, cannot be stopped at the stage of the monobromo derivative [72]. A little 2-acetyl-5-bromofuran can be isolated

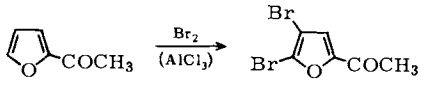
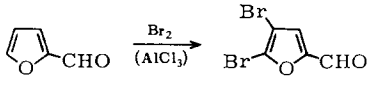
only at low temperatures and with short reaction times, together with 2-acetyl-4,5-dibromofuran *(15)*, which is the principal product at room temperature.

The yield of 2-acetyl-4,5-dibromofuran *(15)* rises from 34 to 62% when the molar ratio of bromine to 2-acetylfuran is increased to 2:1. The structure of *(15)* is proved by oxidation to the known 4,5-dibromo-2-furancarboxylic acid, which is also obtained directly by bromination of 2-furancarboxylic acid [71].



(14) *(15)*

It was later found that furfural [41, 73] behaves in the same way as 2-acetylfuran on bromination in the presence of an excess of aluminum chloride, *i.e.* two atoms of bromine enter the nucleus at the same time, and 4,5-dibromofurfural *(16)* is formed as the sole product (identification by oxidation to the carboxylic acid).



(16)

The bromination of furfural itself [68] and of its diacetate [69] in the absence of catalyst leads exclusively to 5-bromofurfural.

2.3. Influence of the Solvent

According to *Pearson et al.*, the bromination of an alkyl aryl ketone such as acetophenone, or of an aromatic aldehyde, without a solvent and with 2.5–3 moles of aluminum chloride per mole of aldehyde or ketone exhibits the "swamping catalyst effect". *Pearson* claims that three conditions are essential to ring halogenation [51]:

1. The carbonyl compound must be present as the aluminum chloride complex until the bromine is added.
2. Solvents must not be used.
3. The complex must be liquid, so that the mass can be stirred during the addition of the bromine.

Critical investigation of these conditions [74] has shown that the absence of solvents is not necessary, and sometimes actually hinders the isolation of the product from the reaction mixture and leads to low yields. It can be concluded from the proposed course of the reaction (see Section 2.1) that an excess of aluminum chloride and a practically homogeneous medium are essential to the success of the bromination. Any solvent that is inert under the conditions of the reaction may be used if it dissolves the complex of the aluminum chloride and the carbonyl compound without noticeable dissociation, and does not prevent the activation of the halogen by formation of a stable complex with the excess of aluminum chloride. The quantity of solvent that may be used is naturally limited, since the complex may dissociate if the solution is too dilute.

Even a small excess of aluminum chloride should direct the reaction in the desired direction; however, the optimum quantity that ensures an adequate reaction rate must be determined experimentally.

These conclusions have been fully confirmed by experiment. In the bromination of acetophenone in chloroform, we obtained the same results as under the conditions described by *Pearson*, and it was unnecessary to use 2.5 moles of aluminum chloride per mole of carbonyl compound. The same reaction direction and yield were obtained with only 1.5 mole of aluminum chloride per mole of ketone. A further decrease in the quantity of aluminum chloride leads to a decrease in the rate of the reaction, but the bromination, as before, still takes place on C-4 (see Table 2).

Table 2. Bromination of acetophenone in chloroform with various quantities of aluminum chloride [a].

$AlCl_3$:acetophenone (mole)	Acetophenone recovered (%)	Yield of *m*-bromoacetophenone (%)
2.5:1	4.2	57.0
1.5:1	11.6	60.0
1.3:1	24.0	45.0
1.1:1	69.0	29.5
1.0:1	68.0	— [b]

[a] In all the experiments the aluminum chloride was added to a solution of 0.1 mole of acetophenone in 50 ml of chloroform, and 0.1 mole of bromine was then added. The mixture was heated for 2 hours, allowed to stand for 18 hours at 20 °C, and then worked up in the usual way. The product was finally distilled off.

[b] In addition to the recovered acetophenone (68%), a high-boiling fraction (24% of the weight of acetophenone used) was obtained. Apart from acetophenone, this fraction contained traces of *m*-bromoacetophenone and phenacyl bromide (detected by gas chromatography).

The yield of *m*-bromoacetophenone increases to 80–85% when the bromination of acetophenone is carried out in dichloroethane. Methylene chloride, carbon tetrachloride, and carbon disulfide may also be used as solvents. On the other hand, bromination does not proceed in nitrobenzene; this is due to the low activity of the catalyst (the excess of aluminum chloride forms a complex with nitrobenzene). Saturated hydrocarbons are unsuitable, since the complex of acetophenone with aluminum chloride is completely insoluble in these solvents.

As expected, the bromination of 2-acetylthiophene, of 2-thiophenecarbaldehyde, and of furfural in solvents led to the same results as those obtained earlier under *Pearson*'s conditions. Both the products obtained by *Pearson*'s method and those obtained under our conditions contained 0.5–1.5% of the initial carbonyl compound, which was difficult to eliminate, and in the case of the ketone 0.5–1% of ω-bromo ketone.

The formation of the ω-bromo ketone in the presence of an excess of aluminum chloride can be attributed to the low equilibrium concentration of free ketone. An increase in the quantity of solvent used naturally favors the dissociation of the complex, and so leads to an increase in the quantity of ω-bromo ketone formed. Thus with 300 ml of chloroform instead of 50 ml per 0.1 mole of acetophenone (see Table 2), the bromination product consists almost entirely of phenacyl bromide.

Thus the solvent does not cause any essential change in the character of the reaction, and no specific "swamping catalyst effect" exists. In our opinion the only advantage of the large excess of aluminum chloride is that it lowers the melting point of the reaction mass. On the other hand, the use of a solvent permits an appreciable reduction of the quantity of aluminum chloride used, and also simplifies the isolation of the product; it is well known that when no solvent is used, the reaction mixture frequently solidifies toward the end of the reaction.

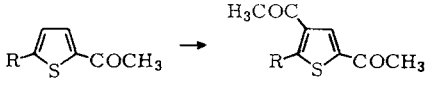
2.4. Acylation of Thienyl Ketones

On the assumption that bromination is not the only electrophilic substitution in the thiophene series to which the blockage of the carbonyl group by an excess of aluminum chloride could be applied, *Goldfarb* and *Litvinov* studied the acylation of some thienyl ke-

[73] *Ja. L. Goldfarb* and *L. D. Tarasova*, Izvest. Akad. Nauk SSSR, Ser. chim. *1965*, 1079.

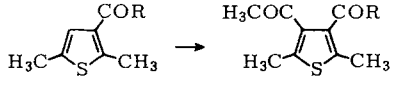
[74] *L. I. Belenkij, G. P. Gromova*, and *Ja. L. Goldfarb*, Izvest. Akad. Nauk SSSR, Ser. chim. *1967*, 1627.

tones [75]. It is known that the action of acetic anhydride on 2-acetylthiophene in the presence of zinc chloride leads to 2,5-diacetylthiophene [45], but only in 6% yield. It was hoped that 2,4-diacetylthiophene, possibly contaminated with the 2,5-isomer, might be obtained by the action of acetyl chloride in the presence of an excess of aluminum chloride and without a solvent, *i.e.* under *Wulf*'s conditions for the diacetylation of *m*-xylene [48]. However, the expected reaction did not take place, and the 2-acetylthiophene was recovered unchanged [75]. The introduction of the second acetyl group into position 4 proceeds only when the α position is occupied by an alkyl group, as in 5-methyl- *(17)* and 5-ethyl-2-acetylthiophene *(18)*.



(17), R = CH_3
(18), R = C_2H_5

It should be noted that 2,5-dimethyl-3-acetylthiophene *(19)* and *tert*-butyl 2,5-dimethyl-3-thienyl ketone *(20)* are acetylated in yields of up to 87% [75] with an excess of $AlCl_3$ and in absence of solvents, though in these cases, in contrast to the 5-alkyl-2-acetylthiophene, the orientation toward position 4 is absent.



(19), R = CH_3
(20), R = $(CH_3)_3C$

There are two possible reasons for this. The first is the high activity of the β position in 2,5-dialkylated thiophenes; the activity of this position in 2,5-dimethylthiophene is approximately the same as that of the α position in unsubstituted thiophene [76]. The second possible reason is that the carbonyl group in the β position is not coplanar with the thiophene ring [77] so that the withdrawal of electrons from position 4 by the −M effect is hindered.

2.5. Chloromethylation of Aldehydes and Ketones of the Thiophene and Benzene Series

It seemed interesting to examine the question of whether an excess of aluminum chloride can also be used for the chloromethylation of the ring in acetophenone, 2-acetylthiophene, and 2-thiophenecarbaldehyde. Little is known about the chloromethylation of aldehydes and ketones. In 1936, the chloromethylation products of pinacolone and of diethyl and dipropyl ketones [78] were obtained in 30–35% yield; acetone was later chloromethylated and the chloromethylation products of acetaldehyde and of methyl ethyl ketone were isolated in lower yields [79].

The unsubstituted aliphatic-aromatic and aromatic aldehydes and ketones (acetophenone [80–82], benzophenone [82], anthraquinone [83]) cannot be chloromethylated. However, two methyl groups in the ring of an aliphatic-aromatic ketone permit the introduction of the chloromethyl group into the ring [82]. Chloromethylation is even easier in ketones containing alkoxyl or hydroxyl groups. 4-Alkoxyacetophenones [84], 2-hydroxyacetophenone [85], and 2-hydroxypropiophenone [86] react in high yields. The chloromethylation of salicylaldehyde, of *o*-homosalicylaldehyde [87], and of anisaldehyde [88] has also been reported. Thus the reaction is facilitated by the presence of a hydroxyl or methoxyl group. Acetophenone, propiophenone, 4-methylacetophenone, and 3,4-dimethylacetophenone have been chloromethylated in the side chain in the presence of boron trifluoride-ether [89,90].

Even less work has been done on the chloromethylation of ketones of the five-membered heterocycles. It is interesting to note that in all the known cases prior to our work, the substituent entered the ring in position 5 (2-acetyl-5-chloromethylfuran [91], 2-acetyl-5-chloromethylselenophene [92], and 2-acetyl-5-chloromethylthiophene [46]). The yield in the case of 2-acetylthiophene was 5.7% based on the ketone introduced or 37% based on the ketone that reacted. According to the work of *Lukeš et al.* [46], *Hartough*'s report [93] that 2-acetylthiophene is chloromethylated in the side chain by formaldehyde and hydrochloric acid must be regarded as unsupported. We were unable to reproduce the work of *Janda* and *Dvořak* [94,95] on the orienta-

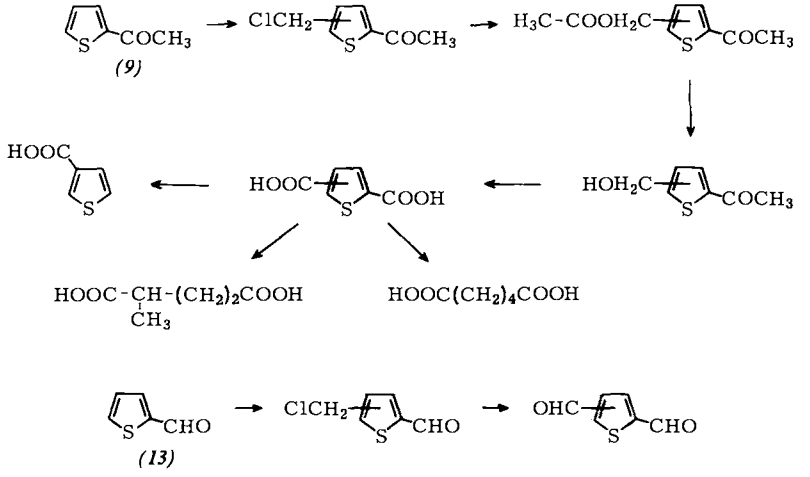
tion of the chloromethylation in 2-propionylthiophene [96].

The chloromethylation of acetophenone with chloromethyl methyl ether in the presence of 2.5 moles of aluminum chloride and without a solvent [97] led to *m*-chloromethylacetophenone (39% yield based on the acetophenone introduced, and 54% based on the acetophenone that had reacted), a compound that had not previously been described in the literature. The structure of the product was proved by oxidation to isophthalic acid, which was identified in the form of its dimethyl ester.

The chloromethylations of 2-acetylthiophene [97] and of 2-thiophenecarbaldehyde with an excess of aluminum chloride are not so simple. The product in both cases was a mixture of the 4- and 5-chloromethylation products, in which the 4 isomer predominated.



The reasons for the difference in orientation in the chloromethylation and in the bromination are not yet clear. There is still also some uncertainty concerning the action of the chloromethyl ether in normal chloromethylations; this evidently explains the contradictions in the literature [98,99,83].

In the chloromethylation of aromatic compounds in the presence of aluminum chloride, diarylmethane derivatives are often formed as by-products. We found that acetophenone and 2-acetylthiophene are partly converted into derivatives of diphenyl- and dithienylmethane on chloromethylation [97].

It is interesting in this connection to note that 5-ethyl-2-acetylthiophene, which gives 5-ethyl-4-chloromethyl-2-acetylthiophene *(21)* in 47 or 76% yield when formaldehyde or paraformaldehyde, respectively, is used under normal conditions, is converted exclusively into bis(2-ethyl-5-acetyl-3-thienyl)methane *(22)* (yield 77%) by the action of chloromethyl methyl ether and an excess of aluminum chloride [100].

2.6. Some Reactions of the Synthesized Products

The blockage of a carbonyl group in derivatives of thiophene and furan permits the easy introduction of a functional group into position 4 of the ring. 4-Bromo-2-acetylthiophene, 4-bromo-2-thiophenecarbaldehyde, and 2-acetyl-4-bromofuran (which is obtained from 2-acetyl-4,5-dibromofuran by elimination of the bromine from the α position [101]) are readily obtainable starting materials for a number of syntheses. In particular, the reduction of the carbonyl group in these compounds, followed by replacement of the bromine in position 4 by lithium, offers a convenient method for the preparation of 5-ethyl- and 5-methyl-3-thiophenecarbaldehyde [102,41], 5-methyl-3-thiophene-

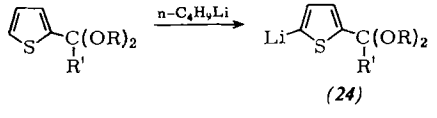
carboxylic acid [41], a series of new furan derivatives with a functional group in the β position, *etc.* 5-Ethyl-3-methylthieno[3,2-*b*]thiophene-2-carboxylic acid *(23)* has been prepared from 4-bromo-2-acetylthiophene [103].

3. Metalation of Acetals of the Thiophene and Furan Series; Syntheses on this Basis

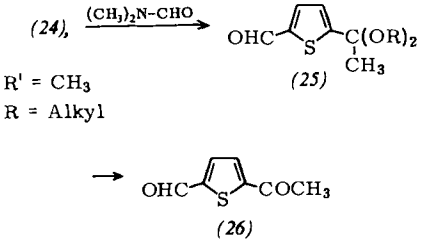
New synthetic paths are opened up by a reversible reaction in which a carbonyl derivative of thiophene or furan is converted in the usual manner into the acetal, which is then treated with an organolithium compound.

In contrast to the reaction of organomagnesium compounds with acetals [104, 105], the acetal group remains unchanged and lithium is introduced into position 5 of the ring. The resulting lithium-substituted acetal *(24)*, which need not be isolated, can be converted into a bifunctional compound [*e.g. (25)*]; the acetal group can, if necessary, be readily changed into an aldehyde or keto group, depending on the starting compound. The special feature of this method is that it permits the preparation of bifunctional thiophene derivatives having similar or different substituents, the synthesis of which is always very difficult, if not practically impossible, by other routes.

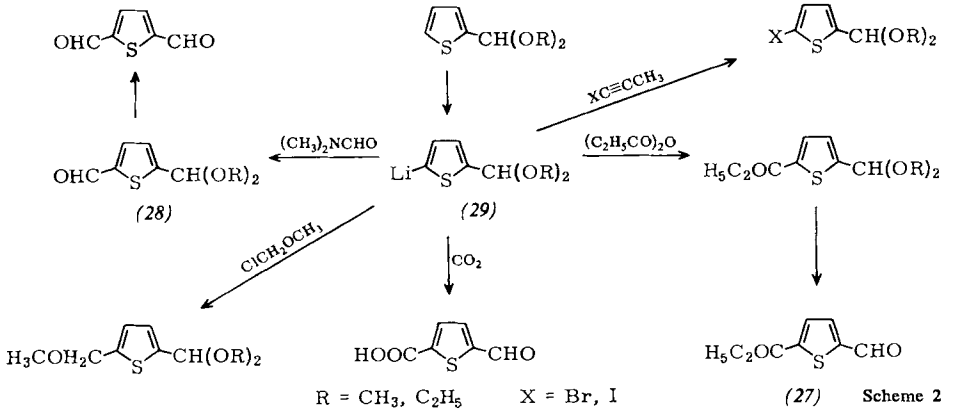


3.1. Syntheses of 2,5-Disubstitution Products

Ring metalation of compounds of the thiophene series containing a carbonyl group protected by acetalization, and subsequent replacement of the lithium with a second carbonyl group by the action of dimethylformamide, was first achieved in 1960 [106]. 5-Formyl-2-acetylthiophene *(26)* was obtained in this way. In this synthesis, the thiophene derivative was metalated by butyllithium exclusively in position 5 of the thiophene ring, as was shown by the oxidation of *(26)* to 5-acetyl-2-thiophenecarboxylic acid [106] and 2,5-thiophenedicarboxylic acid [96].



Some reactions of the acetals of 2-thiophenecarbaldehyde are illustrated in Scheme 2 [96, 107, 108].



Scheme 2

5-Propionyl-2-thiophenecarbaldehyde *(27)* was obtained, not only by the method shown in Scheme 2, but also by the action of dimethylformamide on the diethyl ketal of 5-lithium-2-propionylthiophene [96]. Compound *(27)* is crystalline, m.p. 101 °C, and can be oxidized to the carboxylic acid (proof of structure). On the other hand, a product obtained from 5-chloromethyl-2-propionylthiophene, which was thought to be *(27)*, is a liquid [94, 95].

The syntheses of unsymmetrical bifunctional thiophenes from the monoacetal of thiophene-2,5-dicarbaldehyde *(28)* [109] are particularly important. The acetal group in the monoacetal is not affected during the reduction of the free aldehyde group and its condensation with amines, hydroxylamine, compounds containing active methylene groups, *etc.* (see Section 3).

The Schiff bases *(30)* can be readily reduced to the amino acetals *(31)* by $NaBH_4$. Under the usual conditions these give the *N*-acyl derivatives *(32)*, which form the acylamino aldehydes *(33)* on careful hydrolysis. When *(28)* is heated with malonic ester, the sub-

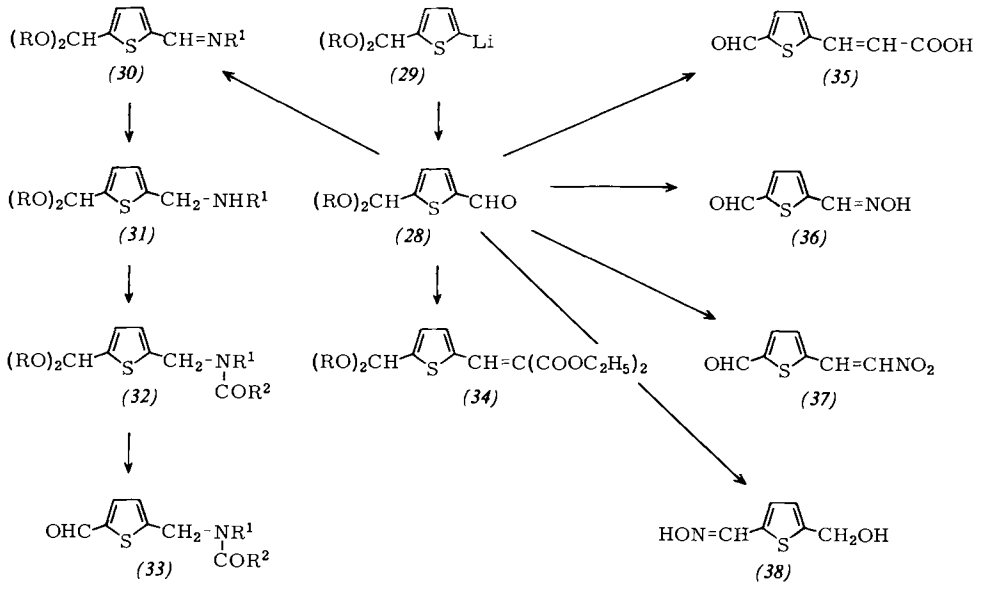
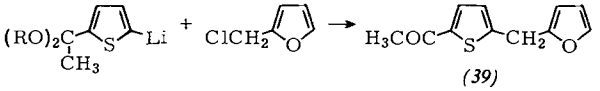


Scheme 3 $R = C_2H_5$; R^1 = n-C_6H_{13}, cyclo-C_6H_{11}, C_6H_5; $R^2 = CH_3$, C_6H_5

stituted thenylidenemalonic ester *(34)* is formed. The reactions of the monoacetal *(28)* with malonic acid, hydroxylamine, and nitromethane, followed by hydrolysis, lead to *(35)*, *(36)*, and *(37)* respectively. The oxime of the hydroxymethyl aldehyde *(38)* can be obtained by reduction of *(28)* to the alcohol. 5-Furfuryl-2-acetylthiophene *(39)* [110] has been synthesized by the reaction of the diethyl ketal of 5-lithium-2-acetylthiophene with 2-chloromethylfuran.

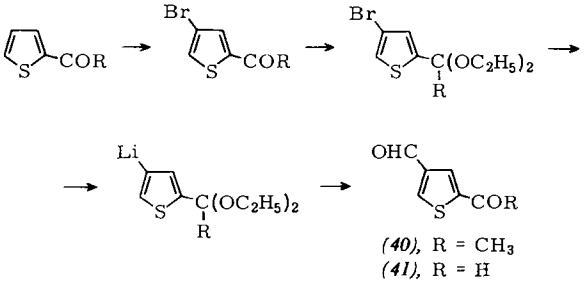


(39)

3.2. Syntheses of 2,4-Disubstitution Products

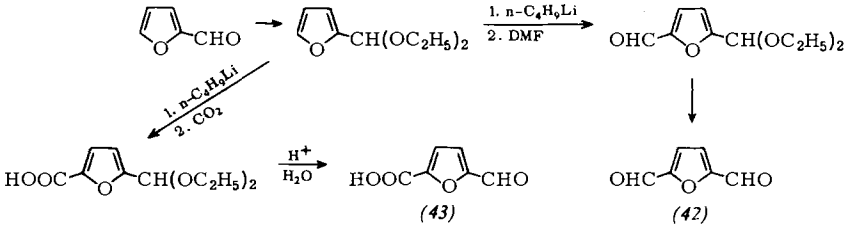
By combination of the two blocking methods and replacement of the β′-bromine atom in the thiophene acetal by lithium, we obtained 4-formyl-2-acetylthiophene *(40)* [106] and 2,4-thiophenedicarbaldehyde *(41)* [41].

Thus in the thienyl ketones, it is possible to direct bromine into the side chain (under normal conditions), into position 4 (by complex formation with an excess of aluminum chloride), or into position 5 (by bromination of the ketal).



(40), R = CH_3
(41), R = H

The blockage of a carbonyl group by acetalization also increases the range of methods available for the preparation of symmetrical and unsymmetrical bifunctional furan compounds. 2,5-Furandicarbaldehyde *(42)* and 5-formyl-2-furancarboxylic acid *(43)* were synthesized as early as 1962 [112].



(43) *(42)*

It should be finally recalled that the acetalization of the carbonyl group also permits the bromination of the thienyl ketones in position 5 [111] (see Section 2.1 [29]).

The compounds *(45)*–*(48)* in Scheme 4 have been prepared [113] from the acetal of 4,5-dibromofurfural *(44)*.

The monoacetal of 3-bromo-2,5-furandicarbaldehyde *(49)* is particularly important for the synthesis of unsymmetrical bifunctional compounds.

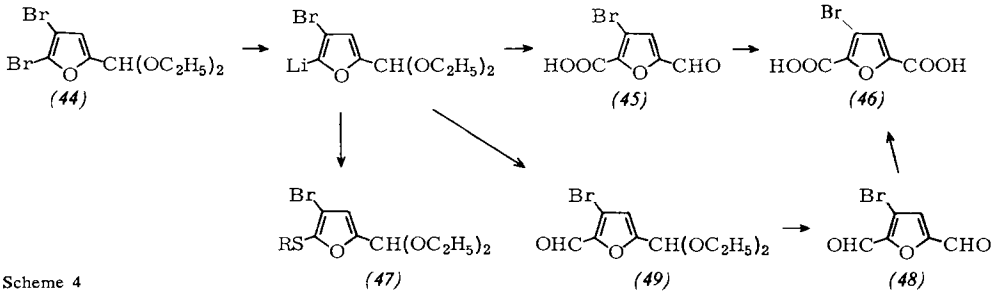
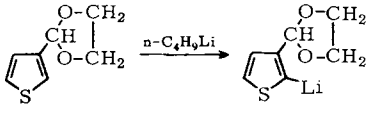


Scheme 4

3.3. Further Applications of Protection by Acetal Formation

The value of protection by acetal formation is also illustrated by the following examples. Whereas the synthesis published in 1967 for the preparation of 5-formyl-2-thiophenecarboxylic acid from 2-methylthiophene involves seven steps [114], we synthesized the acid in two steps from 2-thiophenecarbaldehyde. The first step is the acetalization, while the second includes metalation, reaction with CO_2, and hydrolysis of the acetal; the intermediates need not be isolated [109].

Gronowitz et al. [115] used the method of protection by acetal formation in the metalation of 3-thiophenecarbaldehyde with *n*-butyllithium; the adjacent free α position of the thiophene ring reacts in this case.



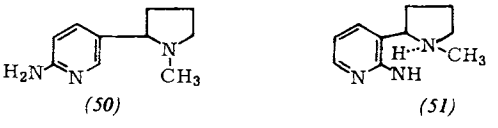
Pastour, *Savalle*, and *Emery* [116] obtained 2,3-thiophenedicarbaldehyde with the aid of this reaction. *Gronowitz* and *Bugge* [117] treated the acetals of 3-bromo-2-thiophenecarbaldehyde and of 4-bromo-3-thiophenecarbaldehyde with *n*-butyllithium and then with tributylboron to obtain 2- and 4-formyl-3-thiopheneboronic acids respectively. The method was recently used for the synthesis of organosilicon derivatives of 2-acetylthiophene and of 2-thiophenecarbaldehyde [118, 119], and the authors published their results as original work, though our findings had been published and abstracted some time before.

Similar investigations have also been reported in the furan series. In 1966 *Pastour* and *Plantard* independently synthesized 2,5-furandicarbaldehyde [120]. *Thames* and *Odom* [121] obtained 5-formyl-2-furancarboxylic acid by the acetalization method, which they also used in conjunction with metalation to obtain 5-benzoylfurfural, [5-D]-furfural, and some organosilicon derivatives of furfural. The method has recently been used for the synthesis of 2-formyl-3-furancarboxylic acid [122]. Finally, *Paulmier* and *Pastour* [123] have prepared 2,5-selenophenedicarbaldehyde and 5-formyl-2-selenophenecarboxylic acid by this method.

4. Conclusions

Two methods of blockage of the carbonyl group have been discussed, *i.e.* complex formation with aluminum chloride and acetalization. The primary purpose of blockage in this case is to provide the conditions necessary for the establishment of a new reaction center, but it should also protect the functional group against attack.

Blockage in this sense can obviously also be applied to other functional groups and be effected by processes other than acetalization and complex formation. The use of complexes involving the hetero atom and of chelates as intramolecularly blocked compounds would be particularly interesting. Compounds with an intramolecular hydrogen bond would also belong to this group. One example is the difference in the reactions of alkyl halides with the isomeric α-*(51)* and α'-aminonicotines *(50)* [124]. *(50)* is alkylated exclusively,



(50) *(51)*

or mainly, on the pyrrolidine nitrogen, whereas *(51)*, in which this nitrogen is involved in hydrogen bonding [125], reacts mainly at the pyridine nitrogen under comparable conditions.

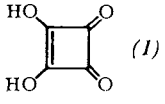
Cyclobutenediylium Dyes

BY H.-E. SPRENGER AND W. ZIEGENBEIN [*]

In agreement with the aromaticity and electrophilic behavior of squaric acid, a cyclobutenediyliumtetroxide ion is formulated as a limiting form of the squarate dianion. These views are confirmed by the structure of a series of new compounds that are readily obtainable from squaric acid or its derivatives, and most of which are deeply colored. The compounds contain the cyclobutenediyliumdioxide grouping as the chromophore, and form a new class of dyes, for which the name cyclobutenediylium dyes is proposed.

1. Introduction

Squaric acid *(1)* is a strong dibasic acid, which is thermally very stable and fairly stable toward oxidizing agents. The preparation and properties of its simple derivatives such as esters, amides, and halides are



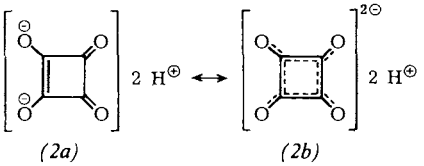
(1)

described in a recent review [11]. Condensations of squaric acid and its derivatives with nucleophilic compounds have recently been reported [2–6], and these reactions form the subject of the present article.

2. Limiting Structures of the Squarate Dianion

The readiness to react with nucleophiles points to limiting forms that would express the electrophilic reactivity of the squarate ion. Limiting structures of this nature have not previously been considered.

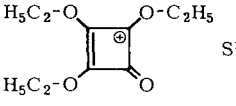
West et al. explained the aromatic character and the equivalence of the four oxygen atoms in the squaric acid molecule on the basis of resonance between *(2a)* and *(2b)* [7–9]:



(2a) *(2b)*

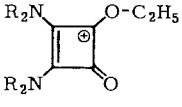
However, this formulation gives no indication of the electrophilic behavior of squaric acid. The resonance should therefore involve further limiting structures including carbonium ions. This is supported by some reactions of the esters and diamides of squaric acid [1].

Thus we have found that diethyl squarate can be smoothly ethylated with triethyloxonium hexachloroantimonate to give a colorless, salt-like, extremely hygroscopic product, to which the structure *(3)* can be assigned [10].



(3)

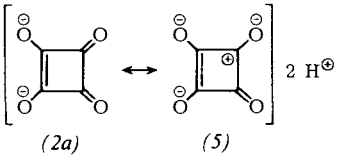
Diamides are converted in the same manner into salt-like, nonhygroscopic compounds *(4)*.



(4)

R_2N = Morpholino, Piperidino, Pyrrolidino

Ethylation to give *(3)* obviously depends on the polarization of a carbonyl group of the cyclobutenedione system in the diethyl squarate. Consideration of these observations would lead to the limiting forms *(2a)* and *(5)*.



(2a) *(5)*

However, structure *(5)* is in conflict with the aromatic properties of squaric acid, since only three of the oxygen atoms would be equivalent. We therefore propose a resonance between *(2a)* and the cyclo-

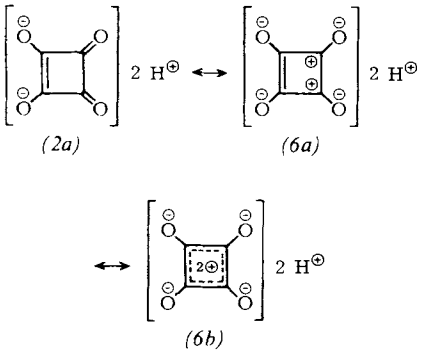
[10] *H.-E. Sprenger*, unpublished.

butenediyliumtetroxide limiting structures *(6a)* and *(6b)*, which may be thought of as resulting from the inclusion of both carbonyl groups of the squaric acid in the resonance system. These formulas express both the aromaticity and the electrophilicity of squaric acid.

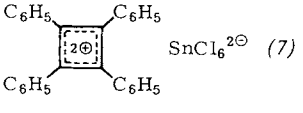


(2a) *(6a)* *(6b)*

Similar bonding and charge distributions occur in the anions of very stable inorganic acids. Thus the equivalence of the oxygen atoms in the phosphate, sulfate, and perchlorate ions can be explained by the participation of limiting structures in which the central atom carries one or more positive charges. These positive central atoms correspond to the doubly positive cyclobutenediylium skeleton of squaric acid.

The same cyclobutenediyliumtetroxide limiting structure of the squarate dianon follows from a comparison with cyanine dyes, which leads to contradictions, since the resonance in the cyanine dye molecule is best described by an alternating charge distribution along the C–C chain [11].

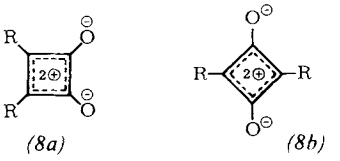
Finally, according to *Hückel*, a cyclobutene ring carrying two positive charges should be a homolog of ethylene, and should possess aromatic properties [12]. Cyclobutenediylium compounds have recently been prepared by *Freedman* and *Frantz jr.* [13]. Thus, the deep red tetraphenylcyclobutenediylium hexachlorostannate *(7)* is surprisingly stable in dry air and is relatively stable in general.



(7)

3. Condensations of Squaric Acid and its Derivatives

According to the views presented in Section 2, squaric acid and its esters should undergo condensations with nucleophilic compounds. This prediction has been confirmed by the synthesis of a number of new compounds, most of which are deeply colored. These compounds were prepared in our research laboratories [4–6], and independently by *Treibs* and *Jacob* [2,3], from squaric acid and nucleophilic compounds. The previously unknown chromophores in these dyes are the cyclobutenediyliumdioxide groups *(8a)* or *(8b)* [6].



(8a) *(8b)*

Organic dyes are generally characterized by a polymethine structure with alternating charges [11]. This is not so in the compounds prepared by *Treibs* and by our team. On the contrary, instead of a single positive carbon atom in the cyanine chain, these dyes contain the cyclobutenediyliumdioxide group as a doubly positive charge center and are therefore to be considered as a new class of dyes.

3.1. Condensations with Esters of Squaric Acid

We have found that squarates condense smoothly with compounds having acidic hydrogen atoms on carbon in alcoholic solution in the presence of sodium alkoxide. Pyridinium and benzothiazolium iodides bearing a methyl group in the 2- or 4-position, and an ethyl group on the N atom, were used as model compounds. These salts readily lose hydrogen iodide to form reactive bases, which react with esters of squaric acid to give colored products *(9)* that have been found to be derivatives of the unknown cyclobutenedione, the *o*-quinone of cyclobutadiene [6] (see Table 1).

Compounds *(9a)–(9e)* are not very soluble in alcohols or ethers, but dissolve more readily in high-boiling polar solvents such as dimethylformamide and benzonitrile. The deep color of all the new compounds can be explained by the contribution of a cyclobutenediylium limiting form to the resonance hybrid:

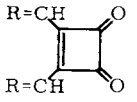
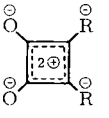
Table 1. Colored products *(9)* obtained from esters of squaric acid and *N*-ethyl nitrogen bases.



(9)

	R	M.p. (°C)	Yield (%)
(a)	*N*-Ethyl-1,4-dihydro-4-pyridylidene	328 (decomp.)	35
(b)	*N*-Ethyl-1,2-dihydro-2-pyridylidene	218 (decomp.)	16
(c)	*N*-Ethyl-1,4-dihydro-4-quinolylidene	257 (decomp.)	68
(d)	*N*-Ethyl-1,2-dihydro-2-quinolylidene	320	55
(e)	*N*-Ethyl-2,3-dihydro-2-benzothiazolylidene	274 (decomp.)	28

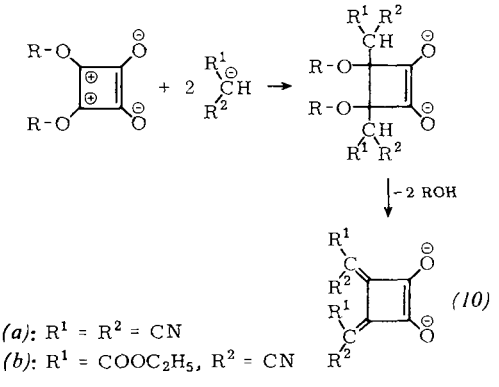
Esters of squaric acid react with compounds such as malononitrile in the presence of alkali metal alkoxide to form deep yellow salts *(10)* [6], which are soluble in water and remain unchanged on heating to 360 °C. The yields of *(10a)–(10c)* are 93, 89, and 97% respectively.



(10)

(a), $R^{\ominus} = {}^{\ominus}C(CN)_2$
(b), $R^{\ominus} = {}^{\ominus}C(COOC_2H_5)CN$
(c), $R^{\ominus} = {}^{\ominus}N{-}CN$

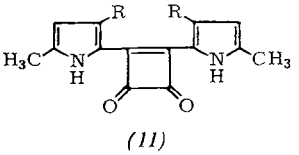
The smooth, ready formation of compounds *(10)* can be formulated as an addition of the nucleophile to the cyclobutenediyliumdioxide form of the squarate. The final product is then formed by elimination of alcohol. The reaction thus corresponds to an ester condensation.



(a): $R^1 = R^2 = CN$
(b): $R^1 = COOC_2H_5$, $R^2 = CN$

3.2. Condensations with Squaryl Diacetate

Treibs and *Jacob* [3] also obtained 1,2-derivatives of cyclobutenedione *(11a)* and *(11b)* (m.p.'s 245 °C and 205 °C; yields 45% and 19%) from squaryl diacetate and 2-methyl- or 2,4-dimethylpyrrole in acetic anhydride. 1,3-Derivatives of cyclobutenediyliumdioxide were also isolated as by-products.



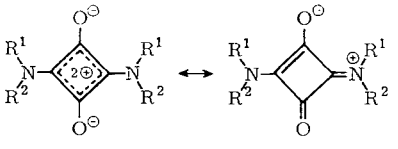
(11)

(a), R = H
(b), R = CH_3

3.3. Condensations with Squaric Acid

The reaction of squaric acid with excess secondary amines does not lead to diamides of squaric acid. Instead, colorless to pale yellow stable compounds *(12)* of high melting point are formed, presumably by way of hydrosquarates [10, 14]. These products form a new class of intramolecular salts, and are derived from 1,3-bisaminocyclobutenediyliumdioxides (see Table 2).

Table 2. Intramolecular salts *(12a)–(12d)* from squaric acid and secondary amines, and *(13a)–(13g)* from squaric acid and aromatic amines.



(12), (13)

	R^1	R^2	M.p. (°C)	Yield (%)

(13b)	C_6H_5	H	> 360	87
(13c)	C_6H_5	C_6H_5	360 (decomp.)	66
(13d)	α-Naphthyl	H	340	85
(13e)	β-Naphthyl	H	313	63
(13f)	1-Anthraquinonyl	H	> 360	80
(13g)	2-Anthraquinonyl	H	353 (decomp.)	96

Similar condensation products *(13)* have been prepared from squaric acid and aromatic amines [14, 15] (see Table 2).

Compounds *(13)* were prepared by azeotropic removal of the water of reaction in butanol/benzene mixtures. These stable, high-melting substances are pale yellow to deep brown, depending on the nature of the aromatic substituent. Although not involved in the resonance, the aromatic group has a color-deepening effect. This leads one to assume that reaction occurs *ortho* or *para* to the amino group, as is the case with other reactions of anilines. However, condensation on the phenyl substituent of the amino group can be definitely ruled out on the basis of ^1H–NMR studies.

In the case of *N,N*-dialkyl aromatic amines or nucleophilic tertiary amines having an enamine character, on the other hand, condensation should occur on the substituents of the amino group. The products should be phenylogs or vinylogs of the 1,3-diaminocyclobutenediyliumdioxides described above. *Treibs* and *Jacob* actually obtained deep blue, high-melting 1,3-dipyrrolylcyclobutenediyliumdioxides *(14)* from squaric acid and reactive pyrroles; as expected, these products are vinylogs of 1,3-diaminocyclobutenediyliumdioxides [2, 3] (see Table 3).

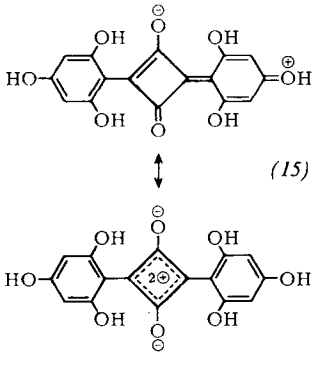
	R^1	R^2	R^3	R^4	M.p. (°C)	Yield (%)
(a)	H	CH_3	C_2H_5	CH_3	265	90
(b)	H	CH_3	H	CH_3	240–250	75
(c)	CH_3	CH_3	H	CH_3	242	79
(d)	H	CH_3	$CO_2C_2H_5$	CH_3	296	60
(e)	H	CH_3	$COCH_3$	CH_3	299	76

The condensation is carried out in ethanol or acetic acid. *Treibs* and *Jacob* assigned the IR band at 1640 cm^{-1} to a vinylogous carboxylate grouping. It appears to us that the spectroscopic findings agree more closely with the presence of a cyclobutenediylium moiety.

In a similar manner, these authors readily obtained compounds of the same type by reaction of nucleophilic phenols, *e.g.* phloroglucinol. The wine-red, very stable compound *(15)* melts at 340–345 °C, and is obtained in yields of 67%.

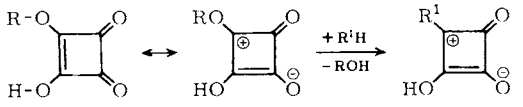


(15)

Independently of *Treibs*, we found that squaric acid reacts under surprisingly mild conditions with a number of classes of nucleophilic compounds in the absence of catalysts. Condensation takes place in a butanol/benzene mixture, so that the water formed can be removed azeotropically as the reaction proceeds. The resulting high-melting, extremely stable dyes, which are 1,3-derivatives of cyclobutenediyliumdioxide, are obtained as crystalline solids, usually in an analytically pure state, toward the end of the reaction or after cooling.

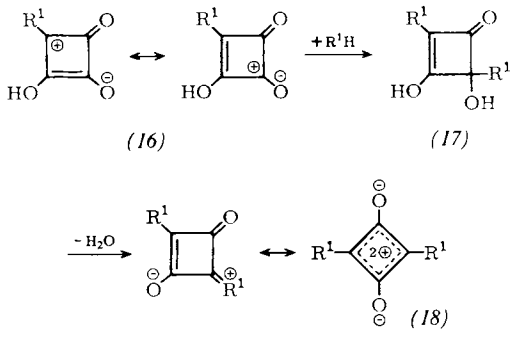
The dyes *(18)* are not very soluble in alcohols or ethers, but dissolve more readily in high-boiling polar solvents such as DMF, benzonitrile, or nitrobenzene. They dissolve in cold concentrated sulfuric acid, with lightening of the color, probably because of salt formation; however, they are reprecipitated on addition of water. The compounds are not very stable toward bases, and are generally decomposed with formation of brown products. Strong reducing agents, such as rongalite solutions, decolorize the dye solutions. A strong IR absorption band between 1500 and 1630 cm^{-1}, which we regard as evidence of a cyclobutenediyliumdioxide structure, is common to all compounds.

The formation of these dyes can be explained as follows. It is known from investigations by *Cohen et al.* that when squaric acid is heated in alcohols it forms a half-ester [16], which probably reacts with the nucleophilic compound R^1H, subsequent elimination of alcohol leading to the formation of the 1:1 reaction



(16)

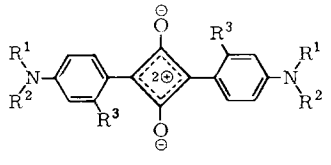
product *(16)* containing one electrophilic C atom [17]. A further molecule of nucleophile R^1H can add to this remaining electrophilic center; dehydration of *(17)* then yields the final product *(18)*.



(16) *(17)* *(18)*

To obtain phenylogs of the 1,3-diaminocyclobutenediyliumdioxides, we allowed squaric acid to react with *N,N*-dialkylanilines. Stable 1,3-bis(dialkylaminophenyl)cyclobutenediyliumdioxides *(18a)–(18e)* were formed in good yields [5] (see Table 4). In agreement with our concepts these products are deep blue. Furthermore, we condensed nucleophilic quinaldine, benzothiazole, and benzoselenazole bases with squaric acid to obtain vinylogous 1,3-diaminocyclobutenediyliumdioxides *(18f)*, *(18g)*, and *(18h)* [6] (m.p.'s 320 °C, 300 °C, and 286 °C; yields 31%, 80%, and 42%, resp.).

Table 4. Dyes with cyclobutenediyliumdioxide structure *(18a)–(18e)*.



(18a)-(18e)

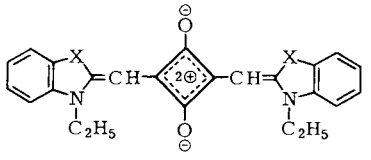
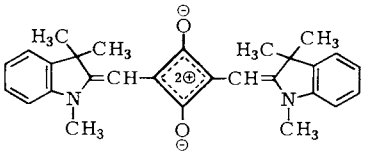
(18f)



(18g), X = S
(18h), X = Se

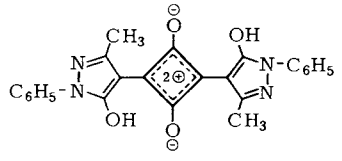
A similar vinylogous 1,3-diaminocyclobutenedioxide derivative *(18i)* was obtained from squaric acid and Fischer base[6] (m.p. 301.5 °C; yield 92%). The deep



(18i)

blue stable dye was obtained independently by *Treibs* and *Jacob*, though by a different route[3]. The identity of the two products was verified by thin layer chromatography.

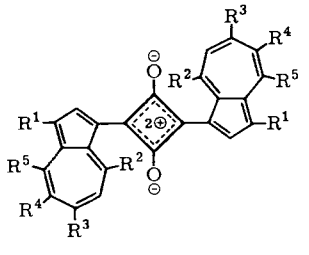
We also condensed 3-methyl-1-phenyl-5-pyrazolone with squaric acid. The product was a yellow-red dye *(18k)*, which is soluble in alcohols and crystallizes from the solutions as long needles[10] (m.p. 170 °C; yield 54%).



(18k)

Azulenes, which are nucleophilic in position 1 or 3, react similarly with squaric acid to give high yields of thermally stable, 1,3-cyclobutenediyliumdioxides *(18l)–(18n)* (see Table 5). These compounds are deep blue-green in solution, and separate out as green crystals with a metallic luster[4]. It is interesting to note that in this case a hydrocarbon is sufficiently nucleophilic to react.

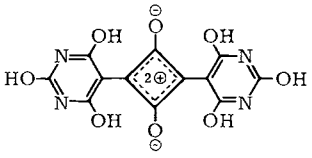
Table 5. Dyes with cyclobutenediylium structure *(18l)–(18n)*.



(18l)-(18n)

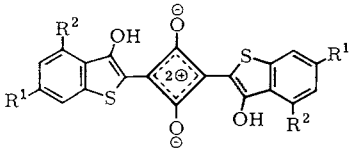
	R^1	R^2	R^3	R^4	R^5	M.p. (°C)	Yield (%)
(l)	H	H	H	H	H	240–245 (decomp.)	90
(m)	CH_3	CH_3	H	$CH(CH_3)_2$	H	245–250 (decomp.)	80
(n)	H	CH_3	CH_3	H	CH_3	> 350	90

An analogous product was obtained from barbituric acid and squaric acid. The deep red dye *(18o)* is insoluble in all common solvents[10] (m.p. 330 °C; yield 72%).



(18o)

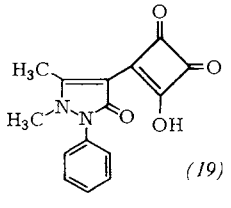
No dye is formed in the reaction of indoxyl with squaric acid. The investigation of the product obtained has not yet been completed[10]. On the other hand, 3-hydroxybenzothiophene gives deep violet, bronze-colored crystals *(18p)* (m.p. 290 °C; yield 12%). From 6-chloro-3-hydroxy-4-methylbenzothiophene the compound *(18q)* is obtained as bronze colored crystals [m.p. 326 °C (decomp.); yield 35%][10]. *(18p)* and



(18p), $R^1 = R^2 = H$
(18q), $R^1 = Cl$, $R^2 = CH_3$

(18q) are slightly soluble in dimethylformamide, but are otherwise insoluble in the usual solvents, even in concentrated sulfuric acid.

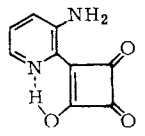
Mention should also be made of some other products obtained by reaction of squaric acid with nucleophiles. An attempt to condense antipyrine (which is nucleophilic in position 4) with squaric acid did not yield the expected 1,3-cyclobutenediyliumdioxide, since only one antipyrine molecule combined with squaric acid to form *(19)*[18] (m.p. 238 °C; yield 56%). The bright yellow crystalline product is formed on azeotropic removal of the water formed in the reaction.



(19)

3-Aminopyridine reacts likewise with squaric acid to give a deep yellow, sparingly soluble compound, for which we propose the structure *(20)*[10] [m.p. 324 °C (decomp.); yield 91%]. The deep yellow color points to ring condensation of the 3-aminopyridine with the squaric acid. Owing to the low solubility of the compound, its NMR spectrum could not be recorded.

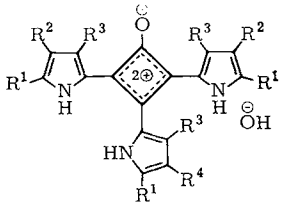
[18] *H.-E. Sprenger*, German Pat. Appl. C 39587 IVd/12p (July 12, 1966), Chem. Werke Hüls.



(20)

On condensation of squaric acid with ethyl 2,4-dimethyl-3-pyrrolecarboxylate *Treibs* and *Jacob* obtained equal quantities of the cyclobutenediyliumdioxide dye and a bright yellow compound to which they assigned the structure of a 3:1-condensation product *(21a)* [3] (see Table 6).

Table 6. Condensation products *(21a)*—*(21c)* from squaric acid and pyrrole derivatives.

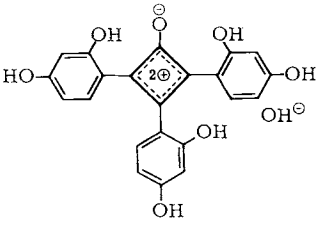


(21)

	R^1	R^2	R^3	R^4	M.p. (°C)	Yield (%)
(a)	CH_3	$CO_2C_2H_5$	CH_3	$CO_2C_2H_5$	130—135	15
(b)	CH_3	$CO_2C_2H_5$	CH_3	C_2H_5	185—188 (decomp.)	93 [a]
(c)	CH_3	$CO_2C_2H_5$	H	$CO_2C_2H_5$	266—268 (decomp.)	79

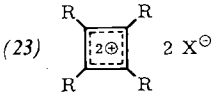
[a] Crude product.

However, the compounds are not very stable, since the third pyrrole ring is readily split off by electrophilic reagents, with regeneration of the 1,3-bispyrrolylcyclobutenediyliumdioxide. *Treibs* and *Jacob* also obtained a 3:1 condensation product from resorcinol and squaric acid under more vigorous conditions. As in the case of the pyrrole, however, the resulting compound *(22)* (m.p. 273–274 °C; yield 24%) is unstable, and readily loses resorcinol to form the 1,3-derivative [3].



(22)

It should in principle also be possible to prepare 1,2,3,4-tetrasubstituted cyclobutenediylium derivatives having the formula *(23)* from squaric acid and nucleophilic compounds.



(23)

Attempts to do so have been made both by *Treibs* [17] and by our own group, but so far without success.

We are very grateful to Prof. Becher of the Universität Münster and to Dr. Böhm-Gössl, Dr. Frenzel, and G. Peitscher of Chemische Werke Hüls AG for the recording and discussion of the spectra.

We thank the Management of the Company, and particularly Prof. H. Hellmann, for their support of this work and for permission to publish it.

A New Pteridine Synthesis [**]

By *W. Pfleiderer* and *H.-U. Blank* [*]

Traube [1] reported that 7-benzyl-8-phenylpurines are obtained by the action of 2 molecular equivalents of benzaldehyde on 4,5-diaminopyrimidines. However, his 7-benzyl-8-phenyltheophylline was not identical with the substance obtained by us by cyclization of 4-benzylamino-5-benzylideneamino-1,3-dimethyluracil [2] or by benzylation of 8-phenyltheophylline.

We have found that purines are not formed on treatment of the 4,5-diaminopyrimidine *(1)* or *(2)* with 2 molecular equivalents of benzaldehyde or of the readily accessible 4-amino-5-benzylideneaminopyrimidines *(3)*—*(6)* with 1 molecular equivalent of benzaldehyde, in each case at 180 °C; instead, the 6,7-diphenylpteridine derivatives *(7)*—*(10)* are obtained. The reaction course is not completely homogeneous, but pteridines always form the main product and can be isolated by fractional crystallization.

2,4,5-Triamino-6-pyrimidinol *(11)* or its 5-benzylidene derivative *(15)* similarly affords the 6,7-diphenylpterin *(13)* in 53% yield, but *(12)* or *(16)* undergoes an obscure reaction to afford a difficultly separable mixture of many products, in

It can be assumed that in the new pteridine synthesis 4-amino-5-benzylideneaminopyrimidines and then the 4,5-bis-benzylideneaminopyrimidines are first formed, and that the latter, which cannot be isolated, are stabilized by valence isomerization and subsequent dehydrogenation with formation of the pteridine ring system. This assumption is supported by the corresponding valence isomerizations of double Schiff's bases of 1,2-diamines[7].

1-Methyl-6,7-diphenyllumazine (8):

4,5-Diamino-3-methyluracil (0.8 g) *(2)* is heated with benzaldehyde (1.2 g) for 4 h at 180 °C. The mixture is then cooled, treated with ethanol (10 ml), set aside for a day, and subsequently filtered under suction; the crystalline mass recovered is then recrystallized from ethanol. Yield: 1.0 g of colorless needles.

3-Methyl-6,7-diphenyllumazine (9):

4-Amino-5-benzylideneamino-1-methyluracil (0.6 g) *(5)* is heated with benzaldehyde (0.4 g) for 4 h at 180 °C. The mixture is cooled, treated with ethanol (5 ml), set aside for 2 days, and filtered; the solid is then recrystallized from ethanol. Yield: 0.5 g of small colorless needles.

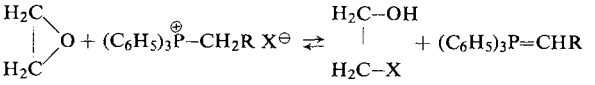
Wittig Reactions with the Aid of Ethylene Oxide

By *J. Buddrus*[*]

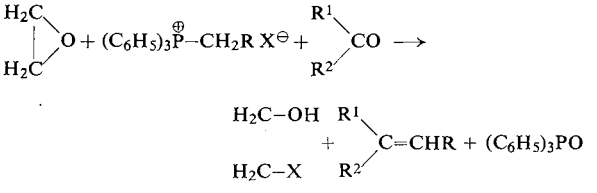
In the presence of some catalysts, epoxides behave as strong bases[1–3]. They remove hydrogen halide from haloforms, being converted in the process into halo-alcohols, while the dihalocarbene and olefins form α,α-dihalocyclopropanes. Soluble halides such as quaternary ammonium[1] and phosphonium[4] halides are suitable catalysts.

Epoxides also remove hydrogen halide from phosphonium salts. Ethylene oxide *(1)* and an alkyltriphenylphosphonium halide *(2)* enter into equilibrium with the 2-haloethanol *(3)* and the alkylidenetriphenylphosphorane *(4)*.

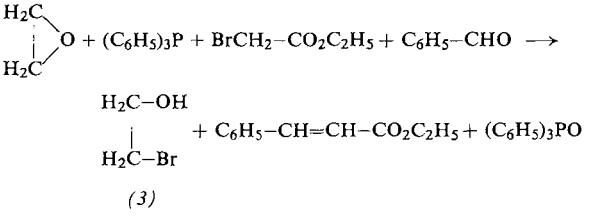


(1) *(2)* *(3)* *(4)*

The phosphorane *(4)* can be isolated in some cases (R = CO_2R'), and in others can be recognized by its color (R = C_6H_5, red). Conversely, the compounds *(3)* (X = Br) and *(4)* (R = C_6H_5) react to yield *(1)* and *(2)*. If at the beginning of the experiment an aldehyde or ketone is added that reacts with *(4)*, then there is complete conversion of *(1)* (or some other epoxide) and *(2)* into *(3)*, an olefinic compound, and triphenylphosphine oxide. Separate preparation of the phosphorane *(4)* is not necessary.



It is also often unnecessary to prepare the salts; triphenylphosphine, a halide R–CH_2–X (R = CO_2R', CH=CH_2, or C_6H_5), and *(1)* are allowed to react directly with the carbonyl compound. The oxide *(1)*, $(C_6H_5)_3P$, and ethyl bromoacetate react with benzaldehyde at 25 °C to give ethyl cinnamate (91%; *trans*:*cis* = 93:7), with crotonaldehyde at 25 °C



(3)

to give ethyl 2,4-hexadienoate (81%), and with cyclohexanone at 100 °C (sealed tube) to give ethyl cyclohexylideneacetate (68%). The oxide *(1)*, $(C_6H_5)_3P$, benzyl bromide, and propionaldehyde at 25 °C afford β-ethylstyrene (89.5%; *trans*:*cis* = 56:44). Benzyltriphenylphosphonium chloride and *(1)* react with cyclohexanone at 100 °C to give benzylidenecyclohexane (69%), but the weaker acid triphenylpropylphosphonium bromide reacts only at 150 °C with *(1)* and benzaldehyde, to yield β-ethylstyrene (74%; *trans*:*cis* = 40:60). The last example shows, incidentally, that ethylene oxide can replace even strong bases such as Li alkyls, which are used for formation of phosphoranes from phosphonium salts[5].

Experimental

$(C_6H_5)_3P$ (6.6 g, 0.025 mole), benzaldehyde (2.6 g, 0.025 mole), ethylene oxide (2.5 ml, 0.05 mole), and, with cooling, ethyl bromoacetate (4.2 g, 0.025 mole) are dissolved in methylene chloride (5 ml). The solution is allowed to stand overnight at room temperature and then distilled, whereupon 2-bromoethanol (2.45 g, 78%), b.p. 55 °C/17 torr, and ethyl cinnamate (4.0 g, 91%), b.p. 142–144 °C/17 torr, are collected

as distillate. The distillation residue of triphenylphosphine oxide solidifies (m.p. 150 °C, 97%, 6.75 g).

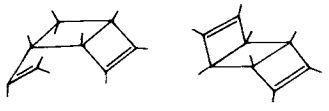
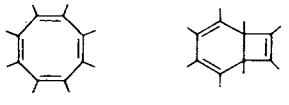
Octamethylsemibullvalene

By *R. Criegee* and *R. Askani*[*]

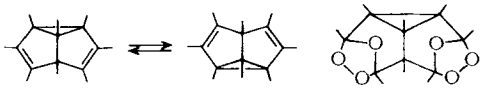
When any of the valence-isomeric hydrocarbons *(1)*, *(2)*, and *(3)* is heated in 1% Na ethoxide solution in ethanol at 240 °C a hydrocarbon $C_{16}H_{24}$ of m.p. 23 °C is formed to which the constitution *(4)* of an octamethylbicyclo[4.2.0]octatriene was previously provisionally assigned[1]. This constitution is incorrect and is to be replaced by that of octamethylsemibullvalene (octamethyltricyclo[3.3.0.$0^{2,8}$]octa-3,6-diene) *(5)*.



(1) *(2)*



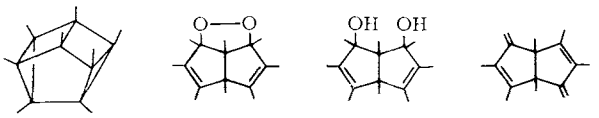
(3) *(4)*



(5) *(6)*

As a result of the extremely rapid valence isomerization of this system[2] the NMR spectrum is independent of temperature down to −100 °C; in pyridine/CCl_4 (9:1) it shows 3 singlets at τ = 8.52, 8.58, and 9.10 in the intensity ratio 1:2:1. The UV spectrum shows no maximum, only a shoulder at 240 nm, which requires additional assumptions on the basis of structure *(4)* but is at once intelligible on the basis of *(5)*. With tetracyanoethylene and azodicarboxylic ester the new hydrocarbon gives adducts that are different from those obtained from *(3)*, whereas those from *(3)* and *(4)* must be identical. The new hydrocarbon gives the crystalline diozonide *(6)*[3], whose NMR spectrum shows that, apart from the four CH_3 groups on the ozonide ring [τ = 8.41 (s), 8.43 (s)], all the methyl groups are attached to saturated C atoms [τ = 8.87 (s), and 8.90 (s)].

Thus, the hydrocarbon can contain only two double bonds, *i.e.* it must be tricyclic. The two double bonds present in *(5)* can add to each other photochemically (1% ethereal solution, 100 W low-pressure lamp, 0 °C, 12 h), affording the saturated hydrocarbon, octamethylpentacyclo[3.3.0.$0^{2,4}$.$0^{3,7}$.$0^{6,8}$]-octane *(7)* in 10–20% yield. M.p. 92 °C. NMR (CCl_4): τ = 8.92 (s), 9.13 (s), and 9.15(s) in the proportions 1:2:1.



(7) *(8)* *(9)* *(10)*

The change of formula *(4)* to *(5)* for the hydrocarbon requires that the structures of the products derived from it also be changed. Thus the peroxide (m.p. 78 °C), which is also formed in the dark, is now to be formulated as *(8)*, and the hydrocarbon of m.p. 55 °C obtained by way of the diol *(9)* or directly from *(5)* with silver nitrate is to be formulated as *(10)*. In accord with their different symmetries the H atoms of the bridgehead methyl groups in *(8)* show in the NMR spectrum two singlets lying close together (τ = 9.03 and 9.10), whereas *(10)* shows only one singlet (τ = 8.90). Following the unsubstituted parent[2] and a bis(trifluoromethyl) derivative[4], compound *(5)* is the third semibullvalene. In contrast to the other two it is not formed by a photoreaction and it is relatively easily accessible in gram quantities. The fourth semibullvalene (with eight methoxycarbonyl groups) was prepared by *J. C. Kauer* and *H. E. Simmons*[5]. Recently *L. A. Paquette* obtained an azasemibullvalene[6].

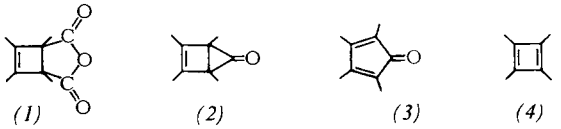
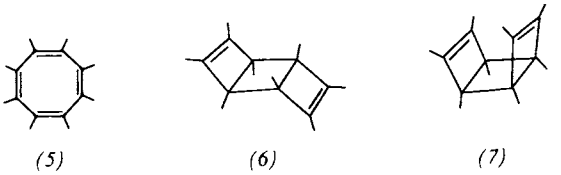
Photolysis of Tetramethylcyclobutenedicarboxylic Anhydride, a Possible Route to Tetramethylcyclobutadiene

By *G. Maier* and *U. Mende*[*]

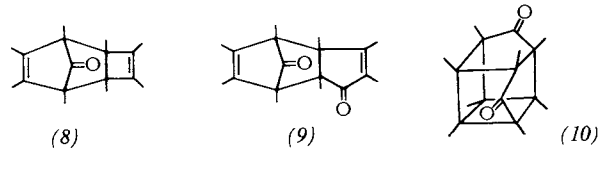
In connection with attempts to synthesize a compound with the ring skeleton of tetrahedrane we illuminated the anhydride *(1)* (Hanovia 450W high-pressure mercury lamp, Vycor filter, ether, 20 °C, 40 min). The following products were isolated by chromatography on silica gel:



(1) *(2)* *(3)* *(4)*



(5) *(6)* *(7)*



(8) *(9)* *(10)*

octamethylcyclooctatetraene *(5)* (5.3% yield), the dimers *(6)* (2.5%) and *(7)* (0.6%) of tetramethylcyclobutadiene *(4)*, hexamethylbenzene (0.7%), the peroxide (3%) and photoisomer (2%) of octamethylsemibullvalene[1], the ketone *(8)* (28%), the dimer *(9)* of tetramethylcyclopentadienone *(3)* (14%), and the cage diketone *(10)* (8.5%).

The structures of the new compounds, octamethyltricyclo-[4.2.1.$0^{2,5}$]nona-3,7-dien-9-one *(8)*, m.p. 192 °C, octamethyltricyclo[5.2.1.$0^{2,6}$]deca-4,8-diene-3,10-dione *(9)*, m.p. 190 °C, and octamethylpentacyclo[5.3.0.$0^{2,6}$.$0^{3,9}$.$0^{5,8}$]decane-4,10-dione *(10)*, m.p. 260 °C, are proved by elemental analysis, osmometrically determined molecular weights, and spectral data [NMR: CCl_4; *(8)*: 4 s at τ = 8.37, 8.63, 8.99, 9.12 (relative intensity 1:1:1:1); *(9)*: 2 m (J = 1 Hz) at 8.08, 8.42; 5s at 8.53, 8.80, 8.87, 8.99, 9.16 (1:1:2:1:1:1:1); *(10)*: 4 s at 9.08, 9.10, 9.15, 9.24 (1:1:1:1); IR: CCl_4; *(8)*: 1757; *(9)* 1765, 1690, 1640; *(10)*: 1745 cm^{-1}].

It is probably not dimerization of intermediate tetramethylcyclobutadiene that leads to compounds *(6)* and *(7)*; rather, the ketone *(8)* seems to be the effective intermediate. Irradiation of pre-isolated *(8)* gives the same hydrocarbons as are obtained from *(1)*, and the proportions in which the hydrocarbons are formed are the same. Apparently, removal of the CO bridge does not lead exclusively to octamethylbicyclo-[4.2.0]octatriene which could then give octamethylcyclooctatetraene *(5)* by valence isomerization or could be cleaved to hexamethylbenzene and butyne; instead, it provides to some extent a stereoselective formation of a new four-membered ring.

Control experiments showed that octamethylcyclooctatetraene *(5)* cannot be derived from *(6)* or *(7)*, but that octamethylsemibullvalene[1] and its photoisomer are to be considered as derived from *(5)*, which is formed from the ketone *(8)*. The cage diketone *(10)* is to be regarded as a photoproduct of *(9)*; the dimer *(9)* thus has the *endo*-configuration.

Formation of the ketone *(8)* is preferably considered as evidence for the occurrence of tetramethylcyclobutadiene *(4)* as intermediate product. We presume that first *(1)* is converted into *(2)*, that this then isomerizes to *(3)*, which in turn partly dimerizes to *(9)* and partly reacts with *(4)* [formed from *(2)* by loss of CO] to yield *(8)*. However, direct addition of *(2)* to *(3)* and formation of the ketone *(8)* from this adduct cannot be excluded[**].

[1] *R. Criegee* and *R. Askani*, Angew. Chem. *80*, 531 (1968); Angew. Chem. internat. Edit. *7*, 537 (1968). A comprehensive review of the chemistry of cyclobutadiene is given by *M. P. Cava* and *M. J. Mitchell*: Cyclobutadiene and Related Compounds. Academic Press, New York 1967

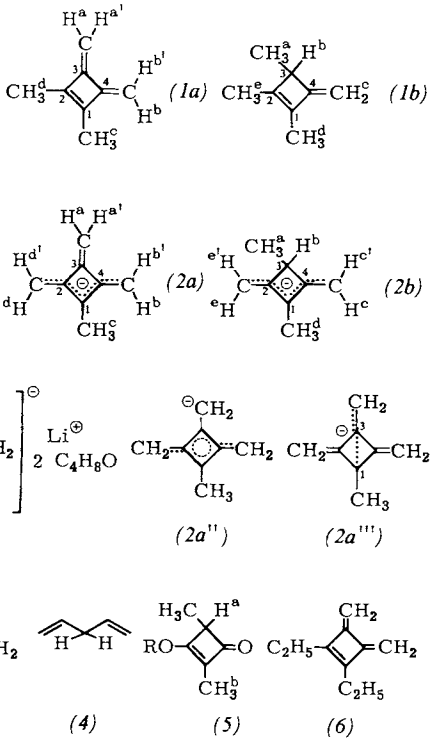
[**] Note added in proof (June 21, 1968): Meanwhile 3,4-dimethyl-3-cyclobutene-1,2-dicarboxylic anhydride has been irradiated. The products formed indicate that the main reaction is again the addition of 1,2-dimethylcyclobutadiene to 3,4-dimethylcyclopentadienone.

H. Prinzbach also photolyzed *(1)* and found ketones and octamethylcyclooctatetraene *(5)* (personal communication).

1-Methyl-2,3,4-trimethylenecyclobutenide Ion

By *D. Seebach* and *B. Graf* [*]

The first report about production of pentadienyllithium compounds in solution was published in 1967[1]. We were interested in whether we could prepare the anion *(2a)* derived from dimethyldimethylenecyclobutene *(1a)*[2], which would be a C_8 compound with seven coplanar sp^2-hybridized C atoms and a total of eight π-electrons. In the presence of strong bases would *(1a)* (free valence index on the *exo*-methylene C atom F = 0.86[3a]) give up a proton, add the base, or polymerize anionically? What influence would be exerted on or by the methylene group that does not participate[3b] in the pentadienyl system, perhaps through a resonance structure such as *(2a'')*? Would comparison of the anions *(2a)* and *(2b)* provide an indication of the often discussed[4] overlap between the p-orbitals of C-1 and C-3 (separation *ca.* 2 Å, calculated resonance integral $\beta_{1,3}$ = 0.76 eV) [as indicated in *(2a''')*]? Are reactions of the anion *(2a)* with electrophiles of value for preparation of substituted trienes *(3)*[5]?



Experience to date[1a] shows that butyllithium in THF gives pentadienyl anions only from 1,4-pentadienes *(4)*, and not from 1,3-pentadienes. However, crystals separate within 5 min of mixing butyllithium and *(1a)* (see Experimental); NMR spectroscopic studies in 1,2-dimethoxyethane (Fig. 1) show that these crystals are the lithium compound *(2a')* containing two molecules of THF. Integration of the THF signals and the signals of the anion gives a ratio of (2.0 ± 0.1):1. With respect to the starting material *(1a)* the signals of the protons H^c are shifted by 0.26, and those of H^a by about 0.55 ppm, towards higher field. The difference is considerable when one remembers that the CH_3^c group is bound directly to the central C atom of the pentadienyl system (the charge density

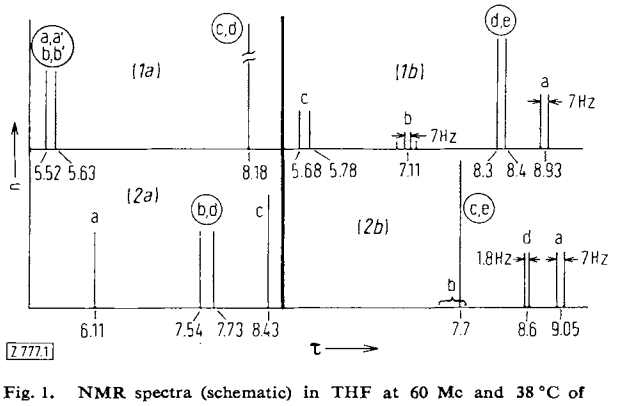


Fig. 1. NMR spectra (schematic) in THF at 60 Mc and 38 °C of compounds *(1a)*, *(1b)*, *(2a)*, and *(2b)* (n = number of protons, shifts in τ-units, standard THF (referred to TMS))[**].

is a maximum at the central and terminal C atoms), and that the distances from H^a and H^c to the terminal C atoms of this system are about the same. The protons H^b and H^d, and also $H^{b'}$ and $H^{d'}$ at the ends of the anion system, are identical; their chemical shift is not altered at 0 °C. Study of other pentadienyl anions[1b] showed that the signals of their protons of the type H^b and $H^{b'}$ coalesce below or up to 35 °C (Li ions are probably covalently bonded in the process)[1b,6]. Since *(2a)* shows two sharp signals even at 38 °C (half-width HW = 2.5 Hz) for these protons, this anion is more resistant to rotation than any other known pentadienyl anion[**].

Metalation of the diene *(1b)*[2a] to give *(2b)* occurs only above −30 °C. The NMR spectrum of the product proves the structure shown: here the four terminal protons H^c, $H^{c'}$, H^e, and $H^{e'}$ are identical at 38 °C (two signals at 0 °C[**]) as in all the pentadienyl anions studied to date. The signals of the protons H^d of the methyl group on C-1 are again shifted by about 0.25 ppm upfield; owing to the well-known coupling[7] [see *(5)*: J_{ab} = 2.5 Hz] with the single proton H^b on C-3 they appear as a sharp 1.8-Hz doublet (HW = 1.5 Hz). The signal of the protons H^a that appears as a doublet as in the starting material now occurs shifted by about 0.12 ppm upfield, although these protons are somewhat nearer to the negative charge than are the methylene protons H^a in the anion *(2a)*. This difference, and also the appreciably greater readiness of formation and the high rotational barrier of *(2a)*, might be be construed as arguments for participation of the resonance structures discussed above.

The methyl-ethyl-triene *(3)*, R = CH_3, is metalated exclusively on the methyl group. Treatment of the resulting lithium compound with methyl iodide affords compound *(6)*, b.p. 71–74 °C/25 torr, in 60% yield. The preparation of *(6)* and of the products *(3)* given in the Table, whose structures have been established by IR and NMR spectroscopy, demonstrate the preparative importance of the anions described here.

Table 1. Products *(3)* from the 1-methyl-2,3,4-trimethylenecyclobutenide ion *(2a)* and electrophiles.

Electrophile	*(3)*, R	Yield [a] (%)	B.p. (°C/torr)
$(CH_3)_3SiCl$	$(CH_3)_3Si$	80	90–92/18
CH_3I	CH_3	94 [b], 60 [c]	55–57/25
Ethylene oxide	$HOCH_2-CH_2$	40	63–64/0.1
Acetone	$(CH_3)_3C(OH)$	20	50/0.08
CH_3S-SCH_3	CH_3S	30	62–64/2

[a] Losses are considerable owing to the enormous tendency of the crude products to polymerize on distillation.
[b] By gas-chromatographic analysis of the reaction solution.
[c] Product isolated by distillation.

Experimental:

A solution of *n*-butyllithium (2 M in hexane, 20% excess) is added to a solution, stirred at −78 °C, of the triene *(1a)* (1.60 g) in THF (25 ml). Crystals begin to separate after 5 min, and after 5 h the red solution is sucked through a sinter disk. The crystals are recrystallized from THF/pentane at −40 to −78 °C and then washed with pentane. Adhering solvent is removed first at −40 °C, then at 25 °C/0.01 torr. All operations are conducted in an atmosphere of pure nitrogen. The yield of fine, pale yellow crystals of *(2a')* amounts to about 1 g. The substance becomes black immediately on exposure to air, or it ignites spontaneously. Dilute solutions in ethers are bright yellow, concentrated ones are red. *(2a')* decomposes in water to yield *(1a)*, LiOH, and THF; for reactions of *(2a)* molar amounts of *(1a)* and butyllithium are used and the reaction time increased.

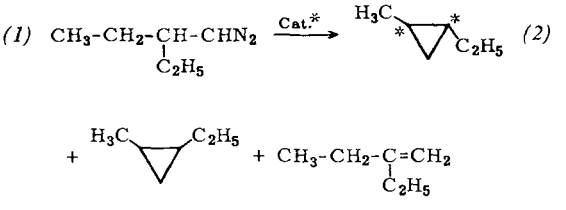
Asymmetric Induction in Intramolecular Reactions of Carbenoids

By *W. Kirmse* and *H. Arold*[*]

Alkylcarbenoids, which are intermediates in the α-elimination from haloalkanes[1] and in catalytic decomposition of diazoalkanes[2], give the same intramolecular insertion products as "free" alkylcarbenes. Carbenoids, however, show a higher selectivity in favor of secondary and tertiary C–H linkages[1,2] and larger isotope effects[3]. A possible explanation for the behavior of carbenoids is the participation of metal salts in the product-determining step of the reaction. We can now confirm that assumption by demonstrating an asymmetric induction on use of optically active catalysts.



Decomposition of 2-ethyl-1-diazobutane *(1)*[4] by silver salts of optically active acids gave optically active *trans*-1-ethyl-2-methylcyclopropane *(2)* (yield 20–30%) (see Table 1).

Table 1. Catalytic decomposition of 2-ethyl-1-diazobutane *(1)* by silver salts in *n*-pentane at 20 °C to yield *trans*-1-ethyl-2-methylcyclopropane *(2)*

Catalyst: silver salt of	*(2)*, $[\alpha]_{365}^{20}$
(*S*)-(+)-Alanine	+0.093
(*R*)-(−)-Alanine	−0.107
(*S*)-(+)-Camphor-1-sulfonic acid	+0.106
(*S*)-(+)-Ketopinic acid	+0.271
(*R*)-(+)-6,6'-Dinitro-2,2'-diphenic acid	+0.049

The (1 *R*, 2 *R*)-configuration is assigned to (−)-*trans*-1,2-dimethylcyclopropane, $[\alpha]_{365}^{20} = -125°$, because of its synthesis from (*S*)-(−)-2-methylbutan-1-ol[6]. (−)-*trans*-1-Ethyl-2-methylcyclopropane probably has the same configuration and a similar molar rotation. Catalytic decomposition of 2-methyl-1-diazobutane[7] by silver (+)-ketopinate (= (+)-7,7-dimethyl-2-oxonorbornane-1-carboxylate) afforded *trans*-1,2-dimethylcyclopropane with $[\alpha]_{365}^{0} = +0.27°$, in good agreement with the value for *trans*-1-ethyl-2-methylcyclopropane given in Table 1. The optical yield in this case, which is the most favorable so far, amounts to 0.22%.

Thermolysis of 2-ethyl-1-diazobutane *(1)* in (−)-α-methylbenzylamine or (−)-2-methylbutan-1-ol leads to inactive cy-

Table 2. Thermolysis of 2-ethyl-1-diazobutane *(1)*, to *trans*-1-ethyl-2-methylcyclopropane *(2)*.

Solvent	Temp. (°C)	*(2)*, $[\alpha]_{365}^{20}$
(*S*)-(−)-α-Methylbenzylamine	170	±0.002
(*S*)-(−)-α-Methylbenzylamine + $AgNO_3$	80	+0.039
(*R*)-(+)-α-Methylbenzylamine + $AgNO_3$	80	−0.057
(*S*)-(−)-2-Methylbutan-1-ol	120	±0.002
(*S*)-Ethyl (−)-lactate	145	−0.040
(*R*)-Dibutyl (+)-tartrate	170	+0.082

clopropane derivatives (no asymmetric induction by optically active solvent). Yet on addition of silver ions to the α-methylbenzylamine asymmetric induction is again observed (Table 2).

Weak proton donors (alcohols with acidifying substituents) recall the picture of a carbenoid reaction[2]. Presumably the proton can play the role of a metal ion in carbenoid catalysis. In accord with this hypothesis we obtained optically active *trans*-ethyl-2-methylcyclopropane on thermolysis of 2-ethyl-1-diazobutane in (*S*)-ethyl (−)-lactate or (*R*)-dibutyl (+)-tartrate. Carbonium ions $R'CH_2^{\oplus}$ cannot occur in these reactions. The catalyzing proton must retain a relation to the carbene-carbon as well as to the asymmetric alkoxide ion.

Because of the low optical yields, the above reactions are not well suited for asymmetric synthesis of cyclopropane derivatives. But they show unequivocally the participation of the catalyst in the product-determining step of intramolecular reactions of carbenoids[8].

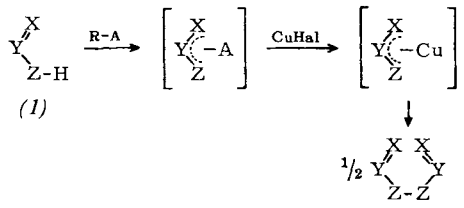
Dimerization of Oxaallyl, Azaallyl, Oxaphosphaallyl, and Oxathiaallyl Groups by Way of Organocopper Compounds[1]

By *Th. Kauffmann*, *G. Beissner*, *H. Berg*, *E. Köppelmann*, *J. Legler*, and *M. Schönfelder*[*]

Compounds of type *(1)* are formally derived from allyl compounds by replacement of allyl-carbon atoms by hetero atoms and may thus be termed heteroallyl compounds. In several cases they can be dehydrodimerized in accord with the following scheme[2,3]:

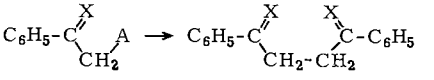


(A = alkali metal; Cu = Cu^{I} or Cu^{II})

Dehydrodimerization of heteroarylated alkanes[4] is a particular case of this reaction principle.

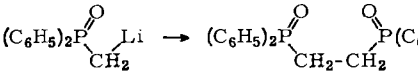
Continuing these investigations we have now observed dimerization of the 1-oxaallyl group on treatment of *(2)*[5,6] with one molar equivalent of CuCl in ether at 35 °C. The yield of dimerization product *(3)* of only 11% for this case increases to 42% if the 1-azaallyl compound *(4)* is used and dimerization (treatment with CuI in ether at 35 °C) is followed by hydrolysis with 2 N HCl[7]; compound *(4)* is formed by the action of $NaNH_2$ on acetophenone anil in ether at 35 °C.

Yields are still better [52% for *(7)*, 84% for *(9)*] in the analogous reaction (treatment with CuCl at −60 to +20 °C, then with O_2 at 20–65 °C; solvent tetrahydrofuran) of *(6)* and *(8)*, which were obtained on treatment of the corresponding ketazines with lithium diisopropylamide in tetrahydrofuran at 10 °C. The dehydrodimerization of ketazines thus disclosed may open a convenient route to long-chain azapolyenes.



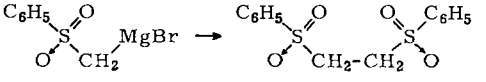
(2), X = O; A = Na
(3), X = O
(4), X = N-C_6H_5; A = Na
(5), X = N-C_6H_5
(6), X = N-N=C(C_6H_5)CH_3; A = Li
(7), X = N-N=C(C_6H_5)CH_3
(8), X = N-N=C(C_6H_5)$_2$; A = Li
(9), X = N-N=C(C_6H_5)$_2$

The 1-oxa-2-phosphaallyl group of *(10)*[8] can be dimerized, giving *(11)* (43%), by treatment with 1 molar equivalent of CuCl at −40 to +20 °C in tetrahydrofuran and subsequently with O_2 at 20 °C.



(10) *(11)*

The 1-oxa-2-thiaallyl group of compound *(12)*[9], which arises on reaction of phenylmagnesium bromide with methyl phenyl sulfone in benzene at 20 °C, was dimerized on treatment with 1 molar equivalent of CuCl at −68 to +20 °C in ether/benzene/tetrahydrofuran (*ca.* 1:3:4), yielding *(13)* (20–25%).



(12) *(13)*

Surprisingly, the 2-azaallyl group of *(14)*, which can be dimerized by use of CuI[3], was cyclized on treatment with 1 molar equivalent of $CuBr_2$ in ether at 35 °C, affording *(15)* in 18% yield (presumably not optimal).

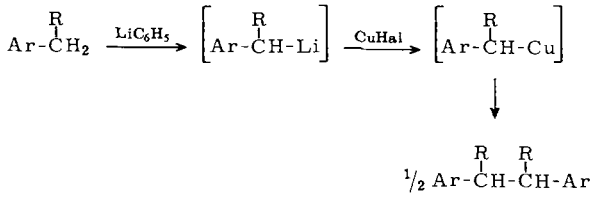
Dehydrodimerization of Heteroarylated Alkanes by Way of Organocopper Compounds[1]

By *Th. Kauffmann, D. Kuhlmann, W. Sahm*, and *H. Schrecken*[*]

We recently reported the dehydrodimerization of 2-methylpyridine (78% yield)[2]. Analogously the heteroarylated alkanes listed in the Table can be converted into the corresponding dehydrodimers according to the scheme indicated. Since the yields are mostly satisfactory this seems to be a useful method for preparation of bis(heteroaryl)ethanes and thus of bis(heteroaryl)ethylenes and -acetylenes.



Ar	R	CuHal	Dehydrodimers, yield (%)
2-Pyridyl [a]	CH_3	CuCl	63
	C_6H_5		65
6-Methyl-2-pyridyl [a]	H	$CuCl(CuBr_2)$	71 (77)
4-Pyridyl [a]	H	CuCl	54
	CH_3		40
	C_2H_5		34
	C_6H_5		65
2-Quinolyl [b]	H	CuCl(CuBr)	67 (69)
4-Quinolyl [b]	H	CuCl	58
2-Phenyl-4-quinolyl [b]	H	CuCl	74
3-Methyl-2-quinoxalinyl [b]	H	$CuCl(CuBr_2)$	61 (65)

[a] Reaction in tetrahydrofuran/diethyl ether (*ca.* 1:1).
[b] Reaction in dimethoxyethane/diethyl ether (*ca.* 1:1). To obtain a higher boiling point the diethyl ether was distilled off on decomposition of the organocopper compounds.

For preparation of the necessary lithium compounds the heteroarylated alkanes were treated with 1 to 1.1 molar equivalents of phenyllithium in the solvents listed, at −10 to 0 °C under N_2. Then 1 molar equivalent of CuCl or $CuBr_2$ was added at −60 to −40 °C and the mixture was warmed slowly to 60 to 80 °C, whereupon the organocopper compounds (brown or red; not isolated) which were formed as intermediates decomposed with precipitation of elemental copper or of CuBr according to whether CuCl or $CuBr_2$ had been used.

It is remarkable that the compounds formed by this process are mostly susceptible to further reactions of the same type. For instance, the dehydrodimer of 2-methylpyridine[2] can be converted into the two isomers of constitution *(1)* (yield 73%; ratio racemic:*meso*-form = *ca.* 1:1), and the product from 2,3-dimethylquinoxaline (see Table) can be converted into the pentacyclic compound *(2)* (yield 25%) if the dilution method is used. On the other hand, attempts to convert the dehydrodimer of 2,6-dimethylpyridine (see Table) into the known compound *(3)*[3] failed.

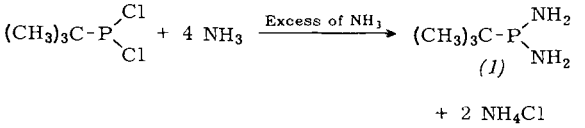
Diamino-*tert*-butylphosphine. – Synthesis and Conversion into *N*-Silylated Aminophosphine Imines with Non-equivalent Replaceability of the Hydrogen Atoms

By *O. J. Scherer* and *P. Klusmann*[*]

Alkyl diaminophosphines and diaminoarylphosphines[1] have not been described previously, and phosphorodiamidous acid derivatives[2] are polymeric substances.

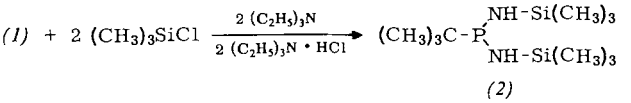
Ammonolysis of *tert*-butyldichlorophosphine[3] in ether at −50 °C gives the diamino-*tert*-butylphosphine *(1)* in *ca.* 60% yield.



(1)

+ 2 NH_4Cl

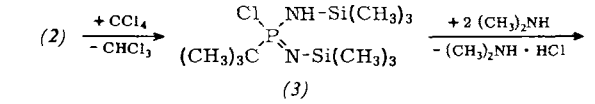
(1): colorless crystals, subliming at 75–85 °C/12 torr, extremely sensitive to oxygen and hydrolysis, m.p. 77–79 °C, readily soluble in ether or benzene. ^1H-NMR: $J^{31}PCCH$ = 12.5 Hz (δNH_2, broad signal, observable only on integration). Treatment of *(1)* with chlorotrimethylsilane gives *tert*-butylbis(trimethylsilylamino)phosphine *(2)* in 70% yield.



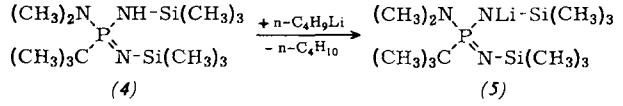
(2)

(2): b.p. 51–55 °C/0.1 torr, $J^{31}PCCH$ = 12.7 Hz, $J^{31}PNSiCH$ = 0.75 Hz, very sensitive to oxygen and hydrolysis, readily soluble in ether or benzene. Reaction of compound *(2)* with

CCl_4 gives *P-tert*-butyl-*P*-chloro-*N*-(trimethylsilyl)-*P*-(trimethylsilylamino)phosphine imine *(3)*[4], which with dimethylamine affords compound *(4)*. This can be metalated by *n*-butyllithium, affording the lithium amide derivative *(5)* in good yield.



(3)



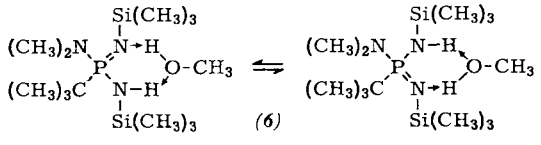
(4) *(5)*

(3): b.p. 55–59 °C/0.1 torr, m.p. 11–12 °C, $J^{31}PCCH$ = 20.4 Hz, yield 70%.

(4): b.p. 54–58 °C/0.1 torr, m.p. −26 °C, $^{31}JPCCH$ = 16.3 Hz, $J^{31}PNCH$ = 9.1 Hz, yield 70%.

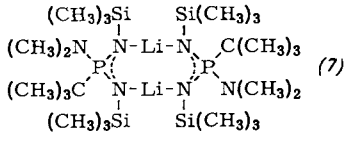
(5): m.p. 137–140 °C, sublimes at 190–200 °C/0.1 torr, $J^{31}PCCH$ = 14.9 Hz, $J^{31}PNCH$ = 8.8 Hz.

Although the ^1H–NMR spectrum of *(3)* shows two sharp signals even at *ca.* 60 °C (pure substance or dilute solution), for the non-equivalent trimethylsilyl groups, compound *(4)* (pure substance or in 10% solution in CCl_4 or benzene) at +35 °C gives only one, slightly broadened signal. If the benzene solution of *(4)* is diluted approximately tenfold, two trimethylsilyl signals appear (separation *ca.* 9 Hz), which combine to a single one on warming or on addition of *ca.* 5 mg of methanol (alcoholysis is observable only at higher concentration). This finding is best interpreted by assuming that in *(4)* transfer of the proton (that becomes stationary on strong dilution) is effected *(a)* intermolecularly within one molecule [cf. formula *(7)*; in the IR spectrum, *(4)* gives no indication (strong dilution) of bonding by fixed hydrogen bridges] and *(b)* by the alcohol molecule as in *(6)*.



(6)

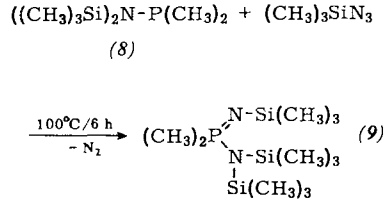
In contrast to the monomeric *(4)*, the "lithium salt" *(5)*, which is readily soluble in ether, CCl_4, or benzene, is dimeric in the last-mentioned solvent (cryoscopic determination). The ^1H–NMR spectrum of *(5)* shows only one sharp signal for the trimethylsilyl groups (even on strong dilution). These facts are best accounted for by the suggested formula *(7)*.



(7)

Attempts to convert *(3)* into a "phosphine diimine" by elimination of HCl and to substitute *(5)* by chlorotrimethylsilane were unsuccessful.

If impure dimethylbis[(trimethylsilyl)amino]phosphine *(8)*[5] [prepared from $((CH_3)_3Si)_2NNa$ and $(CH_3)_2PCl$] is treated with trimethylsilyl azide, the thrice-silylated aminophosphine



(8) *(9)*

imine *(9)*, b.p. 70–74 °C/0.1 torr, m.p. 4–6 °C, is obtained in 10% yield.

As in metalorganic amidines[6] the non-equivalent trimethylsilyl groups of *(9)* appear in the ^1H–NMR spectrum at 35 °C only as a single, broadened signal, which splits into two signals at *ca.* −20 °C (separation ≈ 20 Hz in $CDCl_3$; area ratio 2:1).

Preparation of Single Crystals of Chromium Thiospinels by Means of Transport Reactions

By *H. D. Lutz* and *Cs. von Lovász* [*]

Nitsche et al.[1] prepared single crystals of thiospinels – in particular of indium and gallium thiospinels – by using iodine as transport agent in transport reactions. Single crystals of chromium thiospinel, which we required for electrical studies of thiospinel semiconductors[2], cannot be prepared in this way since, in contrast to chromium chloride, chromium sulfides are not transported by halogens – apparently the entropy of reaction of the corresponding gas-phase reaction is negative.

Chromium sulfides and chromium thiospinels can, however, be transported by anhydrous aluminum chloride:

$$Cr_2S_{3(s)} + 4\,AlCl_{3(g)} \underset{T'}{\overset{T}{\rightleftharpoons}} 4\,AlCl_{(g)} + 2\,CrCl_{4(g)} + 3/2\,S_{2(g)}$$

We obtained the following chromium thiospinels as black octahedra (sides of length 1 mm) as well as various modifications of chromium sulfide such as Cr_2S_3 as hexagonal leaflets of 10 mm size:

$MnCr_2S_4$ 1000→900 °C
$ZnCr_2S_4$ 1000→850 °C
$CdCr_2S_4$ 1000→800 °C

$FeCr_2S_4$, $CoCr_2S_4$, $CuCr_2S_4$, and $HgCr_2S_4$ could not be transported by $AlCl_3$.

2 g of the substance was transferred, together with 0.2 g of anhydrous $AlCl_3$, to a 10 cm long, evacuated quartz ampoule in a dry box and then heated for about 80 hours in a temperature gradient oven.

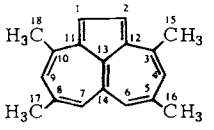
Crystal Structure and Molecular Structure of 3,5,8,10-Tetramethylaceheptylene

By *E. Carstensen-Oeser* and *G. Habermehl*[*] [**]

3,5,8,10-Tetramethylaceheptylene, $C_{18}H_{18}$ *(1)*, a hydrocarbon with a 14 π electron system, was prepared by *Hafner et al.*[1] and has been subjected to quantum-mechanical study[2]. To test the quantum-mechanical conclusions about molecular geometry we carried out an X-ray crystal structure analysis.



(1)

3,5,8,10-Tetramethylaceheptylene forms monoclinic crystals from benzene but orthorhombic ones from light petroleum. The lattice constants of the monoclinic modification are $a = 8.43 \pm 0.03$ Å, $b = 13.24 \pm 0.03$ Å, $c = 12.44 \pm 0.03$ Å, $\beta = 107.7 \pm 0.1°$. The space group is $P\,2_1/c$; the unit cell contains four molecules. The orthorhombic form gave the following crystallographic results: $a = 17.27 \pm 0.03$ Å, $b = 10.98 \pm 0.03$ Å, $c = 7.00 \pm 0.03$ Å; space group $Pna\,2_1$, with four molecules in the unit cell.

We have first worked with the orthorhombic structure. Analysis of the monoclinic modification is in progress.

Measurement of the intensities of 865 symmetry-independent reflections of the layers *hk* 0 to *hk* 4 was carried out on an automatic Weissenberg diffractometer with punched-tape control, system Stoe-Güttinger. We determined the sign of 66 reflections by *Sayre, Cochran,* and *Zachariasen*'s method[3]. A Fourier synthesis with the *E* values of these 66 reflections as coefficients could be interpreted unambiguously. Refinement was effected by further Fourier and difference Fourier syntheses, as well as by the method of least squares. Finally we reached an *R* factor of 7.6%. Anisotropic thermal motion was taken into account for the carbon atoms in these calculations.

The calculations show that the molecule is completely planar except for the hydrogen atoms of the methyl groups. Bond distances and bond angles can be read from Figures 1 and 2. The values agree well with the bond lengths calculated for the parent aceheptylene by *Ali* and *Coulson*[2] using the MO method and by *DasGupta* and *Ali*[2] using the Pople SCF method. *Coulson*'s relation[4] was used for calculations between bond order and bond length.

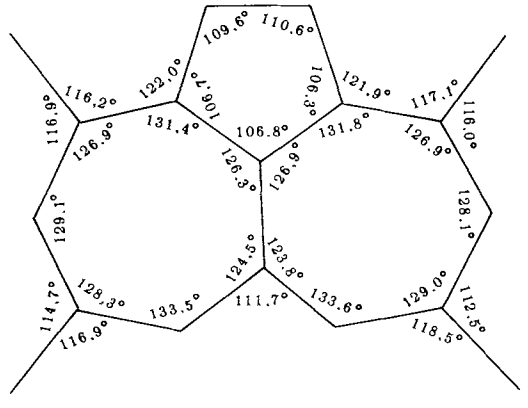


Fig. 1. Bond distances in 3,5,8,10-tetramethylaceheptylene; max. error, ±0.008 Å.

Fig. 2. Bond angles in 3,5,8,10-tetramethylaceheptylene; max. error, ± 1°.

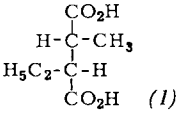
The Absolute Configuration of (−)-*threo*-2-Ethyl-3-methylsuccinic Acid[1]

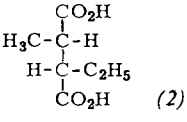
By *H. Brockmann jr.* and *D. Müller-Enoch*[*]

By comparison of the molar optical rotations of anhydrides of mono- and di-alkyl-substituted succinic anhydrides the (2*R*, 3*R*)-configuration was recently[2] assigned to (+)-*threo*-2-ethyl-3-methylsuccinic acid *(1)*, and thus the absolute configuration of bacteriochlorophyll was determined. We have now proved the (2*S*, 3*S*)-configuration of (−)-*threo*-2-ethyl-3-methylsuccinic acid *(2)* by a chemical method, in that we converted *(2)* by total reduction into (3*S*)-(−)-2,3-dimethylpentane *(5)*, whose absolute configuration is known[3].

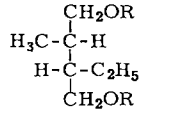
Compound *(2)* [m.p. 66–68 °C, $[\alpha]_D^{20} = -17.8°$ ($c = 2.5$, in water), corresponding to 68% optical purity] was reduced by lithium aluminum hydride in ether to the diol *(3)*, which was converted by *p*-toluenesulfonyl chloride in pyridine at 0 °C into the ditosylate *(4)*; the yield was 53% calculated on *(2)*. Crystallization of *(4)* gave several fractions, with various optical activities, $[\alpha]_D^{20} = -2.1°$ to $-2.9°$, and various melting points (56 to 60 °C). A partly oily preparation with $[\alpha]_D^{20} = -3.2°$ ($c = 2.5$, in chloroform) was used for further reduction. It was treated with lithium aluminum hydride in di-*n*-



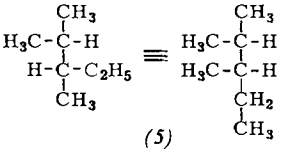
(1)



(2)



(3), R = H
(4), R = $SO_2C_6H_4$-p-CH_3



(5)

butyl ether and, after decomposition of the excess of hydride with sulfuric acid, the product *(5)* was distilled off together with some solvent. By extraction with conc. sulfuric acid and distillation over sodium we obtained a 37% yield of the hydrocarbon *(5)*, b.p. 87 °C and $[\alpha]_D^{20} = -7.8°$ (c = 2.5, in chloroform), which had a faint smell of petrol.

In comparison with the rotation $[\alpha]_D^{20} = -11.4°$ given by *Freudenberg*[3] for the optically pure hydrocarbon our value indicates an optical activity of 68%. The purity of *(5)* was proved by its mass spectrum: $M^+ = 100$, $(M-15)^+$, $(M-29)^+$, $(M-43)^+$.

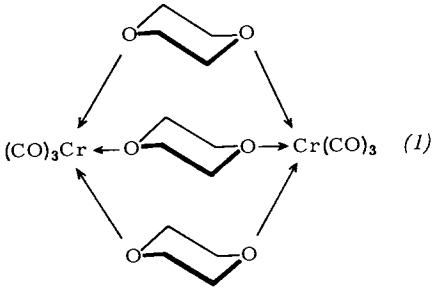
A Binuclear Chromium Complex with Dioxane as Bridging Ligand

By *H. Werner* and *E. Deckelmann*[*]

Recently we reported the synthesis of hexaalkylborazole-tricarbonylchromium compounds, the first representatives of borazole-transition metal complexes. These are most profitably obtained by starting with $(CH_3CN)_3Cr(CO)_3$ or analogous compounds of the type *cis*-$A_3Cr(CO)_3$ (A = amine)[1,2]. The choice of solvent is decisive for success in this method of preparation; dioxane has so far proved most suitable for this purpose. Measurements of absorption in the visible region indicated at once that in the reaction of tris-(amine)tricarbonylchromium compounds with hexaalkylborazoles the dioxane clearly acts, not merely as solvent, but also as coordination partner.

We have now confirmed this assumption by isolating the binuclear complex $(C_4H_8O_2)_3Cr_2(CO)_6$ *(1)*. This orange, diamagnetic substance is extremely sensitive to air and glows on exposure to even traces of oxygen; as expected, it does not sublime and it decomposes slowly even at room temperature. Darkening is observed from 90 °C if the material is heated rapidly under nitrogen in a sealed tube. In the region of the CO stretching vibrations, the IR spectrum (in KBr) shows two strong bands of relative intensities 1:2 at 1919 and 1763 cm^{-1}, thus confirming the existence of a $Cr(CO)_3$ group. Absorptions at 1455, 1370, 1289, 1252, 1119, 1103, 1047, 879, and 866 cm^{-1} are ascribed to the coordinately bonded dioxane molecules (cf. free dioxane[3]: 1451, 1366, 1292, 1255, 1124, 1085, 1049, and 879 cm^{-1}). The presence of $C_4H_8O_2$ ligands is also proved by the mass spectrum[4].



(1)

In the NMR spectrum of *(1)* (in deuterioacetone) a sharp signal is observed at $\tau \approx 6.45$ (referred to tetramethylsilane as internal standard), which is hardly shifted in comparison with that for free dioxane ($\tau = 6.44$). However, in this connection a very rapid exchange between solvent molecules and the dioxane ligands in solution cannot be excluded; this would explain why it has not yet been possible to recover the dioxane complex from its solution in acetone or deuterioacetone; moreover, on addition of acetonitrile to *(1)* an extremely rapid exchange of ligands occurs, with quantitative formation of $(CH_3CN)_3Cr(CO)_3$.

The binuclear nature of the complex is shown by elemental analysis and determination of the molecular weight, and on the basis of the above results we assume structure *(1)* with three dioxane molecules as bridging ligands. The weak donor character of the ether oxygen atoms is probably mainly responsible for the low stability of the compound. On the other hand, its extreme reactivity, shown in the synthesis of the hexaalkylborazole-tricarbonylchromium compounds, makes it predestined as a starting material for the preparation of other $Cr(CO)_3$ complexes. In this connection it may be noted that very recently tris(dimethylamino)borane-tricarbonyltungsten was obtained by reaction of $(CH_3CN)_3W(CO)_3$ with $B[N(CH_3)_2]_3$ in dioxane[5]. It can be assumed that here also a carbonyldioxanetungsten complex analogous to *(1)* is formed as intermediate and that this then reacts rapidly with the tris(dimethylamino)borane by ligand exchange.

Experimental:

1 g of $(CH_3CN)_3Cr(CO)_3$ was treated with two successive portions, each 50 ml, of dioxane in a two-necked flask under nitrogen, and the solution was evaporated almost to dryness in vacuum at a bath temperature of *ca.* 15 °C. The resulting crystalline mass was made into a slurry with a little dioxane and filtered rapidly through a G 3 fritted filter. The orange solid thus isolated was washed several times with a few ml of cold dioxane, then with ether, and was finally dried under a high vacuum. The yield was 75%.

Hammett Constants of Phosphorus-containing Groups Determined from Nuclear Magnetic Resonance Spectra of *para*-Phosphorus-substituted Toluenes[1]

By *G. P. Schiemenz*[*]

Earlier[2] we found Hammett constants of *ca.* +1 for substituents $-\overset{\oplus}{P}RAr_2$ on the aromatic ring. Onium-phosphorus is thus disclosed as a stronger electron acceptor than positive nitrogen[3,4]. In view of the electronegativity series N > P

this finding could not be explained as an inductive effect alone.

By proton magnetic resonance spectroscopy of anilinium salts *Fraenkel*[5] showed that the inductive effect of the 'onium atom is almost wholly abolished by ion-pair formation. We found, also by nuclear magnetic resonance spectroscopy, that triarylmethylphosphonium salts in chloroform associate to contact ion pairs, in which the anionic charge is localized on the phosphorus[6]. Thus, Hammett constants, determined in the same medium and by the same method, should provide information about the non-inductive portions of the electronic effect of 'onium phosphorus.

For compounds $X-C_6H_4-Y-H$ the position of the nuclear resonance signal of $-Y-H$ is often linearly dependent on the Hammett constants σ of X ($-Y-H$ = CHO[7], OH[8], or NH_2[9]), so that σ values for new substituents X can be determined from δ ($-Y-H$). In this way we obtained "satisfactory"[3] correlation for *para*-substituted toluenes ($-Y-H$ = CH_3) in $CDCl_3$ between δ and σ[3] of groups X that contain no free electron pair [X = NO_2, SO_2CH_3, CN, $COOC_2H_5$, $COCH_3$, COC_6H_5, CHO, C_6H_5, H, $Si(CH_3)_3$, $CH(CH_3)_2$, CH_3, $C(CH_3)_3$; equation (1)][10]. The experimental points for 16 toluenes whose substituents X do carry a free electron pair all lie below the best straight line [X = F, Cl, Br, I, NH_2, $NHCH_3$, $N(CH_3)_2$, NHCHO, $NHCOCH_3$, $NHCOC_6H_5$, OH, OCH_3, OC_2H_5, OC_6H_5, SH, SCH_3][10]. Thus new substituent constants can be calculated from equation (1), although for groups with free electron pairs these are only minimal values.

$$\delta = 0.142 \cdot \sigma + 2.332 \qquad (1)$$

$r = 0.960$, for δ $s = \pm 0.016$ ppm, for σ $s = \pm 0.11$ σ unit

In this way we determined σ_{para} values for 28 groups X that contain phosphorus or, for comparison, sulfur or nitrogen (Table 1). For all phosphonium groups σ_{para} is again about 1; σ_{para} is larger when electron-donating methyl groups are replaced by electron-attracting aryl groups. The three sulfur-containing groups also have Hammett constants near 1, whereas, in agreement with earlier results[2], phosphinyl- and thiophosphinyl-phosphorus usually behaves as a moderately strong electron-acceptor (in two cases σ_{para} does not differ significantly from 0).

Table 1. Chemical shifts δ (ppm) of the NMR signals of the CH_3 protons in *p*-$X-C_6H_4CH_3$ [*ca.* 0.9 mole of *p*-$CH_3C_6H_4$ group/1000 g of $CDCl_3$; $(CH_3)_4Si$ as internal standard] and Hammett constants of the substituents X.

[a] Multivalent groups carry a corresponding number of *p*-$CH_3C_6H_4$ groups. [b] Third decimal place estimated. [c] Calculated according to eq. (1). [d] Approximate values.

Martin and *Griffin*[11] determined Taft constants σ^* of some phosphorus-containing groups, some of which are so similar to our substituents that the inductive portion σ_I of their Hammett constants can be determined from σ^* by *Taft*'s method[12] (see Table 1). Using the relation $\sigma = \sigma_I + \sigma_M$ then affords for phosphonium-phosphorus a mesomeric contribution σ_M that greatly exceeds that of the ethoxycarbonyl group ($\sigma_M^{COOC_2H_5} = +0.20$[12]). 'Onium-phosphorus thus behaves as a strong (−M)-substituent, whereas in the chalcogenides phosphorus gives no indication of a (−M)-effect.

Hammett Constants of Phosphorus-containing Groups Determined from Nuclear Magnetic Resonance Spectra of *meta*- and *ortho*-Phosphorus-substituted Toluenes[1]

By *G. P. Schiemenz* [*]

We found[2] phosphorus Hammett constants $\sigma > 1$ for *para*-tolyl-substituted phosphonium salts $Ar_2\overset{\oplus}{P}(CH_3)C_6H_4CH_3$-*p* $I^{\ominus}$ although, because of formation of contact ion pairs, there should be no good grounds for an inductive effect. We wished to use the same method to test applicability of this remarkable finding to the *meta*- and *ortho*-isomers.

Exner's equation[3]

$$\sigma_{para} - \sigma_{meta} = 0.12 \cdot \sigma_{para}$$

should apply to the *meta*-compounds, *i.e.* σ_{meta} of 'onium phosphorus should be somewhat smaller than σ_{para} but still around +1. Eleven phosphorus-free *meta*-substituted toluenes *m*-$X-C_6H_4CH_3$ without an electron pair on X [X = NO_2, CN, CHO, $COOC_2H_5$, $COOCH_3$, COOH, $COCH_3$, $CH=CH-C_6H_5$, H, CH_3, or $C(CH_3)_3$] gave a markedly poorer correlation in the plot of $\delta(CH_3)/\sigma_{meta}$ of X than did the *para*-compounds; the best linear relation [equation (1)], with $r = 0.850$, is according to *Jaffé*[4] less than "satisfactory"

and thus gives only approximate σ_{meta}-values for new substituents; in view of this low accuracy it must be considered as almost identical with the corresponding relation for the *para*-series. The points for substituents carrying a free electron pair (X = F, Cl, Br, I, OH, OCH_3, NH_2, $NHCOC_6H_5$) again lie under the best straight line, so that equation (1) gives only minimal values for such groups. For all the substituents studied, σ_{meta} is somewhat lower than σ_{para}, but for 'onium-phosphorus it has the expected value of *ca.* +1. (It should be noted that in compounds containing several tolyl groups the part of the molecule considered as substituent in one $CH_3C_6H_4$ group is not quite the same in the *para*- as in the *meta*-series.)

$$\delta = 0.135 \cdot \sigma_{meta} + 2.338 \quad (1)$$

$r = 0.850$, for δ $s = \pm 0.024$ ppm, for σ $s = \pm 0.15$ σ unit

$$\delta = 0.323 \cdot \sigma_{ortho} + 2.321 \quad (2)$$

$r = 0.996$, for δ $s = \pm 0.018$ ppm, for σ $s = \pm 0.05$ σ unit

For anilines $X-C_6H_4NH_2$ *Lynch, Macdonald,* and *Webb*[5] found an excellent correlation between $\delta(NH_2)$ and σ of X, into which the *ortho*-substituted compounds fit if σ_{ortho} is put equal to σ_{para}. In analogy to this, eleven toluenes o-$X-C_6H_4CH_3$ with or without free electron pairs on X, including o-$CH_3C_6H_4SO_2Cl$ (with the σ-value evaluated from the NMR spectrum of the *para*-isomer[2]) give an "excellent"[4] regression line [equation (2), X = SO_2Cl, NO_2, CN, I, Br, Cl, H, CH_3, OCH_3, OH, NH_2] which, however, is not followed by any C=O compound (X = $NHCOCH_3$, $OCOCH_3$, COOH, $COOC_2H_5$; such substituents were not investigated in the aniline series[5]). Unlike the case for the anilines, the line for the *ortho*-compounds is steeper than those for the *para*- and *meta*-compounds. For phosphine-, phosphine-oxide-, and phosphine-sulfide-phosphorus, equation (2) leads to positive Hammett constants in good accord with σ_{para}-values determined previously[6] from the pK values of *para*-phosphorus-substituted benzoic acids. However, σ is unexpectedly small for 'onium-phosphorus. *ortho*-Tolylphosphonium salts do not differ from their *para*- and *meta*-isomers in ion pair association but do in a staggering of the tolyl groups[7] as in tri-*ortho*-tolylphosphine[8]. Thus a steric hindrance to mesomerism may express itself in the low δ values.

Table 1. Chemical shifts δ (ppm) of the NMR signals of the CH_3 protons of *m*- and *o*-$X-C_6H_4CH_3$ [*ca.* 0.9 mole of $CH_3C_6H_4$ group/1000 g of $CDCl_3$; $(CH_3)_4Si$ as internal standard] and Hammett constants of the substituents X.

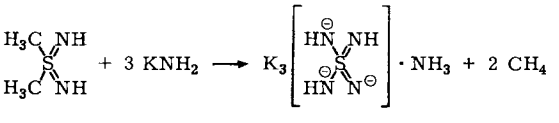
Diaminosulfur Diimide, the Aza Analog of Sulfuric Acid[1]

By *R. Appel* and *B. Ross*[*]

The aza analogs of sulfuric acid and sulfur trioxide have hitherto been missing from the series of isoelectronic oxygen and nitrogen compounds of sulfur. We have now found that a tripotassium salt of diaminosulfur diimide can be prepared by treating *S,S*-dimethylsulfur diimide (sulfodiimine)[2,3] with potassium amide in liquid ammonia. When the reaction is effected above 60 °C in an autoclave two methyl groups are removed quantitatively as methane and replaced by amino groups. Diaminosulfur diimide is then precipitated as its colorless potassium salt *(1)* in small crystals:



(1)

The structure of the tetraazasulfate *(1)* follows from its synthesis, elemental composition, and hydrolysis in a stream of moist nitrogen; in the last-mentioned reaction, three molar equivalents of ammonia are removed and sulfamide is formed:

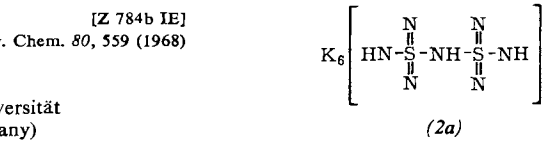
$$K_3[SN_4H_3]\cdot NH_3 + 5\,H_2O \rightarrow O_2S(NH_2)_2 + 3\,KOH + 3\,NH_3$$
(1)

The additional NH_3 in compound *(1)* is very probably present as crystal ammonia and not bound as an ammonium ion. It cannot be exchanged for K^+ by means of an excess of potassium amide, and of the two characteristic IR bands of the NH_4^+ ion[4] at 3340–3030 cm^{-1} and 1480–1390 cm^{-1} only the strong NH stretching vibration at 3220 cm^{-1} is present.

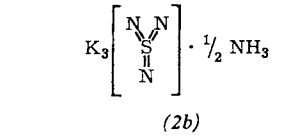
When heated in a stream of dry N_2 to 100 °C, compound *(1)* loses 1.5 moles of NH_3 per mole, and is converted into a yellow highly explosive powder, which is also crystalline; this can be reconverted into *(1)* by liquid ammonia:

$$2\,K_3[SN_4H_3]\cdot NH_3 \underset{\text{liquid } NH_3}{\overset{-3NH_3\,(100\,^\circ C)}{\rightleftharpoons}} K_6[S_2N_6]\cdot NH_3$$
(1) *(2)*

Whether compound *(2)* is potassium di(tetraazasulfate) *(2a)* or the potassium salt of sulfur triimide *(2b)* cannot yet be decided.



(2a)



(2b)

Experimental:

S,S-Dimethylsulfur diimide (4 g) and KNH_2 (8 g) in liquid NH_3 as solvent are heated to 80–100 °C for 10 h in a steel autoclave fitted with a glass lining. The reaction product is washed free of potassium amide with liquid NH_3 under inert conditions. Diaminosulfur diimide *(1)* can be stored indefinitely under nitrogen; it detonates on shock and on contact with water.

Structure of the Principal Aglycon of Horse Chestnut Saponin[1]

By *W. Hoppe, A. Gieren*, and *N. Brodherr*[*]
also *R. Tschesche* and *G. Wulff*[**]

The seeds of the horse chestnut (*Aesculus hippocastanum* L.) contain a mixture of saponins known as aescin, whose chemical structure has not previously been fully clarified. In particular, the positions of the ester groups were not clear because the acyl groups are readily removed or undergo migration[2]. We have now succeeded in obtaining an aglycon with unchanged ester groups and clarifying its structure by X-ray analysis.

On mild extraction of chestnuts with 2-propanol and subsequent separation on Sephadex an aescin was obtained that was as "genuine" as possible. The sugars were removed from this by hydrolysis with snail enzyme (from *Helix pomatia*), this yielding a mixture made up of esters of barringtogenol C and of protoaescigenin. The principal constituent, a pure protoaescigenin diester *(1a)*, was thence obtained by chromatography on silica gel; it had m.p. 241–252 °C (from benzene), $[\alpha]_D^{20} = +25.6°$ (chloroform). Alkaline cleavage of this product *(1a)* converts it into protoaescigenin and two molar equivalents of acids (acetic acid, tiglic acid, angelic acid, α-methylbutyric acid, and isobutyric acid in the ratio 8:6:4:1:1). The main product *(1b)* of the diester *(1a)* should contain 1 equivalent of acetic acid and 1 equivalent of tiglic acid (angelic acid).

For the three-dimensional X-ray analysis we used monoclinic crystals of *(1a)* obtained from benzene. Crystallographic data are: $a = 22.18_6$ Å, $b = 14.14_5$ Å, $c = 6.82_5$ Å, $\gamma = 69.0_7°$, $d_{obs} = 1.18$ g·cm^{-3}. The space group is $P\,2_1$. The asymmetric unit contains one molecule of $C_{37}H_{58}O_8$ and one of C_6H_6 ($d_{calc} = 1.18$ g·cm^{-3}). All the reflections with $\theta \geqslant 70°$ were measured with Cu–K_α radiation on our single-crystal diffractometer ($\theta/2\theta$ scan, 5-point measurement). Of 4142 independent reflections, only 562 were unobserved ($J < 2\sigma J$).

We were able to locate 15 structurally connected atoms by a combination of the convolution molecule method, group refinement[3a], and the determination of signs in the centrosymmetrical projection by triple product methods[3b]. The complete structure was solved ($R = 27\%$) by several weighted[3c] Fourier syntheses. Refinement by the method of least squares (full matrix) required overlapping cycles because of the large number of parameters. Difficulties arose through the strongly librating benzene and the disorder in the region of the 21-acyl group; these were largely overcome by difference Fourier syntheses, and the isotropic refinement closed with $R = 18.1\%$. On anisotropic calculation the R value then decreased to 10.1%. In the last cycle the change in the parameters was on average 0.12 of the respective standard deviation. We are continuing the refinement of the structure. In one difference Fourier synthesis we have found most of the expected hydrogen atoms.

Figure 1 shows the molecular structure. The constitution and configuration of protoaescigenin agree with the recently revised data in the literature[7]. The acetyl group is on C-22, and the unsaturated acyl group (mostly tigloyl) is on C-21.

The conformation of the ring system is determined mainly by the interactions of the axial substituents. Ring D is flattened by sp^2 hybridization at C-13 and by the α-axial substituents on C-14, C-16, and C-18, which diverge from one another.

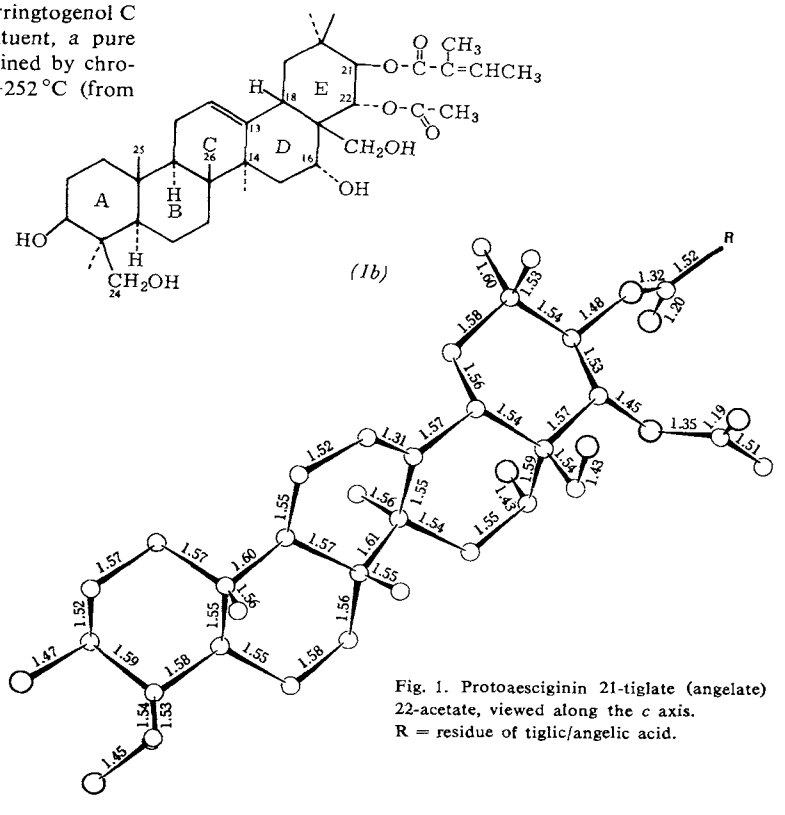

Fig. 1. Protoaesciginin 21-tiglate (angelate) 22-acetate, viewed along the *c* axis.
R = residue of tiglic/angelic acid.

As a consequence the *cis*-decalin system D/E also flattens out appreciably. Rings A, B, and C have a form that minimizes mutual repulsions of atoms C-24, C-25, and C-26. Apart from solving the special problems concerning the aglycon of aescin these results lay the foundation for the stereochemistry of various triterpenes that have recently been correlated chemically with protoaescigenin.

First Synthesis of a Thioacylium Cation

By *E. Lindner* and *H.-G. Karmann* [*]

In principle acylium salts are accessible in two ways, namely by treatment of acyl fluorides with BF_3 [1] or MF_5 [2] (M = P, As, or Sb) or by reaction of the anhydrous complexes $Ag[MF_6]$ with acyl chlorides or bromides in polar, aprotic solvents [2, 3]. However, since the corresponding thio compounds have been unknown, except for the perfluorinated thioacyl fluorides and chlorides [4] that polymerize rapidly, our initial investigations concerned the behavior of C_6H_5CSCl *(1)*, a compound that has long been accessible, with $Ag[SbF_6]$ *(2)* in dry, liquid SO_2. Thiobenzoylium hexafluoroantimonate(v) *(3)* is thereby obtained if stoichiometric amounts of *(1)* and *(2)* are used at −40 °C:

$$\underset{(1)}{C_6H_5CSCl} + \underset{(2)}{Ag[SbF_6]} \xrightarrow{-40\,^\circ C} \underset{(3)}{[C_6H_5CS][SbF_6]} + AgCl$$

The thio complex *(3)* is extremely hygroscopic but remarkably stable at room temperature; it dissolves very readily in liquid SO_2 with a deep reddish-brown color but with decomposition in other polar solvents such as acetone or alcohols. The ionic nature of *(3)*, whose composition is proved by elemental analysis, could be proved by measurement of the concentration- and temperature-dependent conductivity in liquid SO_2 (equivalent conductivity at −50 °C: $v = 376.5$ l·mole^{-1}; $\mu = 80.9\ \Omega^{-1}\cdot cm^2\cdot mole^{-1}$). Further, the IR spectrum proves that *(3)* exists as an ion pair: in comparison with *(1)*, whose ν(C−S) vibration appears at 1250 cm^{-1}, the band for the C−S stretching vibration of the $[C_6H_5CS]^+$ cation *(3)* is shifted to shorter wavelengths [1332 (vs) cm^{-1}]. The satellite of varying intensity (w−m) at 1355 cm^{-1} is probably to be ascribed to decomposition that must have occurred after the thin film of substance had been placed on the AgCl window for the measurement. The IR-active, three-fold degenerate SbF_6 stretching vibration of the species T_{1u} absorbs, as expected, at 673 (vs) cm^{-1}. The $[C_6H_5CS]^+$ cation can thus be said to exist mainly in two mesomeric limiting forms, which have approximately equal importance

$$H_5C_6\text{-}C{\equiv}\overset{\oplus}{S}: \longleftrightarrow H_5C_6\text{-}\overset{\oplus}{C}{=}S:$$

so that the mean bond order for C−S is 2.5. Further limiting forms are obtained by including the benzene nucleus in the mesomerism. Stabilization of the cation *(3)* thus follows from delocalization of the positive charge.

A purely chemical proof that a thiobenzoylium cation occurs in compound *(3)* was also obtained. When *(3)* is treated with anhydrous benzene at temperatures higher than 6 °C and the reaction mixture is worked up as for Friedel-Crafts syntheses, thiobenzophenone *(4)* is obtained:

$$\underset{(3)}{[C_6H_5CS][SbF_6]} + C_6H_6 \rightarrow \underset{(4)}{(C_6H_5)_2CS} + H[SbF_6]$$

The product can be identified by IR spectroscopy [ν(C−S) = 1226 cm^{-1}], as well as by preparation of the 2,4-dinitrophenylhydrazone, m.p. 238 °C. Already hydrolyzed *(4)* was purified chromatographically and worked up to give benzophenone [ν(C−O) = 1666 cm^{-1}; m.p. 48 °C], the total yield being *ca.* 20%.

This reaction may constitute the first synthesis of a thioketone by the Friedel-Crafts method.

Experimental:

Thiobenzoylium hexafluoroantimonate(v) *(3)*: Very pure $AgSbF_6$ *(2)* (3.44 g, 10 mmole) is dissolved in liquid SO_2 (*ca.* 100 ml) and treated at −40 °C with a solution of $C_6H_5CSCl_2$ *(1)* (1.56 g, 10 mmole) also in liquid SO_2 (*ca.* 100 ml) and the mixture is stirred vigorously for 3 h. After filtration, the solvent is removed at −50 °C under high vacuum. The yield is almost quantitative.

Thiobenzophenone *(4)* and benzophenone: An excess of benzene is added to *(3)* (3.5 g, 10 mmole) and the reaction mixture is allowed to stand for about 2 days. The mixture is then shaken rapidly with acidified ice water and the deep blue organic phase is separated off and dried as quickly as possible. After the benzene has been removed under vacuum, a blue-violet product can be separated off, which proves to be thiobenzophenone *(4)*, m.p. 50 °C. If the remaining crude product is dissolved in ether and hydrolyzed with water for a few hours, benzophenone is obtained. Neutral Al_2O_3 ("Woelm") was used for chromatographic purification of the product.

^{13}C-Experiments on Carbon Skeleton Rearrangements: Automerization of Naphthalene

By *H. A. Staab* and *M. Haenel* [*]

In investigations of rearrangements of organic compounds using ^{14}C-tracers, localizing the label requires most frequently a series of degradative reactions which might give rise to errors. On the other hand, labeling with ^{13}C which has a nuclear magnetic moment permits the non-degradative determination of the label in the intact molecule on the basis of (a) the ^{13}C−NMR spectra, (b) the ^{13}C satellites of ^1H−NMR

spectra, and (c) the ^{13}C hyperfine structure of ESR spectra (with compounds which can be converted into radicals).

Balaban and *Fărcaşiu*[1] recently deduced from activity determinations on degradation products that treatment of [1–^{14}C]-naphthalene with aluminum chloride in benzene for 2 hours at 60 °C leads to complete rearrangement of the carbon skeleton and thus to a statistical scrambling of the ^{14}C label over all ten positions of naphthalene. Because of the far reaching consequences of this result we have tried to detect this "automerization" directly in ^{13}C-labeled naphthalene by the three resonance methods mentioned above.

By analogy with known methods[2], [1–^{13}C]-naphthalene was prepared by the following route: Treatment of the Grignard compound of 1-bromo-3-phenylpropane with [^{13}C]-carbon dioxide (from barium [^{13}C]carbonate; 50.9% enriched) yielded [1–^{13}C]-4-phenylbutyric acid, which was cyclized to [1–^{13}C]-1-tetralone; Clemmensen reduction and catalytic dehydrogenation of the [1–^{13}C]-tetralin afforded [1–^{13}C]-naphthalene (yield 55% based on barium [^{13}C]carbonate). The ^{13}C enrichment was determined mass spectrometrically to be 50.6%. The selective α-labeling follows from the intensities of the ^{13}C satellites of the ^{1}H–NMR spectrum considering the known assignments of the proton resonance signals[3]; it is further confirmed by the analysis of the ESR spectrum of the radical ion obtained with potassium in 1,2-dimethoxyethane[4].

The automerization experiments were carried out with 2 g quantities of [1–^{13}C]-naphthalene in benzene using aluminum chloride according to the method proposed by *Balaban* and *Fărcaşiu*[1]; the yields of re-isolated and purified naphthalene were of the same order as those obtained in the above authors' experiments (45%).

The ^{13}C–NMR spectra[5] were identical before and after the automerization experiment. Intensity ratios and splitting pattern of the ^{13}C satellites in the ^{1}H–NMR spectrum (100 MHz) were in complete agreement with those of the starting material. That a statistical distribution of ^{13}C labeling on the α, β, and γ positions did *not* in fact occur followed also from the ESR spectrum of the radical anion, which, likewise, was unchanged after the automerization experiment: no decrease in intensity in the lines attributed to the ^{13}C coupling at the α-position was noticeable; the β and γ ^{13}C satellites appear only in intensities corresponding to the natural ^{13}C abundance.

A degree of automerization of the order of 5% would have been clearly detected by these methods. Thus, investigations with the non-degradative ^{13}C method do not confirm the results in the literature[1] on the automerization of naphthalene[6].

Tris(imidodiphosphinato) Cationic Complexes of Silicon, Germanium, and Tin[1]

By *A. Schmidpeter* and *K. Stoll*[*]

Whereas cyclic phosphazenes and siloxanes have long been known, rings containing both such units have not yet been prepared. Compounds *(3)*, M = Si, Y = Cl, or Br, which contain the ring system of a 1,3,5,4,6,2-dioxazadiphosphasiline, are formed on treatment of bis(diphenylphosphinyl)-imine *(1)* with $SiCl_4$ or $SiBr_4$. Three halogen atoms are always replaced independently of the proportions of the reactants and of the conditions. The remaining halogen is ionically bound; it is built into complex halogen anions without change in the IR spectrum and is exchanged for nitrate on reaction with $AgNO_3$. The tricyclic structure of the cation follows from the equivalence of all the phosphorus atoms that is detected in the ^{31}P–NMR spectrum; three edges of the central SiO_6 octahedron each carry a phosphazene bridge, and 12 phenyl groups form the periphery of the ion.

ClO$_4$ (m.p. 400 °C decomp.)
MnO$_4$ (violet)
OH (m.p. 188 °C)

$GeCl_4$ reacts like the silicon halides in boiling tetrachloroethane, but there is no reaction at 25 °C. Reaction of *(1)* with $SnCl_4$ or $SnBr_4$ is different[2]; in these cases adducts are first formed that disproportionate readily to the bis(imidodiphosphinato)tin dihalides *(2)*; the third imidodiphosphinate group can be introduced into *(2a)* only by means of $Na[N(Ph_2PO)_2]$ at elevated temperature. Reaction of *(2a)* with $AgNO_3$ results in further disproportionation and gives tris(imidodiphosphinato)tin nitrate *(3)*, M = Sn, Y = NO_3.

The tris(imidodiphosphinato)tin cation is formed remarkably easily from *(2c)* either on heating or under the action of basic reagents such as $NaOCH_3$ or of electrophiles such as I_2, CH_3I, HgI_2, or $AgNO_3$. Its preferential formation corresponds to a high stability; the iodide *(3)*, M = Sn, Y = I, is

not attacked by boiling sodium methoxide solution (but is attacked by NH_3) and is merely converted into the perchlorate by an excess of anhydrous $HClO_4$.

The hydrophobicity and the considerable size resulting from their structure render these cations excellently suited for extraction of weakly hydrated anions from the aqueous phase. When shaken with *(3)*, M = Sn, Y = NO_3, in CH_2Cl_2 an aqueous solution of $KMnO_4$ is completely decolorized. Addition of ether to the methylene dichloride solution then precipitates the permanganate *(3)*, M = Sn, Y = MnO_4, as violet crystals. Cations with M = Si or Ge behave similarly but are slowly hydrolyzed in the process. The size of the cation may be responsible for the fact that with an excess of iodine *(3)*, M = Sn, Y = I, gives, not only a triiodide, but also an octaiodide corresponding to Cs_2I_8 [3].

Shielding of the phosphorus in *(3)* decreases with increase in the acceptor capacity of the central atom:

(3), Y = Cl, M =	Si	Ge	Sn
$\delta^{31}P$	−29.4	−31.3	−35.7 ppm ref. to 85% H_3PO_4

The resonance signals are shifted strongly downfield from those for the imidodiphosphinate anion (−12.7 ppm [4]); they lie in the same region as that of the dimethylated cation $[N(Ph_2POCH_3)_2]^+$ (−35.0 ppm [4]), thus indicating strong involvement of the ligands.

Experimental:

(3), M = Si, Ge: A suspension of compound *(1)* (12.5 g) in 100 ml of a suitable solvent (CH_2Cl_2 for M = Si, s-$C_2H_2Cl_4$ for M = Ge) is treated with 0.01 mole of MX_4, X = Cl, Br. HX is liberated and clear solution results on standing or after several hours' refluxing, respectively. Compounds *(3)*, Y = X, crystallize out quantitatively from this solution on addition of ether.

(3), M = Sn: Compound *(2)* (X = Cl, I [2]) and $AgNO_3$ is each dissolved in acetonitrile in a molar ratio of 1:2. The hot solutions are combined, precipitated AgX is filtered off, and the filtrate is evaporated to dryness. The residue is dissolved in CH_2Cl_2 and addition of ether to the resulting solution causes crystallization of *(3)*, X = NO_3.

CONFERENCE REPORTS

Redox Behavior of the Latent Image in Silver Halide Films

By *E. A. Frei* [*]

According to the "silver nucleus theory" latent image specks in photographic silver halide films are small centers consisting of silver atoms. This being so, the question arises: Is the latent image silver more noble or less noble than metallic silver, or are the two equivalent?

To provide an answer, photographic films were treated for ~ 24 h with buffered solutions at variable redox potentials and at a fixed silver equilibrium potential. After development the degrees of blackening were compared with a control (no redox treatment). In such a system only the redox potential can be measured directly with a Pt electrode. The potential measured with a Ag electrode is not an equilibrium potential since a mixed potential is set up at this electrode. The silver equilibrium potential can, however, be measured directly in the special circumstance where the silver potential and the redox potential are equal. It was thus possible to determine the effect of the ions used for buffering on the silver equilibrium potential.

By measuring the redox potential of a Pt electrode coated with gelatine in comparison with an ordinary Pt electrode it was shown that there is no Donnan potential between the swollen gelatine phase and the pure electrolyte solution.

Surprisingly, appreciably more negative redox potentials were obtained in the gelatine phase shortly after its immersion in the buffered solution than existed in the surrounding solution. This temporary depression of the potential shows that in the initial stage of the redox treatment the gelatine phase is more strongly reducing than the pure electrolyte phase, and this was particularly marked for formalin-hardened films.

A series of commercial films (including one with gold-sensitized emulsion) was studied. One that was successively fixed, treated with redox buffers, and physically developed gave the same results as a chemically developed film.

1. For all the emulsions except the gold-sensitized one, no latent image can any longer be developed after redox treatment in a solution whose redox potential equals the silver equilibrium potential.

2. Latent image nuclei formed by longer illumination at correspondingly weaker light intensities exhibit increased stability; also they are partly developed by redox solutions that completely bleach the latent image formed by short exposure.

3. The results with the gold-sensitized emulsion agree with those reported by *Bourdon* and *Bonnerot* [1] and by *Matejec* and *Moisar* [2]: the nuclei were bleached only at redox potentials that were more positive than the silver equilibrium potential.

4. The results described in 1 and 2 can be understood on *Reinders'* [3] and *Hillson's* [4] assumption that the free enthalpy of the latent image is greater than that of massive silver. The difference in free enthalpies lies between 0.04 and 0.07 eV according to the amount of illumination. The stability of the latent image nucleus against external influences, which is surprising in view of its size, can be explained thermodynamically if we assume that the latent image nucleus contains not only silver atoms but also impurities in the form of the components of the sensitivity centers. In this way the free surface enthalpy of the nuclei is strongly reduced and the nuclei themselves are thus protected against external attack.

New Sideramins from Molds

By *H. Diekmann* [*]

Along with known sideramins, other hydroxamic acids have been found [1] in mold cultures (*Fusarium* spp., *Penicillium* spp.) grown with a deficiency of iron, and after their extraction and purification their structures have been elucidated. Fusigen *(1)* is the iron(III) complex of a basic hydrophilic trihydroxamic acid, in which three molecules of fusarinin are joined together in a ring by means of ester groups [2]. Hydrolysis of fusigen under mild conditions gives first an open-chain trihydroxamic acid (fusigen B), and then fusarinin and a dihydroxamic acid (fusigen C) by cleavage of a further ester group. The instability of the hydroxamic acid grouping in fusarinin eventually has the result that *cis*-5-hydroxy-3-methyl-2-pentenoic acid *(2)* can be extracted from the cultures [3].

Other sideramins that have not yet been isolated contain *trans*-5-hydroxy-3-methyl-2-pentenoic acid *(3)* and are related to coprogen. This acid *(3)* occurs to the extent of about 10 mg/l in cultures of some molds (*Penicillium variabile*, *Spicaria* spp., *Neurospora crassa*, *Myrothecium roridum*, *Myrothecium verrucaria*, *Fusarium* spp.) and can be prepared in good yield by isomerization of *(2)*. After purification by Craig distribution and chromatography on silica gel (solvent: chloroform/ethanol/formic acid, 94.5:5:0.5, v/v), the acid *(3)* was crystallized as its *N,N'*-dibenzylethylenediammonium salt (m.p. 64 °C). UV, IR, and NMR spectra, and also thin-layer chromatography, prove its structure.

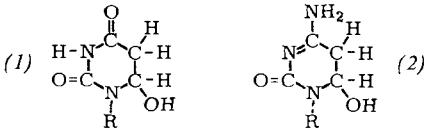
Investigations of the Chemical Causes of Biological Irradiation Damage

By *E. Fahr* [*]

The action of UV radiation on nucleic acids and their components involves, in the main, two photochemical reactions: formation of so-called "reversible irradiation products" and dimerization of pyrimidine bases to "dimeric pyrimidines".

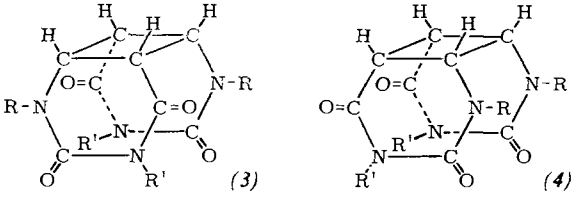
We have isolated the reversible irradiation products of uracil, uridine, and uridylic acids and have proved their structures to be *(1a–e)* by independent syntheses. By an analogous route we have proved that the very unstable reversible radiation products of cytosine, cytidine, and cytidylic acid have structures *(2a–c)*. Their radiation products *(2)* pass into *(1)* by deamination in a dark reaction. The photochemical formation of 5,6-dihydro-6-hydroxycytosine derivatives *(2)* in the DNA and their subsequent deamination to *(1)* are likely to be the cause of the mutations induced by UV radiation.



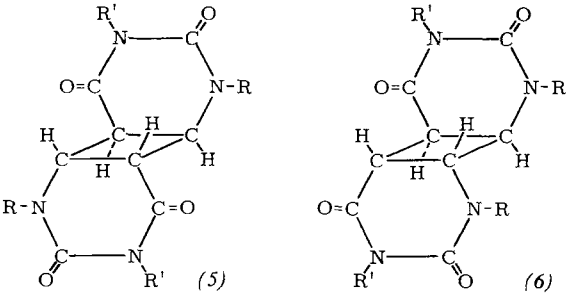
(1) *(2)*

(a): R = H
(b): R = Ribosyl
(c): R = Ribosyl-2'(3')-phosphate
(d): R = Ribosyl-5'-phosphate
(e): R = Ribosyl-5'-triphosphate

By degradation to cyclobutane derivatives we have shown that structure *(4a)* applies to the dimeric uracil that is formed on UV irradiation in an ice matrix. The *trans*-dimeric uracil *(5a)* was synthesized chemically.



(3) *(4)*



(5) *(6)*

(a): R = R' = H
(b): R = Ribosyl, R' = H
(c): R = R' = CH_3

Also the four possible dimeric dimethyluracils *(3c)–(6c)* have been prepared, as well as other dimers.

When we studied the action of ionizing radiation (radiation dose *ca.* 500000 rad/min) on aqueous degassed solutions of nucleic acid components we obtained a large number of radiation products. Pyrimidine components were attacked mainly by H atoms and/or OH radicals at the C=C double bond. Irradiation of cytosine, cytidine, and cytidylic acid showed that the mutations caused by ionizing radiations probably arise owing to the following processes: attack by H atoms and OH radicals on the C=C bond of the cytosine

part of the DNA with formation of derivatives of structure *(2)* and then deamination to *(1)*.

UV mutations and mutations induced by ionizing radiation can thus be interpreted by means of the same primary irradiation product.

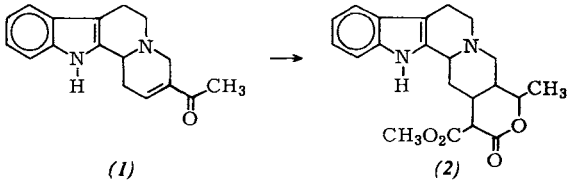
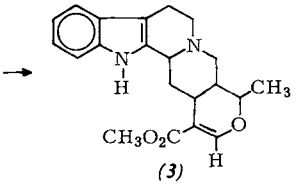
Synthesis and Configuration of Heterocyclic Indole Derivatives. The Stereoselective Total Synthesis of DL-Akuammigine and DL-Tetrahydroalstonine

By *E. Winterfeldt* [*]

The α,β-unsaturated ketone *(1)* is useful for synthesis of heterocyclic indole alkaloids of type *(3)*. Michael addition of malonic ester and subsequent reduction by $BH_4^{\ominus}$ affords the lactones of type *(2)*, which can be converted into *(3)* by reduction and loss of water [1].

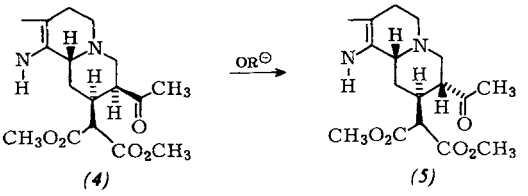


(1) *(2)*



(3)

In the stereoselective preparation of *(2)* the Michael addition to *(1)* occurs with simultaneous formation of a *cis*-quinolizidine system. Compound *(4)*, with the axial acetyl group, is the product obtained under kinetic control and on treatment with alkali affords the thermodynamically favored product *(5)* containing equatorial substituents.



(4) *(5)*

Under thermodynamic control, compound *(5)* is thus obtained stereospecifically.

The keto group can also be reduced stereospecifically. Compound *(4)* reacts with $BH_4^{\ominus}$ to give exclusively *(6)*, whereas compound *(5)* with $BH_4^{\ominus}$ in the cold gives mainly *(7)* but with $Li[AlH_2(OR)_2]$ in tetrahydrofuran gives mainly *(8)*. The configurations follow from the IR and NMR data.

Reduction and dehydration of the sterically homogeneous lactones gives compounds of type *(3)* with the *cis*-quinolizidine system which are convertible into *trans*-quinolizidines by dehydrogenation [with $Pb(OAc)_4$] and subsequent reduction with $BH_4^{\ominus}$. In this way compound *(4)* yields DL-akuammigine stereospecifically and then DL-tetrahydroalstonine by reversal of configuration at C-3.

Mechanism of the Oxo Synthesis

By *J. Falbe* [*]

Although the oxo reaction (conversion of olefins into aldehydes by CO/H_2) was discovered by *O. Roelen* in 1938 [1] and the annual world capacity of such plants will exceed 1.5×10^6 tons in 1968, the mechanism of the reaction is not yet fully clarified.

Many proposed mechanisms had to be discarded because they could not be brought into accord with the equation set up by *G. Natta et al.* [2] for the kinetics of the reaction:

$$d[\text{Aldehyde}]/dt = k[\text{Olefin}][\text{Co}][p_{H_2}]/[p_{CO}].$$

A reaction route by way of carbonium ions had to be rejected because the carbon chain was not isomerized in the reaction.

A reaction involving radicals is also unlikely because reaction is not hindered by radical-trapping agents such as iodine and sterically hindered phenols.

A scheme proposed by *R. F. Heck et al.* [3] is largely in accord with the kinetics of the oxo reaction:

$$HCo(CO)_4 \rightleftharpoons HCo(CO)_3 + CO \qquad (1)$$

$$HCo(CO)_3 + H_2C{=}CH_2 \longrightarrow H_2C{=}CH_2 \quad (2)$$
$$\downarrow$$
$$HCo(CO)_3$$

$$H_2C{=}CH_2 \rightleftharpoons H_3C{-}CH_2{-}Co(CO)_3 \qquad (3)$$
$$\downarrow$$
$$HCo(CO)_3$$

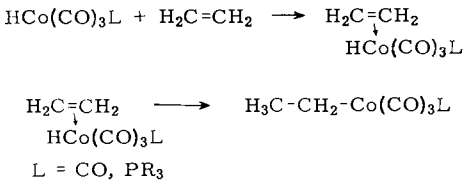
$$H_3C{-}CH_2{-}Co(CO)_3 \underset{-CO}{\overset{+CO}{\rightleftharpoons}} H_3C{-}CH_2{-}Co(CO)_4 \qquad (4)$$

$$H_3C{-}CH_2{-}Co(CO)_4 \rightleftharpoons H_3C{-}CH_2{-}\underset{\underset{O}{\|}}{C}{-}Co(CO)_3 \qquad (5)$$

$$H_3C{-}CH_2{-}\underset{\underset{O}{\|}}{C}{-}Co(CO)_3 + H_2$$
$$\longrightarrow H_3C{-}CH_2{-}CHO + HCo(CO)_3 \qquad (6)$$

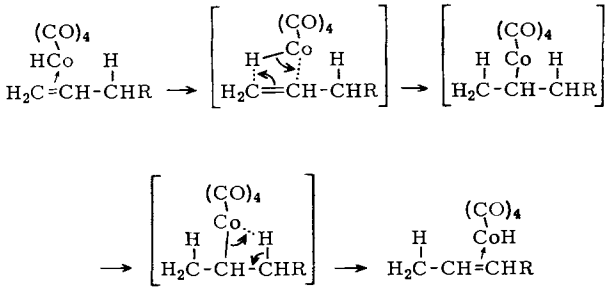
However, all attempts to detect tricarbonylhydridocobalt or alkyltricarbonylcobalt compounds under the conditions of the oxo reaction have failed. Recent investigations also indicate that a course involving (1)–(3) is doubtful since the oxo reaction occurs also at high pressure where the equilibrium in (1) should lie wholly to the left-hand side; against this mechanism is also the fact that the reaction can be carried out in the presence of complexes of the type $HCo(CO)_3PR_3$ in which the metal-carbon bond is so strong that loss of CO and formation of a coordinatively unsaturated carbonyl under the conditions of the reaction seem unlikely.

Equations (7) and (8) are therefore proposed as alternatives to (1)–(4).

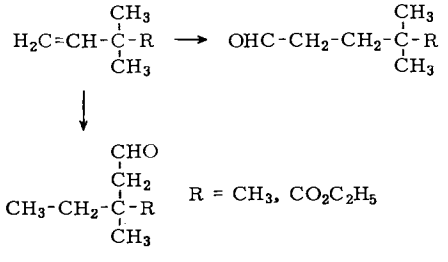


The π-complex formulated in (7) may occur as dsp^3-hybrid in the form of a trigonal bipyramid, in which the hydrogen is bonded as hydride ion in the outer sphere and cobalt has formally a single positive charge. The Co-alkyl compound pictured in (8) may also be a trigonal-bipyramidal dsp^3-hybrid.

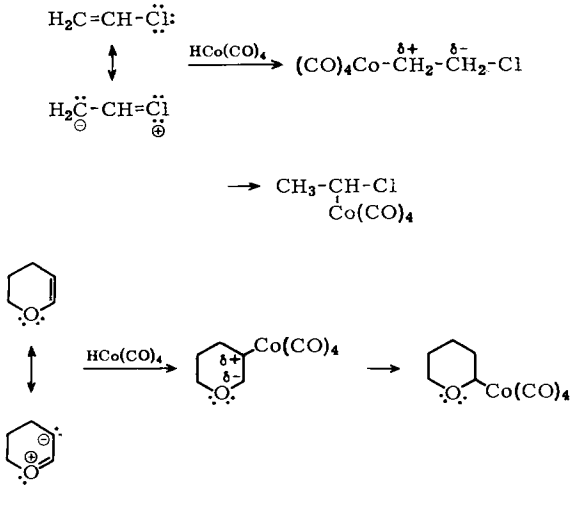
One of the factors promoting conversion of the alkyl into the acyl compound (equation 5) is to be found in the decrease in steric hindrance on the conversion dsp^3 (trigonal bipyramid) → sp^3 (tetrahedral). The mechanism proposed also agrees well with the isomerizations of Co-alkyl and -acyl compounds experimentally established as occurring during the oxo reaction, whereby according to *Orchin et al.* [4] a hydrogen shift from the allyl position occurs.



Compounds that do not possess hydrogen in the allyl position do not isomerize.



With vinyl chloride and dihydropyran the primary addition of cobalt to the C=C double bond and the subsequent isomerization occur in different directions:



In most of the known oxo reactions tetracarbonylhydridocobalt reacts as the hydride; it may react as protonic acid in the oxo reaction of epoxides.

Photolysis and Radiolysis of Carbon Monoxide in the Gaseous, Liquid, and Solid State at 298 °K, 77 °K, and 20.4 °K

By *W. Groth* [*]

In the gas phase CO is excited by light quanta (Kr or Xe resonance wave lengths, I line at 2062 Å, Hg sensitization) or γ-rays first to the $a^3\Pi$-state and then reacts with CO in the ground state to give CO_2 and C_3O_2. Excitation of the $A^1\Pi$ state and of triplet states of CO by the Kr and Xe resonance wavelengths can be detected by fluorescence studies.

Pure liquid CO is not decomposed by the 2062 Å I line. In CO–CH_4 mixtures ethane and acetaldehyde are formed by way of excited CO molecules.

In the γ-radiolysis of CO at 298 °K addition of noble gases shows that ionic reactions do not occur but that electronically excited CO molecules play an important part in the primary process. The dependence of $G(CO_2)$ on the pressure can also be explained by means of excited CO molecules which can pass into another excited state.

Radiolysis of pure liquid CO at 77 °K gives CO_2 with $G(CO_2)$ of 0.22, but no C_3O_2 is formed. In CO-CH_4 mixtures there are formed, besides CO_2 and C_3O_2, also aldehydes, ketene, ethane, and acetylene, whose mode of formation has been clarified by use of isotope techniques. In mixtures of CO and O_2 there are formed in the liquid phase (77 °K) CO_2, C_3O_2, and O_3, but in the solid phase (20.4 °K) only CO_2 and O_3. The dependence of the G values for CO_2, C_3O_2, and O_3 are explained for the liquid phase by assuming various excited states of CO ($A^1\Pi$, higher triplet states, $a^3\Pi$), and for the solid phase by assuming intermediate formation of CO_3.

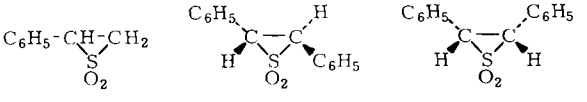
Twelve-membered polyether rings, namely 1,4,7,10-tetraoxacyclododecanes, cyclic tetramers of olefin oxides, have been obtained by *R. J. Kern* from propylene oxide, epichlorohydrin, and 2-ethylethylene oxide by treatment with BF_3 or triethyloxonium tetrafluoroborate, $(C_2H_5)_3OBF_4$, in CCl_4 or CH_2Cl_2. Conversion amounted to 30–40 %. Larger rings and a cyclic dimer were found in smaller amounts; no cyclic trimer was formed. Of the 23 geometric isomers of propylene oxide tetramer, *R. J. Katnik* and *J. Schaefer* detected 22 by gas chromatography, and by NMR and mass spectroscopy. / J. org. Chemistry *33*, 384, 388 (1968) / –Ma. [Rd 854 IE]

Aminotransferase activity of thermally prepared polylysine *(1)* has been observed by *G. Krampitz, S. Baars-Diehl, W. Hass*, and *T. Nakashima*. *(1)* catalyzes the transfer of amino groups of urea to α-oxoglutaric acid in the presence of Cu ions (pH optimum: 7.0). The transamination follows Michaelis-Menten kinetics. Depolymerization of *(1)* causes loss of the aminotransferase activity. The results contribute to clarification of the way in which the first enzymes may have been formed under prebiological conditions. / Experientia *24*, 140 (1968) / –Ma. [Rd 849 IE]

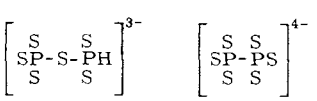
Decomposition of the thiirane 1,1-dioxides (episulfones) *(1)–(3)* at room temperature was studied by *F. G. Bordwell, J. M. Williams Jr., E. B. Hoyt Jr.*, and *B. B. Jarvis*. These compounds decompose in a first order reaction to styrene or stilbene and SO_2. The rate of decomposition depends greatly on the ionizing power of the solvent. The solvolytic decomposition of *(2)* and *(3)* is stereospecific. In the presence



(1) *(2)* *(3)*

of methoxide (faster decomposition), however, *trans*-stilbene is formed from both *(2)* and *(3)*. Deuterium-exchange experiments showed that *(3)* first rearranges to *(2)* and that this finally decomposes slowly by reaction with the methoxide ion. The reaction is held to proceed by way of diradicals. / J. Amer. chem. Soc. *90*, 429 (1968) / –Kr. [Rd 841 IE]

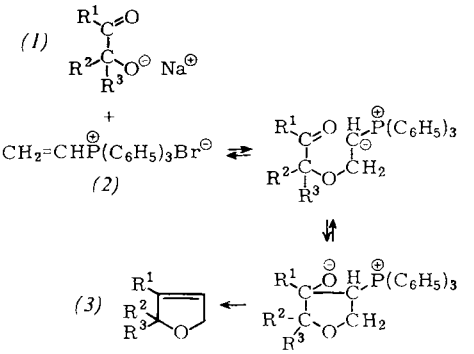
Sodium hexathiohypophosphate, $Na_4P_2S_6 \cdot 6H_2O$, a salt of a new acid of phosphorus has been prepared by *H. Falius* by the dropwise addition of PCl_3 to a solution of Na_2S in an open vessel (colorless, birefringent monoclinic crystals; a = 20.3, b = 7.1, c = 23.3 Å; $\alpha = \beta = \gamma = 90°$). Of the two possible structures *(1a)* or *(1b)* of the anion, only *(1b)* is



(1a) *(1b)*

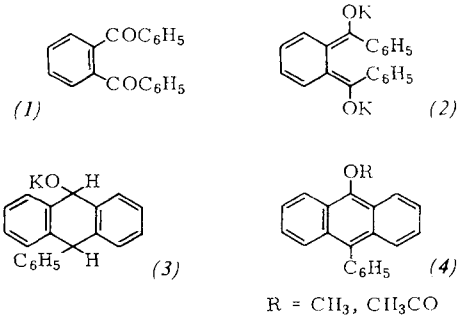
compatible with the facts that sulfur-free hypophosphate is formed with H_2O_2/NaOH, and diphosphate(v) with Br_2/$NaHCO_3$. In agreement with this, the NMR spectrum contains only one signal. The ion is very stable in aqueous solution; it forms colored precipitates with a number of heavy metals. / Z. anorg. allg. Chem. *356*, 189 (1968) / –Kr. [Rd 871 IE]

A general synthesis of 2,5-dihydrofurans *(3)* has been provided by *E. E. Schweizer* and *J. G. Liehr*. The sodium salt of an α-hydroxy ketone *(1)* is treated in DMF with triphenylvinyl-



phosphonium bromide *(2)* at room temperature or with heating, and the mixture is decomposed with water. The yields depend markedly on the purity of the starting materials. / J. org. Chemistry *33*, 583 (1968) / –Ma. [Rd 846 IE]

Formation of anthracene derivatives on treatment of *o*-dibenzoylbenzene *(1)* with potassium in the absence of air was noted by *B. J. Herold* and *H. E. Faustino*. Decomposition of the reaction mixture with CH_3I or acetyl chloride gave the compounds *(4)* in *ca.* 50 % yield. The reaction presumably involves reduction by the metal and intramolecular addition to



(1) *(2)* *(3)* *(4)*

R = CH_3, CH_3CO

the quinone methide *(2)* and to the intermediate *(3)*, whence *(4)* is formed by elimination. 9,10-Dimethoxy- and 9,10-diacetoxy-anthracene were formed as by-products by loss of a phenyl group as phenylpotassium. / Tetrahedron Letters *1968*, 467 / –Ma. [Rd 852 IE]

A carbon atom at the center of a Ru_6-octahedron has been located in $Ru_6C(CO)_{14}C_6H_3(CH_3)_3$ by X-ray crystallography. *R. Mason* and *W. R. Robinson* found that the edge length of the Ru_6C cluster (Ru–Ru distance) is 2.88 Å. In the Ru_6-octahedron, which is only slightly deformed, the Ru–C distance is 2.04 Å, the maximum deviation being 0.16 Å (σ = 0.04 Å). The coordination number of all the Ru atoms is 8 [4 Ru, 1 C, 3 CO, or $C_6H_3(CH_3)_3$ as nearest neighbors]. One CO group is in a bridging position. Of the combination of six d_{z^2} orbitals of the Ru atom, those with A_{1g} and T_{1u} symmetry can overlap with the s and p orbitals of the central C atom. / Chem. Commun. *1968*, 468 / –HB. [Rd 859 IE]

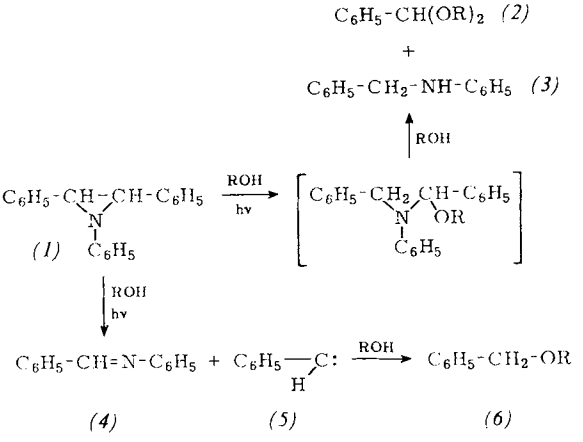
$OsOF_5$, the first compound with heptavalent Os, has been prepared by *N. Bartlett* and *N. K. Jha* as the main product (> 90 %) of the fluorination of OsO_2 at 250 °C. It is also

formed, alongside OsF_6, in the reaction of osmium with a F_2/O_2 mixture. $OsOF_5$ is a volatile, emerald green crystalline substance, orthorhombic below 32.5 °C and cubic above 32.5 °C; it is characterized by m.p. 59.2 °C and b.p. 100.6 °C, and has a temperature-independent magnetic moment of 1.47 BM (Θ = 6 °K). The vibrational spectrum is similar to those of $ReOF_5$ and IOF_5, and suggests a C_{4v} symmetry in the vapor phase. X-ray crystallographic analysis by *N. Bartlett* and *J. Trotter* indicates for the orthorhombic phase a distorted octahedral symmetry of $OsOF_5$ with the following distances: OsO 1.74, *trans*-OsF 1.72, *equatorial*-OsF 1.76 (2x), and 1.80 Å (2x) (± 0.03 Å for all). The unpaired electron of Os is antibonding; it is presumably located in the plane perpendicular to the OsO axis and is responsible for the weakening of the equatorial OsF bonds. / J. chem. Soc. (London) *A 1968*, 536; 543 / –HB. [Rd 860 IE]

Electrical properties of linear polyacetylene $(CH{\equiv}CH)_n$ have been investigated by *D. J. Berets* and *D. S. Smith*. Because of the special precautions taken during the polymerization, the product contained only 0.7 % of oxygen. The electrical resistivity, measured on tablets with a pore volume of about 7 %, increased from $\rho_{min} = 7.5{\times}10^5\ \Omega$ cm with the oxygen content. The thermoelectric EMF, the sign of which indicates that polyacetylene is a p-type semiconductor, also increased. On the other hand, the activation energy for the conduction is independent of the oxygen content. The resistivity is lowered by adsorbed electron acceptors (BF_3, BCl_3), while it is increased by about three orders of magnitude when electron donors (NH_3, CH_3NH_2) are introduced. However, they cause no change in the spin density measured by the ESR spectroscopic method ($3.8{\times}10^{18}\ cm^{-3}$). The deviations from earlier values for the resistivity are ascribed to differences in the degree of crystallinity, a property that is clearly as important for good conduction as is chemical purity. / Trans. Faraday Soc. *64*, 823 (1968) / –Hz. [Rd 864 IE]

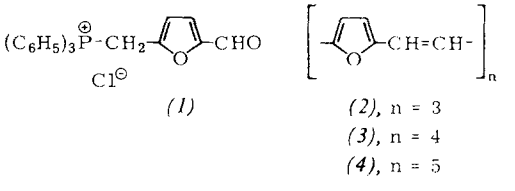
Energies of bonding electron states in simple molecules (here methane and ethane) have been measured by *K. Hamrin et al.* by a method which they call electron spectroscopy for chemical analysis (ESCA). Electrons are knocked out of the sample gas by monochromatic soft X-rays or very far-UV rays, and the kinetic energy of the electrons is measured in a spectrometer. The bonding energy is given by the difference between the energy of the radiation and the kinetic energy of the electrons. The X-rays used here (AlK_α and MgK_α) made it possible to determine the bonding energies of core electrons and valence electrons. The bonding energies of core electrons (C-1s) in methane and ethane is 290 eV. In methane, the valency electrons occupy two levels of type a_1 (two electrons with bonding energy of 23.1 eV) and the type t_2 (six electrons with bonding energy of 13.6 eV) of the tetrahedral group T_d. In ethane, there are five levels with the bonding energies of 23.9, 20.3, 14.7, and 10.7 eV. The last energy belongs to two molecular states characterized by accidental degeneracy. / Chem. Physics Letters *1*, 613 (1968) /–Hz. [Rd 865 IE]

The photochemistry of 1,2,3-triphenylaziridine *(1)* has been investigated by *H. Nozaki, S. Fujita,* and *R. Noyori*. UV irradiation (λ_{max} = 239 nm) of alcoholic solutions causes a new type of alcoholic cleavage of the aziridine ring: it leads



to benzaldehyde acetals *(2)* and *N*-benzylaniline *(3)*. In competition therewith, fragmentation affords benzylideneaniline *(4)* and phenylcarbene *(5)*, the latter being trapped by alcohols as alkyl benzyl ethers *(6)*. Photolysis in cyclohexene leads to 1,3-cycloaddition that provides octahydro-1,2,3-triphenylisoindole *(7)* as a mixture of two stereoisomers. / Tetrahedron *24*, 2193 (1968) / –Ma. [Rd 847 IE]

A synthesis of annulene polyoxides from saccharose is described by *J. A. Elix*. 5-(Chloromethyl)furfuraldehyde, which is readily accessible from saccharose by means of HCl, gives the phosphonium salt *(1)*, m.p. 228–230 °C, when treated with triphenylphosphine in benzene. Slow addition of $LiOC_2H_5$ to a solution of this salt in DMF leads to a Wittig reaction providing, presumably by way of an ylide, a mixture whence the following annulene polyoxides can be isolated by chromatography on Al_2O_3: 1,4:7,10:13,16-triepoxy[18]-annulene *(2)*, red plates, 0.07 % yield; two isomers of 1,4:7,10:13,16:19,22-tetraepoxy[24]annulene *(3)*, m.p. 216–217 °C, dark-violet prisms, 0.7 %, and m.p. 269–270 °C,



violet prisms, 0.8 %, severally; two isomers of 1,4:7,10:13,16:19,22:25,28-pentaepoxy[30]annulene *(4)*, m.p. 218 to 220 °C, deep red to black prisms, 0.4 %, and m.p. 192 to 194 °C, deep red needles, 0.15 %, severally. / Chem. Commun. *1968*, 343 / –Ma. [Rd 848 IE]

BOOK REVIEWS

Hoppe-Seyler/Thierfelder, Handbuch der physiologisch- und pathologisch-chemischen Analyse, für Ärzte, Biologen und Chemiker. (Hoppe-Seyler/Thierfelder, Handbook of Physiological and Pathological Chemical Analysis for Physicians, Biologists and Chemists). Edited by *K. Lang* and *E. Lehnartz* with the collaboration of *O. Hoffmann-Ostenhof* and *G. Siebert*. Volume 6: Enzyme, Part C. Springer-Verlag, Berlin-Heidelberg-New York 1966, 10th Edit., xii, 998 pp., 63 figures, DM 396.–.

The present Part C concludes the Enzyme part of "Hoppe-Seyler/Thierfelder" and completes the 10th edition of this work after 13 years of instalments [*]. A quarter of the volume is occupied by the index of the three parts, and another quarter is devoted to exopeptidases. The remaining half of the volume treats lyases, isomerases, ligases, and the so far undiscussed hydrolases.

[*] Cf. Angew. Chem. *79*, 876 (1967); Angew. Chem. internat. Edit. *6*, 893 (1967).

The appearance of the extensive cumulative index at last permits the work to be used to the full, as in the past a thorough knowledge of enzyme chemistry was sometimes needed to find one's way through the haphazardly classified material. The index contains several references to compounds which appear in the text under different names and the reader is expected to know that he will have to consult "adenylic acid" for full information about AMP after studying "adenosine monophosphate" and "adenosine phosphate". The coenzyme of numerous dehydrogenases is found both under "NAD" and "DPN". Once again two camps – the adherents to modern and to old nomenclature – are found in a book where uniformity is so desirable. Finally, depending on whether the contributions happen to be English or German, there are references to the same enzyme as *e.g.* "pancreatic carboxypeptidase" and "pancreas carboxypeptidase". Surprisingly, the action of amethopterin (and the same holds for aminopterin) on deoxyribonuclease is recorded, but not the much more significant action on the folic acid-dependent enzymes (*e.g.* Part B, p. 196).

The contents of the third part are assembled in a similar way to those of the first two. In some instances literature references extending to very recent times are included, in others (*e.g.* aconitase, carboanhydrase, thiamine pyrophosphate-containing enzymes) only those to the end of the fifties. Both encyclopedic articles and short contributions restricted to descriptions of methods are found side by side. The absence of an article on catalases or peroxidases is regrettable.

Handbooks such as this quickly become dated, especially, if some of the contributions are already out of date on the day of publication. Will it be wise to bring out a new edition soon? The reviewer thinks not, unless the structure of the handbook is fundamentally altered. Articles more than 100 pages in length will make it increasingly difficult to find qualified authors who will deliver on time manuscripts incorporating the latest advances. A large number of short articles would surely be entirely adequate for a book of enzyme methods. The editors would then have to coordinate the contributions and edit them systematically. The "Methods in Enzymology" should serve as a model. If each enzyme were treated by one author, it would be possible to go one step further in a future edition to keep the handbook abreast of new developments. Law books have for some time been issued in the form of loose-leaf editions, so that parts can be replaced as required. This arrangement seems eminently suited for a handbook on enzymology and should be imitated.

H. Sund [NB 705 IE]

Grundlagen der Tribochemie (Fundamentals of Tribochemistry). By *P.-A. Thiessen, K. Meyer,* and *G. Heinicke.* Abhandlungen der Deutschen Akademie der Wissenschaften zu Berlin, Kl. f. Chemie, Geologie und Biologie, 1966, No. 1. Akademie-Verlag, Berlin. 1967, 1st Edit., 194 pp., 159 figures, 24 tables, cloth, DM 33.–.

The book is divided into three monographs: Physicochemical investigations of tribomechanical processes (*Thiessen*), Energetically excited states in tribomechanical processes (*Meyer*), Physicochemical investigations of tribochemical processes (*Heinicke*); the common introduction is by *P.-A. Thiessen.*

The first contribution presents an excellent and concise survey of the phenomena caused by tribomechanical processes. Starting from the investigations by *Smekal* and *Bowden* on microplasticity and friction in solids, the magma-plasma model is taken as the basis, by virtue of its being subject to least contradiction. It is shown that the various associated phenomena of tribomechanical processes, such as detaching of lattice structural units, generation and migration of dislocations, material transfer, luminescence phenomena, charge transfer, emission of electrons, and increase in chemical reactivity are in accord with the requirements of this model.

The second contribution deals at length with fractureless mechanical deformation and the induced electrical phenomena. In the last contribution the chemical reactions that occur during mechanical processing are discussed in detail. The present book gives a good survey of a field which, scientifically, is still in its infancy, and which is in urgent need of further experimental and theoretical investigation. At the same time, the significance of these investigations for technology becomes evident. *I. N. Stranski* [NB 698 IE]

Praktikum der qualitativen Analyse (Practical Handbook of Qualitative Analysis). By *M. Becke-Goehring* and *J. Weiss.* Theodor Steinkopff. Dresden 1967. 1st Edit., x, 122 pages, 10 figures, DM 10.70.

"Praktikum der qualitativen Analyse" is the continuation of the successful "Kurze Anleitung zur qualitativen Analyse" (Short Introduction to Qualitative Analysis) by *Medicus/Goehring,* which ran to 28 editions. The concise presentation is retained in the present revised edition.

The individual elements and their characteristic reactions are discussed in the sequence of the classical methods of analytical separation. Special organic reagents are not dealt with apart from a few exceptions.

The separation processes for cations and anions are compiled in tabulated form. Supplementary chapters on the individual groups indicate peculiarities and possible sources of error. Evidently, it was decided to retain macro-scale analysis even within the framework of this small volume, so that only a few short paragraphs are devoted to semimicro methods. Separate discussion of some rarer elements makes the separation schemes clearer. On the other hand, the presentation is too condensed for the undergraduate majoring in chemistry, who will also have to turn to larger, more comprehensive works. This is all the more true as the theoretical basis has been almost entirely ignored.

Because of the clear presentation and well arranged content, the book can be recommended especially to those for whom chemistry is a subsidiary subject. *E. Blasius* [NB 700 IE]

The Industrial Chemistry of the Lanthanons, Yttrium, Thorium, and Uranium. By *R. J. Callow,* Pergamon Press, Oxford-London-Edinburgh 1967. 1st Edit. vii, 248 pp., several figures, 60 s.

An introductory historical survey is followed by nine chapters that are devoted to the production and technical applications of these elements as well as a discussion of analytical methods and the purity of commercial compounds and workable ores. A brief concluding chapter deals with problems associated with the radioactivity of thorium and uranium – understandably tailored to a British viewpoint. The individual chapters are well written and in general offer a clear presentation of the subject. Those dealing with the preparation, separation, and purification of the elements are particularly valuable, and reveal the depth of the author's knowledge of the field. The excellent flow sheets of the individual processes make a substantial contribution to the ease of comprehension. In the reviewer's opinion the chapter on the applications of the elements is a little skimped, not only in the selection but also in the detail. For example, no mention is made of the use of europium compounds as lasers, while that of thorium and uranium for nuclear energy is dismissed in an entirely inadequate and in some respects out-of-date section under the heading "Some possible applications". In the chapter on analysis the currently very important activation analysis for uranium is restricted to the sentence "neutron activation is applicable in some cases but necessary facilities are not generally available". Revision of certain chapters, particularly 8 and 9, would considerably enhance the value of this intrinsically satisfactory and instructive book. The author should not only discuss the fields that he himself considers important – as he states in the preface – but also devote to those problems in which he may be less interested the same care and thoroughness as he does, for instance, to Chapters 4 to 6. *C. Keller* [NB 716 IE]

Structure of High-Resolution NMR Spectra. By *P. L. Corio*. Academic Press, New York-London 1966. 1st Edit., xii, 548 pages, numerous illustrations, $ 15.00.

NMR spectroscopy is another subject that has today reached the stage where a detailed treatment is possible only by a separate study of its various aspects. *P. L. Corio*'s rendering of the particularly important field of mathematical fundamentals of high-resolution spectra is therefore most welcome.

The first four chapters (127 pages) describe the physical principles of NMR spectroscopy and the quantum-mechanical treatment of single and multiple spin systems. The five chapters (320 pages) forming the main part of the book embrace the theory of spectra, the analysis of spin systems with two groups of magnetically equivalent nuclei, the perturbation and moment theory, the analysis of symmetrical spin systems, and the treatment of multiple quantum transitions, double resonance, and spin-echo experiments. These descriptions are complemented by numerous illustrations of spectra of the highest experimental quality. A 100-page appendix contains mathematical expositions and numerical data for certain spin systems (A_2B, A_3B, A_4B, A_2B_2, A_3B_2). The author is undoubtedly right in stating in the introduction that his book is mathematical in character, and the chemist who has limited knowledge of quantum mechanics is likely to find it difficult to use the generally formulated relationships to solve his specific problems. Because of its formal approach and because it makes no mention of *e.g.* computer analysis, the book is less a practical guide than an all-embracing and thorough derivation of the mathematical laws of the spectra. It is therefore recommended as a reference and guide to the NMR spectroscopist for all problems encountered in this field. The detailed treatment of systems with magnetically equivalent nuclei and the tracing of higher spin systems back to simple subspectra is in many instances of general interest.

H. Günther [NB 708 IE]

Heteroatom Ring Systems and Polymers. By *H. R. Allcock*. Academic Press, New York-London 1967. 1st Edit., xi, 401 pages, $ 16.50

Heteroatom-containing molecules with linear, branched, or cyclic structures, particularly polymers consisting of such compounds which contain silicon, phosphorus, boron, and aluminum as structural units in addition to carbon, oxygen, sulfur, and nitrogen, have been the subject of discussion in many publications during recent years. Rapid development in this field has been promoted *inter alia* by a demand from the aerospace industry for novel materials possessing remarkable properties.

The author is not so much concerned with reproducing the available material in a fully comprehensive manner – such an ambition could not in any case be fulfilled in 400 pages of print – but rather aims at a systematic comparison between the heterocycles in respect of similarities, for instance interaction of the "delocalized" π-electrons and the "localized" σ-electrons (of aromatic character). This systematic treatment of similarities embraces the relationship between molecular structures, π-bonds, and steric hindrance in the specific hetero ring systems with examples selected from the thermodynamics of polymerization, depolymerization, and oligomerization of the heteroatom systems.

Chapters 1–4 are devoted to general and theoretical fundamentals, and in particular Chapter 2 discusses the atomic structure and the theory of the chemical bond.

The author deserves the reader's gratitude for proposing and using a uniform nomenclature in the field. The IUPAC committee on nomenclature should adopt these proposals if order is to be restored. (For example, there are five names for the trimer of phosphorus nitrochloride, $(NPCl_2)_3$.) A further welcome feature is the detailed survey of the possible synthetic routes to cyclic heteroatom compounds, giving 281 literature references and some valuable hints. The presentation of polymers is limited to addition polymerization reactions; polycondensations and other mechanisms leading to heteropolymers are not mentioned.

The reader is offered a large number of literature references, particularly following Chapters 5 and 8, and well prepared author and subject indexes. Having regard to the rapid expansion of this field (especially in the USA) any survey, and particularly one that deals with fundamentals, is welcome. It is to be hoped that supplementary volumes will be published to keep the work up-to-date.

A. Gumboldt [NB 710 IE]

The Chemistry of Non-Aqueous Solvents. Edited by *J. J. Lagowski*. Vol. II of the series "Acidic and Basic Solvents". Academic Press, New York-London 1967. 1st Edit. xv, 398 pp., $ 18.50.

In recent years the interest shown by chemists in reactions in non-aqueous ionizing solvents has increased sharply, because in these solvents novel reactions are possible that are observed neither in water nor in simple organic solvents. The latest work on progress in the chemistry of non-aqueous solvents has been edited by *J. J. Lagowski* and comprises several volumes.

The first volume deals with the physicochemical behavior of non-aqueous solvents (acid-base concepts, solvation, electrode potential) and with the experimental methods involved in dealing with low-boiling and high-melting non-aqueous solvents. The present, second volume is devoted to the chemistry of acid and basic solvents: halohydric acids (*F. Klanberg, M. Kilpatrick*, and *G. Jones*), sulfuric acid, nitric acid (*W. H. Lee*), organic acid amides (*J. W. Vaughn*), and liquid ammonia (*J. J. Lagowski* and *G. A. Moczygemba*).

The articles describe the preparation of the anhydrous solvents, their physicochemical properties are considered in some detail, and selected chemical reactions in these solvents are presented. An additional chapter, going beyond the scope of the present volume, describes the physical properties of solutions of metals in non-aqueous solvents (*J. C. Thompson*) in which solvated electrons are formed by ionization of the metals in question. Naturally, solutions of the alkali metals in ammonia are pre-eminent. A deficiency does exist in that there is little mention of the versatile chemical reactions of metal solutions (addition of electrons to aromatic systems, Birch reactions, *etc.*), which are of special interest to the organic chemist.

The text is supported by a wealth of tabulated data and illustrations. A total of 1200 references provides a good coverage of the principal original work, at least up to 1964; only three of the seven contributions include more recent literature.

The book's clear, concise, and readable text, written by competent authors, merits a wide distribution among all who are interested in any way in non-aqueous solvents.

U. Schindewolf [NB 691 IE]

Solvated Electron. Advances in Chemistry Series No. 50. Edited by *R. F. Gould*. American Chemical Society Publications, Washington 1965. 1st Edit., viii, 304 pp., numerous figures and tables, cloth, $ 8.00.

Since the discovery only a few years back that solvated electrons play an important role as intermediates in radiation-chemical processes in aqueous and water-like systems, this simplest and most reactive particle in chemistry (it was first observed in ammonia 100 years ago and some of its properties were described 50 years ago) has become the subject of extensive study. The present book, which consists of 21 papers read at a symposium in Atlantic City, reviews the present state of knowledge about solvated electrons.

Three of the lectures are theoretical in nature and are devoted to the description of the quantum mechanics of solvated

electrons and of electron transfer processes. Seven contributions deal with the structure, electrical and optical properties, and the kinetics of solvated electrons in solutions of metals in amines or liquid ammonia. The remaining lectures describe the formation of solvated electrons by radiation-chemical and photochemical processes, their reactions and physical properties in liquid and in frozen aqueous or alcoholic systems.

It becomes clear from the lectures that we are far from understanding the physics of solvated electrons, though many of their properties are known; the name is a term of convenience to describe particles whose structure is yet unknown. However, the chemistry of the particle has retained fewer secrets; several hundred reactions have been studied, their rates measured, and in many cases even the short-lived intermediates have been identified.

The contributions are highly readable, and are often supplemented by graphs and tables. A glance through the literature references reveals that next to no German contributions are listed. Unhappily, this reflects the facts. The solutions of metal in ammonia containing solvated electrons, as well as the direct proof of the existence of solvated electrons produced by radiation-chemical means, were first described in German periodicals, but have scarcely been mentioned in them since.

The symposium report was available little more than three months after the meeting. Both the editor and the publisher deserve commendation on this account, but unfortunately the speed of setting up the material in print has prevented the discussions from being included in the publication.

U. Schindewolf [NB 690 IE]

Handbook of Industrial Toxicology. By *E. R. Plunkett*, Chemical Publishing Company, Inc., New York, 1st Edit., 1966, viii, 448 pages, $ 16.50.

The author has attempted to bring to the attention of "chemists, managers, doctors, medical students, nurses, and poison control centers" the hazards to health posed by the chemicals, drugs, and insecticides which he regards as the most important. In addition to the usual alphabetical classification (Abrin to Zirconium) synonyms, appearance, possible occupational exposure, threshold limit values, toxicity (absorption, pathology, symptoms of poisoning, diagnosis, suggested treatment) and measures to prevent poisoning are given.

Unhappily, this laudable attempt has misfired completely. Even the selection of the substances is startling: does the occurrence of abrin in Buddhist rosaries justify its inclusion in this book? The only drugs mentioned in the book are resorcinol, salicylic acid, and tamarind.

It is untrue that yellow phosphorus is still used in matches, let alone in fertilizers. Dichloroacetic acid and trichloroacetic acid are listed as synonyms of acetic acid. Acetic acid is stated to produce black skin and hyperkeratosis; no mention of its hemolytic effect is made. According to the book practically all substances have a "sensitizing" action and one is practically as dangerous as another. For many substances the threshold limit values are taken from a scarcely reliable list compiled by ICI in 1952 (acetophenone = 20 ppm; acetylene = 5000 ppm). The difference in toxicity between acetone and acetone cyanhydrin can be no more than suspected from the value of 1000 ppm given as the threshold limit for acetone, and the absence of a figure for the cyanhydrin. Not a word to tell us that the cyanhydrin acts practically like prussic acid; it is even claimed to produce a "depression of the central nervous system" and a "cytotoxic anoxia".

Under toxic substances such as allyl alcohol no mention is made of the typical liver-damaging action. By contrast, the relatively harmless amyl acetate is accused of precisely this, as well as of causing renal damage. Aniline is stated to depress the cardiac action, the smooth musculature and the central nervous system, and occasionally to produce intravascular hemolysis. Tetrafluoroethylene – "a colorless, flammable gas" – is equated with Teflon and its decomposition products, and so on and so forth.

The three pages of bibliography list the well-known, excellent English-language textbooks and reference works on toxicology. Had the author consulted these books, this inaccurate, useless compilation would not have seen the light of day, and it would not now be necessary to warn the reader against it. The well-intentioned attempt by the author shows that it is necessary to possess toxicological and chemical knowledge to compile the essential information, even using good textbooks. In this task the present author has, regrettably, failed. One can only marvel at his audacity in wanting to write such a compendium, and one that is even described as a handbook, without being sure of the facts. *H. Oettel* [NB 695 IE]

Isomerizations in Cyclobutenes[**]

BY R. CRIEGEE[*]

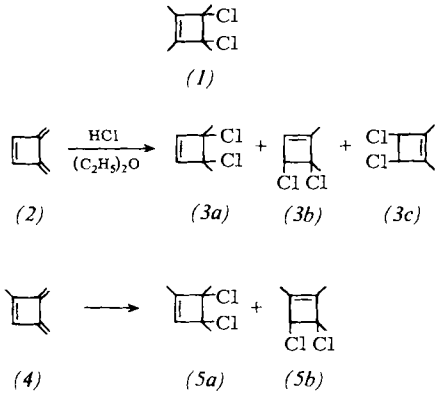
The present article deals with acid-catalyzed rearrangements and thermal valence isomerizations in cyclobutenes. The characteristic features of small rings, i.e. their practically planar structure and the ring strain, are in fact the causes of the rearrangements discussed.

1. Acid-Catalyzed Rearrangements

The great stability of cyclobutenyl cations, which has now been known for some time, was first brought to our attention by the unusually high rate of solvolysis of dichlorotetramethylcyclobutene *(1)* [1]. Aqueous acetone converts this compound into the corresponding diols within a few minutes at room temperature. *Katz* [2] later proved the existence of stable cyclobutenylium salts by UV and NMR measurements. Possible reasons for this stability include the planar structure, the symmetry, the electron-donating effect of the methyl groups, and possibly a nonclassical 1,3-interaction, all of which should favor the fundamental ion on energy grounds.

The great stability of the ion leads to rapid dissociation of the chlorine atoms in *(1)*, particularly in the presence of complexing agents such as zinc chloride or tin tetrachloride. Recombination with the chloride ions in the two possible positions in the mesomeric ion leads to equilibration of the methyl groups, which *Katz* [3] detected by the appearance of a lone singlet in the NMR spectrum.

We found the same phenomenon during the addition of HCl to the trienes *(2)* and *(4)*, which can be obtained as described by *Huntsman* [4]. In the reaction of *(2)*, *Eberius* [5] obtained a mixture of the isomeric dichlorides *(3a)–(3c)*, which could be separated by gas chromatography, while *(4)* gave a mixture of *(5a)* and *(5b)*, which could not be separated in this way.



Rapid equilibration takes place in both cases with zinc chloride in ether. However, the equilibrium is completely displaced toward *(3c)* and *(5b)*, *i.e.* the compounds having both the maximum number of secondary chlorine atoms and the maximum number of methyl groups attached to doubly-bonded carbon atoms.

However, cyclobutenylium cations are formed by the protonation of methylenecyclobutenes as well as by the dissociation of chloride ions. This is illustrated by the ready addition of hydrogen chloride to *(2)* and *(4)*, as mentioned above. Other nucleophiles also add rapidly to the semicyclic methylene group in the presence of protonic catalysts. Thus an HCl concentration of only 10^{-3} mole/l is sufficient to cause the addition of methanol to the diene *(6a)* to form the ether *(7a)*, the half-reaction time being about 1 hour at 24 °C. The reaction of *(6b)* is twice as fast. How-

[3] *Th. J. Katz* and *E. H. Gold*, J. Amer. chem. Soc. *86*, 1600 (1964).

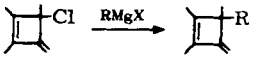
[4] *W. D. Huntsman* and *H. J. Risters*, J. Amer. chem. Soc. *85*, 3308 (1963); *89*, 342 (1967); *W. D. Huntsman, J. A. DeBoer*, and *M. H. Woosley*, *ibid.* *88*, 5846 (1966).

[5] *R. Criegee, W. Eberius*, and *H. A. Brune*, Chem. Ber. *101*, 94 (1968).

ever, it seems questionable whether the high reactivity of the methylenecyclobutenes is connected with the 1,3-interaction mentioned, since the reaction of 1-methyl-3-methylenecyclopentene, in which an interaction of this type is not to be expected, is only slightly slower [6].

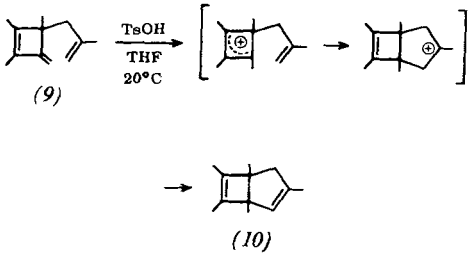
(6a), R = H *(7a)*, R = H
(6b), R = CH_3 *(7b)*, R = CH_3

The cyclobutenylium cation can react, not only with "foreign" nucleophiles, but also with nucleophilic groups in the same molecule. In this case the addition may be regarded as an intramolecular rearrangement. We shall consider only those reactions in which the nucleophilic group is an ethylene grouping in a side chain. Compounds of this type can be readily obtained from the dichloride *(1)* by treatment with quinoline to obtain the monochloride *(8)*, followed by reaction with unsaturated Grignard compounds.



(8)

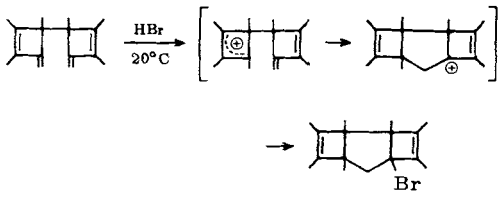
A simple example is the rearrangement of the methallyl compound *(9)* with *p*-toluenesulfonic acid (TsOH) in tetrahydrofuran (THF) at 20 °C. The bicyclo[3.2.0]-heptadiene derivative *(10)* is formed in 78 % yield. A cyclobutenyl cation and the bicyclic tertiary carbonium ion formed from it probably occur as intermediates [7]. Many ring closures of this nature are known, but the surprising point in this case is the mildness of the conditions.



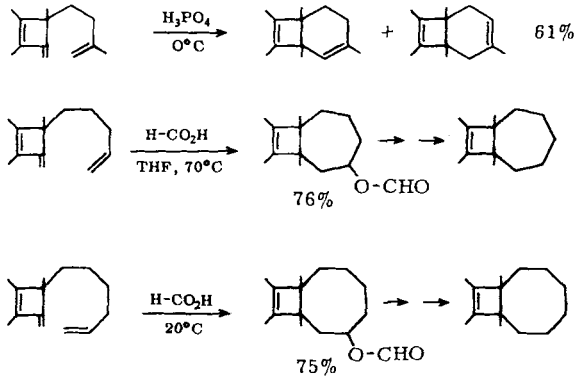
(9) *(10)*

The intermediate carbonium ions can also achieve stability by the addition of an anion, as was shown for a complicated case by *Dekker* in 1963 [8]. 1-Bromo-3,4,5,6,7,8,9-heptamethyltricyclo[5.2.0.$0^{3,6}$]nona-4,8-diene is formed in 88 % yield. In this case, stabilization of the intermediate by the loss of a proton would have led to an increase in strain.

Six-, seven-, and eight-membered rings can be fused on to the cyclobutene ring in the same way. The good yields obtained in ring closures of this type again



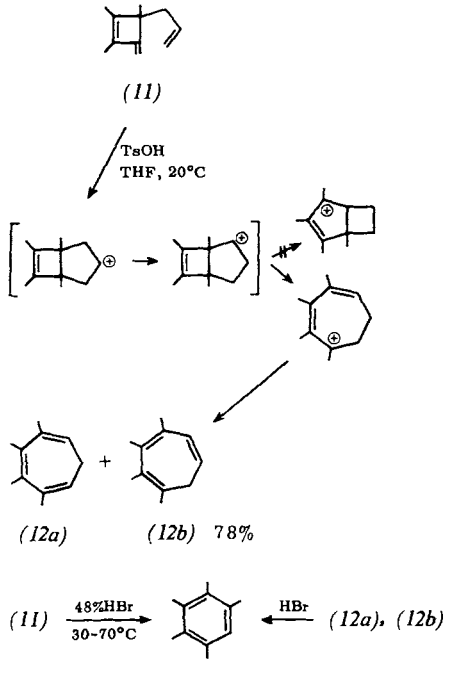
confirm the high stability of the intermediate cyclobutenyl cations [9] (see Scheme 1).



Scheme 1

In the last two cases shown, the formates obtained can be converted into the fundamental bicyclic hydrocarbons by conventional methods.

With cyclobutenes having allyl side chains and structures such that a secondary instead of the tertiary bicyclic carbonium ion is formed [as in *(11)*], complications occur as a result of further rearrangements and cycloheptatrienes and even benzene derivatives can be formed. The first step is thought to be the rearrangement of one carbonium ion into another by a hydride shift or by successive deprotonation and protonation. In any case, the result is an ion having the charge on



(11) *(12a)* *(12b)* 78%

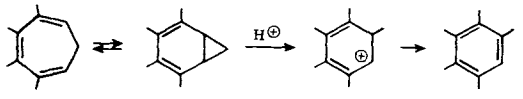
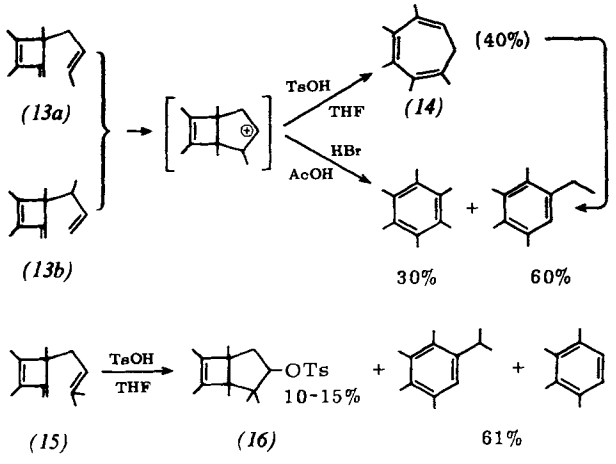
the C atom next to the bridgehead. This ion can change by a classical carbonium ion rearrangement either into another bicyclic ion or (with cleavage of the bicyclic bond) into a cycloheptadienyl cation. The strain in the system decreases only in the latter case. The reaction products obtained from *(11)* depend on the conditions. Methylated cycloheptatrienes *(12a)* and *(12b)* are formed with *p*-toluenesulfonic acid in THF, whereas 48 % hydrobromic acid gives an 80 % yield of pentamethylbenzene. This last rearrangement involves the cycloheptatrienes *(12a)* and *(12b)* as intermediates, since these are converted into pentamethylbenzene under the same conditions.

The rearrangement into the benzene derivative depends on the cycloheptatriene-norcaradiene valence isomerization. The norcaradiene derivative finally undergoes acid-catalyzed opening of the three-membered ring.



Similar rearrangements take place in compounds having 2-butenyl side chains, such as *(13a)*. Thus the reaction of the mixture of hydrocarbons *(13a)* and *(13b)* obtained in the Grignard synthesis proceeds *via* the common carbonium ion to give either pentamethylcycloheptatriene *(14)* or (with hydrobromic acid) a mixture of 30 % of hexamethylbenzene with 60 % of ethyltetramethylbenzene. The hydrocarbon *(15)* gives tetramethylisopropylbenzene and tetramethylbenzene as well as the secondary *p*-toluenesulfonate *(16)*.



Some views on the course of the reaction are illustrated in Scheme 2.

Perhaps it should be mentioned that in all these examples the opening of the four-membered ring has nothing to do with thermal isomerization. This pyrolysis, which also leads to cycloheptatrienes, and which will be discussed later, takes place only above 350 °C.

The cyclobutenyl cation can also make an electrophilic attack on an aromatic nucleus situated in the side chain[10]. The

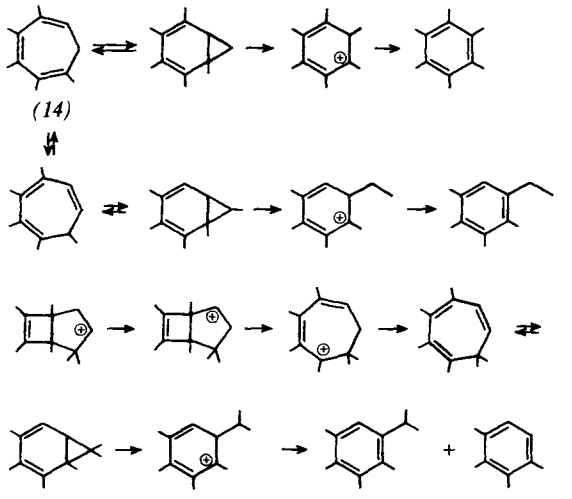
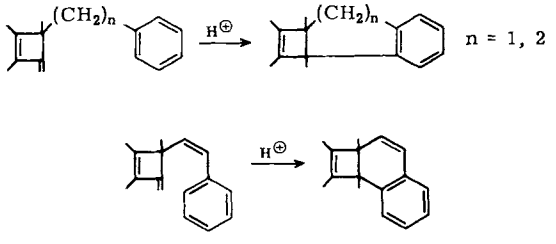


Scheme 2

isomerization with acids leads in these cases to tricyclic compounds containing a benzene ring (see Scheme 3).



Scheme 3

2. Thermal Valence Isomerizations

The formation of a butadiene by pyrolysis of a cyclobutene is one of the simplest of valence isomerizations. The reaction is normally thermally irreversible since a cyclobutene cannot exist in detectable quantities in the equilibrium, owing to the difference in the energy levels of about 11.5 kcal[10a]. Exceptions occur among fluorinated derivatives and cyclic butadienes having a *trans* double bond[*], as well as in a few other cases[11]. Since a stereospecific reaction course was first observed by *Vogel* (1954)[12], the pyrolysis of cyclobutenes has been intensively studied by several research groups. The conrotation of the 3,4-substituents during the rearrangement was brilliantly explained by *Woodward* and *Hoffman*[13] in 1965.

[13] *R. B. Woodward* and *R. Hoffmann*, J. Amer. chem. Soc. *87*, 395 (1965).

However, this theory provides no information about the dependence of the activation energy, and hence of the reaction rate, on the number, nature, and arrangement of the substituents on the cyclobutene ring, nor can it predict accurately when conrotation will give way to disrotation, which is in itself energetically less favorable. At present such information can only be gained from empirical observations based on extensive series of experiments. A few observations of this type will be reported in connection with known data. The kinetics of the rearrangements can be measured by UV or NMR spectroscopy or by gas chromatography, depending on the case in question. Since sufficiently accurate rate measurements have not been carried out in every case at various temperatures, and frequently cannot be carried out at all, the temperatures at which the rate constant has a value of exactly 10^{-4} are used together with the activation energies as reference values. The half lives at this "characteristic reaction temperature" $T_{k=10^{-4}}$ are approximately 2 hours.

We shall now consider some results obtained by *Walters* [14] and by *Frey* [15], who investigated the valence isomerization of cyclobutene and some of its methyl derivatives in the gas phase (Table 1, upper part).

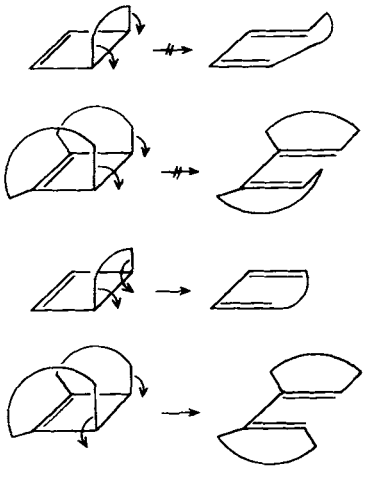
Table 1. Activation energy E_A and characteristic reaction temperature $T_k = 10^{-4}$ of the valence isomerization of cyclobutene and methylcyclobutenes.

Cyclobutene, Methyl on C—	E_A (kcal/mol)	$T_k = 10^{-4}$ (°C)	Ref.
—	32.5	145	[14]
1	35.1	155	[15]
3	31.5	121	[15]
1,2	36.0	168	[15]
1,3	33.0	135	[15]
1,4	33.4	143	[15]
1,2,3,4, *trans*	32.0	130	[15a]
1,2,3,4, *cis*	35.8	176	[15a]
1,2,3,3,4	34.0	163	[15a]
1,2,3,3,4,4	40	185	[15a]

It can be seen from the data available that methyl groups in the various positions affect the reaction rate, but that the order of magnitude is always approximately the same. This is confirmed by a number of measurements obtained in our own institute [15a]. These measurements were carried out in homogeneous solution. Since the rate showed no dependence on the solvent, the results should be comparable with those of reactions in the gas phase.

Interesting points arising from our results (Table 1, lower part) are that increasing substitution in positions 3 and 4 makes the reaction more difficult, and that there is a considerable difference in rate between *cis* and *trans* isomers, the *trans* compounds isomerizing much more readily than the *cis* isomers. This difference is found qualitatively even in the dichlorocyclobutenes, of which only the more stable *cis* isomer survives the pyrolysis from the starting material [16], and may be assumed to be due to the greater steric hindrance in the transition state of the *cis* compound, in which the incipient rotation brings a methyl group or a chlorine atom close to a hydrogen atom. In the tetrasubstituted compounds, it is even necessary for two methyl groups to approach each other.

The situation is entirely different when a conrotation would lead to diolefins with at least one of the double bonds as a *trans* double bond in a relatively small ring. This would be the case in cyclobutenes in which one or more rings are fused to the *cis*-3,4 bonds of the cyclobutene (Scheme 4).



Scheme 4

In these cases, unstrained reaction products, and hence a less strained transition state, can normally result only from disrotation. However, since the double bond provides no electronic assistance in disrotation, the activation energy for the cleavage of the C–C bond must be much higher.

A particularly extensive literature exists on the bicyclo[3.2.0]heptenes and related compounds [17]. These compounds are characterized by a high thermal stability, and pyrolyze only above 350 °C. Isomerization to form cycloheptadiene or cycloheptatriene derivatives

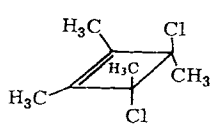
is generally complicated by secondary or side reactions. It is unimportant in these cases whether the fused five-membered ring is carbocyclic or heterocyclic, and whether it is saturated or unsaturated. Some examples are shown in Scheme 5. The characteristic reaction temperatures ($T_k = 10^{-4}$) for the pyrolysis are shown under the formulas.

The first four compounds in Scheme 5, which have only hydrogen or methyl groups at the bridgeheads, isomerize only above 350 °C. The reaction proceeds much more readily when the bridgehead substituents are phenyl or alkoxycarbonyl groups [18]. This can be explained by the assumption that the disrotation proceeds *via* short-lived diradicals, which are stabilized by these groups.

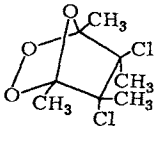
With larger fused rings, the valence isomerization must also yield larger rings. Consequently, the strain due to a *trans* double bond is smaller. It may therefore be expected that the conrotation mechanism will become possible again above a certain ring size. This should result in an increase in the reaction rate in such a system.

The acid-catalyzed ring closure reaction discussed in Section 1 permits the preparation of cyclobutenes with rings fused in position 3 and 4, which are suitable starting compounds for pyrolysis. However, the steric linkage of the two rings is important, whereas a *trans* linkage would lead to considerable strain in bicyclo-[3.2.0]heptenes and bicyclo[4.2.0]octenes, *trans* linkage of larger rings is quite feasible.

We have checked this question in the case of tetramethyl-bicyclo[6.2.0]decenes by a method developed by *Korber* [19] for the dichloride *(1)*. The problem was to determine whether the chlorine atoms in this compound were *cis* or *trans* to each other. In both cases the methyl groups can be classified into equivalent pairs, so that only one singlet is to be expected for each of the two types of methyl groups. The ozonide of *(1)* can occur in three forms *i.e.* one *trans* and two *cis* forms. Whereas the methyl groups in the *cis* forms are again grouped into equivalent pairs, this is no longer so in the *trans* form *(17)*. In this case the dihedral angles between the chlorine valences and the methyl valences are different, so that the methyl groups in positions 1 and 2 and those in positions 3 and 4 have different environments. The *trans* arrangement of the chlorine atoms in the ozonide, and hence also in the dichloride *(1)*, is confirmed by the observed splitting of the methyl singlet in the NMR spectrum [20].



(1)



(17)

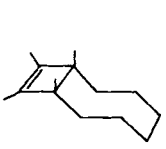
A similar situation is found in the hydrocarbon *(18)*. Whereas the methyl groups at the bridgeheads in *(18)* are equivalent both in the *cis* and in the *trans* form, this is true of the ozonide of *(18)* only in the *cis* form.

[18] *J. Rigaudy* and *P. Courtot*, Tetrahedron Letters *1961*, 95; *P. Courtot*, Ann. Chimie (13) *8*, 197 (1963); *R. Askani*, Chem. Ber. *98*, 2322 (1965).

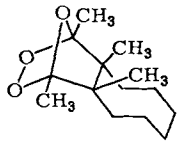
[19] *H. Korber*, Dissertation, Universität Karlsruhe 1968.

[20] This observation is contrary to an earlier belief. Cf. *R. Criegee* and *K. Noll*, Liebigs Ann. Chem. *627*, 1 (1959).

However, the NMR signal for the bridgehead methyl groups in the hydrocarbon *(18)* and in the ozonide *(19)* is a sharp singlet, so that the ring must be *cis*-fused.

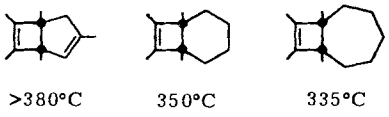


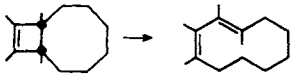
(18)



(19)

Scheme 6 shows the characteristic reaction temperature ($T_k = 10^{-4}$) for the pyrolysis of four hydrocarbons of the 4.5, 4.6, 4.7, and 4.8 series [9].





(20)

Scheme 6

Whereas the values for the first three compounds are similar, a large jump occurs between the third compound and the fourth, which contains an eight-membered ring. Thus the thermal isomerization proceeds much more readily in this case. The characteristic reaction temperature is almost the same as that of a tetrasubstituted monocyclic cyclobutene. As in the latter, conrotation evidently occurs. The reaction product must therefore be a *cis,trans*-cyclodecadiene *(20)*, which can be built from models without appreciable strain. In agreement with the behavior of unsubstituted *cis,trans*-1,3-cyclodecadiene, the compound gives no UV maximum [21]. The configuration of the diene cannot unfortunately be decided from the remaining spectral data. Investigations with systems containing larger rings, preferably with both types of fusion, are therefore desirable [*].

For quite different reasons, the valence isomerization proceeds more readily if the fused second ring is a four-membered or three-membered ring. The energetically favored conrotation is again no longer possible, but the disrotation is facilitated by the additional strain of the second ring. The values in Table 2 are selected from a large volume of data [15a].

The reaction temperatures are approximately the same as or lower than those found for hexamethyl-cyclobutene. Though the introduction of a double bond also produces a stable aromatic system in the second four-membered ring, and though the enthalpy of reaction should be increased by about 36 kcal, the

(21c)	CH_3	CO_2CH_3	28	97	−67
(21d)	H	H		55	

reaction rate shows no sudden increase. The effect of the substituents is greater than that of the second double bond. The fact that this double bond has any effect at all can be explained by the higher strain of a cyclobutene ring as compared with a cyclobutane ring.

Only one example of a cyclobutene with a fused three-membered ring is known. Disrotatory ring opening again takes place readily, leading in this case to cyclopentadiene [22].

A final series of investigations was concerned with cyclobutenes having a ring fused in each of the 1,4 and 2,3 positions. There are two possible stereoisomers of compounds of this type, in which the side rings are fused to C atoms 3 and 4 of the cyclobutene in the *cis* or *trans* position. The *cis* compounds are *meso* forms and the *trans* isomers are racemic forms. The compounds with six-, seven-, and eight-membered side rings were investigated.

As was shown by *Crowly* [23] and later by *Dauben* [24] in the case of the 6.4.6 ring compound, one series is formed by exposure of biscycloalkenyls to light. *Reinhardt* [25] obtained the other two *meso* forms in the same way. This author also obtained the three isomeric racemates by Birch reduction of the tricyclic dienes, which were obtained from the monocyclic allenes with six, seven, and eight ring atoms [26] (Scheme 7).

Valence isomerization can lead with conrotation to bicyclic compounds having *cis* double bonds in both rings only in the case of the racemic forms. All the racemic compounds should therefore isomerize at lower temperatures than the *meso* compounds. This is confirmed by the results of measurements.

Scheme 8 shows the characteristic reaction temperatures ($T_k = 10^{-4}$) of the hydrocarbons *(22a)* to *(22f)*.

(22a), n = 2 261°C *(22d)*, n = 2 87°C
(22b), n = 3 273°C *(22e)*, n = 3 109°C
(22c), n = 4 261°C *(22f)*, n = 4 119°C

Scheme 8

The *cis*-cyclobutene derivatives require a temperature 140–180 °C higher than that of the *trans* derivatives for isomerization. The activation energies in the first group (indicated in measurements which have been carried out) are 12 to 18 kcal higher than in the second group.

There are two interesting features here. The particularly ready isomerization of the 6.4.6 racemate is a reflection of the high strain in this system, which is evident even with Dreiding models. Even more remarkable is the fact that the three *meso* tricyclic compounds pyrolyze much less readily than the racemic isomers, but more readily than the bicyclic compounds with fused rings in the 3,4 position, though disrotation occurs in both cases and the decrease in strain on isomerization should be similar. If it is assumed, as mentioned above, that unstable diradicals occur as intermediates in disrotation, the bicyclic compounds (all of which have methyl groups at the condensation points) should react more rapidly, since the diradicals in these cases would be ditertiary. Four reasons can be suggested for the greater activity of the tricyclic compounds:

1. In the case of the tricyclic compounds, only two H atoms come close to each other in the transition state during the disrotation, whereas two methyl groups are involved in the case of the bicyclic compounds.

2. The isomerization of the tricyclic compounds leads to an increase in the entropy of the system, since the products are biscycloalkenyls having free rotation about the central C–C bond.

3. The formation of *cis* double bonds requires an outward disrotation of the large groups in the tricyclic compounds, but an inward disrotation in the bicyclic compounds. An inward disrotation is possible only if the four carbon atoms of the cyclobutene ring are simultaneously twisted out of the planar position. This presumably means that the transition state would have a very high energy.

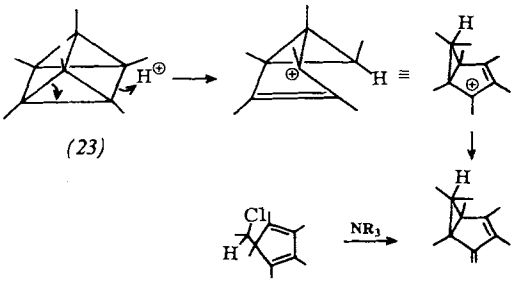
4. Ring opening in the tricyclic compounds yields dienes with true conjugation, whereas the absence of conjugation in the dienes formed from the bicyclic compounds is shown by the absence of a UV maximum.

Moreover, a strong transannular interaction is to be expected in the reaction products in this case.

It is not possible to tell from the existing experimental data which of these factors is actually involved.

3. Acid-Catalyzed Isomerization of Hexamethylprismane

So far we have considered only isomerizations of cyclobutenes. However, at least one example should now be given of an isomerization of a cyclobutane that is extremely readily rearranged by acids. When the saturated hydrocarbon hexamethylprismane *(23)*, which consists of three four-membered rings and two three-membered rings, is treated with catalytic quantities of trifluoroacetic acid at room temperature in CCl_4 solution it isomerizes within a few hours. In contrast to the thermal or metal-catalyzed rearrangement, however, neither of the valence isomers hexamethyl-Dewar-benzene or hexamethylbenzene is formed; the reaction proceeds instead by a hydrogen shift to give an almost quantitative yield of pentamethylmethylene-bicyclo[3.1.0]hexene *(25)*. The reaction is stereospecific, since of the two possible stereoisomers, the only one formed is that containing an *exo*-methyl group on C-6. This substance has already been obtained by *Schäfer* [27], together with small quantities of the *endo* isomer, by treatment of hexamethyl-Dewar-benzene *via* the cyclopentadiene derivative *(24)* [27a] with bases. The reaction course shown in Scheme 9 may be regarded as probable.



(23) *(24)* *(25)*

Scheme 9

Hexamethyl-Dewar-benzene cannot occur as an intermediate in this reaction, since it remains unchanged under the same conditions. The proton opens a bond between two four-membered rings. The driving force of the reaction is the decrease in the high ring strain of the prismane system.

Small Antiaromatic Rings [**]

BY R. BRESLOW [*]

According to quantum mechanical calculations, systems with $4n\,\pi$ electrons ought to have anti-aromatic character, i.e. be destabilized by resonance. This prediction is examined for the case of cyclopropenyl anion, the simplest system having $4n\,\pi$ electrons ($n = 1$). Isolation of compounds containing the cyclopropenyl anion has not, as yet, been achieved; however, kinetic measurements indicate the existence of the ion and confirm the unusual properties predicted.

1. Introduction

Extensive efforts have been devoted to the study of cyclic conjugated systems with $4n + 2\,\pi$ electrons; from such studies the quantum-mechanical prediction of aromaticity has in general been well confirmed. By contrast, the predictions of molecular quantum mechanics for $4n\,\pi$ electron systems have not been so extensively explored. It is, of course, quite clear by now that such molecules as cyclobutadiene [1] are not aromatic (strongly stabilized by resonance) but it is not clear whether this compound is simply nonaromatic (not appreciably stabilized by resonance, and highly reactive because of strain, *etc.*) or whether it is actually anti-aromatic (destabilized by resonance).

We have discussed the definition of "anti-aromaticity" previously [2, 3], and have pointed out that there are

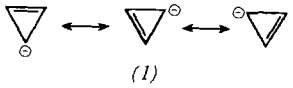
various ways of defining "the opposite of aromaticity", depending on whether magnetic, spectroscopic, kinetic, or thermodynamic criteria are used. Although the various manifestations of aromatic character are, in fact, closely related, we prefer to emphasize the thermodynamic definition in which aromaticity describes a particularly large negative contribution by electron-delocalization to the energy of a cyclic conjugated system. Thus an *anti-aromatic* system is one in which electron delocalization considerably raises the energy.

2. Quantum Mechanical Predictions

Before discussing the evidence for antiaromaticity let us see whether quantum mechanics contains a prediction of such an unusual situation. It turns out that the most striking predictions – as well as the best evidence – are for cyclopropenyl anion *(1)*, a 4 π electron system.



(1)

$H_2C{=}CH{-}CH_2^{\ominus}$

(2)

By a simple Hückel calculation the delocalization energy of *(1)* is 0.00 β. Thus comparing it with the components of the conjugated system – a double bond and a carbanion – we would call it non-aromatic. However, it is common to refer aromatic compounds to open-chain analogs, comparing benzene with linear hexatriene for instance. If we compare cyclopropenyl anion *(1)* with allyl anion *(2)*, considering the latter an example of normal conjugation, then *(1)* is antiaromatic since *(2)* has 0.82 β of resonance energy. From a comparison of cyclic and open-chain systems [4] it can be seen that both cyclopropenyl cation (2 electrons) and cyclopentadienyl anion (6 electrons) are predicted to be strongly stabilized relative to their linear analogs, as is known experimentally, but that both the cyclopropenyl anion and the cyclopentadienyl cation are predicted to be destabilized relative to the linear analogs.

A similar prediction arises from more sophisticated calculations. In Table 1 are presented the results of a π-electron calculation on cyclopropenyl and allyl anions using the standard Pariser-Parr parameters [5] and including a complete configuration interaction treatment [6]. The table also lists the results of such calculations for cyclopentadienyl and linear pentadienyl cations, in which only some of the excited configurations were considered. In all cases simple regular geometries were assumed, although the actual molecules might well undergo distortions.

[4] For a graphical method see *R. Breslow* and *E. Mohacsi*, J. Amer. chem. Soc. *85*, 234 (1965).

[5] *R. G. Parr*: The Quantum Theory of Molecular Electronic Structure. Benjamin, New York 1963.

[6] We wish to thank Prof. *M. Karplus* and Dr. *D. Lazdins* for making their computer program available.

Table 1. Results of PPP–SCF–CI calculations.

Molecule	Singlet energy (eV)	Triplet energy (eV)
Cyclopropenyl anion *(1)*	– 61.448	– 62.290
Allyl anion *(2)*	– 61.903	– 59.164
Cyclopentadienyl cation	–123.147	–123.465
Pentadienyl cation	–105.014	–

In comparing these systems a "core correction" for the change in carbon-carbon interaction has to be applied (1.60 eV in the three-carbon case and 19.06 eV in the five-carbon case). The result is a prediction that the singlet state of *(1)* is antiaromatic by 2.0 eV, and that of cyclopentadienyl cation by 0.9 eV. These calculations confirm the prediction of the simple Hückel method that both cyclic 4 π electron systems are destabilized relative to open-chain analogs, but that the effect is greater in the cyclopropenyl anion than in the larger cyclopentadienyl cation. This is a general result: the small cyclopropenyl anion is the best place to look for evidence of antiaromaticity.

A second fact derivable from Table 1 is that both the cyclopropenyl anion and the cyclopentadienyl cation are predicted (assuming symmetrical polygonal geometry) to have triplet ground states. However, again the prediction is stronger for the smaller ring: the singlet-triplet gap is 0.842 eV for cyclopropenyl anion and only 0.318 eV for cyclopentadienyl cation. An additional point of interest is that the singlet states are lowered more in energy when excited configurations are included in the calculation than are the triplet states, so this configuration-interaction calculation decreases the predicted energy advantage of the triplets by 0.3 eV for the C_3 system and 0.15 eV for the C_5 system.

3. Attempts to Synthesize the Cyclopropenyl Anion

With such striking quantum-mechanical predictions it became clear that the cyclopropenyl anion was a system of major interest, perhaps surpassing that of the cation [7]. It was already known that this anion was not strongly stabilized. For instance, *Wiberg* had shown [8] that treatment of β-bromocyclopropanecarboxylic ester with base caused elimination to a cyclopropene which exchanged its vinylic [9], but not its allylic, hydrogen. Further evidence corroborating the proposition that electrons added to cyclopropenyl

[9] The acidity of the vinyl protons has also been studied in later work: *R. Breslow* and *L. J. Altnan*, J. Amer. chem. Soc. *88*, 504 (1966), and further literature cited there.

cations go into high-energy orbitals was obtained from our electrochemical studies[10] on cyclopropenyl cations by oscillopolarography (Table 2). As the Table shows, reduction of the cyclopropenyl cations to radicals takes approximately 1 eV more energy than does reduction of triphenylmethyl cation, and this corresponds well to the predictions of M.O. theory, since β for electrochemical reductions is of the order of 2 eV.

Table 2. Electrochemical reduction potentials [a].

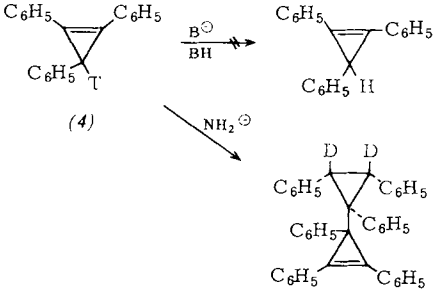
[a] Solutions 0.2 mM in cation perchlorates in dry acetonitrile with 0.1 M tetraethylammonium perchlorate were examined by oscillopolarography against $Ag/AgClO_4$ electrode taken as +0.380 V *vs.* saturated calomel electrode.

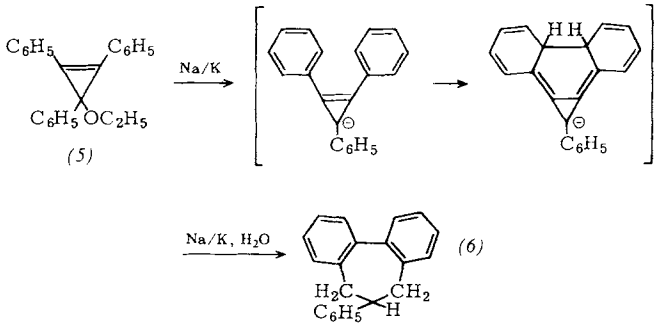
In this work it proved impossible to attain potentials which would add a second electron to afford the anion, since reduction of solvent occurred first. Although this helps to confirm the predictions of M.O. theory on which the proposition of antiaromaticity in the anion is based, it is not, of course, direct evidence about the anion.

Several other unsuccessful attempts have been made to isolate derivatives of cyclopropenyl anion, and such work is actively continuing. For instance, with *P. Dowd* we investigated[11] the treatment of [3-T]-triphenylcyclopropene *(4)* with various bases, and found that no exchange of the tritium could be detected with base under conditions much more vigorous than those required to exchange [1-T]-triphenylmethane. With some strong bases triphenylcyclopropene affords a dimer, but mechanistic studies show that the anion is not involved; the mechanism of this process has been discussed[11].



(4)

Reduction of triphenylcyclopropenyl ethyl ether *(5)* with sodium-potassium alloy might be expected to furnish the triphenylcyclopropenyl anion, but the product is in fact[12] a dibenzocycloheptene derivative *(6)*. Quenching part way through the reaction affords starting ether *(5)* and the final product *(6)* with no triphenylcyclopropene; if the triphenylcyclopropenyl anion is involved it rearranges rapidly. Interestingly, if the final mixture is quenched in D_2O, the product *(6)* is about one third trideuterated and one half dideuterated.



(5) *(6)*

Recently, *T. Higgs*[13] confirmed that tribenzoylcyclopropenyl anion is present in equilibrium in strongly basic solution.

4. Kinetic Investigations

In the absence at the present time of isolable derivatives of cyclopropenyl anion we must turn to kinetic evidence on stability. The correlation between kinetic and thermodynamic acidity has been examined by many investigators, and is summarized in *Cram*'s monograph[14]. Within closely related series kinetic and thermodynamic acidities usually run parallel (the Brønsted Law), and when solvents are much more acidic than the substrates reprotonation of enolate ions, *etc.*, is almost diffusion controlled; rates and equilibria must therefore run parallel for related structures. A correlation between the rate of ionization and the stability of the product ion would, of course, be expected; for almost all exchange processes the ionization step is rate determining.

However, several cases of exchange have been found[15], in studies utilizing all three hydrogen isotopes, in which k_H/k_D is less than 1.0. Such an inverse isotope effect shows that the C–H bond is not breaking in the rate determining step; in such special cases, therefore, the exchange rate is apparently determined by diffusion of solvent into and out of a solvated carbanion complex.

Recently the isotope effect for hydrogen exchange in cyclopropanecarbonitrile has been measured, and k_H/k_D has been found[16] to be 1.9. Although the authors suggest this is so low that ionization is probably not rate determining, we feel that with a positive isotope effect of this magnitude there is no

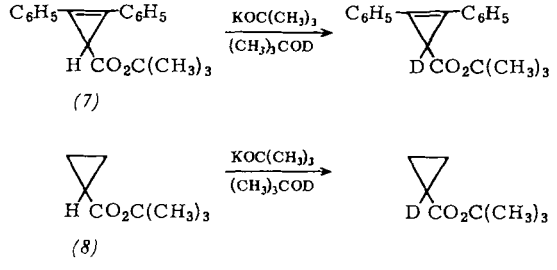
need to involve any unusual hypotheses. Accordingly, in what follows we will discuss rates of exchange in terms of the stability of the product ion, as is usual, while keeping in mind possible special steric effects in the transition states.

The earliest evidence for a remarkable destabilization of cyclopropenyl anion was the finding [17], with *Battiste*, that deuterium exchange in a cyclopropene ester *(7)* proceeds at least 300 times slower than that in a cyclopropane ester *(8)* [8]. (This exchange rate and that mentioned in the following example refer to

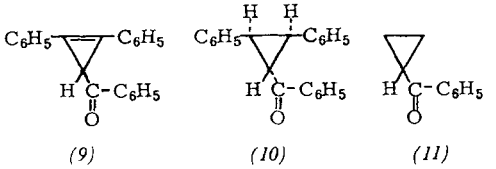


(7)

(8)

similar conditions and at ≈ 25 °C.) This was a remarkable observation, since the anion derived from *(7)* should have extra stabilization from conjugation with the double bond and through it with the two phenyl groups. The enolate ion of *(7)* [cf. *(12)*] deuterates very rapidly at C-1. Isomerization of the double bond at the position between C-1 and C-2 (conjugation with the ester group) with subsequent addition of solvent across the double bond [18] takes place much more slowly.

Striking as this observation was, later work showed that these preliminary kinetic data actually underestimate the destabilization in a cyclopropenyl anion. Kinetic studies on 3-benzoyl-1,2-diphenylcyclopropene *(9)* show that its base-catalyzed exchange is 6000 times slower than that of the corresponding cyclopropane derivative *(10)*, and that this difference is reflected in the activation energies, not entropies [3].



(9) *(10)* *(11)*

	(9)	*(10)*	*(11)*
Rate of exchange	1	6000	2000
E_a	26 (kcal/mole)	20.3 (kcal/mole)	—
log *A*	11.2	10.6	—

As expected, phenyl substituents on the cyclopropane increase the rate slightly by an inductive effect.

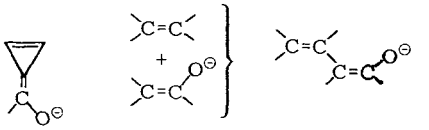
[18] *M. Battiste*, Ph. D. Thesis, Columbia University, New York 1958.

5. Experiments on the Significance of the Kinetic Behavior

The factors which might be involved in a 6000-fold decrease in exchange rate in the case of *(9)*, compared with *(10)*, have been discussed in detail [3] and can be summarized briefly.

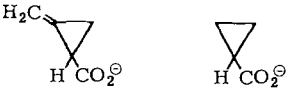
1. Antiaromaticity of the cyclopropenyl anion. The interaction between the double bond and the developing negative charge may actually be destabilizing. Ordinary Hückel calculations do not suggest this, but Pariser-Parr-Pople SCF calculations show a loss of stability (about 0.34 eV or about 2.0 eV, respectively) in the enolate ion *(12)* compared with the open-chain analogs *(13)* and *(14)*.



(12) *(13)* *(14)*

2. Steric effects. In this category one can imagine three principal effects. One is a possible difference in I Strain on ionization of the cyclopropene, because of its smaller bond angle. We have presented arguments [3] that this is unlikely to be a major factor. A second possible effect is relief of eclipsing in the cyclopropane ionization; again this does not seem to play an important role in cyclopropane chemistry. The third possible effect is eclipsing in the cyclopropenyl anion between the activating group and the other groups (phenyls) in the cyclopropene plane. This last effect is excluded by our finding that replacement of the phenyls by smaller methyl groups actually leads to a decrease, not increase, in the rate of exchange in the cyclopropene. It is also excluded by data mentioned below for a cyclopropene carbonitrile.

It should be mentioned that the introduction of a trigonal carbon in a cyclopropane need not decrease the rate of base-catalyzed exchange. *Bottini* has found [19] that deuterium exchange in methylenecyclopropanecarboxylate ion *(15)* is 10^5 times faster than in the simple cyclopropanecarboxylate *(16)*.



(15) *(16)*

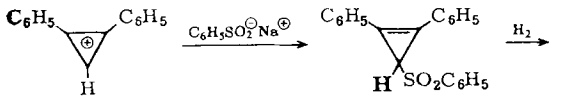
100000 1

Although in this comparison steric factors similar to those discussed above could also play a role, with about half the magnitude of that in the case of cyclopropene, the normal conjugative and inductive effects of a double bond strongly accelerate the exchange. The comparison between the effect of a double bond exocyclic or endocyclic [in *(15)* and *(9)*] to the cyclo-

[19] *A. T. Bottini* and *A. J. Davidson*, J. org. Chemistry *30*, 3302 (1965).

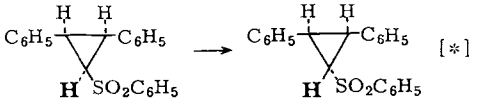
propane anion is particularly striking, and reflects the comparison between normal open-chain and cyclic antiaromatic conjugation.

A comparison has also been made between cyclopropane and cyclopropene exchange rates with other activating groups, for example sulfonyl groups [3]. Some suggestions have been made [20] that carbanions next to sulfonyl groups may have grossly different



(17)

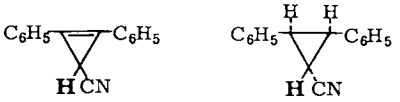
1



(18)

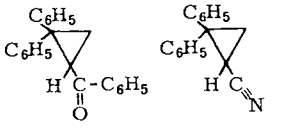
1000

hybridization from, for instance, those next to carbonyl. Our data show that the antiaromatic effect, whatever its origin, is observed for such an anion as *(17)* also. Perhaps more striking is the observation on the compound *(19)* with a cyano group as activating substituent [21]. Since the cyano group is smaller than a benzoyl group, many of the steric effects we have mentioned should be smaller in this case, but PPP-SCF calculations suggest that the electronic antiaromatic effect should be larger. (Essentially because the cyano group removes charge less effectively so that the hybrid anion has more cyclopropenyl anion character.) Experimentally, the apparent antiaromaticity is the largest so far observed, which is consistent with the electronic explanation.



(19) 1 *(20)* 10700

All of the possible steric explanations for the apparent antiaromaticity of cyclopropenyl anions involve postulated difficulties with rehybridization of the cyclopropene carbon to flat trigonal geometry. *Walborsky* has observed [22] that deuterium exchange in some optically active cyclopropane derivatives occurs with partial retention of configuration, and one of the explanations offered for this is non-planarity of the intermediate anion. If steric effects were responsible for the apparent antiaromaticity then optically active cyclopropenes should show an even greater tendency to exchange without racemization. If on the other hand antiaromatic electronic interactions are involved in the cyclopropenyl anions, then one would expect a decreased k_e/k_r (e = exchange, r = racemization) since repulsion by the double bond should force more negative charge into the activating group thus flattening the carbon. Such increased flattening as more charge disperses into the activating group presumably explains the difference in *Walborsky*'s data [22,23] for the ketone *(21)* and the nitrile *(22)*.



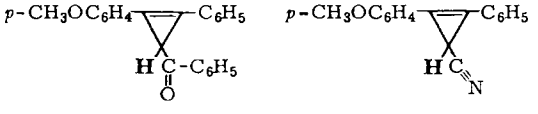
(21) *(22)*

Table 3. Some k exchange/k racemization values.

Compound	Solvent	k_e/k_r	Ref.
(21)	CH_3OH	1.64	[22,23]
(22)	CH_3OH	8080	[22,23]
(22)	$(CH_3)_3COH$	77	[22,23]
(23)	C_2H_5OH	1.0 ± 0.1	[21]
(24)	$(CH_3)_3COH$	4.0 ± 0.2	[21]

We have prepared [21] an optically active cyclopropenyl ketone and carbonitrile by resolution of the corresponding cyclopropenecarboxylic acid, and standard conversion of the carboxyl group into the other functions. The observation is that k_e/k_r for the cyclopropenyl ketone *(23)* is much less than that for the cyclopropyl ketone *(21)*; in the case of the carbonitriles, the value for *(24)* is smaller than that for *(22)*. This is again consistent with the idea that electronic antiaromaticity is involved (see Table 3).

One must consider the possibility that *Walborsky*'s retention data reflect "asymmetric solvation" of the anion although he specifically rejects this alternative [22]. Even if this were the explanation, the increased racemization would result from an increased tendency in the cyclopropenecarbonitrile anion for



(23) *(24)*

protonation on nitrogen rather than on carbon, again because of electronic antiaromatic interaction. It need hardly be added that the increased tendency for racemization in the cyclopropenes cannot be due to a *stabilizing* interaction of the flattened anion with the double bond, since the exchange rate is decreased in the cyclopropenes.

There is an additional quantum-mechanical prediction about some antiaromatic systems which is of interest. Systems with $4n$ π electrons and C_3 or greater symmetry may have triplet ground-states. Predictions from PPP–SCF–CI calculations on cyclopentadienyl cation and cyclopropenyl anion have already been

[20] For a summary cf. ref. [14], pp. 110ff.

described in Section 2: assuming symmetric geometry, the triplet states were much lower in energy than the singlets.

Experimentally, symmetric derivatives of cyclopropenyl anion are not yet available (cf. Section 3[13]); however, triplet states have been detected for several cyclopentadienyl cations. Since this work has been described in detail recently[24], only the principal conclusions will be cited.

Pentachlorocyclopentadienyl cation is a ground state triplet. Pentaphenylcyclopentadienyl cation is a ground state singlet, but its triplet state is only 0.35–1.15 kcal/mole higher. Apparently this molecule can distort away from perfect five-fold symmetry; the results also confirm the general conclusion that the energetic advantage of triplet state is decreased in larger molecules.

In molecules with less symmetry, such as β-naphthyltetraphenylcyclopentadienyl cation, a triplet state is even higher in energy. However, NMR spectra show that the triplet state and the ground singlet state are in rapid thermal equilibrium. The existence of such a rapid equilibrium vitiates the chemical criteria often applied to such molecules as cyclobutadiene to determine whether they are singlets or triplets.

The aromaticity of various new systems which fit *Hückel*'s $4n + 2$ rule, including cyclopropenyl cation, is by now well established. The even more interesting properties of some $4n$ π electron systems – antiaromaticity and in some cases triplet ground states – must be explored further. However, it seems that several of the most unusual predictions of molecule quantum mechanics about such systems have in fact been confirmed.

Syntheses of Cyclopropylcarbonyl Compounds[**]

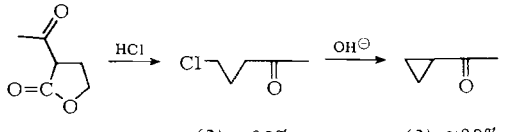
BY J. M. CONIA[*]

There are three important direct routes to cyclopropylcarbonyl compounds: 1. Cyclization of chains of three carbon atoms, the first or third of which is adjacent to a carbonyl or potential carbonyl carbon atom (this type includes syntheses by intramolecular alkylation of γ-halogeno ketones or related compounds in alkaline media); 2. insertion of a methylene group or substituted methylene group into the olefinic double bond of an α,β-unsaturated carbonyl compound; and 3. introduction of an acetonyl group into the double bond of an olefin. However, cyclopropylcarbonyl compounds can also be obtained from 1,2-epoxycyclobutane and 2-bromocyclobutanone derivatives by ring contraction. Another possibility is the dehalogenation of α,α-bis(bromomethyl)cycloalkanones. This review concludes with a discussion of these little known routes and of a particularly suitable method which involves the reaction of methylene iodide, a Zn–Cu couple, and α,β-unsaturated ketones.

1. Intramolecular Alkylation

1.1. Cyclization of γ-Substituted Ketones

The more recent publications in this connection deal mainly with improved syntheses of ketones intended for subsequent conversion into cyclopropyl ketones *(3)* by the action of bases. Thus methyl cyclopropyl ketones can be synthesized *e.g.* from α-acetyl-γ-lactone *(1)* by treatment with hydrochloric acid to obtain the γ-chloro ketone *(2)*, followed by cyclization with sodium hydroxide, potassium hydroxide, or sodamide[1,2].



(1) *(2)*, ≈90% *(3)*, ≈80%

α-Substituted α-acetyl-γ-lactones give methyl cyclopropyl ketones having a substituent in the α-position of the ring[3]. Corresponding β-substituted cyclopro-

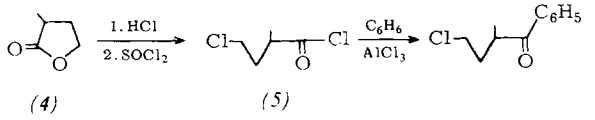
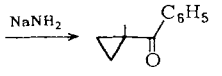
pyl ketones are obtained from the β-substituted γ-chloro ketones [4].

Phenyl cyclopropyl ketones *(6)* can also be obtained from unacetylated lactones, *e.g. (4)*, which are hydrolyzed by hydrochloric acid and give γ-chlorinated acyl chlorides *(5)* on treatment with thionyl chloride. A Friedel-Crafts reaction of the acyl chloride *(5)* with benzene leads to the γ-chlorinated phenyl ketone, which then yields the desired phenyl cyclopropyl ketone *(6)* on treatment with sodamide [1,2].

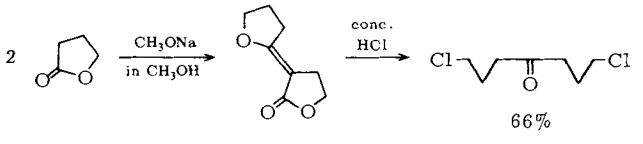


(4) *(5)*



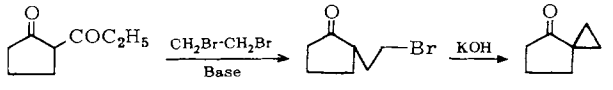
(6), 58%

Dicyclopropyl ketone *(7)* can be obtained directly from γ-butyrolactone in an overall yield of 50–60% [5].



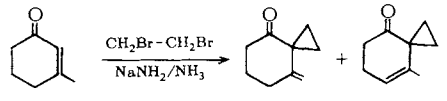
(7), 70%

The starting compound may also be a keto ester such as *(8)*, which is converted into the spiro ketone *(9)* by alkylation with 1,2-dibromoethane and ring closure with KOH [6].



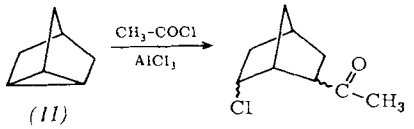
(8) *(9)*

A similar double alkylation should also be possible in α,β-unsaturated ketones *(10)* [7].

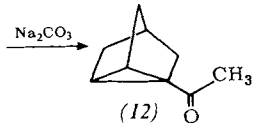


(10)

One method that may occasionally be of interest for the synthesis of cyclopropyl ketones is the simultaneous acetylation and chlorination of a cyclopropane. This process yields an open-chain γ-halogeno ketone, which is recyclized by treatment with a base. 1-Acetylnortricyclene *(12)* can be obtained in this way from nortricyclene *(11)* in an overall yield of 40–60% [8].

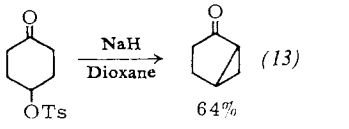


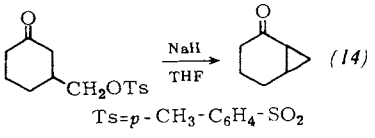
(11)



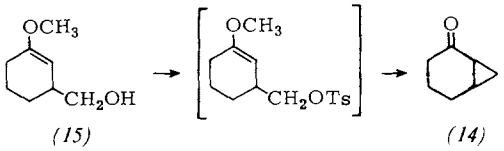
(12)

Cyclic ketones containing a *p*-toluenesulfonyl group on the γ-carbon atom inside or outside the ring yield interesting bicyclic ketones such as *(13)* and *(14)* on α,γ-elimination [9,10].





2-Norcaranone *(14)* can also be obtained from the enol ether *(15)* by cyclization of the *p*-toluenesulfonate in pyridine [11].



(15) *(14)*

1.2. Reaction of α,β-Unsaturated Ketones with Ylides

A very versatile variant of the intramolecular alkylation is the reaction of ylides, particularly dimethyloxosulfonium methylide *(16)*, with α,β-unsaturated ketones. It is well known that the reaction of dimethylsulfonium methylide $(CH_3)_2S{=}CH_2$ with ketones of this type leads, not to cyclopropyl ketones, but to epoxides. On the other hand, the reaction with dimethyloxosulfonium methylide leads, with loss of di-

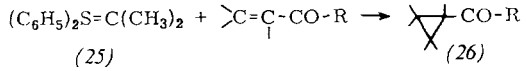
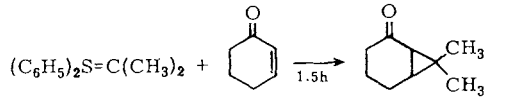
[15] *C. Agami*, Bull. Soc. chim. France *1967*, 1391; *C. Agami* and *C. Prevost*, *ibid. 1967*, 2299.

The synthesis of cyclopropyl ketones from α,β-unsaturated ketones and dimethyloxosulfonium methylide loses its importance when the ketones are unstable in alkaline solution. Though mesityl oxide still gives good yields (approximately 40 %), methyl vinyl ketone and phenyl vinyl ketone simply resinify [15], and the starting material can be isolated unchanged from the mixture with 3-penten-2-one. The corresponding cyclopropyl ketones can be more successfully prepared with the aid of Simmons reagent (see Section 2.1).

Diphenylsulfonium isopropylide *(25)* reacts with the olefinic double bond of α,β-unsaturated carbonyl compounds, and is thus excellently suited for the synthesis of geminal dimethylcyclopropyl ketones such as *(26)* and *(27)* [16].

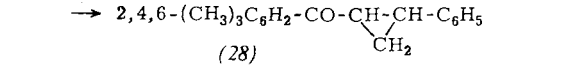


(25) *(26)*



(25) *(27)*, 74%

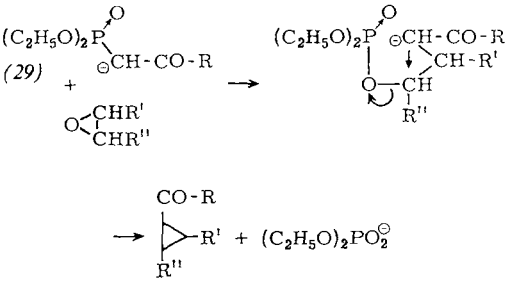
Little is known about the formation of cyclopropyl ketones from phosphonium ylides and α,β-unsaturated ketones. One example is the synthesis of the cyclopropyl ketone *(28)* from triphenylphosphonium methylide (methylenetriphenylphosphorane) and mesityl styryl ketone, the carbonyl group of which is strongly sterically hindered [17].



(28)

1.3. Reaction of Epoxides with Ylides

The reaction of stabilized phosphonium ylides with epoxides, which leads in the case of the ylide ester $(C_6H_5)_3P{=}CH{-}COOC_2H_5$ to the expected cyclopropyl esters, can be successfully extended to the synthesis of corresponding ketones. Ketone ylides (*e.g.* the carbanion of the diethyl β-oxophosphonate *(29)*) give numerous cyclopropyl ketones in an apparently general reaction with epoxides [18].



(29)

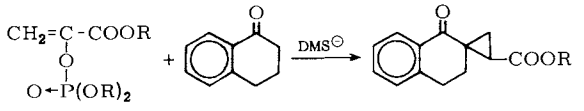
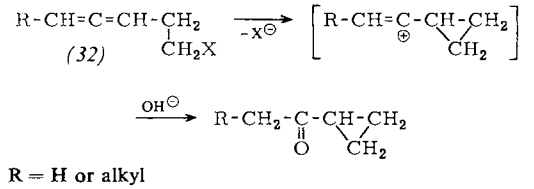
A synthesis that proceeds *via* an intermediate of the same type, despite the use of different starting compounds, is the reaction of triethylphosphoenol pyruvate *(30)* with a compound containing an active methylene group in the presence of a strong base. In this way, tetralone gives the spirocyclopropyl ketone *(31)* with an ester group attached to the three-membered ring [19].



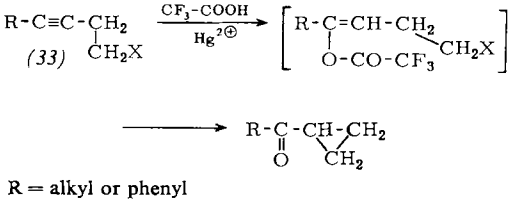
(30) *(31)*, 80%

1.4. Other Syntheses of Cyclopropyl Ketones

Mention should also be made of new cyclization reactions such as the solvolysis of allene sulfonates *(32)*, which proceeds *via* a vinyl cation [20], and the reaction of acetylenesulfonates *(33)* with trifluoroacetic acid, which leads in the presence of Hg^{2+} to cyclopropyl ketones [21].



R = H or alkyl
X = sulfonate



R = alkyl or phenyl
X = sulfonate

2. Insertion Reactions

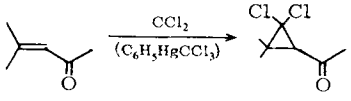
2.1. Insertion in α,β-Unsaturated Ketones

The cyclopropylcarbonyl system can also be synthesized by direct insertion of a substituted or unsubstituted methylene group into the olefinic double bond of an α,β-unsaturated carbonyl compound or by the insertion of an acetonyl group into the double bond of an olefin.

The direct insertion is apparently difficult to achieve. Thus the action of diazomethane or phenyldiazomethane on chalcone or other ketones leads *via* a pyrazoline to, at best, very small yields of cyclopropyl ketones [22].

In the reaction of halogeno- and dihalogenocarbenes the α,β-unsaturated ketones and aldehydes are probably unable to withstand the strongly basic conditions required for the formation of the carbenes. The synthesis of halogenated cyclopropyl ketones cannot be achieved even by blockage of the carbonyl group *e.g.* by acetalization, since the double bond then frequently migrates to the β,γ-position.

On the other hand, the reaction of dichlorocarbene (which is formed under mild conditions from $C_6H_5-HgCCl_3$) with mesityl oxide *(34)* leads to very good yields of dichlorodimethylcyclopropyl methyl ketone *(35)* [23].



(34) *(35)*, 83%

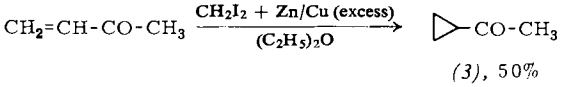
The Simmons reaction

$$CH_2I_2 + Zn/Cu + \text{olefin} \rightarrow \text{cyclopropane derivative}$$

can also be applied to unsaturated compounds containing functional groups such as –OH, –OAc, or –COOR and to many α,β-unsaturated ketones [35,36].

We found that no cyclopropylcarbonyl compounds are obtained when the reaction is carried out with aldehydes (acrolein, crotonaldehyde, cinnamaldehyde), but that the reaction mixture simply resinifies.

However, cyclopropyl ketones are readily formed from vinyl ketones and from untautomerizable, α,β-unsaturated ketones with no hydrogen in the γ-position. On heating in ether for 48 h methyl vinyl ketone gives a 50 % yield of methyl cyclopropyl ketone *(3)* together with unreacted starting ketone and resinous compounds. Nevertheless, this is the best method for the preparation of methyl cyclopropyl ketone.



(3), 50%

trans-Benzilideneacetone is also readily converted into the *trans* isomer of 1-phenyl-2-acetylcyclopropane *(36)* (40 % yield). The reaction with *trans*-chalcone leads to *(37)* in yields that vary considerably with the reactivity of the Simmons reagent.

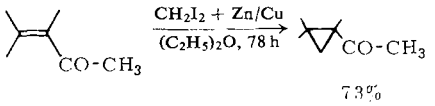
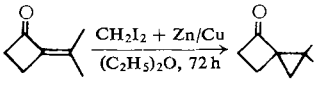
The behavior of tautomerizable α,β-unsaturated ketones is interesting. Whereas 3-methyl-2-cyclopenten-1-one and 3-methyl-2-cyclohexen-1-one (as well as isophorone) do not react, the corresponding unmethylated compounds add to the methylene group in good yields. This offers a very simple synthesis of 2-norcaranone *(14)* (90 % yield after 36 h).

Under the same conditions, mesityl oxide sometimes remains unchanged and sometimes resinifies, to a greater or lesser extent, whereas the α-methylated derivative (3,4-dimethyl-3-penten-2-one) yields the expected cyclopropyl ketone.



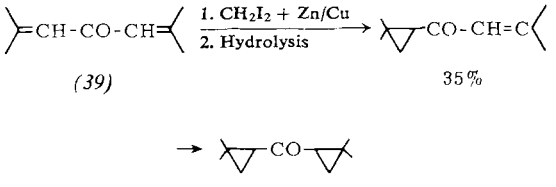
73%

Pulegone and 2-isopropylidenecyclopentan-1-one do not react, while 2-isopropylidenecyclobutan-1-one gives the expected spiro ketone *(38)* together with resin and unreacted starting ketone.



(38), 37%

Dienones appear to react well. Thus phorone *(39)*, unlike mesityl oxide, reacts first with one methylene group and then, after hydrolysis, with a second.



(39)

35%

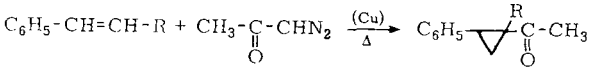
dl + meso
80%

The α,β-unsaturated ketones can therefore be divided into two classes according to their reaction with Simmons reagent (ICH_2ZnI). In addition to ketones that give the normal olefin reaction, *i.e.* the formation of cyclopropyl ketones (a prior 1,4 addition has never been observed), there are others in which the carbonyl group takes part in the reaction; these compounds probably give a stable complex from which the original ketone is regenerated on hydrolysis.

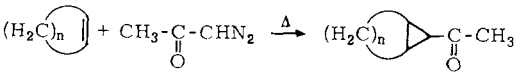
It is not easy to predict how an α,β-unsaturated ketone will behave, since small differences in structure can cause a complete change in behavior. The results are influenced by steric hindrance of the carbonyl group, the nature of the enone system, the polarity of the carbonyl group, *etc.* In our experience, all unsaturated ketones with which the Simmons reagent does not give insertion of a methylene group (*e.g.* many β-substituted ketones) can be readily alkylated *e.g.* with sodium *tert*-pentoxide (see, *e.g.*, ref. [37]); the opposite is the case with the other unsaturated ketones (*e.g.* many α-substituted ketones).

Ketocarbenes offer an interesting method for the preparation of cyclopropyl ketones from olefins, since these carbenes can be readily prepared from diazomethane derivatives by heating, by exposure to light, or by the action of catalysts.

Acetylcarbene, which is prepared from diazoacetone, adds readily to the double bond of olefins. Thus the reactions with styrene, stilbene, and cyclic olefins lead to the expected methyl cyclopropyl ketones *(36)*, *(40)*, and *(41)* [24].

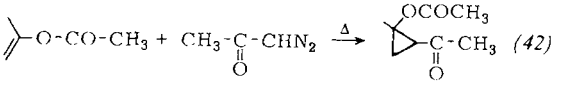


(36), R = H
(40), R = C_6H_5

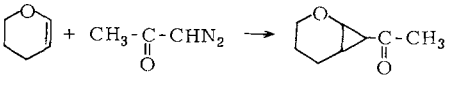


(41)

The reaction proceeds differently with benzene and thiophene, whereas with enol acetates and unsaturated heterocyclic compounds, such as dihydropyran and benzofuran, the normal products *(42)* and *(43)* are obtained.

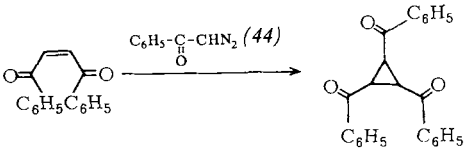


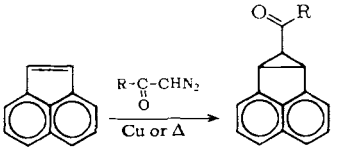
(42)



(43)

Similar results are obtained with diazoacetophenone *(44)* and similar compounds [25, 26].





If the diazoketone itself contains a double bond, the thermally, photolytically, or catalytically (Cu) formed ketocarbene undergoes double ring closure. It is

(45)

3. Cyclopropylcarbonyl Compounds by Ring Contraction

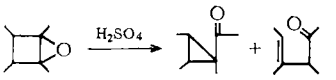
The three other methods for the synthesis of cyclopropylcarbonyl compounds, as well as the reaction with Simmons reagent, have been investigated particularly thoroughly in our laboratories.

Two of these methods use four-membered carbocyclic starting materials. These are the rearrangement of 1,2-epoxycyclobutane derivatives by acids or by heat to form cyclopropyl ketones or cyclopropyl aldehydes and the rearrangement of bromocyclobutanones by nucleophilic reagents or by water into cyclopropylcarbonyl compounds such as acids, esters, and amides, which can subsequently be converted into aldehydes and ketones. However, these two rearrangements are suitable only in exceptional cases for the preparative synthesis of cyclopropylcarbonyl compounds, since it is first necessary to prepare the cyclobutane derivatives. On the other hand, the dehalogenation of α,α-bis-(bromomethyl)cycloalkanones by zinc, which leads to spirocyclopropyl ketones (Section 4), and the reaction of Simmons reagent with α,β-unsaturated ketones (Section 2.1) are of preparative interest.

3.1. Ring Contraction of 1,2-Epoxycyclobutane Derivatives

Unlike the 1,2-epoxycyclohexanes, 1,2-epoxycyclopentanes exhibit no ring contraction reactions. However, 1,2-epoxycyclobutanes react differently: the action of sulfuric acid on 1,2,3,4-tetramethyl-1,2-epoxycyclobutane *(46)* leads to 1,2,3-trimethylcyclopropyl methyl ketone (ring contraction) and to the open-chain 3,4-dimethyl-4-hexen-2-one [28].

Substituted 1,2-epoxycyclobutanes, which are readily obtainable by the action of perbenzoic acid on the corresponding cyclobutenes, rearrange to give cyclo-

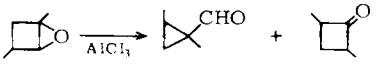


(46)

propylcarbonyl compounds. The ring contraction product predominates in the presence of protonic acids, whereas Lewis acids such as $AlCl_3$ lead to the formation of greater quantities of the unrearranged product, *i.e.* a substituted cyclobutanone [29].

In media containing sulfuric acid, 1,2-epoxycyclobutane, 1-methyl-1,2-epoxycyclobutane, and 1,2-dimethyl-1,2-epoxycyclobutane give only the ring-contraction products cyclopropanecarbaldehyde, 1-methylcyclopropanecarbaldehyde, and 1-methylcyclopropyl methyl ketone in yields of about 70 %, whereas in the presence of $AlCl_3$, the first epoxide gives 5 % of cyclobutanone and the second gives 30 % of 2-methylcyclobutanone.

In the case of more highly substituted epoxides, the nature of the acid has no influence, and mixtures of products of both types are obtained. Moreover, these epoxides rearrange even at room temperature and in neutral media. On the other hand, in the presence of $AlCl_3$, the epoxide *(47)* gives up to 70 % of 2,4-dimethylcyclobutanone (overall yield 70 %), which in our experience is one of the most difficult methylcyclobutanones to prepare.



(47) 15% *cis* 15% *trans* 70% *cis* + *trans*

3.2. Ring Contraction of 2-Bromocyclobutanones

This very easy rearrangement, which can be initiated even by water, and which gives good yields of ring contraction products, has been the subject of a series of publications (cf. *e.g.* Parts 5, 6, 8, and 9 in the series "Investigation of Small Rings" [30]) (see Table 1). At least the rearrangements of this type that begin with a nucleophilic attack proceed by a mechanism similar to that of the semibenzilic acid rearrangement [30d, 31].

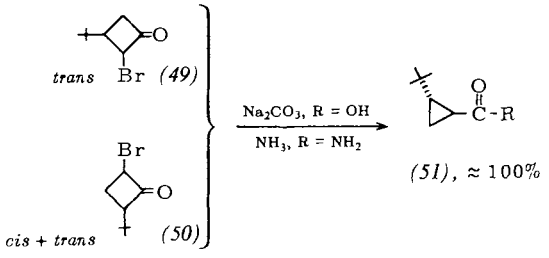
[30] a) *J. M. Conia* and *J. L. Ripoll*, Bull. Soc. chim. France *1963*, 755; b) *ibid. 1963*, 763; c) *ibid. 1963*, 773; d) *J. M. Conia* and *J. Salaün*, *ibid. 1964*, 1957.

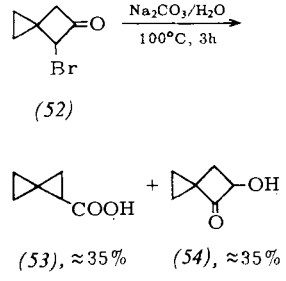
[31] *C. Rappe* and *L. Kunntsson*, Acta chem. scand. *21*, 163 (1967).

The exact function of the nucleophilic agent is unknown. Secondary amines, alkali metal phenoxides, and sodium acetate, which are all weak nucleophiles, give the substitution product [30a].

This rearrangement provides a route to particular cyclopropylcarbonyl compounds. For instance, we have been able to prepare some strongly sterically hindered cyclobutanones by this method. The 2-brominated 2-*tert*-butylcyclobutanones give no ring contraction, whereas other derivatives, such as *trans*-2-bromo-3-*tert*-butylcyclobutanone *(49)* and *cis*- and *trans*-2-bromo-4-*tert*-butylcyclobutanone *(50)* give the *trans* isomer of the ring contraction product *(51)* in almost quantitative yield from aqueous sodium carbonate solution or liquid ammonia [32].

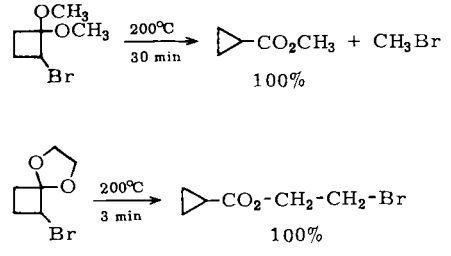


A similar ring contraction is also possible in some spirocyclobutanones. The brominated spirohexanone *(52)* can be converted into the acid *(53)* with a smaller ring and an isomerized substitution product *(54)* by the action of aqueous sodium carbonate [33].

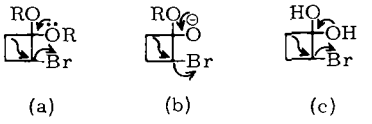


3.3. Ring Contraction of 2-Bromocyclobutanone Acetals [*]

A third method for the contraction of a four-membered ring has recently become known [32]: 2-Bromocyclobutanone acetals, which are readily prepared by the action of bromine on cyclobutanone in alcoholic solution, are converted quantitatively into cyclopropanecarboxylates on heating.

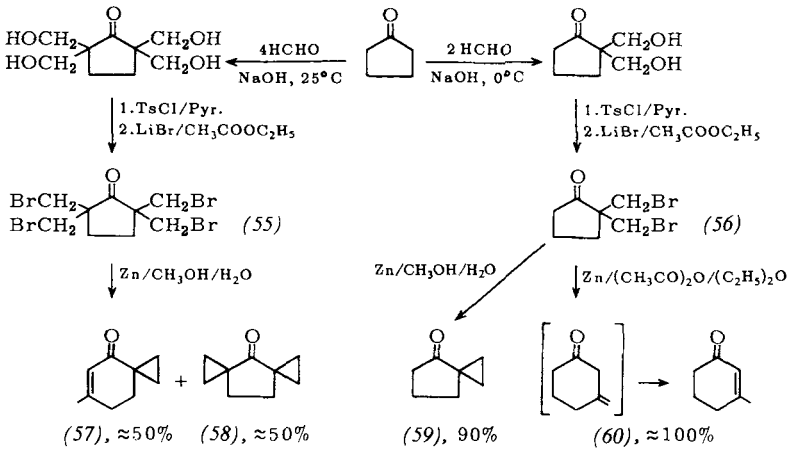


The mechanism (a) for this thermal rearrangement is probably similar to that which was shown [30d] to apply for ring contraction of 2-bromocyclobutanones in basic medium (b) (with RO^-) or in water alone (c).



4. Dehalogenation of α,α-Bis(bromomethyl)cycloalkanones

The dehalogenation of α,α-bis(bromomethyl)cycloalkanones (which are readily obtainable by the aldol condensation of cycloalkanones with formaldehyde) with the aid of zinc is another route to cyclopropyl ketones, or rather to spirocyclopropyl ketones. The solvent influences this reaction in a manner that cannot yet be explained. The normal ring closure to give the cyclopropane derivative and ring expansion, two reactions that are themselves interesting, also occur [34].



Thus 2,2-bis(bromomethyl)cyclopentanone *(56)* is quantitatively converted into the rearranged 3-methyl-2-cyclohexen-1-one *(60)* by zinc in acetic anhydride, whereas reduction in aqueous methanol leads almost exclusively by normal ring closure to the spiro ketone *(59)*. In aqueous methanol, 2,2,5,5-tetrakis(bromomethyl)cyclopentanone *(55)* gives the monospiro ketone *(57)* and the dispiro ketone *(58)*.

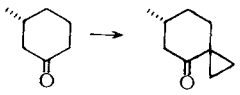
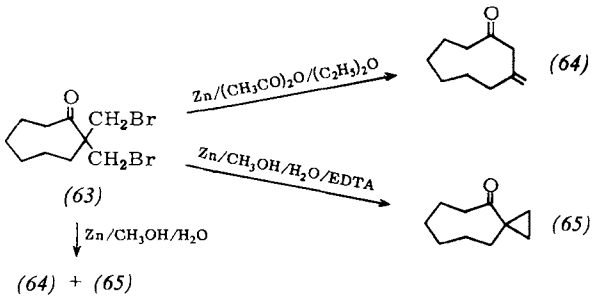
[37] *J. M. Conia*, Record chem. Progr. *24*, 43 (1963).

(−)-6-Methylspiro[2.5]octan-4-one *(62)* is obtained by a similar synthesis from (+)-3-methylcyclohexanone *(61)* [34]. Compound *(62)* is the first cyclopropyl ketone whose absolute configuration has been determined. Its Cotton effect does not correspond to the predictions of the octant rule.



(61) *(62)*

No ring expansion takes place on dehalogenation of 2,2-bis(bromomethyl)cyclohexanone with zinc; the spiro ketone is formed quantitatively in aqueous methanol after a normal ring closure. The higher cycloalkanone derivatives exhibit both reactions. 2,2-Bis(bromomethyl)cyclooctanone *(63)* is particularly interesting in this respect, since it can be reduced to



(63) *(64)* *(65)* *(64)* + *(65)*

the ring expansion product *(64)* in acetic anhydride/ether, to a mixture of *(64)* and the normal ring closure product *(65)* in aqueous methanol, or exclusively to the ketone *(65)* in aqueous methanol in the presence of ethylenediaminetetraacetic acid.

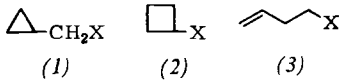
Recent Developments in the Stereochemistry of Cyclopropane Ring Opening [**]

BY S. SAREL, J. YOVELL, AND M. SAREL-IMBER [*]

This review article deals with the stereochemistry of the following ring opening reactions: 1. Homoallylic rearrangement of secondary and tertiary cyclopropyl alcohols in the presence of electrophilic reagents, 2. The addition of carboxylic acids to vinylcyclopropanes, 3. The thermal rearrangement of vinylcyclopropanes into cyclopentenes. An account is also given of the NMR spectroscopic determination of the conformations of substituted vinylcyclopropanes.

1. Introduction

The most striking feature of chloromethylcyclopropane is its enhanced reactivity in solvolytic S_N1 reactions that lead to the formation of cyclopropylmethyl *(1)*, cyclobutyl *(2)* (ring-expansion), and 3-butenyl *(3)* (ring-opening) compounds [1]. *Roberts* and his co-workers have formulated the carbonium ion intermediates which occur in the anionotropic interconversion of derivatives of *(1)*, *(2)*, and *(3)* as non-classical unsymmetrical "bicyclobutonium ion" intermediates [2]. More recently, *Schleyer* has presented evidence favoring the symmetrical "bi-sected" intermediates [3] put forward earlier by the other school [4–6].



(1) *(2)* *(3)*

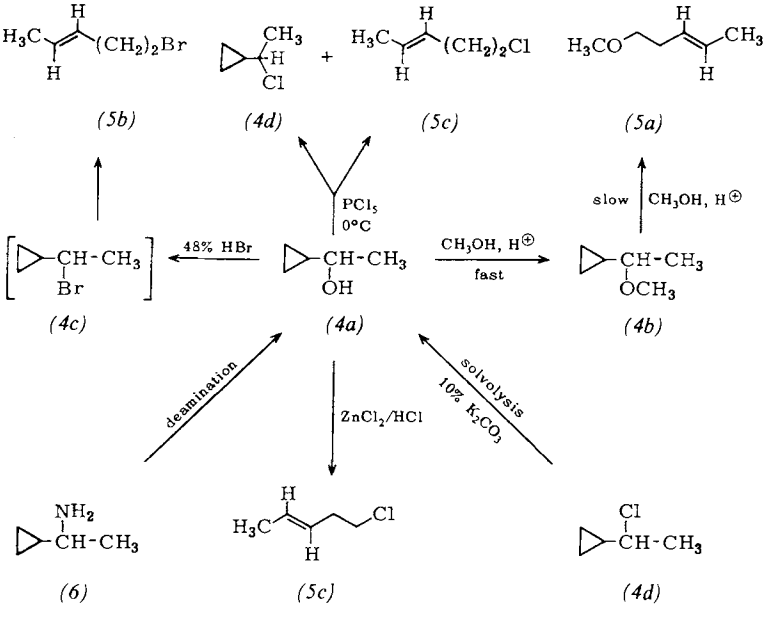
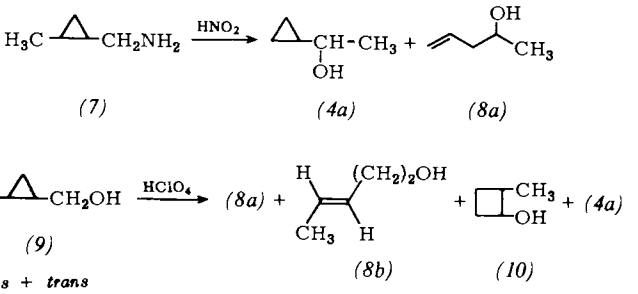
fied by several groups[8], manifests significant differences with regard to rates and products relative to the above solvolytic and deamination reactions.

These are illustrated by the cases of 1-chloro-1-cyclopropylethane *(4d)*, (1-cyclopropylethyl)amine *(6)*, and 1-cyclopropylethanol *(4a)*. When the optically active enantiomer of *(6)* is deaminated[9] or *(4d)* is solvolyzed[10], the alcohol formed in both cases is the same racemic alcohol *(4a)* but not the homoallyl alcohol corresponding to *(5a)*. Furthermore, the acid catalyzed exchange of *(4a)* with $H_2{}^{18}O$ occurs without rearrangement[11]. In contrast, when *(4a)* is treated with methanolic HCl, the methyl ether *(4b)* is formed



trans-(2-methylcyclopropyl)methanol *(9)*. When this compound is treated with 1 N aqueous perchloric acid, the reaction products are mixtures composed of homo-



rapidly but the final product is the open-chain compound of the *trans* structure *(5a)*[12]. Likewise, the final product in treatment of *(4a)* with 48%-HBr is the *trans* compound *(5b)*[13], which could similarly be formed *via (4c)* (not observed). On the other hand, when *(4a)* is treated with PCl_5, a mixture of 88% *(4d)* and 12% *(5c)* is obtained[10].

The reaction product from the deamination of 1-aminomethyl-2-methylcyclopropane *(7)* is a mixture of alcohols, of the cyclopropylmethyl- *(4a)* and the homoallyl-structures *(8)*[14], but not of the cyclobutyl derivative *(10)*. A more complicated situation is found in the acid-promoted rearrangement of the *cis*- and allyl alcohols (predominant) *(8a)* and *(8b)*, 2-methylcyclobutanol *(10)*, and 1-cyclopropylethanol *(4a)*[15]. Although homoallyl alcohols are known to give rise to cyclobutyl derivatives on treatment with strong acids[16], this type of rearrangement has not previously been encountered in the acid-promoted rearrangement of secondary and tertiary cyclopropyl alcohols, or in the solvolysis of tertiary cyclopropylmethyl sulfonates[17].

2. Acid-Promoted Homoallylic Rearrangement of Secondary Cyclopropyl Alcohols

The homoallylic rearrangement of branched cyclopropyl alcohols of structures *(11)* and *(12)* can be effected by a large variety of protonic acids (48%-HBr, HCl, $HCl/ZnCl_2$, $HClO_4$, H_2SO_4, HCOOH, and CH_3COOH), acid chlorides (PX_3, PX_5, $SOCl_2$, and CH_3COCl), and acid anhydrides (acetic and trifluoro-

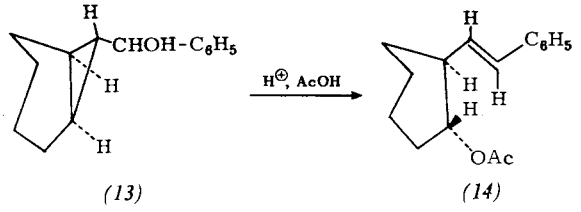
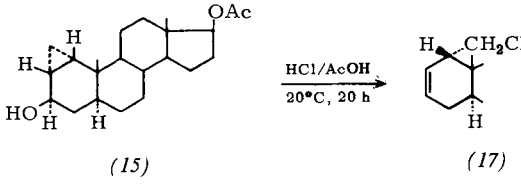
(12)

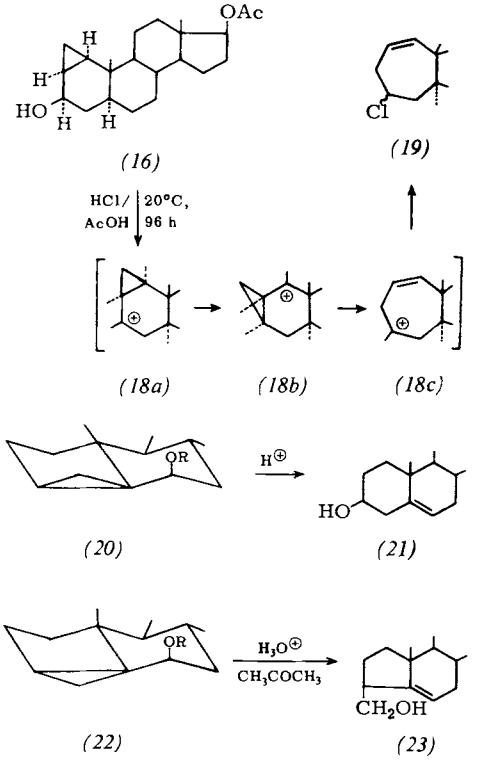
The stereochemistry at the double bond in the rearrangement products of *(11)* has not been thoroughly studied; however, there is sufficient evidence to conclude that small-ring opening and product formation occur in a stereoselective manner, giving rise to the formation of the *trans* isomer as main product. This is illustrated by the reactions *(13)*→*(14)*, *(15)*→*(17)*, *(16)*→*(19)*, *(20)*→*(21)*, and *(22)*→*(23)*.



(13) *(14)*



(15) *(17)*



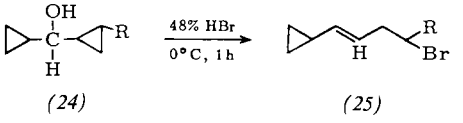
(16) *(19)* *(18a)* *(18b)* *(18c)* *(20)* *(21)* *(22)* *(23)*

An example of the type of stereochemical situation found in this series of rearrangements, is afforded by (bicyclo[4.1.0]hept-7-yl)benzyl alcohol *(13)*. Treatment of this compound with mineral acid in acetic acid leads to the formation of *trans*-2-(*trans*-styryl)cyclohexyl acetate *(14)* [18]. From product study it is apparent that the substituted C atom of the small ring retains its configuration in the process of ring fission and double-bond formation, whereas the bridgehead carbon atom undergoes inversion upon attack by the acetate ion.

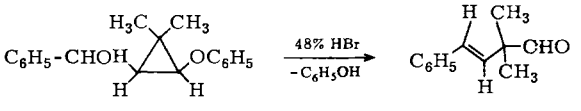
Of particular interest is the effect of the configuration of the bicyclo[4.1.0]heptyl system on the course of the rearrangement. If 1α,2α-methylene-3β-hydroxy-17β-acetoxy-5α-androstane *(15)*, in which the fused ring system of the bicyclo[4.1.0]heptyl grouping is more rigid, is treated with a saturated solution of HCl in glacial acetic acid, only compound *(17)* is formed. The rearrangement of the 1β,2β-methylene compound *(16)*, in which a *cis* relationship of the hydrogens on C-2 and C-3 results in a much less rigid conformation of the fused ring system, is slow and gives rise to formation of the seven-membered ring compound *(19)*.

The reaction is interpreted as proceeding *via* several classical homoallylic carbonium ions [*(18a)*→*(18b)*→*(18c)*→*(19)*] [19]. Similar positional effects have been observed in the steroidal fused-ring system of the bicyclo[3.1.0]hexane type. The 6α- or 6β-alkyloxy derivatives of 3α,5α-cyclocholestane *(20)* are known to yield cholesterol *(21)* [20]; under the same conditions 3β,5β-cyclo-6β-alkyloxycholestane *(22)* yields the A-nor β,γ-unsaturated primary alcohol *(23)* [21].

In the acid-catalyzed rearrangement of simple substituted dicyclopropylmethanols, the *trans* isomer again predominates in the product. Compound *(24)* (R = CH_3) gives *(25)* (R = CH_3) [17c]. In cyclopropylmethyl compounds of structure *(26)*, which carry a phenoxyl and a *gem*-dimethyl group on the cyclopropane ring, the bond opposite to the *gem*-dimethyl group is cleaved, and the *trans* isomer again predominates in the product *(27)* [22].



(24) *(25)*



(26) *(27)*

The stereochemistry of the rearrangement, however, is not determined by inductive effects alone; the acid strength and the reaction medium also play a major role in deciding the course of reaction. For example,

[18] *P. Besinet, R. Fraisse, R. Jacquier*, and *P. Viallefont*, Bull. Soc. chim. France *1960*, 1377.

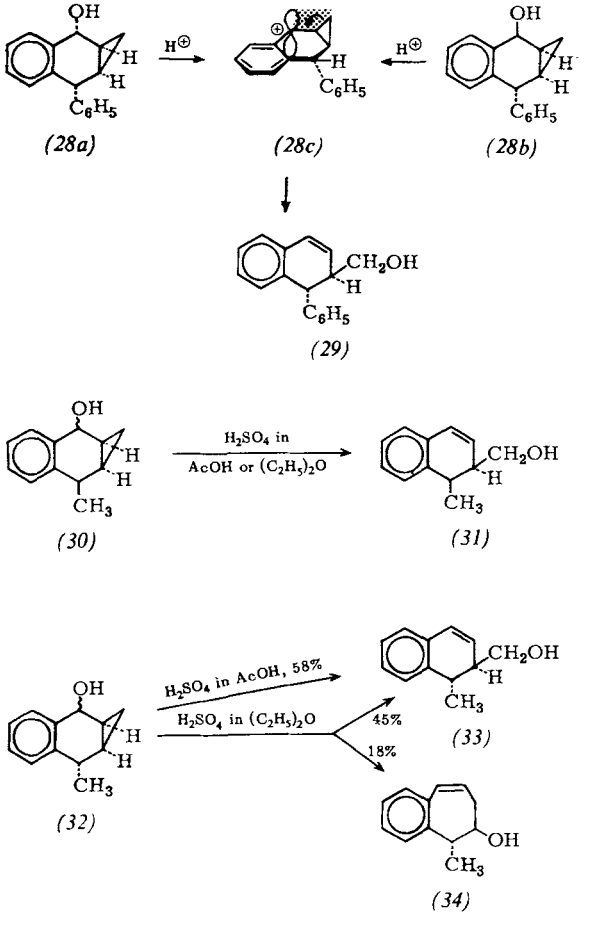
[21] *W. G. Dauben* and *J. A. Ross*, J. Amer. chem. Soc. *81*, 6522 (1959); see also, *N. L. Wendler* in *P. de Mayo*: Molecular Rearrangements. Interscience, New York 1963, Vol. II, p. 1075.

[22] *M. Julia* and *M. Baillarge*, Bull. Soc. chim. France *1966*, 734; *M. Julia et al., ibid. 1966*, 717, 732, 743.

the epimeric alcohols *(28a)* and *(28b)*, on treatment with acid, rearrange to the same alcohol *(29)*. Likewise, compound *(30)* gives preponderance to the analogous product *(31)* upon acid treatment in acetic acid or ether. However, the isomeric compound *(32)* on similar treatment in ether gives 1,2-dihydronaphthylmethanol *(33)* (45 %) and the 6,7-dihydro-5*H*-benzocycloheptyl derivative *(34)* (18 %) [13]. Apparently, the stereochemistry of the ring-opening in the conversion *(30)* → *(31)* is governed mainly by conjugative interactions of the type represented by formula *(28c)*, whereas in the conversion of *(32)* → *(33)* + *(34)* the solvent (ether) exerts influence on the mode of ring opening by diminishing the difference in energy between the respective modes [23].



Of particular interest is the case of compound *(35a)*, which on treatment with 48 %-HBr, affords *(37a)* and not *(38a)* as implied from the inductive effect. However, in less stringent acidic conditions, such as 3.6 N H_2SO_4 in acetic acid, or even in sodium acetate/acetic acid, compounds *(37a)* and *(35b)* give rise to *(38b)* [24]. The ready rearrangement of *(37b)*, and the fact that cyclobutyl derivatives are not observed in the products, suggest that the rearrangement *(35)* → *(38)* may involve the non-classical carbonium ion *(36)*.

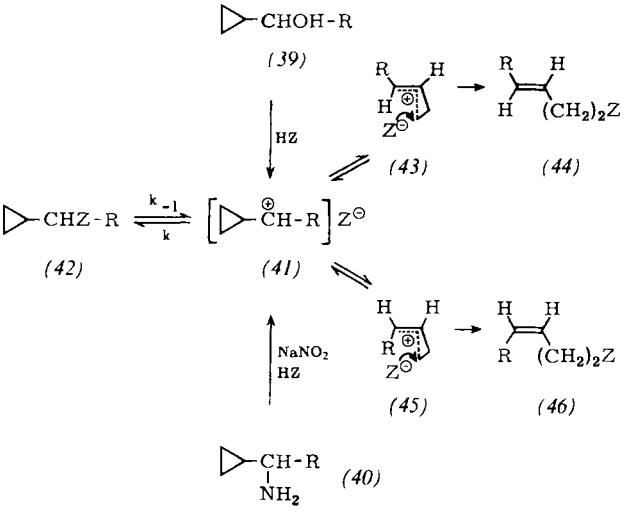
(38b), X = R = OAc

The rearranged product from the acid and the phosphorus halide treatment of secondary cyclopropyl alcohol *(39)*, as well as the formation of compounds *(44)* and *(46)* from the deamination of dicyclopropylmethylamine *(40)*, R = cyclopropyl, can be explained in terms of initial formation of several isomeric carbonium-ion intermediates *(41)*, *(43)*, and *(45)*.



The rearrangement of *(39)* and *(40)* depends largely on the equilibrium *(42)* ⇄ *(41)*. If $k \gg k_{-1}$, cyclopropylmethyl compounds of structure *(42)* accumulate in the reacting system. If $k < k_{-1}$, the allyl compounds *(44)* and *(46)* are formed by way of the carbonium ions *(43)* and *(45)*. The preponderance of the *trans* isomer *(44)* in the rearrangement products can be best explained by the relative abundance of the low energy conformer *(43)*.

In this connection, the rearrangement of arylcyclopropylmethyloxyborane *(47)* and of bis(cyclopropylbenzoxy)borane *(49)* may be considered. When treated with BF_3-ether at 0 °C for a short time, compound *(47)* invariably gives *(48)* [25],

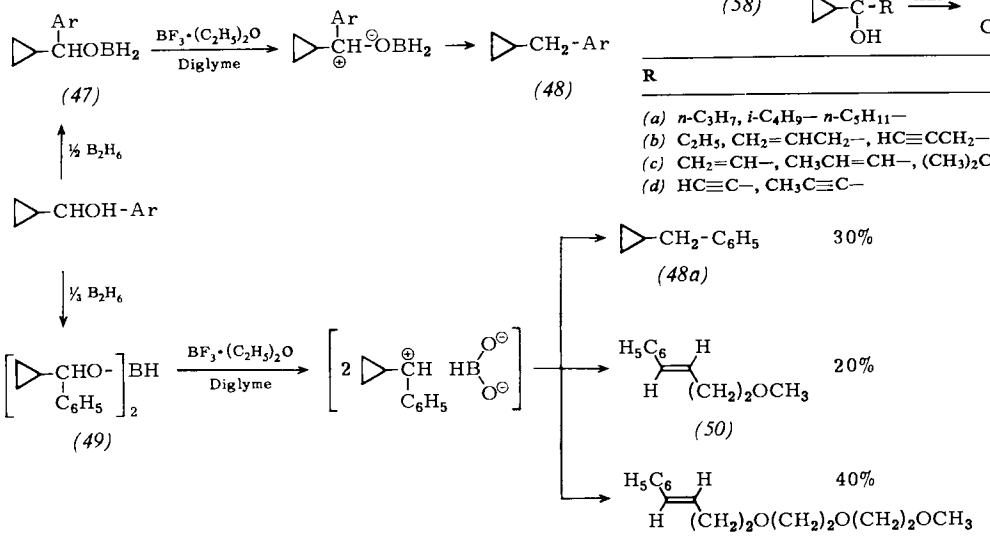
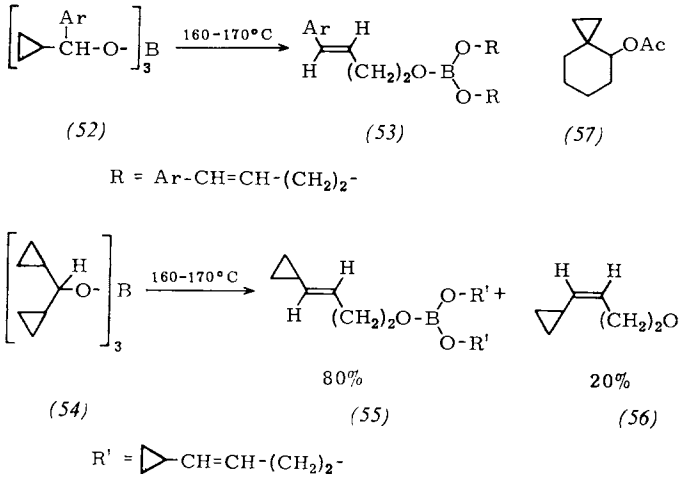
whereas *(49)* gives a mixture of *(48a)* and the open-chain compounds *(50)* and *(51)* [26]. In the presence of an excess of diborane the compounds of type *(41)* lead predominantly to a hydrogenolysis product [*(48)* or *(48a)* ≡ *(42)*, Z = H, R = Ar or C_6H_5]. In the presence of deficient amounts of diborane, the interconversion *(41)* ⇄ *(43)* is followed by an attack of the solvent (diglyme) to yield open-chain compounds [*(50)* and *(51)* ≡ *(44)*, R = C_6H_5, Z = OCH_3 or $OCH_2OCH_2OCH_3$].



At elevated temperatures, the organoborates *(52)* and *(54)* rearrange to the respective homoallyl derivatives *(53)* or *(55)* and *(56)* [27]. The thermal rearrangement shows solvent dependence. After one hour, the conversion in diglyme is 90%, in the less polar *o*-dichlorobenzene 50%, and negligible in the least polar solvent, decalin. In *o*-dichlorobenzene the conversion is complete after 4 hours [28].



That the observed ratio of *(55)*:*(56)* amounts to 4:1 is attributed to a change in the relative abundance of the preferred conformations *(43)* and *(45)* as a result of temperature increase (cf. [17c]). Recently, *Hanack* and co-workers suggested that the rearrangements during pyrolysis of *(57)* proceed *via* an ionic mechanism [29].

formed, the rearrangement of tertiary cyclopropyl alcohols leads to the formation of several isomeric products (see Tables 1–3). In the rearrangement of compound *(58)* under the influence of hydrobromic acid (Table 1), the *cis*:*trans* distribution of products varies rather dramatically on passing from a sp-

hybridized C-atom attached to the carbinol carbon atom *(58d)*, to a trigonal C-atom *(58c)*. This variation is much less pronounced on passing to a tetrahedral C-atom[*(58b–58a)*] [30]. A similar tendency is observed in the dicyclopropyl alcohols (Table 2). The *trans* isomer predominates in the products from the rearrangement of *(58c)*, whereas in the products from *(59b)* the *cis* isomer predominates. The explanation conceivably rests in the conformational preference of the cyclopropane rings in the carbonium ion species *(60-I)*, *(60-II)*, and *(60-III)*.

(60-I) *(60-II)* *(60-III)*

↓ ↓ ↓

cis *cis + trans* *trans*

The relative abundance of conformer *(60-III)* increases with increasing size of R, because of the nonbonded interactions between the cyclopropane and the methyl hydrogens of R.

The preferred formation of the *cis* isomer in the rearrangements of arylcyclopropylmethyl alcohols (Table 3), suggests that the *(61-I)* conformer dominates the

ionic population in the assumed intermediate. Examination of models reveals that the aromatic nucleus in *(61-I)* can, indeed, comfortably assume coplanarity with the sp^2 C atom, the result being a gain in resonance energy; this is not the case so far as the *(61-II)*

(61-I) *(61-II)*

conformer is concerned. On replacement of the methyl group by an isopropyl group, however, the converse is true, presumably because the loss in energy due to the increased nonbonded interactions between the cyclopropane and the isopropyl hydrogens outweighs the loss in resonance energy.

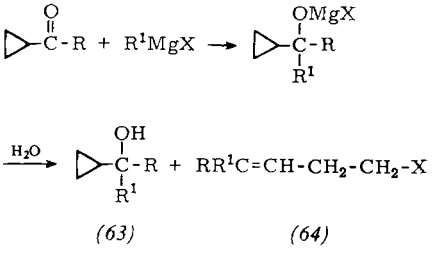
4. Homoallylic Rearrangement of Cyclopropylmethoxymagnesium Halides

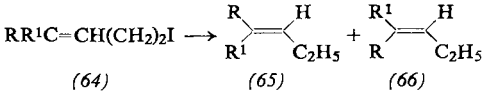
In our laboratory *Yovell*[32] observed that the addition of dicyclopropyl ketone to an excess of alkylmagnesium iodide in boiling ether gives rise to homoallylic products *(64)*, in addition to the desired alcohol *(63)*.



(63) *(64)*

The yield of *(64)* depends on the nature of the halogen and on the reaction conditions, and increases with increase in concentration of the organomagnesium halide, and with increase in temperature. The effect of the halogen on the yield of *(64)* increases in the order $Cl < Br \ll I$ [35].

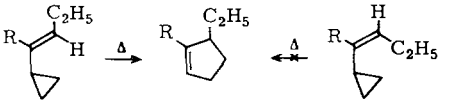
The homoallylic products *(64)* proved to be mixtures of stereoisomers. The respective parent compounds *(65)* and *(66)* were obtained by reduction with $LiAlH_4$ followed by preparative vapor-phase chromatography.



(64) *(65)* *(66)*

Structure determinations were based on spectroscopic, particularly NMR, findings; these will be discussed in Section 6.

The structure of the vinylcyclopropane derivatives *(67)* and *(68)* is derived from the difference observed in the ability of the isomeric pair to undergo thermal isomerization into cyclopentene: the *cis* structure was



(67) *(69)* *(68)*

assigned to the isomer undergoing complete conversion into cyclopentene at 380–390 °C *(67)*→*(69)*, and the *trans* structure to the isomer that is stable in this temperature range.

The similar *cis-trans* distribution among the homoallylic compounds, whether derived from cyclopropyl alcohols and acetic acid (see Tables 2 and 3) or from cyclopropylmethoxymagnesium iodide (see Table 4), indicates that similar conformational factors determine the stereochemistry of the cyclopropane ring-opening in both reactions.

The homoallylic rearrangement of dicyclopropylmethoxymagnesium iodides could proceed by an ionic type mechanism in which ring-opening results from attack by iodide ion on the non-classical symmetrical homoallylic ion, represented by the three limiting conformations, *(60-I)*, *(60-II)*, and

[35] *S. Sarel, J. Yovell*, and *M. Sarel-Imber*, Israel J. Chem. *4*, 21p (1966).

Table 4. Distribution of isomers in the homoallylic rearrangement of cyclopropylmethyloxymagnesium iodide.

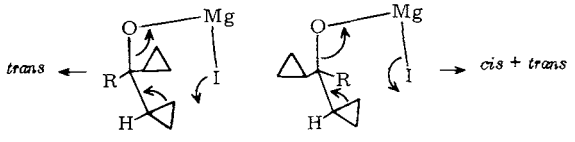
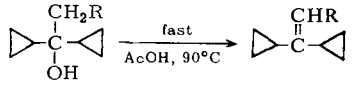
(60-III). Alternatively, the reaction could be envisioned as involving a cyclic "transition-state"[36], represented by two limiting antipode conformations *(70)* and *(71)*. Conformation *(70)* seems more crowded than *(71)*. To explain the effect of branching of R on *cis-trans* distribution in the products, the same stereochemical considerations should apply for either type of mechanism.



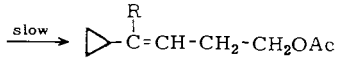
(70) *(71)*

5. Addition of Carboxylic Acid to Vinylcyclopropane

The acetic-acid promoted rearrangement of cyclopropyl alcohols of structures *(72)* and *(75)* is in fact a multireaction process[32,33,37,38] proceeding by way of elimination[37] followed by 1,5 addition[38] with simultaneous ring-opening.



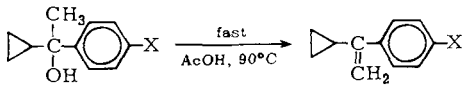
(72) *(73)*



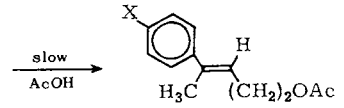
cis + trans (74)

By means of vapor-phase chromatography it can be shown that at the beginning there is a fast buildup of *(73)* or *(76)*, which is subsequently slowly converted into *(74)* (*cis* and *trans*) or *(77)* (*trans* only). The rate of dehydration and addition reactions decreases in the order *(75a)*→*(76a)* > *(72a)*→*(73a)* > *(72b)*→*(73b)* > *(75c)*→*(76c)* > *(75d)*→*(76d)*.

When the vinylcyclopropanes *(73)* and *(76)* are treated with acetic acid, the products are precisely the same as those obtained in the rearrangements of *(72)* (Table 2) and *(75)* (Table 3), respectively.



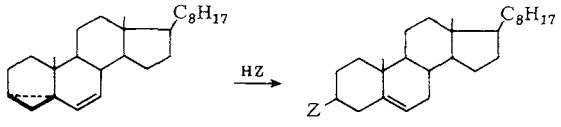
(75) *(76)*



(77)

(72a)–(74a), R = H; *(72b)–(74b)*, R = C_2H_5; *(75a)–(77a)*, X = OCH_3; *(75b)–(77b)*, X = CH_3; *(75c)–(77c)*, X = H; *(75d)–(77d)*, X = Cl.

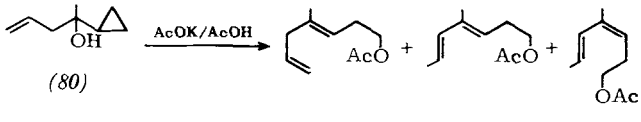
Riegel and co-workers have recently reported on this type of addition to the vinylcyclopropane system of 3,5-cyclocholest-6-ene *(78)* to *(79)*[39]. Conjugative additions of HCl to the vinylcyclopropane system in α- and β-cubebene also proceed according to the same scheme[40].



(78) *(79)*

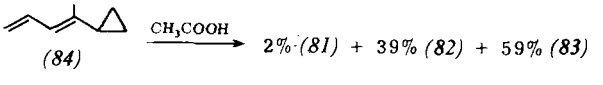
Z = OAc, CH_3O, OH, Cl, Br, I

That the homoallylic rearrangement of 1-cyclopropyl-1-methyl-3-buten-1-ol *(80)* can proceed by the above dehydration-addition path has been observed by *Julia et al.*[30]. If compound *(80)* is treated with potassium acetate in acetic acid, a mixture of open-chain acetates, consisting chiefly of *(82)* and *(83)*, is obtained. A similar mixture is formed when compound *(84)* is treated with acetic acid.



(80)

(81)	*(82)*	*(83)*
16%	30%	54%



(84)

The notable difference in the amount of *(81)* obtained by reaction of *(80)* relative to that obtained by reaction of *(84)* can be attributed to two possible modes of dehydrations in *(80)*: the one, leading to *(84)*, gives almost exclusively *(82)* and *(83)*, whereas the other, which yields 2-cyclopropyl-1,4-pentadiene, is likely to give *(81)*.

The ring-opening in the rearrangements of *(85)* into *(86)*[41], and of *(87)* into *(88)*[42], can be considered to involve the addition of HBr across the vinylcyclopropane moiety at some stage of the reaction.

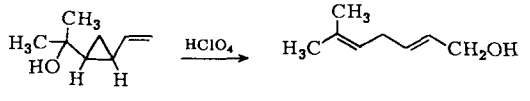
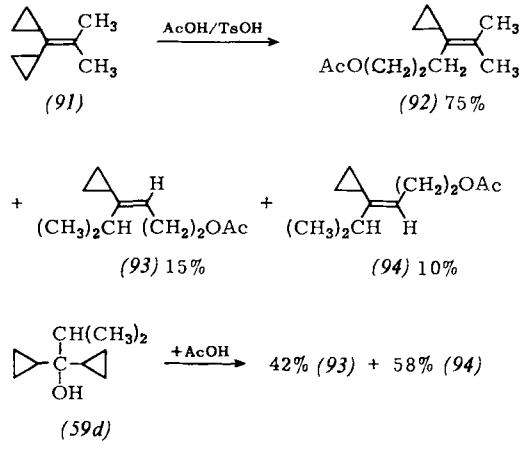
Compound *(89)* is worthy of note as another example showing that substituents and reaction conditions play a major role in deciding the course of the reaction. When this compound is treated with $HClO_4$, the product is the open-chain primary alcohol *(90)* [43].



(89) *(90)*

The replacement of both olefinic protons in 1,1-dicyclopropylethylene, by methyl groups precludes the addition of acetic acid across the vinylcyclopropane system in *(91)*. However, in the presence of catalytic amounts of toluenesulfonic acid, a mixture of adducts



(91) *(92)* 75%

(93) 15% *(94)* 10%

(59d)

is obtained, which consists chiefly of *(92)*. The stereoisomers *(93)* and *(94)*, which are the only products from the rearrangement reaction of *(59d)*, are minor products in the catalyzed reaction. The proportion of *(92)*:*(93)*:*(94)* constitutes an equilibrium mixture [31]. Finally, it would be instructive to outline the stereochemical consequences of the mechanisms in addition reactions of the vinylcyclopropane systems.

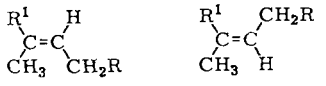
Scheme 1

The addition reactions are stereoselective, whether they proceed *via* the carbonium ion, or *via* the carbanion. Neither of the two routes yields the cyclobutyl derivative.

6. Conformations of Substituted Vinylcyclopropanes

In the ^1H–NMR spectra of the stereoisomers *(67)* and *(68)*, the allylic methyl protons of the *cis* compound are shifted downfield relative to those of the *trans* isomer [32,46]. This is contrary to the prevailing view that the signals of the allylic methyl protons in the *cis* compound *(95)* appear at higher fields than those in the *trans* isomer *(96)* [30b,47].



(95) *(96)*

This apparent contradiction is explained in terms of variations in conformational preference of the cyclopropane ring in the two isomers.

Conflicting evidence has been presented as to whether the barrier to internal rotation in vinylcyclopropane is twofold or threefold in form [48–51]. Two limiting

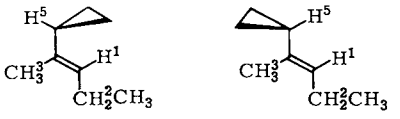
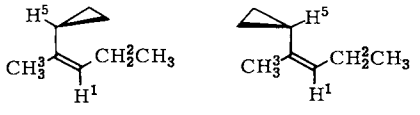
[51] *G. R. DeMare* and *J. S. Martin*, J. Amer. chem. Soc. *88*, 5033 (1966).

conformations are envisioned for each of the isomers – a *cisoid* conformation *(97-I)* and *(98-I)*, and a *transoid* conformation *(97-II)* and *(98-II)* (the *S-trans* form [50]) in which the dihedral angle relating H^5 and the CH_3–C bond is 180 °.



(97-I) *(97-II)*



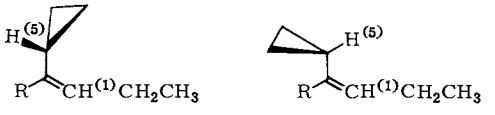
(98-I) *(98-II)*

In the case of the *cis* isomer, conformation *(97-I)*, rather than *(97-II)*, is preferred since there is less interaction between the methyl group and the cyclopropane ring. In the *trans* isomer, however, the greater interaction between the ethyl group and the cyclopropane ring renders the *transoid* conformation *(98-II)* more favorable than the *cisoid (98-I)*. On the basis of *Walsh*'s hypothesis [52], *(97-I)* and *(98-I)* should correspond to the low-energy conformation if the steric effects are negligible. The magnetic susceptibility of the cyclopropane ring [53] implies that the signals ascribable to the allylic methyl protons (H^3) in the *cisoid* conformation should be shifted downfield and that the corresponding protons in the *transoid* conformation, because of their proximity to the threefold axis of the cyclopropane ring, should be strongly shielded. These protons, conceivably, lie closer to the plane [4, 54]. As is to be expected the signal of the olefinic proton (H^1) in the *cisoid* conformation *(97-I)* and *(98-I)* appears upfield relative to the signal of the corresponding olefinic proton in the *transoid* conformation *(97-II)* and *(98-II)*. This suggests that the preferred conformer in the *cis* isomer is *(97-I)* and that in the *trans* isomer is *(98-II)*.

The ratio of the high-energy conformers (A) to low-energy conformers (B) in *cis*- and *trans*-2-cyclopropylpent-2-ene *(99)* [R = CH_3; X = H] was determined by the method of *DeMare* and *Martin* [51]. By plotting the values of δ_H1/δ_H3 against temperature changes, a slope of −0.210 is obtained. This permits the calculation of the dihedral angle between the cyclopropane-methine-hydrogen (H^5) and the CH_3–C=C bond, from the relative magnitudes of the H^3 and H^1 shielding shifts, $\Delta\delta_H3/\Delta\delta_H1$, by use of the point-dipole ring-current approximation method [54]. The upper-state dihedral angle in (A) is found to be 73 °, which is close to the value (79 ° in CCl_4) reported by *DeMare* and *Martin*, for the unsubstituted vinylcyclopropane [50, 55]. (These compare to electron-diffraction values of *ca.* 40 ° for bicyclopropyl [50b] and 0 ° (the *S-cis* form) for cyclopropylaldehyde [48a].) In view of this similarity, it is assumed that no significant variation in the dihedral angles of the high energy conformer (A) should occur as a result of branching of the saturated C atom in C–C=C, adjacent to the cyclopropane.

The A:B ratios in a series of substituted vinylcyclopropanes of the structure *(99)* have been estimated by two different approaches: (1) by the modified point-dipole approximation (MPDA) [54] and (2) by the ring-current model [53]. From the data assembled in Table 5, it can be seen that the values obtained by the MPDA method are in striking agreement with those derived from the ring-current model when the relevant molecular and electronic parameters are: A = 0.88 Å, N = 6 electrons, and/or A = 1.01 Å, N = 4.5 electrons.

Table 5. Ratio of the conformations A:B in substituted vinylcyclopropanes *(99)* at room temperature (see also Fig. 1).



A B

Method	R = CH_3		R = n-C_3H_7		R = $(CH_3)_2CH$	
	cis	*trans*	*cis*	*trans*	*cis*	*trans*
Modified point-dipole approximation (*McConnell*)	76:24	53:47	97:3	87:13	100:0	100:0
Ring-current model						
(A = 0.88 Å, N = 6)	76:24	53:47	100:0	96:4	100:0	100:0
(A = 1.01 Å, N = 4.5)	75:25	52:48	100:0	95:5	100:0	100:0

The decrease of *S-trans* in the conformational population with increasing branching of R provides in essence a measure for the hindrance to free rotation of the cyclopropane exerted by the neighboring bulky substituents. This compares to a substitution effect in 2-substituted 1,3-butadienes, in which a bulky group R displaces the conformational equilibrium *S-cis* ⇄ *S-trans* in favor of the strainless *S-cis* conformation [56].

Interscience, New York 1966, p. 21.

It also provides a sensible explanation for the observed increase in $\delta_{trans}-\delta_{cis}$ values for the H^1 and H^2 protons in *(99)* with increasing branching of R (Table 6). Furthermore, this substantiates the view put forward earlier for the directive influence exerted by substituents in *(59)* on the steric course of cyclopropane ring-opening (Table 2).

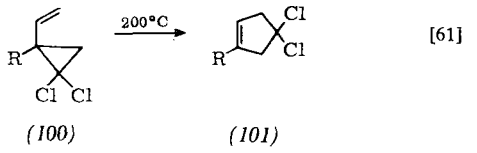
	i-C_3H_7	OAc	18.6	11.4

7. Thermal Rearrangement of Vinylcyclopropanes

Cyclopropanes are known to undergo three types of bond-reorganization processes: (i) geometric *cis-trans* isomerization [57], (ii) structural rearrangement to olefins [58], and (iii) vinylcyclopropane-cyclopentene rearrangement [59,60]. They are discernible thermodynamically by the quantity of their activation energy (ΔE). This is 60–65 kcal in the case of the isomerizations (i) and (ii) [57d], and about 50 kcal for reaction (iii). Processes of types (i) and (ii) are beyond the scope of this article, and will not be considered here.

Experience accumulated so far indicates that substitution in the vinylcyclopropane system, both on the ring and around the double-bond, exerts influence on rates of reaction and plays a determinative role in the course of thermal rearrangement into cyclopentene. The examples shown in Scheme 2 illustrate this effect.

Ring Substitution:



[61]

(100) *(101)*

R = CH_3, $k_1 \times 10^5$ = 6.5 sec^{-1}(200°C)
ΔE = 50.2 kcal (234°C)
R = H, CH_3

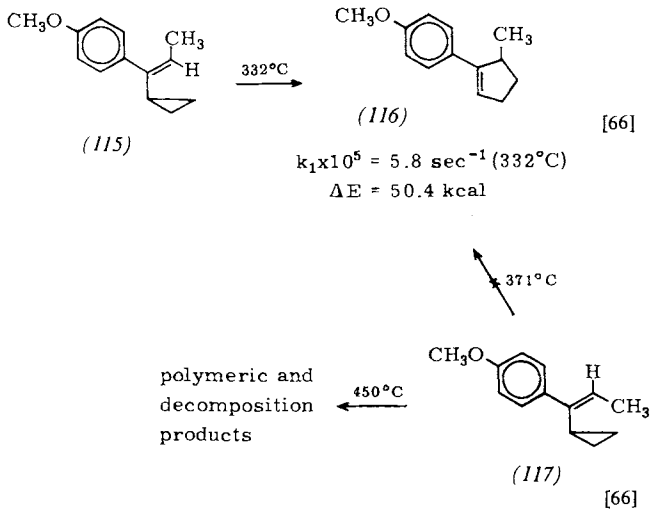
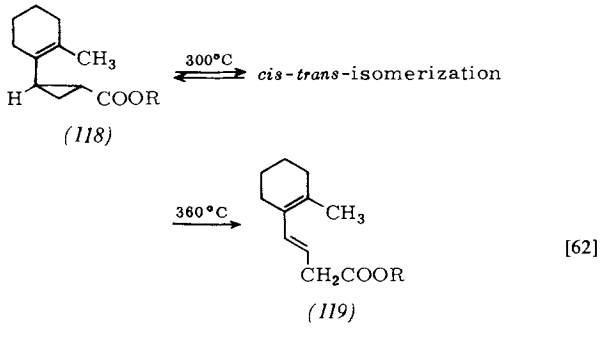
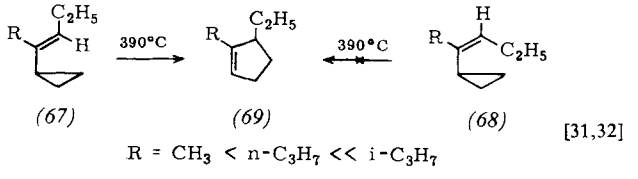
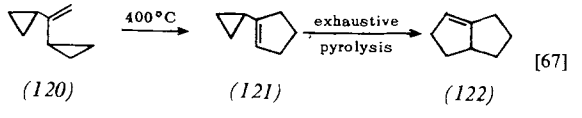
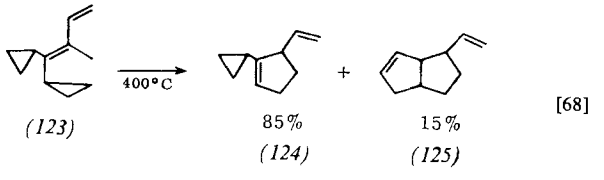










Scheme 2

Comparative kinetic study has shown that substitution of chlorine on C-2 of vinylcyclopropane *(100)* enhances considerably its rate of rearrangement to the cyclopentene *(101)* relative to the conversion *(106)*→*(107)*. The exclusive formation of the cyclopentenes corresponding to the expected diradicals from *(100)* and *(105)* suggests that the rearrangement may not involve simultaneous bond rupture and bond formation [69].

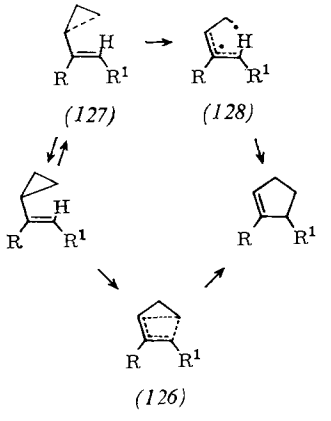
Introduction of chlorine on the terminal carbon of the double bond (compounds *(108)*, *(109)*, and *(110)*) apparently diminishes the interaction of the π-electrons in the opening of the small ring so that other types of thermal rupture of the ring must take place, demanding higher activation energy.

Of particular interest is the effect of alkyl substitution on the terminal carbon of the double bond. If a methyl or ethyl group is placed *cis* to the cyclopropyl, for example in compounds *(117)*, *(118)*, and *(68)*, (R = CH_3, *n*-C_3H_7, *i*-C_3H_7), the rate of thermal rearrangement is strikingly reduced and it also leads to formation of polymers and/or structural rearrangements to olefins. In contrast, when the alkyl group is situated *trans* to the cyclopropyl (examples: *(106)*, *(115)*, and *(67)* (R = CH_3, *n*-C_3H_7, *i*-C_3H_7)), it has no diminishing effect on rates of rearrangement.

In compound *(123)*, the terminal vinyl group does not seem to interact with the *cis* cyclopropyl group to give a seven-membered ring compound. Moreover, it probably actually inhibits rearrangement to the cyclopentene. The formation of *(124)* probably involves the rearrangement of the cyclopropyl group *trans* to the vinyl group.

The kinetic data for the conversion *(113)*→*(114)* show that the rates for all except the fluoro derivative are the same. This is an indication that the vinylcyclopropane rearrangement is relatively insensitive to polar effects, at least as transmitted through C-1.

The vinylcyclopropane rearrangement can be explained by a mechanism in which the rate-determining step is the opening of the cyclopropyl ring either to the diradical *(128)* or to the "expanded ring" *(127)* [57a,57d], followed by ring closure as a result of intramolecular coupling of the reactive ends of the diradical. On the other hand, it can also be interpreted in terms of concerted mechanism, proceeding directly through a Cope-type transition state such as *(126)* [64,69].



Recently, *Wilcott* and *Cargle* [70] were able to conclude, from NMR investigations, that in thermolysis of monodeuteriovinylcyclopropane the loss of stereospecificity at the deuterium-labeled site in the cyclopropyl ring is at least five times as fast as the conversion to cyclopentene, thus substantiating the diradical mechanism. Interpretation of data from pyrolysis of

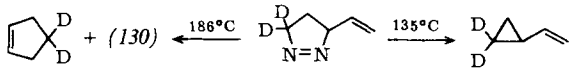
Frey,* J. chem. Soc. (London) *1964*, 959; d) *K. W. Egger, D. M. Golden,* and *S. W. Benson,* J. Amer. chem. Soc. *86*, 5420 (1964).

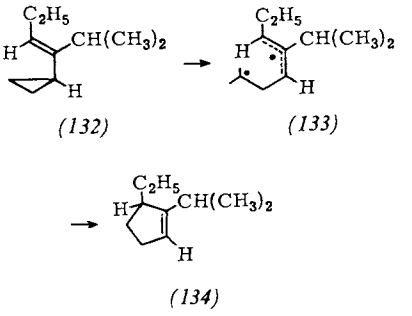
[70] *M. R. Wilcott* and *V. H. Cargle,* J. Amer. chem. Soc. *89*, 723 (1967).

(129) at various temperatures led *Crawford* and *Cameron* [71] to the conclusion that the ring closure of the assumed diradical intermediate to *(130)* should be considerably greater than to the cyclopentene *(131)*.



(131) *(129)* *(130)*

The enhanced tendency to thermal rearrangement of *(132)* relative to *(67)*, where R = CH_3, *n*-C_3H_7, can be attributed to conformational factors. The conversion *(132)*→*(134)*, evidently, requires only slight



(132) *(133)* *(134)*

conformational changes throughout, since the conformation of *(132)* in the ground state is almost the same as in the activated state *(133)*.

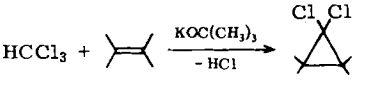
Synthesis of Cyclopropyl Ethers and Cyclopropanols by Carbene Transfer – Acetolysis of Cyclopropyl *p*-Toluenesulfonates[**]

BY U. SCHÖLLKOPF[*]

The reaction of chloromethyl phenyl ether with butyllithium in olefins yields phenoxycyclopropanes. 1-Chloro-1-phenoxycyclopropanes can be prepared in a similar manner, though the yields are poor. Alkoxycyclopropanes are formed when dichloromethyl alkyl ethers are treated with methyllithium/lithium iodide in the presence of olefins. Cyclopropanols can be obtained in good yields by reaction of (β-chloroethoxy)cyclopropanes either with butyl- or ethyllithium or with bases. – As was shown by acetolysis experiments with cyclopropyl p-toluenesulfonates having a known steric configuration, the rearrangement of a cyclopropyl derivative into an allyl cation proceeds in accordance with the Woodward-Hoffmann-DePuy rule. The solvolysis of exo-bicyclo[n.1.0]alkyl p-toluenesulfonates is assumed to proceed via "semi-open" intermediates, which are somewhere between an allyl cation and a cyclopropyl cation.

1. Introduction



(1)

Following kinetic studies by *Hine* [1] on the mechanism of the alkaline hydrolysis of haloforms, *Doering* and *Hoffmann* [2] allowed chloroform to react with potassium *tert*-butoxide in olefins and obtained dichlorocyclopropanes *(1)*.

This was the first step in the rapid development of carbene chemistry. At the same time it provided an extremely flexible synthetic principle, *i.e.* "carbene transfer", which offered ready access to many heterosubstituted cyclopropanes [3] and cyclopropenes [3], and so gave great momentum to research on small rings [3].

The reason for the use of the loose term "carbene transfer" to describe the process is that it is not clear in most cases how the three-membered ring is formed. Though it is certain that α-metal-α-halogen compounds are formed as intermediates, there is some controversy as to whether the reaction of these with the

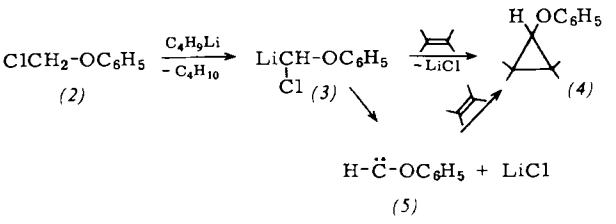
double bond is direct, *i.e.* carbenoid[4], or indirect, *via* a carbene (cf. *e.g.* Scheme 1).

Carbene transfer is excellently suited for the synthesis of alkoxy- and aryloxycyclopropanes[5]. This and a good synthesis of cyclopropanols are described in the first part of this article, while the second part is devoted to the acetolysis of cyclopropyl *p*-toluenesulfonates. The object of these investigations, which are at present being carried out jointly with *Schleyer* and his co-workers (Princeton University), is to carry out an experimental check on the *Woodward-Hoffmann-DePuy* rule for the stereochemistry of the conversion of a cyclopropyl derivative into an allyl cation.

2. The Syntheses

2.1. Phenoxycyclopropanes

Phenoxycyclopropanes *(4)* are formed (cf. Table 1, column 6) when chloromethyl phenyl ether *(2)*[6] is allowed to react with butyllithium at −15 to −20 °C in the presence of an olefin[7] (see Scheme 1).



Scheme 1. Synthesis of phenoxycyclopropanes *(4)* (with alternative mechanisms).

It can be assumed (see above) that the reaction starts with a metalation, *i.e.* a hydrogen-metal exchange. The resulting phenoxychloromethyllithium *(3)* which is thermally extremely labile and has not yet been intercepted, then reacts with the olefinic double bond, either in a carbenoid reaction[4] or *via* phenoxycarbene *(5)* (cf. Scheme 1 and below).

As far as can be seen from investigations so far, the synthesis can also be applied to ring-substituted chloromethyl aryl ethers. For example, the reaction of chloromethyl 2,4-dichlorophenyl ether with butyllithium in isobutene yields 50 % of 2-(2,4-dichlorophenoxy)-1,1-dimethylcyclopropane *(6)*[7]. Heterocyclic chloromethyl ethers should react similarly.

In addition to the adducts *(4)*, small quantities of pentyl phenyl ether *(9)* are also formed. It is not yet known whether this is due to a Wurtz reaction (Scheme 2, a) or to a carbenoid

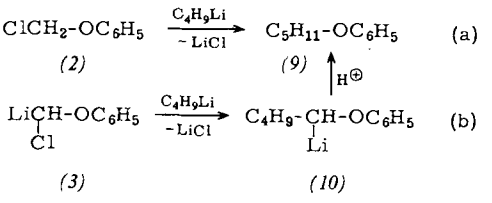
reaction of phenoxychloromethyllithium *(3)* with butyllithium to form phenoxypentyllithium *(10)*, followed by protonation (Scheme 2, b). If potassium *tert*-butoxide is used instead of butyllithium, substitution becomes the principal reaction. An example of this is the reaction of this base with chloromethyl 2,4-dichlorophenyl ether (in cyclohexene), which gives (2,4-dichlorophenoxy)-*tert*-butoxymethane *(8)* in 77 % yield[7].



Scheme 2. Possible modes of formation of pentyl phenyl ether, (a) by Wurtz reaction, (b) by carbenoid coupling.

The structure of the phenoxycyclopropanes *(4)* is clearly shown by their NMR spectra[7]. Conclusive evidence is provided by the high resonance field strengths of the cyclopropyl protons[8] and the magnitudes of the geminal[9] and vicinal[10] coupling constants. This is illustrated by the spectrum of 1,1-dimethyl-2-phenoxycyclopropane *(7)*, which is of the readily analyzable ABX type[11] (Fig. 1). Satisfactory agreement is found between the calculated and experimental spectra taking $|J_{AB}$ 5.9 Hz, $|J_{BX}|$ 3.1 Hz, J_{AX} 6.6 Hz, and $\delta_X = 6.7\,\tau$, $\delta_A = 9.36\,\tau$, and $\delta_B = 9.67\,\tau$. The chemical shifts are appreciably higher than those of corresponding hydrogen atoms in open-chain phenyl alkyl ethers. The relatively low value of the geminal coupling constant J_{AB} indicates an H–C–H angle of 114–118 °[10], as is also assumed in cyclopropanes[12].

With olefins having no center of symmetry and no axis of symmetry along the double bond, two stereoisomers (*exo* and *endo* isomers) are formed. The main product with *cis*-2-butene or 2-methyl-2-butene is the *endo* isomer, while cyclohexene and *p*-dioxene give mainly the *exo* isomers (cf. Table 1).

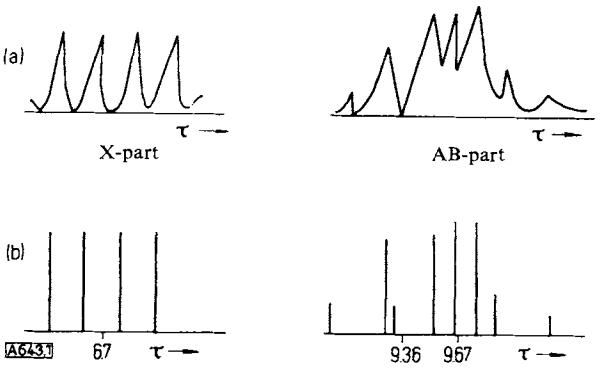


Fig. 1. (a) Observed and (b) calculated NMR spectrum of the cyclopropyl protons of 1,1-dimethyl-2-phenoxycyclopropane *(7)*.

This suggests a delicate and rather complex interplay of steric and electronic factors in the transition state of the cycloaddition[13].

Since empirical[9b] and theoretical considerations[9b] indicate that the spin-spin coupling of *cis* protons in the three-membered ring is more effective than that of *trans* protons, the configuration of the isomers can be deduced from their NMR spectra. Figure 2 shows (schematically) the α-proton signals; the ratio of the areas of the signals corresponds to the ratio of the isomers. In the adducts of open-chain olefins, the stronger of the two signals shows the greater splitting, and this signal must therefore be assigned to the *endo* epimer. The reverse is found for the adducts of cyclohexene and *p*-dioxene.

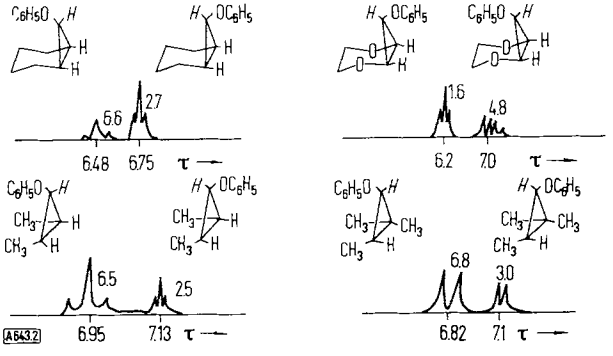

Fig. 2. NMR signals of the α protons of stereoisomeric phenoxycyclopropanes (the figures above the signals are the coupling constants in Hz). ($J_{cis} > J_{trans}$ in the three-membered ring.)

Apart from the hydrogen atom of the *p*-dioxene adduct, the (*endo*!) hydrogen atom of the *exo* isomer absorbs at higher field strengths (see Fig. 2). As we concluded[14], and as was recently demonstrated quantitatively by *Longone*[15], a cyclopropyl proton *cis* or *trans* to a C–C bond is situated in the anisotropy region of this bond in such a way that it experiences shielding or deshielding, respectively (Fig. 3). This effect, which we also observed with alkoxycyclopropanes (see Fig. 5) as well as with phenylthio-[16] and phenylselenocyclopropanes[17], can be used for the determination of configurations if the coupling constants cannot be deduced from the spectra.

[8] The reason for the increased screening of cyclopropyl protons is not yet clear. It may be due to a ring current produced by the relatively mobile bonding electrons in the magnetic field; cf. *D. J. Patel, M. E. Howden,* and *J. D. Roberts.* J. Amer. chem. Soc. *85*, 3218 (1963); *K. B. Wiberg* and *B. J. Nist, ibid. 83*, 1226 (1961).

[9] (a) For the angular dependence of geminal coupling constants, see *H. S. Gutowsky, M. Karplus,* and *D. M. Grant,* J. chem. Physics *31*, 1278 (1959). Though objections have been made to this relationship, the values found for cyclopropanes agree (in magnitude) with the expected values (4.5–7 Hz). Cf. (b) *J. D. Graham* and *M. T. Rogers,* J. Fig. 3. Cyclopropyl protons in the anisotropy field of an adjacent C—C bond (schematic).

As was shown by experiments with *cis*- and *trans*-2-butene, the formation of the cyclopropane ring is *cis*-stereospecific. Therefore, the product-forming species can be regarded as electrophilic. In agreement with this conclusion, ketene diethyl acetal, with its electron rich double bond, is attacked 16 times as rapidly as isobutene (Table 2)[13]. However, 2-methyl-2-butene, which is also more nucleophilic, reacts only slightly faster, while 2,3-dimethyl-2-butene actually reacts more slowly than isobutene. The accelerating electronic affects are evidently balanced or outweighed in these cases by inhibiting steric effects. Similar, though less pronounced, behavior has been observed in addition reactions of other (electrophilic) carbenes[18].

Table 2. Competition constants (k_{rel}) of *(3)* or *(5)* for olefins (see Scheme 1).

Olefin	Isobutene	Ketene diethyl acetal	2-Methyl-2-butene	2,3-Dimethyl-2-butene	Cyclohexene
k_{rel} (−15 °C)	1	16	1.03	0.43	0.2

Two mechanisms (cf. Scheme 1) must be considered for the formation of the three-membered ring (this is also true of the syntheses described in Sections 2.2 and 2.3); these are the carbenoid[4] addition of phenoxychloromethyllithium *(3)* to the olefinic double bond and the course involving the phenoxycarbene *(5)*. Since both intermediates must be assumed to behave as electrophilic[4], the detection of the electrophilicity is of no help in deciding between the two possibilities. The results of another set of experiments (Table 3), in which fluoromethyl, chloromethyl, and bromomethyl phenyl ethers were allowed to react with butyllithium in cyclohexene under comparable conditions, also failed to provide the required evidence. On metalation with butyllithium containing LiBr, the *endo/exo* ratio of the phenoxynorcarane formed, and hence the selectivity of the intermediate, is almost independent of the nature of the leaving group (Table 3, column 2). This appears at first glance to support the carbene mechanism, since one could argue that in this case the lithium halide is eliminated before the product-forming step, and so has no specific influence in the transition state. However, the true situation is rather more complicated. The invariance of the isomer ratio appears to be accidental, since when butyllithium is used in the absence of salts, the ratio of the epimers shows a distinct increase in the order bromide, chloride, fluoride (Table 3, column 3). This observation could be interpreted as favoring the carbenoid mechanism [*(3)* → *(4)*][13], but it is unlikely that a change in medium would lead to a change in mechanism.

Table 3. *endo/exo* Ratios of the 7-phenoxynorcaranes formed from halogenomethyl phenyl ethers, butyllithium, and cyclohexene.

Halogen	with LiC_4H_9 (containing LiBr)	with LiC_4H_9 (salt free)

Cl	1:2.45	1:4.8
Br	1:2.1	1:4.3

2.2. 1-Chloro-1-phenoxycyclopropanes

1-Chloro-1-phenoxycyclopropanes *(12)* are of interest as possible precursors for phenoxy-substituted, *i.e.* resonance-stabilized cyclopropyl cations. They are obtained (Table 4) (though only in poor yields, and not with all alkenes) on dehydrochlorination of dichloromethyl phenyl ether *(11)*[19] in olefins with potassium *tert*-butoxide[20].

[20] *E. Ruban*, Dissertation, Universität Göttingen, 1968.

case, but led, irrespective of whether the reaction was carried out with or without olefin, to a complex mixture from which the following compounds could be isolated[21]: *cis*- and *trans*-1,2-dichloro-1,2-diphenoxyethylene, *cis*- and *trans*-1-chloro-1,2-diphenoxy-1-hexene, 1-butylpentyl phenyl ether, and *trans*-4-nonene. The phenoxydichloromethyllithium [$LiC(Cl_2)-OC_6H_5$] assumed to occur as an intermediate evidently undergoes a carbenoid reaction either with itself or with other organolithium compounds present in the solution. The ratio of the products depends on the experimental conditions; with three equivalents of butyllithium, for example, *trans*-4-nonene is formed in 82 % yield[21]. Further experiments will have to be performed to decide whether this reaction, which can also be carried out with other alkyllithiums, can have any importance for the synthesis of olefins[22].

In the experiments with *cis*-2-butene and 2-methyl-2-butene, only one isomer, which was presumably the "*endo*-chloro" form *(12c)* or *(12d)*, was found in each case. This configuration is assigned on the basis of the methanolysis constants of the compounds, which differ from each other and from those of the other members of the series by factors similar to those found for the acetolysis constants of the corresponding cyclopropyl *p*-toluenesulfonates *(13)*, the configurations of which have been proved (cf. Table 4). The *exo* isomers, which, according to the Woodward-Hoffmann-De Puy rule (see below), should be thermally less stable than the *endo* epimers, are probably lost during isolation. The isomeric purity of both products is demonstrated by their sharp melting points (cf. Table 4) and the linearity of the plots of $\ln[(V_0 - V_\infty)/(V_t - V_\infty)]$ against time for the methanolyses (Fig. 4).

Because the relative rates of solvolysis in the two series run parallel to each other, and because a concerted mechanism has been established for the acetolysis of the *p*-toluenesulfonates *(13a)–(13c)* (see below), we would assume that ionization and ring opening during methanolysis of the chlorides *(12a)–(12c)*, which affords allylic compounds or dienes[20], are concerted. Apparently the mesomeric effect of a phenoxyl oxygen atom is insufficient to lower the energy level of a cyclopropyl cation below that of the corresponding allylic cation[20].

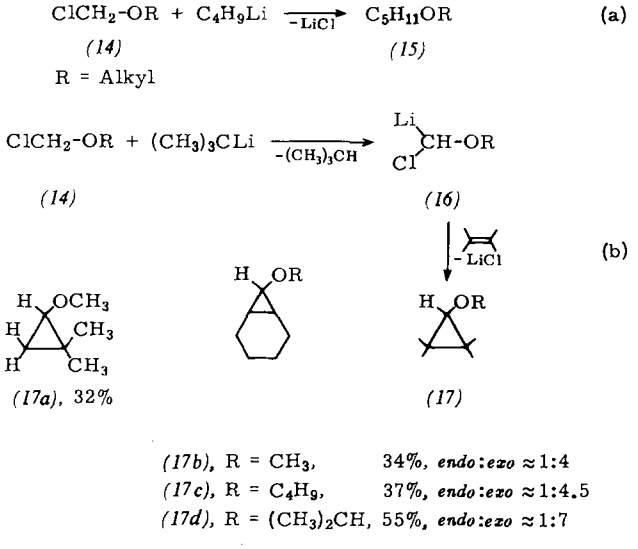
[22] Analogies are given by *K. D. Berlin* and *B. S. Rathore*, Tetrahedron Letters *1964*, 2547; *V. Franzen* and *L. Fikentscher*, Chem. Ber. *95*, 1958 (1962).

[23] According to *H. Böhme* and *A. Dörries*, Chem. Ber. *89*, 719 (1956), chloromethyl aryl ethers are solvolyzed more slowly than chloromethyl alkyl ethers. The differences in reactivity should, however, be smaller in the S_N2 reactions assumed here.

Unlike the chloromethyl aryl ethers, chloromethyl alkyl ethers *(14)* are not metalated but substituted by *n*-butyllithium[14a] (Scheme 3a). Replacement of the phenyl group by an alkyl group reduces the acidity of the methylene hydrogen atoms and simultaneously increases the ease of substitution of the halogen[23]. However, alkoxychloromethyllithiums *(16)* are formed in yields of at least about 50 % when the more bulky *tert*-butyllithium is used. On metalation in olefins, alkoxycyclopropanes *(17)* can be isolated in yields of up to about 60 %[14a] (cf. Scheme 3b).

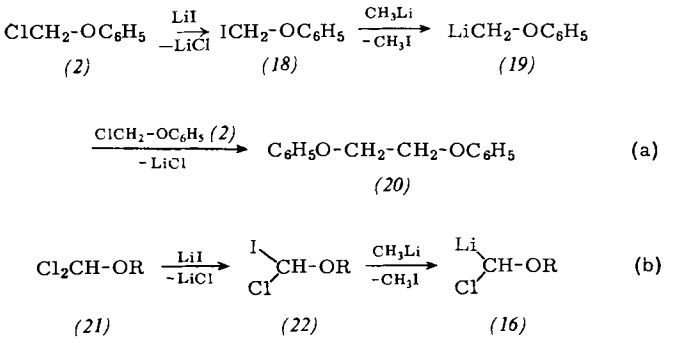


Scheme 3. Reaction of chloromethyl alkyl ethers (a) with *n*-butyllithium and (b) with *tert*-butyllithium in olefins.

However, this method is not recommended for the synthesis of *(17)*. *tert*-Butyllithium is an unsatisfactory reagent, which decomposes solvents and reacts with olefins to form undesirable by-products. It was therefore necessary to find a gentler method for the preparation of the metalated halogeno ethers *(16)*.

An indication of how this might be achieved was provided by the observation[24] that the reaction of chloromethyl phenyl ether *(2)* with methyllithium (instead of butyllithium) in isobutene led, not to 1,1-dimethyl-2-phenoxycyclopropane *(7)*, but surprisingly to 1,2-diphenoxyethane *(20)*. Since the methyllithium used had been prepared from methyl iodide, and so contained one mole of lithium iodide, the obvious interpretation (cf. Scheme 4, a) is that nucleophilic chlorine/iodine exchange first leads to the formation of iodomethyl phenyl ether *(18)*; this then undergoes a halogen-metal exchange with methyllithium to form phenoxymethyllithium *(19)*, which reacts with unreacted *(2)* to form *(20)*. If this interpretation were correct, the desired lithiochloromethyl alkyl ethers *(16)* would be obtained [*via* the intermediates *(22)*] on treatment of dichloromethyl alkyl ethers *(21)* with methyllithium (cf. Scheme 4, b).

[24] *J. Paust*, Diplomarbeit, Universität Heidelberg, 1963.



Scheme 4. Paths for the formation of (a) diphenoxyethane *(20)* and (b) lithiochloromethyl alkyl ethers *(16)* (cf. text).

This is in fact the case; if methyllithium is added dropwise to a solution of a dichloromethylalkyl ether *(21)* in an olefin until a positive Gilman test is obtained, alkoxycyclopropanes *(17)* are formed, sometimes in excellent yields (cf. Table 1, columns 10, 12 and 14).

The synthesis proceeds very rapidly even at ≈0 °C, and can therefore also be used with olefins that normally react with organolithium compounds, such as cyclopentadiene or butadiene. This and the ready availability of the dichloromethyl alkyl ethers *(21)*, which are obtained from formates and phosphorus pentachloride[5], ensure this method a wide field of application (cf. Table 1). It should be mentioned in passing that phenoxycyclopropanes *(4)* can also be obtained in this way from dichloromethyl phenyl ether *(11)*[20] (cf. Table 1, column 8).

As in the addition reactions of phenoxychloromethyllithium *(3)* or phenoxycarbene *(5)*, the isomer ratio of the adducts formed in the reactions with unsymmetrical olefins (cf. Table 1, columns 9, 11, 13, and 15) again point to a subtle interplay of steric and electronic factors in the transition complex. For example, "methoxycarbene" gives the *exo* form in the higher yield with cyclopentene, but the *endo* form with cyclopentadiene. Similarly, cyclooctene gives mainly *endo*-methoxybicyclo[6.1.0]nonane with "methoxycarbene", but mainly *exo*-(β-chloroethoxy)bicyclo[6.1.0]nonane with "(β-chloroethoxy)carbene". The *endo* additions are always favored in the case of open-chain olefins.

As with the phenoxycyclopropanes *(4)* (cf. Fig. 2), the configurations can again be definitely established from the NMR spectra (cf. Fig. 5). Mention should again be made of the relationship between the chemical shifts of the α-hydrogen atoms and their position in relation to the vicinal C–C bond.

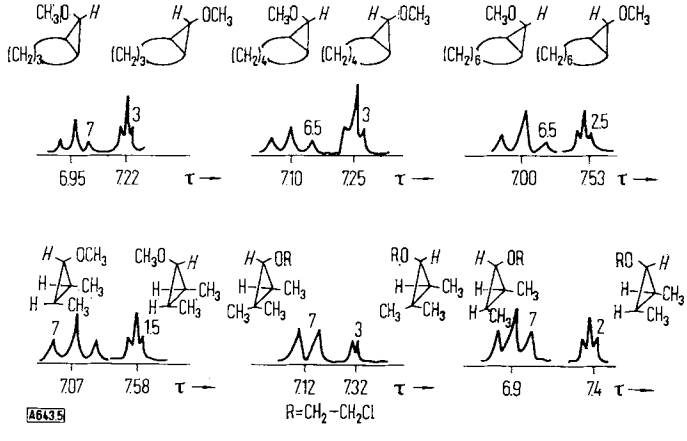


Fig. 5. NMR signals of the α protons of *exo*/*endo*-isomeric alkoxycyclopropanes *(17)* (the figures above the signals are the coupling constants in Hz).

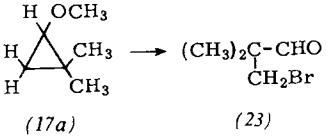
Since cyclopropyl ethers should resemble the enol ethers in their reactivity, they should readily undergo electrophilic ring opening. So far as is known at present, this appears to be the case. For example, 2-methoxy-1,1-dimethylcyclopropane *(17a)* reacts with bromine in glacial acetic acid to give β-bromopivalic aldehyde *(23)* (yield 83 %)[25], a compound that can only be obtained in poor yields by conventional methods[25a].



(17a) *(23)*

2.4. Cyclopropanols

It seemed an obvious step to apply the above cyclopropyl ether synthesis to the preparation of (secondary) cyclopropanols *(33)*, for which no satisfactory synthesis was previously known. The problem was to find a group R that could be removed from the oxygen of cyclopropyl ethers *(17)* under such mild conditions that the three-membered ring would remain intact. The β-chloroethyl group was found to be particularly suitable.

The usual methods adopted for the synthesis of cyclopropanols are summarized briefly in Scheme 5. Unsubstituted cyclopropanol *(25)* is most readily obtained by *Cottle*'s method[26], in which magnesium bromide, ferric chloride, ethylmagnesium bromide, and acid are added in succession to epichlorohydrin *(24)*. A variant of this synthesis due to *DePuy*[27] is particularly suitable for the preparation of 1-arylcyclopropanols *(27)*. In this method, dichloroacetone is allowed to react with arylmagnesium chloride, and the magnesium salt *(26)* is subjected to treatment with $FeCl_3$/ethylmagnesium bromide/acid. 1-Alkylated cyclopropanols are obtained only in poor yields by this route. Another path to cyclopropanols proceeds *via* cyclopropyl acetates *(30)*, which can be cleaved with $LiAlH_4$ or (better) with methyllithium[27]. They are obtained either by *Emmons*'s method[28], which involves a Baeyer-Villiger rearrangement of the ketones *(28)*, or (very elegantly) by *Freeman*'s method[29], which involves thermolysis of pyrazol-1-in-3-yl acetates *(29)*. This method is also suitable for preparation

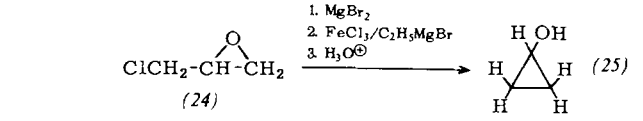
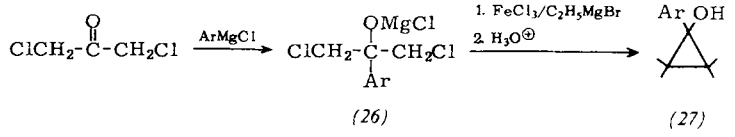
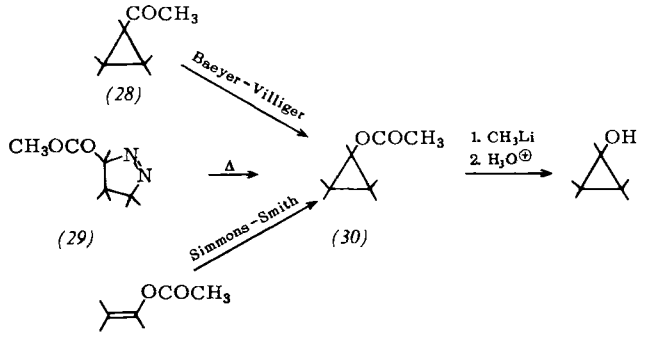
of tertiary cyclopropanols [29a]. *Simmons-Smith* cyclopropanation of vinyl acetates [30] is possible in principle, but the yields are poor.

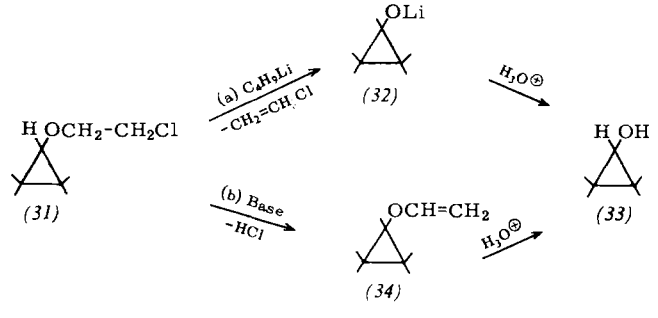






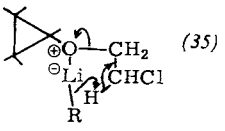
Scheme 5. Syntheses of cyclopropanols.

Two methods have proved particularly suitable for the conversion of β-chloroethyl cyclopropyl ethers *(31)* (cf. Table 1, column 14) into secondary cyclopropanols *(33)* (Table 1, column 16) [31]. One is the reaction of *(31)* with butyllithium (or ethyllithium), a single step leading in this case to the lithium cyclopropoxide *(32)*, together with vinyl chloride (cf. Scheme 6a). This method, which we discovered by accident and for which no analogy exists, gives good yields and is easy to use; it is therefore probably the best method in most cases (cf. Table 1, column 16 and footnote [c]).



Scheme 6. Conversion of β-chloroethyl cyclopropyl ethers *(31)* into cyclopropanols *(33)*.

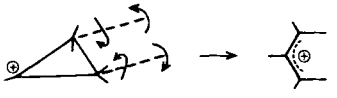
The mechanism of this remarkable reaction is not yet known. The organolithium reagent (R—Li) is presumably first complexed by the oxygen atom of *(31)* to form *(35)*, which decomposes as indicated by the arrows.



The other method (cf. Scheme 6, b) consists in the dehydrohalogenation of *(31)* with potassium hydroxide or potassium *tert*-butoxide, followed by hydrolysis of the resulting vinyl cyclopropyl ether *(34)* (cf. Table 1, column 16 and footnote [d]).

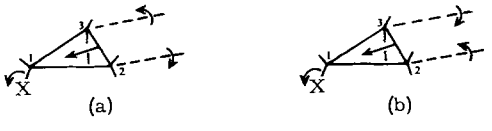
3. Acetolysis of Cyclopropyl *p*-Toluenesulfonates

According to the principle of conservation of orbital symmetry [32], the electrocyclic rearrangement of a cyclopropyl cation to an alkyl cation is disrotatory. Both possible directions of rotation (indicated by two pairs of arrows in Scheme 7) are electronically equally probable [33].



Scheme 7. Disrotatory rearrangement of a cyclopropyl cation into an allyl cation [32a].

If, however, ionization and ring opening occur synchronously, the rotation direction in which the ligand situated *cis* to the leaving group rotates inward and the *trans* ligand outward should be favored (cf. Scheme 9). This is shown by detailed Hückel calculations [32] carried out by *Hoffmann* and *Woodward* as a result of an observation reported by *DePuy* (cf. below).



Scheme 8. (a) Electronically favorable and (b) electronically unfavorable disrotation during the ionization of a cyclopropyl derivative with ring opening.
X = leaving group.

The reason for this can be best seen from the molecular models shown in Figure 6 [34]. The atomic orbitals on C-1, C-2, and C-3 are assumed for simplicity to be p orbitals. The orbital on C-1 (in the front of the photograph) is at an

[34] Designed by *W. Kutzelnigg*.

angle to the ring to demonstrate the fact that the configuration on this carbon atom at the beginning of the ionization is almost tetrahedral. The leaving group X is not shown; it should be imagined to be under (and partly bonded to) C-1. Better overlap of the orbitals is possible in the upper model [case (a), Scheme 8] than in the lower [case (b), Scheme 8].

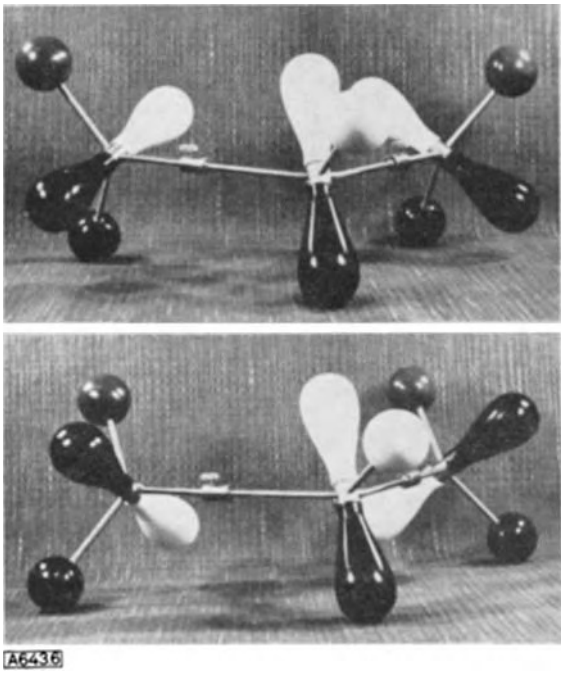

Fig. 6. Molecular models to illustrate the overlap of the orbitals (cf. text). The upper model corresponds to case (a) and the lower model to case (b) in Scheme 8.

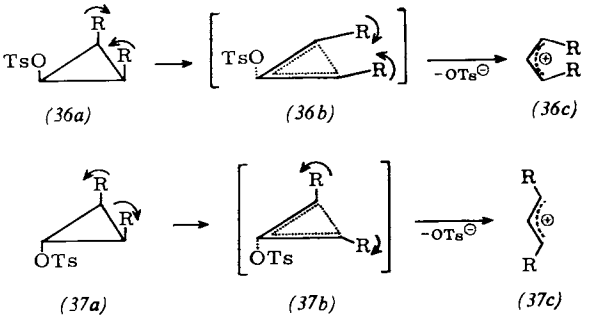
To test this hypothesis, we converted the cyclopropanols obtained in the course of our synthetic investigations (cf. Section 2.4) into their *p*-toluenesulfonates [31] and studied the acetolysis of the latter [35, 36]. This reaction seemed well suited for such a study, since individual observations had already shown that this reaction proceeds by a concerted mechanism with formation of alkyl acetates.

Though the acetolysis of the unsubstituted cyclopropyl *p*-toluenesulfonate is slower than that of cyclohexyl *p*-toluenesulfonate by a factor of about 10^5 [37], it is still a few orders of magnitude faster than it should be, according to the Schleyer-Foote relation [38, 39], if it proceeded *via* a cyclopropyl cation. According to *DePuy* [40], *cis*- and *trans*-2-phenylcyclopropyl *p*-toluenesulfonates are acetolyzed 16 and 280 times as fast, respectively, as the unsubstituted compound at 100 °C. This is also incompatible with the intermediate formation of a cyclopropyl cation. In this case the phenyl group should retard the reaction because of its –I effect. *DePuy* [33] also suggested that the difference in the ease of solvolysis of the two epimers might be related to the direction of rotation of the phenyl group. As was mentioned earlier, this opinion led to theoretical investigations on the problem.

3.1. Acetolysis of Monocyclic 2,3-Dimethylcyclopropyl *p*-Toluenesulfonates [35]

If the Woodward-Hoffmann-DePuy rule is valid, the *endo p*-toluenesulfonates *(36a)* (R = CH_3) should be solvolyzed more slowly than the *exo* isomers *(37a)* (R = CH_3), since the "inward" disrotation should be associated with steric strain in the transition state *(36b)*, while "outward" disrotation, in which the transition state *(37b)* is less strained than the initial state, should lead to steric acceleration of the reaction (cf. Scheme 9). The direction of rotation should be recognizable from the configuration of the solvolysis products as well as from the (relative) rates of solvolysis, since *(36a)* should lead [*via (36c)*] to a *cis* product, and *(37a)* [*via (37c)*] to a *trans* product. However, this criterion must be used with caution in acetolysis, since subsequent isomerizations are possible.



Scheme 9. Ionization of 2,3-disubstituted cyclopropyl *p*-toluenesulfonates having *endo* and *exo* configurations (a): initial state, (b): transition state, (c): intermediate.

The acetolysis constants clearly show the dependence on structure and configuration expected from the Woodward-Hoffmann-DePuy rule [41] (cf. Table 5).

When two *cis*-methyl groups are introduced into cyclopropyl *p*-toluenesulfonate, their effect depends on whether they are *endo* or *exo* with respect to the leaving *p*-toluenesulfonate group. In the latter case their stabilizing effect on the transition state is clearly recognizable (factor 18000); if they are in the *endo* position, on the other hand, their electronic contribution is almost completely offset by steric hindrance (factor 4). Successive replacement of the hydrogen atoms in positions 2 and 3 of the *endo*-2,3-*cis*-dimethyl derivative by methyl groups leads to an increase in the rate of solvolysis (factors 20 and *ca.* 1400 respectively). This is understandable, since the added methyl groups stabilize the transition state electronically without increasing the steric hindrance. The considerable Pitzer strain in tetramethylcyclopropyl *p*-toluene-

CH_3	CH_3	CH_3	CH_3	5500
CH_3	H	CH_3	H	260
CH_3	CH_3	H	H	330

[a] $k = 7.76 \times 10^{-6}$ sec^{-1} [37]

sulfonate probably accounts for the somewhat greater accelerating effect of the introduction of the fourth methyl group compared with that of the third. It is not surprising that 2,2-dimethylcyclopropyl and *trans*-2,3-dimethylcyclopropyl *p*-toluenesulfonates are solvolyzed at comparable rates, since the changes in strain associated with ring opening are roughly the same in both cases (one methyl group rotates inward and the other outward in each case), and the degree of stabilization of a transition state leading to an allyl cation by two methyl groups depends only to a limited extent on whether both groups are in the α- or γ-position, or whether one is in the α-position and the other is in the γ-position.

3.2. Acetolysis of *endo*- and *exo*-Bicyclo[*n*.1.0]alkyl *p*-Toluenesulfonates [36]

3.2.1. *endo* Series

Table 6 shows the acetolysis constants of the *endo*-bicyclo[*n*.1.0]alkyl *p*-toluenesulfonates *(38)* together with the products isolated.

Table 6. Relative acetolysis constants and acetolysis products of *endo*-bicyclo[*n*.1.0]alkyl *p*-toluenesulfonates *(38)*.

[b] At 75 °C.

[c] As well as 1,3-cyclooctadiene, which is evidently in equilibrium with the acetate.

The values of k_{rel} are readily compatible with the reaction course *(38)* → *(39)*. They probably reflect the stability of the *cis*-cycloalkenyl cations. According to Dreiding models, the cyclohexenyl cation (n = 3 in *(39)*) is almost strain-free, while the cycloheptenyl and cyclooctenyl cations (n = 4 or 5, respectively, in *(39)*) exhibit both torsional and transannular strain. This explains the steep decrease in rate between the bicyclo[3.1.0] and the bicyclo[4.1.0] systems, although a reduction in Pitzer strain could also promote ionization in the former case. The cyclononenyl cation is found from the model to be more flexible than its seven- and eight-membered homologs. This could be the reason for the slightly higher reaction rate of bicyclo[6.1.0]nonyl *p*-toluenesulfonate. Further experiments should establish whether the ease of solvolysis generally increases again beyond n = 6.

The solvolysis products are also in agreement with the proposed course of the reaction (Table 6). Though thermodynamic control of the product is to be expected under the conditions used, *trans*-cycloalkenyl acetates can be ruled out as precursors since they do not always give the *cis* isomers with glacial acetic acid (cf. below).

3.2.2. *exo* Series

The electronically favored "outward" disrotation for the ionization of the *exo*-bicyclo[*n*.1.0]alkyl *p*-toluenesulfonates [40] should be strongly hindered by strain factors, particularly when n is small. This presents the question of how the molecules behave on acetolysis. The results are shown in Table 7.

Table 7. Relative acetolysis rates and acetolysis products of *exo*-bicyclo[*n*.1.0]alkyl *p*-toluenesulfonates *(40)*.

[c] Estimated value at 175 °C (darkening); no solvolysis at 150 °C.

[d] The first product is the precursor of the following two.

[e] As well as small quantities of an isomer, probably the *trans* compound.

[f] Prepared by *C. H. DePuy* [40].

The first sriking point is the extreme reluctance of the bicyclo[3.1.0]hexyl derivative to solvolysis. After being heated for three months at 150 °C in (acetate-buffered) acetic acid, more than 90 % of the compound could be recovered unchanged. This shows that the ionization of a cyclopropyl *p*-toluenesulfonate does in fact proceed by a concerted mechanism, as was assumed by *Schleyer*[38], *Foote*[39], and *DePuy*[40]. It also provides an impressive demonstration of the validity of the Woodward-Hoffmann-DePuy rule. The ionization is obviously strongly hindered if disrotation in the "correct" direction is prevented by strain. Solvolysis *via* a normal cyclopropyl cation or ionization with disrotation in the "wrong" direction (and this is particularly remarkable) evidently require a great deal of energy. It is probably permissible, therefore, to assume in the discussion of further results that the ionization begins with an "outward" disrotation. The increase in the ease of solvolysis with increasing *n* then shows that the resistance to ring opening decreases in this direction, *i.e.* that the stability of the intermediate cations increases. How should we picture these intermediates? Cations of the type *(42)* may be ruled out, since these give strain-free Dreiding models only beyond the 12- or 13-membered ring. We assume that the intermediates are somewhere between a cyclopropyl and an allyl cation, and can be formulated as "semi-open" [see *(41)*]. As illustrated in Figure 7, they lie in a potential minimum resulting from a balance between π-delocalization energy and strain energy.

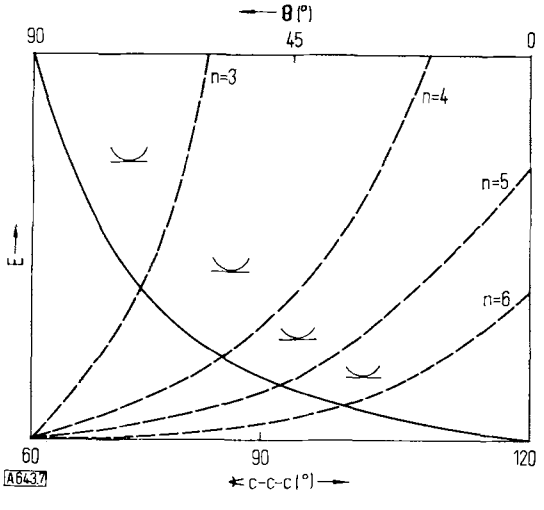

Fig. 7. Energy changes (schematic) during the outward disrotation of a bicyclo[*n*.1.0]alkyl cation of the type *(41)* (cf. text). ——: π-electron energy [42]; ----: strain energy; arcs: total energy; horizontal lines: energy levels of *(41)*; Θ: torsion angle formed by the plane through the geminal ligands and the cyclopropyl carbon atom and the cyclopropyl plane.

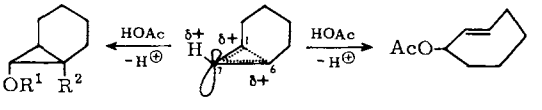
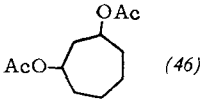
Owing to the gain in resonance energy associated with the disrotation[42], the *p*-toluenesulfonyl residue is released and a "nascent" cation is formed. The latter tends to twist further to form the stable allyl cation, thus leading to increased strain in the methylene bridge. The gain in resonance energy is initially greater than the increase in strain energy, so that the total energy decreases at first. At a certain point on the reaction coordinate, however, the situation is reversed, and further twisting then leads to an increase in the total energy of the ion. The shape, charge distribution, and energy content of the intermediate at the energy minimum are determined by *n*. The greater the value of *n*, the more strongly the intermediate resembles the stable allyl cation. Since a similar gradation must also be assumed for the energy levels of the transition states, we now have an explanation for the values of k_{rel}.

Corresponding to their midway position, intermediates of the type *(41)* should have three electrophilic centers, their cyclopropyl character increasing with decreasing *n* and their allyl character with increasing *n*. The solvolysis products of 7-norcaryl *p*-toluenesulfonate are interesting in this respect. The formation of both products [*exo*-7-norcaryl acetate *(43)* and *cis*-cycloheptyl 1,3-diacetate *(46)*] can be readily explained on the basis of the cation *(44)*, which adds acetic acid both at C-7 and at C-1 (C-6). The primary product in the latter case is *trans*-2-cyclohepten-1-yl acetate *(45)*, which is extremely highly strained[43] and adds acetic acid to form *(46)*.



(43), R^1 = Ac, R^2 = H
(47), R^1 = Ts, R^2 = D

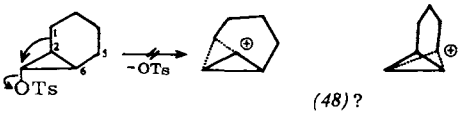
(44) *(45)*



(46)

The high stereoselectivity of the formation of *(43)* is remarkable. The *endo* isomer, which is stable under acetolysis conditions, cannot be detected either by gas chromatography or by NMR spectroscopy. This can hardly be explained by steric approach control in the attack of the nucleophile on C-7 of *(44)*, particularly since *(44)* should already be very flat. On the basis of a suggestion by *Kutzelnigg*[44], we assume that the orbital on C-7 (which has a pyramidal configuration) is not a pure p orbital, as was assumed in Figure 6, but possesses a certain s component, and is therefore more accessible on the *exo* side.

We originally thought that *(43)* was formed *via* the bridged ion *(48)*, which would result from neighboring-group participation of a bond between C-1 and C-2 (C-5 and C-6) during the ionization. However, *(48)*, in which the three cyclopropyl carbon atoms should be equivalent, can be ruled out since an acetolysis experiment with *(47)* showed that the labeled carbon atom retains its position.



(48)?

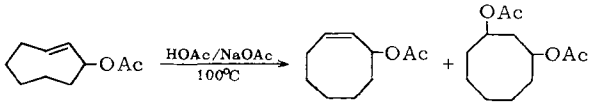
[42] According to detailed HMO calculations, a particularly large gain in delocalization energy occurs in the early stage of the change. Cf. *W. Kutzelnigg* [32b].

[43] *trans*-Cycloheptene and *trans*-cycloheptenone have recently been detected. Both exhibit a particularly strong tendency to undergo additions to the double bond. Cf. *E. J. Corey, F. A. Carey*, and *R. A. Winter*, J. Amer. chem. Soc. *87*, 935 (1965); *E. J. Corey, M. Tada, A. LeMahieu*, and *L. Libit, ibid. 87*, 2051 (1965); *P. E. Eaton* and *H. Lon, ibid. 87*, 2052 (1965).

[44] *W. Kutzelnigg*, personal communication. Cf. also [32b].

When $n > 4$, the allyl character evidently predominates in the intermediates. In any case, only monocyclic solvolysis products are then formed (cf. Table 7). The primary products are probably *trans*-2-cycloalken-1-yl acetates, but under acetolysis conditions these undergo *trans* → *cis* isomerization or [like *(45)*] add acetic acid at the double bond.

Whitham[45] has in fact shown that *trans*-3-cycloocten-1-yl acetate *(49)* is converted into the *cis*-isomer *(50)* and into



(49) *(50)*, ≈ 66% *(51)*, ≈ 33%

cis-cyclooctyl 1,3-diacetate *(51)* on heating in acetic acid/sodium acetate, *i.e.* under the conditions of *p*-toluenesulfonate solvolysis.

Why *(45)* and *(49)* should react with acetic anhydride to form *cis*-1,3-diacetates is an interesting problem that still awaits theoretical interpretation. On the other hand, the *cis-trans* isomerization *(49)* → *(50)* is readily interpreted as a concerted allylic shift, as has been demonstrated by *Goering*[46] in a number of other cases.

The author wishes to acknowledge, also on behalf of Prof. v. R. Schleyer, the enthusiastic cooperation of Dr. A. Lerch, Dr. W. Pitteroff, Dr. J. Paust, Dipl.-Chem. K. Fellenberger, Dr. M. Patsch, Dr. H. Schumacher, Dr. E. Ruban, and Dipl.-Chem. A. Al-Azrak (Heidelberg and Göttingen) and of Dr. G. W. van Dine and T. Su (Princeton). Recent Developments in the Adhesives Field

BY A. MATTING AND W. BROCKMANN[*]

The applications of adhesives have been greatly extended by the use of synthetic organic high polymers. It is possible nowadays to bond, not only wood, leather, and paper, but also glass, high-strength plastics, and metals with adhesives of this type. They give satisfactory adhesion, flexibility, and mechanical properties even at high temperatures. A particularly important advance was the introduction of chemically or mechanically blocked polymer systems, which can reduce the cost of curing equipment when used as adhesives.

1. Introduction

The use of adhesives has been known for thousands of years. In this process, a pasty or liquid substance that first wets the surfaces and then solidifies is applied between the parts to be joined. After solidifying, this substance transfers forces from one part to the other.

High molecular weight organic substances in colloidal form, which were obtained from plants, skins, muscle tissue, or bones, were used long ago as adhesives. These substances include collagen (molecular weight 20000 to 200000), which is still commonly used in aqueous solution as a glue for the bonding of wood, paper, and textiles. After the water has penetrated into the porous surfaces, the adhesive hardens.

The casein glues represent another group of natural adhesives. Casein (molecular weight about 300000) resembles the collagen glues in its technological behavior, but has the advantage that it can be made water-resistant[1,2]. Casein glues are still widely used, and give good results in the bonding of wood, though the strength and weather resistance of these glues cannot always satisfy rigorous requirements.

The use of casein adhesives for the bonding of wood is illustrated by the Schütte-Lanz rigid airship. The entire hull structure of these craft, which were built before and during the first world war, consisted of glued plywood girders. Despite the use of protective paints, however, these bonds could not withstand the effects of weather, particularly over the North Sea.

Natural adhesives made from blood and based on albumin and hemoglobin were used in pre-Roman times. Adhesives of this type can be modified with formaldehyde, ketones, phenols, and alcohols, and are still used in some countries for the manufacture

of plywood. Starch and cellulose adhesives as well as rubber-based products, which can be modified in many ways, are cheap and widely used.

However, a demand has recently arisen for adhesives having such high cohesive strengths, adhesion values, and resistance to environmental factors that products of plant or animal origin are often no longer satisfactory.

Synthetic high polymers were first used successfully as adhesives some thirty years ago, initially in the wood industry. The technology of synthetic adhesives began with the bonding of wood by means of phenol-formaldehyde polycondensates. It soon became possible to form very strong bonds even to metals with organic bonding agents; the resulting bonds can transfer forces at temperatures as high as 450 °C.

2. Requirements for Adhesives

2.1. Wetting and Setting

Before setting, adhesives must be in a liquid or low-viscosity state to allow complete wetting of the adherends, the surfaces of which should adsorb as many molecules of adhesive as possible. Consequently, adhesives that are already in their final chemical state must be made into colloidal suspensions or solutions. If the surfaces are porous, they may absorb the solvent. With non-porous surfaces, however, the solvent must be able to evaporate before the parts are joined; contact pressure must also be applied. The strength of the bond depends on the molecular forces acting within the adhesive layers as the adherends are pressed together.

This is also true of fusible substances, such as tars or synthetic thermoplastic materials, which soften when heated and solidify again on cooling. Joints made with adhesives of this type have limited thermal stability.

A third possibility is to use substances that are applied and adsorbed in the low molecular weight state, and then converted on hardening into a high molecular weight product. The importance of adhesives of this type is that the chemical bonds formed during hardening give maximum strengths without excessive heating of the adhesive. These reactions generally proceed without critical volume changes, and any internal stresses produced are small. It is also possible by chemical crosslinking to convert the thermoplastic adhesive, which is originally in the form of prepolymerized filament molecules, into a three-dimensionally crosslinked network, and so to obtain a bond having good thermal and deformation behavior.

These adhesives are hardened after the parts to which they have been applied are brought together.

2.1.1. Initiation of Crosslinking

Some adhesives having prepolymerized molecules can be crosslinked by heating without the addition of catalysts; adhesives of this type need not consist of two or more miscible components. Typical examples are phenolic resins and their modifications. Pressure must be applied during hardening, in order to drive the water vapor formed during polycondensation out of the adhesive. These adhesives are used as solids (often in the form of films), as pastes containing solvents, or as aqueous dispersions. Expensive heating equipment and presses or autoclaves are usually required for curing, though the curing time is relatively short (about 30 to 90 min).

Other adhesives require the addition of a curing agent and possibly other components before application. These adhesives crosslink slowly at room temperature, and much more rapidly when heated. In the case of polyesters, for example, the curing agent consists of catalysts (mainly peroxides), whereas the crosslinking of epoxide resins involves the reaction of two substances, *e.g.* of the epoxide resin with primary or secondary amines, and proceeds with cleavage of the epoxide ring The curing time (during which the parts must be clamped together because the uncrosslinked adhesive cannot transfer forces) is about 6 to 24 hours. The time required can be shortened by heating, but more expensive equipment is then necessary.

Crosslinking can also be initiated by removal of a chemical or mechanical blockage in polymerizable mixtures (see Section 4).

2.2. Adhesion

In addition to ease of setting and a high cohesive strength, adhesive films must adhere firmly to the adherends. If the adherends are porous, as in the case of wood or paper, or if at least the surfaces can be swollen or dissolved by components of the adhesive, so that the latter can penetrate into the material, the adhesion is "mechanical", and depends only to a limited degree on the chemical structure of the materials. The adhesion may then be regarded as mechanical clamping.

If, on the other hand, the adherends are smooth and nonporous, so that there is no possibility of mechanical clamping, the adhesion is described as "specific". Even where the adherends are different, as in the case of plastics and metals, the strength of the joint after suitable surface treatment is often greater than the cohesive strength of the plastic. The adhesion is mainly due to the fact that intermolecular van der Waals forces, dipole-dipole (Keesom forces), and induced dipole interactions (Debye forces) contribute more to the bond energy than dispersion forces (London forces). To provide good adhesion in the bonding of polar or polarizable materials, therefore, the adhesive molecules must contain polar groups [3]. It is also possible to copolymerize monomers containing polar and reactive groups together with the main substance in order to obtain improved adhesion. Adhesives that contain no polar groups are suitable only for the bonding of non-polar and non-polarizable materials.

[3] *N. A. de Bruyne*, J. appl. Chem. *6*, 303 (1956).

The reactions that lead to adhesion at interfaces between similar and between dissimilar materials have not yet been satisfactorily explained. The ability of wetting adhesives to be adsorbed on the surfaces to be joined and to form primary bonds can be predicted from their chemical structure. However, our knowledge of the processes at the surfaces, *e.g.* of wood or metals, that determine the adhesive strength is still inadequate.

Nevertheless, it has been shown in isolated cases that even dissimilar materials can form chemical bonds, which are very much stronger than van der Waals forces. Thus the adsorption of aliphatic carboxylic acids on aluminum materials, the surfaces of which are nearly always covered with oxides and oxide hydrates, is followed by chemisorption [4]. When such surfaces are bonded by phenolic resin adhesives, aluminum phenoxides can be detected along the interfaces [5]. Moreover, the adhesive forces to plastics that are difficult to bond, such as polypropylene, have been greatly improved by grafting with reactive groups, *e.g.* dihydroxyboranyl or epoxy groups [6]. The properties necessary in an adhesive for the firm bonding of given substances after a specific pretreatment (*i.e.* after the surface of the solid has been "keyed") are known only empirically, and this knowledge is still inadequate.

2.3. Deformation Properties

Adhesive joints are composite articles in the technological sense; they often consist of parts that differ considerably in their nature. The behavior of a joint under load is not simply a function of the strength and adhesion of the components. In particular, it must not be regarded as homogeneous if the components have different deformation properties. Owing to the heterogeneous structure of the joint, the supportable load cannot simply be calculated as the mean stress from the total load and the loaded cross section, though the supportable load and the mean stress may be assumed to be equal under comparable conditions for a homogeneous article. Because of the difference in the deformation of the two components of a joint under the same load, the stress is non-uniform and exhibits pronounced peaks. The supportable load of the joint thus depends on the local stress, and fracture can occur even when the mean stress is relatively low.

The stress distribution in an adhesive joint can be influenced by the design of the joint, *e.g.* by its shape. On the other hand, the properties of the adhesive may be such that large differences in stress can be compensated for by plastic deformation. This can be achieved in two ways. Firstly, the thermosetting base resin may be combined with thermoplastic resins, as in the combination of phenolic resins with polyvinyl compounds such as polyvinyl alcohols, polyvinyl chlorides, polyvinyl acetate, or polyvinyl formal. These thermoplastics exhibit steric effects that prevent tight crosslinking of the condensate, and partly react with the hydroxymethyl groups of the phenol-formaldehyde resol. They also reduce the viscosity of the mixture before curing, and so improve its wetting properties. In some cases, the thermoplastic component also sets, but prevents the complete formation of a three-dimensional network, which would be brittle because of its "molecular bracing" [7]. Similar types of modification have proved suitable for other types of resin, as is illustrated by the modification of epoxide resins with polyamides. Moreover, the resins preferred for use as adhesives are those that have a low tendency toward "crystallization", *i.e.* toward micelle formation, during crosslinking, owing to the presence of bulky side chains or lack of symmetry. These types include polyvinyl esters, polymethacrylic acid, and epoxide and phenolic resins.

Secondly, the ease of deformation of a plastic can be influenced by the use of plasticizers. These are monomers that do not take part in crosslinking, prevent complete three-dimensional crosslinking, and facilitate movement between the macromolecules in the solid state by acting as "lubricants". They must form stable mixtures with the base resin and contain long hydrocarbon chains to provide the "lubricating action", while at the same time reducing the volatility and diffusibility, and in plastics with dipoles, the plasticizers must also contain dipoles. An example of a useful plasticizer is butyl adipate *(1)* [8].

$$CH_3-(CH_2)_3-OOC-(CH_2)_4-COO-(CH_2)_3-CH_3 \qquad (1)$$

Flexible plastics are basically weaker, and tend to creep under a permanent load. It must therefore be decided in each individual case whether flexibility is more important than strength.

The flexibility of adhesives, which also depends on the temperature, can be determined by the torsional vibration test, from which it is possible to calculate the damping of the adhesive as a function of temperature as well as its shear modulus. The shear modulus at a given temperature is characteristic of the state of the adhesive. It is possible in this way to find the width of the freezing-in and softening ranges, in which the maximum damping occurs, as well as that of the rubbery-elastic range. A comparison of the temperature-dependent rigidity modulus with the strength of adhesive joints shows that the strength decreases considerably in the rubbery-elastic state [9] To obtain adhesives having a high heat resistance, the occurrence of this state must be postponed to higher temperatures by modification of the structure.

The existing experimental results do not, however, provide a sound basis for definite conclusions. Secondary damping maxima that occur at high temperatures and disappear after prolonged heating suggest that the thermosetting and thermoplastic components of an adhesive retain their independence

when combined, so that the torsional vibration test can also provide information about the degree of crosslinking.

As a result of the development of synthetic adhesives, high-strength materials such as thermosetting polymers, glass fiber reinforced plastics, and metals can now be bonded with adhesives as well as the materials such as wood, paper, and textiles that have been bonded in this way since ancient times. Substances of the first group are far superior to most adhesives in their strength and, as far as the metals are concerned, in their heat resistance.

In order to take advantage of the high strength of these materials with the weaker adhesives, the joints should be designed in such a way that when the cross sections of the adherends are very small, relatively high stresses are transferred by large joint areas. The joint area for adherends having a given cross section may be of any size if it is parallel to the load. The adhesive is then subject to a shear stress (Fig. 1). The strengths of adhesive joints are therefore usually given

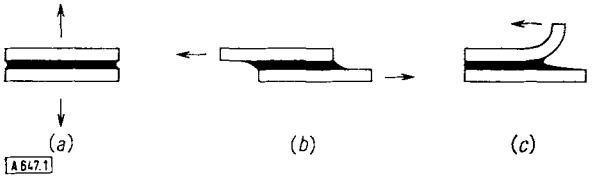

Fig. 1. Loading of adhesive joints: (a) tensile ,(b) shear, (c) peel.

as shear strengths, while tensile strengths (Fig. 1a) are important only when the adherends have a low internal strength, since the joint areas in this case cannot be greater than the cross sections of the adherends.

Another type of loading, which places great demands on the plasticity and tensile strength of the adhesive, is peeling (Fig. 1c). Adhesives are generally very sensitive to peeling forces (to which structural components are frequently subjected), since the stress acts along a line, and is therefore very highly concentrated. The peel strength of an adhesive is consequently of great importance [10].

The strength and heat resistance of synthetic adhesives depend on their chemical composition. Adhesives that set in a few minutes at room temperature are important. These adhesives play a valuable part *e.g.* in mass production processes.

3. Types of Adhesives

Practically any high polymer may be used as a base resin for adhesives. The substances listed in Table 1 are particularly suitable because of their adhesive properties coupled with relatively high cohesive strength, adequate heat resistance, and considerable resistance to aggressive media, as well as their ease of use.

The problem of increasing the strength and heat resistance of macromolecules can only be solved if as

Polymethacrylates	

many chemical bonds and hydrogen bonds as possible are allowed to form, since, owing to their high bond energy, these bonds are better able to withstand high mechanical and thermal stresses than are intermolecular van der Waals forces.

The maximum strength that can theoretically be attained by a high polymer bound exclusively by chemical bonds is easy to calculate. If polyethylene chains are packed together as densely as possible and parallel to one another, approximately 5×10^{14} chains can be fitted into each square centimeter. When a bundle of chains packed in this way is broken by a longitudinal stress, each C–C bond passing through the cross section contributes about 5×10^{-4} dyne to the tensile strength, giving a total of 25×10^{10} dyne/cm^2. In practical terms, this corresponds to a tensile strength of 2500 kg/mm^2, which is far greater than that actually found for crystalline polyethylene. This difference is due to defects, which lead to stress peaks and premature failure.

If the chemical bonds are replaced by hydrogen bonds, which have a strength of about 10^{-5} dyne, the stress required to cause breakage in the model is 50 kg/mm^2. This corresponds approximately to the values found for highly oriented fibers. Thus in these fibers, the hydrogen bonds are broken before the stresses destroy the stronger covalent bonds [12].

These considerations are important if a high polymer is to be stable above 300 °C and to exhibit a useful strength, since the van der Waals forces no longer contribute to cohesion in this temperature range, their bond energy then being less than the kinetic energy of the chain segments [12].

Owing to the need for heat resistance, the molecular chains must be made so rigid between the nodes of the three-dimensional network that very little rotational energy can accumulate in them. This rigidity can be achieved *e.g.* by the incorporation of cyclic structures [12].

3.1. Phenolic Resins

The phenolic resins were among the earliest of the modern high-strength adhesives. Owing to the large number of possible modifications, they are suitable for the bonding of nearly all materials. They are formed by the reaction of phenol with formaldehyde to give hydroxymethylphenol, which condenses with elimination of water. Phenols can be linked by CH_2 or CH_2-O-CH_2 groups. The products are resols, self-

[11] *L. Dimter*: Klebstoffe für Plaste. VEB Deutscher Verlag für Grundstoffindustrie, Leipzig 1966.

[12] *H. E. Mark* in: Haftsysteme und Haftfestigkeit. Dechema Monograph No. 51. Verlag Chemie, Weinheim 1966.

curing resins, or novolacs, which can be cured by substances that remove formaldehyde [11].

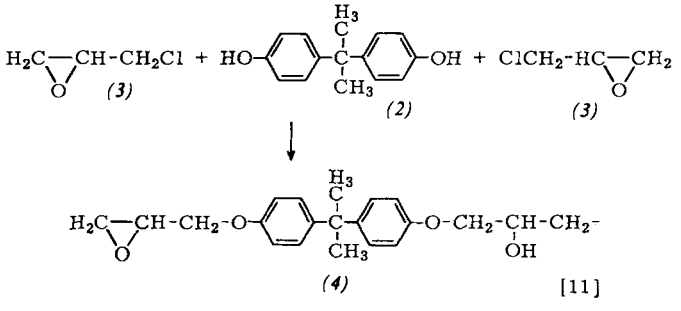
A more important group within this class of adhesives is formed by the polyvinyl formal-, polyvinyl acetal-, and polyvinyl butyral-modified types. Polyvinyl formal-modified phenolic resins were the first metal adhesives to be used in aircraft construction. They are characterized by high strength and aging resistance. Their tensile strength is between 8 and 10 kg/mm² and their shear strength about 3.5 kg/mm². Above 80 °C, however, the strength decreases very rapidly.

About 70 % of the joints in the fuselage and wings of the Fokker F 27 "Friendship", a light-metal aircraft, are bonded in this way. Some 400 of these machines have been in use over a period of more than eight years in countries with widely different climates. Despite this long service, the adhesive joints have retained their strength in full [13].

Phenolic resins can also be modified with elastomers such as rubber to give good deformation properties and strength at low temperatures. Similar results are obtained by modification with polyamides, which increase the impact strength and improve adhesion to many materials. The hot strength of phenolic resins, however, was improved only when they were combined with a second group of resins, *i.e.* epoxide resins.

3.2. Epoxide Resins

Epoxide resins *(4)* are formed by the condensation of polyfunctional phenols, such as bisphenol A *(2)*, with epichlorohydrin *(3)*.

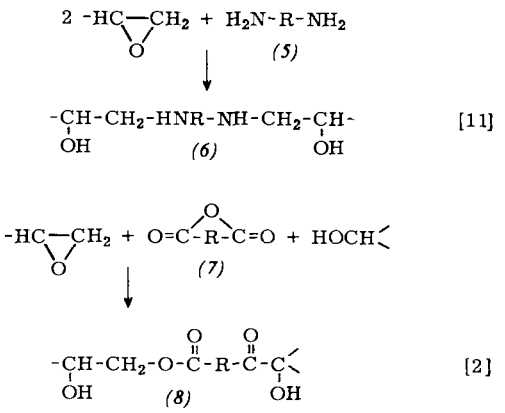


[11]

The most important characteristic of these resins, which is responsible for many of their properties, is the presence of terminal, extremely reactive epoxy groups.

The epoxide resins are cured by addition of polyamines *(5)* or acid anhydrides *(7)*, which add to the epoxy groups to form *(6)* and *(8)*.

Their low shrinkage on curing is an important advantage in adhesive and casting applications. Since their OH groups also react, the molecules not only become larger on curing, but are also crosslinked to form three-dimensional networks. Amine-based curing agents react even at room temperature, and epoxide resins can therefore be used in two-component cold-setting adhesives. Curing agents based on acid anhydrides can be added to epoxide resins by the manufacturer, since the curing reaction begins only above 100 °C. The resulting products are one-component thermosetting adhesives, which can be supplied in the form of solids, powders, or pastes [14].



[11]

[2]

The strong adhesion of epoxide resins to nearly all materials was utilized in adhesive technology as long ago as 1948 [15]. This adhesion is due, not only to the polarity of the resins, but also to the presence of "unused" epoxy groups, which form chemical, and therefore extremely strong, bonds with the molecules on the surfaces of the adherends, *e.g.* metal oxides and hydroxides, or even polyamides.

The versatility of the epoxide resin adhesives, which can be modified in many ways, is too well known to need further elaboration here. They are generally inferior to phenolic resins in their strength and aging resistance, particularly in unfavorable climates, and their strength decreases rapidly above 80 to 100 °C. On the other hand, in addition to good adhesion, they are distinguished by ease of handling.

It has recently been found that the hot strength and stability of the epoxide resins can be appreciably improved, firstly by increasing the epoxide content to allow higher crosslink densities, *i.e.* more chemical bonds per unit volume, and secondly by the synthesis of resins containing aromatic glycidylamines or glycidyl tetraphenylglyoxal resins as stable chain segments. Systems have also been tried in which alicyclic epoxide resins are formed by reaction of peroxy acids with unsaturated cyclic compounds [14]. In these cases the epoxy groups are directly attached to the ring. Heat-resistant epoxide resins, when used to bond metals, still have shear strengths of 0.9 kg/mm², *i.e.* 70 % of the strength at room temperature, at temperatures of up to 250 °C.

The second way in which the good adhesive properties of the epoxide resins can be utilized for heat-resistant adhesives is by combination with other polymers, such as phenolic resins.

3.3. Epoxide-Phenolic Resin Combinations

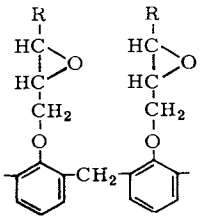
Epoxide-phenolic resin combinations provided an early solution to the problem of producing joints having satisfactory shear strengths between −200 and

[13] *R. J. Schiekelmann* in: Fachtagung Schweissen und Kleben im Luft- und Raumfahrzeugbau. Technische Presse der Deutschen Messe- u. Ausstellungs-AG. Hannover 1966, p. 25.

[14] *B. J. Hayes*, Adhäsion *11*, 97 (1967).

[15] *E. Preiswerk*, Technica *1965*, 247.

+300 °C. The principal component of these resins [*e.g. (9)*] is phenolic resin.



(9) [11]

The curing in these resins, which have a low epoxide content, is assumed to be due only to reaction of the phenol component, the epoxy groups playing no part in the crosslinking [16].

Another group of epoxide-phenolic resin adhesives, which have a much higher content of epoxide groups, are crosslinked by the addition of a curing agent for epoxides. Their strength and heat resistance are better than those of the first group. However, they are difficult to handle, and their shelf life at room temperature is short; prolonged storage is possible only at −10 to −20 °C. The peel strength of adhesives of this type is often unsatisfactory.

3.4. Nylon-Modified Epoxide Adhesives

Nylon-modified epoxide adhesives have proved advantageous where high strength and toughness, and particularly high peel strength between −250 and +60 °C are required. Owing to their cohesive strength, coupled with good flexibility, they possess excellent properties at low temperatures and in dynamic stress situations. They are therefore used for the production of highly stressed joints, particularly in aircraft construction.

The types of nylon that are suitable for use in these adhesives can absorb up to 20 % of water in a moist atmosphere. They must therefore be stored and used only in air-conditioned rooms. They are sensitive to moisture even when set. Until the development of nylons that dissolve in epoxide resins and also do not absorb much moisture, it will be necessary to paint over nylon-modified epoxide adhesive films to protect them against the penetration of water vapor [14].

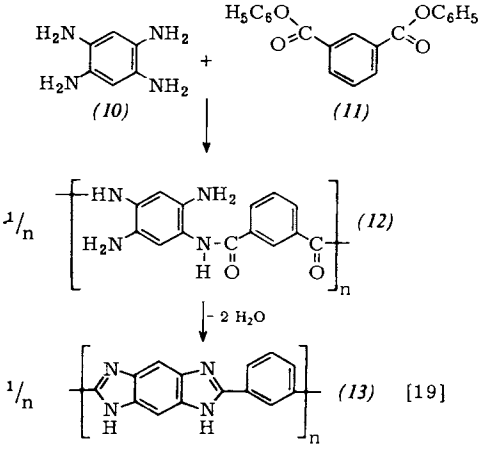
The thermal stability of adhesives based on common organic polymers can also be increased by the addition of amphoteric inorganic oxides such as As_2O_5 [17]. It does not, however, appear possible to use these adhesives above 300 °C. Moreover, the high hot strength is gained in most cases at the expense of flexibility, and hence of the technological characteristics at low temperatures.

Adhesives based on new polymers first prepared only in the past few years offer greater promise. The use of these substances as adhesives will depend on their existence in the form of prepolymers that finally set only in the adhesive joint.

[16] *K. W. Humphreys* in *D. J. Alner*: Aspects of Adhesion. University of London Press, London 1965, p. 66.

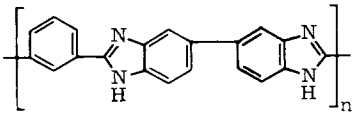
[17] *H. H. Levine*, Brit. Plastics *34*, 395 (1961).

Because high hot strength in adhesives can be obtained, not only by introducing as many chemical bonds or hydrogen bonds as possible into the crosslinked substance, but also by introducing thermally stable chain segments between the nodes of the network, interest was turned to base resins consisting of fully aromatic and in some cases linear, polymers. The chains of these polymers are so rigid and absorb so little rotational energy that the crosslinking points need not be situated close together, with the result that the flexibility is greatly improved. Adhesives based on polybenzimidazoles have already been extensively tested [18]. Aromatic polybenzimidazoles *(13)* are formed by melt condensation of aromatic tetramines *(10)* with diphenyl esters *(11)* of aromatic dicarboxylic acids [19].



(10) *(11)* *(12)* *(13)* [19]

The reaction leads initially, at 220 to 260 °C, to a polyamino amide *(12)*, from which the polybenzimidazole *(13)* is formed on setting above 300 °C. Another polybenzimidazole, which has the formula *(14)*, can also be cast into films, since it is soluble in dimethyl sulfoxide and formic acid.



(14) [19]

Adhesives having the same shear strength (≈ 2.0 kg/mm²) at 260 °C as at room temperature are obtained from polybenzimidazoles stabilized with inorganic arsenic compounds. As the temperature is raised to 420 °C, the strength falls to a value of 1.5 kg/mm², which is still of practical use.

The polybenzimidazoles are sensitive to prolonged storage at 260 to 300 °C. At 310 °C, the shear strength decreases to 0.52 kg/mm² in only 100 hours. These adhesives are cured at about 320 °C. Since volatile components are eliminated, heated presses are required for curing [18].

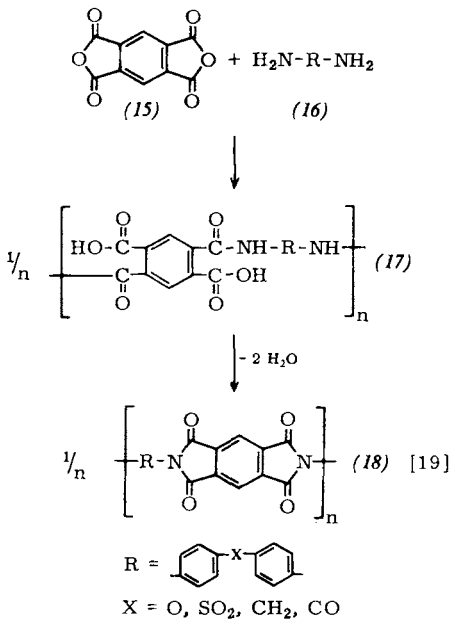
[19] *F. T. Wallenberger*, Angew. Chem. *76*, 484 (1964); Angew. Chem. internat. Edit. *3*, 460 (1964).

3.6. Polyimide Adhesives

The adhesive properties can be considerably improved by the use of polyimides *(18)* as the base resins instead of polybenzimidazoles. The polyimides can be prepared by the reaction of pyromellitic dianhydride *(15)* with aromatic diamines *(16)* in a ratio of 1:1 in dimethylformamide or diethylacetamide [19].



The intermediate pyromellitamidic acid *(17)* can be cast. On subsequent heating, intramolecular cyclodehydration leads to insoluble, infusible polyimide *(18)*.

The shear strength of adhesive joints between stainless steel adherends with polyimide adhesives is ≈ 2.0 kg/mm² at room temperature, ≈ 0.73 kg/mm² at 420 °C, and ≈ 0.42 kg/mm² at 530 °C; its value at −196 °C is greater than 2.8 kg/mm².

The aging resistance of polyimide adhesives can be seen from the following values: Storage of titanium adhesive joints at 310 °C for more than 4000 h led to a decrease in shear strength from the original value of ≈1.41 kg/mm² to 0.88 kg/mm², while storage at 260 °C for more than 2000 h resulted in no loss of shear strength [18]. The aging properties of polyimide adhesives, like those of the polybenzimidazoles, can be improved by the addition of arsenic compounds [19].

The mechanical properties of the polyaromatic adhesives at high temperatures are compared in Figures 2 and 3 with those of heat-resistant adhesives based on conventional resins. Figure 2 shows the variation of the shear strength with the testing temperature, while Figure 3 shows a plot of the shear strength against storage time at 260 °C [20].

The outstanding properties of these polyaromatic adhesives, particularly at high temperatures, make them suitable for use *e.g.* in the construction of aircraft for speeds of two to three times the speed of sound. During flight, the outer skins of

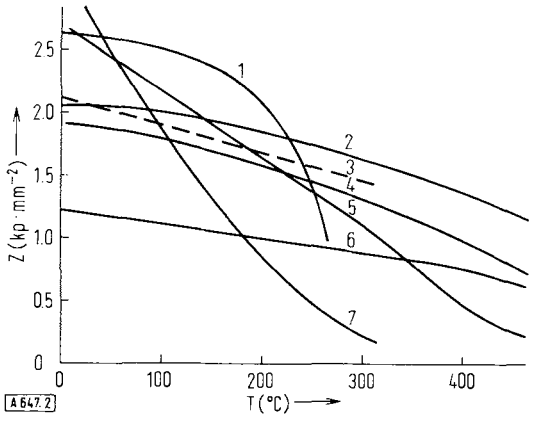


Fig. 2. Shear strength (Z) of joints between metal adherends with different adhesives as a function of temperature. 1: Modified epoxides; 2: polybenzimidazoles; 3: amides, imides; 4: polyimides; 5: epoxide-phenolic; 6: epoxide-silicone; 7: nitrile-phenolic.

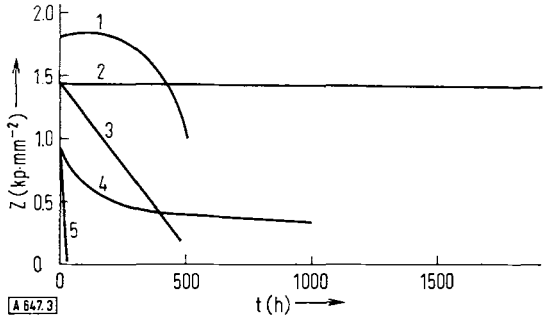

Fig. 3. Shear strength (Z) of joints between metal adherends at 260 °C as a function of storage time at 260 °C. 1: Polybenzimidazoles; 2: polyimides; 3: epoxide-phenolic; 4: epoxide-silicone; 5: modified epoxides.

such aircraft heat up to 200 to 260 °C because of friction with the air and the intense solar radiation at altitudes above about 25000 ft. Light alloys based on aluminum fail at these temperatures, and it is necessary to use materials based on titanium or high-strength steel, which are difficult to weld. The joints are therefore made with adhesives, which have the added advantage that they permit the production of structural elements having large smooth surfaces. New construction methods such as sandwich and laminated constructions are totally dependent on adhesive techniques.

3.7. Further Development of Polyaromatic Adhesives

The use of adhesives based on aromatic polymers has only started. Of the many aromatic polymers, mention should be made of two such substances, that are likely to become important as adhesives, not only for metals, but also for high-temperature plastics. The polybenzothiazoles *(19)* exhibit outstanding resistance to oxidative deterioration up to about 600 °C, while the phenylene sulfide polymers *(20)* should be thermally stable up to 900 °C.

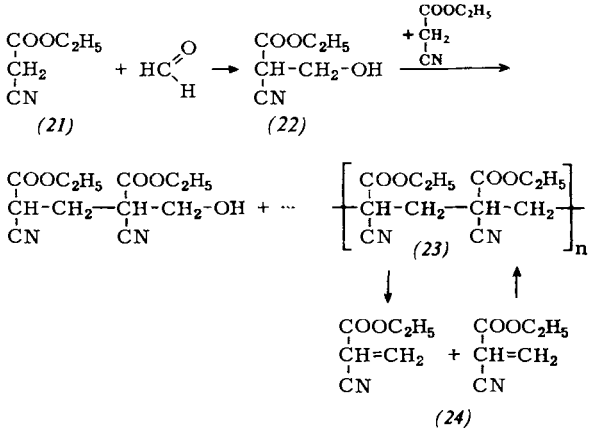
[21] *R. C. Kausen*, Mater. Design Engng. *60*, 108 (1964).

No details of the technological behavior of these materials as adhesives are yet available.

4. One-Component Adhesives as Blocked Polymer Systems

In the use of adhesives, the required operations to start the crosslinking process often present difficulties in practice (see also Section 2.1.1.). The difficulties relate to the mixing of two-component adhesives and the long setting times at room temperature. One-component systems that crosslink by condensation are expensive to use because of the cost of heated presses or autoclaves. There is therefore considerable interest in adhesives that need not be mixed and that set between the adherends, whenever possible without the application of heat or pressure. This requirement can be satisfied if chemically or mechanically blocked polymer systems are used as adhesives.

Typical examples of chemically blocked polymers are the cyanoacrylates *(23)*, which can be prepared from alkyl cyanoacetates *(21)* and formaldehyde *(22)* in the presence of basic catalysts.



The resulting polymers *(23)* are pyrolyzed to form cyanoacrylate monomers *(24)*, which repolymerize in the presence of weak bases, *e.g.* water (which is adsorbed on the surface of the adherends) or alcohols [2]. The polymerization is probably initiated by the strongly electron-attracting nitrile and ester groups situated very close to ethylenic double bonds. When these double bonds are polarized by weak bases, fast polymerization takes place, and the originally liquid adhesive sets within a few minutes.

To suppress spontaneous setting during storage, inhibitors are added to the cyanoacrylates. Mixtures of this type give bonds as strong *e.g.* as those obtained with epoxide resins. The disadvantage of these adhesives is that they cost about ten times as much as commercial epoxide resins. Since the monomers are very fluid and set only in the vicinity of the interfaces, cyanoacrylate adhesives are only suitable for joints with thin adhesive film thicknesses. Their thermal stability is also poor, since the polymerized substance is thermoplastic.

Other chemically blocked adhesives are diacrylates such as tetraethylene glycolyl dimethacrylate [22]. This adhesive sets with cumene hydroperoxide as the catalyst and benzenesulfimide as an accelerator to give a polymer. The monomer remains liquid in air. This is an advantage in the bonding of rings and wheels to shafts and in the fixing of ball bearings or screw joints.

A promising alternative to the chemical blockage of the reactants in cold-setting one-component adhesives appears to be mechanical separation of the reactive polymer from the catalyst. This can be achieved with the aid of molecular sieves, *e.g.* aluminum silicates (zeolites) [23]. The adhesive components in the cavities can be displaced by water, which is more strongly adsorbed in the crystals, or liberated by heat. The thermal energy must be greater than the adsorption energy in the cavities.

For example, benzoyl peroxide, which is a common catalyst for the curing of polyester resins, may be "accommodated" in molecular sieves and added to the resin by the manufacturer. The resulting one-component adhesive can be stored for long periods, and can be cured by the addition of water or by heating. The toxicity and flammability of these products before and during use are also reduced.

$S_E(P)$: Electrophilic Substitution at Phosphorus[**]

BY S. G. WARREN[*]

Reactions belonging to the formal category of electrophilic substitutions at phosphorus are classified according to mechanism and the coordination number of the phosphorus atom.

1. Introduction

Nucleophilic substitution at carbon, at the more familiar hetero elements, and even in metal complexes presents a well organized, useful array of mechanisms. The reactions which belong to the formal category of electrophilic substitution, however, do not normally form a conceptual entity. Electrophilic substitution in an aromatic system is rarely compared with the reactions of Grignard reagents or with the decarboxylation of acetoacetic acid; this is perhaps sensible since there seems little similarity between these mechanisms.

Electrophilic substitution at phosphorus is rather different. Phosphorus rarely forms more than one double bond and unsaturated systems involving phosphorus are normally attacked at the phosphorus atom by nucleophiles. The reactions corresponding to S_E(Aryl) are thus absent or unimportant in organophosphorus chemistry. Most electrophilic substitutions at phosphorus involve changes in the σ bond structure about the phosphorus atom. Electrophilic substitution at phosphorus therefore provides a unifying classification for certain well known reactions (*e.g.* the reactions of dialkyl phosphites with electrophiles) and some "anomalous" reactions (*e.g.* P–C bond cleavage in phosphonates).

This article is intended to supplement the many reviews of nucleophilic substitution at phosphorus, and nucleophilic attack by phosphorus[1,2], with a survey of the reactions from the literature under a reasonable classification of electrophilic substitutions. In most cases there is no precise mechanistic evidence.

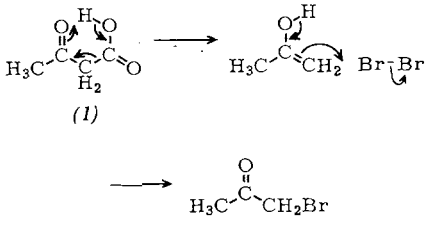
2. Electrophilic Substitution

Electrophilic substitution is the replacement of one group by another at the *substrate atom* (A) in which the *leaving group*[2a] (X) departs without its bonding electrons and the *electrophile* (Y) accepts electrons into an empty orbital to form the new bond with the substrate atom:

$$A{-}X + Y^{\oplus} \rightarrow A{-}Y + X^{\oplus}$$

An example from carbon chemistry is the decarboxylation of acetoacetic acid *(1)* with bromine.

The substrate atom (A) is the carbon (methylene) of acetoacetic acid, the leaving group (X) is CO_2, and the electrophile ($Y^{\oplus}$) is bromine. The reaction is in fact a two-step process with the enol form of acetone as an intermediate[4].



(1)

There are fundamentally, four types of mechanism possible for each valency state: S_E1, S_E2, addition-elimination, and elimination-addition.

3. S_E(P-3) Reactions

The trivalent phosphorus atom has a lone pair of electrons which may react with electrophiles[5]. Normally the first step is addition; the reaction may stop at this stage:

The addition step may alternatively be followed by an expansion of the valency shell of the phosphorus atom to form *(2)*.

Neither of these reactions is a substitution at the phosphorus atom: this is the third alternative in which

[**] The following notation is used in this article: S_E1 and S_E2 for monomolecular and bimolecular electrophilic substitution respectively. The symbol and number in brackets after these symbols denote substrate atom and its coordination number: P-3 is X_3P, P-4 is $X_3P{=}Y$, $P^{\oplus}$-4 is (phosphonium) $X_4P^{\oplus}$, P-5 is X_5P; X can be any atom or group of atoms and Y is normally O, S, Se, NR, or CR_2.

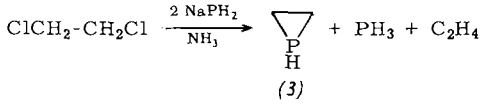
(2)

the trivalency is regenerated by the loss of an electrofugal substituent:

3.1. S_E1(P-3) Reactions

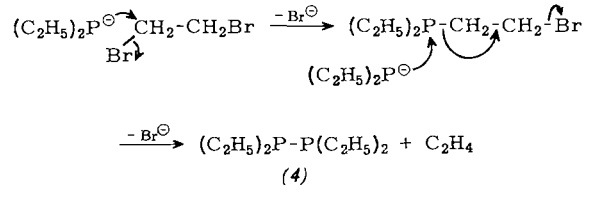
Alkali metals remove a hydrogen atom from primary or secondary phosphines to give salts [6]. These salts react readily in dry organic solvents with alkyl or acyl halides [7] to give secondary or tertiary phosphines in good yield.

Phosphirane has recently been prepared in this way by the action of sodium hydrogen phosphide in liquid ammonia on 1,2-dichloroethane [8]. Two electrophilic substitutions by the S_E1(P-3) mechanism are presumably involved.



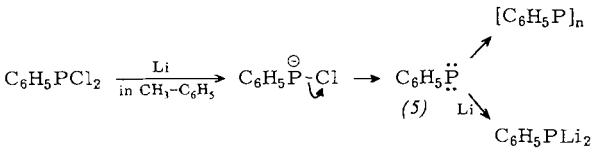
(3)

1,2-Dihaloethanes also react with dialkylphosphide anions. Ring formation is not, of course, possible and the second mole of $R_2P^{\ominus}$ ion apparently prefers the hard P-3 electrophile to the softer sp^3 carbon atom. A diphosphine is formed with the elimination of ethylene [9].



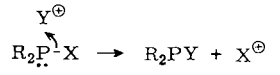
(4)

Salts may also be prepared from halophosphines and alkali metals [10] but if the anion bears a nucleofugal substituent (*e.g.* another halogen atom), an alternative reaction – elimination – occurs with formation of *(5)* [11]. These highly reactive intermediates either polymerize or combine with nucleophiles.

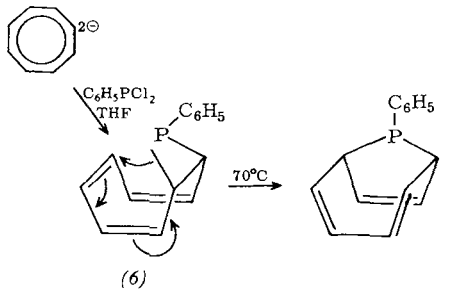


Phosphide anions react readily with other electrophiles such as epoxides [12], carbon dioxide [13], the halogens [14], and protic solvents [14].

3.2. S_E2(P-3) Reactions

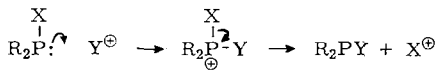


This mechanism seems unlikely since electrophiles will presumably prefer the lone pair electrons on the phosphorus atom to the relatively inaccessible electrons in a σ bond. The only reported example of a S_E2(P-3) reaction is the isomerization of the phenylphosphinecyclooctatetraene adduct *(6)* [15]. This is probably better described as a valence tautomerism.



(6)

3.3. Addition-Elimination



This mechanism is followed by the majority of S_E(P-3) reactions – not surprisingly, since the initial interaction between the lone pair of electrons and the electrophile must be particularly favorable. This step is well known, well documented [5], and mechanistically straightforward. The second step, the loss of the electrofugal substituent, has not been studied in detail but it may be inferred in many cases.

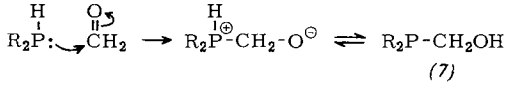
3.3.1. P–H Compounds

3.3.1.1. Addition of Phosphines to Carbonyl Compounds

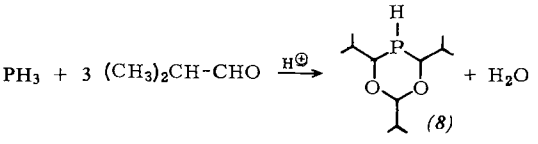
Phosphine, and substituted phosphines, react with most carbonyl compounds. The initial substitution gives an hydroxyalkylphosphine *(7)* [16].



(7)

This reaction is often followed by further additions (if phosphine or a primary phosphine is used) or further reactions with the carbonyl group since even trisubstituted phosphines are still nucleophilic, and complex cyclic products are usually formed [17].

Thus, when gaseous phosphine and liquid isobutyraldehyde are simultaneously introduced into a mixture of tetrahydrofuran and concentrated hydrochloric acid, the cyclic acetal *(8)* is obtained in 85% yield [18]. Presumably by condensation of the bis-hydroxyalkylphosphine which is first formed with a further molecule of aldehyde.



(8)

3.3.1.2. The Formation of P–P Bonds

Phosphines attack a P-3 atom which bears a nucleofugal substituent (*e.g.* a halogen atom) forming diphosphines *(9)* [19]. Even a disubstituted amine is expelled in this way, the equilibrium being 89 % to the

$$(CH_3)_2P{-}N(CH_3)_2 + (CH_3)_2PH \rightleftharpoons (CH_3)_2P{-}P(CH_3)_2 + (CH_3)_2NH$$

(9)

right at room temperature. The diphosphine *(9)* may be obtained more quickly by heating (yield up to 85 %).

3.3.1.3. Other Reactions

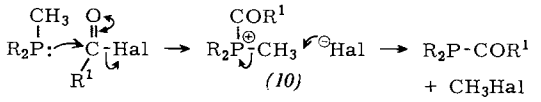
Trivalent P–H compounds react with most electrophiles including halogens [20], epoxides [21], carbon disulfide [22], acyl halides [23], isocyanates [24], oxidizing agents [25], and sulfur [20].

3.3.2. P–C Compounds

P–C bond cleavage is often regarded as anomalous. It is, however, an expected consequence of electrophilic attack on the phosphorus atom of a P–C compound if the carbon atom is electrofugal.

3.3.2.1. sp^3-Carbon as Leaving Group

The methyl group acts as an electrofugal leaving group when a methyl phosphine is attacked by an acyl halide, since nucleophilic attack by the phosphine on the halide generates a phosphonium compound *(10)*, and the methyl group is then attacked by the halide ion released in the first stage of the reaction [26].



(10)

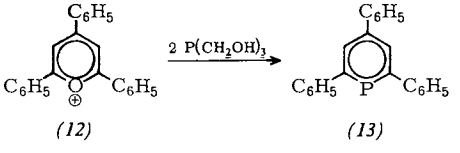
An oxygen substituent makes an sp^3 carbon atom a leaving group even without nucleophilic attack. Hydroxymethylphosphines, such as *(11)*, decompose in acidic solution and react with a number of electrophiles with loss of formaldehyde [27].

$$(HOCH_2)_3P + 3\,(CH_2{=}CHCN \rightarrow P(CH_2CH_2CN)_3 + 3\,CH_2O$$

(11)

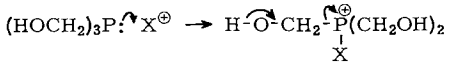
Tris(hydroxymethyl)phosphine is used to insert a phosphorus atom into electrophilic molecules. Thus, pyrylium salts *(12)* are converted into phosphabenzenes *(13)* with the loss of three molecules of formaldehyde [28, 29].

These reactions must involve a series of electrophilic substitutions in which a hydroxymethyl group is lost.



(12) *(13)*

$$+ 3\,CH_2O + O{=}P(CH_2OH)_3$$



3.3.2.2. sp^2 Carbon as Leaving Group

Nucleophilic attack on the carbonyl group provides the driving force for the decomposition of α-ketophosphines *(14)*. Oxygen, nitrogen, and phosphorus nucleophiles all react in this way [30].

The electrophile in these reactions, $H^{\oplus}$, is generated by the initial nucleophilic attack on the carbonyl group.

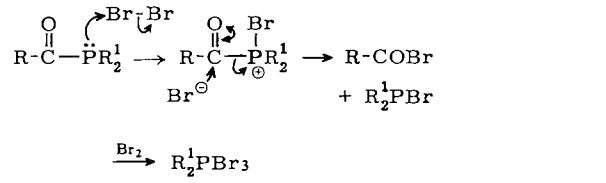
(14)

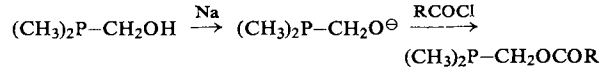
NuH = H_2O, C_2H_5OH, $(C_2H_5)_2NH$, $(C_6H_5)_2PH$

Ketophosphines also decompose with reagents such as bromine whose initial electrophilic attack at phosphorus generates a nucleophile for attack at the carbonyl group [30]. A quantitative yield of $R^1_2PBr_3$ is obtained from *(14)* in carbon tetrachloride solution at room temperature.

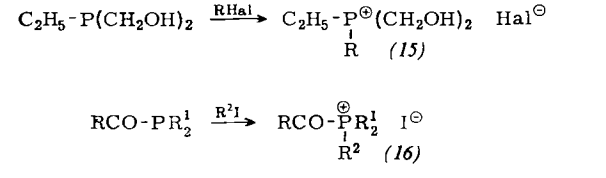


3.3.2.3. Other Reactions with Electrophiles

The reaction of a P-3 compound bearing an electrofugal substituent with an electrophile does not always lead to electrophilic substitution. Many electrofugal substituents are nucleophilic and may react with the electrophiles themselves – thus, hydroxymethylphosphines react with sodium and acid chlorides at oxygen and not at phosphorus [31].



Even when the electrophile does attack the phosphorus atom, the leaving group does not always depart; hydroxymethyl- *(15)* [31] and α-ketoalkylphosphonium [30] salts *(16)* may be prepared by the alkylation of the respective phosphines. The phosphine and alkyl halide are briefly heated under reflux in acetone [30].

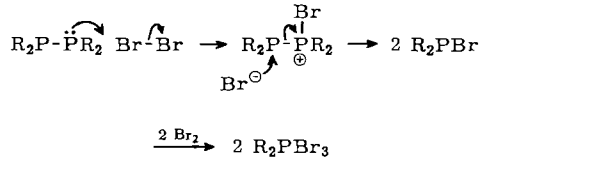


(15)

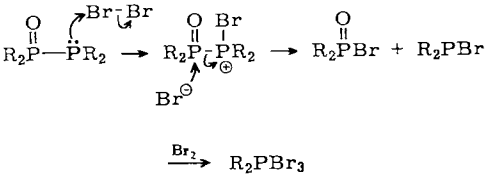
(16)

3.3.3. P–P Compounds [19]

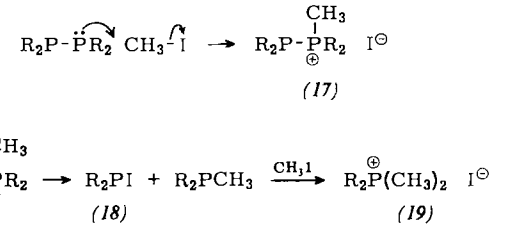
Diphosphines and diphosphine monoxides are susceptible to electrophilic substitution reactions since electrophilic attack on the lone pair electrons of one phosphorus atom may be followed by nucleophilic attack at the other phosphorus atom. Bromine, for example, cleaves diphosphines quantitatively in carbon tetrachloride solution at room temperature [32,33].



Diphosphine monoxides are attacked by the electrophile at the P-3 atom and by the nucleophile at the P-4 atom; for example, an equimolar mixture of the bromides is produced [34].



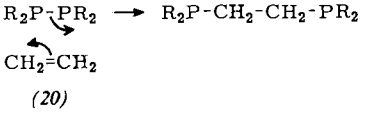
Even alkylation can lead to P–P bond cleavage. Tetramethyl and tetraethyl diphosphines give phosphonium salts *(17)* with methyl iodide but tetracyclohexyldiphosphine [32] and other diphosphines with bulky [32], aromatic, or electron-withdrawing substituents [35–37] are cleaved by alkylation; compounds *(18)* and *(19)* are formed.



(17)

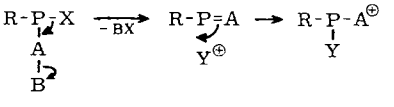
(18) *(19)*

A few reactions of diphosphines with electrophiles follow different courses: although oxidation with 2 M nitric acid does give rapid P–P cleavage of tetraalkyl diphosphines with the production of phosphinic acids, dry air bubbled through a benzene solution of the diphosphine gives the dioxide [35]. P–P cleavage may also be a cyclic process; with olefins, diphosphines insert two carbon atoms into the P–P bond in a reaction which seems best described as a cycloaddition *(20)* [38].



(20)

3.4. Elimination-Addition



This mechanism probably does not occur since the indications are that intermediates of the structure

[38] *A. B. Burg*, J. Amer. chem. Soc. *83*, 2226 (1961).

R–P=A react with nucleophiles rather than with electrophiles [39].

4. $S_E(P^{\oplus}\text{-}4)$ Reactions

It would be surprising if positively charged atoms were readily attacked by electrophiles, and indeed the only mechanism whereby the positively charged phosphorus atom substitutes electrophilically appears to be the $S_E1(P^{\oplus}\text{-}4)$ mechanism in which the positive charge is lost *before* electrophilic attack occurs. This mechanism is in fact simply the addition-elimination mechanism for $S_E(P\text{-}3)$ with the two steps in the reverse order

$$R_3\overset{\oplus}{P}\text{-}X \longrightarrow R_3P: \curvearrowright Y^{\oplus} \longrightarrow R_3\overset{\oplus}{P}Y$$

The one important example of this mechanism is the reaction of hydroxymethylphosphonium salts *(21)*. These compounds lose formaldehyde on treatment with base to give a phosphine which may then be alkylated before another mole of formaldehyde is in turn removed by treatment with base. In this way asymmetrically substituted phosphines may be synthesized [40].

$$HO^{\ominus} \curvearrowright H\text{–}O\text{–}CH_2\text{–}\overset{\oplus}{P}(CH_2OH)_3 \longrightarrow (HOCH_2)_3P + CH_2O$$

(21)

$$(HOCH_2)_3P \xrightarrow{RI} (HOCH_2)_3P^{\oplus}RI^{\ominus} \xrightarrow{NaOH} (HOCH_2)_2PR + CH_2O$$

$$(HOCH_2)_2PR \xrightarrow{R^1I} (HOCH_2)_2P^{\oplus}RR^1\ I^{\ominus} \longrightarrow \textit{etc.}$$

Tetrakis(hydroxymethyl)phosphonium salts *(21)* react with dimethylamine to give tris(dimethylaminomethyl)phosphine *(22)* in an interesting variation of this reaction. Here the liberated formaldehyde combines with the phosphine and the dimethylamine in a Mannich reaction [41].

$$(HOCH_2)_4P^{\oplus}X^{\ominus} \xrightarrow{(CH_3)_2NH} (HOCH_2)_3P + CH_2O + (CH_3)_2NH_2^{\oplus}\ X^{\ominus}$$

(21)

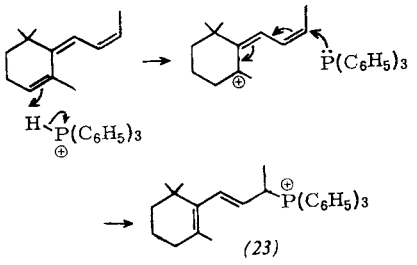
$$CH_2O + (CH_3)_2NH \longrightarrow (CH_3)_2\overset{\oplus}{N}{=}CH_2$$

$$(CH_3)_2\overset{\oplus}{N}{=}CH_2 \curvearrowleft :P(CH_2OH)_3 \longrightarrow$$

$$(HOCH_2)_3\overset{\oplus}{P}\text{-}CH_2\text{-}N(CH_3)_2 \longrightarrow\longrightarrow\longrightarrow 3\ CH_2O + [(CH_3)_2N\text{-}CH_2]_3P$$

(22)

One route to Wittig reagents uses this mechanism: olefins add protonated phosphines to give phosphonium salts *(23)* [42]. Subsequent treatment with strong base generates a Wittig reagent.



(23)

5. $S_E(P\text{-}4)$ Reactions

The range of reactions which are formally $S_E(P\text{-}4)$ is very large and contains representatives of most classes of electrophiles and leaving groups. In a few cases mechanistic studies have been attempted and for one mechanism at least (the "tautomerism" mechanism) it is possible to present well documented examples.

5.1. $S_E1(P\text{-}4)$ Reactions

$$R_2\overset{O}{\overset{\|}{P}}\text{-}X \longrightarrow R_2\overset{O}{\overset{\|}{P}}{}^{\ominus} \curvearrowright Y^{\oplus} \longrightarrow R_2\overset{O}{\overset{\|}{P}}\text{-}Y$$

Phosphite diesters are useful synthetic reagents and many reactions are known in which their anions react with electrophiles. Secondary phosphine oxides are less well known but react in much the same way. (A full account of these reactions is given in Houben-Weyl [43].) Leaving groups other than the proton are known. It is assumed that $S_E\text{-}(P\text{-}4)$ reactions that occur in strong bases have an anion as an intermediate.

5.1.1. Reactions of P–H Compounds with Base and Electrophile

Dialkyl and diaryl phosphites react with alkali metals in inert organic solvents to give the anions $(RO)_2PO^{\ominus}$, which combine with most electrophiles. Their alkylation and acylation are standard synthetic procedures [43].

These anions also attack phosphorus atoms. Attack is possible through phosphorus or oxygen and a mixture of compounds is normally formed [44]. This remains, however, the best method of preparing hypophosphates since yields of up to 60% may be obtained by adding cold (0–5 °C) phosphorohalidate to a solution of the anion in benzene. The hypophosphate *(24)* is collected by distillation. Higher yields are obtained by generating the phosphorohalidate in the presence of the anion with a reagent such as sulfuryl chloride [45].

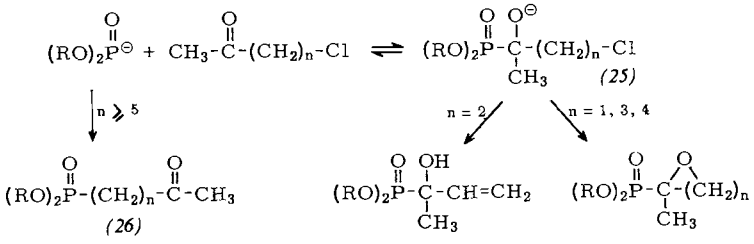
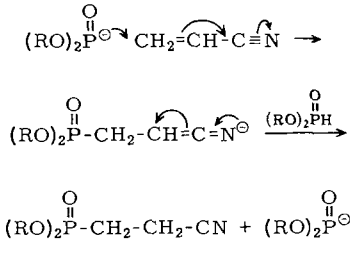
(24)

Phosphite anions are hard bases and prefer the hard electrophiles [46] (such as the carbonyl group) to the softer sp^3 carbon atoms. Halo ketones are therefore normally attacked first at the carbonyl group and the intermediate *(25)* trapped by displacement of the halide ion with the negatively charged oxygen atom produced. If the chain is sufficiently long, however, reversible addition to the carbonyl group allows the thermodynamically favored product, oxophosphonate *(26)*, to be formed [47].

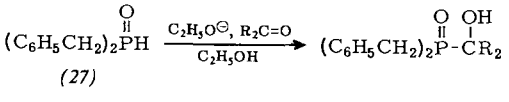


(25) *(26)*

Only a trace of base is needed to catalyze the addition of dialkyl phosphites to electrophilic olefins [48], since the dialkylphosphite anion is continuously regenerated by protonation of the product. The reactions are normally carried out in alcohol with a trace of alkoxide as catalyst. Secondary phosphine oxides also form anions which react with electrophiles and oxidizing agents [49], *e.g.* $R_2P(O)^{\ominus}$ reacts with H_2O_2 or R^1Hal to give $R_2PO_2^{\ominus}$ or $R_2P(O)R^1$.

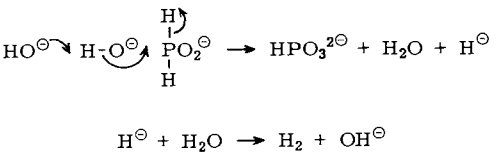


The phosphine oxides *(27)* also undergo base-catalyzed additions to aldehydes [49], ketones [50], and α,β-unsaturated ketones [50]. These reactions are again carried out in alcohol with a trace of alkoxide as catalyst.



(27)

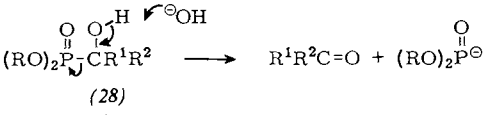
Strong hard bases [46], such as hydroxide ion in water, attack the phosphorus atom in $H_2PO_2^{\ominus}$ directly, expelling hydride ions as hydrogen gas [51]. This reac-



tion even occurs with hypophosphorous acid [52] although kinetic work shows that catalysis is needed since the rate is proportional to the *square* of the hydroxide ion concentration.

5.1.2. P–C Bond Cleavage

α-Hydroxyphosphonates *(28)* are cleaved by strong base in aqueous solution to a carbonyl compound and a phosphite [53, 54]. The hydroxide ion presumably removes a proton from the hydroxyl group with consequent P–C cleavage and elimination of a phosphite anion. This is the reversal of the formation of α-hydroxyphosphonates which is normally carried out in non-aqueous solvents with a weak base (tertiary amine) or only a trace of strong base as catalyst [55].



(28)

The phosphorus atom is an alternative site for nucleophilic attack and side reactions include the elimination of the carbon atom as an alcohol [*(28)*, R = R^1 = C_6H_5, R^2 = H] [49] or even the evolution of hydrogen gas [*(28)*, R = C_6H_5, R^1 = R^2 = CH_3] [51].

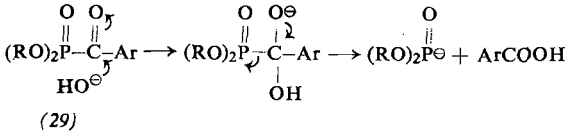
[55] Ref. [6], Part 1, p. 475.

When the β carbon atom of the phosphonate *(28a)* has a nucleofugal substituent, a rearrangement occurs producing a phosphate ester with elimination of the nucleofuge [54,56] as an anion.

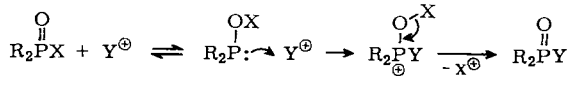
α-Ketophosphonates *(29)* are also cleaved by aqueous base, since addition of hydroxide ion to the carbonyl group provides a good leaving group [57].



(29)

Very strong bases are not needed for this reaction; benzoyl phosphonates are used as benzoylating agents for such nucleophiles as thiophenolate anion [58]. Uncharged nucleophiles such as hydrazine, hydrogen sulfide, hydrogen cyanide, or dialkyl phosphites, however, add to the carbonyl group without C–P cleavage since no anion is generated [59].

5.2. Tautomerism Mechanism

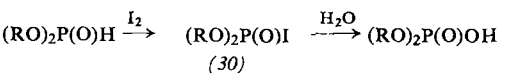


This mechanism is particularly favorable when X = H and is probably correct for most reactions of dialkyl phosphites and phosphine oxides which are not catalyzed by strong base. The phosphite-phosphonate tautomerism, which forms the first step, is essentially completely to the left. The rate determining step is often the formation of the phosphite-tautomer.

5.2.1. Oxidation and Exchange of the P(O)H Group [60]

Compounds with a P(O)H group, such as dialkyl phosphites, react with oxidizing agents to give the P(O)OH group, and with deuterium oxide to give the P(O)D group.

Hydrogen-deuterium exchange in dialkyl phosphites is catalyzed both by acids [61] and by bases [62]. The rate expression has terms for uncatalyzed, base-catalyzed, and both general and specific-acid catalyzed reactions. Oxidation (with iodine, for example) gives an identical rate expression and the rate constants for oxidation and exchange are very similar [63,64] (see Table 1). Oxidation with iodine must involve the formation of a phosphoroiodate intermediate *(30)* which is rapidly hydrolyzed to a phosphate diester. The rate, however, is independent of the iodine concentration. These facts suggest that there is a common



(30)

rate-determining step for oxidation and exchange and that this is the phosphonate-phosphite tautomerism:

Deuterium isotope effects for the oxidation reaction confirm this conclusion since the rate of oxidation of $(RO)_2P(O)D$ is substantially lower than that of the proton equivalent (see Table 1) [63].

Table 1. Oxidation and exchange with dialkyl phosphites [61–64].

acid catalyzed: rate = $(k_w + k_{H\oplus}[H^\oplus])[(RO)_2P(O)H]$

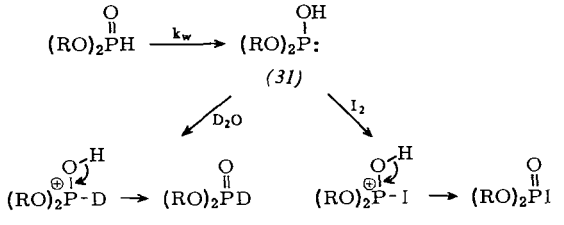
base catalyzed:

rate = $(k_w + k_{AcO\ominus}[AcO^\ominus] + k_{AcOH}[AcOH])[(RO)_2P(O)H]$

Catalyst	Rate Constants [a]		k_H/k_D $((RO)_2P(O)D)$
	Exchange	Oxidation	
$H^\oplus$	$k_{H\oplus} = 6\times10^{-2}$ $k_w = 8\times10^{-3}$ (23 °C)	3×10^{-2} 5×10^{-3} (20 °C)	4 1.7
$AcO^\ominus$	$k_{AcO\ominus} = 0.52$ (21 °C)	0.32 (20 °C)	–

[a] $k_{H\oplus}$, $k_{AcO\ominus}$ in $l\cdot mol^{-1}\cdot mm$; k_w in mm^{-1}.

The mechanism for the uncatalyzed reaction may therefore be written



Similar results have been obtained with phosphorous acid [65], hypophosphorous acid [66–68], phenyl hydrogen phosphinic acid $(C_6H_5)P(O)H\cdot(OH)$ [69], phosphites [70], and secondary phosphine oxides [71].

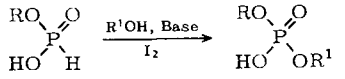
The final stage in the oxidation of phosphorous acid [72,73] or its monoesters [74] is nucleophilic attack by water. If the oxidation is carried out in an alcohol, phosphorylation of the alcohol then occurs [72,73] and a high yield of mono- or diester of phosphoric acid is obtained.



R = H or Alkyl

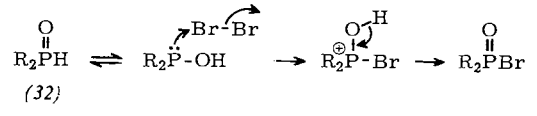
5.2.2. Other Reactions of P(O)H Compounds

5.2.2.1. Dialkyl Phosphites

No other quantitative work has been done on the reactions of dialkyl phosphites with electrophiles but very many such reactions are known. They are summarized in Houben-Weyl [75].

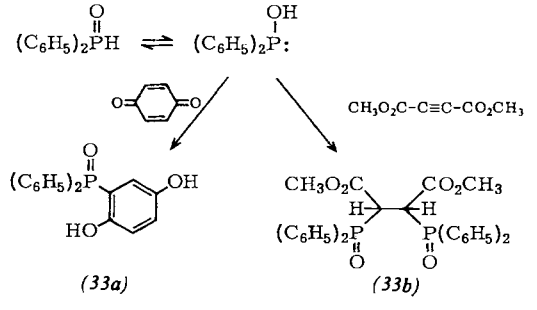
5.2.2.2. Secondary Phosphine Oxides [76]

Dialkyl- [50,76] and diaryl- [71] phosphine oxides *(32)* react with halogens, oxidizing agents such as nitric acid or hydrogen peroxide [77], and sulfur without base catalysis. The mechanism is presumably the same as that for the phosphite diesters.



(32)

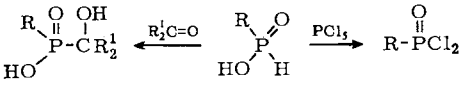
Addition to unsaturated compounds also occurs: diphenylphosphine oxide, for example, gives 1:1 and 2:1 adducts, *(33a)* and *(33b)*, respectively, with quinone and acetylenedicarboxylic ester [51].



(33a) *(33b)*

5.2.2.3. Hydrogen Phosphinates RP(O)(OH)H

These acids *(34)* are readily oxidized to phosphonic acids, react with halogenating agents to give phosphonic dihalides, and add to carbonyl groups to give phosphinic acids [78,79]. Phosphorous and hypophosphorous acids (R = OH and H respectively) behave similarly [80].



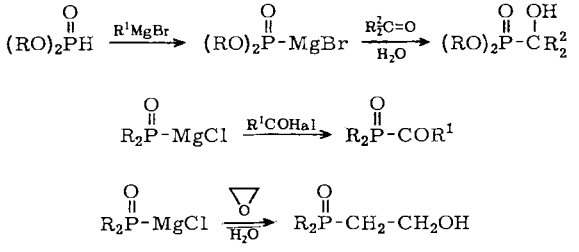
(34)

5.3. S_E2(P-4) Reactions

Base-catalyzed S_E(P-4) reactions have been assumed to be S_E1(P-4) (Section 5.1.) while those with $H^{\oplus}$ as leaving group (not base catalyzed) have been treated under the tautomerism mechanism (Section 5.2.). Other reactions will be treated here.

5.3.1. Organometallic Compounds

The substituted metal atom, one of the classical electrofugal leaving groups in carbon chemistry [81], is also known in organophosphorus chemistry. Grignard reagents, for example, can be prepared from dialkyl phosphites [82], and dialkyl- [50] or diaryl-phosphine oxides [71]. They are powerfully nucleophilic and react with ketones, acyl halides, and epoxides to give good yields of a variety of P–C compounds.



5.3.2. Phosphorus Migrations

There are a number of reactions which are very difficult to explain without a 1,2 Wagner-Meerwein type of migration of a phosphorus atom along a σ bond. The reaction of diethyl benzoylphosphonate *(35)* with diazomethane [82] is an example. The reaction product *(36)* has a methylene group "inserted" between the carbonyl group and the phosphorus atom. This is a well-known reaction in carbon chemistry leading to ring expansion in cyclic [83] or migration in acyclic ketones [84].

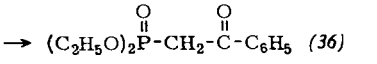
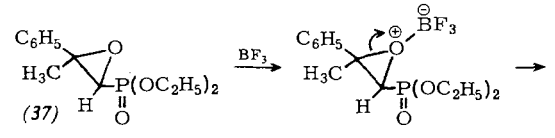
(35)

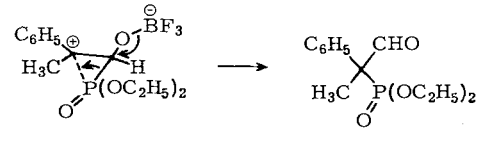


(36)

If this mechanism is correct, the $(C_2H_5O)_2P(O)$ group migrates better than the phenyl group. The same group apparently migrates when α,β-epoxy phosphonates are heated or treated with boron trifluoride in ether [85].

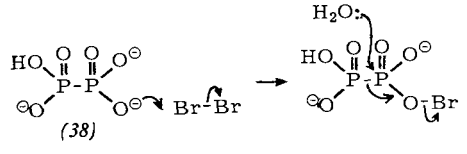


(37)

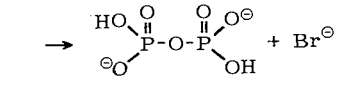


5.3.3. The Oxidation of Hypophosphoric Acid

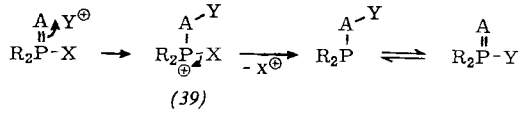
Hypophosphoric acid *(38)* reacts with bromine water at pH = 7 to give pyrophosphoric acid in 97% yield [86]. The pH-rate profile for the reaction is bell shaped: the two inflections correspond to the third dissociation constant of hypophosphoric acid and the reaction of bromine with hydroxide ion. The reaction is thus one between the trianion of the acid and bromine. The very high yield suggests that the reaction is not one of cleavage to phosphate and a phosphorylating fragment since the latter would be expected to phosphorylate the solvent. A better explanation is phosphorus migration:



(38)



5.4. Addition-Elimination

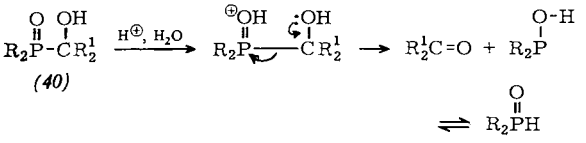


(39)

This mechanism involves the same steps as the tautomerism mechanism but in the reverse order. The first step is attack by the electrophile on the phosphoryl oxygen (or sulfur *etc.*) atom (A), the expected site for electrophilic attack in a P-4 compound. The intermediate phosphonium compound *(39)* can react in many ways however, and only if X is a good electrofuge will substitution occur. The mechanism is especially favored if X = H since the last stage, the phosphite-phosphonate tautomerism, is then rapid.

5.4.1. α-Hydroxyphosphonates

The P–C bond of an α-hydroxyphosphonate *(40)* [87] (or phosphine oxide) [50] is quantitatively cleaved in aqueous acidic solution to form a carbonyl compound and a phosphite. The reaction is reversed in the absence of water and with base catalysis. The cleavage reaction is presumably initiated by protonation of the phosphoryl oxygen atom.

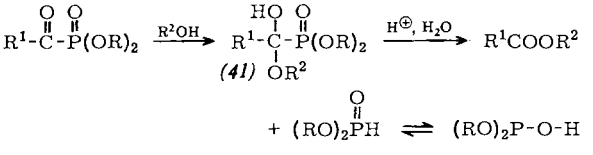


(40)

Other electrophiles, such as acid chlorides or anhydrides, attack the OH group without P–C bond cleavage [88].

5.4.2. α-Ketophosphonates

When an α-ketophosphonate is dissolved in an alcohol, the carbonyl adduct may be isolated. This adduct decomposes to a carboxylic ester and a phosphite when treated with aqueous acid [89].



(41)

Ketophosphonates are also hydrolyzed by aqueous acid; the same mechanism presumably applies. The hemiacetal *(41)* and the diol *(42)* are stable until protonated, whereupon a good leaving group (phosphite) is formed [57,90].

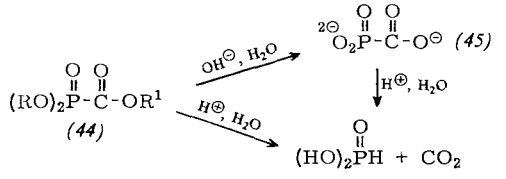
[90] *B. Ackermann*, *T. A. Jordan*, *C. R. Eddy*, and *D. Swern*, J. Amer. chem. Soc. *78*, 4444 (1956).

In the absence of water, treatment with acid removes only the esterifying groups to give pure ketophosphonic acid *(43)* (70–100 % yield)[91].

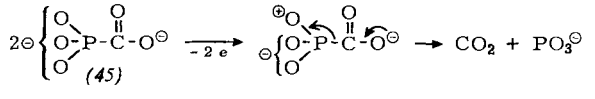
$$(RO)_2P(O)-COR^1 \xrightarrow[2.\ H_2O]{1.\ HBr} (HO)_2P(O)-COR^1 + 2\ ROH$$

5.4.3. Phosphonoformates

Phosphonoformate esters *(44)* hydrolyze rapidly in aqueous alkali to give the trianion *(45)* of phosphonoformic acid. In aqueous acidic solution, however, both the ester and the acid decarboxylate to give phosphorous acid[92–94].



The decarboxylation of the acid shows uncatalyzed and acid catalyzed reactions[82,83]. The trianion also reacts with oxidizing agents with loss of carbon dioxide and formation of phosphate in aqueous solution[96] or alkyl phosphate in alcoholic solution[95]. This reaction, represented formally, is the removal of two electrons from the trianion *(45)* leading to the loss of CO_2 and the generation of a phosphorylating agent – probably metaphosphate[95].



5.4.4. Phosphonates and Phosphine Oxides

The thermal decomposition of alkyl phosphonates and phosphine oxides is not acid catalyzed but the elimination of olefin as one product suggests an electrocyclic process in which a hydrogen atom is transferred from the β carbon atom to the phosphoryl oxygen atom[97].

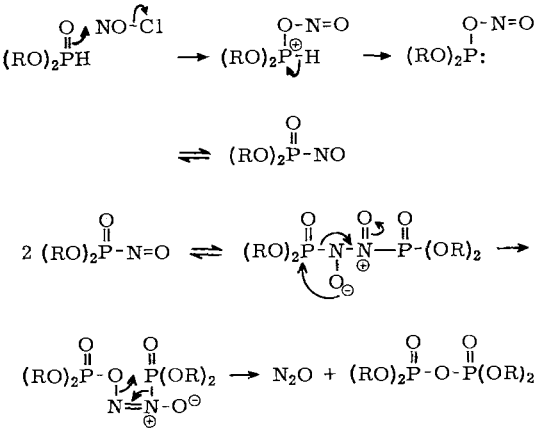
[97] *W. J. Bailey, M. W. Muir,* and *F. Marktscheffel,* J. org. Chemistry *27,* 4404 (1962).

5.4.5. Phosphites

The Michalski reaction between a dialkyl phosphite and nitrosyl chloride, which, in benzene, gives up to 90 % of tetraalkyl pyrophosphate[98] has aroused some mechanistic speculation[99].

$$2\ (RO)_2P(O)H \xrightarrow{2NOCl} (RO)_2P(O)-O-P(O)(OR)_2 + N_2O + 2\ HCl$$

The reaction is first order in both reagents; ^{18}O studies show that the pyrophosphate oxygen atom comes exclusively from the nitrosyl chloride and there is a negligible deuterium isotope effect when $(RO)_2P(O)D$ is used. The tautomerism- and S_E2-mechanisms are excluded by these facts and the most likely mechanism seems to be initial attack on the phosphoryl oxygen atom followed by a series of rearrangements:



The dimerization of nitroso compounds, the three-membered cyclic rearrangement at phosphorus[53], and the four-membered electrocyclic process (like the Wittig reaction[100]) are all well established reactions. Another example of this mechanism is the acid catalyzed deuterium exchange and oxidation of dialkyl phosphites discussed above (Section 5.2.1.).

5.4.6. P–P Compounds

Hypophosphoric acid[101] and its esters[44], diphosphine dioxides[102] and their thiono analogs[103,104], are all attacked by electrophiles with P–P bond cleavage. The reactions are satisfactorily explained by initial electrophilic attack at phosphoryl oxygen or sulfur (which generates a phosphonium center) and subsequent nucleophilic attack at the other phosphorus

[98] *J. Michalski* and *A. Zwierzak,* Chem. and Ind. *1960,* 376; Roczniki Chem. (Ann. Soc. chim. Polonorum) *35,* 619 (1961).

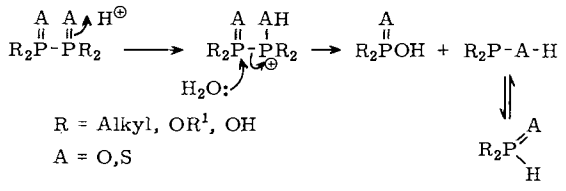
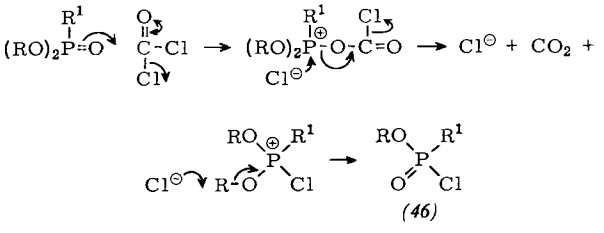
atom releasing the phosphite tautomer of the product. Acids, halogens, and sulfuryl chloride all react in this way.



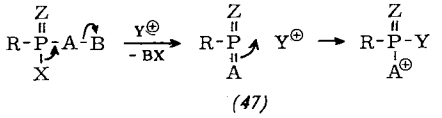
5.4.7. Electrophilic Attack on Phosphoryl Oxygen

Phosphates and phosphonates are attacked electrophilically at the P=O group by many reagents without *electrophilic* substitution at the phosphorus atom. Thus phosgene converts phosphonate diesters to phosphonochloridates by electrophilic attack at P=O followed by *nucleophilic* substitution at the phosphorus atom [105].



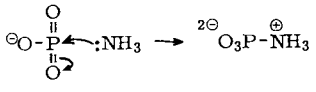
(46)

5.5. Elimination-Addition



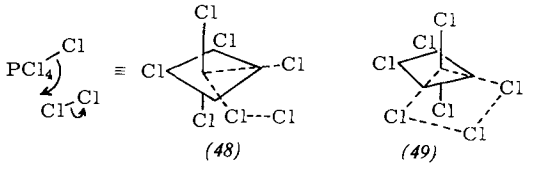
(47)

This mechanism has not yet been reported and it seems rather unlikely since metaphosphate reacts with nucleophiles rather than electrophiles.



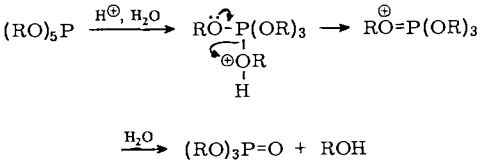
6. S_E(P-5)

The reaction of PCl_5 with radioactive chlorine [106] is the only S_E(P-5) reaction so far reported. Three chlorine atoms are replaced, presumably the three equatorial chlorine atoms, which precludes any ionic mechanism since the generation of $PCl_4^{\oplus}$ or $PCl_6^{\ominus}$ would make four chlorine atoms equivalent. A transition state such as *(48)* or *(49)*, which preserves the asymmetry of the trigonal bipyramid, is suggested.



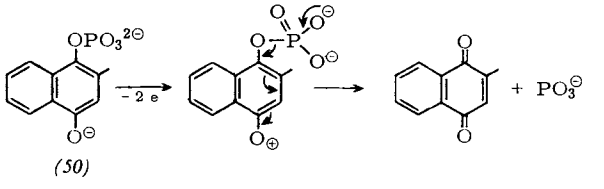
(48) *(49)*

Most P-5 compounds react with electrophiles with a change in coordination number [107].



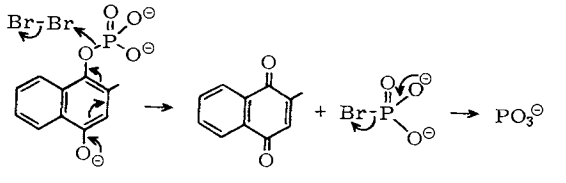
7. Oxidative Phosphorylation

One of the most intriguing biological-chemical problems is that of the reactions in the electron oxidation and cytochrome chain in which inorganic phosphate and ADP are converted into ATP under oxidizing conditions [108]. A chemical model for one of these steps is the oxidation of a quinol phosphate [109]. The usual description of such reactions is as



(50)

nucleophilic substitutions at the phosphorus atom [110]; they can, however, be interpreted as S_E(P-4) reactions.



Models for this process are the phosphorylation of alcohols by the oxidation of phosphorous acid [72] or phosphonoformate trianion [95]. Other oxidative phosphorylations include the treatment of thiol esters with iodine [111], the

oxidation of nitrone-phosphate adducts[112], and of phosphate esters of ascorbic acid[113].

In any event there must be at least two stages in an oxidative phosphorylation reaction: (i) the incorporation of inorganic phosphate into some organic molecule and (ii) the phosphorylation of ADP by this organophosphorus compound. One at least of these stages must be an oxidation. Naturally, there could be more stages between incorporation and phosphorylation.

There are three separate points in the cytochrome chain at which oxidative phosphorylation occurs, each presumably involving different metabolites[114]. Yet more reactions are involved in the analogous photosynthetic phosphorylations[115].

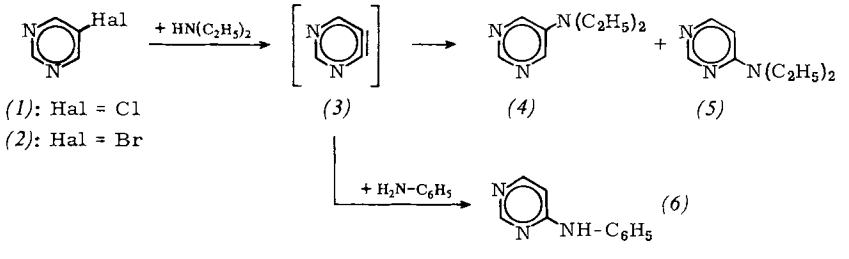
The Third Mechanism (AE_a) of Nucleophilic Aromatic Substitution[1]

By *Th. Kauffmann, R. Nürnberg*, and *K. Udluft*[*]

Reaction of the 5-halopyrimidines *(1)* or *(2)* with diethylamine at 130 °C (autoclave) affords 4-diethylaminopyrimidine *(5)* as well as the 5-isomer *(4)*; in the reactions with piperidine the *cine*-substitution product *(7a)* is formed[3,4]. The *EA* mechanism, involving *(3)*, which is thus indicated is supported by the observation that, in analogous reactions of *(1)* and *(2)* with diethylamine + aniline or with piperidine + aniline (in all cases 1:1), compound *(6)* is formed (yield 20–35%) in addition to the products named above, whereas aniline alone does not react with *(1)* or *(2)* under the same conditions.



Since the reaction of *(1)* and *(2)* with diethylamine gives the substitution products *(4)* and *(5)* [yield of *(4)* + *(5)* from *(1)* 29%, and from *(2)* 43%] in quite different molar proportions (82:18 and 40:60, respectively), a pure *EA* reaction by way of *(3)* is excluded and a mixture of *EA* and AE_n[3] is probable. The base-competition method was used to clarify the situation[2]. In separate experimental series at 130 °C compounds *(1)* and *(2)* were treated simultaneously with piperidine and diethylamine, which were used in various defined proportions. In each case the *cine*-substitution products *(5)* and *(7a)* were formed alongside the 5-substituted pyrimidines *(4)* and *(7b)*.

In a mixed EA/AE_n reaction, *(5)* and *(7a)* would be formed exclusively by way of *(3)*. Their relative amounts must thus remain constant if the halogen atom of the starting material is varied. As shown in Figure 1, this is not the case. *(5)* and *(7a)* thus certainly do not arise by way of *(3)* alone; some other *cine*-substitution mechanism must be operative. This mechanism, like the AE_n mechanism and unlike the *EA* mechanism[3], is not suppressed on addition of a good proton donor, so that it can hardly be other than the anomalous addition-elimination mechanism (AE_a)[3], with formulation by way of *(8)* and *(9)* being particularly probable.

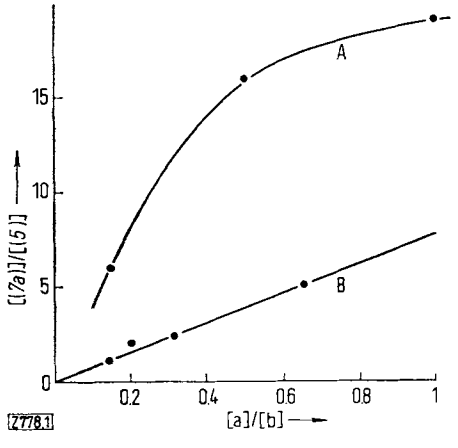


Fig. 1. Results of base-competition experiments with *(1)* (A) and *(2)* (B). *(5)* and *(7a)* were determined by gas chromatography [5] [a]/[b] = [piperidine]/[diethylamine].

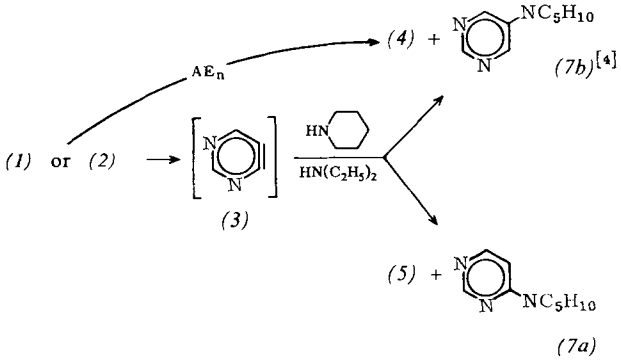
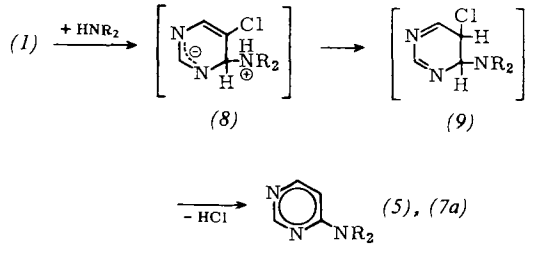
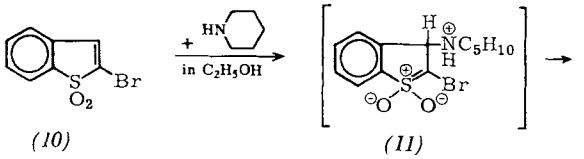


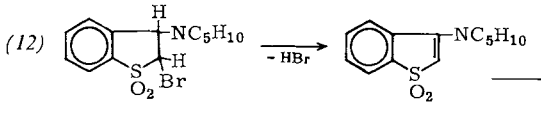


We assume that the AE_a mechanism is concerned with *cine*-substitution of *(1)* but not of *(2)*. This is because the experimental points lie on a curve for the competition experiments with *(1)* but on a straight line for those with *(2)*; in our experience – admittedly only for *EA* and AE_n substitutions – a mixed mechanism is displayed by non-linear dependence of the molar proportions of the substitution products on the molar proportions of the competing bases, whereas a pure mechanism leads to linear dependence[2,6,7]. Further, reaction of *(1)* with piperidine to yield *(7a)* is not inhibited by ethanol whereas the corresponding reaction with *(2)* is wholly suppressed on addition of ethanol, facts which indicate participation of the AE_a mechanism only in the competition experiments with *(1)*. The change from chloride *(2)* to bromide *(1)* apparently favors the AE_a mechanism over the *EA* mechanism[8].

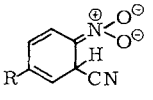
The AE_a mechanism was previously demonstrated only for the reaction of piperidine with *(10)*[9]. This reaction, in which intermediate *(12)* was isolated, can be formulated as



(10) *(11)*



(12)



(13)

proceeding by way of *(11)* [cf. *(8)*]. The close resemblance to the "von Richter carboxylation reaction"[10] (nucleophile: $CN^{\ominus}$; anionic leaving group: $NO_2^{\ominus}$; hypothetical intermediate: *(13)*; solvent: ethanol) should be pointed out.

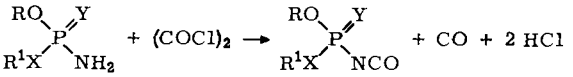
Phosphorus(v) Isocyanates

By *L. I. Samaraj, O. I. Kolodjažnij,* and *G. I. Derkatsch*[*]

Recently we reported[1] a simple synthesis of diester isocyanates of phosphoric and thiophosphoric acid *(2)* by the action of oxalyl chloride on the corresponding diester amides *(1)*. The reaction is effected at 0 °C in an inert solvent such as carbon tetrachloride or benzene.

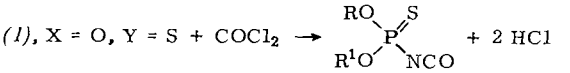


(1) X, Y = O, S *(2)*

We have now found that isocyanates *(3)* are also formed by the action of phosgene on diaryl thiophosphoramidates in boiling toluene or chlorobenzene[2].

Diaryl phosphoramidates do not react under these conditions. Dialkyl phosphoramidates and thiophosphoramidates do react, even at 0 °C, but the isocyanates are then formed in only poor yield.

Finally we have used organic bases (pyridine, triethylamine) as HCl acceptors in the reaction of phosphorus(v) amides



(3)

	R	R^1	Yield (%)	B.p. (°C/torr)	n_D^{20}	d_4^{20}	Ref.

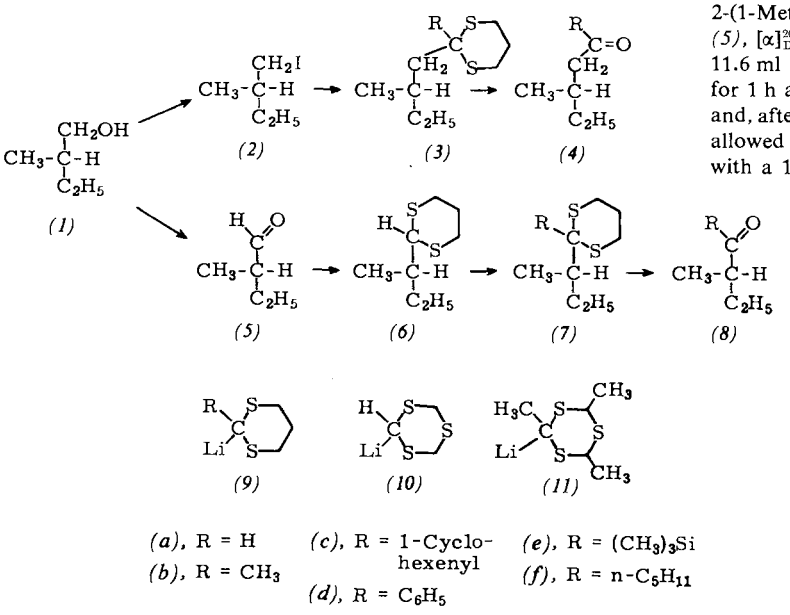
Preparation of (*S*)-2-Methylbutyl and (*S*)-*sec*-Butyl Ketones from Optically Active 2-Methyl-1-butanol by the Dithiane Method

By *D. Seebach* and *D. Steinmüller* [*]

Since optical resolution of aldehydes and ketones is difficult, optically active members of these series are usually prepared from other optically active compounds. Thus the carbonyl compounds *(4)* can be prepared from fermentation alcohol (2-methyl-1-butanol) *(1)* by way of *(2)* and its metal derivatives [yield *(2)*→*(4)* < 50%] [1].

The dithiane method [2] offers a suitable means for replacement of the halogen atom in *(2)* by an acyl group. For example, with 2-lithio-1,3-dithiane *(9a)* the iodide *(2)* gives a 65% yield of compound *(3a)* (b.p. 74 °C/0.3 torr) and thence by hydrolysis the aldehyde *(4a)*. The optically active ketones *(4b)*–*(4e)* can be obtained similarly. The lithio derivatives *(10)* [2b] and *(11)* were also used as "masked" acyl anions.



(a), R = H *(c)*, R = 1-Cyclohexenyl *(e)*, R = $(CH_3)_3Si$
(b), R = CH_3 *(d)*, R = C_6H_5 *(f)*, R = $n\text{-}C_5H_{11}$

(7), R = Li, + $n\text{-}C_5H_{11}I$	*(8f)*	50	+13.4	+22.4	—

[a] *(2)*: $[\alpha]_D^{23} = +4.8$ (pure liquid) (*ca.* 85% opt. pure); *(6)*: see experimental section.

[b] The crude products *(3)* and *(7)* were hydrolyzed directly. Yields refer to once distilled carbonyl compound.

[c] Calculated on optically pure starting material *(1)*, *(2)*, *(6)*, or *(8)*, R=OH; cf. experimental section.

[d] Hydrolysis affords first the dimethyl acetal of *(4a)* in 80% yield; b.p. 72 °C/50 torr, $n_D^{20} = 1.4073$, $[\alpha]_D^{19} = +4.3$ ($c = 11$, ether). This was hydrolyzed to the free aldehyde.

[e] In $CHCl_3$.

Optically active ketones of type *(8)* containing acidic hydrogen at the center of asymmetry racemize readily through the enol form. Since acidic or basic conditions cannot be avoided in the methods conventionally used for synthesis and resolution, preparation of such ketones presents particular problems. We have found that *(8f)* [3] and even *(8d)* [1d, 3], which has an enolizable H atom only on the asymmetric C atom, lose less than 5% of their optical activity when their aqueous-methanolic solutions are boiled for one to three hours with 2 molecular equivalents of $HgCl_2$ and one of HgO [2] or $CdCO_3$ [4] (these being conditions for neutral hydrolysis of the dithianes). Further, (*S*)-2-methylbutyraldehyde, which is readily prepared from the alcohol *(1)*, is converted by 1,3-propanedithiol into the dithiane *(6)*, whence hydrolysis [5b] regenerates the aldehyde with only 20% loss of activity (an average of 10% in each step).

The aldehyde *(5)* can thus be converted by way of *(6)* and its Li derivative into the dithianes *(7)* and thence into (*S*)-ketones such as *(8b)* and *(8f)*. Since compounds *(6)* and *(7)* cannot racemize, danger of racemization is confined to preparation of *(6)* and the hydrolysis *(7)*→*(8)*. From the experiments outlined it can be concluded that the loss of activity in passing from the aldehyde to the ketones *(8)* is probably less than 20%.

Owing to the manifold reactivity of the readily accessible Li derivatives of *(3a)* and *(6)* the dithiane method is superior to the methods previously customary for synthesis of compounds of type *(4)* and *(8)* [3].

Experimental:

2-(1-Methylpropyl)1,3-dithiane *(6)*: A solution of 10.0 g of *(5)*, $[\alpha]_D^{20} = +21.0$ (pure liquid) (60% optical purity [5a]) and 11.6 ml of 1,3-propanedithiol in 350 ml of $CHCl_3$ is stirred for 1 h at room temperature. The solution is cooled to 0 °C and, after passage of a fast stream of dry HCl gas for 2–3 min, allowed to stand in a refrigerator for 4 h. It is then washed with a 10% aqueous solution of KOH, dried over K_2CO_3, and distilled to yield 14–17 g of *(6)*, b.p. 67–70 °C/0.6 torr, $n_D^{20} = 1.5387$; $[\alpha]_D^{20} = -0.50$ ($c = 15$, ether).

Alkylation of *(6)* to give 2-(1-methylpropyl)-2-pentyl-1,3-dithiane *(7f)*: 3.85 g of *(6)* is metalated in 70 ml of THF with a 5% excess of butyllithium [2a]. After addition of 3.6 ml of 1-iodopentane, the mixture is allowed to stand for 3 days at −30 °C and then for another 3 days at 0 °C. Working up [2a] and distillation affords 4.20 g of *(7f)*, b.p. 105 °C/0.6 torr, $n_D^{20} = 1.5222$, $[\alpha]_D^{23} = -15.4$ ($c = 16$, ether).

Hydrolysis of *(7f)* to yield 3-methyl-4-nonanone *(8f)*: A mixture of *(7f)* (4.00 g, 16.4 mmole), HgO (32.5 mmole), $HgCl_2$ (32.5 mmole), H_2O (18 ml), and CH_3OH (180 ml) is

stirred vigorously at 20 °C for 16 h, and then at 65 °C for 1.5 h. The mixture is filtered while hot and the residue is washed with CH_3OH. The filtrate is diluted with water and extracted with pentane[2a]. Crude yield of *(8f)* 2.05 g, $[\alpha]_D^{22} = +13.6$ (c = 4, ether). Distillation affords 1.67 g of *(8f)* (overall yield calculated with respect to *(6)*, 51.4 %), b.p. 65–68 °C/7 torr, $n_D^{20} = 1.4232$, $[\alpha]_D^{23} = +13.4$ (c = 5, ether) [corresponds to +22.4 calculated with respect to optically pure *(6)*].

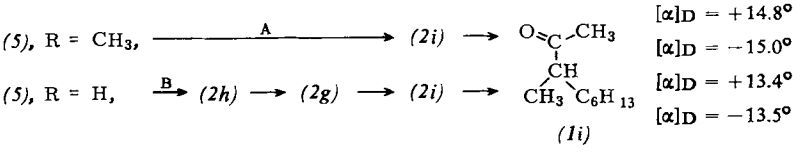
Synthesis of (*R*)- and (*S*)-Aldehydes and -Ketones from Chiral *sec*-Alkyl Halides

By *D. Seebach*, *D. Steinmüller*, and *F. Demuth* [*]

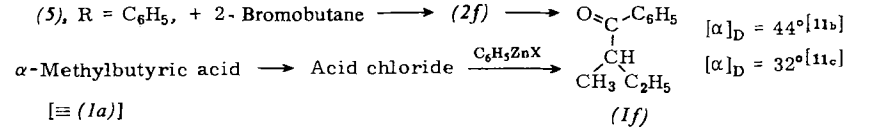
Ketones and aldehydes of type *(1)* are valuable for mechanistic studies and as reactive starting materials for the synthesis of other optically active compounds but they have not hitherto been simple to prepare[1]. We describe here a new method by which secondary alcohols, which are available easily and in large variety by resolution of racemates[2], can be converted into the compounds *(1)* by way of the halides[3] such as *(3)*[4] or *(4)*[5]. Alkylation of 2-lithio-1,3-dithianes *(5)* with optically active bromides or iodides involves inversion of configuration at the asymmetric C atom and leads to dithianes *(2)*, whose hydrolysis affords the carbonyl compounds *(1)*. The antipodes (*R*)-(−)-*(1)* and (*S*)-(+)-*(1)* can both be obtained in this way. Configurational assignment of the products *(1)* and thus also of the intermediate dithianes is effected by comparison with compounds of known absolute configuration[1,6] [for *(1c)*–*(1f)* and *(2c)*–*(2f)*] and by the fact that the sign of rotation is not changed when $R^1 = C_2H_5$ in substances of this type is replaced by $R^1 = C_6H_{13}$[7] [for *(1h)*–*(1j)* and *(2h)*–*(2j)*].

	R	R^1
(a)	OH	C_2H_5
(b)	Li	C_2H_5
(c)	H	C_2H_5
(d)	CH_3	C_2H_5
(e)	$n\text{-}C_5H_{11}$	C_2H_5
(f)	C_6H_5	C_2H_5
(g)	Li	$n\text{-}C_6H_{13}$
(h)	H	$n\text{-}C_6H_{13}$
(i)	CH_3	$n\text{-}C_6H_{13}$
(j)	C_6H_5	$n\text{-}C_6H_{13}$

The degree of inversion (proportion of the S_N2 reaction with Walden inversion) on alkylation of lithiodithianes with (*S*)-bromobutane *(3)*[4a] exceeds 85 %, as is seen by comparison of the numerical rotations of the resulting (*R*)-dithianes *(2c)*–*(2e)* with those of the (*S*)-dithianes[1] prepared from the (*S*)-aldehyde *(1c)*[8] [since the rotations of the optically pure iodides *(3)*[4b] and *(4)*[5] are not known, a corresponding statement cannot yet be made for their reaction with *(5)*]. We found that the amount of inversion depended on the structure of the lithiodithiane used. Treatment of *(5)*, R = CH_3, with optically active 2-iodooctane and subsequent hydrolysis afforded 3-methyl-2-nonanone *(1i)*[9] (route A), which was prepared also from the unsubstituted Li compound (route B). The rotation of the ketone obtained by route B was



about 10 % lower than that obtained by route A. This result was reproducible within experimental error (average error of the mean value ±0.1) for both antipodes (see Table), even when the conditions (temperature, molar proportions, reaction time, concentration) were purposely varied both in the alkylation step and in the hydrolysis. Thus the degree of inversion must be slightly higher in the reaction of the methyl derivative than in that of the unsubstituted compound[10] (cf. the higher yield on alkylation in the former case). From the rotation of the phenone *(1f)* prepared by the dithiane method it follows that the optical yield in the reactions bromobutane



→ ketone is in this case 40 % greater than when this compound is prepared from methylbutyric acid[6] by the usual methods. The overall chemical yields (alkylation of the anions and hydrolysis) lie between 30 and 60 % (Table).

1-Halogenoalkyl Isocyanates

By L. I. Samaraj, O. W. Wischnewskij, and G. I. Derkatsch[*]

In our studies of organic isocyanates[1] we found that reaction of ketimines (1) with phosgene (100–110 °C, in inert solvents) or oxalyl dichloride (50–60 °C) usually gives N-(chloroformyl)-ketimines (2) (cf. ref. [2]).

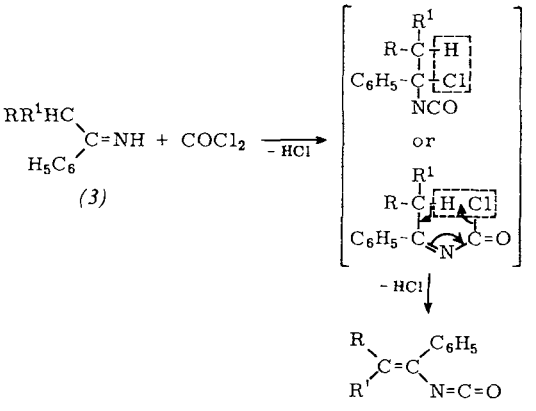
	R	R^1	Yield (%)	B.p. (°C/torr)	M.p. (°C)	n_D^{20}
(2a)	tert-C_4H_9	C_6H_5	85	118/9	—	1.5243
(2b)	C_6H_5	C_6H_5	87	135/0.1	42–45	—
(2c)	C_6H_5	p-$CH_3C_6H_4$	75	141/0.06	—	1.6170
(2d)	C_6H_5	α-$C_{10}H_7$	80	183/0.05	73–75	—

However, alkenyl isocyanates (4) are obtained from ketimines (3) and phosgene, probably by way of 1-chloroalkyl isocyanates as intermediates.

Reaction of bisketimines with phosgene affords diisocyanates.

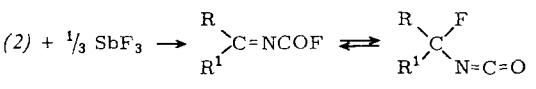
Treatment of the ketimine (3), R = H, R^1 = n-C_3H_7, with oxalyl dichloride leads to 4-isopropyl-5-phenylpyrrole-2,3-dione (5), as dark red prisms, m.p. 143–144 °C (from benzene), in 49 % yield.

1-Halogenoalkyl isocyanates (2) are very reactive. We have studied their reactions with water, alcohols, ammonia, primary and secondary amines, alkoxides, silver cyanate, and sodium azide. That with antimony trifluoride at 120–140 °C gives N-(fluoroformyl)-ketimines (6).



(3) (4)

	R	R¹	Yield (%)	B.p. (°C/torr)	n_D^{20}	d_4^{20}
(4a)	H	n-C_3H_7	70	115–117/7	1.5420	1.0767
(4b)	CH_3	CH_3	75	97–98/8	1,5455	1.0373



(2) + 1/3 SbF_3 → (6)

	R	R¹	Yield (%)	B.p. (°C/torr)	M.p. (°C)
(6a)	C_6H_5	C_6H_5	40	115/0.1	57–59
(6b)	C_6H_5	p-$CH_3C_6H_4$	30	120/0.01	44–46

The IR spectra of compounds (2) and (6) contain pronounced bands at 2260 cm^{-1}, 1640 cm^{-1}, and 1770 cm^{-1}, which indicate the presence of N=C=O, C=N, and a halogenoformyl group. The spectra show that compound (2a) exists wholly in the isocyanate form, but that (2d) exists almost wholly in the *N*-(chloroformyl) form. The other compounds exist as an equilibrium mixture of the isocyanate and the *N*-(halogenoformyl) form. Triethylamine shifts the equilibrium towards the isocyanate form.

Synthesis of Dipotassium Difluorodiphosphate by Thermal Reaction of Tetraphosphorus Decaoxide with Potassium Fluoride

By *H. Falius* [*]

Salts of difluorodiphosphoric acid $H_2[P_2O_5F_2]$ were first prepared from the corresponding ester[1] by a multi-step synthesis starting from $POCl_2F$. By contrast, the thermal reaction between P_4O_{10} and KF is complete within a short time (*ca.* 1 h) and affords $K_2[P_2O_5F_2]$ (1) directly.

$$P_4O_{10} + 4\,KF \xrightarrow{\Delta} 2\,K_2[P_2O_5F_2]$$

When an intimate mixture (prepared with exclusion of moisture) of the two components in stoichiometric proportions is heated to relatively low temperatures spontaneous reaction takes place, the mixture suddenly becoming liquid; heating is then stopped immediately. The melt solidifies to a brittle glass, which, when crushed, readily dissolves in water to give an almost neutral solution. Compound (1) is readily obtainable in crystalline form by fractional precipitation with ethanol.

The reaction does not proceed exclusively according to the equation given; approximately equal quantities of $[PO_2F_2]^-$ (2), $[PO_3F]^{2-}$ (3), $[P_3O_{10}]^{5-}$, $[P_3O_9]^{3-}$, and $[P_4O_{12}]^{4-}$ are formed alongside the difluorodiphosphate. Thus, such reactions as $P_4O_{10} + 4\,KF \rightarrow 2\,K[PO_2F_2] + 2/n(KPO_3)_n$ (where $n = 3,4$) also occur. However, isolation of (1) presents no difficulties because it is the only product to crystallize during work-up of the reaction mixture; the polyphosphates form oils and fluoromonophosphates remain is solution.

The properties of compound (1) have not hitherto been documented. The colorless, doubly refracting crystals ($d_4^{20} = 2.34$) decompose on heating to give (2), (3), $[P_2O_7]^{4-}$ (4), and $[(PO_3)_n]^{n-}$. The anion is stable in neutral aqueous solution. On warming in acid solution, hydrolysis takes place to give $[PO_4]^{3-}$ and (4); in alkaline solution (3) is formed. Difluorophosphate does not form a difficultly soluble precipitate with any metal cation, nor with nitrone.

The ^{31}P–NMR spectrum of an aqueous solution of (1) shows a 1:1 doublet with $J_{PF} = 943$ Hz and $\delta = +17.8 \pm 1.0$ ppm (85% H_3PO_4 as external reference); the ^{19}F–NMR spectrum also has the structure expected for an AA'XX' system with $J_{PF} = 940$, $J_{PP'} = 2.5$, $J_{PF'} = -8$, and $J_{FF'} = 0$ Hz and $\delta = +72.6$ ppm ($CFCl_3$ as external reference). IR spectrum: 1295 s, 1160 s, 1120 m, 1045 (sh), 1007 vs, 869 vs, 834 vs, 736 vs, 530 vs, 490 m, 463 m, 397 m, 307 s, 163 w (br), 145 w (br), 134 w (br), 98 m, 84 m. (For assignments and couplings, see reference[2].) Elemental analysis and molecular-weight determination correspond to the composition (1).

Representative procedure:

P_4O_{10} (14.2 g, 0.05 mole) and KF (11.6 g, 0.2 mole) are heated as described above. On slow addition of 50 ml of ethanol to a solution of the reaction product in water (25 ml), an oil is precipitated. Further addition of 30 ml of ethanol to the decanted solution causes precipitation of a small volume of oil and a few crystals. A third precipitation with 75 ml of ethanol affords crystals that can be reprecipitated with ethanol from a small volume of water. The yield (1 g = 4%) is not high but this is not a great disadvantage because the starting materials are cheap.

The solubility of the sodium salt thwarted attempts at its preparation from NaF by an analogous procedure.

Structure of the Anion $[O_3P-P(O_2)-PO_3]^{5-}$ in Pentasodium Triphosphate(IV,III,IV)-14-water

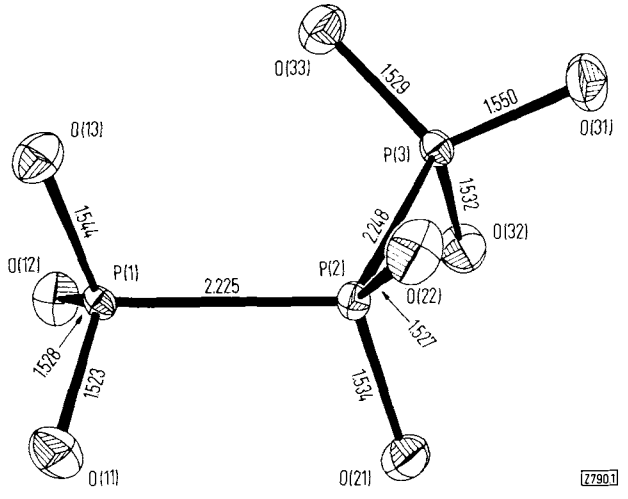
By *D. Mootz* and *H. Altenburg* [*]

Pentasodium triphosphate(IV,III,IV)-14-water, $Na_5P_3O_8 \cdot 14\,H_2O$ (1), which contains a chain of three contiguous phosphorus atoms, was first prepared by *Blaser* and *Worms*[1]. *Falius* described a more simple isolation from the reaction mixture produced on oxidation of red phosphorus with chlorite in an acid medium[2]. An incomplete crystal-structure

analysis[3] of a salt, $Cs_6[(PO_2)_6]\cdot xH_2O$ *(2)*, of the P_6 cyclic acid, and a more detailed one[4] for diammonium dihydrogen hypophosphate $(NH_4)_2H_2P_2O_6$ *(3)*, have been published and it seemed of interest to determine also the structure of *(1)* by X-ray methods.

Compound *(1)* crystallizes in the triclinic system with the space group $P\bar{1}$ with two formula units in the unit cell. The structure analysis (3332 independent data; precession camera with molybdenum radiation) was carried out according to the usual methods (Patterson function, Fourier syntheses, least-squares refinement, location of hydrogen atoms by the difference Fourier technique) and gave an *R* factor of 0.082.

The figure shows the structure of the anion with the atomic thermal vibration ellipsoids and bond lengths[5]. The estimated standard deviations are *ca.* 0.005 Å for P–P and 0.010 Å for P–O. Thus both P–P distances do not deviate significantly from their mean value 2.237 Å, although the observed difference could be correlated with the almost staggered conformation (see Figure) of the shorter bond



and the almost eclipsed conformation of the longer one. A P–P bond length of 2.20 ± 0.05 Å (mean value) was found in *(2)*, and 2,170 ± 0.003 Å in *(3)*. The relative lengthening in *(1)* may arise from the higher electric charge of the anion ($^5/_3$ electrons per P atom in *(1)* against 1 electron in *(2)* and *(3)*).

Within the limits of accuracy, the P–O distances are all equal and have a mean value of 1.533 Å. The bond angles are 109.9 ± 0.2° for P–P–P, 103.3 to 111.1° for P–P–O, and 110.8 to 115.8° for O–P–O. The Na^+ ions form puckered layers by corner-, edge-, and, in one case, face-linkage of more or less distorted NaO_6 octahedrons. Eight of the fourteen water molecules participate in three hydrogen bonds each and the other six are involved in two hydrogen bonds each; all the protons are involved in hydrogen bonding.

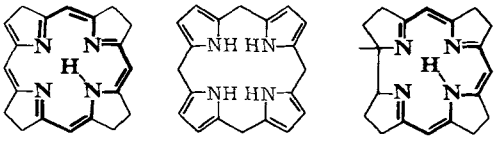
Corphin, a Corrinoid-Porphinoid Ligand System

By *A. P. Johnson, P. Wehrli, R. Fletcher*, and *A. Eschenmoser*[*] [**]

The structural details of the formation of the corrin nucleus of vitamin B_{12} in nature are still unclear[1]. From a purely chemical point of view the question may be raised in this connection as to what the properties of compounds of type *(1)* would be. This hitherto unknown ligand system[2] is in the oxidation state of a hexahydroporphin; it is thus isomeric with the known structural type *(2)* of porphinogen and differs formally from the corrin structure *(3)* by a reductive ring contraction. In order to study the chemistry of this system we have been concerned with the development of methods for its synthesis; we describe here the preparation of the palladium complex *(9)* and a preparatively remarkable difference in the topological control of a reaction by nickel(II) and palladium(II) ions.



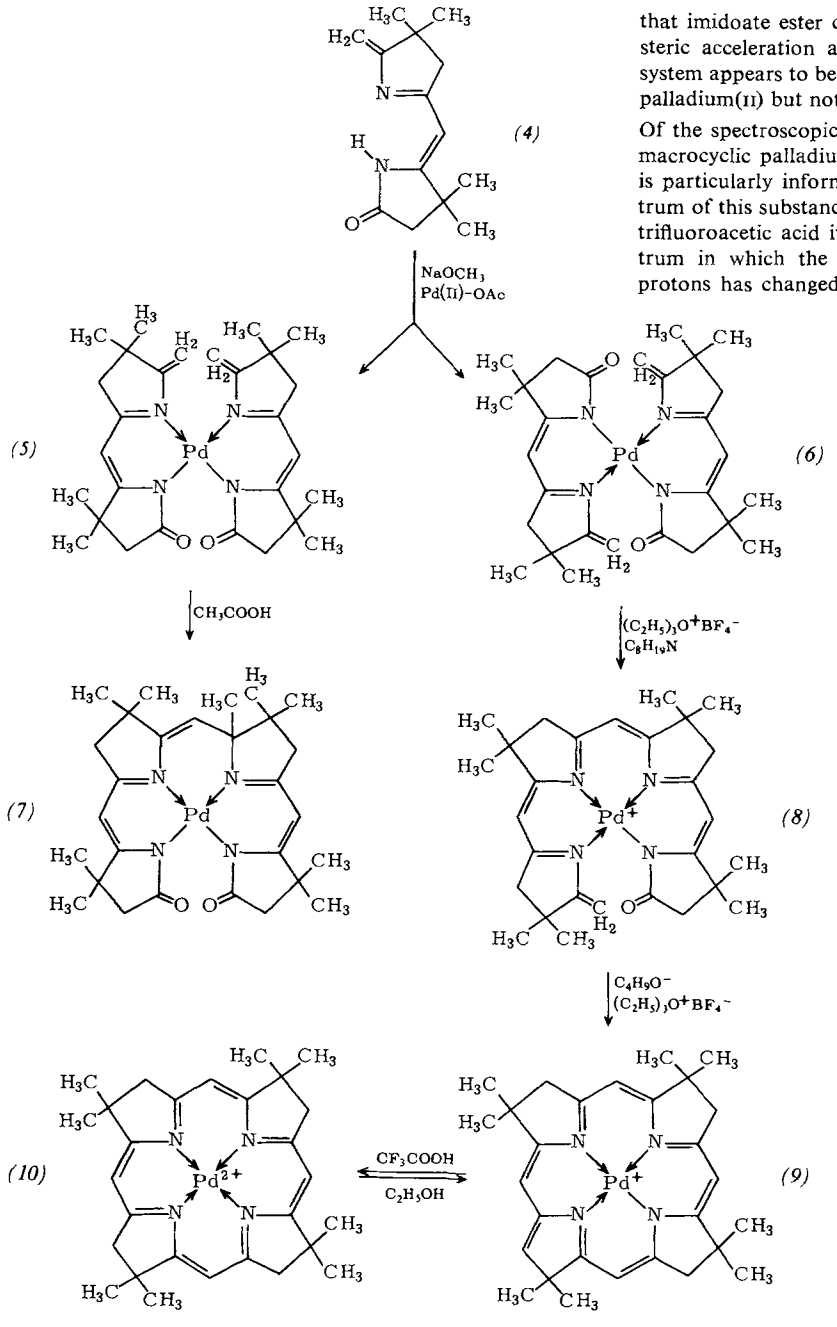
(1) *(2)* *(3)*

Complex formation from the sodium salt of the known bicyclic lactam *(4)*[3], *e.g.* by anhydrous palladium(II) nitrate (or acetate[4]) in acetonitrile (RT/*ca.* 15 min), leads to the diastereoisomeric, diamagnetic and therefore clearyl planoid complexes *(5)* and *(6)*; they are differentiated on thin-layer chromatography and can be separated by fractional crystallization (yields 26 and 24 %). The *cis*-configuration of the isomer *(5)* follows from the fact that under the influence of acetic acid at room temperature the compound is converted into a condensation product of structure *(7)*; in contrast, the centrosymmetric *trans*-isomer *(6)* is unchanged under these conditions (1.0 equivalent of CH_3COOH in CH_2Cl_2/RT/24 h). After treatment of the *trans*-isomer *(6)* with triethyloxonium tetrafluoroborate-diisopropylethylamine[5] in methylene chloride at room temperature the complexes *(8)* and *(9)* can be isolated as crystalline perchlorates in yields of *ca.* 20 % and 40–45 %, respectively. The mono-condensed complex *(8)* can be cyclized very easily by triethyloxonium tetrafluoroborate to give *(9)*; preliminary deprotonation of the positively charged lactam complex ion being necessary[8].

The changes *(6)* → *(8)* and *(8)* → *(9)* involve base-catalyzed imidoyl ester condensations of the type previously described in the synthesis of corrin complexes[3,9]. The intramolecular condensation steps occur very rapidly and intermediate imidoyl ester derivatives could not be observed.

All our attempts to achieve condensation between two molecules of the bicyclic lactam *(4)* by treatment of the corresponding free alkyl imidoate derivatives[3,9,10] with bases or acids failed. Equally unsuccessful were attempts to achieve with nickel(II) or cobalt(II) complexes what was finally accomplished with palladium(II). Treating the potassium salt of *(4)* with 1 equivalent of anhydrous nickel(II) or cobalt(II) perchlorate in acetonitrile leads in each case to a complex of structure *(11)*[11], which can be isolated in crystalline form in yields of 80–90 %. These products are homogeneous on thin-layer chromatography, paramagnetic in $CHCl_3$ solution, and presumably tetrahedroid in structure. The corresponding imidoate diperchlorates *(12)*[12] can be isolated in crystalline form and are also paramagnetic in $CHCl_3$; no intramolecular cyclization of these complexes could be detected by UV spectroscopy when they were subjected to thermal treatment or exposed to various basic conditions.

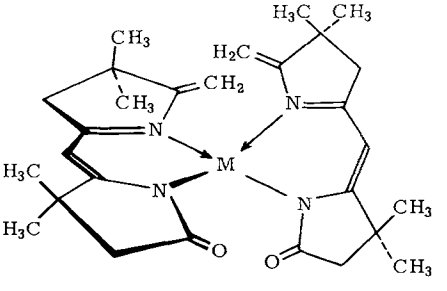
The palladium(II) ion is known to have a stronger tendency than nickel(II) to planoid coordination[13]. The difference in



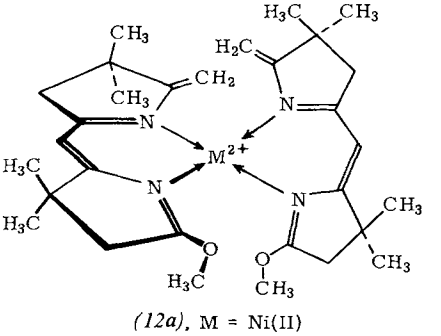
that imidoate ester condensations in this system do require steric acceleration and the necessary strain in the ligand system appears to be provided by the "planarity pressure" of palladium(II) but not by that of nickel(II).

Of the spectroscopic data that support the structure of the macrocyclic palladium(II) complex *(9)*, the NMR spectrum is particularly informative. In deuteriochloroform the spectrum of this substance consists of 12 separate singlets, but in trifluoroacetic acid it appears as a sharp three-singlet spectrum in which the intensity ratio of the vinyl:methylene protons has changed from 5:6 to 4:8. In deuteriotrifluoroacetic acid the intensity of the CH_2 singlet at 3.05 ppm[16] is time-dependent, the signal disappears almost completely within a few hours at room temperature. Thus, in trifluoroacetic acid the compound exists as the protonated centrosymmetric tetraketimine complex *(10)*; in agreement therewith, the UV spectrum in ethanol, but not in trifluoroacetic acid, has the character of a bathochromically shifted corrin

behavior of the complexes *(6)* and *(11a)* serves as a drastic preparative illustration of this property. However, failure of the imidoate ester condensation with the nickel complexes *(11a)* and *(12a)* should not be ascribed to any resistance of the nickel ion to a flattening of the ligand system since *(11a)* is converted into a diamagnetic nickel complex of type *(7)* under the influence of protic acids[10]; rather it seems



(11a), M = Ni(II)
(11b), M = Co(II)



(12a), M = Ni(II)
(12b), M = Co(II)

New Boron Heterocycles

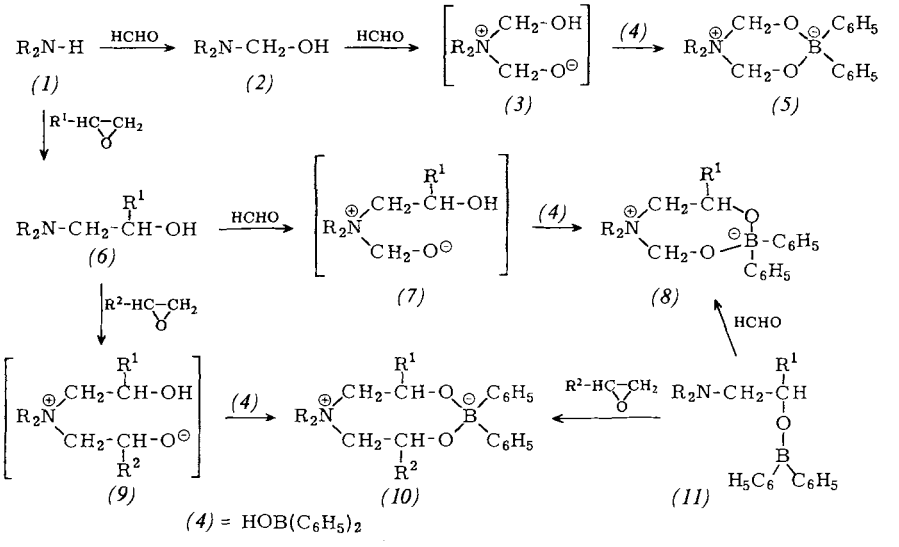
By *W. Kliegel*[*]

In the reaction of secondary amines *(1)* with formaldehyde the hypothetical[1] second reaction intermediate, the betaine-like formaldehyde adduct *(3)* of hydroxymethylamine *(2)*, can be trapped by esterification with hydroxydiphenylborane *(4)*. The free electrons of the negatively charged oxygen atom can go into the empty orbital of the boron atom, thus leading to fixation of the aldehyde molecule in the ring.

Ethanolic solutions of *(1)* are heated briefly to boiling with two molecular equivalents of formaldehyde in aqueous solution and one molecular equivalent of *(4)*[2]. The difficultly soluble[3] compound *(5)* crystallizes out of the reaction solution in analytically pure form.

In the same way, *N*-(2-hydroxyalkyl)dialkylamines *(6)* react with formaldehyde and *(4)* to give heterocyclic compounds having seven-membered rings *(8)*.

If the reaction is carried out with epoxides in place of formaldehyde, corresponding eight-membered rings *(10)* are formed.



(4) = $HOB(C_6H_5)_2$

		Decomp. point (°C)
5a)	$R_2 = -(CH_2)_3-$	157
5b)	$R_2 = -(CH_2)_4-$	135
5c)	$R_2 = -(CH_2)_5-$	125
5d)	$R_2 = -(CH_2)_2-O-(CH_2)_2-$	96
5e)	$R = C_2H_5$	114
5f)	$R = n\text{-}C_3H_7$	100

		Decomp. point (°C)
8a)	$R = C_2H_5$, $R^1 = H$	154
8b)	$R_2 = -(CH_2)_5-$, $R^1 = H$	106 [a]
8c)	$R_2 = -(CH_2)_5-$, $R^1 = CH_3$	164
10a)	$R = C_2H_5$, $R^1 = H$, $R^2 = CH_3$	203 [a]
10b)	$R = C_2H_5$, $R^1 = R^2 = H$	229

[a] Present as the hydrate.

Compounds *(8)* and *(9)* are also obtained when corresponding esters of *(4)* and amino alcohols *(11)*[4] are allowed to react with formaldehyde or epoxides, as was established with *(8a)* and *(10a)* – identical products were obtained by both routes. The yields vary between 30 and 70%. The colorless, highly stable compounds decompose on heating. Formaldehyde is liberated on pyrolysis of *(5)* and *(8)*[5].

The insolubility of the heterocycles in weakly polar solvents, their IR and NMR spectra[6], as well as their elemental analyses, are in accord with the betaine structure suggested.

Identification of the n-σ* Transition in the Electron Excitation Spectrum of 2-Butanone

By *H.-H. Perkampus*[*]

Three electronic transitions are to be considered for the carbonyl group[1]. The spectroscopic properties of one of these, the longwave n-π* transition, have been known for a long time[2]. In contrast, there is still some uncertainty surrounding the electronic transition in the range 50000–56000 cm^{-1}. In many monographs and books, this transition in the near vacuum-ultraviolet is assigned to an N–V transition, *i.e.* to a π-π* transition analogous to that of an ethylenic double bond[3]. However, according to *McMurry*[4] it is a permitted n-σ* transition, whose oscillator strength should be about 0.02. The π-π* transition then lies at higher wave numbers ($\tilde{\nu} > 60000\ cm^{-1}$)[1], as is evident from measurements in the vacuum ultraviolet[5].

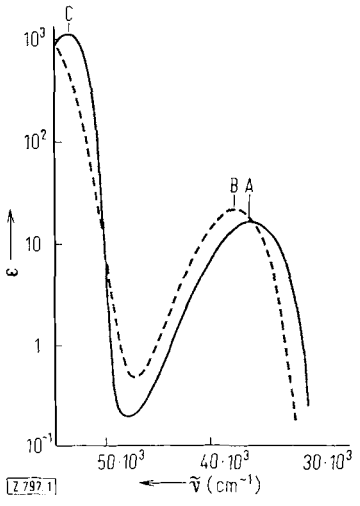

Fig. 1. Electron excitation spectrum of 2-butanone.
— *n*-Heptane; $c = 2.94 \times 10^{-3}$, 2.26×10^{-2}, and 2.26×10^{-1} M
----- Water; $c = 5.04 \times 10^{-3}$ and 5.04×10^{-2} M.
A: $\tilde{\nu} = 36100$ cm^{-1} ($\varepsilon = 17$), B: $\tilde{\nu} = 37500$ cm^{-1} ($\varepsilon = 21$),
C: $\tilde{\nu} = 53700$ cm^{-1} ($\varepsilon = 1250$).

The measurements were carried out with a Zeiss spectrophotometer PMQ II (double monochromator MM12 with CaF_2 prisms, Suprasil cuvettes of layer thicknesses 0.10 and 1.00 cm); a stream of dry nitrogen was passed through the instrument before and during use. The spectral resolving power was 70 cm^{-1} at 54000 cm^{-1}; the scattered light was below 1% at 55000 cm^{-1}.

It should be possible to decide whether the second transition is a n-σ^* or a π-π^* transition from the solvent dependence of the ultraviolet spectra[6]. The ultraviolet spectrum of 2-butanone in *n*-heptane and water as solvents (see Figure) clearly shows that the second electronic transition, like the n-π^* transition, undergoes a hypsochromic shift as the solvent changes from nonpolar to polar. Since a bathochromic shift is generally to be expected for a π-π^* transition[6], the assignment according to *McMurry*[4] is reasonable. In *n*-heptane the oscillator strength for this n-σ^* transition is found to be $f = 0.018$.

H. Wolf has recently reported similar hypsochromic shifts for the second electronic transition[7] in the CD spectra of saturated lactams.

A Generator System for 1-(2-Chloroethyl)-aziridine

By *H. M. Rauen, K. Norpoth*, and *H. Schriewer*[*]

Whereas aziridine is accessible in any amount desired for synthetic purposes, 1-(2-chloroethyl)aziridine has not yet been made on a preparative scale. We here describe a generator system by which a solution of this reactive compound may be obtained.

In buffered aqueous solution *N,N*-bis(2-chloroethyl)amine undergoes, as first reaction step, Cl^- heterolysis to 1-(2-chloroethyl)aziridine ($k = 5.0 \times 10^{-4}$ sec^{-1} at 10^{-3} M, 37 °C, pH = 7.2; $k = 12.3 \times 10^{-4}$ sec^{-1} at 10^{-3} M, 43 °C, and pH = 7.2; in each case 0.2 M phosphate buffer[1]). However, the reaction continues *via* hydrolytic ring opening to *N*-(2-chloroethyl)-*N*-(2-hydroxyethyl)amine, renewed Cl^- heterolytic ring closure to 1-(2-hydroxyethyl)aziridine ($k = 1.0 \times 10^{-4}$ sec^{-1} at 10^{-3} M, 37 °C, and pH = 7.2; $k = 2.7 \times 10^{-4}$ sec^{-1} at 10^{-3} M, 43 °C, and pH = 7.2; in each case 0.2 M phosphate buffer[1]), and hydrolytic ring opening to diethanolamine.

The rate constants of the hydrolytic ring opening reactions are probably lower than those of the Cl^- heterolytic ring closures. Since the ring opening reactions are rate-determining, the aziridine derivatives accumulate in a static reaction system. In the conditions given above, the yield of 1-(2-chloroethyl)aziridine increases rapidly at first, remains constant between 60 and 120 min (37 °C), and then falls less rapidly[2]. If the static reaction system is disturbed by a continuous stream of inert gas, then the gaseous 1-(2-chloroethyl)aziridine is carried over in the gas stream. The effluent is passed into an ice-cooled double trap (Normag No. 9213) containing equal volumes of chloroform and water. The entry tube terminates just above the boundary between the solvents. The water largely prevents the volatile chloroform being removed in the gas stream. The gaseous 1-(2-chloroethyl)-aziridine that passes over dissolves first in the water but then immediately goes into the chloroform, in which it is much more soluble (partition coefficient $H_2O/CHCl_3 = 0.13{:}1$). When the chloroform layer is removed it provides a solution of 1-(2-chloroethyl)aziridine suitable for preparative purposes.

Identification (proposal by *H. Arnold*): Add HBr-glacial acetic acid, keep at room temperature for 12 h, remove the solvent. *N*-(2-Bromoethyl)-*N*-(2-chloroethyl)amine crystallizes (analysis and comparison with an authentic product).

If the concentration of *N,N*-bis-(2-chloroethyl)amine is raised, so as to increase the yield of aziridine derivative, then it is advisable to use a pH-stat in spite of the presence of the phosphate buffer. Direct extraction of the incubation solution with chloroform (*i.e.* without transferring the gaseous products with a stream of inert gas) is not advisable since undecomposed starting material is also soluble in chloroform (partition coefficient $H_2O/CHCl_3 = 0.09{:}1$).

A Novel Tricarbonylchlororhenium(I) and Reactions of Substituted Carbonylchlororheniums(I) with Water and Other Oxygen-containing Ligands

By *W. Hieber* and *W. Rohm*[*]

Continuing our work on replacement reactions of carbonylhalogenorhenium complexes $Re(CO)_5X$ and $[Re(CO)_4X]_2$ with organyl chalcogenides[1] we examined the thermal behavior of a binuclear complex containing diphenyl sulfide, namely $[Re(CO)_3S(C_6H_5)_2Cl]_2$[1].

$S(C_6H_5)_2$ is evolved when this compound is heated above 90 °C in a high vacuum; there remains a residue that contains chlorine but no sulfur and whose IR spectrum shows only the ν(CO) vibrations of three carbonyl groups. This material consists of a chlorotricarbonyl $[Re(CO)_3Cl]_x$. Starting material and products are in thermal equilibrium: treat-

ment of the solid product with diphenyl sulfide quantitatively regenerates the starting material:

$$[Re(CO)_3S(C_6H_5)_2Cl]_2 \overset{\Delta}{\rightleftharpoons} (CO)_3Re\begin{matrix}Cl\\ \diagup\ \diagdown\\ Cl\end{matrix}Re(CO)_3 \quad (1)$$
$$+\ 2\ S(C_6H_5)_2$$

In the cold the thermolysis product is soluble only in acetone, but when heated it dissolves without evolution of gas in polar solvents, *i.e.* in reagents containing a donor atom. From this fact, from the IR spectrum and elemental analysis, and above all from the reactivity, we conclude that we are dealing with a binuclear structure containing one free coordination position per rhenium atom; however, a higher polymer is not excluded.

The very hydrophobic substance *(1)*, wholly insoluble also in boiling benzene, dissolves on prolonged heating in ethers, alcohols, and even in water with formation of binuclear and mononuclear complexes[1] obtained by addition of solvent molecules, namely $[Re(CO)_3LCl]_2$ or $Re(CO)_3L_2Cl$. Specifically, pure crystalline compounds $[Re(CO)_3LCl]_2$ were obtained with ligands (L) = tetrahydrofuran *(2)*[1], ethanol *(3)*, and methanol *(4)*. Reaction with water affords an aqua complex that is indicated by preliminary work to be $Re(CO)_3(H_2O)_2Cl$ *(5)*.

The IR spectrum (KBr disk) of *(5)* shows two sharp ν(OH) stretching vibrations and the δ(HOH) band, whereas only one sharp ν(OH) absorption is observed for *(3)* and *(4)*.

	ν(CO) (cm^{-1})	ν(OH) (cm^{-1})	δ(HOH) (cm^{-1})
(5)	2018 vs, 1930 vs (sh)	3607 m, 3541 m	1603 m
(3)	2045 vs, 1931 vs, 1903 vs	3546 m	
(1)	2064 vs, 1946 vs (sh)		

In all the complexes, "ether-like"-bound (sp^3 hybridized) oxygen behaves as a donor atom. Hitherto the only known carbonylhalogenorhenium compounds containing oxygen-donor ligands of that type have been those with "ylide-like"-bound (sp-hybridized) ligands[2] such as pyridine 1-oxide, triphenylphosphine oxide, and the corresponding bidentate derivatives.

Whereas carbonyl complexes of several metals containing cyclic ethers (some of them unstable) are known[3], compounds *(3)–(5)* are the first in which it has been possible to introduce alcohols and even water as donor ligands into the carbonyl derivative. (In ionic reaction products of metal carbonyls with alcohols, *e.g.* $[V(CH_3OH)_6][V(CO)_6]_2$[4], the alcohol and carbon monoxide are not bound to one and the same metal atom.)

Meanwhile, starting with *(1)* we have isolated also carbonylchlororhenium complexes containing dioxane, diisopropyl ether, and acetone (with which *(1)* reacts even in the cold) and studied their IR spectra. Further, reactions with *sec*- and iso-butyl alcohol, ethylene glycol, benzophenone, benzil, and acetylacetone have been observed. Moreover, weakly basic nitrogenous compounds such as diphenylamine and triphenylamine react with *(1)*; but the substances formed in these reactions have not yet been investigated.

Experimental:

Di-μ-chlorohexacarbonyldirhenium(I) *(1)*:

$[Re(CO)_3S(C_6H_5)_2Cl]_2$ was heated in a sublimation apparatus at 120–130 °C in a high vacuum for one day. Diphenyl sulfide separated as drops on the cold finger. The pale yellow residue was digested several times with hot benzene, to remove undecomposed starting material, and then dried in a high vacuum. It contained a small proportion (*ca.* 4%) of insoluble, undefined decomposition products.

Preparation of complexes *(2)–(5)*:

Compound *(1)* is heated on a fritted filter (G 4) with tetrahydrofuran[1], ethanol, methanol, or water until dissolution has occurred, then a small residue is filtered off, and the solvent is removed in a vacuum. The products, usually first precipitated as oils, crystallize during a few hours' drying in a high vacuum and can be recrystallized from chloroform.

Degradation of Fructose Amino Acids to *N*-(2-Furoylmethyl)amino Acids. Intermediates in Browning Reactions[1]

By *K. Heyns, J. Heukeshoven*, and *K.-H. Brose*[*]

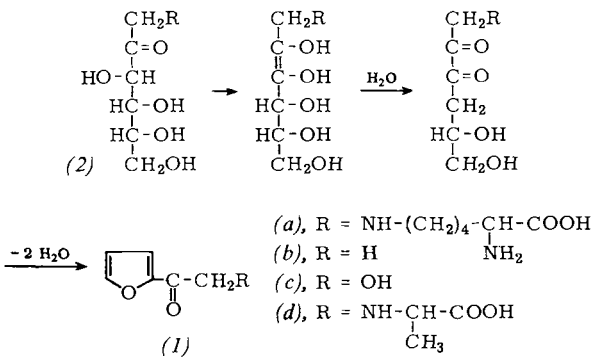
On ion-exchange chromatography of milk-powder hydrolyzates, *Erbersdobler* and *Zucker*[2,3] found the elution region of the basic amino acids to contain, besides arginine, a ninhydrin-positive substance X that was formed also on mere heating together of glucose with lysine or lysine-containing proteins and subsequent treatment with acid. These reactions occur also in browning reactions of Maillard type, and they decrease the biological value of the protein.

We obtained this substance X by heating ε-fructose-lysine *(2a)*[4] with 6 N HCl at 90 °C (1 h) and isolated it in a pure state by preparative ion-exchange chromatography. It is, however, not necessary to use pure *(2a)* for the acid hydrolysis; crude *(2a)*, which is prepared by heating glucose with lysine in methanol, leads to the same substance. Its analytical data indicate structure *(1a)*, that of a lysine-containing derivative of acetylfuran *(1b)*.

The IR, UV, and NMR spectra of the two compounds are very similar. IR (KBr) for *(1a)*: 3440 s, 2980 s, 1740 vs, 1682 vs, 1570 m, 1465 s, 1400 s cm^{-1}; for *(1b)*: 344 s, 2980 s, 1685 vs, 1565 m, 1455 s, 1390 m cm^{-1}. The strong band in the IR spectrum of *(1a)* at 1740 cm^{-1} is due to the carboxyl group of the lysine residue. The bands at 1682 and 1570 cm^{-1} are assigned to the conjugated carbonyl group. The UV bands are characteristic of the furan ring: for *(1a)* (dil. HCl): 281 and 227 nm; for *(1b)* (H_2O): 275 and 226 nm. The furan ring protons appear in the NMR spectra with fully corresponding chemical shifts and coupling constants, except that the signals for *(1a)* are shifted by 0.15–0.20 ppm downfield with respect to those for *(1b)* (in D_2O, tetramethylsilane as internal standard). For *(1a)*: H-3 τ = 2.35; H-4 τ = 3.20; H-5 τ = 2.05; $J_{3,4}$ = 3.7 Hz; $J_{5,4}$ = 1.5 Hz; $J_{3,5}$ = 0.5 Hz. For *(1b)*: H-3 τ = 2.57; H-4 τ = 3.35; H-5 τ = 2.21; $J_{3,4}$ = 3.7 Hz; $J_{5,4}$ = 1.6 Hz; $J_{3,5}$ = 0.7 Hz.

Vigorous treatment with acid degrades *(1a)* to lysine. Fluorodinitrobenzene converts *(1a)* into a mono(dinitrophenyl) derivative that is cleaved to α-(dinitrophenyl)lysine on vigorous action of acid, whereby it is proved that the ε-amino group of the lysine of *(1a)* is bound to the acetylfuran[5]. *(1a)* takes up 3 mol. equiv. of H_2 on catalytic hydrogenation.

Formation of *(1a)* from *(2a)* appears to parallel that of 1-(2-furyl)glycolaldehyde *(1c)* on acid treatment of fructose *(2c)* [6].



On treatment of fructose-alanine *(2d)* with acid an analogous series of reactions leads to *N*-(2-furoylmethyl)alanine *(1d)*. *N*-(2-Furoylmethyl)methylamine hydrochloride could be prepared as model substance from 1-methylamino-1-deoxy-fructose (yield 60 %).

Synthesis of Santolinatriene

By *W. Sucrow* [*]

Santolinatriene was isolated by *Thomas* and *Willhalm* in 1964 from *Santolina chamaecyparissus* L. and was identified as 2,5-dimethyl-3-vinyl-1,4-hexadiene *(1)* [1].

Our work on preparation of 1,4-dienes from derivatives of *N,N*-dimethylpropionamide [2] suggested that the Claisen rearrangement of ketene *O,N*-acetals described by *Eschenmoser et al.* [3] might be useful for synthesis of a precursor of *(1)*.

When boiled with the 2.5-fold amount of 1-ethoxy-*N,N*-dimethylpropenylamine *(3)* [6] in xylene, 5-methyl-2,4-hexadien-1-ol *(2)* [4] (prepared by us by reducing 5-methyl-2,4-hexadienal [5] with $NaBH_4$), gives a 78 % yield of *N,N*-dimethyl-2,5-dimethyl-3-vinyl-4-hexenamide *(4)* [b.p. 80 °C (bath temp./0.1 torr. IR: $-CH=CH_2$ 3080, 992, 914; $-CON(CH_3)_2$ 1655 cm^{-1}. ^1H–NMR: $H_3C-C-CO$ (d) $\delta = 0.98$; $(H_3C)_2C=$ (d) 1.58, (d) 1.65; $>CH-CO$ (dq) 2.55; $-N(CH_3)_2$ (s) 2.83, (s) 2.99; $=C-CH-C=$ (m) about 3.1; $=CH_2$ (m) 4.88, (m) 5.02; $-CH=C<$ (m) about 4.9; $-CH=CH_2$ (ddd) 5.57 ppm]. Reducing *(4)* with $LiAlH_4$ in ether leads to *N,N*-dimethyl-*N*-(2,5-dimethyl-3-vinyl-4-hexenyl)amine *(5)* [b.p. 100 °C (bath temperature)/22 torr. IR: $=CH_2$ 3080, 1640, 998, 914 cm^{-1}) in 86 % yield. With 30 % hydrogen peroxide in methanol *(5)* affords the amine oxide (not further characterized), whose Cope degradation at 150 °C and 2 torr gives 57 % of *(1)*, which corresponds in all its properties to natural santolinatriene [1] [b.p. 143 °C. IR: 3085, 1670, 1643, 996, 916, 896 cm^{-1}. UV: $\lambda_{max}^{C_2H_5OH}$ = 202 nm, ε = 12700. ^1H–NMR and mass spectra are superposable on those of the natural *(1)* [1]; M^+ at *m/e* 136.1249, calc. 136.1252]. IR and NMR spectra were measured for CCl_4 solutions.

Bis(chloromercuri)-2,4-pentanedione, an Unusual Acetylacetone Derivative

By *F. Bonati* and *G. Minghetti* [*]

Surprisingly, mercury(II) acetylacetone [1] does not dissolve in the usual solvents. Its structure is not yet fully clarified. In an attempt to prepare it by dropwise addition of 5.14 ml of acetylacetone to a saturated aqueous solution of mercury(II) chloride (6 g in 100 ml) [1], we obtained a chlorine-containing colorless crystalline compound (2.0 g; m.p. ~152 °C). This was filtered off from the now acid solution and washed with a little cold water, in which it is difficultly soluble. The ^1H–NMR spectrum, measured for a hexadeuterioacetone solution, contains only one signal, at τ = 7.10. In the IR spectrum C=O, Hg–Cl, and two Hg–C stretching vibrations were observed at 1690 vs, (broad), 343s, 521s, and 566 cm^{-1}. The compound is not an electrolyte in acetone or acetonitrile; its reaction with iron results in separation of mercury and in chloroform it consumes one molar equivalent of

bromine. The molecular weight in acetone is 228. (The compound is insoluble in other solvents; it attacks steel, the soluiton becoming immediately red.) All these facts can be accounted for by formula *(1)*.

(1) *(2)*

Formula *(2)* would require only one Hg–C stretching vibration and one Hg–Cl vibration at lower wave numbers; for Hg_2Cl_2 the latter is at 260, for C_6H_5HgCl at 331, and for $HgCl_2$ at 375 cm^{-1}. Organomercury derivatives with a Hg–Hg bond are not known.

Mercury(II) bromide, cyanide, and acetate do not react with acetylacetone under the above conditions; nor does mercury(I) chloride.

N-Fluorosulfamidoyl Fluoride, Pentafluorosulfur *N*-Fluoro-*N*-(fluorosulfonyl)amide, and *N*-(Dichloromethylene)fluoroformamide [1]

By *H. W. Roesky* [*]

Sulfamidoyl fluoride *(1)* [2] reacts with elemental fluorine at room temperature, giving *N*-fluorosulfamidoyl fluoride *(2)*.

$$FSO_2NH_2 + F_2 \rightarrow FSO_2{-}NHF + HF$$
(1) *(2)*

(2) is a colorless liquid that decomposes appreciably in Pyrex glass vessels within one day, with formation of SiF_4. It can be considered as the first derivative of difluoroamine HNF_2 in which one fluorine atom has been replaced by the FSO_2 group. Reaction of *(2)* with an excess of fluorine gives *N,N*-difluorosulfamidoyl fluoride *(3)* [3].

$$(2) + F_2 \rightarrow FSO_2NF_2 + HF$$
(3)

Formation of sulfonyl fluoride SO_2F_2 was not observed during the fluorination.

Elemental analysis proves the composition of *(2)*. The ^{19}F–NMR spectrum shows a doublet at $\delta_F = -39.6$ ppm for the FSO_2 group and a doublet at $\delta_F = 91.8$ ppm for the NF group (referred to CCl_3F, external; intensity ratio 1:1; $J_{FF} = 7.7$ Hz). The ^1H–NMR spectrum contains a singlet at $\delta_H = -7.8$ ppm (referred to TMS, external).

The following absorptions appear in the NaCl and KBr regions of the IR spectrum (capillary film on AgCl plates): 3700s, 3250s, 3050m, 2780m, 1638m, 1472vs, 1370m, 1240vs, 1000vs, 820vs, 695vs, 575vs, 480s cm^{-1}. In this determination some *(1)* was probably also formed.

The mass spectrum shows, besides the molecular ion FSO_2NHF^+ 117 (62.9 %), fragments at *m/e* 98 (13.5 %) SO_2NHF, 85 (61.8 %) FSNHF, 83 (100 %) FSO_2, 67 (43.8 %) FSO, 64 (67.3 %) SO_2, 48 (35.9 %) SO, and 99 (33.7 %) FSO_2NH_2.

Difluorosulfur *N*-(fluorosulfonyl)imide *(4)*, prepared from *(1)* and tetrafluorosulfur [4], reacts with elemental fluorine, giving pentafluorosulfur *N*-(fluoro)-*N*-(fluorosulfonyl)amide *(5)*.

$$FSO_2N{=}SF_2 + 2\,F_2 \rightarrow FSO_2{-}NF{-}SF_5$$
(4) *(5)*

(5) is a clear liquid that can be kept in glass vessels. The NaCl and KBr regions of the IR spectrum contain absorptions at 1490vs, 1440w, 1303w, 1250vs, 1032w, 1010w, 925vs, 885vs, 862s, 810vs, 715w, 623w, 572vs, 524w, 490w cm^{-1}.

The mass spectrum shows fragments at *m/e* 227 (0.2 %) $FSONFSF_5$, 224 (0.6 %) FSO_2NFSF_4, 208 (0.2 %) $FSONFSF_4$, 205 (0.7 %) FSO_2NSF_4, 188 (0.13 %), 186 (1.6 %) SO_2NSF_4, 167 (0.3 %) SO_2NSF_3, 127 (100 %), 128 (1.1 %), 129 (6.4 %) SF_5, 108 (6.3 %), 110 (0.05 %) SF_4. Further fragments, SF_3, SO_2F, SF_2, SOF, SO_2, SF, SO, and SN, were also detected. The following chemical shifts were obtained from the ^{19}F–NMR spectrum: $\delta_{NF} = +23.2$ ppm, $\delta_{SO_2F} = -41.0$ ppm, $\delta_{SF} = -61.7$ ppm, $\delta_{SF_4} = -69.0$ ppm (referred to CCl_3F, external).

After the preparation of *N*-(fluoroformyl)iminosulfur dichloride [5] we succeeded in synthesizing *N*-(dichloromethylene)fluoroformamide *(7)* by fluorination of *N*-(dichloromethylene)chloroformamide [6] with silver monofluoride.

$$Cl{-}\overset{O}{\overset{\|}{C}}{-}N{=}CCl_2 + AgF \longrightarrow F{-}\overset{O}{\overset{\|}{C}}{-}N{=}CCl_2 + AgCl$$
(6) *(7)*

(7) is a liquid that has a pungent odor, b.p. 78–80 °C; its composition is proved by elemental analysis. The ^{19}F–NMR spectrum shows a singlet at $\delta_F = -12.65$ ppm (referred to CCl_3F, external).

The infrared spectrum of the liquid in the NaCl and KBr region shows bands at 2270m, 1850vs, 1730w, 1660vs, 1180vs, 1061m, 955vs, 908s, 778m, 742w, 637vs, 538s cm^{-1}. They are provisionally assigned to the following vibrations: ν(CO) 1850, ν(C=N) 1660, ν(CF) 1180, ν_{as}(CCl) 995, and ν_s(CCl) 908 cm^{-1}.

Experimental:

Synthesis of *(2)*:

Fluorine and nitrogen (F_2:N_2 = 1:2, *ca.* 60–70 bubbles/min) are led through 50 g of *(1)* in a quartz trap for 24 h; *(2)*, a little *(3)*, and some SiF_4 remain in the vessel. In an attached receiver (cooled in dry ice) 48 g of *(3)* is collected, and in a further trap (cooled by liquid air) SiF_4 separates. SiF_4 is formed by reaction of the HF with the glass. *(2)* is distilled from the reaction mixture in a vacuum into a precooled receiver: b.p. 29–30 °C/32 torr; yield 5 g.

Synthesis of *(5)*:

10 g of fluorine is condensed onto 33 g of *(4)* contained in a 100 ml nickel autoclave cooled to the temperature of liquid nitrogen. The mixture is then warmed to room temperature, kept there for 3 days, and then warmed at 70 °C for a further 3 days. The volatile products are removed; they can be identified by infrared spectroscopy as SO_2F_2, FSO_2NF_2, SOF_2, SF_4, and SF_6. The residue in the autoclave is distilled in a vacuum. 3 g of *(5)*, b.p. 30–31 °C is obtained alongside unchanged *(4)*.

Synthesis of *(7)*:

20 g of *(6)* is fluorinated by 60 g of AgF at 120–140 °C in a glass vessel. The volatile products are collected in a cooled receiver (acetone/dry ice). Then the trap is warmed to room temperature and the contents fractionated under atmospheric pressure. Unchanged *(6)* is then accompanied by 10 g of *(7)*, b.p. 78–80 °C.

Organic Compounds in Fossil Plants (*Voltzia brongniarti*, Coniferales)[1]

By *H. Knoche, P. Albrecht*, and *G. Ourisson*[*]

We recently reported our work on a fossil horsetail recovered from a clay inclusion in the variagated sandstone of the Northern Vosges (Trias, 2×10^8 years old)[3]. The fossil plants *Voltzia brongniarti* (Coniferales) are also found in this same sandstone[3]. Pieces of this fossil plant, about 1–5 cm long, were collected in Hangviller (Moselle), care being taken during collection to obtain as pure specimens as possible and the working up being controlled by blank experiments. Inorganic analysis gave a content of 60% goethite, $Fe_2O_3\cdot H_2O$[4].

The dry fossil (2.6 kg) was ground and extracted with a 3:1 benzene-methanol mixture (3 l) under the action of ultrasound. After centrifugation, decantation, and removal of the solvent by distillation, there remained 42 mg (16 ppm) of residue. The hydrocarbon fraction (3 mg, 1.2 ppm) was isolated by column chromatography on silica gel; it was crystalline and was shown by its gas chromatogram[5] to consist almost wholly of one component. This substance was identified as *n*-$C_{28}H_{58}$ by gas chromatography on filled and capillary columns[6], by inclusion in molecular sieves (Linde 5 Å), and by the mass spectrum. *n*-Octacosane has not previously, to our knowledge, been found as chief component of the cuticular wax of a plant. As is well known, it is mainly the odd-numbered hydrocarbons that occur in such waxes, and furthermore as mixtures of homologs; in conifers nonacosane, $C_{29}H_{60}$, occurs most frequently, alongside hydroxy esters and alcohols[7,8].

We regard it as extremely unlikely that *Voltzia*, alone among the conifers, contained an almost homogeneous even-numbered hydrocarbon, and we conclude that we are dealing with a transformation product. It is not possible to study directly what its precursor in *Voltzia* was, since this plant is extinct. Of extant conifers the family Taxodiaceae is the most closely related[9]. We have therefore studied the wax of two members of this family in the hope of identifying possible precursors of the *n*-octacosane. In the wax of *Cryptomeria japonica* Don. only 10-nonacosanol was found – this is a widely distributed constituent of many conifer waxes; it can hardly be considered as precursor of the octacosane. However, the wax of *Taxodium distichum* Rich. contains 1-octacosanol as well as 10-nonacosanol. The former alcohol was previously found only in the wax of one other conifer, *Gingko biloba* L.[10]. We presume that *n*-$C_{28}H_{58}$ was formed in the fossil by reduction of the primary alcohol *n*-$C_{27}H_{55}$–CH_2OH; 10-nonacosanol either was not present or was degraded in an unknown way. In this connection it is interesting that, according to *Hoering*, octadecanol is reduced to octadecane simply by heating it with sedimentary rocks[11].

Bis(tricarbonylcyclopentadienylchromium), a Catalyst for Selective Hydrogenation

By *A. Miyake* and *H. Kondo*[*]

Tricarbonylcyclopentadienylhydridochromium *(1)* is converted by conjugated dienes at room temperature quantitatively into bis(tricarbonylcyclopentadienylchromium) *(2)*. The conjugated dienes are hydrogenated in the process, *e.g.* isoprene to 2-methyl-2-butene.

$$2\ C_5H_5(CO)_3CrH + CH_2{=}\overset{\overset{CH_3}{|}}{C}{-}CH{=}CH_2 \longrightarrow$$

(1)

$$[C_5H_5(CO)_3Cr]_2 + CH_3{-}\overset{\overset{CH_3}{|}}{C}{=}CH{-}CH_3$$

(2)

We also obtained *(2)*, in *ca.* 80% yield from bis(cyclopentadienyl)chromium, by the following reaction, without the need to isolate *(1)*:

$$(C_5H_5)_2Cr \xrightarrow[70°C]{CO,\ H_2} (1) \xrightarrow[20°C]{\text{isoprene}} (2)$$

In contrast to dienes with conjugated double bonds, olefins with isolated –C=C– bonds are totally unreactive towards *(1)*. Since *(1)* is regenerated from *(2)* by hydrogen[1], *(2)* can with advantage be used as catalyst for selective hydrogenation. Some examples are given in Table 1. Characteristics for hydrogenation catalyzed by *(2)* are the following:

1. Isolated double bonds are not hydrogenated.

2. Double bonds do not migrate.

3. Hydrogenation occurs smoothly above 70 °C and at H_2 pressures > 50 atm, but also slowly at room temperature or atmospheric pressure.

4. Except for sterically hindered dienes, the hydrogen is added preferentially at the ends of the conjugated system.

Experimental:

Preparation of *(2)*:

A solution of bis(cyclopentadienyl)chromium (5.57 g) in benzene (50 ml) is transferred under argon to a 100 ml autoclave. The solution is heated under H_2 (p_{H_2} = 50 atm) and CO (p_{CO} = 150 atm) with constant shaking for 20 h at 70 °C.

Table 1. Selective hydrogenation of polyenes catalyzed by *(2)*.

Polyene	Hydrogenation products (mole-%)		
[a]	(95)	(3)	(2) [b]
	(100)	(*trans* 88, *cis* 12)	
	(78)	(22)	
	(100)		
	(74)	(26)	
	(66)	(34)	
	(46)	(29)	(25)
	(51)	(29)	(20)

[a] Conditions of hydrogenation: isoprene 2.0 g and *(2)* 0.15 g in benzene 10 ml, p_{H_2} = 90 atm, 70 °C, 5 hr. Approximately the same conditions also for the other polyenes.

[b] No isoprene and only traces of 2-methylbutane were observed in gas chromatograms.

After cooling the excess gas is released and the reaction mixture is treated at 20 °C with isoprene (5 ml); the initial pale green mixture turns deep green in color. The solvent is distilled off under vacuum at room temperature. On sublimation of the dark green residue in high vacuum at 90–110 °C, 4.80 g (78 %) of compound *(2)* (color: blue green) is obtained.

Cycloheptasulfur, S_7, and Cyclodecasulfur, S_{10} — Two New Sulfur Rings

By *Max Schmidt, B. Block, H. D. Block, H. Köpf*, and *E. Wilhelm* [*]

The first successful experiments designed to yield thermodynamically unstable compounds containing only one kind of atom (element modifications) led [1] to the preparation of cyclohexasulfur, S_6, and cyclododecasulfur, S_{12}, by kinetically controlled "metathetic reactions" according to the equation:

$$H_2S_x + Cl_2S_y \rightarrow 2\ HCl + S_{x+y}\ (x + y = 6 \text{ or } 12)$$

In the meantime S_{12} also was isolated from sulfur melts [3] in clear contradiction to predictions [2] of its instability, and this induced us to study further the experimentally difficult reactions of sulfanes with chlorosulfanes in the hope of obtaining new sulfur rings.

We have meanwhile succeeded in our purpose by two different processes: Bis(π-cyclopentadienyl)titanium(IV) pentasulfide, $(C_5H_5)_2TiS_5$ *(1)*, which was recently described [4], reacts with lower chlorosulfanes quantitatively under mild conditions, according to the equation:

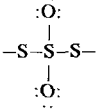
$$\underset{(1)}{(C_5H_5)_2TiS_5} + S_xCl_2 \rightarrow \underset{(2)}{(C_5H_5)_2TiCl_2} + \frac{1}{n}\ S_{(5+x)n}$$

From *(1)* and SCl_2 (x = 1) we obtained almost 100 % of *(2)* and sulfur that could be separated into 87 % of pure S_6 (n = 1) and 11 % of pure S_{12} (n = 2).

Reaction of *(1)* with S_2Cl_2 (x = 2) is also quantitative. From the sulfur formed thereby we have, up to the present, isolated a 23 % yield of the hitherto unknown cycloheptasulfur, S_7 (n = 1).

This, the first odd-numbered sulfur ring, is of particular interest because it is inconceivable [5] that a seven-membered ring should have the same atomic distances, bond angles, and dihedral angles and thus the same energy content of all the sulfur atoms (if the unlikely flat ring, with dihedral angles of 180 °, is excluded by reasons of bonding theory). S_7 crystallizes from toluene in centimeter-long, intensely yellow needles, which, unlike the much paler S_8, retain their color on cooling. S_7 melts reversibly at 39 °C and becomes successively highly viscous by polymerization at ~ 45 °C, mobile at ~ 115 °C, highly viscous at 159 °C, and mobile on further heating. Under the influence of light and also storage at room temperature it changes readily into S_8 by way of a polymer; however, it can be kept unchanged for weeks in the cold and the dark. X-rays rapidly decompose S_7 at room temperature, but good single-crystal photographs were obtained at −80 °C (space group: Cmma. Lattice constants: a = 21.77 Å, b = 20.97Å, c = 6.09 Å, 112 atoms = 16 formula units in the orthorhombic unit cell; the structure is being calculated) [6].

Because of the instability of the group [7]



reaction of sulfuryl chloride with *(1)* also leads quantitatively to sulfur rings, with loss of SO_2.

$$(1) + SO_2Cl_2 \rightarrow (2) + \frac{1}{n}\ S_{5n} + SO_2$$

By this reaction we have now isolated pure cyclodecasulfur, S_{10} (n = 2). It crystallizes in characteristic, intensely yellow, rhombic platelets (from CS_2). Like S_6, S_{10} does not show a sharp melting point or decomposition point, but above ~60 °C polymerizes to a viscous state. Its sensitivity to light also parallels that of cyclohexasulfur. Even in the dark, it must

be stored at low temperature (~ −40 °C) if decomposition is to be avoided. As expected, the new sulfur modification is only slightly vaporizable without decomposition even under high vacuum, as is shown by the mass spectrum [8].

As a result of our experiments towards planned synthesis fo thermodynamically unstable element modifications the following defined cyclic sulfur molecules are now available for comparative observations: S_6, S_7, S_8, S_{10}, and S_{12}.

Experimental:

Synthesis of S_6 and S_{12}: Compound *(1)* (5 g, 14.8 mmoles) in CS_2 (250 ml) is treated in absence of light, at 0 °C, with stirring, with SCl_2 (1.52 g, 14.8 mmoles) in CS_2 (100 ml) (color change from violet to pale pink). The precipitated *(2)* is filtered off and S_6 is extracted with cold CS_2 (30 ml) from the orange-yellow solid residue obtained by evaporation of the filtrate. The undissolved residue is taken up in hot CS_2 (250 ml) from which it crystallizes on cooling. Yield of *(2)* 3.6 g (98 %), of S_7 2.48 g (87.3 %), and of S_{12} 0.32 g (11.3 %).

Synthesis of S_7: Compound *(1)* (1.35 g, 4 mmoles) in CS_2 (50 ml) with S_2Cl_2 (0.54 g, 4 mmoles) in CS_2 (10 ml); reaction as above. After 1 hour's stirring, the filtrate from *(2)* is evaporated in a vacuum. The orange-yellow oily residue is extracted 2–3 times with cold toluene (10 ml) and the extracts are cooled to −78 °C. 0.21 g (23.4 %) of S_7 crystallizes. Mol. wt. 218 (cryoscopic), 224 (osomometric) in benzene.

Synthesis of S_{10}: Compound *(1)* (0.68 g, 2 mmoles) in CS_2 (180 ml) is treated, dropwise at −78 °C with stirring and exclusion of light, with SO_2Cl_2 (0.27 g, 2 mmoles) in CS_2 (20 ml). After 3 h the precipitated *(2)* is filtered off in the cold, the solution is evaporated to 5 ml below −10 °C in a vacuum, and then treated with cold pentane (100 ml; −78 °C). A precipitate of S_{10} (0.11 g, 35 %) is formed, which is purified by dissolution in CS_2 and concentration of the solution. Mol. wt. 315 (osmometric) in benzene.

Mass-Spectrometric Study of Cycloheptasulfur, S_7 and Cyclodecasulfur, S_{10}

By *U.-I. Záhorszky* [*]

The usual cyclooctasulfur, S_8, as well as cyclohexasulfur, S_6 [1] and cyclododecasulfur, S_{12} [2], have previously been prepared and studied by mass spectrometry.

The modifications cycloheptasulfur, S_7, and cyclodecasulfur, S_{10}, recently prepared for the first time [3], show the expected molecular weights in the mass spectrometer. When the usual electron energy (70 eV) is used the molecular ion peak (*m/e* 224) does not appear clearly in the spectrum of S_7, but if the energy is lowered this signal grows in relative intensity (Fig. 1, compare with Fig. 2). Because of the great volatility, the total ion flux could not be kept constant during the measurement [4].

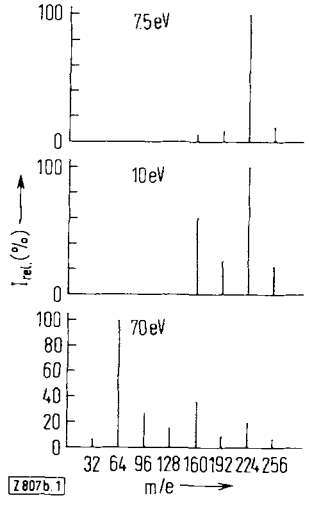

Figure 1. Mass spectrum [5] of S_7 at 70, 10, nd 7.5 eV.

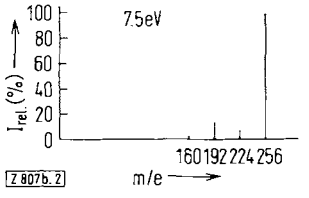

Figure 2. Mass spectrum [5] of S_8 at 7.5 eV.

In the spectrum of S_{10} the signal of highest mass number is the molecular ion peak (*m/e* 320). However, as in the case of S_{12}, the overall spectrum consists mainly of the spectrum of S_8 overlaid by the less intense spectrum of S_{10} (Table 1). It must therefore be assumed that the thermally labile modification passes mainly into S_8 during its residence in the mass spectrometer [4].

Table 1. Signal heights in the mass spectrum of S_{10}.

Tetrakis(cyclopentadienyl)neptunium(IV)

By *F. Baumgärtner, E. O. Fischer, B. Kanellakopulos,* and *P. Laubereau* [*]

Tetrakis(cyclopentadienyl)neptunium(IV) *(1)* is the first purely aromatic neptunium complex. It was obtained for the first time by treating $NpCl_4$ (3.8 g) with a five-fold molar amount (excess) of KC_5H_5 in benzene suspension under a protecting gas (argon).

$$NpCl_4 + 4\ KC_5H_5 \xrightarrow{\text{Benzene}} Np(C_5H_5)_4 + 4\ KCl$$

The mixture was heated under reflux for 160 h, then evaporated to dryness, and the residue was extracted for 50 h with benzene. This yielded the reddish-brown product (3.6 g, 72%) in analytically pure form.

The product *(1)* dissolves as monomer in benzene (osmometric mol. wt. in C_6H_6: 496). Its sensitivity to oxygen and water is considerably less than that of $Pu(C_5H_5)_3$ [1] and $Am(C_5H_5)_3$ [2]. It dissolves in benzene and tetrahydrofuran with different colors (benzene, greenish; tetrahydrofuran, yellowish-brown). The solubility is *ca.* 1.9 mg/ml in tetrahydrofuran and *ca.* 1.0 mg/ml in benzene.

The substance decomposes above 220 °C. Its IR spectrum, measured for polycrystalline samples in Nujol and Hostaflon, indicate the exclusive presence of symmetrical five-membered rings with characteristic bands at 780 and 810 (γ_{CH}), 1008 (δ_{CH}), 1447 (ω_{CC}), and 3077 cm^{-1} (ν_{CH}). The intensities and the positions of the bands correspond closely to those for $U(C_5H_5)_4$ [3], so that an analogous molecular structure is to be assumed.

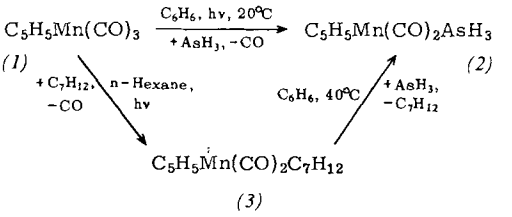
Arsinecyclopentadienyldicarbonylmanganese(I)

By *E. O. Fischer, W. Bathelt, M. Herberhold,* and *J. Müller* [*]

Following our recent publication [1] concerning the preparation of the first stable transition-metal derivatives of PH_3 [2] we now wish to report the first preparation of an analogous AsH_3 transition-metal complex.

The compound arsinedicarbonylcyclopentadienylmanganese(I) *(2)* has been prepared by the following two methods: firstly, by UV irradiation of a benzene solution of π-$C_5H_5Mn(CO)_3$ *(1)* under an atmosphere of AsH_3 and secondly, by the ligand exchange reaction which occurs when a benzene solution containing the π-cycloheptene complex $C_5H_5Mn(CO)_2C_7H_{12}$ *(3)* [3,4] is stirred at 40 °C under an atmosphere of AsH_3. The latter method of preparation is preferred to the former because in the former difficulties arise in the separation of the volatile product *(2)* from the more stable $C_5H_5Mn(CO)_3$ *(1)*.

On the basis of the method of preparation and analytical and spectroscopic data, the yellow, air- and light-sensitive,



sublimable arsine complex *(2)* is formulated as a substitution product of *(1)* of the well known type $C_5H_5Mn(CO)_2L$.

The infrared spectrum of *(2)* (KBr disc) shows a band of medium strength situated at 2150 cm^{-1}, which is attributed to the ν_{AsH} vibration. One of the two bands expected for the δ_{AsH} vibrations is observed at 911(s) cm^{-1} and the other is thought to be contained in the envelope of the strong band occurring at 1003 cm^{-1}, as is suggested by the intensity ratio. All three bands occur at similar frequencies to those found in the infrared spectrum of AsH_3 in the gaseous phase [5], *viz.* 2122, 1005, and 906 cm^{-1}, which would indicate a weak metal-arsine bond. This is in agreement with our view that the Mn–As d_π-d_π back-bonding plays the predominant role in the bonding of these arsine derivatives. Characteristic bands in the infrared spectrum of the symmetrical π-bonded C_5H_5 ring occur at 2919(w), 1422(w), 1112(w), 1003(s), and 839/823(m) cm^{-1}. The infrared spectrum of a benzene solution of the complex *(2)* in the metal-carbonyl stretching region shows two equally intense bands at 1937(vs) and 1874(vs) cm^{-1} corresponding to the two ν_{CO} stretching vibrations, which is consistent with the proposed C_{2v} disposition of the carbonyl groups in this molecule. The infrared spectrum of the complex $C_5H_5Mn(CO)_2As(C_6H_5)_3$ in benzene [6] is comparable and shows two bands at 1940 and 1869 cm^{-1}. The similarity of the spectra of the AsH_3 and $As(C_6H_5)_3$ derivatives in the carbonyl stretching region may indicate that the overall transfer of charge resulting from the σ-donating and π-accepting characteristics of these ligands is comparable.

The ^1H–NMR spectrum of *(2)* in $CDCl_3$ solution shows two singlets of relative intensity 5:3 occurring at τ = 5.46 and τ = 6.8 τ which have been assigned to the C_5H_5 and AsH_3 protons, respectively. Both signals are shifted downfield compared with the spectra of the starting materials, *viz.* $C_5H_5Mn(CO)_3$ ($\tau_{C_5H_5}$ = 5.16 in $CDCl_3$) and AsH_3 (τ_{AsH_3} = 8.45 in $CDCl_3$).

The mass spectrum of *(2)* shows a peak corresponding to the molecular ion at m/e = 254 (relative intensity I_{rel} = 26). Fragmentation of this ion occurs either stepwise with simultaneous elimination of the two CO ligands, accompanied by stepwise loss of the arsine hydrogen atoms [$C_5H_5Mn(CO)AsH_3^+$, I_{rel} = 0.2; $C_5H_5MnAsH_3^+$, I_{rel} = 20; $C_5H_5MnAsH_2^+$, I_{rel} = 7.9; $C_5H_5MnAsH^+$, I_{rel} = 1.7; $C_5H_5MnAs^+$, I_{rel} = 2.6], or by elimination of the arsine group and stepwise loss of the carbonyls [$C_5H_5Mn(CO)_2^+$, I_{rel} = 2.1; $C_5H_5MnCO^+$, I_{rel} = 6.8]. Both the arsine and carbonyl groups may be considered to be equally strongly bonded to the manganese atom. The base peak, corresponding to the ion $C_5H_5Mn^+$ (I_{rel} = 100), has been observed generally in the mass spectra of molecules of the type $C_5H_5Mn(CO)_2L$ [7]. Further fragmentation of this ion occurs as follows: $MnAsH_2^+$ (I_{rel} = 5.8); $MnAsH^+$ (7.7); $MnAs^+$ (5.9); $MnC_3H_2^+$ (2.6); MnC_2H^+ (2.4); MnH^+ (2.6); Mn^+ (60).

The mass spectroscopically measured ionization potential of *(2)* is 7.16 ± 0.1 eV. This value falls in the region observed for the ionization potentials of the analogous complexes $C_5H_5Mn(CO)_2L$ [where L = cyclic olefins, $C_6H_{11}NC$, or $(CH_3)_2SO$] (*ca.* 7.00 to 7.30 eV). [7]

Preparation of (2):

All operations must be carefully carried out under a protective gas in a good fume-cupboard. AsH_3 is an extremely poisonous gas and the product *(2)* is also appreciably volatile

at room-temperature, small concentrations in the air causing headache and nausea.

Compound *(3)* (1.2 g, 4.4 mmole) is dissolved in benzene (50 ml) in a 500 ml three-necked flask. The first neck is connected *via* a three-way tap to a manometer and a vacustat and another is connected to a trap containing condensed AsH_3 (cooled with liquid N_2). The reaction flask is then well cooled (−40 °C) and the system is evacuated with a water-pump and then closed. Cooling is then removed from the reaction flask and the trap containing the frozen AsH_3. When the benzene solution and the AsH_3 has attained a static equilibrium the internal pressure is allowed to increase to 10–30 torr. The reaction mixture is then stirred for 3 h at 40 °C during which time the original yellow-brown color of the solution becomes brown-red. The gases are displaced by N_2, the solvent removed *in vacuo*, and the product sublimed from the residue, under high vacuum at 30–40 °C, onto a cold-finger cooled with a methanol-dry ice mixture. The pure product was obtained as the first fraction of a further sublimation at 15 °C. The yellow crystalline product darkens at 39 °C and melts at 41 °C (yield *ca.* 1.5 %). Compound *(2)* is soluble in benzene and hexane giving yellow-red and yellow solutions, respectively; it is quantitatively decomposed within several minutes in hexane solution whereas in benzene solution it appears to be stabilized. In the solid state, *(2)* is light-sensitive and is stable for several hours only at room temperature, although it may be kept for several days at −40 °C without decomposition.

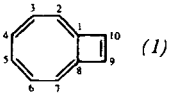
The Bicyclo[6.2.0]decapentaene System

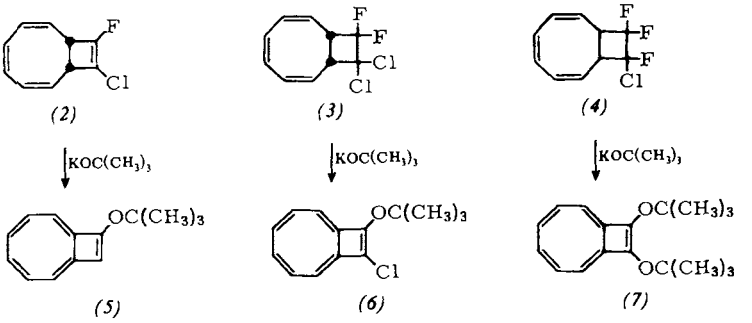
By *G. Schröder* and *H. Röttele* [*]

Bicyclo[6.2.0]deca-1,3,5,7,9-pentaene *(1)* [1] is isomeric with naphthalene and azulene. It contains ten π-electrons and, if it is assumed to be planar, then HMO calculations lead to a delocalization energy per π-electron that is somewhat less than comparable values for benzenoid aromatic compounds [2].

9-tert-Butoxy-10-chlorobicyclo[6.2.0]deca-1,3,5,7,9-pentaene (6): A solution of the cycloadduct *(3)* (1.5 g) [3] in pentane (*ca.* 30 ml) is poured slowly under nitrogen into an ice-cold suspension (excess) of pot. *tert*-butoxid in pentane/ether



(1)



(2) *(3)* *(4)*

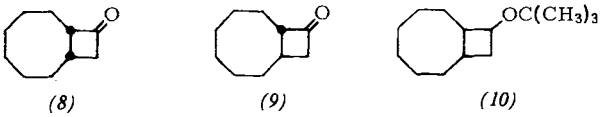
(5) *(6)* *(7)*

(30 ml). The solution becomes dirty red immediately addition is started. The mixture is then stirred for a further 2–3 h at 30–40 °C, treated with water, and extracted with ether. All these operations are effected with exclusion of oxygen. The solvent is susequently removed in a rotatory evaporator and the deep red residue is chromatographed at *ca.* −5 °C, first on basic Al_2O_3 (pentane/ether 9:1) and finally on silica gel (pentane). Pure *(6)* is thus obtained (50 % yield) as a compound that is crystalline up to *ca.* 25 °C, very sensitive to air, thermally stable up to 80 °C, and deep red [UV spectrum in ether: λ_{max} = 282 nm (52000), 376 nm (1100), and many shoulders indicated at 400–500 nm]. The mass spectrum proves the molecular formula [4]; the NMR spectrum shows a ratio of six olefinic (multiplet around τ = 3.9) to nine aliphatic protons (singlet at τ = 8.9).

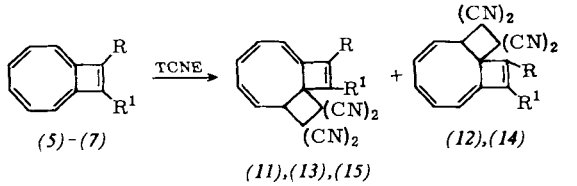
Compounds *(5)* and *(7)* were prepared analogously. 9-Chloro-10-fluorobicyclo[6.2.0]decatetraene *(2)* [3] gives *ca.* 10 % yield of 9-*tert*-butoxybicyclo[6.2.0]decapentaene *(5)*, which is red and very sensitive to air [UV spectrum in ether: λ_{max} = 277 nm (28000), 485 nm (350)]. In its NMR spectrum the six protons of the eight-membered ring appear as a multiplet around τ = 4.0, the cyclobutenyl proton as a singlet at τ = 3.1, and the nine *tert*-butyl protons as a singlet at τ = 8.6.

The cycloadduct *(4)* [5] is the starting material for the synthesis of the red, air-sensitive 9,10-di-*tert*-butoxybicyclo-[6.2.0]decapentaene *(7)* (*ca.* 30 % yield). The mass spectrum proves the molecular formula of this product [4]. The UV spectrum (ether solution) contains λ_{max} = 284 nm (43000) and 430 (2600). The resonance bands of the protons of the eight-membered ring appear in the NMR spectrum somewhat downfield in comparison with those for *(5)* and *(6)*, forming multiplets around τ = 3.5 and 3.8 (2:4); the eighteen *tert*-butyl protons absorb as a singlet at τ = 8.5.

Compounds *(5)*, *(6)*, and *(7)* can be catalytically hydrogenated with ease (Pd/C in C_2H_5OH). From *(5)* one obtains



(8) *(9)* *(10)*



(5)-(7) *(11),(13),(15)* *(12),(14)*

a mixture of *cis*- and *trans*-bicyclo[6.2.0]decan-9-one *(8)* and *(9)*, respectively, as well as a compound whose IR and NMR spectra suggest that it is 9-*tert*-butoxybicyclo[6.2.0]decane *(10)*. The two ketones —(8) is the preponderant product — were separated together from the small proportion of *(10)* by gas chromatography (Carbowax) and were identidifed by comparison of their IR spectra with those of authentic material [6].

Compounds *(5)*, *(6)*, and *(7)* react smoothly with tetracyanoethylene (TCNE), giving, respectively, the colorless crystalline 1,2-cycloadducts *(11)* + *(12)*, *(13)* + *(14)*, and *(15)*. UV and IR spectra support the formulas given [7]. The ratios in which the products *(11)*:*(12)* and *(13)*:*(14)* are formed vary markedly with the nature of the solvent. Tetracyanoethylene and *(5)* in benzene give two cycloadducts, but in acetonitrile give only one. The NMR spectrum of the single cycloadduct *(11)* or *(12)* shows six olefinic protons centered around $\tau = 4.1$, *i.e.* five protons of the eight-membered ring as a multiplet and one cyclobutenyl proton as a sharp singlet at $\tau = 4.5$, one tertiary proton as a multiplet at $\tau = 6.1$, and nine *tert*-butyl protons as a singlet at $\tau = 8.5$; the cyclobutenyl proton is at higher field than that of *(5)* itself ($\Delta = 1.4$ ppm).

Whether the π-electrons in the bicyclo[6.2.0]decapentaene system are delocalized cannot yet be decided.

Proof of $N_\gamma N_\beta$-Elimination from Staudinger Adducts $R_3P{=}N_\gamma{-}N_\beta{=}N_\alpha{-}X$ by ^{15}N-Isotopic Labeling [**]

By *H. Bock* and *M. Schnöller* [*]

The second-order reaction [2, 3] between phosphine derivatives and organic azides

$$R_3P + N_3X \rightleftarrows [R_3PN_3X] \rightarrow R_3P{=}NX + N_2$$

was discovered by *Staudinger* and *Meyer* [1] in 1919. In the rate-determining step it involves the "Staudinger adduct" $[R_3PN_3X]$, which can be isolated, for instance, from the reaction of triphenylphosphine and *p*-toluenesulfonyl azide in diethyl ether at 0 °C quantitatively as a lemon-yellow compound that decomposes at 101 °C [4]. Syntheses on the micro-scale, starting from sodium [^{15}N]nitrite or [β-^{15}N]-azide (prepared from [^{15}N]ammonium chloride) [5] afforded 69 % of the [γ-^{15}N]-compound *(1)* and 52 % of the [β-^{15}N]-compound *(2)*, respectively.

$$Na^{15}NO_2 + H_2N{-}NHTs \xrightarrow{H_2O/CH_3COOH}$$

$$^{15}N_\gamma{=}N_\beta{=}N_\alpha{-}Ts \xrightarrow{R_3P/ether} R_3P{=}^{15}N_\gamma{-}N_\beta{=}N_\alpha{-}Ts \quad (1)$$

$$Na(N_\gamma{=}^{15}N_\beta{=}N_\alpha) + ClTs \xrightarrow{H_2O/acetone}$$

$$N_\gamma{=}^{15}N_\beta{=}N_\alpha{-}Ts \xrightarrow{R_3P/ether} R_3P{=}N_\gamma{-}^{15}N_\beta{=}N_\alpha{-}Ts \quad (2)$$

$R = C_6H_5$

$Ts = p{-}SO_2C_6H_4CH_3$

The linear structure of the Staudinger adducts *(1)* and *(2)* is supported by the IR spectra, in the 4000–400 cm^{-1} region of which distinct ^{15}N-isotope shifts are found only for the P=N stretching vibration ($\nu P{=}N = 1230\ cm^{-1}$, $\Delta^{15}N_\gamma = -17\ cm^{-1}$, $\Delta^{15}N_\beta = -18\ cm^{-1}$) and the N–N stretching vibration ($\nu_{N-N} = 980\ cm^{-1}$, $\Delta^{15}N_\gamma = -12\ cm^{-1}$, $\Delta^{15}N_\beta = -2\ cm^{-1}$) [6].

Thermal decomposition of the Staudinger adducts in benzene at 60 °C occurs with 91 % evolution of N_2. Decision between elimination of $N_\gamma N_\beta$, ($N_\gamma N_\alpha$), and $N_\beta N_\alpha$ can be taken by means of the isotope pattern (Table 1) determined by mass spectroscopy.

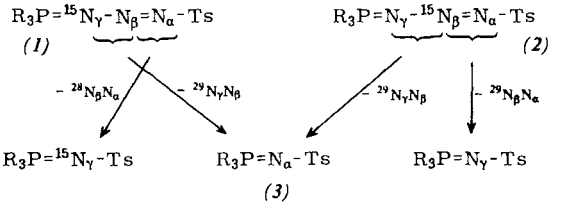

Table 1. Isotope pattern for $^{29}N_\gamma N_\beta$ elimination considering the natural ^{15}N content (0.37 %) and the ^{15}N enrichment in the starting materials $Na^{15}NO_2$ (96.7 %) and $^{15}NH_4Cl$ (95.4 %).

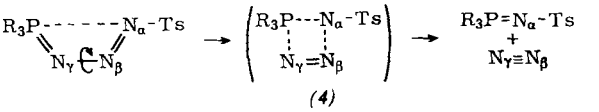
	$^{28}N_2$	$^{29}N_2$	$^{30}N_2$
(1) calc.	8.1	96.3	0.4
found [7]	3.3	91.6	0.3
(2) calc.	4.6	95.0	0.4
found [7]	5.4	94.2	0.4

The elimination of $^{29}N_\gamma N_\beta$ is further confirmed by the fact that the *P,P,P*-triphenylphosphine ^{14}N-toluenesulfonylimine *(3)* from both Staudinger adducts is always unlabeled ($\nu_{P=N} = 1230\ cm^{-1}$).

The elimination of $^{29}N_\gamma N_\beta$ on thermal decomposition of *(1)* and *(2)* in benzene at 60 °C supports the four-membered cyclic transition state *(4)* postulated by *Leffler* and *Temple* [3].



This could arise from a *trans*-Staudinger adduct by, *e.g.*, rotation around the $N_\gamma{-}N_\beta$ bond and subsequent conrotatory ring closure.

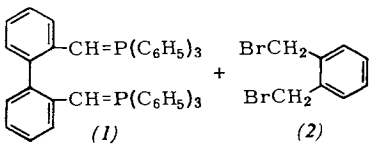
A New Synthesis of Benzocycloalkenes

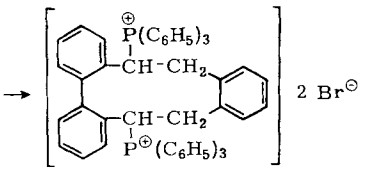
By *H. J. Bestmann* and *D. Ruppert* [*]

The treatment of bisalkylidenephosphoranes with bis(halogenomethyl) compounds opens new possibilities for the synthesis of cyclic compounds, and, in particular, of benzocycloalkenes.

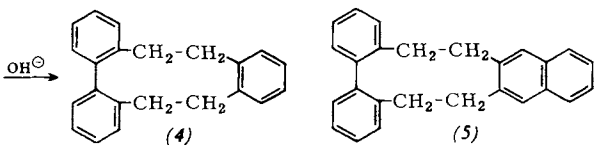
Reaction of the bisylide *(1)* [1] with *o*-xylene dibromide *(2)* gives a bisphosphonium salt *(3)*, which on alkaline hydrolysis gives, as well as triphenylphosphine oxide, a 44 % yield [calc. on *(1)*] of 9,10,15,16-tetrahydrotribenzo[*a,c,g*]cyclodecene *(4)*, m.p. 95 °C [2].



(1) *(2)*



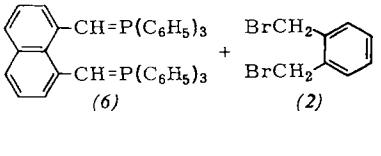
(3)



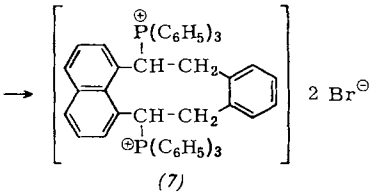
(4) *(5)*

A bisphosphonium salt is obtained analogously from *(1)* and 2,3-bis(bromomethyl)naphthalene and on alkaline hydrolysis affords 9,10,15-16-tetrahydrodibenzo[*a,c*]naphtho[2,3-*g*]-cyclodecene *(5)* [yield 36 %; m.p. 135 °C. NMR: aromatic protons 2.35–3.15 τ (m) (14H), $-CH_2-$ 7.18 τ (broad s) (8H). Mass spectrum: $M^+ = 334$. UV: λ_{max} (*n*-heptane) = 234, 265, 274, 284, 322 nm].

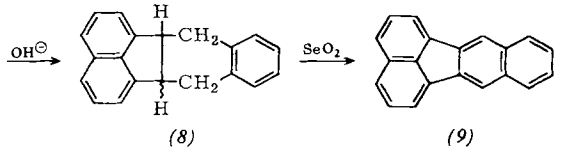
2,2'-Bis(bromomethyl)biphenyl and *(1)* afford a bisphosphonium salt whose hydrolysis gives 9,10,19,20-tetrahydrotetrabenzo[*a,c,g,i*]cyclododecene (50 % yield) which was obtained by *Wittig et al.* [3] by another route; it melts at 261 °C but, when heated, passes into the recorded form [3] having m.p. 266 °C.



(6) *(2)*



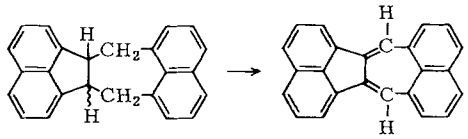
(7)



(8) *(9)*

Reaction of *(6)* [1] and *(2)* gives the bisphosphonium salt *(7)*, whose hydrolysis by alkali is accompanied by a transannular reaction. Triphenylphosphine and its oxide are liberated and 6b,7,12,12a-tetrahydrobenzo[*k*]fluoranthene *(8)*, m.p.158 °C [4], is formed in 44 % yield. Compound *(8)* can be dehydrogenated by SeO_2 to the known benzo[*k*]fluoranthene *(9)*, m.p. 218 °C [5].

The analogous reaction of *(6)* with 1,8-bis(bromomethyl)-naphthalene leads to a bisphosphonium salt whose alkaline hydrolysis also involves a transannular reaction and gives 6b,7,14,14a-tetrahydrodinaphtho[1,18a,8-*a,b*,1,8a,8-*f,g*]azu-6b,7,14,14a - tetrahydrodinaphtho[1,18a,8 - *a,b*,1,8a,8-*f,g*]-azulene *(10)* [yield 10 %, m.p. 276 °C]. NMR (accumulated spectrum): aromatic protons 2.4–3.1 τ (m); aliphatic protons 5.65–7.1 τ (m), 8.55 τ (m). UV: λ_{max} ($CHCl_3$) = 302, 307, 316, 321 nm. Mass spectrum: $M^+ = 306$].



(10) *(11)*

Dichlorodicyano-1,4-benzoquinone dehydrogenates *(10)* to the deep red dinaphthoazulene *(11)* [M.p. 295 °C. NMR (in C_6D_5Br): aromatic protons 2.0–3.3 τ (m), C=C–H 5.2 τ (s); UV: λ_{max}($CH\,Cl_3$) = 273, 281, 300 (shoulder), 394, 416, 442, 470, 516, 550 nm; mass spectrum: $M^+ = 302$].

Experimental:

Preparation of *(4)*: An equimolar amount of *(2)*, dissolved in benzene, is added to a suspension of *(1)* in benzene. After 10 h the precipitated salt *(3)* is filtered off and reprecipitated from chloroform with ethyl acetate. The salt is then boiled for 2 h in 10 % sodium hydroxide (100 ml) and extracted with benzene. The residue remaining after removal of the benzene is shaken thoroughly with petroleum ether (100 ml) and the undissolved triphenylphosphine oxide filtered off. The residue from the petroleum ether extract is chromatographed on aluminum oxide (neutral, activity grade II). On elution with benzene, *(4)* is obtained; this is recrystallized from ethanol and can be sublimed under vacuum. (Yield 44 %, m.p. = 95 °C).

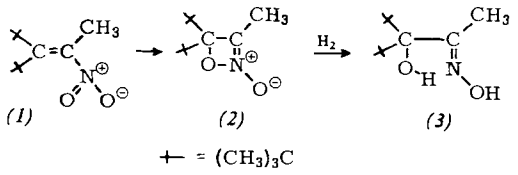
Sterically Induced Intramolecular Cyclization of an α,β-Unsaturated Nitro Compound

By *A. Berndt* [*]

3-*tert*-Butyl-4,4-dimethyl-2-nitro-2-pentene *(1)* [1] is the first α,β-unsaturated nitro compound for which intramolecular cyclization to a four-membered heterocycle has been observed.



(1) (2) (3)

+− = $(CH_3)_3C$

The product 4,4-di-*tert*-butyl-3-methyl-4*H*-1,2-oxazete 2-oxide *(2)* is the first derivative of the new system 4*H*-1,2-oxazete. It was isolated in quantitative yield when a solution of *(1)* in ethanol, after having been allowed to stand overnight, was evaporated down and the residue recrystallized from ethanol.

The structure of *(2)*, which melts at 85 °C and sublimes with spontaneous cyclization at 50 °C/10^{-3} torr, is proved by the following findings: C,H,N analysis; molecular weight (calc. 199; found 205, osmometrically); NMR spectrum (in $CDCl_3$, δ scale), 2 singlets at 1.2 and 2.1 ppm with relative areas 6:1; IR spectrum (in CCl_4), strong band at 1698 cm^{-1} in the stretching vibration region of C=N bonds in rings; UV spectrum, sharp band (half width 27 nm) at 222 nm, $\varepsilon = 7.4\times10^3$ (nitrones have similar UV spectra) [2]. On catalytic hydrogenation (room temperature; atmospheric pressure, Raney Ni, dioxane) the oxazete *(2)* slowly absorbs 1 molecular equivalent of hydrogen. The hydrogenation product *(3)* (m.p. 88 °C, sublimes at 60 °C/10^{-2} torr) is characterized by the following data: C,H,N analysis; NMR spectrum (in $CDCl_3$), four singlets at 1.1, 2.1, 5.0, 8.9 ppm with relative areas 18:3:1:1 (the signal at 8.9 ppm shows the characteristic broadening of oxime protons); IR spectrum in (CCl_4), two bands at 3594 and 3459 cm^{-1} in the O–H stretching region. Like other α-hydroxy oximes [3], compound *(3)* forms a Cu^{2+} complex. The hydrogenation occurs as for isoxazoline *N*-oxides [4].

The kinetics of the isomerization *(1)* → *(2)* was studied in several solvents by measuring the decrease in extinction of the UV band of *(1)* at 345 nm. In all cases, the reaction was clearly of the first order. The velocity increases with increasing polarity of the solvent; half-reaction times are 140 h in *n*-hexane, 70 h in diethyl ether, 2 h in ethanol. Solid *(1)* isomerizes to *(2)* within several weeks.

The unusual cyclization must be due to the strong steric hindrance by the four substituents around the C=C bond. In compound *(1)* this hindrance is avoided by rotation around the C=C bond; in *(2)* this angle of twist amounts formally to 90°. A similar strong rotation is observed also in the anion radical of *(1)* [1].

Compound *(2)* is stable to heat up to at least 100 °C and can be considered as a new example of stabilization of small rings by *tert*-butyl groups [5].

Unit Cells and Absorption Spectra of the Cubic Squarates of Cobalt and Nickel [**]

By *A. Ludi* and *P. Schindler* [*]

On treatment of bivalent metal ions with potassium squarate (squarate anion = $C_4O_4^{2-}$, the anion of squaric acid, 3,4-dihydroxy-3-butene-1,2-dione), *West et al.* [1] obtained from the aqueous solution salts of the composition $MC_4O_4\cdot2\,H_2O$ (M = Ca, Mn, Fe, Co, Ni, Cu, or Zn). According to the temperature at which precipitation occurred and the excess of potassium squarate used we obtained three compounds that were readily distinguishable by X-rays. The pure cubic modification, of composition $MC_2O_4\cdot2\,H_2O$ is formed when a 0.5 M metal salt solution is precipitated at the boiling point by a three-fold excess of 0.5 M potassium squarate and the precipitate is heated under reflux in the mother liquor for a further three hours. When isolated and dried over KOH *in vacuo* the dihydrate shows remarkable thermal stability; loss of the two molecules of water is observed thermogravimetrically only between 200 and 260 °C.

Indexing of the Guinier photographs (internal standard: KCl) yields a simple cubic unit cell containing three formula units $MC_4O_4\cdot2\,H_2O$.

	a (Å)	d_4^{20} (g/cm³)	$d_{X\text{-ray}}$ (g/cm³)
$CoC_4O_4\cdot2\,H_2O$	8.16	1.87	1.90
$NiC_4O_4\cdot2\,H_2O$	8.06	1.93	1.97

The reflectance spectra of the powdered substances are typical of octahedral coordinated cobalt and nickel compounds, with absorption maxima (in cm^{-1}; sh = shoulder) at: $CoC_4O_4\cdot2\,H_2O$: 7800, 11400 sh, 16000 sh, 19600, 21500 sh $NiC_4O_4\cdot2\,H_2O$: 8600, 13300, 15200, 21500 sh, 25300.

The values of the ligand field parameters Dq and the Racah parameters B are collected in the annexed table, where the corresponding values for the hexaaquo complexes [2] are given (in parentheses) for comparison.

	Dq (cm^{-1})	B (cm^{-1})
$CoC_4O_4\cdot2\,H_2O$	890 (930)	860 (970)
$NiC_4O_4\cdot2\,H_2O$	860 (850)	850 (940)

The metal ion is bound to two water molecules and chelated to two squarate ions; it is assumed from the size and symmetry of the unit cell that the two water molecules are in *cis*-positions.

Electrolytic Desulfurization of 2-Mercapto Carboxylic Acids and the Corresponding Disulfides

By *P. Rambacher* and *S. Mäke* [*]

Electrolytic reduction of cystine on tinned electrodes or on copper [1] leads to an almost quantitative yield of cysteine without detectable evolution of hydrogen sulfide. However, in attempts to reduce isocystine [2,2'-dithiodi-(3-amino-propionic acid)] to 3-amino-2-mercaptopropionic acid in the same way reduction was accompanied from the beginning by evolution of hydrogen sulfide, which ceased only when all

the sulfur had been removed. A similar evolution of hydrogen sulfide was also observed when isocysteine was used. The only further reduction product isolated was β-alanine in the form of its benzoyl derivative. This reductive exchange of sulfur for hydrogen occurs also with other 2-mercapto carboxylic acids and their derivatives. For instance, mercaptoacetic acid gives acetic acid, and 2-mercaptopropionic acid gives propionic acid. Desulfurizations of this kind were previously known only for reactions on Raney nickel [2].

Experimental:

Isocystine (12 g) was dissolved in a mixture of concentrated hydrochloric acid (12 ml) and water (200 ml) and reduced electrolytically at 2 A and 5 V at a copper cathode (current density 6 A/dm²). Graphite in hydrochloric acid served as anode, and was separated from the cathode chamber by a diaphragm. The transient SH reaction of the solution disappeared after 4 h, during which time hydrogen sulfide was continuously evolved. The solution was concentrated and 7.1 g of benzoyl-β-alanine (m.p. 133 °C) were isolated on benzoylation.

Isocysteine hydrochloride (4 g) was treated similarly. After 2.5 h at 1 A (current density 3 A/dm²) benzoylation afforded 3 g of benzoyl-β-alanine.

48 mmoles of hydrogen sulfide were evolved from 50 mmoles (4.6 g) of mercaptoacetic acid at a copper cathode (8 A/cm²) within 8 h; it was trapped in cadmium acetate solution and determined iodometrically. 2 g of acetic acid were determined by gas chromatography of the cathode liquid.

Analogous treatment of 50 mmoles (5.3 g) of 2-mercaptopropionic acid gave 47.8 mmoles of hydrogen sulfide and 2.3 g of propionic acid (determined by gas chromatography).

σ,π-$C_8H_8Os(CO)_3$, an Unusual Cyclooctatetraene-Transition Metal Complex

By *M. I. Bruce, M. Cooke,* and *M. Green* [*]

Ultraviolet irradiation of dodecacarbonyltriosmium and cyclooctatetraene in benzene (room temperature, 72 h) affords a pale yellow crystalline complex *(1)*, m.p. 69 °C, of molecular formula $C_{11}H_8O_3Os$ (found: mol. wt. 380.00792; calc. for $C_{11}H_8O_3{}^{192}Os$: mol. wt. 380.00906). The parent ion shows stepwise loss of three carbonyl groups, and the infrared spectrum shows three bands at 2079.5 (s), 2008 (s), and 1995.5 (s) cm^{-1} (cyclohexane), characteristic of the ν_{CO} for an $M(CO)_3$ group. Other bands occur at 1640 (m), 1350 (m), 877 (m), 814 (m), 775 (s), and 708 (m) cm^{-1} (CS_2).

The ^1H–NMR spectrum at room temperature (100 and 220 MHz [1]) remains unchanged on cooling to −140 °C, and shows four absorptions (A, B, C, D; see Table).

Table 1. ^1H–NMR spectrum of *(1)* at 100 and 220 MHz.

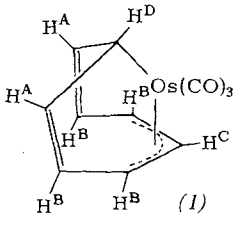
Resonance	τ (CCl_4)	Relative intensity	Multiplicity and coupling constants (Hz)
A	4.0	2	Double doublet; $J_{AB} = 6.5$, $J_{AD} = 4.5$
B	4.9	4	Assymetric complex multiplet
C	5.2	1	Broad triplet; $J_{BC} = 9.5$
D	7.45	1	Triplet; $J_{AD} = 4.5$

Double irradiation of A results in some simplification of B, and D collapses to a sharp singlet. Resonance A becomes a doublet when B is irradiated, and C changes to a broad singlet. The contour of B changes when C is irradiated, and irradiation of D causes A to collapse to a doublet, with some sharpening of resonance C.

Clearly, these NMR data do not correspond to those found with the familiar complexes π-$C_8H_8M(CO)_3$ (M = Fe, Ru), even in their fixed configuration [2]. In particular, the couplings between H_A and H_D, and between H_B and H_C, indicating one hydrogen coupling to two other identical hydrogen atoms in each case, severely restrict the possible structures of this complex.

We propose the novel structure *(1)* for this complex, in which the hydrocarbon is bonded to the $Os(CO)_3$ group by both a π-allyl system and by a metal-carbon σ bond, with the C_8H_8 assuming a boat configuration. The deshielding effect of the vinylic systems on the protons H_B of the π-allyl group causes H_C to be at higher field than H_B. The bands in the infrared spectrum at 1640 ($\nu_{C=C}$) and at 775 cm^{-1} (*cis*-C=C) lend support to this structure.

It is of interest that complex *(1)* isomerizes on gentle warming in solution to an orange-yellow complex *(2)*, m.p. 90.5 °C, which shows ν_{CO} at 2072 (s), 2001 (s), and 1989 (s) cm^{-1} (cyclohexane, and which shows a single resonance at 4.78 τ ($CDCl_3$). Complex *(2)* is evidently analogous to the now well-known iron [3] and ruthenium [2] cyclooctatetraene complexes, and the ease of isomerization is convincing evidence that the hydrocarbon ligand in complex *(1)* has a similar carbon skeleton to that in complex *(2)*.



(1)

As expected, the 1,2 motion of the $Os(CO)_3$ moiety around the ring is slower in complex *(2)* than that found in the iron and ruthenium complexes, as evidenced by the resolution of the ^1H–NMR spectrum at higher temperatures.

Complex *(1)* is not reformed from *(2)* either thermally or by ultraviolet irradiation. We suggest that the formation of *(1)* results from fragmentation of an initially formed complex between cyclooctatetraene and the Os_3 cluster, perhaps analogous to $(C_8H_8)_2Ru_3(CO)_4$ [4] or $C_8H_8Fe_2(CO)_5$ [5], both of which have been shown to contain π-allyl systems.

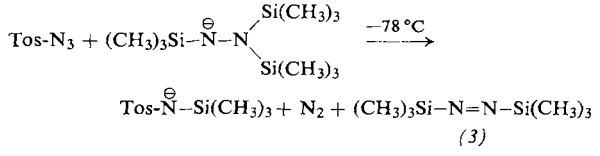
Bis(trimethylsilyl)diimine and Tetrakis(trimethylsilyl)hydrazine[1]

By *N. Wiberg, W.-Ch. Joo,* and *W. Uhlenbrock* [*]

Whereas bisalkyldiimines (azoalkanes) which contain the characteristic atomic grouping *(1)* have long been known, attempts to synthesize bissilyldiimines (azosilanes)[2,3], which contain the atomic grouping *(2)* have hitherto remained unsuccessful[4].

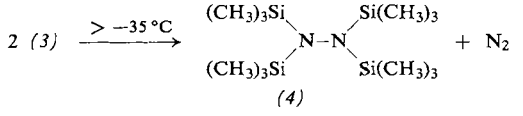
(1) *(2)*

In reaction of *p*-toluenesulfonyl azide[5] with tris(trimethylsilyl)hydrazide we have obtained access to the class of bissilyldiimines:



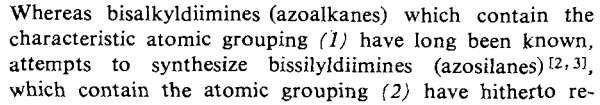
(3)

The product is light blue [λ_{max} = 786 nm (ether)], volatile in a high vacuum at −40 °C, and sensitive to hydrolysis. That it is bis(trimethylsilyl)diimine (hexamethylazosilane) follows from elemental analysis, the mass spectrum (base peak for the molecular ion at m/e = 174), the ^{1}H–NMR spectrum (one signal at δ = −12.5 Hz referred to TMS as internal standard; determined in ether at −40 °C), and thermolysis. The azo compound *(3)* decomposes quantitatively above about −35 °C according to the scheme:



(4)

This affords molecular nitrogen and the sterically hindered tetrakis(trimethylsilyl)hydrazine *(4)* which was previously unknown. The structure of *(4)*, m.p. 271 °C, was proved by analyses, mass spectrum, ^{1}H–NMR spectrum (only one proton signal, namely, at δ = −13.0 Hz referred to TMS as internal standard, recorded in benzene), and by independent synthesis as follows:



Experimental:

Preparation of *(3)*: Suspensions of *p*-toluenesulfonyl azide (12.0 mmoles) and lithium tris(trimethylsilyl)hydrazide (12.0 mmoles) each in ether (25 ml) were mixed at −78 °C with exclusion of moisture and oxygen. After reaction for 2 h at −78 °C, during which 12.2 mmoles of nitrogen was evolved, first the ether was condensed off from the reaction mixture in a high vacuum at −55 °C, and then pure *(3)* at −5 °C (yield 50 to 60%). *N*-Lithio-*N*-(trimethylsilyl)-*p*-toluenesulfonamide, containing *(4)* as an impurity, remained as a solid residue.

Preparation of *(4)*: Equimolar amounts of *N*-lithium tris(trimethylsilyl)hydrazide and trimethylchlorosilane in benzene are heated in a Carius tube at 120 °C for 48 h. After separating off the lithium chloride which has been formed, the benzene is distilled from the reaction solution and the residue *(4)* remaining is purified by several sublimations in high vacuum at 65 °C.

CONFERENCE REPORTS

International Symposium on the Chemistry of Small Rings

The *Société Chimique de Belgique* held a symposium on the chemistry of small rings at Louvain (Belgium) from September 12 to 15, 1967.

From the lectures:

Syntheses of Cyclopropanes and Azirines by Means of Alkylidenephosphoranes

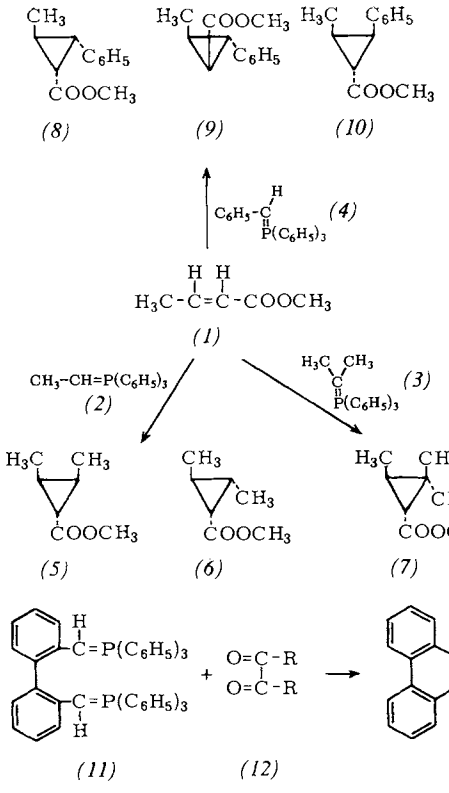
By *H. J. Bestmann* [*]

In the reaction of alkylidenephosphoranes with compounds containing "electron-deficient" double bonds, cyclopropane derivatives and triphenylphosphine are formed[1] by way of an intermediate betaine that is formed in a reversible reaction. The stereochemistry of this cyclopropane formation has been studied in detail. The ylide *(2)* and methyl 2-butenoate *(1)* afford the cyclopropane derivatives *(5)* and *(6)*. 93% of *(5)* and 7% of *(6)* are obtained independently of whether one starts from the *cis*- or the *trans*-ester.

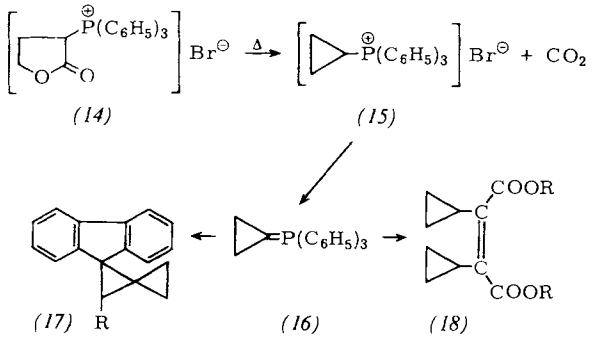
cis- or *trans*-*(1)* and the alkylidenephosphorane *(3)* give the sterically homogeneous cyclopropane derivative *(7)*. The benzylidenephosphorane *(4)* and the ester *(1)* afford the derivatives *(8)* (11%), *(9)* (33%), and *(10)* (56%).

Reaction of the diylide *(11)* with 1,2-diketones *(12)* gives sterically homogeneous dibenzonorcaradiene derivatives *(13)*[2], whose structure was determined by nuclear resonance and in particular the solvent-dependence of the chemical shift[3] of the cyclopropane protons.

When heated above the melting point, the phosphonium salt *(14)* loses CO_2 and gives cyclopropyltriphenylphosphonium bromide *(15)*[4], which can be converted into cyclopropylidenetriphenylphosphorane *(16)* by phenyllithium. This product *(16)* reacts as nucleophile with many compounds,



yielding cyclopropane derivatives[5], *e.g.* with alkylidenefluorenes it gives the spiro compounds *(17)* and with fumaric or maleic ester gives the di(cyclopropyl)maleic ester *(18)*.



On reaction of nitrile oxides with alkylidenephosphoranes loss of triphenylphosphine oxide may be accompanied by formation either of a ketene imine with concomitant rearrangement or of an azirine[6]. The mechanism of these reactions was discussed, as was its dependence upon the substituents present on the alkylidenephosphorane and on the nitrile oxide.

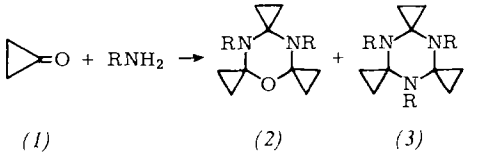
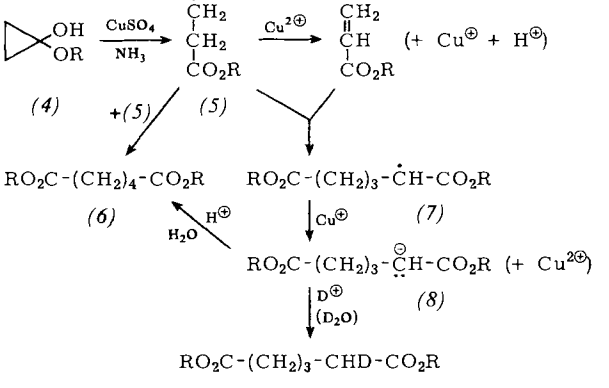
Reactivity of Cyclopropanone and Some of its Adducts

Von *Th. J. de Boer*[*]

Reaction of diazomethane with an excess of ketene in liquid propane at −78 °C yields cyclopropanone *(1)*, which is obtainable as a practically pure liquid after removal of ketene and propane. Cyclopropanone can be stored for a few days at the temperature of liquid nitrogen. At higher temperatures and with traces of water it polymerizes – without ring fission – like formaldehyde. All common nucleophiles, *e.g.* water, alcohols, thiols, acetic acid, hydrocyanic acid, and amines, react with cyclopropanone to form 1:1 adducts. The adducts *(2)* and *(3)* can easily be obtained from *(1)* and amines.



Metal ions oxidize simple adducts like cyclopropanone-hydrate or -hemiacetal *(4)* to adipic acid or its esters *(6)* (R = CH_3).



The intermediary radical *(5)* was detected by ESR spectroscopy. Dimerization of *(5)* yields the ester *(6)*, but only to the extent of 20%; the rest of *(6)* is formed from *(5)* and methyl acrylate *via* the intermediates *(7)* and *(8)*, as was shown when the reaction was carried out in D_2O.

(7) can also be added to other olefinic compounds such as methyl vinyl ketone, cyclopentenone, butadiene, or furan. In the case of methyl- and *gem*-dimethyl-substituted cyclopropanones the ring opening (and thus the product distribution) depends strongly on the nature of the oxidizing metal ions.

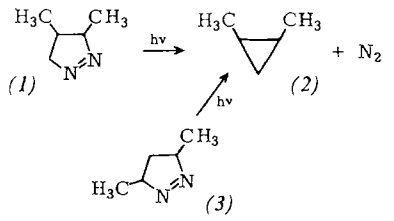
Triplet Trimethylene Species

By *R. J. Crawford* and *R. Moore*[*]

The benzophenone photosensitized decomposition of both *cis*- and *trans*-3,4-dimethyl-1-pyrazoline *(1)* gives rise to a 70:30 mixture of *trans*- and *cis*-1,2-dimethylcyclopropane *(2)*. No 3-methyl-1-butene is produced. It is believed that the triplet pyrazoline decomposes to nitrogen and triplet trimethylene. The latter species is the same as that produced when triplet methylene is added to *cis*- or *trans*-2-butene. Stereochemistry is lost by rotation and both isomers give



rise to the same product ratio. This supports the contention of *Doering* and *Skell* that triplet methylene forms an intermediate that is able to undergo rotation prior to ring closure.

Using *cis*- or *trans*-3,5-dimethyl-1-pyrazoline *(3)* a ratio of 40:60 *cis*- to *trans*-dimethylcyclopropane was produced. This ratio implies that the triplet formed from *(1)* is not readily interconverted to the triplet species produced from *(3)*. The absence of olefins here suggests that in the reactions of triplet methylene with the butenes the olefins are not being formed *via* a 1,4-hydrogen-atom shift.

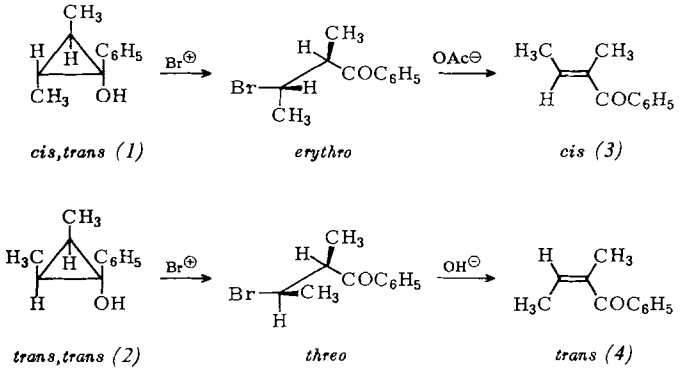
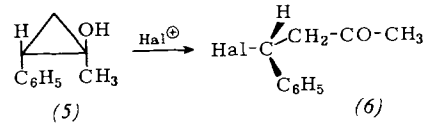
Electrophilic Cleavage of Cyclopropanols by Halogenating Agents

By *C. H. DePuy, W. C. Arney jr.*, and *D. H. Gibson*[*]

Electrophilic ring-opening of cyclopropanols by protons in acid solution has been shown previously to occur with retention of configuration at the carbon to which the hydrogen becomes attached. Many cyclopropanols react readily with sources of positive halogen (*tert*-butylhypohalite, halogen, *N*-halosuccinimide) in a variety of solvents (*tert*-butyl alcohol, CCl_4, acetic acid). *cis,trans*- and *trans,trans*-2,3-dimethyl-1-phenylcyclopropanol (*(1)* and *(2)*, resp.) and their corresponding acetates react stereospecifically with brominating



agents exclusively with inversion to give *erythro*- and *threo*-β-bromo-ketones respectively. These compounds are stereospecifically converted into *(3)* and *(4)* on treatment with weak bases.



Optically active *trans*-2-phenyl-1-methylcyclopropanol *(5)* reacts with chlorinating agents and brominating agents to give 4-halo-4-phenyl-2-butanone *(6)* as the sole product. This reaction also occurs with inversion of configuration. Assignment of configuration of *(6)* was based upon close analogies.

Induced Paramagnetic Ring-current in the Four-membered Ring of Biphenylene and Related Hydrocarbons

By *H. P. Figeys*[*]

Several authors have noted that the signals of the biphenylene protons appear in the NMR-spectrum at a higher field than those of the benzene protons[1,2]. We have found that the same is true for certain protons of the benzobiphenylenes. This behavior can have two different causes: either the occurrence of very low deshielding ring-currents in the various rings, or the presence of an induced paramagnetic shielding ring-current in the four-membered ring of this series of compounds. Such "reversed" ring-currents have indeed been observed in the monocyclic annulenes and dehydroannulenes having $4n$ π-electrons[3].

We have obtained experimental evidence for this second hypothesis by analyzing the NMR-spectrum (solvent $CDCl_3$; standard TMS, internal) of benzo[*b*]biphenylene *(1)*; the spectrum contains a broad singlet at 6.90 ppm which is attributed, by comparison with several substituted derivatives[2], to protons 1 to 5 and 10. Protons 6 to 9 give an A_2B_2 multiplet centered at about 7.30 ppm. However, in the hypothesis of deshielding ring-currents, δH^1 should appear at a lower field than δH^2, whatever the relative values of the individual ring-currents, owing to the closer proximity of rings II, III, and IV. The only way to explain the experimental observations is to postulate a shielding ring-current in the four-membered ring, whose difference in shielding effect on protons 1 and 2 is almost completely compensated by the difference in deshielding effect of rings III and IV.

Calculation of the ring-currents in biphenylene and in benzobiphenylenes by *McWeeny*'s method[4] showed that an induced paramagnetic ring-current occurs in the four-membered ring of each of these compounds. Condensation of a benzene ring onto biphenylene *(2)* along the long axis of the molecule results in a diminution of the shielding ring-current, while condensation in a non-linear way has the opposite influence. Another interesting feature is the very low ring-current in the benzene rings adjacent to the four-membered ring. These two effects are thus responsible for the position of the high-field multiplet in the spectrum of these molecules.

The occurrence of a shielding ring-current in the four-membered ring in biphenylene raised another interesting problem, namely the attributions of the individual resonance frequencies of protons 1 and 2 in *(2)*. The contributions $\delta_{R.C.}$ of the different rings to the calculated chemical shifts are given in the Table.

The calculated chemical shifts are in good agreement with experimental values: 6.598 and 6.702 ppm in $CDCl_3$[6], 6.47 and 6.60 ppm in CCl_4 solution[1]. Theoretical considerations indicate that proton 2 is more deshielded than proton 1. These assignments were confirmed by the analysis of the NMR spectra of [1-D]- and [2-D]biphenylene prepared by unambiguous syntheses[**]. The spectra of the deuterated compounds were in excellent agreement with the calculated 7 H spectra obtained by *S. Castellano* and *A. A. Bothner-By*'s LAOCOON computer program[7].

Finally, in the series of molecules investigated, it appeared that the shielding ring-current decreases when the structure of the four-membered ring changes progressively from the "cyclobutadiene-like" to the "tetramethylenecyclobutane-like" structure.

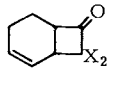
Cycloadditions of Dichloroketene

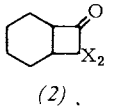
By *L. Ghosez, R. Montaigne, H. Vanlierde*, and *F. Dumay*[*]

Dichloroketene, generated *in situ* from dichloroacetyl chloride and triethylamine in refluxing pentane, reacts readily with cyclopentadiene and cyclopentene[1] according to the cycloaddition scheme 2 + 2 = 4.

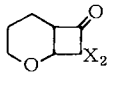
The reaction can be extended to other olefins; for example the 1,2-cycloadducts *(1)* to *(4)*, X = Cl, have been obtained in satisfactory yields (40–75%) from cyclohexadiene, cyclohexene, dihydropyran, and indene.



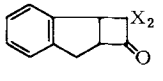
(1)



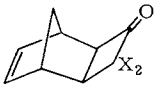
(2)



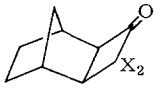
(3)



(4)



(5)



(6)

The *exo*-adducts *(5)* and *(6)*, X = Cl, have been obtained in 25% and 10% yield respectively from the reaction of dichloroketene with norbornadiene and norbornene. All adducts could be dehalogenated in high yield to the parent cyclobutanones *(1)* to *(6)*, X = H, by refluxing in cyclohexane containing two equivalents of tributyltin hydride.

Our present findings can be summarized as follows:

1. Substituting chlorine for hydrogen on a system of cumulative double bonds appears to increase considerably its reactivity (*e.g.* dichloroketene *vs.* ketene; tetrachloroallene *vs.* allene).

2. The orientation of the cycloaddition is uniform and compatible with a nucleophilic attack of the olefin on the central carbon atom of the ketene molecule.

3. No 1,4 cycloadducts are formed even with cisoid dienes such as cyclopentadiene or cyclohexadiene. Furthermore, in contrast to 1,1-dichloro-2,2-difluoroethylene[2] or tetracyanoethylene[3], dichloroketene does not add across the homodiene system of norbornadiene.

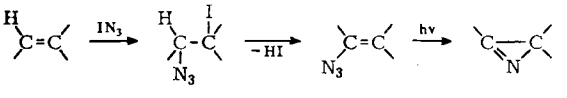
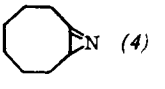
Synthesis and Chemistry of 1-Azirines

By *A. Hassner*[*]

Azirines (azacyclopropenes) *(3)* represent a difficulty accessible ring system. We now describe a general synthesis of azirines from olefins. The sequence involves stereospecific addition of IN_3 to olefins followed by elimination of HI to give vinyl azides *(2)*. The latter are photolyzed to 1-azirines *(3)*. In this manner highly strained azirines such as *(4)* are also accessible as components of bicyclic ring systems.

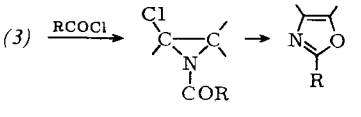


(1) (2) (3)



(4)

Azirines are only weakly basic compounds, insoluble in cold dilute acid, and do not react with alkyl halides. On the other hand, reaction occurs readily with acid chlorides to yield oxazoles *(6)*, *N*-acyl-2-chloroaziridines *(5)* being formed as intermediates.



(5) (6)

Reduction of 2,3-substituted azirines with $LiAlH_4$ occurs stereospecifically from the less hindered side to give *cis*-aziridines. In this way, *cis*-aziridines can be synthesized from either *cis* or *trans* olefins or a mixture of both. The IN_3 adduct of bromophenylacetylene pyrolyzes under mild conditions to diphenyldicyanoethylene, presumably *via* an azirinium ion or radical.

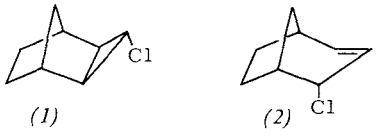
The *exo*-Tricyclo[3.2.1.$0^{2,4}$]octane System

By *C. W. Jefford*[*]

The addition reactions of monochlorocarbenoid to bicyclo[2.2.2]oct-2-ene, to norbornene, and to 1-methyl- and 2-methylnorbornene have been studied. In the case of the last three compounds the *exo* addition took place exclusively. Quite strikingly, for all four olefins the addition occurred with pronounced *anti* stereoselectivity, the *syn-anti* ratios being 1:5, 1:6, 1:1.5, and 1:9.8 respectively. A typical *syn-anti* ratio for a *mono*cyclic olefin is 3:1. It should be pointed out that these ratios apply to the generation of the carbene from equimolar quantities of CH_2Cl_2 and CH_3Li (from CH_3Cl) in the presence of a 25% excess of olefin. The *syn-anti* ratios have been rationalized in terms of dispersion forces.

All the *anti* products, *e.g. anti*-3-chlorotricyclo[3.2.1.$0^{2,4}$]-octane *(1)*, were quite stable to heat and to Ag^+ in aqueous solution. Clearly, ionization of the cyclopropyl chloride portion is prevented by the geometric restriction of the appropriate disrotatory mode.



(1) *(2)*

In the case of the norbornene derivatives, the *syn*-adducts were not observed, only their rearrangement products, the *exo*-4-chlorobicyclo[3.2.1]oct-2-enes, *e.g. (2)*. Although the *syn* adduct from bicyclo[2.2.2]oct-2-ene could be observed below 60 °C, it rearranged readily on warming to 4-chlorobicyclo[3.2.2]non-2-ene. The geometry of the *syn* adducts permits ionization to the allylic system.

The addition of chlorocarbenoid to 2-methylnorbornene gave the stable *exo-anti* adduct and 2-methylenebicyclo-[3.2.1]oct-3-ene which is derived from the *exo-syn* adduct. It can be seen, therefore, that the elimination of hydrogen chloride from the *exo-syn* adduct depends upon prior rearrangement or ionization to the allylic system.

The Photosensitized Decomposition of Diazoketones

By *M. Jones jr.* and *W. Ando*[*]

Whereas diazoketone *(1)* undergoes the photochemical Wolff rearrangement to *(2)*, even in the presence of carbene acceptors, spiroketones are produced in 20–50% yield when the decomposition is photosensitized with benzophenone. The same mixture of the adducts *(3)* and *(4)* is formed from both *cis-* and *trans*-2-butene. Presumably the triplet carbene is produced on photosensitization but does not rearrange to the triplet ketene, adding instead to the acceptor olefin to give the spiroketones observed.

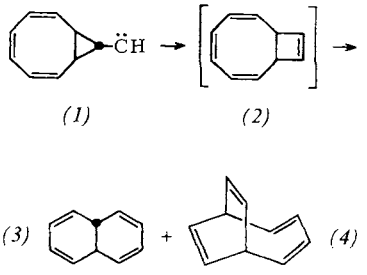
Rearrangements of Highly Unsaturated Cyclopropyl Carbenes

By *M. Jones jr., S. D. Reich, L. T. Scott,* and *L. E. Sullivan*[*]

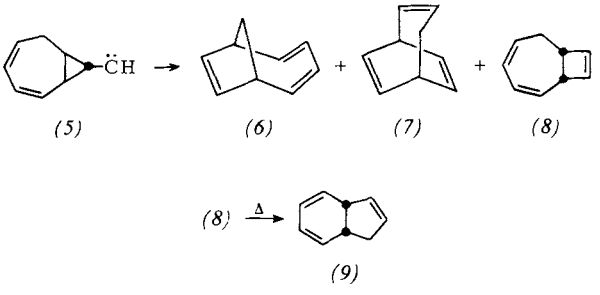
Generation of unsaturated cyclopropyl carbenes of the type *(1)*, *(5)*, or *(12)* yields besides the normal ring-expanded product, other rearrangement compounds[1,2]. Thus *(1)* gives *trans*-9,10-dihydronaphthalene *(3)*, a product derived[3] from the cyclobutene *(2)* and bicyclo[4.2.2.]deca-2,4,7,9-tetraene *(4)*. *A priori (4)* could result from rearrangement of



(1) *(2)*

(3) + *(4)*

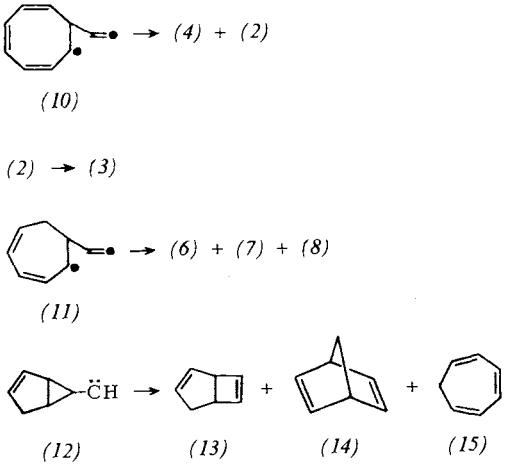
either *(1)* or *(2)*. Rearrangement of *(5)* leads to *(6)* and *(7)*, which are both possible rearrangement products of *(8)*, and *(8)* itself. Compound *(8)*, however, rearranges to *(9)* and not



(5) *(6)* *(7)* *(8)*

(9)

to either *(6)* or *(7)*. It seems likely, therefore, that the carbenes *(1)* and *(5)* are involved in the production of the rearranged products. A mechanism involving the opened species



(12) *(13)* *(14)* *(15)*

(10) and *(11)* is proposed. Similar rearrangements take place in smaller systems. For example *(12)* yields *(13)*, *(14)*, and *(15)*.

The Synthesis and Chemistry of Bicyclo[x.2.0] Systems

By *A. P. Krapcho* and *J. H. Lesser* [*]

The 1,2-cycloaddition of dimethylketene to cycloolefins has been shown to be a general method for the preparation of fused bicyclo[x.2.0]alkanones where $x = 6$ or 7. Product structures were determined by infrared, ultraviolet, and NMR spectroscopy in conjunction with deuterium exchange experiments and elemental analysis.

Several of the bicyclo[x.2.0]alkanones were subjected to isomerization conditions. In these experiments, particular attention was focused on the stability of the *cis*-ring fusion. The NMR spectra of the isomerization products, especially the geminal dimethyl region, facilitated product identification. It was found that the *trans*-bicyclo[6.2.0]decane and -[7.2.0]-undecane ring systems were more stable than their *cis*-analogs for the compounds studied.

Using a model system, the preliminary steps of a synthesis of the sesquiterpene isocaryophyllene were investigated.

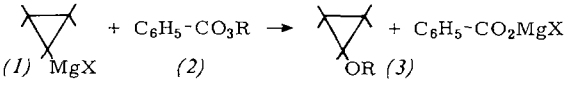
The Direct Conversion of Cyclopropyl Bromides into Cyclopropyloxy Derivatives

By *D. T. Longone* [*]

Cyclopropyl alcohols and esters are key intermediates in a variety of current mechanistic investigations. Detailed studies of these compounds have been limited only by their synthetic availability. Cyclopropyl halides, despite their ease of preparation *via* halocarbene reactions, have not been useful as precursors of cyclopropyloxy compounds (esters, ethers, and alcohols). The halides are virtually inert in S_N2 displacements and react *via* the S_N1 path only with assisted ring-opening.

We wish to report the first synthetically useful conversion of cyclopropyl halides into the corresponding cyclopropyloxy derivatives. The method developed utilizes cyclopropyl carbanions as agents for nucleophilic attack on the oxygen atom of an appropriate substrate. For example, the reaction of a cyclopropyl Grignard reagent *(1)* with benzoyl peroxide *(2a)* or *tert*-butyl perbenzoate *(2b)* affords a cyclopropyl benzoate *(3a)* or a *tert*-butyl cyclopropyl ether *(3b)* in good yield.



(1) *(2)* *(3)*

(a), R = $-\overset{\overset{O}{\|}}{C}-C_6H_5$ *(b)*, R = $C(CH_3)_3$

Compounds of type *(3b)* are particularly useful because they can be converted into acetates in virtually quantitative yield by the reagent acetic anhydride/BF_3-ether. Cyclopropyl esters *(3a)* are reductively cleaved to cyclopropanols by methyllithium or $LiAlH_4$; thus, the conversion of halide to alcohol is possible.

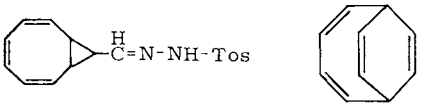
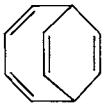
Bicyclo[6.2.0]deca-2,4,6,9-tetraene [**]

By *S. Masamune* [*]

A solution of bicyclo[6.1.0]nona-2,4,6-triene-*trans*-9-carboxaldehyde tosylhydrazone *(1)* in dry tetrahydrofuran containing an equivalent amount of sodium methoxide was irradiated at −30 °C with a Hanovia mercury lamp (Pyrex



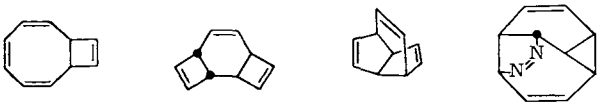
(1)



(2)

filter). Workup, at temperatures below 0 °C, of the reaction products yielded two new compounds, A (45% yield) and B (21%), in addition to bicyclo[4.2.2]deca-2,4,7,9-tetraene *(2)* (7%) and cyclooctatetraene (27%).

NMR-, UV-, and mass-spectrometric data and chemical evidence proved that compound A was bicyclo[6.2.0]deca-2,4,6,9-tetraene *(3)*. The two structures *(4)* and *(5)* were suggested for compound B.



(3) *(4)* *(5)* *(6)*

Compound *(3)* readily and quantitatively isomerizes to *trans*-9,10-dihydronaphthalene. The isomerization is first order and is characterized by the following kinetic data.

$k_{46.8°C} = (6.9 \pm 0.2) \times 10^{-5}\ sec^{-1}$
$k_{74.8°C} = (1.72 \pm 0.05) \times 10^{-3}\ sec^{-1}$
$\Delta H^{\ddagger} = 24.9$ kcal/mole,
$\Delta S^{\ddagger} = -0.4$ cal·deg^{-1}·mole^{-1}

Upon irradiation with a low pressure mercury lamp at −80 °C for one minute, *(3)* isomerized to *trans*-9,10-dihydronaphthalene (20–30% yield), *cis*-9,10-dihydronaphthalene (10 to 15%), *(2)* (50%), and bullvalene (3–10%).

The sodium salt of *cis*-*(1)* provided the pyrazoline *(6)* in excellent yield. Thermolysis of *(6)* at 110–115 °C afforded an approximately 1:1 mixture of bullvalene and *(2)*. Examination of an NMR spectrum (−100 °C) of the photolyzate of VI (photolysis was performed at 77 °K) revealed that the product mixture consisted of *(2)* (65% yield), bullvalene (27%), and compound B (8%). These reactions were compared with the formation of tetracyclo[4.4.0.0^{5,7}.0^{2,10}]deca-3,8-diene.

Preparation of Small Rings by Cycloaddition of Polar Compounds

By *G. Opitz* [*]

Methanesulfonyl chloride and triethylamine in acetonitrile at −40 °C afford mesylsulfene, $SO_2=CH-SO_2-CH_3$. In the presence of vinyl ethers 3-alkoxy-2-mesylthietane 1,1-dioxides are formed in good yields by 2+2 cycloadditions.

Cycloaddition to *cis*- and *trans*-butenyl butyl ether is stereospecific with respect to olefin configuration. The *cis*-olefin gives 86% of *cis,trans*-2-ethyl-3-propoxy-4-mesylthietane 1,1-dioxide, the *trans*-olefin gives an 80% yield of a liquid mixture of 91 parts of *trans,trans*- and 9 parts of the *trans,cis*-isomer.

However, cycloaddition of sulfene (from methanesulfonyl chloride and triethylamine) to 4-(*cis*-propenyl)morpholine is not stereospecific. The *cis*-enamine in ether at −10 °C affords 60–70% yields of a mixture of 51 parts of *cis*-2-methyl-3-morpholinothietane 1,1-dioxide and 49 parts of the *trans*-isomer. As expected, only the *trans*-product was obtained from the *trans*-enamine.

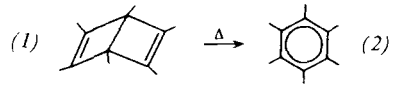
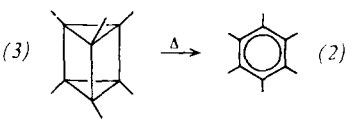
The Kinetics and Thermochemistry of the Thermal Rearrangement of Hexamethyl(Dewar benzene) and of Hexamethylprismane

By *J. F. M. Oth* [*]

Hexamethylbicyclo[2.2.0]hexa-2,5-diene [hexamethyl(Dewar benzene)] *(1)* rearranges thermally into hexamethylbenzene *(2)* above 80 °C.

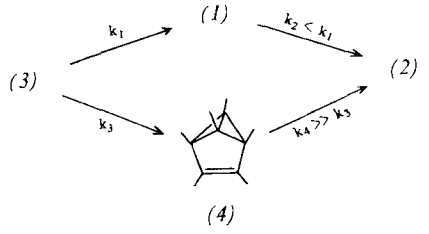


This exothermal reaction was followed in a temperature-programmed calorimeter. From the curve recorded, the kinetic parameters and the heat of the reaction could be deduced (see Table 1).



The curve recorded with the calorimeter, together with kinetic experiments carried out at different temperatures and followed by NMR spectroscopy, showed that this rearrangement *(3)* → *(2)* proceeds *via* two parallel kinetic paths: In one hexamethyl(Dewar benzene) *(1)* is formed as intermediate and accumulates appreciably in the course of the reaction; in the second, the rearrangement proceeds *via* the hexamethyltricyclo[2.1.1.$0^{5,6}$]hex-2-ene (hexamethylbenzvalene) *(4)*, the stationary concentration of which remains always very small [NMR signals at $\tau = 8.375$ (2 olefinic CH_3), $\tau = 9.05$ (2 aliphatic CH_3) and $\tau = 9.17$ (2 aliphatic CH_3)].

The scheme of the thermal rearrangement of *(3)* is thus the following:



with the implications that $k_1 > k_2$ and $k_4 \gg k_3$.

The kinetic parameters for the steps characterized by the rates k_1, k_2, and k_3 are given in Table 1.

The overall heat of isomerization for the reaction *(3)* → *(2)* was found to be:

$$\Delta H_{\text{isom}}\ (3)\rightarrow(2) = H_{(2)} - H_{(3)} = -91.2 \text{ kcal/mole}$$

From this value, the heat of combustion of *(2)*, and thermochemical data we calculated the strain energy in *(3)* to be 116 kcal/mole. This quantity is essentially the strain energy of the prismane skeleton but comprises also the non-bonding interactions between the methyl groups.

Table 1. Kinetic data. All reactions being of first order.

Reaction	$k_{150\,°C}$ (sec^{-1})	E_a (kcal·mole^{-1})	$\log_{10}A$	$\Delta G^{\ddagger}$ (kcal·mole^{-1})	$\Delta S^{\ddagger}$ (kcal·mole^{-1})	$\Delta H^{\ddagger}$ (cal mole^{-1} deg^{-1})	$\Delta H_{\text{isom.}}$ (kcal·mole^{-1})
(1)→*(2)*	$k_2 = 6.57 \times 10^{-5}$	37.2	15.03	33.2	36.4	7.5	−59.5
(3)→*(1)*	$k_1 = 1.06 \times 10^{-3}$	33.8	14.50	30.8	33.0	5.1	−31.7 [a]
(1)→*(2)*	$k_2 = 5.67 \times 10^{-5}$	37.7	15.22	33.3	36.8	8.4	−59.5
(3)→*(4)*	$k_3 = 6.32 \times 10^{-4}$	33.2	13.94	31.3	32.3	2.5	?
(4)→*(2)*	$k_4 \gg 6.32 \times 10^{-4}$	?	?	?	?	?	?
(3)→*(2)*	$k_1 + k_3 = 1.69 \times 10^{-3}$						−91.2

[a] Value obtained by difference (91.2−59.5).

From the heat of isomerization *(1)* → *(2)* ($\Delta H_{\text{isom. } (1)\rightarrow(2)} = -59.5$ kcal/mole), the heat of combustion of *(2)*, and thermochemical data, we have computed the strain energy in *(1)* to be 44.5 kcal/mole. This quantity is essentially the strain energy as accumulated in the bicyclic system, but it also includes the non-bonding interactions between the methyl groups.

Hexamethyltetracyclo[2.2.0.$0^{2,6}$.$0^{3,5}$]hexane (hexamethylprismane) *(3)* rearranges thermally into hexamethylbenzene *(2)* above 60 °C.

Reactions of Cyclopropyl Carbenes

By *I. D. R. Stevens, H. M. Frey,* and *C. L. Bird* [*]

The reaction of cyclopropyl carbene to give cyclobutene and of cyclopropyl methyl carbene to give 1-methylcyclobutene, discovered by *Friedman* and *Shechter* [1], has been shown to be a general reaction of cyclopropyl-substituted carbenes (see Table 1).

The reaction has great synthetic utility for the preparation of cyclobutanes and gives yields in the range of 50–70% (based

Table 1. Rearrangement of symmetrically substituted cyclopropyl carbenes.

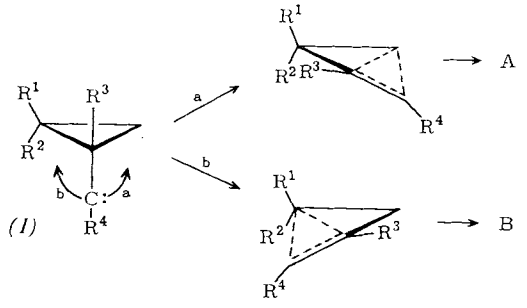
on starting aldehyde or ketone). For those cases in which the cyclopropane ring is not symmetrically substituted (Table 2), a rationalization of the major product is proposed in terms of the steric effects dominant in the intermediate carbene *(1)*.



Conversion to cyclobutene necessarily involves rotation of the "carbene" carbon into the plane of the ring and route (a) or route (b) is followed depending on whether the interaction between R^1, R^2, and the "carbene" carbon is respectively larger or smaller than the interaction between R_1, R_2, and R_3. Thus in *(1a)–(1c)* (Table 2) this leads to preferential migration by route (a) *viz*: the less substituted bond migrates and in *(1d)* these are nearly equal leading to reaction by both routes in equal amounts.

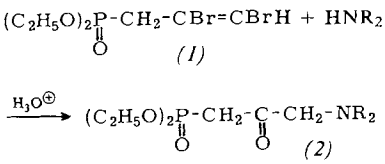
Aminomethyl Cyclopropyl Ketones from 3-Amino-2-oxoalkylphosphonates

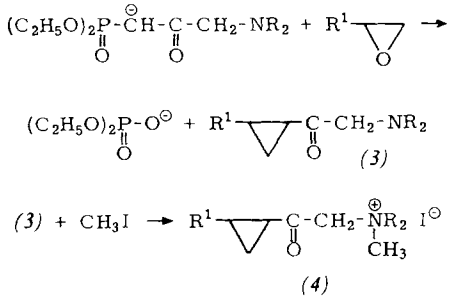
By *G. Sturtz* [*]

Molecules containing cyclopropyl or amino-ketonic groups have interesting pharmacological properties. We therefore tried to include both such groups in one molecule. Diethyl 2,3-dibromoallylphosphonate *(1)* and an amine afford readily the *N,N*-disubstituted 3-aminoacetonylphosphonate *(2)* [1], which serves as our intermediate.



(a), R = CH_3
(b), R = C_2H_5
(c), R_2 = $-(CH_2)_2-O-(CH_2)_2-$
(d), R_2 = $-(CH_2)_5-$

We have shown previously [2] that carbanions from 2-oxoalkylphosphonates react with epoxides to yield alkyl cyclopropyl ketones. The carbanion from *(2)* yields the desired aminomethyl cyclopropyl ketones *(3)* in one step.



For interpretation of the results of the reaction of *(2)* with epoxides (see Table 1) the yields of *(3)* were compared with the differences in the mobility of the protons on each side of the carbonyl group. To a first approximation the difference in mobility can be determined from the chemical shift $\Delta\delta = \delta_{H(P)} - \delta_{H(N)}$ [cf. *(3c)* and *(3d)*]. The substitution on nitrogen appears also to play a part [cf. *(3b)* and *(3c)*]. From gas chromatography it can be seen that preponderatingly (95%) one of the two stereoisomers of *(3)* is formed. The change in the chemical shift by a factor of 2 on going from benzene to $CDCl_3$ indicates a *trans*-configuration [3].

Table 1. $\Delta\delta = \delta_{H(P)} - \delta_{H(N)}$ of *(2)* and yields of *(3)*.

	(a)	(b)	(c)	(d)
$\Delta\delta \cdot 10^{-6}$ of *(2)*	−0.01	−0.12	−0.07	+0.07
Yield (%) of *(3)*	47	54	35	65

Compounds *(3)* react with methyl iodide, yielding salts *(4)* in which R^1 = H, R = R^2 = CH_3; R = R^1 = R^2 = CH_3; R^1 =

$R^2 = CH_3$, $R_2 = -(CH_2)_2-O-(CH_2)_2-$; $R^1 = R^2 = CH_3$, $R_2 = -(CH_2)_5-$. These products have a laming action similar to that of decamethonium[4].

Formation of Small Rings by Intramolecular Nucleophilic Substitution

By *C. J. M. Stirling*[*]

Comparative kinetic information on the ease of ring closure by intramolecular nucleophilic substitution is scarce. Data available[1] show that rates of ring formation are in the following order of ring size: $5 > 6 > 4$. Rates of closure of three-membered rings are always greater than for four-membered rings and sometimes even faster than for five- and six-membered rings (see Table). These variations are to be considered in terms of the balance between the enthalpy and entropy of activation for ring closure; the former is unfavorable and latter is favorable for three-membered rings and *vice versa* for five- and six-membered rings.

In recent work[2] on the formation of aryl cycloalkyl sulfones from aryl ω-bromoalkyl sulfones under basic conditions (Table 1, reaction 5), closure of a three-membered ring occurred much more rapidly than that of a five-membered ring. Measurement of isotope effects showed[3] that the cyclopropyl sulfone was formed in a stepwise process. We postulate that, in a transition state which leads to the formation of a three-membered ring, attachment of a conjugative substituent in such a way as to allow resonant interaction between the ring being formed and the substituent reduces the unfavorable enthalpy term for this process. Such interactions are well known for both ground and excited states of cyclopropanes[4].

The data collected in Table 1, which contains the results of some of our own investigations, support our postulate for systems in which (cf. reactions 1–6 *versus* 10–13) carbocyclic rings are produced. Formation of a five-membered ring, however, is preferred when the nucleophilic atom is that of a first row element other than carbon even when a conjugative substituent is attached to it (cf. reactions 8 and 9).

This behavior is in accord with other experimental evidence on poor conjugation *via* a heteroatom in a three-membered ring[5] and is supported by theoretical considerations[6]. Systems in which the heteroatom is a second-row element appear to obey the generalization (cf. reactions 7 and 13).

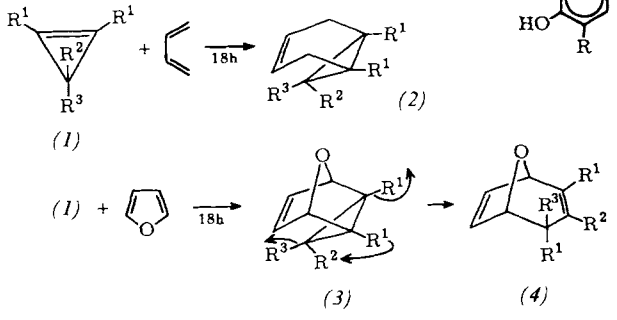
Diels-Alder Reactions of Tetrahalocyclopropenes

By *S. W. Tobey* and *D. C. F. Law*[*]

All tetrahalocyclopropenes of type *(1)*[1] undergo 1,4 addition to butadiene at 80 °C in CCl_4 to give stable Diels-Alder adducts of type *(2)* in high yield. These same cyclopropenes react with furan to provide structures *(3)* and/or *(4)* (see Table 1). Cyclopentadiene reacts with compounds of type *(1)* to provide analogous products.



(1) *(2)* *(3)* *(4)*

Table 1. Relative reaction rate (k_{rel}) of *(1)* with furan at 79 °C in CCl_4.

	(1)			k_{rel}	Product
	R^1	R^2	R^3		
(a)	Br	Br	Br	1.42 ± 0.05	*(4)*
(b)	Cl	Cl	Cl	1.00	*(4)*
(c)	Cl	Cl	F	0.48	*(3)*
(d)	Cl	F	Cl	0.31	*(4)*
(e)	Br	F	F	0.45	*(3)*
(f)	Cl	F	F	0.29	*(3)*

In accord with the predictions of the Woodward-Hoffmann rules, ring opening of *(3)* to *(4)* occurs only *via* ionization of the halide situated *syn* to the double bond. When R^3 = F [as in *(1c)*, *(1e)*, and *(1f)*], the original adduct *(3)* is stable; if R^3 = Cl or Br, ring opening to *(4)* occurs so readily that *(3)* is not isolated.

The observed order of dienophilic character of cyclopropene *(1)* towards furan suggests that in 3,3-difluorinated cyclopropenes [*(1e)* and *(1f)*] ring bonding is stabilized and the energy of the ground state is lowered, thus increasing the activation energy for Diels-Alder adduct formation. The high thermal stabilities of *(2a)* and *(2b)* relative to *(3a)* and *(3b)* reflect the strain built into structures of type *(3)* by the oxygen and methylene bridges. These bridges distort the Diels-Alder adducts in precisely the direction required to initiate disrotatory cyclopropane-ring opening[2].

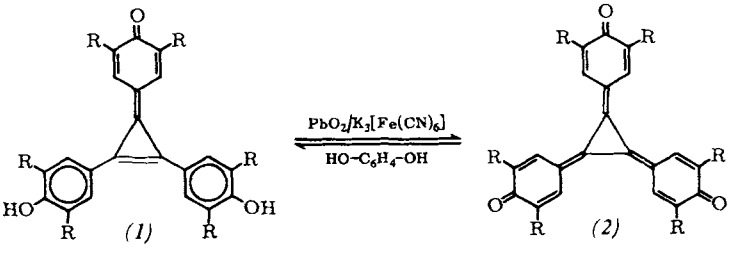
Derivatives of the Trichlorocyclopropenylium Ion

By *R. West*[*]

Trichlorocyclopropenylium tetrachloraluminate, $C_3Cl_3^{\oplus}AlCl_4^{\ominus}$, reacts with aromatic hydrocarbons with replacement of one, two, or three chlorines by aromatic groups. When one of the aromatic rings bears a hydroxyl group, proton elimination takes place and quinocyclopropene is formed readily.

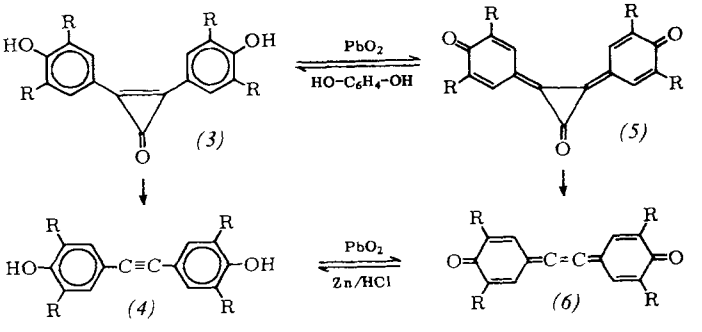
When $C_3Cl_3^{\oplus}$ is allowed to react with three equivalents of a 2,6-dialkyl-substituted phenol, the initially formed triarylcyclopropenylium is converted into a bis(hydroxyaryl)-quinocyclopropane *(1)*. Oxidation of *(1)* leads to the formation of a triquinocyclopropane *(2)*.

All six compounds of type *(2)* that have been prepared so far are dark violet solids which exhibit a strong absorption band at 770 nm. Compounds *(2)* can be regarded as unusually stable derivatives of [3]-radialene; when R = *tert*-butyl these compounds can be heated to 280 °C without decomposition.



(1) *(2)*

The reaction *(1)*→*(2)* proceeds *via* intermediary monoradicals. The ESR spectra of the radical anions of *(2)* show that the unpaired electron is fully delocalized over the three six-membered rings.



(3) *(5)* *(4)* *(6)*

Reaction of 2,6-disubstituted phenols with $C_3Cl_3^{\oplus}$ at 0 °C leads to bis(hydroxyaryl)cyclopropenones *(3)*, which on irradiation lose carbon monoxide and are converted into diarylacetylenes *(4)*. Compounds *(3)* undergo reversible oxidation to compounds *(5)*, which lose carbon monoxide spontaneously to yield diquinoethylenes *(6)*. Compounds *(6)* are also obtained from *(4)* by oxidation.

Structure of Glutamate Dehydrogenase from Ox Liver

By *H. Sund*[*]

Measurement of light scattering as a function of protein concentration (in the concentration range 25 µg/ml–8 mg/ml) afforded results, which, on comparison with the calculated interdependence of apparent molecular weight and protein concentration, indicate that the association-dissociation

equilibrium between the subunits of the glutamate dehydrogenase (molecular weight 270000) and the octamer proceeds in a stepwise manner[1]. From the dependence of the X-ray small-angle scattering on the protein concentration (1–33 mg/ml) it follows that the radius of gyration (R_q = 30.3 Å), the mass per 1 Å length (M/1 Å = 2340), and the shape of the cross-section of glutamate dehydrogenase are independent of protein concentration. From the comparison of the experimental scattering curves with theoretical cross-section curves for elliptical cylinders it is concluded that the cross-section is either circular (diameter 86 Å) or elliptical with an axial ratio of 0.8:1 (long axis 95 Å, short axis 76 Å). The length of the associated molecule was found to be 800–900 Å. On the basis of these results, the shape of the molecule can best be described as cylindrical; furthermore, the results confirm the earlier conclusion that the dissociation of the prolate molecule into subunits involves a transfer cleavage. The mass per unit length measurements and the pronounced side maxima of the scattering curve suggest that glutamate dehydrogenase is very loosely built and posseses voids[2].

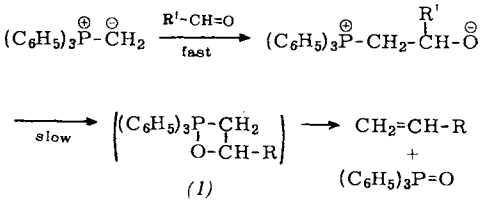
Mechanism and Stereochemistry of Wittig-Olefin Syntheses

By *M. Schlosser*[*]

The velocity of, and the yield obtained in, carbonyl olefination by triphenylphosphonium ylids is strongly influenced by the reaction conditions. Kinetic studies showed that the slowest step is usually the decomposition of the zwitterionic adduct, the betaine, to olefin and triphenylphosphine oxide by way of the oxaphosphetane *(1)*.



(1)

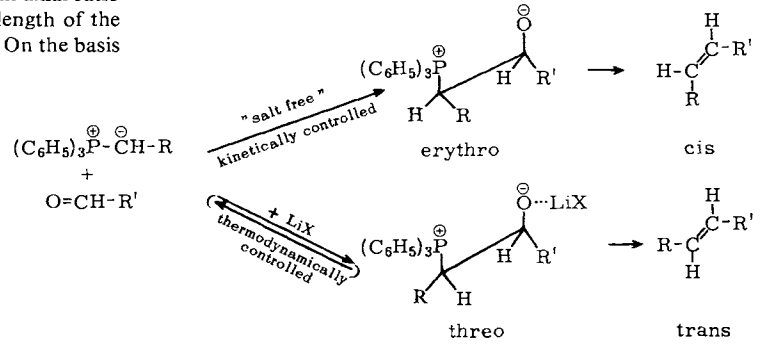
This decomposition is particularly strongly hindered by lithium salts, which give betaine-LiX adducts. In sum the following order of increase in reaction rate is observed: apolar solvent + presence of lithium salts < polar solvent < salt-free apolar solvent.

On the basis of this mechanistic knowledge procedures have been developed that direct the carbonyl olefination according to choice towards *cis*- or *trans*-olefins. For this purpose two stereochemical principles are used:

1. Under kinetic control salt-free phosphorus ylids link to give preferentially the thermodynamically unstable *erythro*-betaines.

2. In the presence of lithium salts the equilibrium between the two diastereoisomeric betaines is shifted far towards the *threo*-epimer.

The equilibrium between the diastereoisomeric betaines can be reliably and rapidly established by way of the betaine ylids. This new type of compound also offers further prepar-



ative possibilities: addition of an electrophile $X^{\oplus}$ (X = *e.g.*, D, CH_3, F, Cl, Br) leads to an α-substituted betaine (*erythro*/*threo* mixture or pure *threo*-form) and thence the corresponding unsaturated compound.

The Biochemistry of Fructose Metabolism

By *W. Lamprecht*[*]

Metabolism of fructose in animal tissues differs markedly from the normal degradation of glucose with respect to organ specificty and the sequence of the metabolic pathway. In mammals, fructose can be degraded only in liver, kidney, and mucosa of the small intestine; only these organs contain the appropriate enzyme pattern. Ketohexokinase catalyzes phosphorylation of fructose to its 1-phosphate; in liver this particular enzyme is about twice as active with fructose than with glucose. Fructose 1-phosphate is further degraded to dihydroxyacetone phosphate and D-glyceraldehyde by liver-aldolase which differs in its specificity from that of muscle. Dihydroxyacetone phosphate enters the normal glycolytic pathway. However, D-glyceraldehyde may function as a substrate in four enzymatic reactions competing with each other:

1. D-glyceraldehyde can be phosphorylated to its 3-phosphate by means of ATP and triokinase.

2. and 3. D-glyceraldehyde can also be reduced to glycerol, either by a NADH- or a NADPH-dependent alcohol-dehydrogenase. Glycerol is phosphorylated to L-glycerol-3-phosphate (an intermediate of normal glycolysis) by means of glycerokinase. The reduction, however, seams rather unlikely in liver, due to the high K_M of the NADH-specific

alcohol dehydrogenase and the low activity of the NADPH-specific enzyme. This is confirmed by isotope experiments. 4. D-glyceraldehyde can be oxidized to D-glyceric acid in a NAD^+-dependent reaction by means of aldehyde-dehydrogenase. By this enzymatic step one "half of the fructose molecule" may bypass the insulin-dependent regulation of triosephosphate-dehydrogenation.

D-glyceric acid either enters the normal glycolytic pathway by phosphorylation to 2-glycerophosphoric acid, or is oxidized to hydroxypyruvic acid, which by transaminations may be converted to the amino acid serine, an important metabolic intermediate.

D-glycerate-dehydrogenase is pyridine-nucleotide-dependent and strongly stereo-specific. Together with lactate-dehydrogenase, which reacts with L-glycerate as well as with L-lactate, the enzyme D-glycerate-dehydrogenase can catalyze a configurational change from L- to D-glycerate, or vice versa.

Since both, NAD^+ and $NADP^+$, are coenzymes for D-glycerate-dehydrogenase, this enzyme may also simulate the function of a transhydrogenase $NADH \rightleftharpoons NADPH$.

Structures of Compounds of Elements in Valence States with $4s^2$ and $5s^2$ Electron Configurations

By *S. E. Rasmussen*[*]

In agreement with the single electron approximation a number of elements exist in a valence state in which the outer electrons have the $4s^2$ or $5s^2$ configuration

[Ar] $3d^{10}4s^2$: Zn^0, Ga^I, Ge^{II}, As^{III}, Se^{IV}, Br^V, Kr^{VI}

[Kr] $4d^{10}5s^2$: Cd^0, In^I, Sn^{II}, Sb^{III}, Te^{IV}, I^V, Xe^{VI}

Since the four sp^3 hybridized orbitals can be occupied by eight electrons it can be assumed that these elements are able to coordinate three ligands provided that each ligand carries a free electron pair. The coordination number 3 should be dominant for these elements in the valence states noted.

Compounds of this type can, however, be described also in other ways.

For halides and oxides the electrostatic description has proved very useful, as has *V. M. Goldschmidt*'s principle of the close packing of spheres for many simple structures.

If there is only a small energy difference between two possible structures for one compound, directed valences playing a dominant role in one structure and geometrical and electrostatic considerations in the other, then it can be expected that a low-temperature modification and a high-temperature-modification will both be possible.

In this connection the structures of Zn^0Sb^0, Cd^0Sb^0, InCl, $HGeCl_3$, GeF_2, $CsGeCl_3$, $Ge^{II}Te$, pilocarpinium trichlorogermanate(II), $CsSnCl_3$, $AsCl_3$, 3CsCl, $2AsCl_3$, $SbCl_3$, H_2SeO_3, $KHSeO_3$, $KBrO_3$, HIO_3, and some other compounds have been investigated. The expected coordination number (3) was confirmed in all cases, and for several compounds a low-temperature as well as a high-temperature modification was found (*e.g.* $CsGeCl_3$ and $CsSnCl_3$).

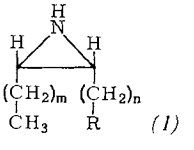
(3)

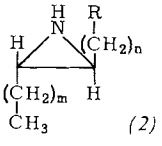
the presence of furan there results a 45 % yield of the adduct *(3)* of furan and 5,6-dichloro-2,3-didehydro-4-piperidylpyridine *(2)*, which reacts as a dienophile. / Chem. Commun. *1968*, 297 / −Ma. [Rd 853 IE]

Synthesis of long-chain *cis*- and *trans*-epiminoalkanes *(1a)* and *(2a)* and the corresponding epiminoalkan-1-ols *(1b)* and *(2b)* has been described by *J. F. McGhie* and *B. T. Warren*. The addition products formed by iodoisocyanate with *cis*-and *trans*-alkenes or *cis*- and *trans*-alkenols react with methanol to give iodocarbamates, which on treatment with alkali afford *cis*- and *trans*-epiminoalkanes and *cis*- and *trans*-epiminoalkan-1-ols in yields of 30–65 %. The aziridine ring of *(2a)* and *(2b)* is stable to NaN_3 and $LiAlH_4$ in alkaline solution. In acid solution, on the other hand, the ring is cleaved. With acetic acid for example, *(2a)* and *(2b)* give



(1)

(a), R = CH_3
(b), R = CH_2OH



(2)

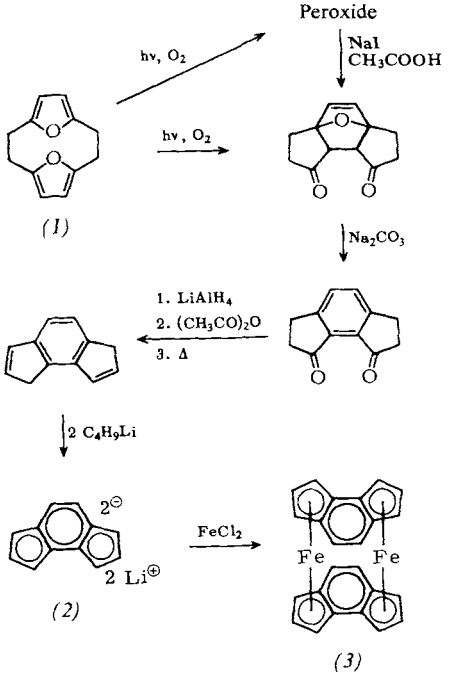
threo- and *erythro*-aminodiol, respectively. Treatment with HN_3 – a new reagent for cleaving the aziridine ring – leads to *threo*- and *erythro*-diamino alkan-1-ols. / Chem. and Ind. *1968*, 253 / −Ma. [Rd 858 IE]

The direct observation of twisting vibration of C_2H_6, CH_3CD_3, and C_2D_6 in the IR spectrum has been achieved by *S. Weiss* and *G. E. Leroi* by the use of large path length (10 m) and high gas pressures (3–7 atm). Under these conditions, the vibration, which is in itself forbidden, becomes IR-active on account of Coriolis interactions with other vibrations. The fundamental twisting frequencies for C_2H_6, CH_3CD_3, and

C_2D_6 are 289, 253, and 208 cm^{-1}, respectively. The first overtone of CH_3CD_3 is at 482 cm^{-1}. This is not found in the other two compounds, since they are symmetrical, and Coriolis interactions cannot activate this overtone. The measured frequencies give what is probably the most reliable value at present for the height of the potential barrier of the twisting in the ethane molecule, namely 2928 ± 25 cal/mole. / J. chem. Physics *48*, 962 (1968) / –Hz. [Rd 861 IE]

Surface tension of liquids can be measured automatically by two devices designed by *T. Smith* and *H. Schlein*. Both measure the pressure differences of bubbles introduced into the liquid from two tubes of different radii (*e.g.* 0.14 and 0.015 cm). In the simpler variant, the fluctuations caused by the non-simultaneous exit of the bubbles (1/sec or slower) from the tubes of different diameters are averaged by an electronic attenuator and relayed to a recorder. This gives an accuracy of 2 % in the measurement of the surface tension. In the more complicated variant, the pressure peaks, converted into electric voltage signals, are compared when the bubbles are expelled from the two tubes. The attending error of measurement is 0.3 %. These devices can be used even without calibration. The accuracy of measurement is then determined by the uncertainty of the radii of the tubes and the pressure difference. / Rev. sci. Instruments *39*, 302 (1968) / –Hz. [Rd 862 IE]

Synthesis of bis(*as*-indacenyliron) *(3)* has been accomplished by *T. J. Katz, V. Balogh,* and *J. Schulman* by treating $FeCl_2$ with dilithium-*as*-indacenide *(2)*, whose preparation from *(1)* is shown below. *(3)* is the first compound in which two metal atoms are sandwiched in between two aromatic ring systems. The reddish brown compound *(3)* belongs to the



space group P $2_1/c$ and can be heated to 350 °C without melting (slow sublimation at 150 °C and 10^{-6} torr). / J. Amer. chem. Soc. *90*, 734 (1968) / –Kr. [Rd 866 IE]

Formulas for the calculation of the detonation properties of explosives containing only C, H, N, and O have been given by *M. J. Kamlet* and *S. J. Jacobs*. When the initial density ρ_0 exceeds 1 g/cm^3, the detonation pressure P (in kbars) is

$$P = K \rho_0 {}^2\varphi$$

and the detonation velocity D (in mm/μsec) is

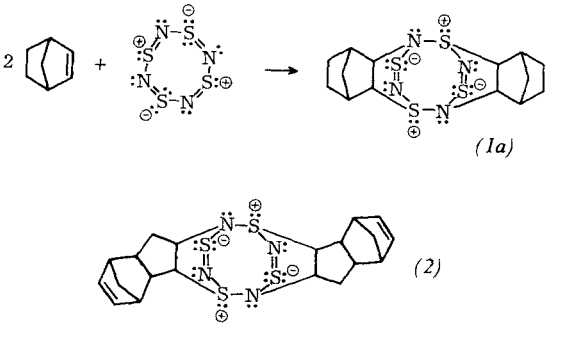
$$D = A \varphi^{1/2} (1 + B\rho_0)$$

where the constants have the following values: $K = 15.58$, $A = 1.01$, and $B = 1.30$, and

$$\varphi = N M^{1/2} Q^{1/2}$$

N is the amount of gaseous products (in moles) per gram of explosive, M is the average molecular weight of the product gases (in g·$mole^{-1}$), and Q is the heat of reaction (in cal/g). The values of N, M, and Q can be calculated with the aid of a rule, according to which N_2, H_2O, and CO_2 are the main products, while practically no CO is formed, and first H and then C are fully oxidized whenever there is an oxygen deficiency. Thus, the only data needed are those of elemental analysis, heat of formation, and the density of the explosive. The detonation pressures calculated with this simple equation do not differ by more than 10 % (generally by considerably less) from the values obtained by a computer with a RUBY program based on a very accurate equation of state, and using exact equilibrium data and heat of reaction values. / J. chem. Physics *48*, 23 (1968) / –Hz. [Rd 863 IE]

Tetrasulfur tetranitride reacts as an inorganic diene, as has been found by *M. Becke-Goehring* and *D. Schläfer*, who obtained the heptacyclic *(1a)* (decomp. 130 °C) with norbornene and the analogous product *(1b)* (decomp. 170 °C) with norbornadiene. Cyclopentadiene forms the 1:4-adduct *(2)* (m.p. 135–136 °C, decomp.). The colorless compounds *(1a)*, *(1b)*,



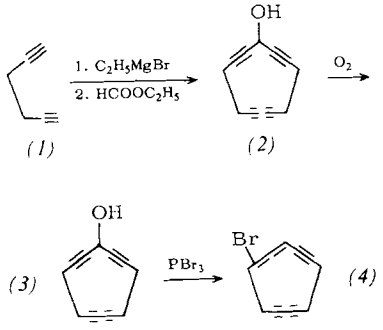
and *(2)* are not sensitive to water. Their solutions in CH_2Cl_2 or $CHCl_3$ turn blood-red after a few minutes; after a longer time, they fade again. Clearly, charge-transfer complexes are formed. / Z. anorg. allg. Chem. *356*, 234 (1968) / –Kr. [Rd 867 IE]

Pentacoordinated metal(0)-trifluorophosphine derivatives of iron, ruthenium, and osmium have been prepared by *Th. Kruck* and *A. Prasch* by the reaction:

$$MX_n + n\,Cu + 5\,PF_3 \xrightarrow[150-250\,^\circ C]{> 400\ atm} M(PF_3)_5 + n\,CuX$$

M = Fe, X = I, $n = 2$, pale yellow crystals with m.p. 45 °C, decomp. 270 °C; M = Ru, X = Cl, $n = 3$, white crystals with m.p. 30 °C. The compound $Os(PF_3)_5$, which is formed only in the absence of hydrogen-containing impurities, is also composed of volatile white crystals. The compounds are entirely non-polar and have a trigonal bipyramidal structure. / Z. anorg. allg. Chem. *356*, 118 (1968) / –Kr. [Rd 868 IE]

1-Bromocyclotrideca-1,2-diene-4,8,10-triine *(4)*, a highly unsaturated cyclic allene, has been synthesized by *C. C. Leznoff* and *F. Sondheimer* from 1,5-hexadiine *(1)* *via* the intermediates *(2)* and *(3)*. The ring closure is effected in a solution highly concentrated for such reactions, the yield

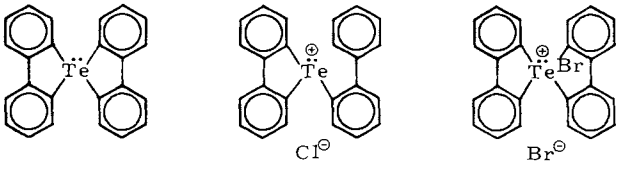


being 80%. Compound *(3)* reacts with PBr_3 in tetrahydrofuran to give the crystalline substance *(4)*, which explodes at about 65 °C and slowly decomposes even at 0 °C in the dark. / J. Amer. chem. Soc. *90*, 731 (1968) / –Kr. [Rd 869 IE]

The perbromate ion has been detected in different ways by *E. H. Appelman*. Thus, on β-decay, $^{83}SeO_4^{2-}$ gives $^{83}BrO_4^-$, which is precipitated by Rb salts in the presence of ClO_4^- and BrO_3^-. The electrolytic oxidation of $^{82}BrO_3^-$ in a divided cell (cold) similarly gives BrO_4^- on being cooled; 2% of the 36-hour ^{82}Br activity can be coprecipitated with $RbClO_4$, but not with $Ba(BrO_3)_2$. The chemical oxidation of $NaBrO_3$ by XeF_2 in aqueous solution also leads to perbromate. The mass spectrum of perbromic acid was investigated by *M. H. Studier*. Alkali metal perbromate solutions were acidified with dilute H_2SO_4, evaporated to dryness at room temperature, and examined in a modified time-of-flight mass spectrometer. As expected, the following ions were observed: $HBrO_4^+$, $HBrO_3^+$, BrO_3^+, $HBrO_2^+$, and BrO_2^+. / J. Amer. chem. Soc. *90*, 1900, 1901 (1968) / –Kr. [Rd 870 IE]

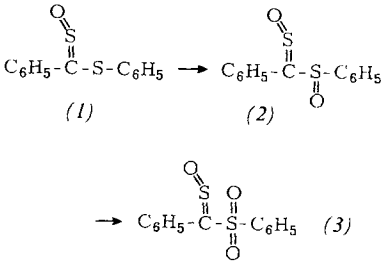
Explosive mixtures of periodic acid and dimethyl sulfoxide have been found by *J. J. M. Rowe, K. B. Gibney, M. T. Yang*, and *G. G. S. Dutton*. 70 ml of DMSO was added to 34 g of periodic acid in a flask covered with aluminum foil, and the mixture was shaken for a short time. An explosion occurred in 5–10 min. Mixtures in unwrapped flasks also exploded, but a batch containing a tenth of the original amount of reagents in a small conical flask did not. / J. Amer. chem. Soc. *90*, 1924 (1968) / –Kr. [Rd 872 IE]

Synthesis of bis(2,2'-biphenylylene)tellurium *(1)*, a tellurium spirane, has been accomplished by *D. Hellwinkel* and *G. Fahrbach* in several ways, *e.g.* by treating $TeCl_4$ with 2,2'-dilithiumbiphenyl (yield 44%), treating 2,2'-biphenylylenetellurium with chloramine T in DMF *via* a 2,2'-biphenylylenetelluridetosylimine (44%), as well as from $Te(OCH_3)_4$ (49%) and $Te(OCH_3)_6$ (48%). Compound *(1)* is a stable substance; it melts between 205 and 214 °C, depending on the rate of heating, and it gives yellow solutions with *e.g.*



THF, benzene, and acetone, these solutions being stable in dry air. With ethanolic HCl, *(1)* gives telluronium salt *(2)*, while with bromine in CCl_4, it gives the salt *(3)*. At temperatures down to –55 °C, the NMR spectrum of bis(4,4'-dimethyl-2,2'-biphenylylene)tellurium contains only one methyl proton signal. This agrees with the assumed rapid interconversion between a trigonal bipyramidal and a tetragonal pyramidal configuration. / Liebigs Ann. Chem. *712*, 1 (1968) –Kr. [Rd 873 IE]

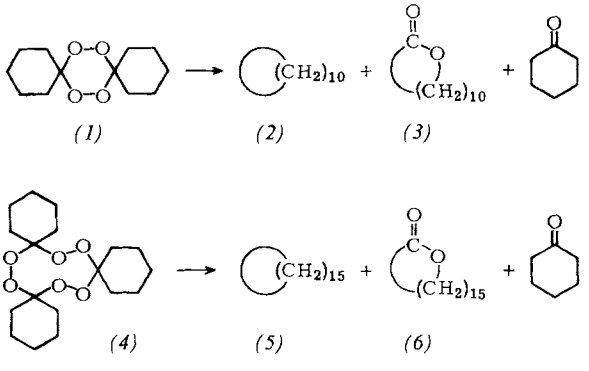
A sulfinylsulfine and a sulfonylsulfine have been described by *B. Zwanenburg, L. Thijs*, and *J. Strating*. The oxidation of the sulfine *(1)* with 0.75 equivalents of monoperoxyphthalic acid at 0 °C affords *trans*-benzenesulfinylphenylsulfine *(2)* (m.p. 131–136 °C, yield 51%). Further oxidation with 1 equivalent



of monoperoxyphthalic acid gives *trans*-benzenesulfonylphenylsulfine *(3)* (m.p. 150–154 °C, yield 59%). Unlike methane sulfonylmethylsulfone, both these compounds are stable. / Tetrahedron Letters *1968*, 2871 / –Kr. [Rd 874 IE]

Synthesis of alkyl iodides has been achieved by *D. D. Tanner* and *G. C. Gidley* in a new way. *tert*-Butylhypochlorite and HgI_2 in CCl_4 gave a purple solution, which can be regarded formally as *tert*-butylhypoiodite. On irradiation (200-w incandescent light bulb), freshly prepared and aged solutions gave with hydrocarbons preparatively useful yields of alkyl iodides. For example: neopentane → neopentane iodide (28%); cyclohexane → cyclohexane iodide (71%); toluene → benzyl iodide (34%). Tertiary hydrogens are not replaced by iodine. The reaction is thought to proceed *via* the radical $(CH_3)_3CO\dot{O}C(CH_3)_3$. / J. Amer. chem. Soc. *90*, 808 (1968) / –Kr. [Rd 875 IE]

A new general synthesis of macrocyclic compounds has been described by *P. R. Story, D. D. Denson, C. E. Bishop, B. C. Clark jr.*, and *J.-C. Farine*. For example, photolysis of *(1)*,



gave *(2)* (14%), *(3)* (10%), and cyclohexanone (*ca.* 20%). Its thermolysis gave *(2)* (44%), *(3)* (23%), and cyclohexanone (21%). The starting material can be obtained from cyclo-

hexanone and H_2O_2. On photolysis, the trimeric cyclohexanone peroxide *(4)* forms *(5)*, *(6)*, and cyclohexanone in yields of 15, 25, and 20% respectively, the corresponding thermolytic yields being 16, < 1, and 15%. Further examples are as follows: dimeric cycloheptanone peroxide → cyclododecane, 13-tridecalactone, and cycloheptanone; dimeric cyclododecanone peroxide → cyclodocosane, 23-tricosalactone, and cyclododecane. The risk of explosion must be remembered while carrying out thermolysis. / J. Amer. chem. Soc. *90*, 817 (1968) / –Kr. [Rd 876 IE]

***cis*- and *trans*-2,4-Diphenylthietane *S,S*-dioxides** *(1a)* and *(1b)* undergo stereospecific rearrangements into *cis*- and *trans*-3,5-diphenyl-1,2-oxathiolan *S*-oxide *(2a)* and *(2b)*, as has been

(1a)  *(2a)*

found by *R. M. Dodson, P. D. Hammen,* and *R. A. Davis* on treating the compounds with *tert.*-butanol and C_2H_5MgBr (1:1) in ether. NMR spectra confirm the structure of *(2a)* (m.p. 121.5–122.5 °C, yield 70%) and *(2b)* (m.p. 73–74.5 °C). *(2a)* has also been synthesized from 3-mercapto-1,3-diphenyl-1-propanol. / Chem. Commun. *1968*, 9 / –Kr. [Rd 877 IE]

The dipole moment of *o*-dimethoxybenzene increases with rising temperature; *L. M. DiBello, H. M. McDevitt,* and *D. M. Roberti* found values of 1.24 to 1.64 D for the pure liquid and for solutions in benzene, decalin, and liquid paraffin between –20 and +165 °C. For solutions in decalin and liquid paraffin, constant values of 1.64 and 1.58 D respectively are reached at about 90 °C; the calculated value based on the assumption of completely free rotation of the methoxy groups is 1.93 D. The difference is explained by the failure of conformers with particularly pronounced steric hindrance to make their full contribution to the dipole moment, even at high temperatures. The dipole moments of *m*- and *p*-dimethoxybenzene are constant in decalin from 20 to 130 °C. / J. physic. Chem. *72*, 1405 (1968) / –Hz. [Rd 887 IE]

The wetting and adhesion behavior of liquid indium on solid aluminum has been studied by *R. G. Aldrich* and *D. V. Keller jr.* A polycrystalline Al surface was produced by vapor deposition, and a drop of liquid indium was forced out of a reservoir onto this surface. The interfacial tension of indium on aluminum at 160 °C and 10^{-10} torr is 658 (± 10%) dyn/cm; the relatively large error may simply be due to the difference in the interfacial tensions at different crystallographic faces. The effects of H_2, N_2, and O_2 at pressures up to 1 torr were also studied. The interfacial tension remained unchanged under H_2 or N_2, but decreased considerably in the presence of O_2, and the drop spread out. The strength of the metal-metal interface after the solidification of the drop of indium was always greater than the tensile strength of indium itself, except when H_2 or N_2 was present before the application of the drop. / J. physic. Chem. *72*, 1092 (1968) / –Hz. [Rd 890 IE]

The arrangement of the atoms in vitreous selenium has been studied by *R. Kaplow, T. A. Rowe,* and *B. L. Averbach* by X-ray diffraction. Comparison with the positions of the atoms in hexagonal and monoclinic selenium was used to find which of the two lattices would give the interatomic distances found in vitreous selenium with the least possible disturbance of the atomic positions. It was found that vitreous selenium must consist predominantly of slightly deformed Se_8 rings (which give monoclinic selenium in an undisturbed arrangement), interspersed with a few rings that are so open that they form a zone with a chain structure related to that of hexagonal selenium. / Physic. Rev. [2] *168*, 1068 (1968) / –Hz. [Rd 891 IE]

Tungsten hexahydride 3(dimethylphenylphosphine) a colorless crystalline compound that is stable in air, was obtained by *J. R. Moss* and *B. L. Shaw* on reduction of *trans*-$WCl_4[P(CH_3)_2C_6H_5]_2$ (from *cis*-$W(CO)_4[P(CH_3)_2C_6H_5]_2$ and Cl_2) with $NaBH_4$ in CH_3OH. The complex melts at 110 to 112 °C with decomposition and dissolves readily in organic solvents. The chemical shift of the WH_6-hydrogen is τ = 11.94 (quartet with $J(^1H^{31}P) = 36.9$ and $J(^1H^{183}W) = 27.8$ Hz); WH stretching frequencies are observed at 1731–1834 cm^{-1}. $WH_6 \cdot 3\,PR_3$ probably corresponds in its structure to the analogous Re compounds ReH_9^{2-} and $ReH_7 \cdot 2\,PR_3$. / Chem. Commun. *1968*, 632 / –HB. [Rd 892 IE]

BOOK REVIEWS

1,4-Cycloaddition Reactions. By *I. Hamer.* Vol. 8 of the series "Organic Chemistry". Edited by *A. T. Blomquist.* Academic Press, New York-London 1967. 1st Edit., xii, 500 pp., numerous figures and tables, $ 22.00.

1,4-Cycloaddition reactions leading to heterocyclic five- and six-membered rings are described in 13 chapters by 17 authors. Applicability and limitations of the reactions, the effect of substituents, and mechanisms are discussed, in addition to further reactions and side reactions. Reaction conditions, yields, and physical properties of the cyclic adducts are compiled in numerous tables. Detailed working instructions are given in some instances.

Generous space is provided for numerous clear and instructive formulas and reaction schemes. Each chapter is self-contained. All the relevant literature to 1964 and some from 1965 has been listed at the end of each chapter. In all, about 1150 references are given. The book's aim of providing an instructive survey of thermal and photochemical 1,4-cycloadditions leading to the formation of five- and six-membered rings has been fully achieved.

I. Hamer introduces the book in the opening 11-page chapter. The make-up of the work is explained and systems that are not dealt with later are briefly mentioned.

S. D. Turk and *R. L. Cobb* are the authors of Chapter 2 (44 pages) on the five-membered cyclic sulfones. Examples are given with SCl_2 and SeO_2 as the dienophiles, as well as for SO_2.

Chapter 3 (50 pages) by *L. D. Quin* describes the reactions of dihalogenophosphines, phosphorus trihalides, and dihalogenated phosphoric esters with dienes and α-dicarbonyl compounds. The ionic formulation of the adducts is preferred. In Chapter 4, *G. J. Janz* reports on the synthesis of pyridine derivatives with cyanogen and nitriles as the dienophiles (30 pages); the literature is only covered up to 1959. Chapter 5 (15 pages) lists the 1,4-cycloadditions with imino compounds and is compiled by *M. Lora-Tamayo* and *R. Madranero.*

B. T. Gillis is the author of Chapter 6 (34 pages), dealing with the reactions of azo compounds with acyclic, cyclic, and aromatic systems to give pyridazines. Tables listing more

than 170 syntheses, reaction conditions, yields, and literature references are given.

In Chapter 7 (25 pages) *N. Lora-Tamayo* and *J. L. Soto* discuss open-chain and cyclic conjugated systems with 2 nitrogen atoms used as dienes. Chapter 8 (16 pages) by *I. Hamer* and *J. A. Turner*, deals with the little-investigated use of carbonyl and thiocarbonyl compounds as dienophiles. *J. Colonge* and *G. Descotes* describe the dimerization of α,β-unsaturated carbonyl compounds and their application as dienes (*C*-vinyl, *O*-vinyl and *N*-vinyl enamines, carbamates, and urea derivatives) in Chapter 9 (38 pages).

K. Gollnick and *G. O. Schenk* wrote Chapter 10 (90 pages) on oxygen as a dienophile. After a brief introduction to theoretical and preparative aspects, the photo-initiated cycloaddition of O_2 to conjugated dienes, the photochemical cycloaddition to aromatic compounds and aryl-substituted carbocyclic and heterocyclic pentadienes is discussed. About 150 transannular peroxides are tabulated (350 references).

In Chapter 11 (74 pages) *G. Pfundt* and *G. O. Schenk* report on cycloadditions to *o*-quinones, 1,2-diketones, and some of their derivatives – 1,4-dioxines, 1,3,2-dioxathioles, 1,3,2-dioxaphospholes, 1,3-dioxoles, and oxazoles representing the possible products. The 1,5-addition of ketenes to *o*-quinone diazides and the thermolysis of the adducts to 1,3-dioxoles or indazoles is reported in detail. In Chapter 12 (33 pages), *I. Hamer* and *M. Ahmad* list the Diels-Alder reactions of nitroso compounds for synthesizing oxazine derivates. In the final Chapter 13 (19 pages) *G. Kresze* reports on the dienophilic reactions of *N*-sulfinyl compounds.

The carefully compiled author index is worth noting; all the co-authors are listed. The printing quality is excellent – only a single misprint was found.

The chemist working in the field of heterocyclic chemistry and Diels-Alder reactions will gladly add the book to his library. The work can be strongly recommended to students on account of its lucid presentation. *W. Ried* [NB 717a IE]

Cyclobutadiene and Related Compounds. By *M. P. Cava* and *M. J. Mitchell*. Vol. 10 of "Organic Chemistry". Edited by *A. T. Blomquist*. Academic Press, New York-London 1967. 1st Edit., xiii, 503 pp., $ 22.00.

As on previous occasions in this series, the editor has succeeded in finding two specialists in the field who have themselves made decisive contributions to the chemistry of cyclobutadiene and benzocyclobutadiene.

The contents can be gleaned from the twelve chapter headings: Cyclobutadiene, Cyclobutadiene-metal-complexes, Cyclobutadiene divalent ions, Cyclobutadienequinone, Methylene analogs of cyclobutadienequinone, Benzocyclobutadiene, Benzocyclobutadienequinone, Methylene analogs of 1,2-benzocyclobutadienequinone, Higher aromatic analogs of benzocyclobutadiene, Biphenylene, The benzobiphenylenes, and Theoretical aspects of the cyclobutadiene problem (the last by *H. E. Simmons* and *A. G. Anastassion*).

A good monograph should be comprehensive, up-to-date, lucid, and critical. All of these epithets may be applied to the present work. The authors have not relied solely on periodicals for source material; extensive reference is made to dissertations, theses, and personal communications collected from enquiries among colleagues in the field. The literature has been abstracted to 1964; an appendix lists work published in 1965 and 1966. A sensible classification marks the individual chapters which are so written that each can be read on its own without having to refer to a previous chapter.

Extravagant use of structural formulas is manifest. The historical introduction and sections describing unsuccessful synthesis of the compounds discussed are outstanding features.

The chemistry of cyclobutadiene is a small but fascinating part of organic chemistry. All chemists, not only those working concerned with the chemistry of small carbon ring systems, can derive much stimulation from this unusually thorough book. All libraries at least should possess a copy.

R. Criegee [NB 717b IE]

Toxikologie-Fibel für Ärzte, Apotheker, Naturwissenschaftler, Juristen, und Studierende (Toxicology Primer for Physicians, Pharmacists, Scientists, Lawyers, and Students). By *W. Wirth, G. Hecht*, and *Chr. Gloxhuber*. Georg Thieme Verlag, Stuttgart (1967). 1st ed., xiv, 394 pp., 17 figures, DM 36.–.

This book is no "primer" but an expansion of Fühner's "Medizinische Toxikologie" (Medical Toxikology), which last appeared 16 years ago under the names of *Wirth* and *Hecht*. The chapter on "General Toxicology" (pp. 1–46), as before, deals with the concept and detection of poisons and general treatment in cases of poisoning. A new feature is the table of MAC values valid in 1966. In "Special Toxicology", substances are again discussed according to their chemical constitution. The topics discussed under "Inorganic Compounds ("pp. 47–129) are cases of poisoning by nonmetals, metals, and radioactive substances, while "Organic Compounds" (pp. 130–246) covers CO, CO_2, aliphatic halogenohydrocarbons, alcohols, acids, *etc.*, up to aromatic or heterocyclic compounds. The next section, on "Poisonous Plants and Plant Poisons" (pp. 247–323), also deals with the toxicity of the alkaloids, ethereal oils, and vitamins; hormones and biogenic amines are discussed under "Animal Poisons and Poisonous Animals" (pp. 324–342).

The topics dealt with under each substance include chemical properties, structural formula, uses, possibilities of acute and chronic poisoning, and symptoms of poisoning. Any possible specific treatments are indicated at the end. References to the original literature are included throughout.

The original literature cited should be consulted frequently, particularly since one then sometimes makes a different assessment of the toxicities from the authors. It was unnecessary, in the reviewer's opinion, to discuss plants so unimportant as *Catha ed.* (p. 258) *Cycas circ.* (p. 290), *Eupatorium urticaefolium* (p. 308) and *Blighia sapida* (p. 309), or water lilies (p. 341) and sea cucumbers (p. 342). The reviewer feels that in any new edition, the subject index at least should contain general headings such as stain removers (astonishingly, only the obsolete stain remover "Puran" is mentioned), paint thinners, and delining agents, since these are the headings under which the practical worker searches to find what the agents generally contain. Owing to the frequency of poisoning with solvents and cleaning agents of unknown composition, any new edition should mention the possibilities of detecting poisons of this type in the exhaled air with Dräger tubes, and the various Dräger tubes should be listed together with MAC and MIC values, as is now universal practice.

It is not wrong to include MAC tables in a textbook on poisons, but the "preamble" to the MAC list should be reproduced in full to enable the values to be used correctly. It seems unnecessary to the reviewer to include MIC values (for short-term and long-term exposure!). Neither the practical physician nor the chemist can know how uncertain is the basis of these MIC values, and that more than just these values has to be taken into account in the case of substances such as nitrobenzene and aniline. Since the book is also intended for scientists and lawyers, there is a danger that not only the MAC values, but also the MIC values will quickly fall into disrepute.

The authors are very cautious in their judgement of tabacco smoke. The sentence (p. 268) "The increase in lung cancer is partly explained by the inhalation of cigarette smoke" no longer reflects the latest knowledge, nor does the advice: "The principal dangers of tobacco smoke can be avoided if low-nicotine tobacco is smoked as slowly as possible, with-

out inhaling, the last third of cigars and cigarettes being rejected. Filtration of the smoke through impregnated wadding also makes smoking more hygienic." The reviewer would have preferred a sterner warning, even in a "primer".

On the whole, however, the book is a welcome addition to the German literature on toxicology. It can be recommended, not only to physicians and hospital doctors, but also to chemists and works managers as a source of ready information on the dangers involved in handling chemicals. Intelligent use of the MAC tables is also important for chemists.

H. Oettel [NB 726]

An Introduction to the Alkaloids. By *G. A. Swan*. Blackwell Scientific Publications. Oxford-Edinburgh 1967. 1st Edit., viii, 326 pp., 63 s.

Because of the tendency to use increasingly smaller molecules for descriptions of chemical and physical methods, many organic chemistry textbooks have become more or less removed from the field of natural products, where many of these methods were in fact developed. However, natural products not only constitute the original and literal object of study in "organic" chemistry, but also a good medium for training students. Their structure and biological function offers an abundance of problems full of methodological and theoretical aspects. Alkaloids represent a particularly good example and in this introduction by *Swan* have been given an excellent presentation very suitable for use in colleges.

A good, competent selection of chemical, biogenetic, and pharmacological information is used to illustrate why the alkaloids have been, and still are, a fascinating object of study. Among others, the stereochemistry of yohimbine and morphine, *Woodward*'s strychnine synthesis, mass spectrometry of the indole alkaloids, the biosynthesis of tropane, opium, and indole alkaloids and the medicinal utilization of quinine and reserpine, all illustrated by excellent formulas, make exciting reading. A further stimulating feature of this book is the occasional interposition of amusing bits of information in the otherwise concentrated scientific text. The reader is told how the Spanish Jesuits calculated the cost of cinchona bark in the 17th century and that spiders spin more regular webs after being given LSD. The contents are divided into 21 chapters on the basis of the heterocyclic structures. The wide margin left on each page to enable supplementary notes to be added is useful. Almost 900 references extending to 1966 are given and few misprints are evident.

The book deserves every recommendation as a modern introduction to the alkaloids for advanced students and others possessing some basic knowledge of heterocyclic compounds. The low price will encourage its wide distribution.

B. Franck [NB 718 IE]

Drugs Affecting the Peripheral Nervous System. By *A. Burger*. Medical Research Series, Vol. 1. Marcel Dekker, Inc., New York 1967. 1st Edit., xxiii, 620 pages, $ 27.50.

In the introductory chapter *S. Ehrenpreis* reports on the transfer of cholinergic stimulation in terms of molecular biology. He finds that it has not so far been possible to isolate the receptor, and that all postulates are thus purely hypothetical. *H. L. Friedman* describes postganglionic parasympathetic stimulants and the variability of the acetylcholine molecule in connection with the muxcarine-like effect. *J. C. Cannon* and *J. P. Long* discuss cholinolytic atropine-like drugs and the relationships between biological action and stereochemical configuration. *L. Gyermek* reports in a remarkably concise and clear manner about drugs stimulating or blocking the peripheral ganglion. Substances which influence the nervous transfer to the skeletal muscle, above all muscle relaxants, are discussed by *J. J. Lewis* and *T. C. Muir* in terms of their mode of action. *J. P. Long* and *C. J. Evans* discuss reversibly acting cholinesterase inhibitors from the aspect of model postulates, whereas the kinetics of the irreversible phosphorus-containing cholinesterase inhibitors are dealt with in a short article by *I. B. Wilson* with reference to the extensive literature. Two other chapters deal with sympathomimetic agents (*A. M. Lands* and *T. G. Brown jr.*) and sympatholytic agents (*N. B. Chapman* and *J. D. B. Graham*). In conclusion, *C. M. Smith* reports on the medicinal influencing of the afferent nervous system, with particular attention to pain, and pressor and chemoreceptors. Despite the certain amount of overlapping inevitable in a collective work, the book seems to be self-contained. The theoretical introduction to each chapter does much to help the reader who is not so familiar with the field, thus making the contents more useful to a wider audience.

G. Quadbeck [NB 712 IE]

Molecular Biophysics. By *D. Chapman* and *R. B. Leslie*. Contemporary Science Paperbacks, Vol. 4. Oliver and Boyd, Edinburgh-London 1967. 1st Edit., vi, 151 pages, several figures and tables, paperback 7s. 6d.

This little book attempts to describe what is meant by molecular biophysics. In doing so it renders a service neither to molecular biophysics nor to the reader, if it is in fact possible to establish for whom this book is intended. For example, the term codon is explained at length, but the term relaxation effect is assumed to be understood by itself. Is one expected to know what this term means and yet to have to be told what nuclear resonance denotes?

The meaning that the authors attach to the term molecular biophysics is likewise obscure. In an initial descriptive part the extended formula of lecithin occupies a special page. It seems that molecular biophysics does not presuppose even an elementary acquaintance with the chemistry of natural products. Then a morphological discussion is used to define molecular biophysics and finally we wander into the theory of evolution. The respiratory chain is once more described on the basis of the redox potentials of the isolated constituents, the nonheme iron and copper are suppressed "for the sake of clarity". The entire Krebs cycle, which can hardly be regarded as forming a part of molecular biophysics, is given; so are the inevitable photographs of the Perutz hemoglobin model. Much is made of electron spin resonance and free radicals without defining the term radical. By contrast, the triplet oxygen molecule, a phenomenon unique to molecular biophysics, is not mentioned.

Finally, Chapter 6 discusses some "selected problems in biophysics". The chapter is a pleasure to read and obviously this is where the interest of the authors lies. In some instances concluding chapters can justify a book; this is not one of them.

P. Hemmerich [NB 724 IE]

L'Analyse Cinétique de la Transformation Chimique (Kinetic Analysis of Chemical Reactions), Vol. 1. By *J. C. Jungers* and *L. Sajus*, with the collaboration of *I. de Aguirre* and *D. Decroq*. Edition Technip, Paris 1967. 1st Edit., 604 pages, 224 figures, 163 tables, bound, F 145.—.

The title of the book defines the scope: kinetics is not discussed for its own sake.

In the preface it is stressed that first gas reactions were treated, then reactions in extremely dilute solutions, while in laboratory and industry one works with solutions as concentrated as possible. It is rightly pointed out that even the choice of reaction systems already involved simplifications.

The present book deals with the analysis and control of complex reactions in concentrated systems of the type usually encountered in practice. Its value lies in the treatment of a large number of experimentally investigated reactions, many of which were carried out in the authors' own laboratory. In this way detailed data are made available to an extent unobtainable in any other work; flow sheets and photographs of operational plants are given in some cases.

A more theoretical background might be desirable, at least with regard to the influence of deviations from ideal behavior. However, the second part of the book, with chapters entitled Study of the medium, Scheme and mechanism, Correlation between reactivity and structure, is still to be published, and it would be unfair to level criticism at this stage.

Despite the empirical orientation this book is the only work known to the reviewer in which empirical data for the fundamentally interesting multicomponent first-order systems[1] have been compiled. The book will be of value to all interested in the field concerned. *W. Jost* [NB 697 IE]

Observations on the Crystal Structures of Electron Donor-Acceptor Complexes

C. K. PROUT AND J. D. WRIGHT[*]

The theoretical interpretation of electron donor-acceptor complex formation in terms of charge transfer interactions has stimulated many structure determinations for these complexes. These fall into three classes, depending on the type of orbitals involved in charge transfer. In σ-σ complexes, intermolecular bonds become shorter and intramolecular bonds become longer as charge transfer increases. Relative orientations correspond to overlap of donor and acceptor molecules in directions of "preferred polarizability". Intermolecular bond lengths in σ-π complexes show similar trends, and the axial orientation in the benzene-halogen complexes is probably the result of the best compromise between orbital overlap and energy factors. π-π Complexes contain stacks of alternate plane-to-plane donor and acceptor molecules, arranged in three characteristic ways. There is little correlation between interplanar spacing in these stacks and charge transfer properties. The relative orientations of donor and acceptor molecules within the stacks are determined by a combination of charge transfer interactions (maximized when aromatic rings of donor and acceptor molecules are displaced by half a ring diameter) and dipole-induced dipole interactions (maximized, for example, when a polar bond of one molecule overlaps a polarizable region of another). Crystal packing requirements and dispersion forces modify these effects, and no satisfactory theoretical treatment of this complex combination of interactions is yet available.

1. Introduction

Molecular complex formation is an association of definite stoichiometry between two molecules of closed shell electronic structures, and is stronger than an ordinary van der Waals interaction. Molecular complexes are frequently formed when molecules of low ionization potential interact with molecules of high electron affinity. These complexes are recognized by the almost invariable appearance of new intense broad spectral bands in the visible or ultraviolet spectrum, generally accompanied by perturbations of the spectral bands arising from electronic transitions of the component molecules and by indications of compound formation in phase diagrams. All complexes have small heats of formation and definite formation constants which may be measured by spectrophotometry and other methods. Dipole moments and semiconductivities are different from those of the component molecules, and marked anisotropies in light absorption, semiconductivity, compressibility and other physical properties are frequently observed. The experimental observations were given a theoretical basis in 1952 by *Mulliken*[1], who interpreted molecular complex formation as the interaction of electron donor and electron acceptor molecules.

Mulliken's theory stated that the electronic ground state wave functions of the complex was a combination of a "no-bond" wave function ψ_0 and one or more "dative bond" functions ψ_1, ψ_2 *etc.* The no-bond function includes the electronic energy of the component molecules, plus terms representing the effect of dipole interactions, dispersion forces, hydrogen bonding, and other intermolecular forces. The dative bond functions represent states where an electron has been transferred from the donor molecule to the acceptor, introducing electrostatic interactions and forming a weak covalent link

between the resulting radical ions. The new ground state wave function ψ_N, which may be written

$$\psi_N = a\psi_0 + b\psi_1 + c\psi_2 + \cdots \quad (1)$$

(where a, b, and c are coefficients with $a > b > c$) corresponds to a more stable state than that represented by any of the component wave functions. Excited states, with a dative structure as the main contributor, have the same form, with the coefficients varied to give predominance to the dative bond contribution.

This treatment immediately provided the theoretical basis for interpretation of spectroscopic and formation constant data, and initiated research on semiconductivity and magnetic properties of molecular complexes. By predicting the preferred relative orientations of donor and acceptor molecules for maximization of charge transfer interactions, it stimulated structural work on donor-acceptor complexes. For maximum charge transfer interaction, the relative orientations of the two molecules must provide maximum overlap of the filled donor orbital and the vacant acceptor orbital. This is known as *Mulliken*'s "Overlap and Orientation" principle[2]. The overlap and orientation principle is neither proved nor disproved by individual crystal structure determinations. It is a theoretical principle applying to idealized systems involving no intermolecular forces other than charge transfer forces. The questions which can be answered by experimental structure determinations are:

(a) What factors affect the relative orientations of molecules in crystalline donor-acceptor complexes?

(b) Which of these factors exert the greatest orientational effects in particular complexes? and

(c) Is there structural evidence for the correlation of the magnitude and importance of charge transfer forces in the crystal and the donor and acceptor strengths of the component molecules?

Finally, *Mulliken*'s treatment provided a simple classification of molecular complexes according to the type of orbitals involved in charge transfer[3]. In this review, the classification is simplified to three general types, $\sigma-\sigma$, $\sigma-\pi$, and $\pi-\pi$, referring to complexes where the orbitals involved in charge transfer are both σ orbitals, one σ and one π, or both π orbitals, respectively. Examples are: –

σ donors: aliphatic amines, dioxane, dithiane, acetone, *etc.*

σ acceptors: halogens, oxalyl halides, BF_3, *etc.*

π donors: aromatic hydrocarbons, metal complexes with aromatic ligands such 8-hydroxyquinolinates and porphyrins.

π acceptors: aromatic or ethylenic hydrocarbons with electron-withdrawing substituents (*e.g.* 1,2,4,5-tetracyanobenzene, 1,3,5-trinitrobenzene, quinones).

(Some compounds have both σ and π donor orbitals *e.g.* heterocyclic aromatics such as pyridine and quinoline.)

2. σ-σ-Complexes

$\sigma-\sigma$-Complexes have been reviewed on previous occasions by *Hassel*[4–6]. The simplest $\sigma-\sigma$-complexes whose structures have been determined are complexes of boron trifluoride[7]. The results are summarized in Table 1.

Table 1. Structural data for some $\sigma-\sigma$ complexes of BF_3.

	BF_3	$CH_3CN{\cdot}BF_3$	$H_3N{\cdot}BF_3$	$(CH_3)_3N{\cdot}BF_3$
N–B distance (Å)	–	1.63	1.60	1.58
B–F distance (Å)	1.30	1.33	1.38	1.39
F–B–F angle (°)	120	114	111	107

In all these complexes the N–B bond length is longer than would be expected for a single covalent bond. As the donor strength increases, charge transfer stabilization of the complex increases and the intermolecular nitrogen-boron distance decreases. As this bond becomes shorter and presumably stronger, the BF_3 molecule distorts from its original trigonal planar form towards a tetrahedral configuration. The lengthening of the B–F bond may indicate that the acceptor orbital is delocalized over the B–F bonds, or it may be the result of a reduced tendency towards intramolecular dative bonding between boron and fluorine as the configuration is changed.

The other $\sigma-\sigma$ complexes that have been investigated show relatively small changes in geometry and interatomic distances of the donor and acceptor molecules. The available structural results are summarized in Table 2. Increasing donor or acceptor strength results in increased charge transfer stabilization, which shortens the donor-acceptor contact and lengthens the intramolecular bond(s) in the acceptor molecule, since the acceptor orbital has antibonding character. The order of donor strength Se > S > O and the order of acceptor strength $I_2 > ICl > Br_2 > Cl_2$ may both be deduced from the variations in bond lengths given in Table 2. In the extreme case of pyridine with iodine, the weakening of the iodine bond by charge transfer is so great that the bond is broken and the final product is $[C_5H_5N.I.NC_5H_5]^+I^-$, with two equal nitrogen-iodine distances of 2.16 Å in the

less likely, may be very different from those observed in single crystals. In a crystal, a particular orientation of donor and acceptor may be favored over others because it allows the formation of a chain structure, while the most stable orientation for a 1:1 gas phase complex may be quite different. The charge transfer bonds in chain complexes are likely to be weaker than those in 1:1 complexes, since the increase in the negative charge on an acceptor molecule involved in two charge transfer bonds reduces the tendency to attract negative charge.

Despite the difficulties in interpreting the structures of complexes which form infinite chains or sheets in the solid state, several of the main features of the relative orientations of the molecules show the influence of charge transfer interactions. The linear arrangements N···X–Y observed in the pyridine and amine complexes maximize the overlap between the lone pair of electrons on the donor atom and vacant orbitals of the electron acceptors, and in the acetone/bromine complex (Fig. 1) the chain structure provides similar good

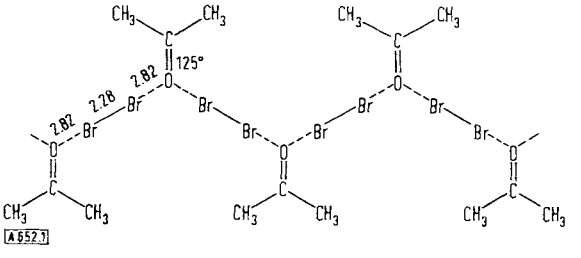

Fig. 1. Schematic diagram of the acetone/bromine complex with interatomic distance in Å.

overlap if the oxygen pair electrons are considered to be in sp^2 hybrid orbitals. This formalism of idealized hybrid orbitals, however, may be misleading, because it could be argued that the most energetically favorable orientation in this complex would involve charge transfer interactions with a pair of electrons in a pure p orbital of acetone, which would have a lower ionization potential. The arrangement about the oxygen atom evidently depends on the best combination of overlap of orbitals and the ionization potentials of electrons in those orbitals. A better qualitative picture is obtained if the donor is considered as having several directions of "preferred polarizability", limited by the number and type of electrons and by their ionization potentials, the actual directions involved in charge transfer being determined by the nature of the electron acceptor and by packing considerations. This has been discussed in a similar way in connection with the role of molecular complexes as reaction intermediates by *Mulliken*[1], and is equivalent to a concept of directional softness and hardness. In complexes of dioxane[16,19], dithiane[26,27], and diselenacyclohexane[27,29] (Fig. 2) the directions of the charge transfer bonds correspond roughly to the axial and equatorial directions of bonding in related carbon compounds, suggesting that the donor atom lone pairs have their preferred polarizability directions coinciding with the 3-fold axes of a tetrahedron. There is evidence that the strongest bonds are formed when the direction of the bond between the donor and acceptor atoms is closest to an ideal axial or equatorial position.

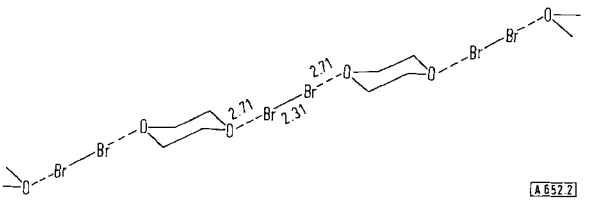

Fig. 2. Schematic diagram of the 1,4-dioxane/bromine complex with interatomic distances in Å.

Table 3 shows that in the SbI_3/1,4-dithiane complex the antimony-sulfur charge transfer bond in the equatorial position is shorter and is closer to the "ideal" direction than is the case with the corresponding axial bonding.

Table 3. Structural data for 1,4-dithiane-antimony triiodide.

	Equatorial	Axial
S–S–Sb angle (°)	147.3	124.6
Ideal equatorial and axial angles (°)	146	105
Bond length (sulfur-antimony) (Å)	3.274	3.336

The equatorial position in dithiane is quite close to the perpendicular to the C–S–C plane, and an acceptor in this position may also benefit from the preferred polarizability perpendicular to the C–S–C plane, corresponding to the formal structure with a lone pair of electrons in a 2 p orbital. In the dithiane/iodine complex, where there is only one charge transfer bond at each end of the dithiane molecule[26], the iodine occupies an approximately equatorial position, 16° from the perpendicular to the C–S–C plane, and in the dibenzyl sulfide/iodine complex[25], where no chains are involved, the S···I–I direction makes an angle of 15° with the normal to the C–S–C plane. The directions of preferred polarizability for diselenacyclohexane are not the same as for dithiane, possibly due to the availability of d orbitals, and the diselenacyclohexane/iodine complex[29] has approximately axial charge transfer bonding.

3. σ-π-Complexes[*]

The crystal structures of the chlorine[35] and bromine[36] complexes of benzene have been determined by two-dimensional methods, assuming the centrosymmetric space group C_{2h}^3. The structure consists of infinite chains of alternate benzene and halogen molecules, with the halogen placed perpendicular to the plane of the benzene ring along the 6-fold axis of the ring and equidistant from the two benzene molecules. The benzene-halogen distances are slightly shorter than the van der Waals distances, but the halogen-halogen distances are the same as in the free halogen molecules (Table 4).

A recent infrared study[37] of single crystals of the benzene/bromine complex shows that the benzene and

Table 4. Bond lengths in $C_6H_6 \cdot Hal_2$ complexes.

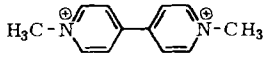
	C_6H_5—Hal distance (Å)	von der Waals radius sum (Å)	Hal—Hal distance (Å)	Hal—Hal distance (Å) (free halogen)
C_6H_5/I_2	3.36	3.65	2.28	2.28
C_6H_5/Cl_2	3.28	3.50	1.99	1.99

bromine molecules are not at centers of symmetry as required by the space group C_{2h}^3, and suggests a structure with alternating long and short benzene-bromine distances. It is possible that this apparent contradiction is a result of disorder in the crystals, even though the anisotropic temperature factors found in the structure determination which are larger in the direction perpendicular to the chain than parallel to it, do not suggest this.

The axial position of the halogen was not predicted originally by *Mulliken*[1], as the theory initially considered only the interaction between the highest energy filled orbital of benzene and the lowest energy vacant orbital of the halogen. The ionization potential for an electron in the highest energy orbital of benzene with the D_{6h} symmetry that is required for charge transfer interaction in the axial model is higher (11.5 eV) than that for the highest energy filled orbital of benzene (9.24 eV). However, the orbital overlap for charge transfer is very probably greater in the axial model with the orbital with 6-fold symmetry than in other possible configurations using the highest energy filled orbital. Therefore the stabilization of the complex by charge transfer may well be greater with the axial model using the lower energy donor orbital than with other arrangements. The balance of overlap and energy factors may give a different arrangement in solution.

Closely related to the benzene/bromine complex is the complex of *p*-xylene with carbon tetrabromide[38], the crystals of which are built up from $(C_8H_{10} \cdot CBr_4)_n$ chains. Two bromine atoms of a CBr_4 molecule are above the centers of two benzene rings 3.34 Å distant. Each *p*-xylene is equidistant from two bromine atoms which lie on the 6-fold axis of the benzene ring, as do the carbon atoms attached to the bromine atoms. There is no cross-linking between the chains.

Some salts of the paraquat ion pq^{2+} *(1)* with metal halides ($CuCl_4^{2-}$, $CuCl_3^{2-}$, $CuCl_2^{2-}$, $CoCl_4^-$ and $FeCl_4^-$) have intense "charge-transfer" spectral bands, and the



(1)

crystal structures show specific interactions which may be associated with charge transfer bonding of the $\sigma-\pi$ type. The compounds $pqFeCl_4$, $pqCoCl_4$, $pqMnCl_4$, and $pqZnCl_4$ are isomorphous[39], $pqCuCl_4$[40] is similar but with a distorted tetrahedral $CuCl_4^{2-}$ ion, and $pq(CuCl_3)_2$[39] and $pq(CuCl_2)_2$[39] have polymeric anions. All the compounds have charge transfer bands in their spectra which are associated with electron transfer from the anion to the pq^{2+} ion.

[40] *S. C. Wallwork*, personal communication.

In all crystals the pq^{2+} ion is planar, and in crystals of each compound there are chlorine to nitrogen contacts along the perpendiculars to the plane of the pq^{2+} at the nitrogen atoms (Fig. 3). These contacts shorten as the charge transfer spectral bands move to lower energy: $pqCoCl_4$, pale green crystals, d(N–Cl) 3.75 Å; $pq(CuCl_3)_2$, dark red crystals, d(N–Cl) 3.47 Å; $pq(CuCl_2)_2$, black crystals, d(N–Cl) 3.23 and 3.27 Å. In $pqPdCl_4$[39] there are no nitrogen-chlorine contacts as short as these, or of the same orientation, the pq^{2+} ion is not planar, and there is no charge transfer band.

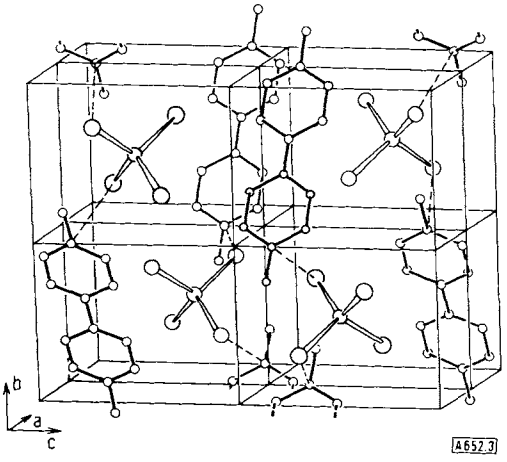

Fig. 3. The crystal structure of "paraquat" tetrachlorocobaltate. The short N—Cl contacts are shown by broken lines.

4. π-π-Complexes

All crystals of $\pi-\pi$ type molecular complexes (*e.g.* 1,3,5-trinitrobenzene/anthracene) are formed from stacks of alternate donor and acceptor molecules. The *Mulliken* treatment[1] suggests that these stacks are to be expected. However, there is little guidance to the relative orientations of molecules within the stacks.

Mulliken considered the hypothetical case of the complex between a polymethyl benzene Me_nBz and a polynitrobenzene $Bz(NO_2)_{n'}$, with n and n' decreasing to zero. If the two molecules were stacked with their symmetry axes coincident and their planes parallel, the symmetry would be D_{6h}. Then ψ_1 and ψ_2 of equation 1, ground state Bz^+ and Bz^-, would be of types $^2E_1$ and $^2E_2$. Although a proper combination of these states gives many states of Bz.Bz, not one is of the species ^1A_1g required for resonance with ψ_0. Hence a different stacking of the two Bz molecules is indicated. To *Mulliken* it seemed likely that an arrangement obtained by sliding one Bz about half a ring diameter over the other would give maximum resonance. Unfortunately, in assessing the relative orientations of two molecules in the plane-to-plane stack it is not possible to separate directly the influence of charge transfer and that of dispersion forces. The latter tend to be largest in orientations bringing maximum polarizabilities into play, and contrast with the former governed by considerations of quantum mechanical symmetry.

The majority of the known crystal structures of $\pi-\pi$ complexes are summarized in Table 5. In this Table, the relative orientations of donor and acceptor molecules are demonstrated by the projection of the donor and acceptor molecules onto the least squares best plane through the atoms of the donor molecules. The diagrams are sketches, and in the case of the less

accurate determinations have been idealized to give molecules of the accepted regular shape.

All the crystals of the 1:1 complexes are formed from approximately plane-to-plane stacks of alternate donor and acceptor molecules, except the adduct of benzotrifuroxane and 13,14-dithiatricyclo[8.2.1.1.^{4,7}]tetradeca-4,6,10,12-tetraene [65] in which the paracyclophane-like aromatic has two plane-to-plane donor groups giving a stack similar to that of the 2:1 complex of *p*-chlorophenol and *p*-benzoquinone [46], in which two donor molecules alternate with one acceptor molecule.

There are three characteristic ways of packing together of the stacks in the crystals (Fig. 4), that can easily be

recognized from the crystallographic space groups. Type A occurs in the space group C_i^1 (No. 2) and requires that both molecules present have centers of symmetry. The crystal may also be regarded as built up from sheets containing donor and acceptor molecules in the ratio 1:1, with each donor molecule surrounded within the sheet by acceptor molecules and *vice versa*. Type B uses space group C_{2n}^5 (No. 14) and also requires that each molecule occupies a crystallographic symmetry centre. The structure is used on occasion by non-centrosymmetric molecules (*e.g.* in bis(8-hydroxyquinolinato)copper(II)/benzo-trifuroxane[64]) and disorder is observed. Type C requires a face-centered lattice, as in space group C_{2h}^3 or C_{2h}^6. The structure appears to be favored by non-centrosymmetric donor and acceptor molecules and is often associated with twinned or disordered crystals. Very many, probably the majority, of the crystals of $\pi-\pi$ complexes appear to be disordered or show complex super-lattice effects.

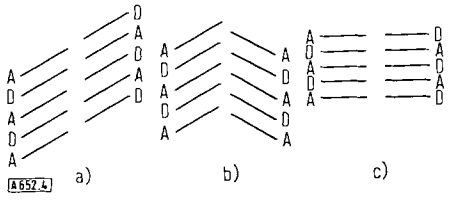

Fig. 4. Typical donor-acceptor stacks in $\pi-\pi$ complexes.

Examination of Table 5 suggests at first sight little system in the relative positions of donor and acceptor molecules. In only one example, *N,N,N',N'*-tetramethyl-*p*-phenylenediamine[42] are the aromatic rings exactly superposed in the eclipsed position. In *p*-iodoaniline/1,3,5-trinitrobenzene[58] which approximates most closely to *Mulliken*'s hypothetical case, the two benzene rings are not superposed, but the positions are in good agreement with the Mulliken prediction of an arrangement obtained by sliding one benzene ring one half a ring diameter over the other. A similar displaced system is found in seven out of the nine structures listed with a *p*-benzoquinone derivative as acceptor. In six of these complexes, the displacement approaches a whole ring diameter, and the overlap of the aromatic rings is very small. They have the common features that the highly polar quinone carbonyl group lies over the center of a benzene ring, with the C–O vector parallel to two C–C bonds of this ring, and that a C–O bond of the donor is similarly placed with respect to the quinonoid ring of the acceptor. It has been suggested[42] that this arrangement is taken by quinhydrone to satisfy the hydrogen bonding requirements of the crystal. However, it is observed in the absence of hydrogen bonding in bis(8-hydroxyquinolinato)palladium(II)/chloranil and in the absence of charge transfer forces in crystals of 1,4-naphthoquinone and its derivatives. It appears more likely that this arrangement is required to maximize the contribution of the highly polar groups to the dispersion forces. The structure of hexamethylbenzene/chloranil and *N,N,N',N'*-tetramethyl-*p*-phenylenediamine/chloranil are exceptional. In the former the donor molecule is without polar groups, and the compound may be thought of as reverting to the *p*-iodoaniline/1,3,5-trinitrobenzene type. The latter compound in the solid state has absorption bands in the visible and ultraviolet region characteristic of the radical ions $(chloranil)^-$ and $(N,N,N',N'$-tetramethyl-*p*-phenylenediamine$)^+$[67] suggesting complete transfer of an electron from donor to acceptor and the possibility of major changes in structure as observed.

The relative orientations of donor and acceptor in tetracyanoquinodimethane (TCNQ) complexes resemble those in the *p*-benzoquinone compounds, the highly polar carbon-carbon double bond of the TCNQ molecule taking up a similar position to the quinone carbonyl group. The position of the carbon-carbon double bond relative to the aromatic ring of the donor is also similar to the donor in the TCNE complexes with naphthalene and pyrene. The charge transfer spectral absorption bands of pyrene/TCNE have been studied in some detail. Charge transfer is from the highest and next highest energy orbitals of the donor to the only available orbital of the acceptor. The two donor orbitals of the pyrene respectively require the carbon-carbon double bond of the TCNE molecule to lie parallel and perpendicular to the long axis of the molecule for maximum overlap. The observed position is said to be a compromise of these two opposing requirements[53]. It is, however, surprising that if charge transfer effects are the main orientating force, the TCNE molecule lies so far from the center of the pyrene molecule.

Complexes of 1,3,5-trinitrobenzene (TNB) have been reasonably thoroughly investigated. The acceptor is much less polar than the quinonoid compounds, and the structures are probably determined largely by charge transfer effects, modified to some extent by crystal packing requirements. The simplest example, *p*-iodoaniline/TNB[58] has been discussed. There are a number of examples of complexes of TNB (or picryl azide) with aromatic donors with two or more condensed ring

systems. In all these compounds, the arrangement in the stack approximates to C-atoms 2, 4, and 6 of 1,3,5-trinitrobenzene being eclipsed with C-atoms 4, 5, and 10 of a naphthalene nucleus. The idealized arrangement approached in numerous compounds is not that claimed for naphthalene/TNB [42]. However, details of the naphthalene/TNB structure determination have not been published. Similar arrangements have been found in complexes of pyromellitic dianhydride [60,61] and for the 1,2,4,5-tetracyanobenzene (TNCB) molecule in the 1:2 complex of bis(8-hydroxyquinolinato)-copper(II) with TCNB [62] that is not interacting with the copper atom shown in the projection in Table 5.

Complexes of bis(8-hydroxyquinolinato)copper(II) and palladium(II) are one of the few groups of complexes where one donor has been taken with a number of acceptors. The system is complex. The donor is a highly polarized system and acceptor molecules appear attracted to the C–O bond in the donor. Further interaction between the copper atom of the donor and the acceptor molecule has been observed in complexes with TCNB [62] and benzotrifuroxane [64].

It has been claimed [42] that "where charge transfer might be expected to be more significant in determining the structure (*e.g.* low ionization potential of the donor) the relative orientation and position of the components are such as to allow the maximum degree of overlap between their molecular π orbitals". The content of this statement implies that high electron affinity of the acceptor would also be acceptable as a criterion for maximum degree of overlap, and *N,N,N',N'* - tetramethyl - p - phenylenediamine/chlor - anil is quoted as the ideal case of maximum overlap.

The facts in Table 5 do not support this statement. Indeed the higher the electron affinity of the acceptor for a given donor *e.g.* in the 8-hydroxyquinolinate series, almost the contrary appears to be true. However, there are two further difficulties. One is the relative importance of dispersion forces in determining orientation. Most of the better electron acceptors are the more highly polar molecules, and the better donors are the most readily polarized molecules. Complexes between them are likely to be those in which dispersion forces assume the greatest importance. Indeed, complexes apparently of the plane-to-plane stacked donor-acceptor type are formed between a polarizable molecule and a polar molecule *e.g.* pyrene/tetramethyluracil [66], without there being any evidence for charge transfer effects. The other difficulty is that as yet there is no detailed theory which states which orbitals of the donor and acceptor are involved in charge transfer, and no one has produced a clear picture of the expected positions for maximum overlap, largely due to a neglect of the symmetry requirements governing the combination of states in equation (1). Indeed, the electronic structures of the more complex electron acceptor molecules are far from being fully understood.

Further, it is assumed that a short interplanar perpendicular separation is associated with a high relative importance of the charge transfer contribution to the intermolecular bonding. If the energy of the charge transfer band is taken to be an inverse measure of the contribution of charge transfer to the bonding energy, then it would be expected that a short interplanar perpendicular distance would be associated with charge transfer bands of low energy, that is, with donors of low ionization potential and acceptors of high electron affinity. In Table 5 there appears to be little correlation between perpendicular interplanar spacing and any of these factors. What correlation there is tends to suggest that short interplanar spacings are associated with molecules in which dispersion forces assume the greatest importance. Some of the shortest interplanar spacings between flat organic molecules are found in crystals of the highly polar barbituric acid derivatives including barbituric dihydrate with a spacing of 3·12 Å [68]. It is to be expected that there may be a correlation between interplanar spacings and the heat of formation and free energy of formation – measurements which take into account all factors in the binding energy. Unfortunately, those complexes for which free energies of formation *etc.* are known are not always those of known structure, and in any case these measurements are generally made in solution and the results may not apply to the solid state.

5. Conclusions

Stimulated by *Mulliken*'s first treatment of the theory of donor-acceptor complexes, and by the growing interest in electronic charge transfer processes in both biological and technological fields, the structure analysts have provided a great deal of information on an apparently rather random choice of donor-acceptor complexes. The choice of compounds has probably been determined by the availability of good single crystals rather than by a coordinated plan. Certain general structural features emerge, the linear groups in the donor-halogen $\sigma-\sigma$ complexes, the axial benzene/halogen $\sigma-\pi$ complexes, the quinone orientation and other recurrent arrangements in $\pi-\pi$ complexes. These features were not all predicted in earlier theoretical work, and to date their theoretical interpretation is largely unsatisfactory. The many physical investigations of molecular complexes since *Mulliken*'s theoretical work suggest that further significant advances in the understanding of charge transfer processes and structural principles in donor-acceptor systems will not be long delayed.

Studies on the Adsorption of Gases on Clean Metal Surfaces with the Aid of Field-Emission and Field-Ion Microscope Techniques

BY W. M. H. SACHTLER [*]

Studies on the adsorption of gases such as xenon, hydrogen, nitrogen, and carbon monoxide on the surface of a single crystal of tungsten with the aid of field-emission and field-ion microscopy have, in the past few years, led to new, fundamental insights into chemisorption and heterogeneous catalysis. Important phenomena which were discovered and elucidated by these techniques include the pronounced face specificity of the adsorption, the fact that several different adsorption complexes of a gas are found on one and the same crystal face, and the rearrangement of the surface atoms through chemisorption. Many of the interpretations thus gained for the systems studied can also be generalized for other chemisorption complexes.

1. Introduction

A number of powerful methods are available for experimental studies concerning the adsorption of gases on solid surfaces. For instance, adsorption complexes can often be characterized by means of IR spectroscopy [1]. As soon as ordered surface structures are formed, they can be identified by their electron diffraction pattern, obtained by low-energy electron diffraction (= LEED) [2, 3]. In the case of adsorption on oxides, for instance, electron spin resonance [4, 5] provides valuable information on the adsorption complex if the adsorbate contains an odd number of electrons or if transition-metal ions with incompletely filled d-orbitals occur in the adsorbing surface. Furthermore, magnetostatic methods [6–8] can record the change in magnetization upon adsorption on para- or ferromagnetic solids. For adsorbing metals [9, 10] and alloys [11] the change in work function caused by adsorption gives important indications as to the character of the bond between adsorbent metal and adsorbate. The change in electrical resistance [12–14] of adsorbing metal films is another tool in studying adsorption phenomena.

As in the course of time evidence was gathered that a given gas may be bound in widely different ways on a given metal [15, 16], so that at a high degree of coverage several different adsorption complexes can be distinguished on one and the same surface, this led to a growing interest in methods providing information on single atomic events and enabling the adsorbing centers and the adsorption complexes to be characterized precisely. Two related methods, which can also be used in combination with each other, have proved particularly useful in solving such problems: field emission microscopy and field ion microscopy. In the following, the scope, the fundamental limitations, and difficulties of these methods will be outlined with regard to the special purpose of studying adsorption complexes; subsequently, results obtained will be discussed. (For a detailed account of the theory and the application of field emission microscopy and field ion microscopy the reader is referred to ref. [17–20].)

2. Field Emission (FE) Microscopy

The potential energy of an electron close to the surface of a neutral metal in the absence of external fields is schematically represented in Fig. 1 (curve 1). In the interior of the metal, at absolute zero, all energy levels up to the Fermi level are each filled by two electrons, all higher energy levels are empty.

The energy of the Fermi level being lower than the energy of the electron *in vacuo* by an amount φ, there is no emission of electrons unless energy is supplied, for instance, by means of light quanta (photoelectric emission) or colliding corpuscles. At higher temperatures energy levels above the Fermi level are also filled, and it is then possible that electrons leave the metal surface.

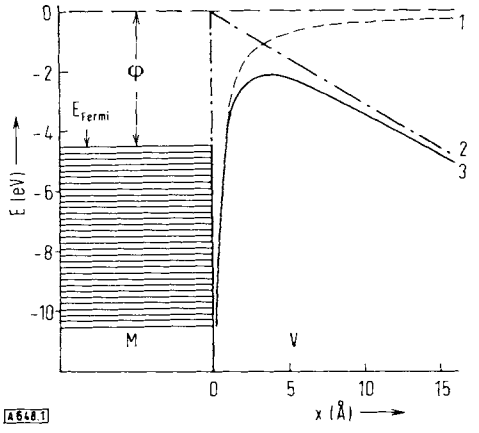

Fig. 1. Potential-energy diagram for an electron near a metal surface. M = metal, V = vacuum. 1) ($E = -e^2/4x$), no external field. 2) ($E = -eFx$), external field $F = 0.3$ V/Å. 3) potential resulting from superposition of curves 1 and 2 after application of external electric field F.

As soon as an external electric field F is applied, with its negative pole at the metal, the potential energy $-eFx$ (curve 2) is superimposed on the potential energy of the electron in the absence of a field. The resulting potential curve (curve 3) shows a maximum (Fig. 1). Evidently, an electron sufficiently far from the metal surface has a lower potential energy than inside the metal: thus, electron emission has become an exothermic process. Whether this process actually takes place is dependent on whether any electrons can be transferred from the left to the right of the potential barrier. Theoretically, this can be achieved in two ways:

1) across the potential barrier (process with positive activation energy);

2) through the potential barrier (quantum-mechanical tunnel effect).

At very low temperature and at field strengths of the order of 10^7–10^8 V/cm (0.1–1 V/Å) it is obviously only the latter possibility that is of interest. We will therefore restrict ourselves to a consideration of such tunneling effects in the following.

For a given metal the field electron emission – field emission for short – increases strongly with field strength. At equal field strength but for different metals it is greatest for the metal with the lowest work function. The relation between current density j, field strength F, and work function φ was derived – after simplifying assumptions – by *Fowler* and *Nordheim* [21].

After some further refinements the "Fowler-Nordheim equation" acquired the following form [22]:

$$j = \frac{1.54 \times 10^{-6}}{t^2(y)} \cdot \frac{F^2}{\varphi} \exp\left[-6.83 \times 10^7 \frac{\varphi^{3/2}}{F} \delta(y)\right], \qquad (1)$$

where $t(y)$ and $\delta(y)$ are functions of the variable:

$$y = 3.79 \times 10^{-4} \frac{F^{1/2}}{\varphi}, \qquad (2)$$

which are available in tabular form.

[21] *R. H. Fowler* and *L. Nordheim*, Proc. Roy. Soc. (London) Ser. A *119*, 173 (1928).

The field strength at the surface depends both on the voltage applied, V, and on the geometry of the surface according to the relation:

$$F = \alpha V \qquad (3)$$

Essentially, α is inversely proportional to the radius of curvature, ρ, of the emitting surface. Hence, extremely high voltages are not necessary if the emitter has the form of a sharp tip with small ρ. In actual practice, chemical and electrochemical etching methods have been developed which enable metal tips to be made with a radius of curvature of the order of 10^{-5} cm. This typical form of the emitter not only renders it possible to reach the desired field strength at voltages that are easy to realize experimentally (several kilovolts but also leads to two additional consequences:

a) Because the equipotential curves are parallel to the tip surface and the electrons emitted follow the orthogonal trajectories through the equipotential curves a diverging beam of electrons is formed. Upon striking a fluorescent screen the electrons produce a strongly magnified image of the emitting surface. The magnification is given by the factor:

$$M = \frac{R}{\beta\rho}, \qquad (4)$$

where R is the distance between tip and screen and β (≈ 1.5) is a compression factor determined by the geometry. For $R = 15$ cm and $\rho = 10^{-5}$ cm the magnification factor M thus amounts to 10^6, which means that 1 mm on the screen corresponds to 10 Å on the surface. As early as in the thirties, these possibilities inspired *E. W. Müller* [22] to design the field emission microscope [23, 24], the principle of which is shown in Fig. 2.

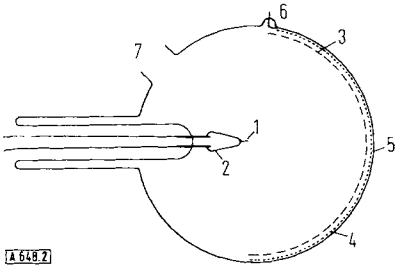

Fig. 2. Principle of the field-emission microscope.
1, metal tip. 2, heating loop. 3, fluorescent screen. 4, conductive coating. 5, glass envelope. 6, anode. 7, to vacuum.

Although in principle it is possible to increase the magnification factor to $M > 10^7$ – by using constructions with large R and small ρ – there is no point in doing so, because there is a fundamental limit to the resolving power. This is due to the fact that the probability of tunneling is greatest for those electrons which, before emission, are at the highest filled level. Since the electrons are distributed in the metal according to Fermi-Dirac statistics these electrons possess considerable energy also at absolute zero, so that after the emission the projectiles generally have a compo-

nent perpendicular to the field gradient, in addition to the component of motion in the direction of the applied field. The resulting unsharpness makes it impossible to realize a resolution in the range of atomic dimensions with the aid of field electrons. This is possible, however, with the field ion microscope, in which images are obtained with projectiles not subject to Fermi-Dirac statistics (see Section 3).

b) Since the radius of curvature ρ is smaller than the crystallites constituting the metal wire, the emitting tip is nearly always part of a *single crystal*. It is a known fact that macroscopic single crystals in thermodynamic equilibrium build up their surface in such a way that the crystal faces with very small Miller indices predominate, whereas the less stable faces only appear in the form of rounded edges and corners; for microscopic crystals, on the other hand, equilibrium is reached when the surface is the nearest approach to the spherical shape. Thus, the surfaces of the tips in the FE microscope contain, in addition to the stable and smooth faces, unstable and rough faces.

Since the effective work function φ_{hkl} is different for different faces[*], but, according to eq. (1), strongly influences the emission current, the electron-optical image of the tip shows a pattern of bright and dark areas corresponding to the distribution of local work functions on the surface. Since as a rule the crystal structure of the emitting metal is known, it is easy to recognize from the symmetry of the image to what crystal face a given area of the image corresponds.

Summarizing, it may be said that the FE microscope produces the strongly magnified electron-optical image of the surface of a well-defined single crystal, in which the brightness of each image point depends on the work function of the emitting crystal face. In addition, the current-voltage characteristic, which is easy to measure, can be analyzed quantitatively. The prospects for FE microscopy as a tool in studying adsorption on metals will now briefly be discussed:

1) As practically every adsorption leads to a change in work function – an increase or a decrease – the adsorption can be recognized and followed *visually* through the change in brightness of the image.

2) Quantitatively, every state of adsorption can be characterized by the parameters of the current-voltage characteristic. In this connection it is of practical value to replace the field strength in eq. (1) by the voltage according to eq. (3) and the current density j by its proportional current strength. To a good approximation, the F(owler)-N(ordheim) equation then acquires the form:

$$\log i\,V^{-2} = \log A - B\varphi^{3/2}V^{-1}. \qquad (5)$$

If the constant B is known and remains unchanged by the adsorption, the parameters log A and φ before as well as after the adsorption can conveniently be derived from the ordinate intercept and the slope of the F–N line, which is obtained by plotting log $(i\,V^{-2})$ against V^{-1}. The work function of the clean metal, φ_0, being known, constant B can be calculated from the F–N line of the clean metal. As both log A and φ generally have different values for the tip covered with an adsorbed gas and for the clean tip, any adsorbed state can be characterized by the two parameters:

$$\Delta \log A = \log A_{\text{covered}} - \log A_{\text{clean}} \qquad (6)$$

and:

$$\Delta\varphi = \varphi_{\text{covered}} - \varphi_{\text{clean}}. \qquad (7)$$

Although Δ log A is easily accessible experimentally, it is difficult to interpret theoretically; cf. the partly conflicting views of *Gomer*[20,58], *Van Oostrom*[29], and *Holscher*[49].

It is common usage to call the parameter Δ log A the pre-exponential factor, and the quantity $-\Delta\varphi$ (sometimes also $+\Delta\varphi$) the surface potential. According to classical physics the surface potential of a double layer should be related to the dipole moment μ and the number of dipoles n per cm^2 according to the Helmholtz equation[25]:

$$-\Delta\varphi = 4\pi n\mu, \qquad (8)$$

where μ is expressed in Debye units and the positive sign of μ applies for dipoles with the adsorbate positively charged with respect to the metal surface. For a surface built up of atoms the moment of the bonding dipole between metal atoms and adsorbate atoms may have different directions; then μ is the projection of the bonding dipole on the surface normal. For adsorptions where there are only very few atoms on the metal surface the model of the Helmholtz double layer derived from classical physics loses validity.

3) At a low degree of coverage the adsorbate will generally not be distributed uniformly over the total surface, but will be concentrated on some preferred crystal faces. Visually this face specificity of the adsorption can be recognized by the fact that at incipient adsorption the brightness of many crystal faces changes considerably, whereas the images of other faces do not, at first, change. As the adsorption proceeds, the brightness ratio of two crystal faces may vary greatly, in some cases even repeatedly be inverted.

4) Quantitatively, for any crystal face with the Miller indices (*hkl*), the face specificity is characterized by the parameters Δ log A_{hkl} and $\Delta\varphi_{hkl}$. This, however, can only be done in a reliable way with the aid of a variant of the FE microscope, the probe-hole tube. It differs from the type already described in that there is in the fluorescent screen a minute hole behind which are mounted a Faraday cage collector and a number of auxiliary electrodes. In this way the partial emission current of a particular surface element is diaphragmed out of the total beam and can thus be measured. As this branch current also obeys the F–N equation, it is possible to determine the parameters log A_{hkl} and

[*] The work functions determined with the aid of the FE microscope refer, not to charge-free infinity, but to points which are still close to the surface and which, with respect to similar points close to another crystal face, have a finite potential. It is therefore not possible to create a *perpetuum mobile* by removing an electron from the metal through one crystal face and re-introducing it through another face.

[25] *J. H. de Boer*: Elektronenemission und Adsorptionserscheinungen. J. A. Barth, Leipzig 1937, p. 50.

φ_{hkl} both before and after the admission of gas for that (*hkl*) face whose emission beam enters the Faraday cage. *Müller*[26,27], *Smirnov* and *Shuppe*[28], *Van Oostrom*[29], and *Holscher*[30] have devised variants which enable the emission beam from any face to be directed into the Faraday cage. This can be realized by means of magnetic deflection of the electron beam or by mechanical shifting of the emitter, for instance, with the aid of a vacuum-tight stainless-steel bellows (cf. Fig. 3).

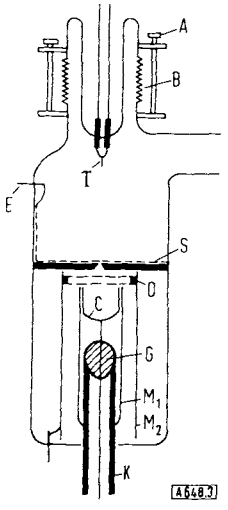

Fig. 3. Field emission probe-hole tube, according to *Holscher* [30]. A, adjusting screw. B, vacuum-tight, stainless-steel bellows. C, collector. D, double grid. E, metal-in-glass seal (connected electrically with the fluorescent screen). G, glass pressing. K, kovar tube. M_1 and M_2, molybdenum cylinders. S, fluorescent screen. T, tip (field cathode).

5) The *heat of adsorption* $-\Delta H$, particularly the face-specific heat of adsorption $-\Delta H_{hkl}$ of a given gas on a given crystal face of the metal considered can be measured with the FE microscope, which in this respect is unrivaled. In principle the $-\Delta H_{hkl}$ values can be determined both by equilibrium measurements and, kinetically, by measuring the activation energies E_{des} and E_{ads} for desorption and adsorption. In the former case use can be made of the thermodynamic equilibrium relation:

$$\frac{\theta^z}{(1-\theta)^z p} = \exp\frac{\Delta S}{R} \cdot \exp\left(-\frac{\Delta H}{TR}\right) \qquad (9)$$

where θ is the degree of coverage, p the equilibrium pressure, ΔS the adsorption entropy, and z the degree of dissociation; R and T have their usual meanings. If it is possible to estimate θ, z, and ΔS theoretically, ΔH can be calculated from a pair of p and T values with the aid of eq. (9).

Another way is simply to start from the assumption that points of equal brightness correspond to the same value of θ and to find experimentally the p, T pairs that correspond to the same emission. Eq. (9) is then written as an adsorption isochor:

$$\ln p = \text{const} + \frac{\Delta H}{RT} \text{ (for } \theta = \text{const)} \qquad (10)$$

from whose slope $-\Delta H$ is calculated.

For the FE determinations of heats of adsorption that have so far become known, however, use has been made of the kinetic method, which is based on the relation between caloric and kinetic quantities:

$$-\Delta H = E_{des} - E_{ads} \qquad (11)$$

For systems in which the adsorption is not an activated process ($E_{ads} = 0$) the problem reduces to that of determining the activation energy of the desorption. This is measured, for instance, by first establishing a certain degree of coverage at a low temperature, then rapidly raising the temperature to a value that can be measured accurately, and measuring the time during which the emission current and thus the brightness of the surface element under consideration change to the value for the clean surface. Again the evaluation can be carried out in either of two ways: either no assumption is made as regards the activation entropy and E_{des} is determined from the temperature dependence using Arrhenius' law, or use is made of the absolute rate theory and a physically acceptable value for the activation entropy of the desorption is inserted in the general rate equation. In the former case the activation energy of the desorption is given by:

$$E_{des} = -R \cdot \frac{d \ln r_{des}}{d(1/T)} \qquad (12)$$

where r_{des} is the rate of desorption measured in arbitrary units. In the latter case the general equation:

$$r_{des} = \frac{kT}{h} \exp\frac{\Delta S^*}{R} \exp -\frac{E_{des}}{RT} \qquad (13)$$

(molecules per adsorption site per second) is valid. For the ideal limiting case $\Delta S^* = 0$ eq. (13) passes into the well-known Frenkel equation[31]:

$$E_{des} = RT \ln (kT/h)\tau \qquad (13a)$$

where k and h are the Boltzmann and Planck constants respectively, and τ is the half-life value of the desorption process (in seconds). In many cases the two methods for determining E_{des} are about equally accurate; but there are also systems for which the assumption $\Delta S^* = 0$ is impermissible[32].

6) The probe-hole technique mentioned under 4) makes it possible to single out from the emission beam very small regions which may correspond to an emitting area of 10×10 atoms. With such small regions, evidently, the building-up and disintegration of the adsorption layer can no longer be described as continuous processes, but represent a sequence of *discrete*

single steps of individual molecules landing or jumping off. Fig. 4 shows a graph – determined with the aid of *Holscher*'s probe-hole tube – of an emission current as a function of time at a residual gas pressure of 10^{-8} torr.

Fig. 4. Emission current versus time plot of a probe-hole experiment. Object: tungsten (110) region. Gas: nitrogen (10^{-8} torr). 300 °K, 340 V, current 10^{-13} to 10^{-12} A.

It is clearly seen that every landing of a gas molecule causes a jump in the emission current. As these measurements do not obey the rules of statistics their reproducibility is necessarily limited.

7) Under 5) mention was made of the possibility of performing *kinetic measurements* with the aid of the FE micoscope. This possibility is not restricted to adsorption and desorption, but also refers to the diffusion of adsorbed atoms over the tip surface.

Gomer [20] and *Ehrlich* directed a beam of gas sideways on to a tip that was cooled to a very low temperature. The emission image clearly showed that only the side of the tip facing the gas source was covered with an adsorption layer. As soon as the temperature was raised to a level at which surface diffusion was possible the adsorbate spread over the total surface at a rate that could be observed and measured.

It appears [33, 34] that in diffusion certain paths are preferred. Extensive investigations of surface diffusion, in which the hopping energy was also determined, were reported by *Gomer* [20], *Ehrlich* [19, 33], and *Drechsler* [34–36]; the last-mentioned author also investigated the dependence of the hopping energy on the field applied.

Other kinetic investigations deal with the desorption process. They do not, however, concentrate on the determination of E_{des}, but mainly on the dependence of the rate of desorption on the degree of coverage, and, hence, on the order of the reaction.

For instance, *Ehrlich* [19, 33] finds that the desorption of β nitrogen from tungsten (see under 8)) is a second-order reaction and concludes from this that the nitrogen must be on the surface in the form of atoms, since for molecularly adsorbed nitrogen the desorption would be expected to be of the first order.

It should be pointed out, though, that an experimentally found relation between rate of desorption and degree of coverage can only be evaluated in this simple way if it is absolutely certain that the activation energy and the activation entropy of the desorption are truly constant, *i.e.* are not dependent on the degree of coverage as well. If they should be, the resulting exponential dependence of the rate on the degree of coverage obscures the actual influence of the reaction order. Unfortunately, systems in which the heat of adsorption and the activation energy and entropy of the desorption are really constant are extremely rare. To what extent these quantities may in fact depend on the degree of coverage has been illustrated very strikingly by results obtained by *Mars*, *Scholten*, and *Zwietering* [37] for the nitrogen/iron system.

8) Often the heat of adsorption varies with the degree of coverage, not continuously, but in discrete steps. This means that the same gas is present on the surface in several discrete "states". If the temperature of a metal covered with gas is uniformly increased, the simultaneous presence of different states is recognized by the fact that the desorption occurs, not uniformly, but for instance in discrete eruptions. The most weakly bonded state is, of course, desorbed at the lowest temperature. Such states can also be recorded without a FE microscope, for instance, by kinetic pressure/time measurements [38–40]. *E.g.*, the α, β, and γ states of nitrogen on tungsten have been distinguished in this way. Furthermore, all physical quantities that are measurably changed through chemisorption are suitable for characterizing the simultaneous presence of several states of adsorption. In particular, the changes in electric resistance [16], in work function of thin metal films, and in magnetization of disperse metal-on-carrier systems have proved the coexistence of several states of adsorption for various metal/gas systems [40]. Nevertheless, with all these methods the question remains whether the various states must be assigned to different crystal faces or whether they can coexist on one and the same face. In this respect the FE microscope is superior to the above-mentioned methods, because it is at once established visually to what crystal face an irregularity in one of the adsorption-dependent parameters corresponds. To anticipate the most important result: coexistence of several states on one and the same crystal face is indeed possible [42].

3. Field Ion (FI) Microscopy

As already mentioned the resolving power of the FE microscope is fundamentally limited by the fact that the electrons in the metal obey Fermi-Dirac statistics, on account of which they possess, also at low temperature, considerable kinetic energy, which is undirected in space. Improved resolving power can only be expected if the image on the fluorescent screen is produced by projectiles whose kinetic energy perpendicular to the applied field is substantially smaller than that of the metal electrons emitted. This is the case for ions generated, by field ionization, from atoms which have

been cooled to very low temperatures. *E. W. Müller* [18,43] succeeded in realizing this idea with the FI microscope, the principle of which is shown in Fig. 5. Outwardly, the FI microscope resembles the FE microscope. The main differences are that the field is of reversed polarity and its strength is higher by about an order of magnitude, that the tip is cooled, for instance, with liquid hydrogen, and that the tube is filled with gas, usually helium at a pressure of 10^{-3} torr.

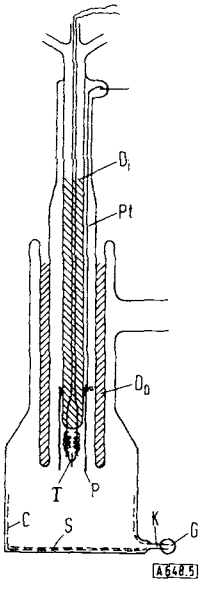

Fig. 5. Principle of the field-ion microscope.
S, fluorescent screen. C, conducting layer. D_i, inner Dewar. D_0, outer Dewar. T, tip. P, polished metal cylinder. K, kovar tube. Pt, platinum wire. G, glass pearl.

Near the surface the helium atoms are exposed to a field of such high strength that an electron can tunnel from a helium atom to a vacant energy level inside the metal. The He^+ ion thus generated is accelerated by the electrical field towards the fluorescent screen, where it produces an image point.

For an understanding of the image it is essential to know that near the surface the equipotential lines follow the atomic profile; at a greater distance the atomic roughness has been levelled out and the equipotential lines have become smooth. Consequently, the potential gradient above the atomic cores is larger than that above the interstices. At correct adjustment – the best image voltage – the ionization probability is much greater for gas atoms above the atomic cores than above the interstices. Therefore, the resulting image shows the surface atoms (as e.g. in Fig. 6). A prerequisite is, of course, that the paths of ions produced above two neighboring metal atoms do not overlap. This is realized by cooling the gas and the tip to very low temperatures.

We shall not go into details of the imaging process, because on account of the great importance of the method for metal science numerous publications have appeared on the subject. With regard to the special purpose of the study of adsorption complexes the following points are important:

[43] *E. W. Müller*, Z. Physik *131*, 136 (1951).

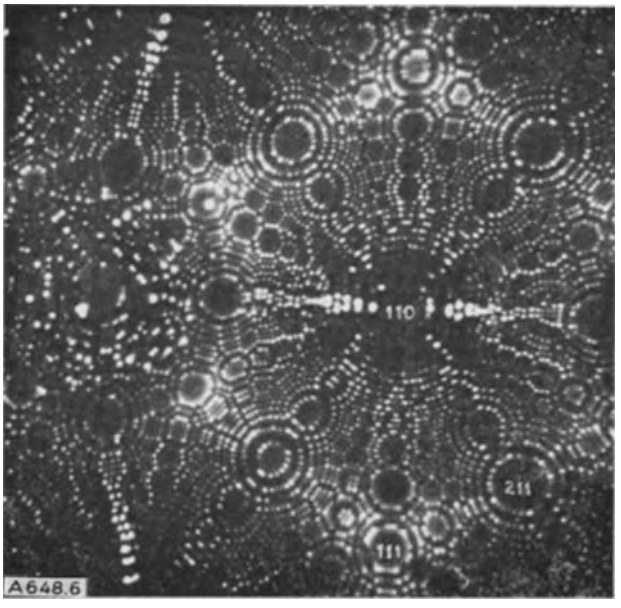

Fig. 6. Field-ion pattern of an ordered tungsten surface, field-evaporated at 20 °K and 10.5 kV.

Under normal operating conditions the adsorption process suffers from serious interference. Gas molecules with a permanent or induced dipole moment are accelerated towards the tip. The partial pressure prevailing in the vicinity of the metal tip may become so high that the tip becomes covered with layers of liquefied or crystallized gas. This fact was utilized by *Inghram* and *Gomer* [44] and by *Beckey* [45,46] to study condensed phases with the field-ion mass spectrometer.

In addition, molecules with a permanent dipole moment or with anisotropic polarizability are oriented in the field, so that dipole vector and field vector are opposed to each other.

Finally, gas molecules with a low ionization potential are already ionized – by the tunnel effect – before they reach the tip and are thus removed because ionization is at once followed by acceleration of the ion away from the tip.

All three effects are also of importance for the adsorption layer. At the voltages usually applied in the helium-filled tube to obtain good imaging of the tip, ionization is predominant in the neighborhood of the surface, since all other gases have a lower ionization potential than helium. Hence, when the field is applied only very few gas molecules are left that succeed in crossing the ionization zone and reaching the metal surface. But also particles that were adsorbed before the voltage was applied or those which are adsorbed at the back of the tip and subsequently diffuse to the image region are strongly affected by the field applied. Many of them are also ionized through the tunnel effect and torn off as ions; this process is known as *field desorption*. But also particles which, at the field strength prevailing at the surface and in the absence of

[46] *H. D. Beckey*, Bull. Soc. chim. belges *73*, 326 (1964).

an "image gas", just escape field desorption can be torn off at imaging conditions. This phenomenon is called *promoted field desorption.* Its physical cause has not yet been satisfactorily explained. Various possibilities are being considered. For instance, it has been pointed out [47] that the electron liberated by field ionization acquires some kinetic energy on its short path from the site of ionization to the metal surface, so that the surface is in fact bombarded by electrons. Greater still is the energy of secondary electrons, which are generated when the He^+ ions hit the fluorescent screen and are then accelerated towards the tip surface. The bombardment of the tip by neutral helium atoms must also be considered [48]. As it is preferably helium atoms with a small velocity component normal to the tip surface that undergo field ionization, the non-ionized helium atoms are no longer in Maxwell-Boltzmann equilibrium, but have a higher effective gas temperature. Thus, they are potential projectiles provoking desorption. Finally, the possibility has been suggested [49] that colliding helium atoms may form short-lived complexes with the adsorbed atom species, which complexes, on account of their relatively low ionization potential, are thought to be very effectively torn off from the tip through field desorption. Which of these explanations is the nearest approach to reality will not be discussed here; suffice it to say that the *promoted field desorption* has been substantiated by reliable experiments – a point of importance for the items to be discussed in the following. In evaluating FI-microscopic images it should be borne in mind that the surface is cleaned by promoted field desorption within a time that is considerably shorter than the minimum time required for producing an image on the fluorescent screen.

For many purposes this implies an advantage. Because field desorption and promoted field desorption continually clean the surface, comparatively strongly contaminated helium can also be used without the surface being poisoned. For the investigator, however, who wishes to study the adsorption of gases on metals, it is a great drawback that the method destroys its object of investigation, *i.e.* the adsorption complex, within an extremely short period of time.

In the past few years, however, two new points of view have come to the fore, which have opened up novel perspectives for the study of adsorption problems by FI microscopy:

1) On the basis of theoretical considerations it was pointed out some considerable time ago [40,41] that an adsorption layer in which the surface atoms remain in their original places in the lattice does not necessarily represent the energetically most favorable state. When, for instance, the bond between metal and adsorbate is a strongly polar one, an energetically more favorable state might possibly be attained through the metal atoms leaving their places in the lattice, which results in another arrangement with optimum coordination of positive and negative ions.

That such rearrangements are actually possible follows from the fact that metals can corrode and from numerous results obtained at elevated temperature [50 to 53]. Whether they also occur at low temperature depends on the activation energy of the process. This energy cannot be predicted exactly, but several years ago the present author pointed out [41,53] that the activation energy should decrease with increasing degree of coverage, as adsorption of gas X_2 on metal M would be attended not only by the destruction of X–X bonds and the formation of M–X bonds, but also by a considerable degree of weakening of the M–M bonds of the surface atoms.

Rearrangements of this kind can be demonstrated with the FI microscope [54,55]. If the gas to be adsorbed reaches the metal tip while no external field is applied and the conditions required for imaging (admission of helium, cooling the tip to the temperature of liquid hydrogen, application of a field) are only applied after evacuating, the majority of the adsorbed atoms will be removed through promoted field desorption, but those metal atoms which during the action of the gas had left their places in the lattice cannot return to them, because at the temperature of liquid hydrogen they are insufficiently mobile. The field ion images of the tip before and after the contact with gas are then different. Even if the metal atoms removed from their places in the lattice are also torn off the surface by promoted field desorption, the vacant sites left by them are visible in the ion image [49,56].

If, however, rearrangement does not occur and the promoted field desorption is complete, the ion images before and after the action of the gas are the same. In this case it is essential that the tube can also be operated as an FE microscope, so that it can be judged from the emission characteristic whether adsorption has in fact occurred.

2) The removal of adsorbed particles upon adjustment of the imaging conditions need not always be complete. If the adsorption is accompanied by atom rearrangements, atoms of the adsorbate can be favorably embedded in the surface and thus escape the influence of the field and, hence, of promoted field desorption. This at once raises the question as to what is the behavior of adsorbed non-metal atoms on the surface of a metal crystal under the conditions of FI microscopy. *Ehrlich* [19,33,57] had assumed that such atoms should

be visible in the ion image as additional bright dots. But *Holscher*[49] pointed out that theoretically it is more likely that metalloid atoms appear as blurred "nebulous patches" or even obscure the metal atoms immediately underneath. The predictions of theory in this respect being too vague, an important research object for FI microscopy is thus outlined. It is to be expected that clarifying the question of how non-metal atoms are imaged will, at the same time, shed a new light on the problem of the bond character in chemisorption. In particular *Holscher*'s finding[49] that chemisorbed nitrogen atoms appear in the ion image as "nebulous patches" seems to confirm the present author's opinion that the chemisorption bond is a localized one and that through chemisorption the atoms of the metal surface are deprived of their typical metal character and thus no longer contribute to the collective properties of the metallic state[41, 53].

4. Related Methods

Some attention should now be given to a few techniques related to field emission microscopy, which can also provide important information on adsorption problems. For instance, *Menzel* and *Gomer*[58] and *Ermrich*[59] used the FE microscope to study the phenomena induced by electron bombardment of the adsorption layer; these topics include the appearance of new states of adsorption and the question of the effective cross-section of adsorbed molecules. Other investigators have concentrated on field desorption, and succeeded in identifying mass-spectrometrically the atoms or atom complexes torn off by the field. In this connection special mention must be made of the work of *Inghram* and *Gomer*[44], *Schmidt*[60], and *Block*[61]. Through utilization of the time of flight principle the sensitivity of the mass-spectrometric methods has in the meantime been increased to such a degree that *Müller*[62] recently announced a single-atom mass spectrometer and reported the first results obtained with it.

Another important technique is that of field evaporation[63], as it is the only means to produce surfaces that are both chemically pure and have nearly all atoms at ideal lattice sites.

Finally, we shall briefly deal with the important role of field cathodes in investigations in which the electrons emitted are decelerated by a retarding field so that their kinetic energy can be measured. Because the electrons are emitted by the tunnel effect, they need not overcome a potential barrier and consequently have – after compensation of the accelerating voltage by a retarding field – exactly the same energy as before the emission. If the temperature of the emitter is 0 °K the highest-energy electrons have exactly the energy of the Fermi level. Such electrons are able to penetrate into the surface of a metallic collector only if its potential is higher than that of the emitter by at least φ_{coll}, *i.e.* the work function of the collector.

Two important quantities can be determined experimentally by this method. *Henderson* and *Dahlstrom*[64] had tried to measure the limiting voltage at which the field-emitted electrons just manage to enter into the collector and thus the work function of the collector, φ_{coll}. The method is independent of the work function of the emitter, but requires excellent electron optics. The latter also applies for the second quantity that can be determined by retarding field measurements, *i.e.* the energy distribution of the electrons. It is characterized by the half-width, whose dependence on the temperature, the work function of the emitter, φ_{em}, and the constant B is known (see eq. (5)). If both the half-width and the slope of the F–N line are known, two equations are available which contain the two unknown quantities B and φ_{em}, and the two parameters can therefore be calculated.

The retarding field method thus enables the absolute values of the work functions of both the emitter, φ_{em}, and the collector, φ_{coll}, to be determined. *Young* and *Müller*[65] used it in particular to measure the energy distribution of the electrons and φ_{em}. *Van Oostrom*[29] combined the retarding-field method with the probe-hole technique and thus determined the work functions of various crystal faces, φ_{hkl}. *Holscher*[66] further developed the possibilities of the retarding-field method to determine the work function – and thus also the change in work function upon gas adsorption – of a collector and used it to study thin metal films deposited by evaporation under ultra-high vacuum conditions. This method is, in several respects, superior to the conventional techniques for determining work functions and surface potentials (photoelectric emission, thermal emission, contact potentials). In particular, if a movable collector is used it is possible to scan very small areas of the collector surface with the aid of a narrow electron beam; in this way slight inhomogeneities are detected. It is even possible to measure an entire alloy system if care is taken that the concentration of one alloy component possesses a lateral gradient along the collector surface.

5. Examples

The possibilities, offered by the methods described in Sections 2–4, of studying adsorption phenomena and the results thus obtained will now be illustrated. Suitable examples are the physisorption of xenon and the chemisorption of carbon monoxide, nitrogen, and hydrogen on tungsten. The fact that tungsten is preferred in most investigations is due to this high-melting metal being particularly convenient to handle; it is easy to clean by annealing and is sufficiently hard, so that there is no risk of the tips being torn off at high field strengths. It should be stressed, however, that metals

with greater ductility, such as platinum or nickel, are also suitable; *Gomer*[67] has even studied mercury crystals in the form of whiskers grown on tungsten.

5.1. The Tungsten / Xenon System

As shown in Section 3, it is not possible, at the present state of knowledge, to study this system with the FI microscope, because the ionization potential of xenon is considerably lower than that of any gas suitable as an imaging gas. For the latter purpose the choice is limited as it is necessary that the imaging gas does not condense at the low temperature required ($\approx 20\,^{\circ}K$) and a pressure of 10^{-3} torr. The FE results of *Ehrlich* and *Hudda*[68,69] are essentially in excellent agreement with those of *Rootsaert*, *Van Reijen*, and *Sachtler*[42]. At low temperature the adsorption is definitely face-specific, contrary to the conventional opinion that physisorption is a phenomenon of low specificity for the adsorbent.

Because adsorbed xenon strongly reduces the work function of tungsten and the brightness in the FE image is consequently increased considerably the adsorption can conveniently be followed visually.

The photographs of Fig. 7 illustrate an experiment in which xenon is adsorbed, at 10^{-5} torr, on a tungsten tip which after having been annealed is cooled at 78 °K.

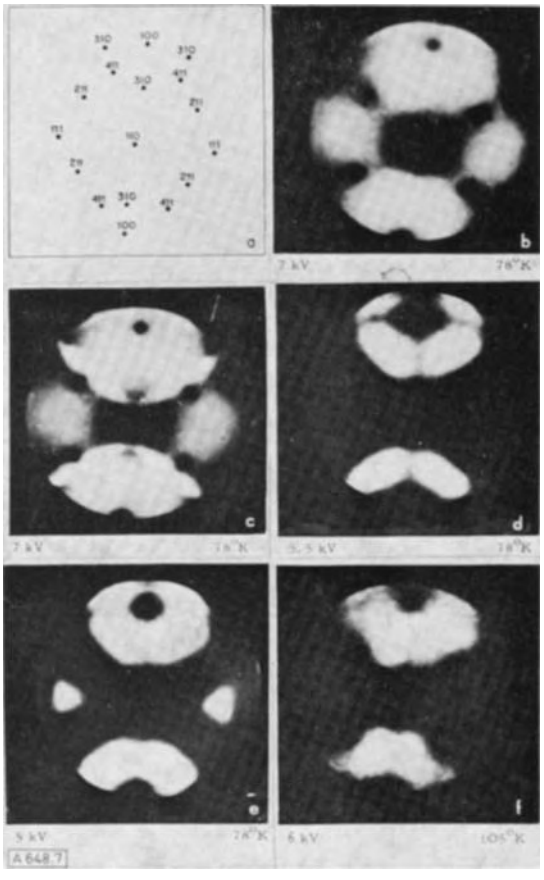

Fig. 7. Adsorption of xenon on tungsten at 78 °K.
a, positions of crystal faces. b, pure tungsten. c–e, increasing coverage with xenon. f, desorption at 105 °K.

At incipient adsorption (Fig. 7c) the areas between the dark (100) and (211) faces are occupied first – strikingly, with a sharp diffusion front, starting from the edge onwards. Visual observation, which cannot be shown photostatically, suggests similarity to a carpet being rolled out from the edges of the (211) faces. The area covered is denoted as the (411) area, after the indexing of its center; this does not mean to say, though, that this area is a smooth crystal face, but it refers to the fact that the configuration of the atoms in this area is essentially that of the (411) faces.

The physical cause underlying the phenomenon of the "unrolling carpet" is clear. The vast (111) and (211) faces serve as capturing areas for xenon. Part of the gas atoms striking these faces are reflected elastically; those that are retained are bonded loosely, so that at the prevailing temperature these atoms can move rapidly across the faces. As soon as they move over the edges into a (411) area they are at once precipitated, because there the heat of adsorption is higher and the rate of diffusion lower; that is why these areas are occupied from the edges onwards. As long as the (411) areas are still incompletely covered they act as "pumps" for xenon which is loosely adsorbed on the neighboring faces; accordingly, these faces are initially covered with xenon to only a very slight extent.

That this explanation is correct has been substantiated by *Ehrlich*'s measurements at 20 °K[19]. At this temperature adsorbed xenon can no longer move about freely; consequently the (411) areas and the (111) faces are, from the beginning, occupied at a comparable rate (the rates need not be exactly the same, because the sticking coefficients may be different), and the phenomenon of the unrolling carpet does not occur.

As soon as at 78 °K the (411) areas are completely covered with xenon they no longer act as "pumps"; the faces with the next highest heat of adsorption are then filled. Fig. 7d shows the state in which the (411) areas have just become more or less completely filled. In the mean time their emission has increased to such a degree that the acceleration voltage had to be reduced to avoid halation of the image and the other faces now appear dark. The apparent darkness is therefore only an indirect consequence of xenon adsorption. The state of coverage of the "second-best" areas ((111) faces and their immediate surroundings) is shown in Fig. 7e. Continued supply of xenon does not bring about any further change of the emission phenomena; hence, as far as can be observed visually, the areas appearing as dark patches are not covered with xenon. Unfortunately, no probe-hole measurements have yet been made, this being the only way to decide whether the F–N parameters of the apparently bare areas are really identical with those of the same areas before admission of xenon. From the F–N line for the total emission it appears that xenon adsorption causes the average work function of tungsten to be lowered by 1.4 eV.

When the tip temperature is increased to 105 °K the (111) faces are rapidly, the (411) areas more slowly freed from xenon. The rates and eq. (13a) and (11) afford a heat of adsorption of 7.5 kcal/gat (8–9 kcal/gat[68]) for the (411) areas and of 5 kcal/gat (5 kcal/gat[68]) for the (111) faces.

The absolute value of the surface potential and the face specificity of the heat of adsorption are particularly interesting on account of their generalizability. That adsorbed xenon reduces the work function of tungsten had already been demonstrated experimentally by *Mignolet*[70] by contact potential measurements. This finding is in agreement with the view that the sign of the surface potential ($-\Delta\varphi$) must be identical with that of the difference ($\varphi-\psi$), with φ standing for the work function of the adsorbing metal and ψ for

[70] *J. C. P. Mignolet*, Recueil Trav. chim. Pays-Bas *74*, 685 (1955).

the Mulliken electronegativity of the gas adsorbed[71,72]. It was not known, however, whether the FE microscope would give the same value as the other methods, for it was feared that the electric field applied would polarize the adsorbed atoms and that an induced dipole moment would thus be imposed upon the natural dipole moment of the adsorption bond. Since in the FE microscope the tip is negative and the screen positive, the induced dipole moment would have to have its negative pole directed outwards away from the metal. Since the adsorption dipole of the W–Xe bond is in a direction opposite to that of the induced dipole, it would be expected that the FE microscope would measure a lower surface potential than *e.g.* the contact potential method used by *Mignolet*[70]. The results show that this is not so; the FE value of 1.4 eV is even slightly higher than the value of 1.14 eV found by *Mignolet*. The difference can be explained by the different averaging methods. Hence, it would seem that the natural bond dipole of the adsorption bond is only slightly affected by the field of 0.4 V/Å. This conclusion is very important with regard to the suitability of FE microscopy for the study of adsorption complexes.

The heats of adsorption measured reveal that in thermodynamic equilibrium at 78 °K and at a low degree of coverage (so that the Xe atoms can freely choose their places) the ratio of the degrees of coverage of the two faces under consideration should be θ_{411}: $\theta_{111} = 10^7$:1, which is in agreement with the observation that the (111) faces remain practically empty until the (411) areas are filled. The face specificity of the heat of adsorption is apparently *not* due to the differences in local work function. On the contrary, since the electrons of the adsorbed xenon are polarized towards the metal it might have been expected that adsorption would be energetically most favorable in the areas of the highest work function, which is not confirmed by the experiments; the work function is highest for the (110) faces.

The preference for the (411) areas, on the other hand, is easy to understand upon considering the geometry of the adsorption centres. In the (411) areas atomic configurations of the type shown in Fig. 8 are predominant. They contain "troughs" in which a xenon atom fits exactly; a xenon atom in such a trough is in contact with six tungsten atoms at a time. No other crystal face of tungsten shows adsorption centers with so high a coordination number. Hence, the results support the hypothesis that for physisorption the strength of the adsorption bond largely depends on the number of nearest neighbors with which the adsorbed atom at an adsorption site is in contact. This principle even allows a quantitative prediction to be made regarding the heat of adsorption of xenon to be expected on other crystal faces, which is experimentally confirmed for the (111) faces – the only ones for which measured values are available.

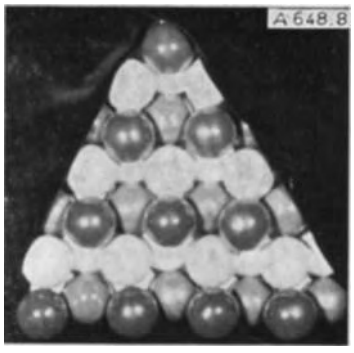

Fig. 8. Geometry of the (411) areas of tungsten.

As is known, physisorption is often used to determine the surface area of solid bodies. It is then important to know the area required per atom adsorbed. In the literature there are serious discrepancies on this point. For instance, for krypton values from 14.6 to 21 Å^2/atom are given[73]. These discrepancies become less surprising if they are considered in the light of the results discussed in this section, for these results suggest that the apparent area requirement per Xe atom is determined by the arrangement of the adsorption centers and, hence, may be different both for different crystal faces and for different metals. In this connection mention should be made of results obtained by *Ricca*[74].

5.2. The Tungsten/Carbon Monoxide System

There are few systems which have been examined as extensively as the W/CO system and for which the interpretations of almost equal experimental results are so widely divergent[19,33,49,56,57,75–83]. The consensus of opinion is that at temperatures up to a few hundred degrees Centigrade no appreciable dissociation of the CO molecule occurs and that at low temperature at least three types of chemisorbed carbon monoxide can be distinguished, to which at higher pressure and very low temperature physisorption must be added. These types can be distinguished by the desorption kinetics as well as by the parameters $\Delta\varphi$ and $\Delta \log A$.

Furthermore, it is commonly agreed that at least some parts of the adsorption process have an appreciable activation energy.

The state created upon adsorption of CO, at 77 °K, by clean tungsten is clearly distinct from the one resulting on a tip covered with CO at 300 °K and subsequently cooled to 77 °K. On the other hand, the state observed at 300 °K is independent of the route, *i.e.* independent of whether the adsorption is effected at 77 °K and the temperature is subsequently raised to 300 °K or whether the virgin tip is covered with CO at 300 °K (cf. Fig. 9).

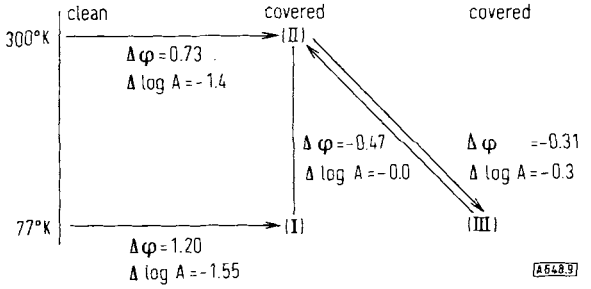

Fig. 9. FE results for the W/CO system [56].
$\varphi_0 = 4.50$ eV; $\log A_0 = -5.5$.

Significant differences of opinion, however, appear in the interpretation of the FI images. In *Ehrlich*'s opinion, all tungsten atoms remain in their places during chemisorption, and he postulates that chemisorbed CO molecules which escape promoted field desorption show up in the FI image as bright dots. *Holscher* and *Sachtler*, on the contrary, advance arguments according to which:

1) the great majority of molecules adsorbed on an undisturbed surface are removed by promoted field desorption and thus do not appear in the FI image;

2) chemisorption of CO, particularly at high coverage and elevated temperature, leads to rearrangement of the W atoms;

3) those CO molecules which manage to escape promoted field desorption (hence, in particular those which, after rearrangement, are embedded in the surface) do not produce bright dots in the FI image, but, on the contrary, reduce the ionization probability for impinging helium atoms and thus lower the image contrast.

To prove the first allegation there is the observation [49, 56] that at a low degree of coverage and low temperature the FI image cannot be distinguished from that of the clean tungsten, although the F–N parameters for this state, which were measured immediately before the image was taken, show unambiguously that the surface was covered with appreciable quantities of carbon monoxide before application of the imaging voltage. Since, however, the heat of adsorption decreases with increasing degree of coverage, it cannot be understood why at a low degree of coverage the strongly bonded CO molecules should be removed quantitatively by promoted field desorption, and at a high degree of coverage, under the same conditions, the much more weakly bonded CO molecules should not be torn off.

If the first allegation is correct the second can hardly be evaded, as the considerable disturbance of the FI image after CO adsorption – particularly at a high degree of coverage or with adsorption at room temperature – must be due to a physical cause (cf. Fig. 10a and b).

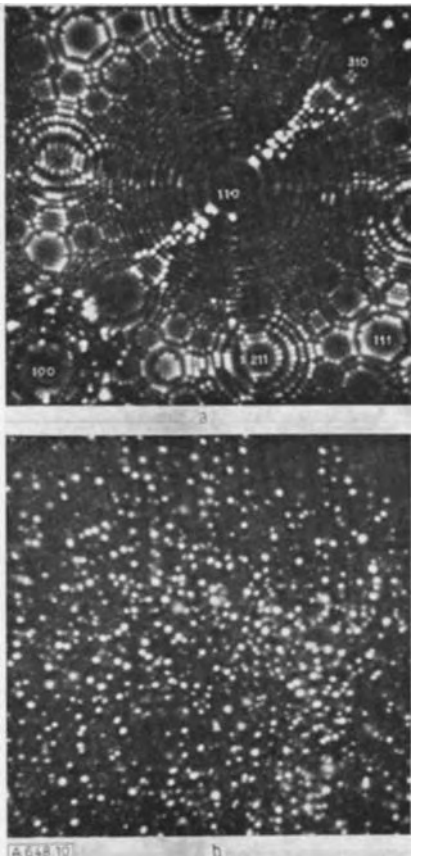

Fig. 10. Comparison of FI images of tungsten (a) before and (b) after chemisorption of CO at 300 °K. Images at 77 °K and at 8.05 and 9.6 kV, respectively.

An independent argument for the second allegation is the increase of the disturbance observed in the FI image with increasing degree of coverage and rising temperature. It is precisely what is to be expected for a rearrangement process, whose activation energy must, of course, be positive and decrease with increasing degree of coverage, if it is true that the metal-metal bonds inside the surface are progressively weakened as the adsorption proceeds. If, on the other hand, adsorbed molecules were directly responsible for the additional dots of light it would rather be expected that the number of these dots would decrease with rising temperature.

A further proof of the second allegation is supplied by an experiment in which after chemisorption the metal atoms of the surface are carefully removed by field evaporation. If it is true that metal atoms leave their places in the surface during chemisorption they should leave behind as many vacancies. At not too low temperatures these vacancies will move into the interior of the crystal through an atom located at some depth hopping into the free place. Accordingly, chemisorption would inject vacancies into the crystal. If afterwards the surface atoms are removed by field evaporation and layer after layer is thus carefully "peeled off" until an undisturbed surface is again exposed, the number of lattice planes indirectly disturbed by chemisorption can be counted.

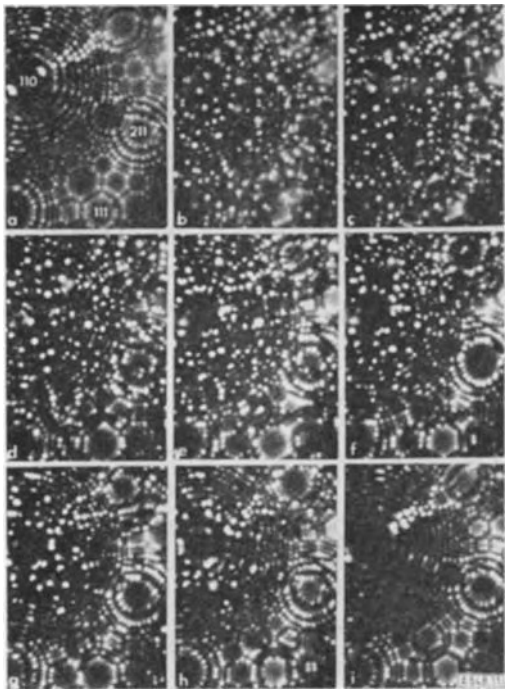

Fig. 11. Field desorption and field evaporation of surface layers after chemisorption of CO on tungsten at 300 °K.

The first picture of Fig. 11 shows the original tungsten surface, the second the state immediately after chemisorption. Subsequently, the field strength was increased stepwise (the photographs were taken at equal field strength, however). Accurate analysis reveals that four layers of tungsten had to be "peeled off" to uncover another undisturbed surface (see last picture). Hence, the lattice disturbances injected by chemisorption had, at 300 °K, migrated into the crystal to a depth of four layers.

We shall not go further into the third allegation – that chemisorbed molecules produce, not bright dots, but perhaps diffuse patches – because an extensive account of the subject will appear elsewhere [84]. Suffice it to say that this allegation follows from theoretical considerations and was confirmed experimentally in particular for the W/N_2 system; for this system diffuse "nebulous patches" were demonstrated that could be removed through field desorption.

If all the phenomena observed on the W/CO system are taken together, this leads to a new, logical, classification of chemisorption phenomena superseding the classification by state (with the Greek alphabet as labeling parameter). For chemisorption we distinguish:

a) Adsorption on an undisturbed crystal surface (*chemi-adsorption*);

b) A rearrangement of atoms, following a) and creating a highly stable state of favorable mutual coordination. On account of its fundamental similarity to corrosion this process is called *surface corrosion or corrosive chemisorption* [41].

c) As in the course of process b) metal atoms or ions which were first covered during a) once more reach the surface, adsorption occurs again. The energetic incentive for this is the same as in adsorption on the cations in the surface of an oxide or chloride, in particular the tendency of these ions to surround themselves by an optimum number of ligands. Thus, this adsorption is called *ligand adsorption.*

An important point is that the transition (a) → (b) may occur before (a) has reached the state of complete coverage. As the activation energy for this transition has different values on different crystal faces, atomic reconstruction of different crystal faces does not, in general, take place simultaneously. The dipole moment projected on the normal to the surface is larger for (a) than for (b), because in (b) the dipoles are no longer perpendicular to the surface but possess a considerable tangential component. Indeed it was established experimentally that the work function decreases during the transition (a) → (b).

In the W/CO system the stable final state of surface corrosion (b) corresponds to the β state of the nomenclature used earlier. At 77 °K state (a) and physisorbed carbon monoxide predominate on the surface; at a high degree of coverage state (b) can just be detected. At 300 °K, on the other hand, states (b) and (c) are predominant.

5.3. The Tungsten/Nitrogen and Tungsten/Hydrogen Systems

The chemisorption of nitrogen on tungsten was investigated in several ways [19,29,30,33,49,57,66,83–86]. As with the W/CO systems, the FI images obtained after chemisorption at room temperature show very little order; the disturbance at 77 °K is even more pronounced than with CO and seems to depend, not only on the degree of coverage, but also on the rate at which the nitrogen was transferred to the tungsten surface. And once again the results that were practically equal are interpreted in different ways by two authors. *Ehrlich* [57] assumes that the chemisorbed nitrogen atoms themselves appear in the image as bright dots; *Holscher* [49], on the contrary, believes that it can be shown that these dots are produced by tungsten atoms after rearrangement, the argumentation being similar to that used for the W/CO system. Again, the stable state, which in *Holscher*'s opinion is created by surface corrosion, corresponds to the β state of the earlier terminology.

The impression may be that surface corrosion occurs with the chemisorption of any gas by any metal at room temperature. But this is not justified, as is illustrated by the tungsten/hydrogen system. In this system chemisorption does not bring about any changes in the image [49]. This refutes the suspicion that the effects found for nitrogen and carbon monoxide may not be brought about by chemisorption at all, but rather by some peculiarity of FI microscopy. Strictly speaking, the very fact that in the W/H_2 system any rearrangement fails to come about is an important argument in favor of the assumption that the chemisorption of N_2 or CO is accompanied by

[84] *A. A. Holscher* and *W. M. H. Sachtler*, Proc. Battelle Meeting 1968, in press.

[85] *T. A. Delchar* and *G. Ehrlich*, J. chem. Physics *42*, 2686 (1965).

[86] *T. Oguri*, J. physic. Soc. Japan *18*, 1280 (1963); *ibid. 19*, 83 (1964).

surface corrosion. For, while tungsten is capable of forming a stable nitride with nitrogen and a stable hexacarbonyl with carbon monoxide, a tungsten hydride does not seem to be stable. From this point of view the absence of corrosion phenomena can be understood. For chromium, which is homologous to tungsten and of which a hydride of low stability – Cr_7H_2 – is known, the remarkable fact has been established that the hydride formation is not attended by a real rearrangement of the metal atoms; the chromium lattice is only slightly expanded – just as in the case of hydrogen adsorption by palladium the lattice is not broken down but only widened. Indeed, according to *Pauling*, the stability of these hydrides is largely due to the metal-metal bonds. Hence, on the basis of the same chemical arguments that lead us to expect a rearrangement of the tungsten atoms for the W/N_2 and W/CO systems a similar rearrangement is excluded for the W/H_2 system. Thus, the experimental findings confirm the expectation also for this system.

The W/H_2 and W/N_2 systems were investigated with the aid of FE microscopy [29,30,42,86–89]. Only for the W/N_2 system have probe-hole measurements been performed, and these produced a result which was at first amazing: nitrogen chemisorption causes the work function of the tungsten on many crystal faces to be increased, on others to be lowered. *Oguri* [86] as well as *Holscher* [30,49], *Van Oostrom* [29], and *Delchar* and *Ehrlich* [85] arrived at this experimental result. Although the $\Delta\varphi_{hkl}$ values reported by the various authors differ, the difference in sign on different crystal faces is no longer a point of discussion.

The interpretation of this finding is still a speculative one. In general it is assumed that it is not the elementary bond dipole proper, but the orientation of the dipoles with respect to the surface normal that is different. According to whether the nitrogen is above or below the surface the component of this vector in the direction of the surface normal has a different sign.

This opinion is shared also by *Ehrlich* [85], who rejects the rearrangement of atoms. He assumes that nitrogen atoms on the rough metal surfaces can penetrate into the "electron gas" without being sterically hindered by the tungsten atoms, which remain in their places. To reconcile this assumption with the results *Delchar* and *Ehrlich* have to invoke a number of postulates; for instance, the (100) face is to be considered a smooth one, the (211) face a rough one; moreover, the nitrogen atom must be the positive, the tungsten atom the negative pole of the elementary bond dipole, although on the basis of electronegativities the opposite would be expected. Besides, this picture would lead to serious difficulties if it were applied, for instance, to the adsorption of hydrogen on tungsten or other metals.

The experimental results can, in our opinion, be interpreted in a more convincing manner if the possibility of surface corrosion is taken into account. That this corrosion may lead to the normal component of the dipole moment vector being reduced has already been established for the W/CO system. It is not difficult to imagine for N_2 – whose chemisorption, unlike that of CO, is dissociative – that during surface corrosion nitrogen atoms will even occupy places beneath the tungsten atoms. As already mentioned, the activation energy for these rearrangements must be face-specific. If the simplest assumption is made, viz. that the rearrangements will occur soonest on those crystal faces where each tungsten atom has the smallest number of nearest (tungsten) neighbors, it can be understood that it is the (100) faces and the (611) areas where the W–N bond dipoles are first seen "from behind". These bond dipoles are polarized as $W^{\oplus}-N^{\ominus}$, in accordance with the electronegativity rule discussed in Section 5.1 [71,72]: $(-\Delta\varphi) \approx (\varphi-\psi)$.

6. Concluding Remarks

Investigations with the aid of the FE and the FI microscope have provided fundamental contributions to the understanding of adsorption and heterogeneous catalysis. After many years of qualitative speculation, concepts like face specificity, adsorption states, and atom rearrangements have become accessible to exact measurements. Considering that the available experimental material mainly refers to a single metal and a small number of inorganic adsorbates it is not difficult to predict that further research on these problems will provide a wealth of valuable information.

Experimental difficulties are dwindling. During the past decade the ultra-high vacuum technique has developed into a standard method for the study of chemisorption on metals. Direct-current sources of sufficient stability as well as image intensifiers – the latter as a by-product of space research – are now commercially available. Liquid hydrogen is available in many places, as it is also required for other research purposes. (For that matter, all results discussed in the present article have been obtained *without* an image intensifier, and FI images of only slightly reduced quality can also be produced at the temperature of solid nitrogen.)

The further development of this field of research is retarded by theoretical rather than by experimental problems. This can be illustrated, for instance, by the fact that studies on the same adsorption system by different investigators lead to practically the same experimental results, which are often interpreted in widely different ways. Considering the poor theoretical basis underlying these interpretations this is not surprising. Therefore, a survey of the application of FE and FI microscopy to research on chemisorption by metals can hardly end otherwise than by making an appeal to theoretical physics. Even the theory of the electron work functions is highly unsatisfactory and far from capable of making quantitative statements. For the work functions of alloys both theoretical starting points and experimental data are lacking [111].

[87] *T. W. Hickmott*, J. chem. Physics *32*, 810 (1960).
[88] *R. Gomer* and *R. Wortman*, J. chem. Physics *23*, 1741 (1955).
[89] *R. Wortmann*, *R. Gomer*, and *R. Lundry*, J. chem. Physics *24*, 161 (1956).

Far more serious for FE microscopy is the fact that the work function is a quantity which can only be defined macroscopically and which, like the surface potential and the Helmholtz equation, loses its meaning if – as is done with the probe-hole technique – the adsorption of a single atom on a minute face element consisting of only a few atoms is considered. It is also doubtful whether the theory of the metallic state can be applied to surfaces largely covered with a metalloid adsorbate. As is known, there is much to be said for the supposition that the surface atoms are demetallized through adsorption [41, 53, 49, 90].

For FI microscopy, in which the individual surface atom plays an even more predominant role than in FE microscopy, the question is raised as to whether the band model of the metallic state may still be applied. What is certain is that the Sommerfeld approximation of the quasi-free electron is an unsuitable starting point, as in this simplest model the parameters of the atoms are amalgamated to those of the band, whereas FI microscopy, conversely, resolves the metal continuum into discrete atoms. A description in terms of the band model, therefore, is acceptable only if it is based on approximations in which the atom cores embedded in the "electron gas" are explicitly considered.

[90] *K. D. Rendulic* and *Z. Knor*, Surface Sci. (Amsterdam) 7, 205 (1967).

It should be borne in mind that all theories of the metallic state have primarily been designed for the interior of the three-dimensional metal. *Dowden* [91] and *Bond* [92] are of the opinion that extrapolation to the metal surface is most promising if it is based on approximations taking into account the spatial orientation of the metal bonds. From this point of view, the models formulated by *Goodenough* [93] and *Trost* [94], in which the spatial orientation of the bonds in the metal is regarded as a consequence of the crystal field, are of particular interest.

As long as no molecular orbital theory of the metal surface or even a theory of the surface demetallized through chemisorption is available, the physicochemist must, of necessity, continue to use the rather crude theoretical tools with which FI microscopy has reached its present, impressive, degree of development.

On the Chemistry of Clay[**]

BY U. HOFMANN[*]

Kaolinite, illite, chlorite, montmorillonite, and vermiculite are among the most important of the clay minerals. Cations are embedded between the silicate layers and on the basal faces of the crystals. Whereas only the cations on the outer faces are exchangeable in the first three of the above minerals, those between the layers can also be replaced by others in montmorillonite and vermiculite. These characteristics and the ability of montmorillonite and vermiculite to undergo intracrystalline swelling and to form inclusion compounds are responsible for the industrial importance of kaolin and clay. The structure of halloysite is particularly interesting, since the silicate layers in this case are rolled up to form tubes. The possible role of the clay minerals as catalysts in the formation of petroleum and in the beginning of life is finally discussed.

1. Form and Crystal Structure of Some Clay Minerals

Only 40 years ago, practically nothing was known about the clay minerals. The reasons for this are that their crystals are so small that they cannot be observed under the optical microscope and that a clay or kaolin is generally a mixture of several minerals. The discovery of the clay minerals was only made possible by X-ray interferences, and the electron microscope soon afterward made it possible to observe their crystals. The clay minerals are very numerous, but we shall deal here only with a few of the important ones.

[**] Based on a plenary lecture to the General Meeting of the Gesellschaft Deutscher Chemiker in Berlin, September 1967.

1.1. Electron Micrographs

The electron micrograph of a well formed kaolinite, which is the principal clay mineral in kaolins, is shown

in Figure 1. The crystal platelets, which are often hexagonal, have a diameter of about 5000 Å and a thickness of about 500 Å.

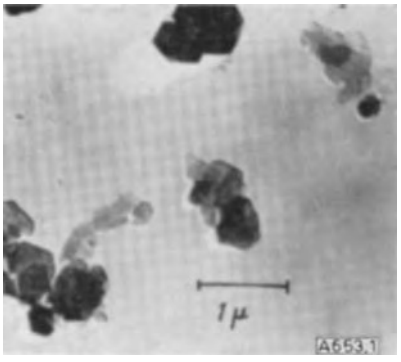

Fig. 1. Electron micrograph of a kaolinite, shadowed with chromium at an angle of 20°.

Figure 2 shows the electron micrograph of a kaolinitic clay, which is characterized, above all, by the presence of very small and very thin crystal platelets that are mostly no longer hexagonal. Their average diameter is 1200 Å and their average thickness 250 Å.

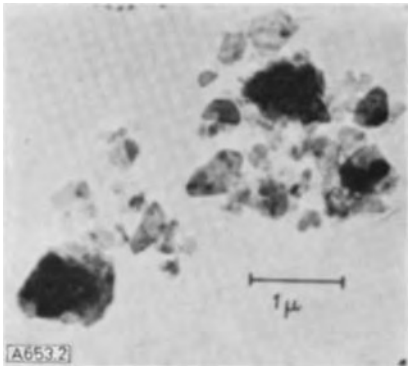

Fig. 2. Electron micrograph of a kaolinitic clay.

Figure 3 shows the electron micrograph of a micaceous clay mineral often known as illite. This mineral rarely occurs in high concentrations, but is often present in clays and sometimes in kaolins, and is particularly frequently the clay mineral present in arable soil. The crystals are irregularly shaped, and are often very small and very thin.

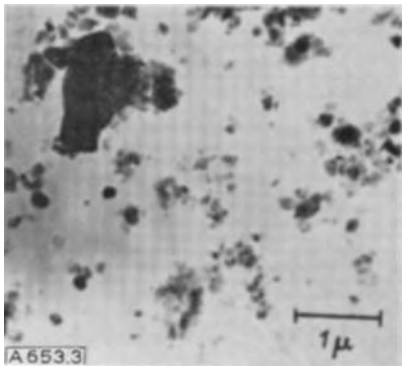

Fig. 3. Electron micrograph of an illite.

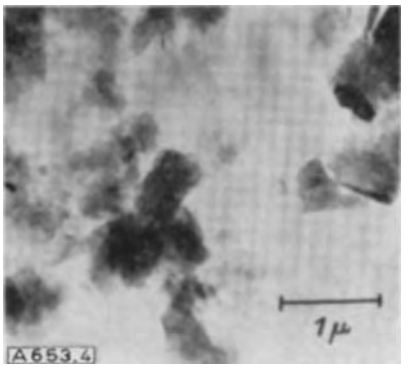

Fig. 4. Electron micrograph of a chlorite.

Figure 4 shows the electron micrograph of a chlorite, which occurs in high concentrations *e.g.* in shales. Chlorite also occurs as the clay mineral in arable soils. The crystals are generally thin lamellae whose diameters are not very small, and which have an irregular outline.

1.2. Crystal Structures

The crystals of the clay minerals mentioned above are platelets and, accordingly, have a layer structure. Figure 5 shows the crystal structure of kaolinite. The structure of the silicate layer was predicted by *Pauling* [1] as early as 1930; a (lower) tetrahedral layer of Si and O is condensed with an (upper) octahedral layer of Al and OH, thus giving the formula $Al_2(OH)_4[Si_2O_5]$. *Hendricks* [2] and *Brindley* [3] established the sequence of the stacked silicate layers, and suggested that the octahedral layer is bound to the tetrahedral layer above by hydrogen bonds to the O atoms.

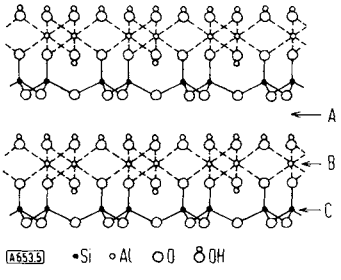

Fig. 5. Crystal structure of kaolinite. A: hydrogen bonds, B: octahedral layer; C: tetrahedral layer. b = 8.93 Å, distance between layers = 7.15 Å.

In fine-particle clay, the silicate layers of the kaolinite exhibit a parallel displacement in relation to one another. The clay is then known as the "fireclay type" [4]. This lattice disturbance is also observed, though to a smaller extent, in kaolins. It is intensified in particular by dry grinding.

The micaceous clay mineral illite was extensively studied in 1937 by *Hofmann* and *Maegdefrau*[5] and by *Grim*[6]. Its structure can be derived from that of coarsely crystalline mica[7,8]; the silicate sheet consists of two tetrahedral layers with the vertices of the tetrahedral pointing inward, these two layers being joined by an octahedral layer (Figure 6). Some of the Si atoms in the tetrahedral layers are replaced by Al atoms, thus giving the silicate sheet a negative charge, which is neutralized by potassium ions situated between the sheets. Al in the octahedral layer may also be replaced by Mg, Fe^{II}, Fe^{III}, *etc.*

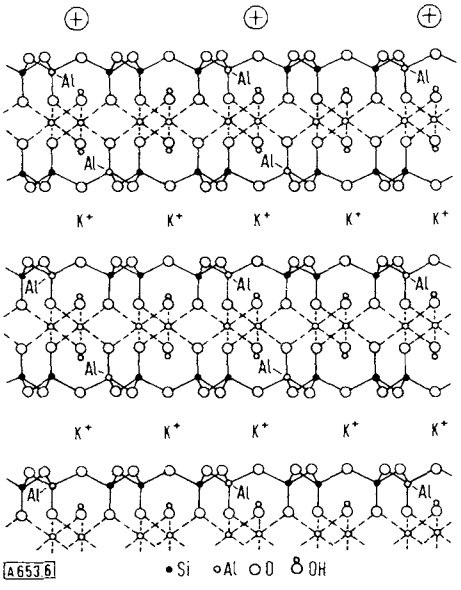

Fig. 6. Crystal structure and cation exchange of mica. Top: a free basal surface with exchangeable cations (⊕); the K ions of the two inner layers are not exchangeable.

Illite is much more finely crystalline than the coarse mica (cf. Fig. 3). It generally has a lower content of potassium ions, as well as distortion of the lattice by parallel displacement of the silicate sheets, so that it can often be indexed as orthorhombic[5]. If the octahedral layer contains mainly trivalent ions such as Al^{3+}, the mineral is described as "dioctahedral", while if this layer contains mainly bivalent ions such as Mg^{2+}, the mineral is "trioctahedral".

Chlorite consists of an alternation of micaceous silicate sheets with magnesium hydroxide or aluminum hydroxide sheets[1,9]. As in illite, the chemical composition may be varied by the replacement of Si by Al and of Mg by Al, Fe^{II}, Fe^{III}, *etc.* The micaceous silicate sheets and the hydroxide sheets are probably oppositely charged and held together in this way. Hydrogen bonds from the hydroxide sheets to the O atoms of the tetrahedral layers may also contribute to the bonding between the layers. Most chlorites are close to the trioctahedral type, though dioctahedral types also occur.

The crystal structure of montmorillonite[10] is shown in Figure 7; the structure of the silicate layers is the same as in mica sheets. An interesting characteristic of montmorillonite is its ability to absorb water (according to the water vapor pressure) between the silicate sheets, with simultaneous unidirectional intracrystalline swelling, perpendicular to the sheets. This intramolecular swelling also occurs with other polar liquids.

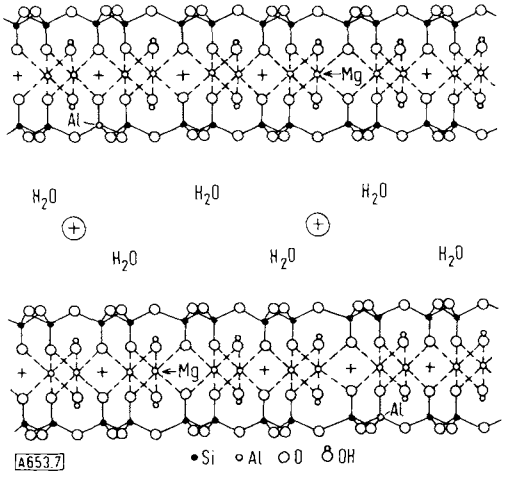

Fig. 7. Crystal structure and intracrystalline swelling of montmorillonite. ⊕ = exchangeable cations; *b* approx. 9 Å; distance between layers approx. 10—20 Å (15.5 Å).

Montmorillonite is occasionally found in clays and kaolins. Clays having high montmorillonite contents are called bentonites. The cations in the tetrahedral and octahedral layers may be replaced in the same way as in micas. Montmorillonite with a high iron content is known as nontronite, whereas the trioctahedral form with a high magnesium content is called saponite or hectorite[11]. As a result of intracrystalline swelling, the silicate sheets lose their orientation with respect to one another, and one then obtains only the interferences of the distance between sheets (001) and the cross-lattice interferences (*hk*) of the individual silicate sheets.

Vermiculite corresponds to a trioctahedral montmorillonite, though its crystals are much larger, occasionally having diameters of up to many cm, and the crystal lattice is more regular. Vermiculite containing no iron is called batavite[12].

Illites having high iron contents are green, and are known as glauconite or seladonite; they are the pigment of veronese green. The Mössbauer spectrum of a glauconite containing 15 % of iron calculated as Fe_2O_3 and 1 % as FeO[13] showed only the γ absorption of Fe^{III} in the octahedral arrangement, and, in agreement with the chemical analysis, no Fe^{II}. Fe^{III} in the octahedral layer possibly colors the mineral green. The same is true of green nontronite, chlorite, and many others.

Table 1. Formulas of some clay minerals.

Mineral	Formula
Kaolinite	$Al_2(OH)_4[Si_2O_5]$
Illite (micaceous clay)	$\approx K^+_{\sim 0.7}\{(Al_2, Mg_3, Fe^{III}_2, Fe^{II}_3)(OH)_2[Si_{3.3}Al_{0.7}O_{10}]\}^{0.7-}$
Montmorillonite	$\approx \{(Al_2, Mg_3, Fe^{III}_2, Fe^{II}_3)(OH)_2[Si_{3.6}Al_{0.4}O_{10}]\}^{0.4-} + 0.4\ M^+$
Vermiculite	$\approx \{(Mg_3, Al_2, Fe^{II}_3, Fe^{III}_2)(OH)_2[Si_{3.35}Al_{0.65}O_{10}]\}^{0.65-} + 0.65\ M^+$
	octahedral layer tetrahedral layer

The structure of halloysite is discussed in Section 1.4. The formulas of the clay minerals are summarized in Table 1.

1.3. Exchangeable Cations

All clay minerals contain exchangeable cations. *Weiss* [14] found that in very finely cleaved micas and in illite, only the potassium ions on the free basal planes are exchangeable. Within the limits of accuracy, the quantity of exchangeable cations agrees quantitatively with the quantity of potassium ions between two silicate sheets in the interior of the crystal. These potassium ions cannot be exchanged. Cation exchange at the edges of the silicate sheets is normally improbable, and may be disregarded (cf. Fig. 6).

The exchangeable cations in nature are mostly calcium and magnesium ions (action of hard water).

The chemical analysis of kaolinite agrees to within the limits of accuracy with the formula, and no substitution of ions that might lead to a negative charge on the crystals has been detected. *Weiss* [15] was able to dissolve kaolinite crystals from the basal surface (octahedral layer) with ammonium fluoride solution. The cation-exchange capacity, based on the original quantity of kaolinite, remained unchanged. It therefore appears that exchangeable cations are practically confined to the basal surface, where the tetrahedral layer is exposed. It is possible that only this one outermost silicate layer carries a negative charge as a result of substitution of its ions.

Weiss [16] has drawn up a table of minerals that in principle contain the same silicate layers. The series extends from pyrophyllite and talc, with the formulas $Al_2(OH)_2Si_4O_{10}$ and $Mg_3(OH)_2Si_4O_{10}$ respectively, in which there are no cations between the silicate layers, to the micas. An extract from this table is shown in Table 2.

Intracrystalline swelling is observed in clay minerals having a medium cation density between the silicate layers. It is caused by the hydration of these cations, which draw the water in between the silicate sheets. If there are no cations between the silicate sheets, the mineral cannot swell. Moreover, if the cation density between the sheets is too high, as *e.g.* in muscovite, the Coulomb forces between the cations and the silicate layers are too great; these forces hold the sheets together, and no swelling takes place. The silicate sheets are held together particularly strongly by potassium ions (see *e.g.* vermiculite). Potassium ions are less strongly hydrated than sodium ions or alkaline earth metal ions, and their size is such that they fit very well into the 12-coordination offered them by the O atoms of the two tetrahedral layers [17].

Table 2. Intracrystalline swelling of layer silicates (after *A. Weiss* [16].

Mineral	Equiv. cations per formula unit [a]	Layer distance (Å) with: Alkaline earth ions dry	Alkaline earth ions in H_2O	K^+-Ions dry	K^+-Ions in H_2O	Na^+-Ions dry	Na^+-Ions in H_2O
Pyrophyllite, Talc	0	constant 9.2					
Montmorillonite	0.24–0.5	11.5	20	10	∞	10	∞
Vermiculite	0.65	11.5	14.5	10	10	10	15
Illite	0.7	—	—	10	10	—	—
Muscovite	0.8–1.0	—	—	10	10	—	—

[a] $(M^{III}_2, M^{II}_3)(OH)_2[(Si, Al)_4O_{10}]$

Alkaline earth metals ions allow only limited swelling in water; up to four layers of water are incorporated in montmorillonite, and up to two layers in vermiculite. Sodium and potassium ions give infinite swelling

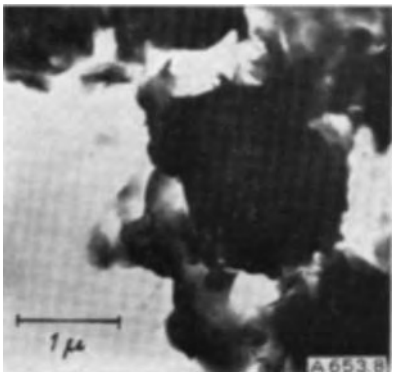

Fig. 8. Electron micrograph of a montmorillonite having exchangeable alkaline earth ions.

[14] *Armin Weiss*, Z. anorg. allg. Chem. *297*, 257 (1958).

[15] *Armin Weiss*, Z. anorg. allg. Chem. *299*, 92 (1959).

[16] *Armin Weiss*, *G. Koch*, and *U. Hofmann*, Ber. dtsch. keram. Ges. *32*, 12 (1955); *U. Hofmann*, Kolloid-Z. *169*, 58 (1960).

[17] *Armin Weiss*, Lecture to the Chemical Society Heidelberg, Jan. 23, 1968.

in montmorillonite, *i.e.* the crystal separates into individual silicate layers.

Figure 8 shows the electron micrograph of a montmorillonite having exchangeable alkaline earth ions; as usual, the sample was prepared from a suspension. In the suspension, the silicate layers move toward one another and dry in such a way that their original outline is indistinct.

The electron micrograph of a freeze-dried montmorillonite gel having exchangeable sodium ions gives a picture of the type shown in Figure 9. Owing to the intracrystalline swelling, the silicate sheets had separated singly or a few at a time. In the gel they form a framework structure with water trapped in its cavities. The silicate layers are flexible, and can be folded like silk ribbons.

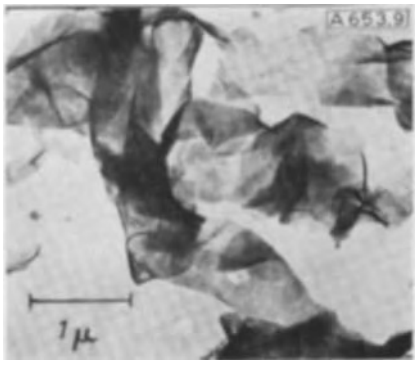

Fig. 9. Skeletal structure of a freeze-dried gel of montmorillonite having exchangeable sodium ions.

If a suspension of a montmorillonite with exchangeable sodium ions is evaporated to dryness for examination in the electron microscope, a film of flat silicate layers is obtained.

Table 3 shows that the content of exchangeable cations in kaolinite, chlorite, and illite increases with decreasing thickness of the crystal platelets. In montmorillonite and vermiculite, the cations between the silicate layers can also be exchanged.

Table 3. Content of exchangeable cations (M^+) in the clay minerals.

Mineral	M^+ (mequiv/100 g)
Kaolinite	1—20
Chlorite	3—40
Illite	10—50
Montmorillonite	60—130
Vermiculite	100—170

1.4. Halloysite

Halloysite occurs in two forms, one having a high and the other a low water content. In the form with the high water content, $Al_2(OH)_4[Si_2O_5]\cdot 2\,H_2O$, [$d(001)$ = 10.1 Å], the kaolinite and water layers alternate. The water is eliminated at about 50 °C to give the form having the low water content [$d(001)$ = 7.3 Å], which consists only of kaolinite layers ($Al_2(OH)_4[Si_2O_5]$) [18]. The crystal structure [19] of the highly hydrated halloysite is shown in Figure 10.

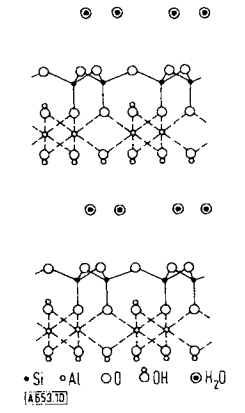

Fig. 10. Crystal structure of the highly hydrated form of halloysite. Distance between layers = 10.1 Å.

The electron micrograph of halloysite having a low water content (Fig. 11) shows fine needles. A needle shape can also be discerned in the highly hydrated halloysite by means of replicas. Closer examination shows that the needles are in fact tubes [20], smaller tubes often being inserted in larger ones. The tubes are most clearly seen in surface replicas [21, 22]; carbon

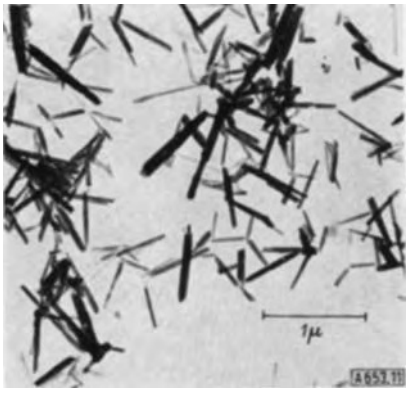

Fig. 11. Electron micrograph of halloysite.

is vaporized onto a piece of halloysite, and the halloysite is subsequently dissolved out with hydrofluoric acid. Halloysite tubes remain embedded in the carbon layer, and it is occasionally possible to see them very clearly in end view (Fig. 12).

It can be seen from Table 4 that the outside diameter as found under the electron microscope gives a smaller calculated surface area if the tubes are assumed to be

These tubes are probably formed as follows. An individual kaolinite silicate layer is formed first, but this layer carries a negative charge as a result of substitution of its ions, and it also carries exchangeable cations. The hydrated cations prevent the formation of hydrogen bonds and hence also combination with another silicate layer. In the single silicate layer, the *a* and *b* axes along the tetrahedral layer (8.95 Å) are theoretically greater than the *a* and *b* axes of the octahedral layer (8.65 Å). In the kaolinite crystal, the hydrogen bonds brace the octahedral layers against the tetrahedral layers of the adjacent silicate layer, and so keep the crystal planar. In halloysite, on the other hand, the individual kaolinite-like silicate layers are able to roll up into a spiral tube, taking with them a layer of water between the silicate layers as a result of the hydration of the cations (Figure 13) [22, 24].

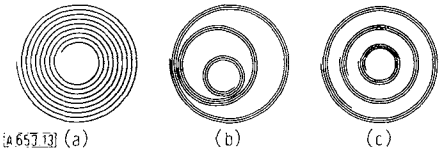

Fig. 13. Cross section through the spiral of the halloysite tube. (a) Highly hydrated form; (b) low water content form; (c) low water content form, silicate layer broken into three tubes.

[23] *R. Reingraber*, Dissertation, Universität Heidelberg, 1968.

[24] Unpublished work by *A. Weiss*.

Kaolinite that has been split into extremely thin layers *via* inclusion compounds can be rolled into halloysite-like tubes by careful treatment [25].

The *b* axis of the kaolinite lattice generally becomes the fiber axis for the halloysite tube.

If the water is driven out of the highly hydrated form of halloysite, the spirals roll up more tightly. They occasionally split in the longitudinal direction to give narrow halloysite tubes inside wider tubes.

Halloysite has a higher cation-exchange capacity in the high-hydration than in the low-hydration state, since some of the cations in the latter are shut in. The content of exchangeable cations is generally between 5 and 30 mequiv/100 g of mineral.

1.5. Dimensions of the Crystals of the Clay Minerals

To determine the average diameter $\bar{d}$ of the crystal platelets of kaolinite and illite, about 1500 crystal platelets were measured in the electron micrograph of each kaolin or clay.

The specific surface area *O* of the clay mineral crystals has been determined by adsorption of nitrogen at its boiling point as described by *Brunauer, Emmett*, and *Teller* (BET method). The best preparations for this purpose are those obtained from gels by freeze-drying, the nitrogen evidently penetrating into the gaps between the crystals of the clay mineral. However, the determination is meaningful only if there is no intracrystalline swelling of the mineral, since the inner surface is not reached in the adsorption of nitrogen. The same area is obtained on determination by the adsorption of phenol from decalin solution.

The thickness *h* of the crystal platelets can be determined from the surface area and the diameter [26]:

$$h = (2\bar{d}^3/\bar{d}^2)/((\rho \cdot O \cdot \bar{d}^3/\bar{d}^2)-4)$$

The density ρ was taken to be 2.6 g/cm³. It is assumed in this equation that the thickness *h* is proportional to the average diameter $\bar{d}$ for any clay mineral crystal. If the calculation is carried out by another equation, in which all particles are assumed to have the same average thickness *h*, the values obtained for the average thickness are smaller. However, the assumption made for the equation given above is more probable.

The results agree very satisfactorily with the average thickness found by measurement of the shadow in the electron micrograph after oblique shadowing. Though the method used for the calculation of the thickness is not very accurate,

[25] *J. Russow*, Dissertation, Universität Heidelberg, 1965.

[26] *U. Hofmann, H. P. Boehm*, and *W. Gromes*, Z. anorg. allg. Chem. *308*, 143 (1961); *U. Hofmann et al.*, Ber. dtsch. keram. Ges. *44*, 131 (1967).

this comparison shows that the value obtained is approximately correct, and is too high rather than too low. It can be seen from Table 5 that kaolins are coarser than clays.

Table 5. Average diameter $\bar{d}$ and average thickness $\bar{h}$ of the crystals of kaolins and clays.

Material	$\bar{h}$ (Å)	$\bar{h}$ (Å)
Very coarse kaolin	7000	1500
Very fine kaolin	2500	340
Very coarse clay	2000	500
Very fine clay	1000	150

1.6. Activities of the Exchangeable Cations

When kaolin is liquefied with soda, calcium ions in the kaolinite are replaced by sodium ions, and sparingly soluble calcium carbonate precipitates out. A bentonite is activated in the same manner.

The cation exchange involves an equilibrium, which is clearly discernible even when a sparingly soluble salt is formed. The equilibrium in the aqueous solution can be described *e.g.* as follows:

$$\text{Ca-kaolinite} + 2\ Na^+ + C_2O_4^{2-} \rightleftharpoons \text{Na}_2\text{-kaolinite} + CaC_2O_4$$

The existence of an equilibrium can be demonstrated by shaking a sodium kaolinite with an excess of calcium oxalate in water. Calcium kaolinite and $Na_2C_2O_4$ are formed. Alternatively, when sodium kaolinite is shaken with $BaSO_4$, a barium kaolinite and Na_2SO_4 are obtained [27].

The concentrations or activities of the Na and oxalate ions in the above equilibrium can be determined in the separated aqueous solution. If a known quantity of $Na_2C_2O_4$ has been added to a pure calcium kaolinite, it is also possible to determine the position of the equilibrium. The activity of the Ca ions in the solution can be calculated from the solubility product of the sparingly soluble calcium oxalate and the measured activity of the oxalate ions. The activity in this case is equated to the activity of the Ca ions which remain on the kaolinite.

Table 6 shows the activities of cations on a clay mineral that is covered half with the cation in question and half with Na ions. These activities are one or more orders of magnitude lower than the activities of the same cations over the sparingly soluble salt in pure water.

This method naturally cannot be used to find the activity, in pure water, *e.g.* of the Ca ions on a kaolinite whose exchangeable cations have been completely replaced by Ca ions. However, the curves in Figure 14 show that even when 90 % of the exchangeable cations are calcium, the activity of the Ca ions is still very low. Exchangeable K, Mg, Ca, Ba, and La ions bound on clay minerals form compounds that are more sparingly soluble than, or roughly as sparingly soluble as $K[B(C_6H_5)_4]$, MgF_2, $CaC_2O_4 \cdot H_2O$, $BaSO_4$, and $La_2(C_2O_4)_3 \cdot 9\,H_2O$ respectively.

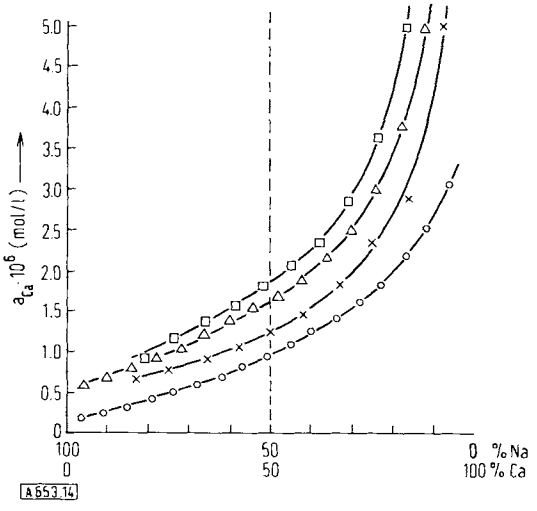

Fig. 14. Activity a_{Ca} of exchangeable calcium on clay minerals as a function of the covering ratio Na:Ca. ---- activity at a covering ratio of 1:1; -□-□-: glauconite (R); -Δ-Δ-: illite; -×-×-: kaolinite; -O-O-: glauconite (U.S.A.).

Table 6. Effective activities of the exchangeable cations on clay minerals.

Clay mineral	Electrolyte	Sparingly soluble compound	Activity of cation (mole/l) in the sparingly soluble compound in pure H_2O	Activity of cation (mole/l) on the clay mineral half covered with the cation and half with Na
K-kaolinite	$Na[B(C_6H_5)_4]$	$K[B(C_6H_5)_4]$	$1.82 \cdot 10^{-4}$	$5_{.0} \cdot 10^{-5}$
K-illite	$Na[B(C_6H_5)_4]$	$K[B(C_6H_5)_4]$	$1.82 \cdot 10^{-4}$	$3_{.2} \cdot 10^{-5}$
Mg-kaolinite	NaF	MgF_2	$1.25 \cdot 10^{-3}$	$1_{.65} \cdot 10^{-6}$
Mg-illite	NaF	MgF_2	$1.25 \cdot 10^{-3}$	$3_{.00} \cdot 10^{-6}$
Ca-kaolinite	$Na_2C_2O_4$	$CaC_2O_4 \cdot H_2O$	$4.5 \cdot 10^{-5}$	$1_{.25} \cdot 10^{-6}$
Ca-illite	$Na_2C_2O_4$	$CaC_2O_4 \cdot H_2O$	$4.5 \cdot 10^{-5}$	$1_{.65} \cdot 10^{-6}$
Ba-kaolinite	Na_2SO_4	$BaSO_4$	$1.00 \cdot 10^{-5}$	$1_{.4} \cdot 10^{-7}$
Ba-illite	Na_2SO_4	$BaSO_4$	$1.00 \cdot 10^{-5}$	$2_{.7} \cdot 10^{-7}$
La-kaolinite	$Na_2C_2O_4$	$La_2(C_2O_4)_3 \cdot 9\,H_2O$	$2.3 \cdot 10^{-6}$	$2_{.84} \cdot 10^{-10}$
La-illite	$Na_2C_2O_4$	$La_2(C_2O_4)_3 \cdot 9\,H_2O$	$2.3 \cdot 10^{-6}$	$4_{.00} \cdot 10^{-10}$

The higher the activity of the cation, the more readily is it exchanged. The lower the activity, on the other hand, the more readily is the cation taken up by the clay mineral. This is clearly shown when *e.g.* an ammonium kaolinite is treated with equivalent solutions of two cations and the ratio of the exchanged cations determined. The order of the activities of the cations corresponds to the Hofmeister series.

$$Na \gg K > Mg > Ca > Ba > La$$

It must be assumed that, unlike the Na ions, K, Mg, Ca, Ba, and La ions simply form a diffuse cloud around the clay mineral crystal.

If a natural kaolin or clay covered with Ca and Mg ions is to be covered with Na ions and then washed until free from salt, it is not advisable to use a sodium salt that gives sparingly soluble Ca and Mg salts, since the sparingly soluble salt would react again with the sodium ions during washing. On the contrary, a large excess of a sodium salt that gives soluble Ca and Mg salts should be used, these salts then being washed out with the excess of sodium salt.

1.6.1. Acid Strength of Exchangeable Hydrogen Ions

Clay minerals are attacked by acids. The best method of covering a clay mineral with exchangeable hydrogen ions is to use a strongly acidic cation exchanger [28]. Clay minerals containing the readily exchangeable Na ion react particularly well. The H-clay mineral can be titrated with CO_2-free sodium hydroxide, potassium hydroxide, or barium hydroxide solution in polyethylene containers under nitrogen with the quinhydrone electrode.

It can be seen from Figure 15 that the H-clay minerals react as acids, though they are less acidic than equivalent acetic acid [29]. (However, the value given by the titration is the average pH value of the clay mineral suspension. The concentration of H_3O ions is undoubtedly much greater immediately adjacent to the surface of the clay mineral.)

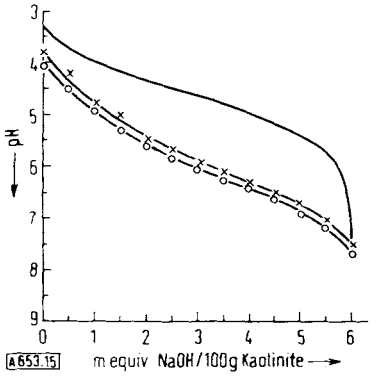

Fig. 15. Neutralization curves. ——: 0.01 N CH_3COOH + 0.1 N NaOH; -x-x-: 1.0 mequiv of H-kaolinite/100 ml of H_2O + 0.1 N NaOH; -O-O-: 0.1 equiv of H-kaolinite/100 ml of H_2O + 0.01 N NaOH.

2. Formation of the Clay Minerals

It seems probable from geological observations and from the synthesis of clay minerals in the laboratory [11,30] that these minerals are formed from aqueous solution.

Kaolinite, $Al_2(OH)_4[Si_2O_5]$, is formed by the weathering of feldspar, *e.g.* $K(AlSi_3O_8)$, in the presence of water containing acid, *e.g.* CO_2. The alkali metal and alkaline earth metal ions liberated are carried away; the excess SiO_2 is also carried away, or forms cristobalite or quartz in the course of time.

Kaolins generally occur in primary deposits. The rock often contains only 30 % of kaolinite, the remainder being quartz, feldspar, mica, *etc.* Clays are generally found in secondary deposits, to which they have been carried by water. Apart from kaolinite (usually of the fireclay type), they contain illite and montmorillonite, as well as quartz, iron oxide, calcium carbonate, humus, *etc.* Clays often contain clay minerals in high concentrations.

The formation of a kaolinite crystal can be explained as follows. A silicate sheet is formed first. The second silicate sheet then grows with its octahedral layer toward the tetrahedral layer of the first sheet, and with formation of hydrogen bonds. The crystal thus grows layer by layer until the concentration of foreign ions in the mother liquor becomes so high that the last silicate layer receives a negative charge as a result of ion substitution. This silicate layer binds exchangeable cations, the hydration of which prevents the formation of hydrogen bonds and hence the growth of a new silicate layer. Consequently, the crystal can grow no further.

A hypothesis proposed to explain the formation of halloysite tubes was described in Section 1.4.

Illite is formed by weathering of potassium feldspar and of micas if the potassium ions cannot be removed from the mother liquor. The weathering of feldspars yields roughly equal quantities of sodium and potassium ions. Ground water, however, contains *e.g.* only 4 mg of potassium ions/l as compared with 30 mg of sodium ions/l, and sea water contains 11 g of sodium ions/l as opposed to only 0.3 g of potassium ions/l. The potassium content of land plants is not sufficient to account for the missing potassium ions, particularly since much of it is recycled between the soil and the plants. The potassium ions have in fact been consumed by the formation of illite and other micas containing potassium.

As a result of weathering in the soil, illite provides the additional potassium required by land plants. Potassium feldspar is less common in soil and is coarser (0.1 to 0.01 mm diameter) and so weathers more slowly.

Montmorillonite results from the weathering of volcanic ashes in the presence of sodium ions, which promote the intracrystalline swelling. Bentonite deposits also contain vitreous weathering residues. The Lower Bavarian bentonite deposits may owe their existence to the impact of the great meteorite in the Tertiary, which formed the giant crater at Nördlingen in the Alb. The crater has a diameter of 20 km. The flying "volcanic" ash was carried south-eastward by the wind, collected in the Lower Bavarian basin, and changed into bentonite.

Investigation of the sediments in the sea around the mouths of large rivers led many workers to believe that montmorillonite sedimented first and then gradually changed into illite [31], taking up potassium ions from the sea water and increasing the negative charge on the sheets *e.g.* by substitution of magnesium for aluminum in the octahedral layer.

3. Properties and Use of Kaolin and Clay

Kaolins are generally washed before use to reduce the content of quartz, feldspar, and mica. Clays are usually worked without being washed. Coarse kaolins

are not very plastic, and for this reason the coarser grades are not used in ceramics. They are used as fillers for paper, as brightening fillers for plastics, as vehicles for insecticides, and for the preparation of ultramarine.

3.1. Plasticity

Kaolins and frequently clays are not worked alone in ceramics, but are mixed *e.g.* with quartz and feldspar for the manufacture of porcelain. Kaolins and clays containing a suitable quantity of water are plastic, *i.e.* they can be shaped, often into thin-walled vessels. They retain the shape of the vessel or model after being formed, and harden on drying.

There is unfortunately no satisfactory method of measuring the plasticity of clays. One method that is widely used is the Pfefferkorn method [32], in which the water content of a wet clay that is flattened to a given thickness by a falling plate is measured. Another method is *Cohn*'s method in which a rod must sink into a wet clay at a given speed, the water content of the clay then being determined. Thus, both of these methods involve the measurement of the water content of the wet clay at a given resistance to deformation.

Clays that are too wet or too dry have lower plasticities. The best method would be to measure the strength of a wet clay at a deformability that corresponds to the most plastic state [33]. Unfortunately, however, the strength cannot yet be determined with sufficient accuracy in the plastic state, since the clay flows. The potter's thumb is therefore still often the measuring instrument used in practice.

Pure quartz sand is fairly plastic in the moist state; the water adheres to the surface of the quartz sand and holds the quartz grains together by its surface tension. When dried, however, the quartz sand becomes mobile, since the only contact between the grains is at points. Clay or kaolin coats the quartz and feldspar grains with its crystal platelets, so providing large contact areas both in the wet and in the dry states, which give the wet mix its strength. The quartz in Figure 16, however, contains only a small quantity of clay, such as is present *e.g.* in a casting sand produced with bentonite. In a plastic ceramic mass, the interstices between the quartz grains are also filled with clay or kaolin platelets.

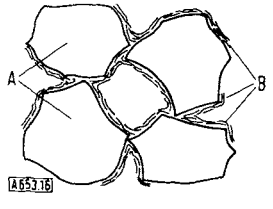

Fig. 16. Binding of quartz sand (A) by clay (B).

[32] *F. Zapp*, Ber. dtsch. keram. Ges. *34*, 12 (1957).

[33] *E. Scharrer* and *U. Hofmann*, Ber. dtsch. keram. Ges. *35*, 278 (1958); *U. Hofmann*, Keram. Z. *14*, 14 (1962).

The better the clay or kaolin conforms, the more plastic is the mixture. The flexibility of the platelets is therefore important. Clays are more plastic than coarse kaolins, but less plastic than fine kaolins.

According to *Weiss* [34], a coarse kaolin can be made very plastic by incorporation of compounds, such as urea, that break hydrogen bonds between the layers. By careful treatment, the kaolinite crystal can then be split into very thin lamellae and the compound added can finally be removed. The Chinese probably prepared their kaolin in this way during the Sung dynasty (960 to 1279) for the production of egg-shell porcelain. They obtained the inclusion compound by allowing decomposing urine to act on kaolin.

Ceramic objects are formed either freehand or on potter's wheels, which were known as early as 3000 B.C. Alternatively a slip may be cast in porous plaster-of-Paris molds; the action of the exchangeable cations can be seen in this case [35]. A plastic clay can be liquefied to a slip without changing its water content by the addition of a small quantity of soda and/or water glass.

In the natural or washed state, kaolin or clay generally contains exchangeable alkaline earth metal ions from the hardening constituents of water or from the flocculation with calcium hydroxide after washing. Soda enters into an equilibrium with the alkaline earth metal ions of the kaolinite or clay mineral, with exchange of sodium ions and precipitation of alkaline earth metal carbonate. Water glass reacts in a similar manner. The alkaline reaction of soda or water glass is necessary for the liquefaction only if the clay or kaolin also contains exchangeable hydrogen ions as a result of contact with acid soil water, *e.g.* humic acid.

Alkaline earth metal ions carry a double positive charge. They cannot completely screen the negative charges on the surface of the clay mineral crystals [35,36]. The negative potential extends outward between

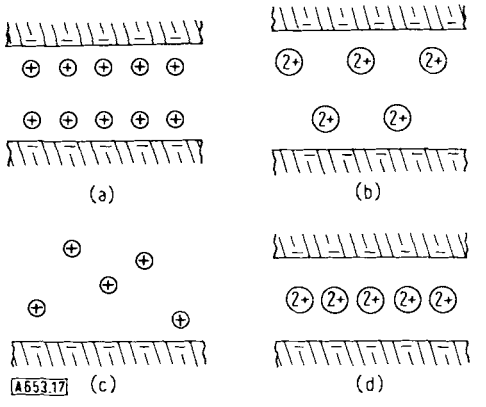

Fig. 17. Saturation of the negative surface charge of the clay minerals by monovalent cations (*e.g.* Na^+) and by divalent cations (*e.g.* Ca^{2+}). (a) Monovalent cations, better charge neutralization, screening of the surfaces; (b) divalent cations, poorer charge neutralization, inadequate screening of the surfaces; (c) diffuse cation cloud over the surface; (d) divalent cations, better charge neutralization by combination of two layers.

[35] *U. Hofmann*, Silikattechnik *8*, 224 (1957); *W. Czerch*, *K. Frühauf*, and *U. Hofmann*, Ber. dtsch. keram.Ges. *37*, 255 (1960).

[36] *Armin Weiss*, Kolloid-Z. *158*, 22 (1958); *U. Hofmann*, *ibid.* *169*, 58 (1960); *U. Hofmann*, *E. Scharrer*, *W. Czerch*, *K. Frühauf*, and *W. Burck*, Ber. dtsch. keram. Ges. *39*, 125 (1962).

the alkaline earth metal ions (Fig. 17b). Clay mineral crystals therefore adhere to one another *via* two layers of water lying between them (Fig. 17d). The adhesion occurs, not only between faces, but also between faces and edges. This structure, which resembles a house of cards, is shown in a greatly exaggerated form in Figure 18a. Because of the water layers between them, the platelets can be displaced in relation to one another and subsequently become fixed again in their new position. This is the explanation of the plastic deformability and the dimensional stability.

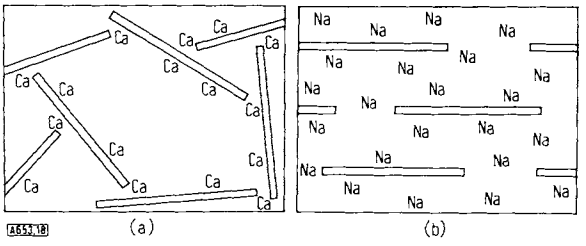

Fig. 18. (a) Plastic structure in the presence of Ca ions; (b) slip in the presence of Na ions (schematic section).

Sodium ions are monovalent, and can screen the negative potential of the clay mineral surface much more effectively. They are also strongly dissociated in water, and form a cation cloud around the clay mineral crystal (Fig. 17a and c). The clay mineral crystals repel one another and assume a parallel orientation, the clay thus becoming liquid. This is shown, again exaggerated, in Figure 18b.

When a slip is poured into the plaster mold, the porous plaster absorbs the water. It can be shown that the clay mineral platelets arrange themselves as nearly as possible parallel to the wall [37]. When the body becomes sufficiently thick, the remaining, unwanted slip is poured out of the mold.

Clay minerals containing exchangeable hydrogen ions also form a plastic mix, since they can form hydrogen bonds, and, since they can dissolve aluminum ions out of the octahedral layers of the crystals, these ions, as $Al(OH)^{2+}$, then act in the same manner as alkaline earth metal ions [38].

3.2. Action of Exchangeable Cations in Arable Soil

Owing to the alkaline earth metal ions normally present in arable soil, the clay minerals have the house-of-cards structure, giving the soil the desired loose and crumbly texture, so that it is permeable to water and to air. If the soil becomes flooded with sea water or if it is fed with too much potassium chloride, the alkaline earth ions are replaced by sodium or potassium ions, which liquefy the clay mineral skeleton in the presence of water having a low electrolyte content. Since the clay mineral platelets are now parallel to one another, the soil can contract to a very dense state on drying, and the fertility of the soil decreases or disappears. It then takes a considerably long time for the alkaline ions to be replaced by the hardening constituents of water. When the soil is fed with moderate amounts of potassium chloride, the clay minerals take up potassium ions as part of their complement of exchangeable ions and prevent them from being washed out of the soil, so that they are available for the plants.

3.3. Dry Bending Strength

Plastic clay mixes consist essentially of the solid particles and water; they contain practically no air. On drying, the water is removed, the clay shrinks, and air pores are simultaneously formed; the smaller the number of pores or the greater the solid content of the material, the higher is the dry bending strength [39].

In clay, the small platelets lie in the interstices between the large platelets in the house-of-cards structure of the plastic mix. The differentiation between small and large platelets is not so pronounced in kaolins, and the interstices between the large platelets are consequently not so well filled. This is shown exaggeratedly in Figure 19. On drying, therefore, the clays give higher densities, higher solid contents, and higher dry bending strengths than the kaolins.

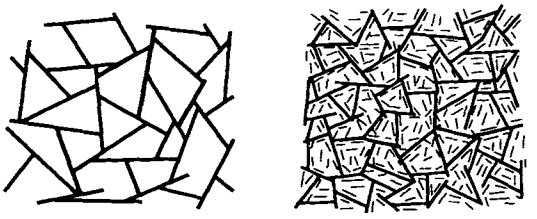

Fig. 19. House-of-cards structure in (a) kaolin and (b) clay (in section).

The dry materials obtained by slip casting have particularly high densities because of the parallel arrangement of the platelets; consequently, higher dry bending strengths are obtained by casting than by shaping of the same plastic material.

Table 7. Plasticity and dry bending strength as a function of the nature of the exchangeable cations (purified Zettlitz kaolin, 6.5 mequiv of exchangeable cations/100 g).

Exchangeable cations	Pfefferkorn plasticity (g H_2O/100 g dry kaolin)	Dry bending strength (kg/cm²)	Solids (Vol.-%)
Na^+	43.5	30	61
K^+	47	18	58
Ca^{2+}	46.5	16.3	59
Ba^{2+}	47.3	10.2	57
La^{3+}	50.6	8.4	54

[39] *U. Hofmann*, *W. Czerch*, and *E. Scharrer*, Ber. dtsch. keram. Ges. *35*, 219 (1958); *U. Hofmann*, *E. Scharrer*, *W. Czerch*, *K. Frühauf*, and *W. Burck*, *ibid. 39*, 125 (1962); *U. Hofmann*, *F. W. Schembra*, *M. Schatz*, *D. Scheurlen*, *H. Friedrich*, and *J. Dammler*, *ibid. 44*, 131 (1967).

Halloysite has a given dry bending strength at a lower solids content than kaolinitic and illitic kaolins and clays. This is in agreement with the fact that a skeleton constructed from tubes (halloysite) can be made lighter for a given strength than can a skeleton constructed from plates (kaolinite and illite).

The effect of the exchangeable cations on the dry bending strength and the plasticity is shown in Table 7. The higher the water content of a kaolin for a given degree of flattening in the Pfefferkorn tester, the lower is the dry bending strength.

3.4. Use of Vermiculite

When vermiculite takes up potassium ions, it loses its capacity for intramolecular swelling; hence potassium ions are more readily exchanged in vermiculites that were previously swellable. Since this behavior is even more pronounced with rubidium and cesium ions, vermiculite is therefore used in the treatment of nuclear fuels to remove ^{137}Cs ions (half life 30 years) from solution.

Vermiculite forms fairly large crystals. When swellable vermiculite with one to two layers of water between the silicate layers is rapidly heated, the water between the layers cannot escape quickly enough. It boils and forces the silicate layers apart, so that the vermiculite swells. If the crystals have a small diameter *e.g.* 1 mm or less, they give worm-like structures, from which the name vermiculite is derived. Crystals greater than 1 cm in diameter give a very loose material having a bulk density of *e.g.* only 100 g/l. The material retains its loose structure up to about 1000 °C. It is a good packing material, and can also be used as a thermal insulator.

3.5. Use of Montmorillonite and Bentonite

Montmorillonite is generally used in industry in the sodium form [40]. Na-montmorillonite exhibits infinite swelling in water, forms very thin lamellae, and so disperses extremely readily in a wet clay. Sodium montmorillonites are sometimes found in nature. However, they can also be obtained by reaction of the more abundant natural alkaline earth metal montmorillonites in the moist state with soda, which leads to the equilibrium mentioned.

In spite of its high plasticity and dry bending strength, little use is made of bentonite in ceramics, since it usually contains some iron in its lattice and so has a brownish to reddish color after firing.

However, 5 % of bentonite is sufficient to make a casting sand sufficiently strong in the wet or dry state, while the permeability to gases is still excellent (cf. Fig. 16).

Sodium montmorillonite gives a suspension a high viscosity. At about 10 wt-% of montmorillonite, the suspension thickens to a gel at rest (thixotropy). This affords a good, strong drilling mud and at the same time, the montmorillonite lamellae seal off the wall of the borehole and prevent the drilling mud from flowing into the rock. Owing to the supporting and sealing effect on the wall, a bentonite suspension is introduced into the slits cut out in slit wall construction before the concrete is poured in.

The use of montmorillonite for the removal of radioactive ^{137}Cs ions from solutions during the treatment of nuclear fuels in nuclear power stations is also being considered [41]. In order to encase the cesium ions in an insoluble ceramic product, it would then only be necessary to fire the montmorillonite.

Still better exchange is obtained with long-chain organic ammonium ions. (These ions even cause intramolecular swelling in illite or muscovite [14,42], though this takes some weeks to occur.) One such montmorillonite is supplied in organic solvents under the name "Bentone" as an additive for paint suspensions and for lubricating greases. Protamines, *e.g.* salmine, which has a high arginine content, are very readily exchanged. However, proteins are also exchanged in acidic solution *via* the basic amino acids [43]. Montmorillonite is therefore used to free wine and export ale from proteins and protein degradation products, which would otherwise flocculate on standing. Montmorillonite absorbs up to its own weight of protein. It is probable that only one end of the protein molecule with basic amino acids is incorporated between the silicate layers of the montmorillonite.

4. Clay Minerals as Catalysts

Clay minerals, particularly montmorillonite are good catalysts [43c,44]. For example, in the presence of air, montmorillonite oxidizes diphenylamine to the blue benzidinium ion or aniline to aniline black. Peptides are cleaved by montmorillonite. This led us to consider the formation of petroleum and of oil shale.

Oil shale contains clay minerals and "kerogen", an organic material, and affords a petroleum-like product on slow distillation. The earth probably contains four times as much potential oil in oil shale as it does free oil.

Evidence in favor of the biological origin of kerogen and petroleum is provided *inter alia* by the detection of porphyrins by *A. Treibs*. Proteins, fats, and possibly also carbohydrates from plankton, algae, and similar microorganisms change in the sludge at the bottom of the sea into gyttja as a result of H_2S-induced oxygen deficiency and into sapropel in the absence of oxygen.

[42] *Armin Weiss*, *A. Mehler*, and *U. Hofmann*, Z. Naturforsch. *11b*, 435 (1956).

[43] a) *L. E. Ensminger* and *J. E. Gieseking*, Soil Sci. *48*, 467 (1939); b) *O. Talibudeen*, Nature (London) *166*, 236 (1950); c) *Armin Weiss*, Angew. Chem. *75*, 113 (1963); Angew. Chem. internat. Edit. *2*, 134 (1963).

[44] *Armin Weiss*, Beitr. Silikose-Forsch., special volume, Grundfragen Silikose-Forsch. *3*, 45 (1958).

It is possible that petroleum is formed from sapropel, and kerogen from sapropel and gyttja [45]. Clay minerals simultaneously sediment into the sludge. The petroleum has emerged from the clay minerals in the course of time, and is now found in porous rocks such as sandstone.

Weiss and *Roloff* [46] have shown that hemin incorporated as a cation into the layer lattice of montmorillonite is stable up to about 300 °C, instead of only up to 200 °C as in the free state. However, clay minerals act as catalysts even above 200 °C on organic substances. Organic ammonium ions, which may be derived from decaying protein, change in the layer lattice of montmorillonite above 200 °C into a mixture of hydrocarbons that corresponds to petroleum and natural gas [47]. The same is true of protein incorporated into montmorillonite. Montmorillonite carrying organic ammonium ions also absorbs fats. The hydrocarbons are formed above 200 °C in every case.

Thus petroleum can be produced in the laboratory from organic ammonium ions, protein, and fats by the catalytic action of montmorillonite. Does this also happen in nature?

We have determined the clay minerals in a series of oil shales [48]. The older shales (Cambrian to Jurassic) contained illite and the younger shales (Jurassic to Middle Eocene) montmorillonite.

In the young Middle Eocene oil shale from Messel, the kerogen is at least partly situated between the silicate sheets of the montmorillonite.

Illites also have a large surface and can act as catalysts. However, the geological sequence suggests that the kerogen was initially formed in the montmorillonite and migrated slowly, while the montmorillonite changed into illite as a result of the absorption of potassium and an increase in the charge on the layers. The free petroleum may also have been formed from the kerogen of the oil shale.

When montmorillonite is heated with organic ammonium ions, an ammonium montmorillonite is formed; above 350 °C and in the absence of air, this changes into an H-montmorillonite [47]. The H ions migrate into the silicate layers, probably into the octahedral layer, and the montmorillonite, loses its intracrystalline swelling capacity, and like pyrophyllite and talc, can no longer swell.

In Trinidad asphalt we [48] found an unswellable layer silicate having a distance of 9.9 Å between the illite layers, but which contains only 0.34 K per formula unit. This may be a montmorillonite with 0.34 potassium ions that has lost the ability to swell because of the temperature of about 300 °C at which the kerogen was formed and driven out to form the asphalt.

It is also possible that montmorillonite or the clay minerals in general were involved as catalysts in the creation of life on earth. Three or four billion years ago, the earth probably had a "primordial atmosphere" of hydrogen, methane, ammonia, and water. The ultraviolet radiation from the sun (which was not absorbed by oxygen as it is now) and electric discharges cooperated in this atmosphere to form the components of the proteins and nucleic acids, *e.g.* formaldehyde, prussic acid, glycine, alanine, aspartic acid, adenine, and sugars. Algae and microorganisms have been detected in rocks as much as three billion years old [49]. The clay minerals, which existed even in the Precambrian, may have catalyzed the formation of "viable" compounds of high molecular weight [50].

Antibiotics as Inhibitors of Nucleic Acid and Protein Synthesis[1]

BY G. HARTMANN, W. BEHR, K.-A. BEISSNER, K. HONIKEL, AND A. SIPPEL[*]

The antibiotics of the rifamycin, actinomycin, chromomycin, and anthracycline groups have been found to be specific inhibitors for the DNA-controlled synthesis of RNA[2] in vitro. Streptomycin, chloramphenicol, and puromycin can specifically suppress certain steps in the biosynthesis of proteins. The investigation of the mode of action of such substances may help us to gain a better insight into the transmission of hereditary information.

1. Introduction

Seven years ago *Reich*, *Franklin*, *Shatkin*, and *Tatum*[3] found that small concentrations of the antibiotic actinomycin in tissue cultures selectively suppress the synthesis of RNA whereas DNA and protein syntheses, on the other hand, remained temporarily almost unchanged. This discovery attracted great interest in connection with the intensive efforts being made to explain the nucleic acid and protein syntheses, since specific inhibitors had already been of great value in the elucidation of the individual reaction steps of other important metabolic chains.

Since then, many antibiotics have become recognized as inhibitors of processes that lead to the imprinting of genetic information[4,5], *i.e.* of processes that differ from normal enzyme reactions in that they involve information-carrying templates. Consequently, the inhibitors for this reaction include, not only those substances that attack the enzyme protein or antimetabolites that resemble the substrate, but also substances that inactivate the template. This has been confirmed by a number of experiments *in vitro*. The examples given in this article are confined to antibiotics whose chemical structures are known, and which directly inhibit the enzymatic polycondensation process.

2. Inhibition of Nucleic Acid Synthesis

2.1. Action of RNA Polymerase

The first step in the transfer of genetic information, which is contained in the base sequence of the DNA, to protein synthesis is the formation of single-strand RNA. Ribonucleoside triphosphate is polycondensed by the catalytic action of the enzyme RNA polymerase (EC 2.7.7.6) with DNA as a template to form RNA whose base sequence corresponds to that of the DNA template[6].

$$\begin{matrix} n_1\ \text{ATP} \\ n_2\ \text{UTP} \\ n_3\ \text{GTP} \\ n_4\ \text{CTP} \end{matrix} \xrightarrow[\text{RNA-Polymerase}]{Mg^{2+},\ \text{DNA}} \text{RNA} + (n_1 + n_2 + n_3 + n_4)\text{PP}$$

Experiments, which have mainly been carried out with RNA polymerase from *Escherichia coli*, have shown that the reaction proceeds in several steps[7–10]. The polymerase protein first adds onto the nucleic acid, which may be single-stranded or double-stranded (Fig. 1a), in a readily reversible manner.

$$\text{DNA} + \text{Enzyme} \rightleftharpoons (\text{DNA-Enzyme})$$

On double-strand DNA the synthesis begins with a strongly temperature-dependent induction phase, the DNA helix evidently having to be locally opened up ("melted") (Fig. 1b), whereas reaction proceeds immediately in the case of single-strand DNA.

A relatively high concentration of purine nucleoside triphosphate is necessary at the beginning of the re-

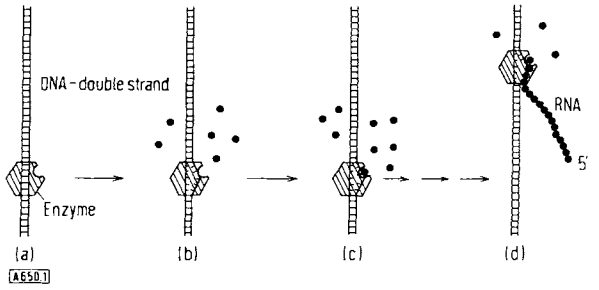

Fig. 1. Start of the DNA-controlled RNA polymerase on the DNA-double-strand. a) Addition of the enzyme to the DNA; b) "melting" of the DNA; c) DNA-enzyme-nucleotide complex; d) polycondensation to give RNA; • = ribonucleotides.

action. Formation of a stable DNA-enzyme-nucleotide complex takes place (Fig. 1c) and, possibly, for it cannot yet be established with certainty, a short RNA segment is also synthesized at this stage.

(DNA-Enzyme) + Nucleotide → (DNA-Enzyme-Nucleotide)

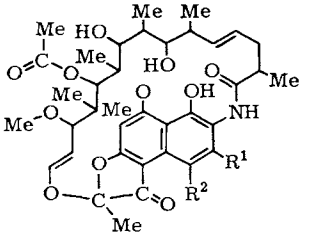
When the other nucleoside triphosphates are added, the synthesis of RNA proceeds with liberation of pyrophosphate, and the enzyme meantime moves along the DNA template (Fig. 1d) thus leading to the

(DNA-Enzyme-Nucleotide) + 4n 5'-Ribonucleoside triphosphate → (DNA-Enzyme-RNA) + 4n PP

formation of a DNA-enzyme-RNA complex [11], which dissociates under suitable conditions; the dissociation may be rate-determining for the reaction as a whole. The liberation of the RNA formed may be accelerated *in vivo* by the subsequent protein synthesis [12].

2.2. Rifamycins as Enzyme Inhibitors

Rifamycin B *(1a)*, its chemically modified derivatives [13–15] [*e.g. (1b)*], and the streptovaricins [16], which have a similar structure, are among the strongest inhibitors of the RNA polymerase from *E. coli.*; a concentration of only 3×10^{-8} M of rifampicin *(1b)* is sufficient to reduce the enzyme activity by half *in vitro* (Table 1). The action of the antibiotic is independent of the base composition and the secondary structure of the DNA used as the template [17–19].



Me = CH_3

(1a), R^1 = H, R^2 = O-CH_2-COOH

(1b), R^1 = -CH=N-N(piperazine)-N-CH_3, R^2 = OH

The inhibitor action is species-specific, since RNA polymerase from rat liver or from ascites cells is not inhibited [19, 20]; this offers interesting possibilities for application *e.g.* in virus research [18, 20a].

Table 1. Antibiotic concentrations for 50% inhibition of the DNA-controlled RNA and DNA polymerases from *E. coli*. Thymus DNA concentration in the RNA polymerase experiments 3×10^{-4} M, in the DNA polymerase experiments 1.3×10^{-4} M [17, 38, 44].

Antibiotic	50% inhibition of	
	DNA-Polymerase (M·10^5)	RNA-Polymerase (M·10^5)
Rifampicin	no inhibition	0.003
Actinomycin X_2	2	0.03
Echinomycin	3	0.3
Chromomycin A_3	2	0.03
Olivomycin	0.6	0.2
Mithramycin	3	0.2
Anthracycline:		
Ruticulomycin A	0.2	0.5
Nogalamycin	0.5	0.5
Cinerubin A and B	3	1
Daunomycin	2	3
Isoquinocycline	5	4

The rifamycins can exert their inhibiting action in full only on the free enzyme protein, the enzyme being protected to some extent, even by DNA, provided that the polymerase has had sufficient time to react with the DNA (cf. Fig. 1b). Much stronger and faster protection is provided by a combination of DNA with one or more nucleoside triphosphates. The antibiotic evidently has much less effect on the resulting initiation complex (Fig. 1c). If it is added after the start of the polycondensation with all four ribonucleoside triphosphates, no inhibition is observed up to the end of the synthesis and the dissociation of the reactants. The polycondensation is thus hindered only by the inhibition of the start of the reaction [19, 21].

The rifamycins [18, 19, 21], and the streptovaricins [22–24], which act in the same manner, are to be considered therefore as very selective inhibitors for the initiation of the DNA-controlled RNA polymerase of microorganisms.

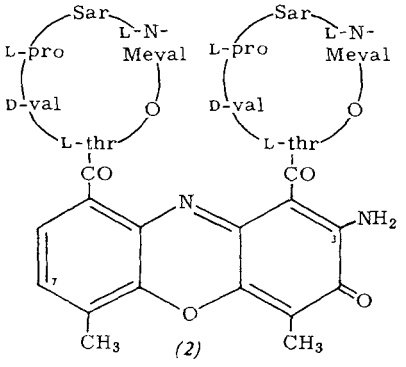
2.3. Inactivators of the Template

2.3.1. Actinomycin

In vitro experiments with the actinomycins *(2)* [25] and the structurally related echinomycin [26] showed some years ago that these antibiotics are strong inhibitors of the DNA-dependent RNA polymerase reaction [27, 28] (Table 1). This explained the specific suppression of RNA synthesis *in vivo* by actinomycin. The fact that the inhibiting action is independent of the source of



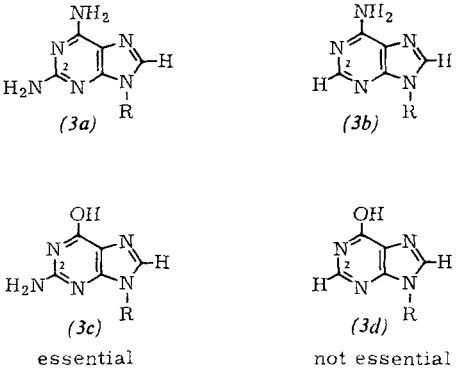
the polymerase preparation [29–31] is evidence that a reaction step is blocked that is independent of the nature of the protein.

Actinomycin does not influence the addition of the enzyme to the DNA (Fig. 1a), even at a concentration such that the overall reaction is almost completely blocked [7]. The point of attack of the antibiotic must therefore occur in a later step.

When DNA is present in excess, the degree to which the reaction is inhibited by a given quantity of actinomycin decreases with increasing DNA concentration. This indicates that the antibiotic reacts with the DNA, since the enzyme can then react with DNA that has not reacted with the antibiotic [32].

Further support for this being the case is afforded by the observation that the RNA polymerase reaction with RNA as the template is not affected by the antibiotic. Moreover, the inhibiting action is strongly influenced by the secondary structure of the DNA, since the RNA synthesis on denatured, *i.e.* largely unordered, DNA is scarcely affected by actinomycin.

The biochemical action of actinomycin also depends strongly on the base composition of the nucleic acid, *e.g.* the lower the guanine content of the DNA, the higher is the antibiotic concentration required for inhibition [27]. Particularly valuable information has been obtained from experiments with synthetic double-strand polydeoxynucleotides such as poly-d(A–T), poly-d(DAP–T), and poly-dGdC, whose sequences are also accurately read off by the polymerase. It was found that the RNA synthesis on poly-d(A–T) is completely unaffected by actinomycin, whereas the syntheses on poly-dGdC and poly-d(DAP–T) are totally suppressed. The action of the antibiotic is therefore entirely dependent upon the presence of a 2-amino grouping in the template, as in *(3a)* and *(3c)* [33].



for the action of the antibiotic (R = deoxyribose)

(3a): 2,6-diaminopurine nucleoside; *(3b)*: deoxyadenosine; *(3c)*: deoxyguanosine; *(3d)*: deoxyinosine.

The prevention of the attack on the DNA by actinomycin may be imagined as prevention of the reaction from proceeding along the template past the points with which the inhibitor has reacted. This is in agreement with the fact that actinomycin suppresses the polymerase reaction instantly, even when it is added only after the beginning of the reaction [34], and leads to the formation of short RNA chains [35].

2.3.2. Chromomycin

Chromomycin A_3 *(4)* [36] and the closely related antibiotics olivomycin and mithramycin [5] have been found to inhibit the RNA polymerase almost as strongly as actinomycin [37–39] (Table 1). The point of attack of these substances is probably again the double-strand DNA template, since the reaction with RNA as the matrix is not inhibited [28]. On the other hand, the action of chromomycin, like that of actinomycin, de-

Me = CH_3; Ac = CH_3-CO

(4)

pends very strongly on the double-stranded state and on the guanine content of the DNA [39]. Experiments with synthetic polydeoxynucleotides (poly-d(A–T), poly-d(DAP–T), poly-dGdC, and poly-dIdC) have also shown that the presence of the 2-aminopurine grouping in the template is absolutely essential to the action of this group of antibiotics [28, 33]. In agreement with the hypothesis that these antibiotics also prevent the continuation of the enzyme reaction along the DNA, it is found that chromomycin inhibits the RNA synthesis immediately on addition [21].

2.3.3. Anthracyclines

The DNA-controlled RNA polymerase reaction is also inhibited by the anthracyclines [40] (*e.g.* daunomycin [41]) and related antibiotics (such as isoquinocycline [42]), the degree of inhibition being once again related to the inhibitor concentration by a hyperbolic function [37,43].

The anthracyclines, however, are distinctly less active than the other antibiotics discussed so far (Table 1). In contrast to actinomycin and chromomycin, the anthracycline antibiotics block the polymerase reaction even with RNA as the template; moreover, their action generally depends only slightly on the base composition of the DNA [28,44].

2.4. Blockage of DNA

2.4.1. Blockage with Actinomycin

The view that actinomycin and similar antibiotics act as template inhibitors is strongly supported by the observation that they can associate with DNA. The equilibrium of the complex is displaced so strongly toward the associate and the dissociation of the complex is so slow [45] that the antibiotic migrates together with the DNA on ultracentrifugation, on gel filtration [46], and in an electric field. As a result of the association, the absorption maximum of the antibiotic in the visible region is displaced by about 20 nm to longer wavelengths, and the extinction simultaneously decreases. The nature of the electric interactions that are responsible for this is not yet known [27]. It is interesting to note that actinomycin can associate, not only with DNA, but also with its degradation products such as apyrimidinic acid, simple oligonucleotides, purine nucleosides, and even β-naphthalenesulfonate; these associations are also accompanied by similar changes in the spectrum [27,45,47,48]. However, the associates differ clearly from the complex of actinomycin with native DNA, particularly in the position of the complex equilibrium and the much higher rates of association and dissociation [45,49,50].

If the inhibition of the RNA polymerase is assumed to be due to complex formation between DNA and the antibiotic, the association should exhibit the same features as the inhibitor action. This is in fact so. Thus in agreement with findings in the polymerase reaction, the antibiotic does not form a complex with single-strand or double-strand RNA [27,45].

The 2-aminopurine grouping as in *(3a)* and *(3c)*, which is essential in the DNA for the biological inhibiting action, is also necessary for complex formation with the antibiotic. The characteristic changes in the absorption spectrum occur only with poly-d(DAP–T) and poly-dGdC, and not with poly-d(A–T) or poly-dIdC [33,51]. Experiments with simple model compounds of actinomycin have shown that the specificity for the 2-aminopurine grouping is due to the chromophore of the antibiotic [45].

All the properties of the actinomycin-DNA associate can be explained on the assumption that on complex formation, the chromophore is inserted into the DNA helix horizontally above or below a guanine-cytosine base pair ("intercalation") [45, 51a].

The biological inhibiting action is probably determined by the rate of dissociation of the complex. The faster the associate can dissociate into free DNA and antibiotic, the shorter is the time during which the RNA

polymerase is prevented from continuing the synthesis along the DNA template. It is found that the DNA complexes with biologically inactive actinomycin derivatives dissociate very rapidly, while the associates with active actinomycins dissociate only slowly [45]. The rate of dissociation of the actinomycin complex with denatured DNA, which is about ten times as high as that of the complex with native, double-strand DNA, is therefore probably responsible for the fact that the antibiotic inhibits the RNA polymerase to a much smaller extent on denatured DNA [52].

2.4.2. Blockage by Chromomycin

The ability of chromomycin to form a complex with DNA suggests that this inhibitor also acts by inactivation of the template [28, 52–56]; however, divalent metal ions such as Mg^{2+} must be added if the DNA preparation does not contain enough. The migration of the antibiotic with DNA in an electric field and on ultracentrifugation is explained by the position of the complex equilibrium

$$\frac{[\text{Chromomycin - DNA}]}{[\text{Chromomycin}]\,[\text{DNA}]} = 0.2 \times 10^6\ (\text{l/mole})$$

and the very low dissociation rate of the complex (half life approx. 110 min at 20 °C). As a result of the association, the absorption maximum of the antibiotic in the visible region is displaced by about 25 nm toward longer wavelengths. This should not be confused with the spectral changes observed on addition of heavy metal ions such as Cu^{2+} [5]. The nature of the electronic interactions is unknown.

The inhibitor properties of chromomycin are evidently determined by the complex formation with DNA, which exhibits the same features as the inhibition of the polymerase reaction. Thus the antibiotic forms associates only with DNA, and not with RNA. The observation that chromomycin has practically no inhibiting effect on the RNA synthesis on denatured DNA corresponds to the observation that chromomycin is bound to a much smaller extent on denatured than on double-strand DNA. This can be demonstrated particularly effectively with poly-dGdC. Unlike the double strand, the single strands poly-dG and poly-dC do not react with the antibiotic [44].

The DNA must contain the 2-aminopurine grouping as in *(3a)* and *(3c)* for the complex formation as well as for the inhibiting action. Experiments with synthetic polydeoxynucleotides gave results similar to those obtained for actinomycin. The specificity for the 2-aminopurine grouping is again due to the chromophore [44, 55].

The very low dissociation rate of the complex is undoubtedly very important to an understanding of the inhibition of RNA polymerase. The dissociation rates of the DNA complexes of chromomycin derivatives increase in order of decreasing enzyme-inhibiting action [52]. The chromomycin-DNA complex dissociates so slowly that it can be degraded with a mixture of deoxyribonuclease (EC 3.1.4.5), phosphodiesterase (EC 3.1.4.1), and phosphatase (EC 3.1.3.1) into smaller fragments containing chromomycin (sedimentation coefficient $s_D^{20} = 2.8 \pm 0.1$ S). The degradation stops with the formation of oligodeoxynucleotides having a guanine content of 33 mole-%. The base composition of the fragments indicates that they are double-stranded; they contain on average one bound chromomycin molecule per four pairs of bases. It can be seen from models that because of steric factors, this is the upper loading limit for the size of the antibiotic molecule, the strand segments encased by the antibiotic evidently being protected against attack by hydrolases [55].

2.4.3. Blockage with Anthracyclines

Anthracyclines also act as template inhibitors, probably because of their ability to associate with DNA. The complex formation is again accompanied by a displacement of the absorption maximum of the antibiotic in the visible range toward longer wavelengths [43, 54, 57]. However, measurements on the daunomycin-DNA complex have shown that the equilibrium is much less in favor of the complex than in the case of actinomycin, and depends strongly on the ionic strength [47, 57, 58]. This may be one reason for the low activity of these antibiotics (Table 1).

The absence of DNA-specificity in the enzyme-inhibiting actions is also found in the association, as is exemplified by daunomycin, which forms complexes, not only with DNA, but also with RNA, oligonucleotides, and mononucleotides [47, 57].

The low dependence of the inhibitor action on the base composition of the template is also seen in the associate formation, *e.g.* nogalamycin reacts almost as readily with poly-dGdC as with poly-d(A—T) [44].

2.5. Inhibition of DNA Polymerase

If the actinomycins, chromomycins, and anthracyclines act as template inactivators, they should also inhibit other reactions controlled by a DNA template, such as the DNA synthesis. The enzyme DNA polymerase (EC 2.7.7.7) catalyzes the polycondensation of deoxynucleoside triphosphates to form DNA on a DNA template in accordance with the equation

$$\begin{matrix} n_1\ \text{dATP} \\ n_2\ \text{dTTP} \\ n_3\ \text{dGTP} \\ n_4\ \text{dCTP} \end{matrix} \xrightarrow[\text{DNA-Polymerase}]{Mg^{2+},\ \text{DNA}} \text{DNA} + (n_1 + n_2 + n_3 + n_4)\text{PP}$$

the base sequence of the synthesized DNA corresponding to the sequence in the template. All antibiotics that act on the RNA synthesis by blockage of the DNA also inhibit this reaction (Table 1) [37, 38, 44] – only the

[58] *K.-A. Beissner*, Diplomarbeit, Universität Würzburg, 1966.

rifamycins, which cannot associate with DNA, have no effect [17].

It is very striking that in many cases, the concentrations of base-specific inhibitors required to obtain a given effect on the DNA synthesis are much higher than those required for the same effect on the RNA synthesis (Table 1). The reason for this difference may be sought in the mechanisms of action of the two enzymes. On a partially degraded DNA helix, the purified DNA polymerase synthesizes preferentially

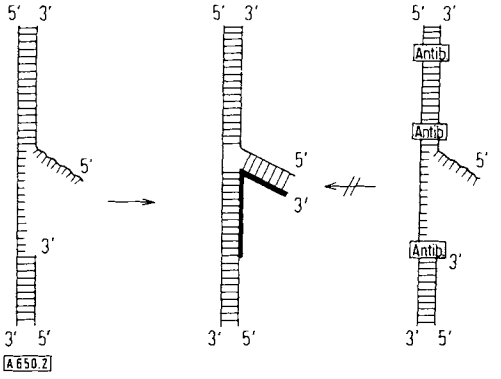

Fig. 2. Mode of action of DNA polymerase on the partly degraded DNA-double-strand and blockage of the reaction with antibiotics (Antib.) such as actinomycin or chromomycin [44, 59]. Bold continuous lines: newly synthesized strand segment.

the missing section along the remaining single strand by starting from the 3'-hydroxy end (Fig. 2). The result is the regeneration of a double strand that once more has its full biological activity [59].

The effects of actinomycin, chromomycin, and mithramycin, which are small in comparison with the inhibition of the RNA polymerase, may be explained by the observation that these give stable, slowly dissociating complexes only with the double strand. Since the enzyme begins to operate on the 3'-hydroxy end of the double strand, the antibiotics can block only the start of the reaction (Fig. 2). Inhibition can no longer be achieved merely by association with any point of a double strand, but requires specific blockage of the ends. Since antibiotics such as mithramycin associate statistically with the guanine residues in the double strand, a much higher inhibitor concentration is now necessary to suppress the reaction to the same degree as the RNA synthesis. The inhibition must depend on the guanine content of the DNA, since if there is no guanine in the end portion, the inhibitor cannot be bound there. This is in fact found [44] (Fig. 3a). It is also to be expected that part of the reaction cannot be suppressed even at very high antibiotic concentrations, since even in DNA having a high guanine content, some of the 3'-hydroxy ends are free from guanine.

The content of guanine-free ends decreases with decreasing adenine and thymine contents; consequently, the higher the guanine content of the template, the

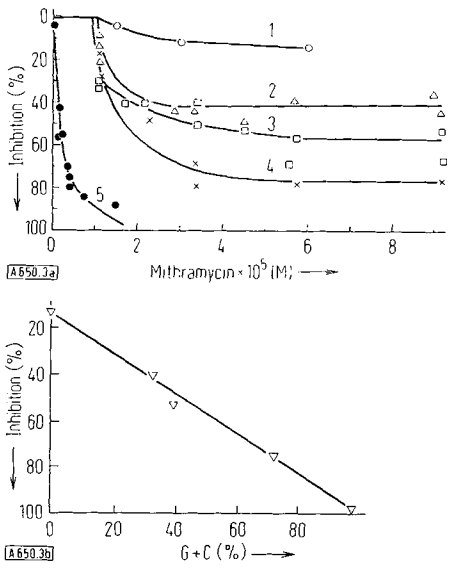

Fig. 3. a) Inhibition of the DNA polymerase reaction by mithramycin with various nucleic acids as templates [44]. 1: Poly-d(A—T), 2: T2-DNA, 3: calf thymus DNA, 4: DNA from *M. lysodeicticus*, 5: poly-dGdC. b) Dependence of the residual DNA polymerase activity at high mithramycin concentrations on the guanine + cytosine (G + C) content of the nucleic acid used [44].

greater is the degree to which the DNA synthesis can be inhibited. These predictions are confirmed by experimental results [44] (Fig. 3b).

As expected, the antibiotics having no pronounced base-specificity do not exhibit these peculiarities; they combine equally well with single-strand and double-strand DNA. Consequently, both DNA-controlled polymerase reactions are inhibited by anthracyclines in the same concentration range, and completely inhibited at higher concentrations (Table 1).

3. Inhibition of Protein Synthesis

3.1. Course of Protein Synthesis

Our knowledge of protein synthesis [60] is mainly based on the cell-free system from *E. coli*. In its essential features, however, it is also valid for other cells. It has been found that protein synthesis takes place on RNA-rich cell particles, the ribosomes, which are made up of two parts characterized by their sedimentation coefficients as 30S and 50S subunits (in the case of *E. coli*). The genetic information is transferred with the aid of mRNA. A number of soluble enzymes are also involved in the protein synthesis. The principal low molecular weight component required, apart from certain inorganic ions, is GTP. The amino acids must be present in the activated form of amino-acyl-tRNA esters. *e.g.* tyrosyl-$tRNA_{tyr}$ *(5)*. The information contained in the nucleotide code of the mRNA is read off from the ribosomes and transferred to the amino acid sequence of the protein being formed. Fig. 4 shows a highly

R = Polynucleotide chain

idealized picture of the reaction steps, the enzymological investigation of which is not yet complete.

Initiation: The *N*-formylmethionyl-tRNA(FM-tRNA$_F$) acting as the initiator first adds to the complex of a 30S ribosome subunit and mRNA. This reaction is enzyme-catalyzed, and is promoted by GTP [61,62] (Fig. 4a).

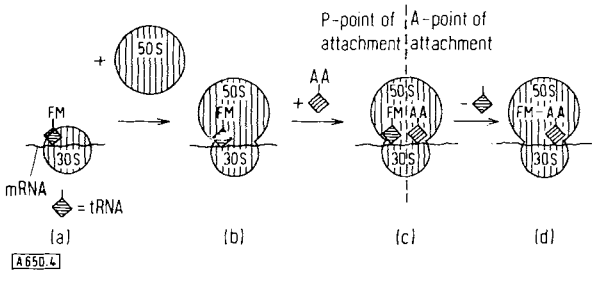

Fig. 4. Start of protein biosynthesis.

a) Addition of *N*-formylmethionyl-(FM)-tRNA to the complex of mRNA with the 30S ribosome subunit; b) addition of the 50S ribosome subunit; c) reading by addition of an amino-acyl-(AA)-tRNA to the A site of the ribosome; d) peptide transfer of the FM-tRNA bound to the P site onto the amino-acyl-tRNA added in step c. When the resulting peptidyl-(FM—AA)-tRNA has been moved to the P site and the mRNA moved in relation to the ribosome, processes c) and d) can be repeated.

Reading step: The 50S subunit adds to the complex formed in the initiation reaction to form the complete 70S ribosome with another point of attachment for activated amino acids [63] (Fig. 4b). The addition of the amino-acyl-tRNA to this point of attachment is very specifically dictated by the nucleotide triplets of the mRNA. Reaction occurs only with those activated amino acids that can interact with the mRNA section to be read off. This step determines the accuracy with which the genetic information is translated in the protein synthesis. The ribosome now carries a peptide-like activated residue (FM—tRNA$_F$) and an amino-acyl-tRNA. The P site on the ribosome (point of attachment of the peptidyl-tRNA) is distinguished from the A site (point of attachment of the amino-acyl-tRNA) (Fig. 4c).

Formation of the peptide linkage: The amino group of the activated amino acid (*e.g.* Tyr-tRNA$_{Tyr}$) attached to the A site is now enzymatically acylated by the *N*-formylmethionyl-tRNA bound to the P site.

$$\text{FM-tRNA}_F + \text{Tyr-tRNA}_{Tyr} \xrightarrow[\text{70-S-Ribosome}]{\text{attached to the}} \text{FM-Tyr-tRNA}_{Tyr} + \text{tRNA}_F$$

This reaction is enzymatically catalyzed by the peptidyl transferase located on the 50S ribosome subunit and results in the formation of the first peptide linkage with liberation of the tRNA residue of the initiator.

When the resulting dipeptidyl-tRNA has been moved to the point of attachment for peptidyl-tRNA and the mRNA moved forward, the process (reading step and formation of the peptide linkage) can be repeated. The peptidyl-tRNA takes over the role of the *N*-formylmethionyl-tRNA. In this way a long peptide chain is built up, one molecule of GTP per peptide linkage being hydrolyzed to GDP and phosphate [64].

Termination of synthesis: The reading process, and hence also the peptide synthesis, is brought to an end by an mRNA section containing a stop signal. The protein formed is released enzymatically from the terminal tRNA [65] and the ribosome dissociates again into its subunits.

Numerous antibiotics that can suppress this process on the ribosomes have recently been discovered and many of them can be distinguished by their effect on the 30S or 50S ribosome subunits, on the P or A site, or on the peptidyl transferase reaction [66–69]. Comparative studies indicate that the ribosomes of plants and bacteria clearly differ, particularly in the P sites [69].

We shall now consider the effects of antibiotics on the ribosome functions, taking streptomycin, chloramphenicol, and puromycin as examples.

3.2. Inhibitors of Protein Synthesis

3.2.1. Streptomycin

Addition of streptomycin in a concentration of 10^{-5} M to protein synthesis *in vitro* leads not only to a reduction of reaction but also to a distinct increase in error in the reading of the genetic information. With a synthetic mRNA consisting of an alternating sequence of the nucleotides UMP and GMP, the presence of streptomycin results in the incorporation of arginine

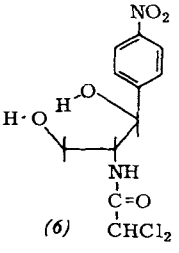
and serine into the polypeptide being formed, which normally consists entirely of cysteinyl-valine units. This and other observations indicate that the antibiotic interfers with the correct reading of the pyrimidine residues of the mRNA [70]. To find out more about the point of attack of streptomycin on the ribosome, the protein synthesis has been studied *in vitro* with genetically different ribosome subunits obtained from streptomycin-resistant or streptomycin-sensitive bacteria. It was found that the reading error in the presence of streptomycin is due to a protein of the 23S-ribonucleoprotein from the 30S ribosome subunit [71].

In agreement with this, other experiments have shown that streptomycin is bound to the 30S ribosome subunit [72], which must therefore be assumed to contain the primary point of attack. The reading errors and the decrease in protein synthesis that is also very often observed can be explained by the assumption that the configuration of the ribosomes is altered by streptomycin. The protein synthesis can still take place, but the high specificity of the interaction between the amino-acyl-tRNA and the mRNA on the ribosome is changed [73]. Thus streptomycin modifies the biological action of the template. Its effect is indicative of the active role of the ribosomes in the reading process.

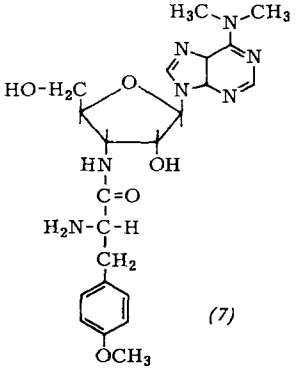
The changes caused by streptomycin in the amino acid sequence of the protein may not be confined to negative effects such as a decrease in the synthesis of an active enzyme. This has been very clearly demonstrated in the case of *E. coli* mutants that can no longer synthesize active ornithine transcarbamylase (EC 2.1.3.3). The addition of streptomycin to the culture medium reinitiates the synthesis of small quantities of the active enzyme [74]. In this case streptomycin is phenotypically equivalent to a suppressor mutation.

3.2.2. Chloramphenicol

The point of attack of many antibiotics on protein synthesis is in the 50S ribosome subunit. One antibiotic of this type is chloramphenicol *(6)* [75].



(6)



(7)

Experiments with the radioactively labeled antibiotic have shown that it is preferentially bound by the 50S subunit of the 70S ribosomes. This is observed only with the biologically active D(−)-*threo* isomer of the antibiotic. Thus the binding reaction exhibits the same stereospecificity as the inhibiting action on protein [76, 77].

Other antibiotics that also inhibit protein synthesis often interfere with the addition of chloramphenicol to the 50S subunit. This provides evidence of the point of attack of these antibiotics [66].

It is interesting to note that chloramphenicol, like some other inhibitors of protein synthesis, is species-specific in its action. Some types of cells that (like yeast or reticulocytes) contain 80S instead of 70S ribosomes cannot bind chloramphenicol [76]. The protein synthesis system with 80S ribosomes is accordingly insensitive to this antibiotic [78]. Ribosomes of different species can thus have different structures though their mode of action is fundamentally the same. This state of affairs is reminiscent of the different effects of rifamycins (and streptovaricins) on the RNA polymerases of different organisms [19, 20].

A clear indication of the mutual effects of the components in the ribosome complex is provided by the observation that the extent of the inhibiting action of chloramphenicol depends on the composition of the mRNA [79].

The manner in which chloramphenicol acts on the 50S ribosome unit has not yet been established; however, it may be concluded from results obtained with the antibiotic puromycin that it blocks the peptidyl transferase [80].

3.2.3. Puromycin

The addition of puromycin *(7)* to protein syntheses leads, not only to strong inhibition of the reaction, but also to the liberation of small peptide fragments [81]. The antibiotic is bound by an amide linkage of the amino group of its *O*-methyltyrosine residue with the carboxyl end of the peptide [82,83]. This is understandable in view of the structural resemblance of puromycin to the end portion of an amino-acyl-tRNA [*e.g.* tyrosyl-tRNA *(5)*] [84]. It acts on the A site of the ribosome, evidently as an inactive analog (antimetabolite) of an activated amino acid and in this role behaves as a competitive substrate for the peptidyl transferase and

takes over the activated peptide residue, which is thus released from the ribosome [85]. The correctness of this

$$H_2N\text{-Peptide-CO-tRNA} + NH_2\text{-Puromycin} \xrightarrow{\text{Ribosome}} H_2N\text{-Peptide-CO-NH-Puromycin} + \text{tRNA}$$

view has been demonstrated with simple, chemically synthesized model compounds of puromycin, such as 2′(3′)-*O*-phenylalanyladenosine. Compounds of this type also act as acceptors for the transferred peptide in the peptidyl transferase reaction [86]. Since no interactions of a further tRNA with the ribosome or the mRNA are necessary in this case for the formation of a peptide linkage, the puromycin reaction is the isolated reaction step of the natural peptide formation. Addition of the initiator *N*-formylmethionyl-tRNA, which is the simplest peptide-like substrate of the P site, leads to the simple dipeptide *N*-formylmethionyl-puromycin [62].

Very simple model compounds of activated peptides, such as the trinucleotide cytidylyl(3′→5′)cytidylyl-(3′→5′)-2′(3′)-*O*-(*N*-formyl)methionyladenosine (abbreviation CCA–FM), are biochemically active substrates of the P sites. The compounds correspond to the adenosine end portion of the *N*-formylmethionyl-tRNA and with them the natural peptide formation can be caused to proceed on the 50S ribosome subunit with puromycin as the acceptor in accordance with the equation

$$\text{CCA–FM} + \text{Puromycin} \xrightarrow[\text{ethanol}]{\text{50S Ribosome}} \text{FM-Puromycin} + \text{CCA}$$

the product being *N*-formylmethionylpuromycin. This isolated peptidyl transferase reaction (fragment reaction) does not require the presence of GTP, tRNA, mRNA, the 30S ribosome subunit, or soluble enzyme. Ethanol, however, must be added [87–89].

Since chloramphenicol and some other antibiotics prevent this reaction, it may be concluded that the point of attack of these inhibitors is the peptidyl transferase [80,90].

4. Outlook

Caution must be exercised in drawing conclusions on the basis of *in vitro* experiments on the action of antibiotics that can lead to damage or death of the cell *in vivo*, since the nucleic acid and protein syntheses are related in a very complex manner, not only with each other, but also with other metabolic reactions in the cell. Cells of different types undoubtedly differ considerably in the degree and nature of the coupling. Thus it is not yet possible to predict the points in the cell metabolism at which even small disturbances in the transmission of the genetic information can have serious consequences. Finally, it is not possible *a priori* to rule out the possibility that the antibiotics in question inhibit other enzyme reactions. This will depend on the concentration of the inhibitor in the cell.

The biochemical importance of the antibiotics discussed here, as well as of many others, lies in the fact that owing to their widely differing modes of action, they are excellently suited for the investigation of the course of the important template-controlled processes in the transmission of genetic information.

It is particularly interesting to note that some inhibitors (actinomycin, chromomycin, streptomycin) are to some extent template-dependent, *i.e.* information-specific, in their action. It seems appropriate to compare these to the repressor proteins, which regulate the RNA synthesis in the cell [91]. Analogies of this nature have raised hopes of finding low molecular weight substances capable of permeating into cells, by means of which information-controlled syntheses (such as the multiplication of viruses in host cells) may be selectively suppressed. Inhibitors of this type could be of great interest in medicine.

Replacement of Plasma by High Molecular Weight Substances[**]

BY W. APPEL AND E. BIEKERT[*]

In the course of the development work, natural and synthetic polymers were examined to see whether they were suitable for use as plasma substitutes. The criteria of a plasma substitute are discussed in this connection. The most important of the base substances used at present (dextran, modified gelatin, polyvinylpyrrolidone, and hydroxyethyl starch) are described, and a typical example of proven therapeutic value is discussed for each type.

1. Introduction

A group of medicaments that have grown in importance during recent years are substances whose aqueous solutions can be introduced directly into the blood stream in quantities of up to several liters. This "infusion therapy" may be used for widely different therapeutic purposes, such as the replacement of lost fluid, of salts, or of biological material, or for the introduction of nutrients, active substances, or drugs. The present article deals only with preparations intended to compensate for loss of blood. The development of these blood "substitute solutions" will be illustrated by the case of dextran, which has been extensively studied and is generally accepted as a plasma substitute.

The most satisfactory "blood substitute" is whole blood. However, blood transfusions, which have become routine operations in all hospitals (blood banks), have certain disadvantages. Though the fatality rate in blood transfusions, which was initially appreciable, has now been reduced almost to zero, even the most careful determination of blood groups and subgroups before the transfusion can never entirely rule out the possibility of incompatibility between the blood of the donor and that of the receiver. The greatest risk, however, is the transfer of pathogenic microorganisms, and 12–17.5% of all whole blood transfusions are followed by hepatitis that is directly attributable to the transfusion.

Since whole blood can only be stored for an average of about three weeks, in spite of stabilization with sodium citrate, blood plasma came into use as a substitute. Plasma, in the fresh, deep-frozen, aged (stored at 32 °C), and particularly freeze-dried states, is one of the most frequently used of the natural blood substitutes. In Switzerland, for example, lyophilized plasma from a single donor is often preferred, whereas aged pool plasma is preferred in the USA; only fresh plasma is used in Sweden. All forms of plasma, however, still carry the risk of hepatitis. The situation is improved to some extent by the use of pasteurized albumin solutions.

One important reason for the switch from whole blood to plasma was the recognition of the existence of the "shock syndrome". Of more than 100 forms of shock that have been described, the only form of interest in this connection is "hemorrhagic" shock, *i.e.* shock resulting from loss of blood. This is the syndrome of an acute hemodynamic disturbance due to such a severe loss of blood that the metabolic processes in important tissues are upset, with the result that functional, and later morphological, disturbances arise.

The use of plasma instead of whole blood is vindicated by the discovery that in cases of loss of blood, the important thing is not the replacement of the shaped blood elements (red and white blood cells and platelets), but the replacement of the lost volume of fluid.

The therapeutic requirement of ready availability, in sufficiently large quantities, of a substitute for lost liquid led to the further development of plasma substitutes. To satisfy the requirements of ready availability, *e.g.* for rescue operations in remote areas or for emergency treatment at the scene of an accident with restricted possibilities for blood-group determination, as well as availability in sufficiently large quantities for such situations as catastrophes or multiple accidents, make it essential that the solutions should have a reasonable storage life. It was only with the use of synthetic colloidal plasma substitutes with storage lives of several years that an adequate stock could be built up.

2. Requirements for Synthetic Colloidal Plasma Substitutes

We shall now discuss some of the properties that are required in a plasma substitute. There are as yet no known substances that satisfy all these requirements.

1. Synthetic colloidal substances intended for use as plasma substitutes must have an adequate colloid-osmotic effect.

2. The colloid should be compatible and nontoxic. It must not be stored in the body, but should be excreted as such or after metabolic transformation. It must not influence or damage any organ, even on repeated administration. In particular, the colloid must not interfere with the kidney function, the performance of the heart, or the biosynthesis of plasma proteins in the liver, or lead to metabolic acidosis.

3. The plasma expander solution prepared from such a colloid should be capable of being administered in concentrations such that its colloid-osmotic pressure corresponds to that of normal blood plasma.

4. The viscosity of such a solution should permit easy intravenous application, and should not impose additional work on the heart muscle.

5. When administered by infusion following loss of blood, about 50% of the solution should remain in the blood stream for at least six, and preferably twelve, hours.

6. In the doses used, the solution should not affect the clotting of blood, and must not cause aggregation or lysis of red or white blood cells (erythrocytes or leucocytes). Above all, it must not interfere with the determination of blood groups.

7. It should not cause allergic reactions or fever. The solution should not have any antigenic action, cause any sensitization, or affect the resistance to infection. It must be sterilizable and free from contamination by viruses.

8. It must be possible to produce the solution fairly cheaply on the industrial scale with constant and fixed properties, and to store it for several years.

Since the use of a substance as a drug requires a constant quality guaranteed by the manufacturer, all drugs are subjected to rigorous final checks. In the case of colloids, these checks are largely based on the analytical methods of polymer chemistry. The purity requirements are particularly high for plasma substitutes, since these, unlike other drugs, must be administered directly into the blood stream in doses of 50 g or more. The purity of the other substances present is also important, *e.g.* the quality of the water used as the solvent, which is introduced into the blood stream in liter quantities. Industrial production depends on freedom from pyrogens, *i.e.* the absence of febrifacient bacterial metabolites, since the entire process must be carried out under sterile conditions. Sterilization of the final solution is not enough, since though any bacteria present would be killed, their metabolites would remain in the solution and would not be inactivated, so that they would still be capable of acting as pyrogens.

2.1. Terminology

The terminology includes a number of terms whose meanings partly coincide, such as blood substitutes, plasma substitutes, plasma volume expanders, or plasma expanders. It should be noted that the term "blood substitute" cannot be used of any synthetic substance, since there are as yet no true blood substitutes, *i.e.* nothing can replace the transport of oxygen by red cells (erythrocytes). The term "expander" should be confined to substances that give the effect of a volume greater than that actually introduced. Since the expander effect is time-dependent because of the elimination of the substance by the kidneys, no definition characteristic of these substances can be derived on this basis. The most suitable term in our opinion is "plasma substitute", which means solutions that normalize a diminished blood volume for a time after intravenous infusion, and can take the place of the plasma components of blood.

3. Physico-Chemical Characterization of Synthetic Colloids

The following discussion refers to all colloids that can be used as plasma substitutes. These colloids are mixtures of molecules having different molecular weights, which are characterized by the molecular weight distribution.

To determine this quantity, the polymeric mixture must be broken down analytically into more homogeneous fractions, and the concentrations and molecular weights of these fractions are subsequently determined. If the fractionation is sufficiently fine to give monodisperse fractions, all molecular weight determination methods give the same value. However, this is not usually the case; the resulting values are therefore known as average molecular weights $\overline{M}$. In the investigation of colloidal plasma substitutes, it is generally satisfactory simply to determine $\overline{M}$.

1. The weight average molecular weight $\overline{M}_w$

$$\overline{M}_w = \Sigma n_i M_i^2 / \Sigma n_i M_i$$

is obtained by methods that depend on the weight of the molecules present, *e.g.* by measurement of sedimentation (ultracentrifuge) or diffusion (light scattering). Both methods, and particularly the second, have proved valuable for routine measurements on colloidal plasma substitutes.

2. The number average molecular weight $\overline{M}_n$

$$\overline{M}_n = \Sigma n_i M_i / \Sigma n$$

is obtained by methods that depend on the number of molecules present. These include osmometry, chemical end-group analysis, and at low degrees of polymerization cryoscopic, ebullioscopic, and vapor pressure measurements.

The frequently used measurement of viscosity is not an absolute method. The viscosity average molecular weight $\overline{M}_v$

$$[\eta] = K \cdot \overline{M}^{\alpha}$$

is strongly dependent on other factors such as the degree of branching. The constants α and K in the above relationship ("Staudinger" equation) must be determined separately for each plasma substitute. $[\eta]$ in this equation is the intrinsic viscosity.

$\overline{M}_w$ and $\overline{M}_n$ have different values for polydisperse substances. The ratio $\overline{M}_w/\overline{M}_n$ gives an indication of the uniformity of the colloid. However, the plasma substitutes can only be accurately characterized by the molecular weight distribution.

The "rapid fractionation method" introduced by *Schulz*[1] is sufficient for practical purposes. In this case an upper and a lower fraction are separated and their weights and degrees of polymerization are determined. In the case of dextran, these values are determined by the A.D.M.P.D. method[*].

4. Historical Development of Plasma Substitutes

As early as 1667, *Denis* described a successful transfer of lambs' blood to human beings. However, this method was soon abandoned because of its serious side effects such as ague or hematuria[2]. Animal blood was again widely used for transfusions in 1870 and 1871 (*Landois*[3]) until it was realized that the side effects could only be reduced by the transfusion of homologous blood. It was later found that in cases of severe loss of blood, life can be saved, in principle, not only by the administration of blood, but, alternatively, by the intravenous application of a liquid. After *Landerer*'s first successful experiments on humans[4], infusions were carried out first with 0.9% sodium chloride solutions, which are isotonic with blood ("physiological saline"), and later with solutions of other electrolytes. This method has proved itself over the decades, and has enjoyed a recent vigorous revival in the USA. However, the use of electrolyte solutions is limited by the rapid elimination of these substances by the kidneys[5].

The search for better plasma substitutes became more pressing during the first world war. *Bayliss*, one of *Starling*'s co-workers, revived the animal experiments by *Ludwig* (1863) and *Morawitz* with gum arabic, and in 1916 he introduced gum arabic preparations as additives for electrolyte solutions[6]. Though these solutions, as expected, remain in the blood stream for a longer time, the foreign protein that is always present causes side reactions, so that this substance never became widely used. At about the same period, *Hogan*[7] (1915) and *Robertson*[8] (1918) tested gelatin as a plasma substitute. The difficulty of sterilization, the presence of allergens, and the fact that the substance is solid at room temperature made further development necessary, and a modified gelatin was finally introduced in 1962[9].

The use of preserved whole blood was extensive in the Spanish civil war and at the beginning of the second world war. Efforts, particularly in the USA, were then directed toward the development of plasma preparations (fresh plasma, stored pool plasma, dry preserved plasma, plasma fractions), as well as the testing of other natural polymers and the development of suitable synthetic polymers. These investigations led to polyvinylpyrrolidone (1943)[10], dextran (1947)[11], and the modified gelatins mentioned above (1962). A modified starch proposed by *Wiedersheim*[12] in 1957 is at present undergoing extensive clinical trials.

The most important and most interesting plasma substitutes are probably solutions of dextrans, modified gelatins, polyvinylpyrrolidone (PVP), and modified starch. One representative commercial preparation of each of these types will now be discussed in detail.

5. Dextrans

5.1. General

During the last century, the syrups in European sugar factories were frequently found to become slimy. This phenomenon was greatly feared because of the resulting serious disturbance of production. The polysaccharide character of the slime was recognized by *Vauquelin*[13], who described it as a variety of cellulose. In 1869 *Scheibler*[13] coined the name "dextran", because of the strong optical dextrorotation of the polysaccharide. *Pasteur*[13] demonstrated the microbial origin of dextran in 1861. In 1878 *Van Tieghem*[13] gave the dextran-forming microorganisms the generic name "Leuconostoc", since the bacteria, like the green algae nostoc, frequently link up to form long, but colorless, chains.

It was realized during the next few decades that the ability to synthesize polysaccharides is very widespread among microorganisms. In 1930, *Hucker* and *Pederson*[14] assigned most of the dextran-forming microorganisms to the family Coccaceae, species *Streptococcaceae*, genus *Leuconostoc*. The most important species are *L. mesenteroides* and *L. dextranicum*. They liberate fructose from cane sugar with formation of a polyglucoside, the degree of branching of which differs with the type of bacterium. Polymerization to form dextran is brought about by dextransucrase, an extracellular bacterial enzyme. Dextran can therefore also be produced by direct synthesis with a cell-free enzyme extract. The first work on this synthesis was carried out by *Hehre* and *Sugg*[14], who also recognized that the presence of sucrose is a necessary and sufficient condition for the formation of dextran.

In 1943, *Grönwall* and *Ingelmann*[11] in Sweden prepared a partly hydrolyzed, fractionated dextran having a molecular weight of about 100000, which largely satisfied the clinical requirements for a plasma substitute, particularly since the α-1,6-glucoside linkage in the linear dextran molecule cannot be cleaved by the α-amylase in the body. This "clinical" dextran rapidly grew in importance, and is now produced industrially.

5.2. Synthesis of Clinical Dextran

Whereas the strain *L. mesenteroides* B7E, *inter alia*, was formerly used for the synthesis of crude dextran, the strain B 512 F is now used almost exclusively. The enzymatic synthesis with partly or highly purified dextransucrose has not yet achieved any industrial importance, nor has the method devised by *Behrens* and *Ringpfeil*[13], in which sucrose is subjected to controlled bacterial polymerization with the addition of a small quantity of very uniform clinical dextran of the desired molecular weight as an initiator.

$$n\,C_{12}H_{22}O_{11} \rightarrow (C_6H_{10}O_5)_n + n\,C_6H_{12}O_6$$

Saccharose — Dextran — Fructose
